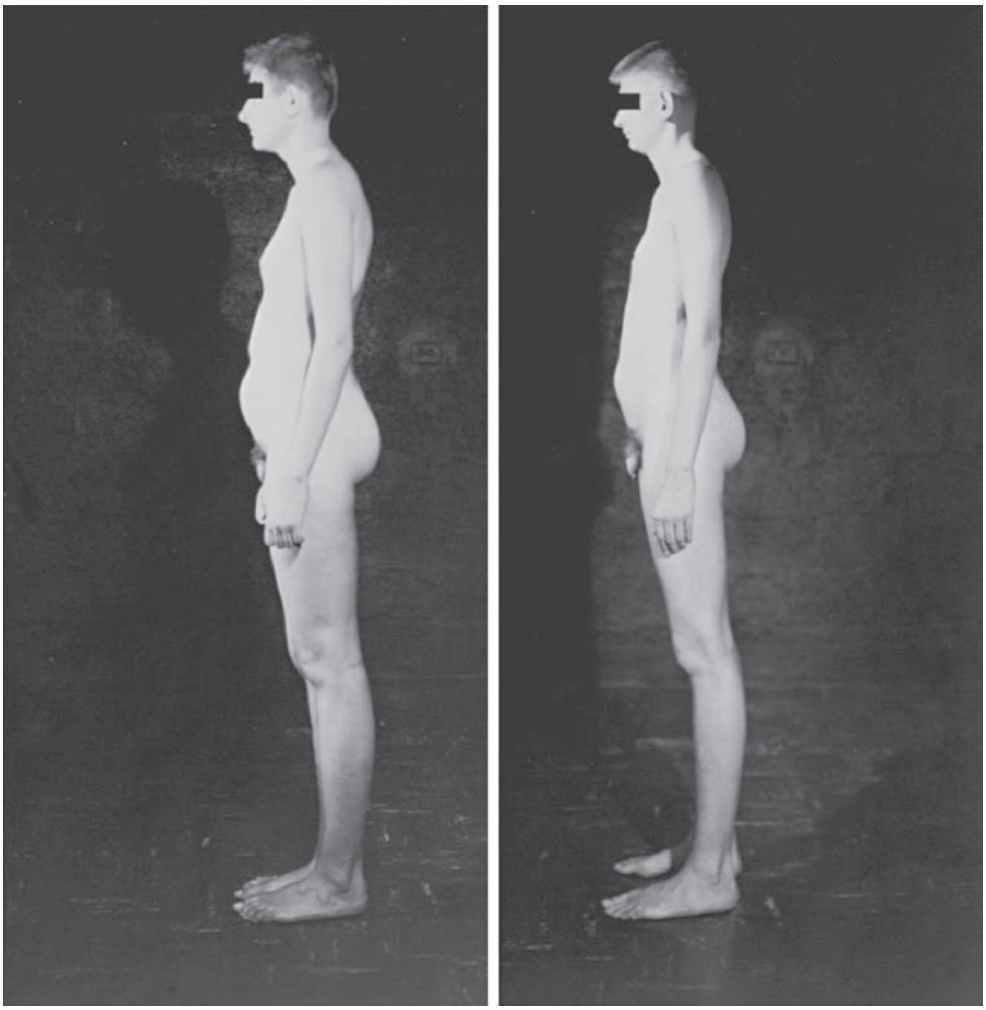
Klinefelter Syndrome and Its Variants (see Chapter 24). Klinefelter syndrome (i.e., syndrome of seminiferous tubular dysgenesis) and its variants occur in approximately 1 in 1000 males, and they are the most common forms of male hypogonadism.[622–624] The invariable clinical features include small, firm testes as an adult (<3.5 cm long); impaired spermatogenesis; and a male phenotype, usually with gynecomastia and long legs but not long arms[622] (Fig. 26.46). Prepubertally, patients can be detected by the disproportionate length of the extremities, decreased U/L body ratio without an increase in arm span rather than eunuchoid proportions, in which arm span and leg length are increased; however, less than 10% are diagnosed prepubertally. With increasing use



• **Fig. 26.46** 47,XXY Klinefelter syndrome in 17-year-old identical twins. At age 15, gynecomastia was observed. The twins had a eunuchoid habitus and poorly developed male secondary sexual characteristics. Both were 187 cm tall; arm spans were 187 cm and 189.5 cm; the voices were high pitched; the testes measured 1.8 × 1.5 cm; and penis length was 7.5 cm. Gynecomastia and signs of androgen deficiency were more evident in the twin on the left. Urinary gonadotropin levels were greater than 50 mU/24 hours. The testes exhibited extensive tubular fibrosis, small dysgenetic tubules, and clumping or pseudoadenomatous formation of Leydig cells; germ cells were rare. The microscopic appearance was typical of seminiferous tubule dysgenesis. (Patient data from Grumbach MM, Barr ML. Cytologic tests of chromosome sex in relation to sexual anomalies in man. *Recent Prog Horm Res.* 1958;14:255–324.)

of karyotype determination in children with behavior problems and in pregnancy for various reasons, diagnosis earlier in life may increase. Tall stature for family size is common in this disorder due to the disproportionate growth of the legs and appears to be related to multiple copies of the *SHOX* gene[624]; however, normal or short stature does not eliminate the diagnosis.

Infants with Klinefelter syndrome have normal INSL3 levels transiently increased at 2 to 3 months of age during the minipuberty of infancy, testosterone levels were below the median of control subjects but within the normal range, and inhibin B and AMH levels were also within normal range.[624] However, FSH levels were above normal in 25% of patients, indicating early evidence of testicular deficiency. Muscle tone is also lower in some.[625]

There is a normal increase in the concentrations of testosterone, INSL3, and inhibin B before puberty. By midpuberty testosterone and INSL3 concentrations remain in the low-normal range, AMH levels were undetectable in XXY adolescents but decreased at an age later than in normal boys, and inhibin B levels decreased from normal to the low levels characteristic of adult Klinefelter syndrome during late puberty after an unequivocal increase in serum testosterone (>2.5 nmol/L) levels and degeneration of Sertoli

cells.[626] Serum LH and FSH usually rise by midpuberty. Rarely, low gonadotropin concentrations occur when hypogonadotropic hypogonadism is associated with 47,XXY Klinefelter syndrome or coexisting constitutional delay.

Prepubertal testes show only subtle histologic changes, although the testes are small, and the germ cell content is reduced, whereas Sertoli cells are normal in abundance and appearance before 2 years of age. Older prepubertal subjects have normal seminiferous tubules. Hyalinization and fibrosis of the seminiferous tubules and pseudoadenomatous changes of the Leydig cells develop after puberty; adult-type spermatogonia are found in peripubertal boys, but older boys had no germ cells; and the testes degenerate in an accelerated manner at the onset of puberty.[627] However, there is a 44% success rate for sperm retrieval from testicular tissues and a 55% success rate for use of microdissection testicular sperm aspiration. Intracytoplasmic sperm injection led to the birth of 101 children, in whom there was no apparent increase in congenital or genetic defects.[628] Cryopreservation of testicular tissue is recommended before degeneration progresses,[629] although coverage for such procedure may be difficult to obtain.

There is variation in Leydig cell function among childhood and pubertal subjects, but the plasma concentration of testosterone fails to rise to normal adult levels. The onset of puberty usually is not delayed, but impaired Leydig cell reserve and low testosterone levels may lead to slow progression or arrest of pubertal changes. Testosterone replacement should be considered when the LH level rises above the normal range of values but is not necessary in all subjects in early puberty.[630] Serum estradiol-to-testosterone ratios and TeBG levels are higher than those in normal males, which indicates an increased estrogen effect and decreased testosterone effect that may account in part for the gynecomastia characteristic of Klinefelter syndrome. Testosterone administration does not appear to reduce the gynecomastia, but dihydrotestosterone may help. Aromatase inhibitors or estrogen receptor antagonists do not seem to be effective treatment for the gynecomastia of Klinefelter syndrome. If the gynecomastia does not regress within 2 years, reduction mammoplasty is required. Monitoring for breast cancer is important in these susceptible individuals.

The *AR* gene is located on the X chromosome and encodes a ligand-dependent transcription factor with highly polymorphic CAGn trinucleotide repeats in the coding sequence of the first exon. The length of the translated polyglutamate tract in the N-terminal transactivation domain of the resulting protein and the length of this polyglutamate tract are inversely proportional to receptor transactivation activity. The shorter the repeat sequence within the range of normal variation, the more active the AR, and small changes in this activity may result in more significant effects in Klinefelter syndrome, in which testosterone secretion may already be impaired. A negative correlation between CAGn repeat length and penile length, but not testicular size, in children has been reported.[581,631] Another study found a positive association between CAGn repeat length and body height, an inverse relationship to bone density and arm span to body height, and the presence of longer CAGn repeats for gynecomastia and smaller testes[632] in adults. A paternal origin of the extra X chromosome is associated with later onset of puberty and longer CAG repeats.[627]

Behavior and Development in Klinefelter Syndrome. Neurobehavioral abnormalities, primarily in language, speech, learning, and frontal executive functions, are common, even universal, in Klinefelter syndrome, but severe retardation is uncommon.[244] These problems may lead to evaluation in childhood and the prepubertal recognition of the syndrome. The prevalence of adjustment problems in adolescence is increased. Adults with Klinefelter syndrome have shorter education, lower income, earlier retirement, and increased unemployment, and more rarely marry than the national average. Fatality among Klinefelter syndrome men was significantly increased (hazard ratio, 1.9).[633] The crime rates for sexual abuse and arson are significantly increased, whereas traffic offenses and drug-related crime are significantly decreased.

The global IQ in unselected populations of Klinefelter syndrome subjects is normal or near normal, but verbal IQ, in contrast to that of patients with Turner syndrome, is usually lower (e.g., 10–20 points) than performance IQ.

Prepubertal Klinefelter syndrome patients have reduced left hemisphere specialization for verbal tasks and enhanced right hemisphere specialization for nonverbal tasks. However, these abnormalities tended to normalize after puberty began, suggesting hemispheric reorganization during puberty. Hypotheses are advanced supporting the effect of prenatal testosterone on cerebral dominance and on language and reading pathology.

There is controversy about the indication for testosterone treatment of infants or adolescents with Klinefelter syndrome. Although there is a growing feeling among parents that testosterone treatment in the infancy or early pubertal period improves language, reading, behavior, and self-image in boys with Klinefelter syndrome, no well-controlled studies supporting this contention are available, and long-term studies are needed.[634,991]

Other Aspects of Klinefelter Syndrome. Conditions associated with Klinefelter syndrome include aortic valvular disease and ruptured berry aneurysms (6 times the normal rate); breast carcinoma (20 times the rate in normal men and one-fifth that of women); other malignancies such as acute leukemia, lymphoma, and germ cell tumors at any midline site; systemic lupus erythematosus; and osteoporosis in about 25% of affected adults. There is an increased risk of diabetes mellitus, thyroid disease, fatigue, varicose veins, and essential tremor.

About 20% of mediastinal germ cell tumors are associated with Klinefelter syndrome, and they occur at a younger age than the mediastinal germ cell tumors that are not associated with the syndrome. With rare exceptions, these germ cell tumors, which may be located in the midline anywhere from the CNS to the pelvis, secrete hCG and induce sexual precocity. Klinefelter syndrome needs to be considered in boys with hCG-secreting germ cell tumors, especially if the tumor is located in the mediastinum or CNS.

Other Forms of Primary Testicular Failure

Cancer Survivors. CHEMOTHERAPY Chemotherapy and direct radiotherapy affect testicular function, and as more children survive with effective therapy for cancer, delayed puberty and adult infertility will result. Cancer therapy, especially irradiation of the gonads or the use of alkylating chemotherapeutic agents, affects testicular function and can lead to adult infertility.[635] Some courses of therapy can cause severe damage to germinal cells without apparent effect on Leydig cells. Chemotherapy for childhood Hodgkin disease, including chlorambucil, vinblastine, Mustargen (mechlorethamine), Oncovin (vincristine), procarbazine, and prednisone (COPP/MOPP), may allow spontaneous progression through puberty, but FSH and LH concentrations may be elevated, and the inhibin B concentrations decrease during puberty. The basal serum FSH level and rise in LH and FSH levels after GnRH correlate with the dose of cyclophosphamide. COPP/MOPP chemotherapy for Hodgkin disease can cause severe damage to Sertoli and germinal cells, but it has less effect

on Leydig cells, even if therapy occurred in the prepubertal period. Lower dosing or limiting therapy to less than three courses is suggested to decrease these complications.[636] Normal basal LH values may raise hope that Leydig cell function is normal, but if there is an exaggerated rise of the LH level after GnRH, compensated Leydig cell damage is present. The combination of Adriamycin (doxorubicin), bleomycin, vinblastine, and dacarbazine (ABVD regimen) can cause germ cell depletion. Although initially it was thought that some degree of prepubertal gonadal maturation was necessary before these drugs could cause gonadal damage, gonadal damage can occur earlier as a result of therapy in the prepubertal period but may not be demonstrable until the age of puberty. Chemotherapeutic agents used in the treatment of nephrotic syndrome or leukemia, such as cyclophosphamide or chlorambucil, have led to Sertoli cell, Leydig cell, and germ cell damage in prepubertal patients; these effects are sometimes reversible, which is indicative of gonadal damage.

Radiation Therapy. Radiation to the gonads can cause primary testicular failure, usually resulting in azoospermia, although normal testosterone secretion may be associated with elevated LH and FSH values (compensated Leydig cell failure); the gonads must be shielded from the treatment, if possible. Direct radiation doses of more than 2 Gy will likely impair spermatogenesis. Exposure to more than 20 Gy carries a recurrence rate of almost 11 of requiring testosterone as an adult.[620]

Preservation of sperm by freezing is being investigated for pediatric cancer patients (in Klinefelter syndrome patients), but the ethical and logistics problems of collecting sperm from adolescents remain substantial, all the more in prepubertal children. Not all sperm may be affected by treatment, and functional sperm may be recovered by microdissection of seminiferous tubules even in individuals who appear to have testicular failure. This may allow fertilization by successful intracytoplasmic sperm injection even if the quantity of sperm is low. The genes responsible for apoptosis are activated when DNA damage from radiation or chemotherapy occurs; manipulation of such genes may allow reestablishment of fertility in the future. Oncofertility is a new field of investigation that aims to preserve fertility in children and teenagers subject to cancer therapy, and new methods will undoubtedly appear.

Survey of adults who were not offered fertility preservation or with whom such an issue was not even discussed at time of diagnosis shows that they feel considerable distress. However, sperm banking in puberty or prepuberty presents ethical concerns as to the procedure, the cost of banking, and the uncertainty of outcome and is not presently standard therapy.[637]

Concern for decreased bone density and risk for fractures is also raised in cancer survivors who have undergone radiation treatment of the hypothalamic-pituitary axis.

Testicular Biosynthetic Defects. The 46,XY disorder of sex development is caused by 17α-hydroxylase/17,20-lyase deficiency resulting from mutations in CYP17A1 at gene map locus 10q24.3; it is associated with sexual infantilism and a female phenotype.[638] The testosterone biosynthetic defect blocks the synthesis of testosterone and adrenal androgens, impairing masculinization at all stages of development. Associated cortisol deficiency and increased mineralocorticoid secretion in this condition lead to hypertension, decreased serum potassium levels, and metabolic alkalosis. Elevated serum progesterone levels and decreased plasma renin activity are helpful diagnostic features.[639] Glucocorticoid replacement suppresses ACTH and mineralocorticoid excess and corrects the electrolyte abnormalities, but no sexual development occurs unless exogenous gonadal steroids are administered. Less severe deficiencies are associated with ambiguous genitalia. *CYP17A1* mutations leading to isolated 17,20-lyase deficiency are rare.

A rare autosomal recessive condition is steroidogenic acute regulatory (StAR) protein deficiency, in which the ability to produce C21, C19, and C18 steroids is lost and a severe impairment of the conversion of cholesterol to pregnenolone results; severely affected patients have lipid-laden adrenal glands.[640] The large adrenal glands may be visualized on ultrasound, CT, or MRI. Death often occurs in infancy if untreated because of unrecognized glucocorticoid and mineralocorticoid deficiencies. Affected individuals physically appear to be sexually infantile females, whether their karyotype is 46,XY or 46,XX; because of the absence of gonadal or adrenal androgen production, the affected XY phenotypic females do not develop secondary sexual characteristics, including pubic hair.[622] However, XX females with a null mutation develop female sex characteristics at puberty, including pubic hair and multicystic ovaries, but they also have primary or secondary amenorrhea. In contrast to the fetal testis, the fetal ovary, which is insensitive to FSH and steroidogenically inactive, is undamaged in fetal life and remains so until the onset of puberty. Under FSH stimulation during puberty and with recruitment of ovarian follicles, the ovaries undergo progressive damage and cyst formation. Ovarian damage and impairment of ovarian StAR-independent steroidogenesis appear to be related to lipid deposition in the ovary.[641]

Luteinizing Hormone Resistance. Presumptive evidence of LH resistance caused by an LH receptor abnormality on the Leydig cell was reported in an 18-year-old boy with a male phenotype, no male secondary sexual development, gynecomastia, elevated plasma LH levels, and early pubertal plasma testosterone concentrations that did not increase after hCG administration; there was no elevation of testosterone precursor levels.[642] The testes were prepubertal in size and had the microscopic appearance of normal prepubertal testes. Plasma membrane receptor preparations from the testes bound only one-half as much radiolabeled hCG as control testes.

In affected males, this autosomal recessive disorder is caused by a mutation in *LHCGR*, the gene encoding the G protein–coupled, seven-transmembrane LH/hCG cell receptor at gene map locus 2p21. Mutations that cause a more severe compromise in *LHCGR* function are associated with XY disorders of sex development. Homozygous deletion of exon 10 or the homozygous missense mutations Ser616Tyr and Ile625Lys of the LH receptor are associated with micropenis (but not hypospadias) due to partial impairment of LH receptor function, leading to a discordance with a poor response to LH but not to hCG.

Nephropathic cystinosis in boys leads to hypergonadotropic hypogonadism.

Anorchia and Cryptorchidism. Cryptorchidism is the condition in which one or both testes have not reached the bottom of the scrotum before birth. Animal and human data demonstrate that testicular descent is influenced by testosterone and INSL3; for example, androgen resistance leads to lack of descent, as also occurs in transgenetic mice without INSL3. When testes are not descended, they may be located in high scrotal, suprascrotal, or inguinal positions or can be nonpalpable, which includes ectopic testes as well.[643] Data collection is variable, but analysis of the literature shows the undescended testis rate in term appropriate weight for gestational age (AGA) babies is 1.0% to 4.6%, whereas in premature or SGA infants it is 1.1% to 4.3%.[644] By 1 year the undescended testis rate in term AGA boys was 1.0%

to 1.5%, at 6 years 0.0% to 2.6, at 11 years 0.0% to 6.6%, and at 15 years 1.6% to 2.2% of boys. Testes may ascend after birth, ascensus testis, which leads to a higher prevalence of undescended testes in prepuberty than at birth in several international reports, and these patients are not always included in cryptorchidism surveys. Study of more than 1 million Danish boys showed the concordance rate of cryptorchidism was 3.4% for paternal half-brothers, 6% for maternal half-brothers, 8.8% for full brothers, 24.1% for dizygotic twin brothers, and 27.3% for monozygotic twin brothers demonstrating effects of genetics and intrauterine environment.[645]

A 46,XY male without palpable testes may have intra-abdominal testes, which carry an increased risk of malignant degeneration; anorchia (i.e., vanishing testes syndrome, caused by perinatal torsion), in which no testes are found at laparotomy; or retractile testes, a variation of normal. About 50% of bilateral, nonpalpable testes are undescended, and the other 50% are testicular remnants from vanishing testes that usually do not contain germ cells, are found in the scrotum, are not at risk for carcinoma, and need not be removed if the history is certain.[646] If there is a male phenotype and male internal ducts, functioning fetal testes capable of secreting testosterone and AMH were present early during fetal life but degenerated thereafter. Serum gonadotropins follow the normal U-shaped curve of high values in infancy and puberty with lower values in midchildhood in anorchia, although the values are above normal.[647] Serum AMH and inhibin B are nondetectable in anorchia.[648] Ultrasound is often used to locate undescended testes, but the accuracy is poor: A meta-analysis demonstrated that a positive ultrasound result increases and negative ultrasound result decreases the probability that a nonpalpable testis is located within the abdomen from 55% to 64% and 49%, respectively.[649] Laparoscopy, however, is recommended in diagnosis of nonpalpable testes.[650]

Discovery of unilateral cryptorchidism may represent the presence of a descended testis on one side and none on the other side, and this presents a diagnostic dilemma. Compensatory hypertrophy occurs if there is no contralateral testis, and this aids the diagnosis. A Japanese study demonstrated that the mean contralateral testicular length and volume in the boys with an absent testis were 22.4 mm and 2.20 mL compared with 16.6 mm and 1.10 mL in boys with a testis present and 16.6 mm and 1.18 mL in control subjects; the optimal cutoff value of 21 mm in length and 1.6 mL in volume led to a predictive accuracy for an absent testis of 87.3%, sensitivity of 81.8%, and specificity of 95.5%, with 85.5%, 84.8%, and 86.4% for the volume, respectively.[651] Because the finding does not universally predict monorchia, laparoscopy can be used for diagnosis of this condition if ultrasound is unsuccessful. If there is a unilateral undescended testis, the increased relative risk of carcinoma in the contralateral descended testis is 1.74 (95% CI, 1.01–2.98), which is lower than in the unilateral undescended testes (6.33; 95% CI, 4.30–9.31).[652]

Hormonal treatment of undescended testes may be successful in causing descent, but evidence is scarce and meta-analysis is difficult owing to variation in dosage and length of treatment. There is no compelling evidence that hormonal therapy in the short term is harmful, but unsuccessful medical therapy should not be allowed to significantly delay surgical therapy. In one schema, a single dose of 1500 IU hCG is administered intramuscularly, and serum levels of LH, FSH, testosterone, inhibin B, and AMH are measured at baseline and at 72 hours afterward. The test was positive in Prader-Willi syndrome when the maximum testosterone level after 72 hours was 2 to 20 times higher than baseline levels in infants aged 3 to 12 months and 5 to 10 times higher, between 2.5 and 9 nmol/L, in infants aged 1 to 4 years.[653] Administration of an hCG dose, 250 IU for infants aged 3 to 12 months and 500 IU intramuscularly for infants aged 1 to 4 years, twice a week for 6 weeks led to a descent of testes in 62% who had a positive stimulation test, and 23% of the testes reached a stable scrotal position. There are studies of longer term administration of hCG or GnRH to either foster a rise in testosterone for diagnosis or for descent of testes for treatment of boys without Prader-Willi syndrome with variable results. The lack of a rise in testosterone concentration, in conjunction with an increased plasma concentration of FSH and LH or an augmented gonadotropin response to GnRH, and decreased AMH and inhibin B are evidence for the diagnosis of bilateral anorchia. Because testicular descent normally occurs by 1 year of age, orchidopexy is recommended between 6 and 12 months in those who have testes that do not descend with medical treatment or upon discovering cryptorchidism after 12 months of age.[654] One study linked testicular descent to an adequate neonatal surge of LH and testosterone by 4 months in AGA infants and by 6 months in premature infants; these study authors recommended treatment be considered earlier than at 1 year.

Cryptorchidism is associated with an increased risk of infertility. Cryptorchid testes may demonstrate congenital abnormalities and may not function normally even if brought into the scrotum early in life. Two critical steps in the maturation of germ cells are described in the normal prepubertal testis that do not occur in the unilaterally undescended testes. First, at 2 to 3 months of age, the gonocytes (primitive spermatogonia) in the fetal stem cell pool transform into the adult dark spermatogonia, which become the adult stem pool (possibly related to the early infancy surge in LH, FSH, and testosterone). Second, at 4 to 5 years of age, meiosis begins, and primary spermatocytes appear. The contralateral descended testis is affected but less so than the undescended testis. Identification of the gonocyte transformation has influenced recommendations on the timing of orchidopexy. Postpubertal orchidopexy is associated with a greater than 85% prevalence of azoospermia or oligospermia. It has been surmised that cryptorchid testes, even if replaced in the scrotum, may never have normal spermatogenic function as a consequence of an early abnormality in germ cell maturation, vascular damage to the testicular circulation during orchidopexy, or an intrinsic testicular defect. Fertility potential varies depending upon preoperative history and laboratory results. Testicular dysgenesis may be indicated by increased gonadotropin levels, and early surgery may be indicated; normal gonadotropin levels and a decreased germ cell number may indicate transient hypothalamus-pituitary-gonadal hypofunction with a poor fertility prognosis; if there are normal gonadotropins, inhibin B, and germ cell number, there is a good fertility prognosis, too.[655] A study of men with cryptorchidism reported a paternity rate of 65% for men who had had bilateral cryptorchidism, compared with 90% for the formerly unilateral cryptorchid men and 93% for control men; the reduction in fertility was supported by semen and hormone analyses.[656] Successful fertilization was reported by the use of intracytoplasmic injection of sperm extracted from the testes of cryptorchid men who had orchiopexy after puberty.[657] Patients undergoing orchiopexy may sustain subtle damage to the vas deferens, leading to the later production of antibodies to sperm that may result in infertility.

Cryptorchidism is associated with an increased risk of cancer of the testes, which is rising. The incidence of testicular carcinoma in England at all ages increased from 2 per 100,000 in 1909 to 4.4 per 100,000 in 1999, with a rise noticed during puberty.[658] Such data are nation specific, and there is an approximately 10-fold range between countries.[646] A recent Swedish study reported the overall relative risk of testicular carcinoma in cryptorchidism is 2.5 to 8, with the highest risk associated with intra-abdominal rather than inguinal testes and higher risks observed for those with abnormal chromosomes, syndromes, or late or no orchiopexy. Undescended testes remain at a higher temperature than descended testes, and undescended testes have a maturation arrest at the conversion of the gonocytes to spermatogonia, which appears to direct the testes toward malignant degeneration. There is a very small risk of carcinoma of the testes in prepuberty, but the absence of carcinoma in situ in prepuberty is not an assurance that carcinoma will not develop in adult life. Periodic sonography of the testis of affected patients is recommended after the onset of puberty.

Adverse environmental factors may be important in the apparent increase in testis cancer, cryptorchidism, hypospadias, and low semen quality, which are all qualities described in the testicular dysgenesis syndrome (TDS).[659] The complexities of clustering such findings without a pathophysiologic explanation has led to criticism of the concept.[654] This remains an important area of research.

Retractile testes can descend into the scrotum but then reascend. They are considered a normal variation, but a requirement for orchiopexy was reported for 22.7% in a series of 150. The finding of one case of testicular carcinoma in a boy with spontaneous descent in this series led to a suggestion of following such cases in the long term.[660] The risk of breast cancer associated with gynecomastia is increased in men with a history of undescended testes, orchiopexy, orchitis, testicular injury, infertility, or any cause of delayed puberty.

Small for Gestational Age. SGA predisposes males to reproductive problems and is also associated with the TDS. Males born SGA tend to have smaller testes and lower testosterone and higher LH[661] levels, suggesting an impairment of fertility, as is found in SGA females. Adult males born SGA have increased aromatase and 5α-reductase activities, leading to elevated levels of estradiol and dihydrotestosterone.[662] Of most concern is the fact that elevated estradiol levels in males increase the risk of testicular cancer and do not provide the protective effect on cardiovascular health as found in females. The level of inhibin B is elevated significantly in SGA boys (i.e., mean birth weights >2 SD below the mean for gestational age), although other studies with higher-birth-weight SGA boys demonstrated no such chages.[647,663]

Girls

Syndrome of Gonadal Dysgenesis and Its Variants.[622]. The most common form of hypergonadotropic hypogonadism in the female is the syndrome of gonadal dysgenesis (Turner syndrome and its variants), a sporadic disorder with an incidence of 1 per 2500 liveborn girls in which all (i.e., X chromosome monosomy with haploinsufficiency) or part of the second sex chromosome (i.e., partial sex chromosome monosomy) is absent.[590,646] About 99% of 45,X conceptuses abort spontaneously, and 1 in 15 spontaneous abortions has a 45,X karyotype. The 45,X karyotype is associated with female phenotype, short stature, sexual infantilism, and various somatic abnormalities.

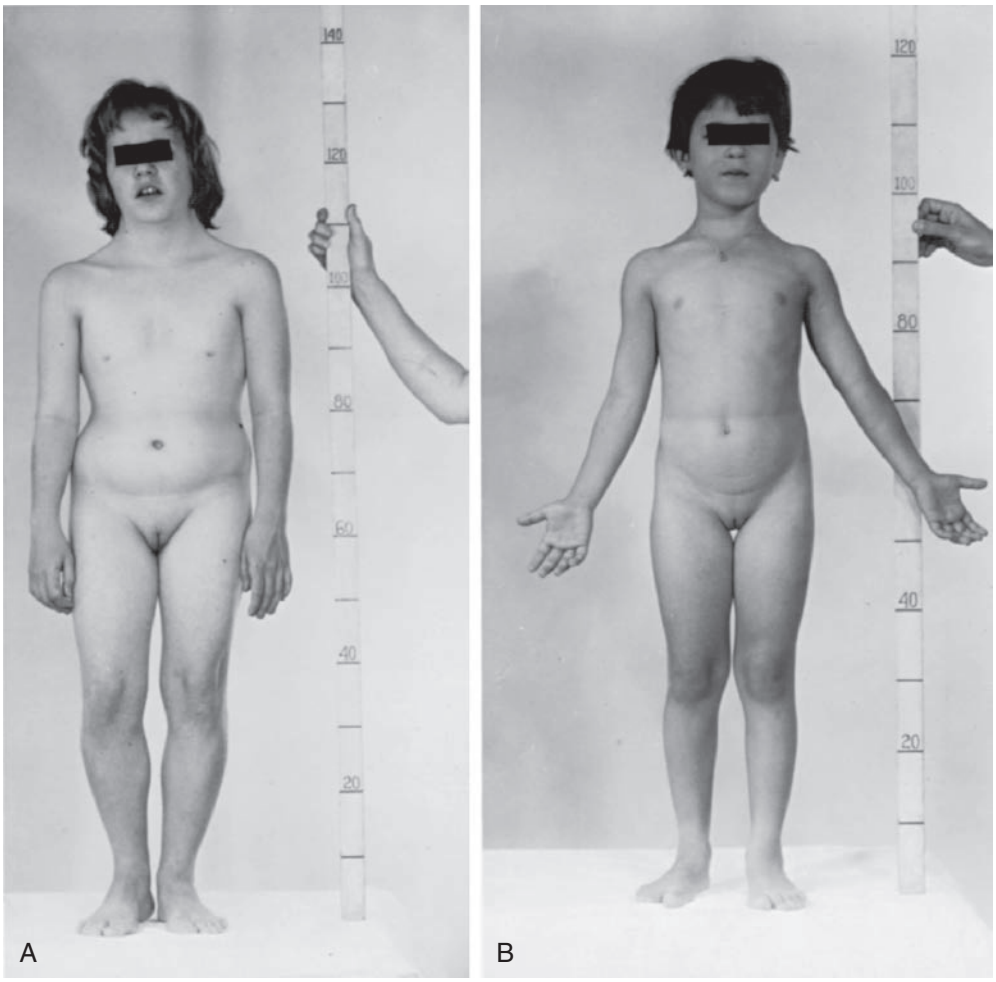
Sex chromosome mosaicism or structural abnormalities of an X or Y chromosome (affects about 40% of individuals with Turner syndrome) may modify the features of this syndrome. The syndrome of gonadal dysgenesis and its variants are found in a continuum ranging from the typical 45,X phenotype to a normal male or female phenotype.[590,622] Comprehensive recommendations for the diagnosis and management of Turner syndrome were presented by an international committee.[649]

45,X Turner Syndrome.[993] Short stature and sexual infantilism are typical features of sex chromatin–negative 45,X gonadal dysgenesis (Turner syndrome), which is the karyotype found in approximately 60% of cases[622] (Fig. 26.47). The short stature is caused by loss of a homeobox-containing gene that is located on the pseudoautosomal region (PAR1) of the short arms of the X (p22) and Y (p11.3) chromosomes and encodes an osteogenic factor. This short stature homeobox-containing *(SHOX)* gene[664] was previously called the pseudoautosomal homeobox osteogenic gene *(PHOG)*. Because it is located on the PAR1 of the short arm of the X and Y chromosomes, it escapes X-chromosome inactivation. *SHOX* haploinsufficiency is responsible for, in addition to abnormal growth, mesomelic growth retardation and Madelung deformity of the wrist (i.e., bilateral bowing of the radius with a dorsal subluxation of the distal ulna as found in Leri-Weill dyschondrosteosis [i.e., *SHOX* haploinsufficiency]). Langer mesomelic dysplasia, which includes severe dwarfism with striking hypoplasia or aplasia of the ulnar and fibula, is caused by *SHOX* nullizygosity. *SHOX* haploinsufficiency appears to be responsible for 2 SD of the approximately 3 SD deficit in stature and the skeletal abnormalities in Turner syndrome. On the other hand, patients with complete gonadal dysgenesis and tall stature had a 45,X/46,X der(X) and three doses of the *SHOX* gene due to the *SHOX* duplication on the der(X) chromosome.

A diagnosis of Turner syndrome may be straightforward in its classic sense, but often there is a delay in diagnosis. For instance, the Danish study found that about 15% are diagnosed below 1 year of age, 33% during the adolescent years, and over 38% during adulthood.[665] The age of diagnosis may be coming down with increased education of providers and the general public, however. The standardized mortality rate for all causes of death for Turner syndrome was 2.86 with the highest prevalence among females with 40 5X and 45 isoXq karyotypes.

Turner syndrome may be recognized in the newborn period or before. More than 90% of Turner fetuses spontaneously abort. The 45,X abortuses have edema and large hygromas of the neck that may be seen on prenatal ultrasound studies. This lymphatic defect is the basis for the loose skinfolds that ultimately form the webbed neck (i.e., pterygium colli). Affected newborn infants may also have lymphedema of the extremities; the term *Bonnevie-Ullrich syndrome* has been applied to newborn infants with these features of Turner syndrome.

Frequent features are distinct facies with micrognathia, a fish-mouth appearance, high-arched palate with dental abnormalities, epicanthal folds, ptosis, low-set or deformed ears, short neck with low hairline, webbing (i.e., pterygium colli), and recurrent otitis media, often leading to impaired hearing (25% of affected adults require hearing aids[622]). A broad, shieldlike chest leads to the appearance of widely spaced nipples, and the areolae are often hypoplastic. Skeletal defects include short fourth metacarpals and cubitus valgus (which may develop after birth), Madelung deformity of the wrist (in about 7%), genu valgum, and



• **Fig. 26.47** (A) A girl aged 14 years and 10 months with the typical form of the syndrome of gonadal dysgenesis (Turner syndrome). The X chromatin pattern was negative, and the karyotype was 45,X. She was short (height, 134.5 cm; height age, 9 years and 5 months) and sexually infantile except for the appearance of sparse pubic hair. She exhibited characteristic stigmata of the syndrome: a short, webbed neck; shield-like chest with widely separated nipples; bilateral metacarpal signs; puffiness over the dorsum of the fingers; cubitus valgus; increased number of pigmented nevi; characteristic facies; and low-set ears. The bone age was 13.5 years; the urinary 17-ketosteroid level was 5.1 mg/day; and the urinary gonadotropin level was greater than 100 mU/day. Vaginal smears and the urocytogram showed an immature pattern in which cornified squamous cells were absent. Female secondary sexual characteristics were induced with estrogen therapy, and the cyclic administration resulted in periodic estrogen withdrawal bleeding. (B) A 45,X girl aged 9 years and 11 months with Turner syndrome. Apart from short stature (height, 118 cm; height age, 6 years and 11 months), increased pigmented nevi, and subtle changes in the fingers and toes, she had few somatic anomalies. In contrast to the patient on the left, the main clinical feature was short stature.

scoliosis. There are extensive pigmented nevi,[622] a tendency to keloid formation, and hypoplastic nails. Lymphatic obstruction leads to the infantile puffiness of extremities and pterygium colli and to a distinctive shape of the ears. Cardiovascular anomalies affect the left side of the heart and include coarctation of the aorta in about 10% (40% of these have associated webbing of the neck), aortic stenosis, and bicuspid aortic valves; the latter individuals are at risk for a dissecting aortic aneurysm. An echocardiogram of the cardiovascular system must be performed, and prophylactic antibiotics are indicated if an anatomic abnormality is demonstrated. Elevated values on the ambulatory arterial stiffness index (AASI) may be another risk factor for later serious cardiac disease.[666] Long-term regular follow-up of adults with Turner syndrome with echocardiography is recommended every 5 years in adulthood.[659] Abnormal pelvicalyceal collecting systems, abnormal position or alignment of the kidneys, and an abnormal vascular supply to the kidney are encountered in 30% to 60% of patients. Recurrent urinary tract infections are common. Defects of the gastrointestinal system include intestinal telangiectasias and hemangiomatoses that rarely can lead to massive gastrointestinal bleeding. The prevalence of inflammatory bowel disease, chronic liver disease, and colon cancer is increased. Autoimmune diseases, such as Hashimoto thyroiditis (16-fold relative risk) and Graves disease, are common, and an association with juvenile rheumatoid arthritis and psoriatic arthritis has been described.

The age of diagnosis of Turner syndrome continues to be delayed, with the exception of newborns with the striking phenotype of the Bonnevie-Ullrich syndrome or those diagnosed on amniocentesis. It is recommended that all prepubertal age girls below −2 SD who have at least two somatic stigmata of the syndrome have a karyotype analysis; early diagnosis is key for optimal management of the growth failure and the detection of occult features of the syndrome.

Pelvic ultrasonography or MRI usually permits the detection of even a small, infantile uterus and reveals streak gonads. Ultrasensitive estrogen bioassays can confirm decreased ovarian function in girls with Turner syndrome because estradiol values are significantly lower than those found in average girls in puberty. Long-term follow-up of affected women previously treated with GH and estrogen demonstrated normal adult uterine length only in those with 45,X/46,XX karyotypes, whereas those with pure 45,X karyotypes had a smaller uterus length and volume.[667] The streak gonads result in sexual infantilism, but in about 10% of cases, puberty, menarche, and (rarely) pregnancy may occur.[667] Women with some of the variants have been able to achieve fertility and deliver normal infants, although cardiovascular risks increase the danger. Affected adults can undergo hormone replacement to prepare the uterus to receive a donated embryo and proceed to delivery. Unfortunately, some patients receiving a donated ovum have died because of dissection or rupture of the aorta, and caution should be used in considering this technique.[622]

Intrauterine growth retardation with a mean deficit in birth length of 2.6 cm (−1.24 SD) and a slow childhood growth rate result in a loss of about 8 to 9 cm (−3 SD) by age 3 years in girls with Turner syndrome.[660,668] A major portion of the height deficit occurs during the first 3 years of life. Decreased growth rate occurs at the time of expected puberty, and the pubertal growth spurt is absent in those without pubertal development. Untreated individuals with Turner syndrome in the United Kingdom and United States have a mean adult height of approximately 142 to 143 cm, which is about 20 cm less than the average height of typical women; the adult stature of these patients correlates with midparental height and with the height of unaffected women of the same ethnic group. Haploinsufficiency of the *SHOX* gene is estimated to contribute two-thirds of the height deficit. It is postulated that a second gene on the short arm of the X chromosome that does not undergo X-chromosome inactivation contributes the other one-third of the deficit. In girls with Turner syndrome with spontaneous puberty, pubertal height velocity was transiently higher than in girls with amenorrhea, but adult height was not different.[669] Specific growth curves are available for plotting the growth of affected children.[622]

GH treatment is approved by the FDA for Turner syndrome to increase growth and adult height.[670] The addition of estrogen therapy at low doses in addition to GH has a modest additive effect on adult height; untreated height was 144.6 ± 5.5 cm, 140.8 ± 5.0 cm for estrogen treatment alone, 147.9 ± 7.2 cm for the GH treatment alone, and 149.3 ± 6.6 cm for GH and estradiol combined over an average 7.2 ± 2.5-year treatment/observation period.[992] The average height gain in various studies has varied from 4 to 16 cm, and a systematic review of the literature shows a 5-cm gain to be the most likely outcome.[671] This variability in gain in height is incompletely understood, but many factors have been implicated, including the age of initiation of therapy, dose duration, age (especially number of years from beginning hGH treatment) at the beginning of estrogen replacement, number of injections per week, compliance, and whether the last measured height represented the adult height. Early initiation of hGH therapy (e.g., 2–8 years of age) leads to greatest effect. GH treatment of Turner patients has been safe, and untoward events are no more common than in other conditions treated with GH. There is some degree of improvement of the abnormal body proportions of Turner syndrome with hGH treatment, but the disproportionate growth of the foot may dissuade some girls from continuing treatment to maximal benefit on height. Five-year follow-up of young adults with Turner syndrome demonstrated continued beneficial effects of GH on blood pressure, lipid levels, and increased adult height.[672]

A nationwide survey of 632 Danish girls with Turner syndrome demonstrated an increased prevalence of fractures, mainly in the forearm, compared with control subjects. The prevalence was higher still in the absence of ovarian function and in girls with family history of fractures and presumed familial disorders of bone density.[673] It appears that estrogen therapy is critical for the prevention and repair of osteoporosis, but for adolescents and adults, the optimal dose preparation and site of delivery for the prevention of osteoporosis are not known. GH treatment of Turner syndrome for at least 1 year showed no difference in volumetric BMD, although LBM was higher and fat mass was lower than in the control subjects.[674]

About 50% of patients with Turner syndrome have a tendency toward impaired glucose tolerance without GH treatment; in some, this may be caused by associated obesity, and risk of type 2 diabetes mellitus is increased. Although glucose values do not change with GH therapy, insulin levels reversibly rise during treatment, indicating an additional degree of insulin resistance caused by the GH.[675] Turner syndrome patients as young as 11 years can already have elevated serum cholesterol concentrations before treatment with GH or estrogen.

The biphasic pattern of gonadotropin secretion in normal infancy and childhood is exaggerated in Turner syndrome[420] (see Fig. 26.27).

The appearance of pubic hair (i.e., pubarche) is often delayed in the syndrome of gonadal dysgenesis, even though adrenarche, as assessed by the increase in concentration of plasma DHEAS, occurs at the normal age.[442] Girls with ovarian failure demonstrate early adrenarche, and therefore higher serum values of DHEAS, but later pubarche, whereas those who demonstrate at least beginning breast development follow a course of adrenarche similar to that of unaffected girls. This suggests that ovarian function is necessary to convert DHEA to the active androgens responsible for the appearance of pubic hair in normal girls. The pubic hair of affected individuals is sparse, but estrogen therapy increases the growth of pubic hair despite a lack of increase in adrenal androgen secretion, and estrogen affects pubic hair appearance.

Behavior and Development of Turner Syndrome. Counseling and a peer support group are exceedingly important components of long-term management. Girls with Turner syndrome younger than 6 years did not perceive that they had a problem with height, but by 7 to 12 years and especially by 13 to 15 years, affected Turner girls have a strong desire for GH therapy and even unrealistic expectations of what GH therapy can accomplish in terms of adult height. GH therapy improved self-esteem even if there remained a significant difference in height between Turner girls and the normal range. Height gained with GH therapy did not affect quality of life, although cardiac defects and otologic complications did.[676] Girls who have discontinued GH therapy after reaching adult height showed no evidence of depression but still had remaining problems with self-perception and bodily attitude

despite significant height gains. Psychologic problems in Turner syndrome are not necessarily diminished with GH treatment and an increase in adult height.

Turner syndrome girls resemble normal girls in verbal and language skills, and IQ is normal when verbal ability, including comprehension and vocabulary, are considered, but visual-constructional or visual-perceptual spatiotemporal processing, visuomotor coordination, and mathematical ability (particularly in geometry) may be impaired, leading to a decrease in the performance of IQ tests due to mistakes on operation and alignment processes.[677] Girls with 45,X mosaicism associated with a 46,XX cell line, 45,X/46,XX, scored closer to normal than those with other types of mosaicisms. Only 3.3% of girls with Turner syndrome have developmental delay in the absence of a variant of Turner syndrome caused by a ring X chromosome. It is useful to monitor the patient's progress in high school mathematics. There are consistent MRI abnormalities in the right parietal lobe and the occipital lobes, and decreased volumes in these areas are implicated in defects in visual-spatial processing. These anatomic data relate to the difficulties in visual-spatial skills found in most studies of girls with Turner syndrome, because these difficulties are most closely linked to the right parietal region.

There is an increased risk of impaired social adjustment in Turner syndrome. Although there was evidence that the origin of the remaining X chromosome in classic Turner syndrome affected behavior due to imprinting, recent evidence could not support the effect of imprinting on social behavior.[678]

Transition of girls with Turner syndrome to adult care is best carried out by an experienced team, which is ideally composed of an endocrinologist, cardiologist, nephrologist, reproductive endocrinologist, audiologic physician, ENT (ear, nose, and throat) surgeon, plastic surgeon, dentist, and psychologist because of the multiplicity of complications that affected individuals may encounter in the areas of growth failure, cardiovascular disease, gonadal failure, and learning disabilities.[677]

Sex Chromatin–Positive Variants of the Syndrome of Gonadal Dysgenesis. Mosaicism of 45,X/46,XX; 45,X/47,XXX; or 45,X/46,XX/47,XXX chromosomes is associated with a chromatin-positive buccal smear and usually with fewer manifestations of the syndrome of gonadal dysgenesis. Likewise, structural abnormalities of the X chromosome can be associated with fewer phenotypic features of the syndrome. Lack of genetic material on the long or the short arm of the second X chromosome can cause decreased gonadal function; loss of all or part of the short arm of the X leads to the physical findings of Turner syndrome.[622] Depending on the location and extent of the deletion on the short arm of the X chromosome, these patients may be more likely to have modest pubertal growth and some spontaneous pubertal development.

Sex Chromatin–Negative Variants of Gonadal Dysgenesis. These variants include 45,X/46,XY mosaicism and structural abnormalities of the Y chromosome. Affected individuals have phenotypes that vary from those of classic gonadal dysgenesis to those of ambiguous genitalia to phenotypic males.[622] Patients may present with short stature, delayed puberty, and a history of hypospadias repair. There is variable testicular differentiation, ranging from a streak gonad to functioning testes. Patients with mosaicism involving a Y cell line or abnormalities of the Y chromosome are at risk for neoplastic transformation of the dysgenetic testes. Gonadoblastomas, which are benign, nonmetastasizing tumors, may arise within the gonad and produce testosterone or estrogens. The neoplasm may become calcified sufficiently to be detected on an abdominal radiograph. The appearance of feminization or virilization in a patient with dysgenetic gonads and a Y cell line may indicate gonadoblastoma formation. Of greater significance is the increased prevalence of malignant germ cell tumors, arising within the dysgenetic gonad or gonadoblastoma. Examples are dysgerminomas, mature teratomas, and testicular intraepithelial neoplasia.[679] These tumors occur more often in postpubertal subjects and rarely in children.[621]

46,XX and 46,XY Gonadal Dysgenesis. The term *pure gonadal dysgenesis* refers to phenotypic females with sexual infantilism and a 46,XX or 46,XY karyotype without chromosomal abnormalities.[621]

Familial and Sporadic 46,XX Gonadal Dysgenesis and Its Variants. The usual phenotype of 46,XX gonadal dysgenesis includes normal stature, sexual infantilism, bilateral streak gonad, normal female internal and external genitalia, and primary amenorrhea. The streak gonad occasionally produces estrogens or androgens, but malignant transformation is rare. Incomplete forms of this condition may result in hypoplastic ovaries that produce enough estrogen to cause some breast development and a few menstrual periods, followed by secondary amenorrhea. This heterogeneous syndrome occurs sporadically or with autosomal recessive inheritance,[621] and in some instances it is associated with other congenital malformations. Some familial cases have been associated with sensorineural deafness (i.e., Perrault syndrome).

Familial and Sporadic 46,XY Gonadal Dysgenesis and Its Variants. A phenotype that includes female genitalia with or without clitoral enlargement, normal or tall stature, bilateral streak gonads, normal müllerian structures, sexual infantilism, and a eunuchoid habitus is typical of 46,XY gonadal dysgenesis. About 15% of the patients have a deletion or mutation in the sex-determining region Y *(SRY)* gene. If the dysgenetic testes produce significant amounts of testosterone, slight clitoral enlargement may occur at birth, and virilization may ensue at puberty. The incomplete form of 46,XY gonadal dysgenesis may involve any degree of ambiguity of the external genitalia and internal ducts. All patients with dysgenetic gonads and a Y chromosome or an *SRY* gene are susceptible to neoplasia or carcinoma formation in the gonad. The evidence on optimal therapy is not supported by high-quality evidence, but gonadectomy is indicated at diagnosis, especially if the gonad cannot be palpated.[673]

The disorder is usually transmitted as an X-linked or sex-limited autosomal dominant trait or less commonly as an autosomal recessive trait.[621]

Other Causes of Primary Ovarian Failure. The prevalence of primary ovarian failure is increasing as a consequence of the long-term effects of cytotoxic chemotherapy and radiation therapy as these agents prolong the lives of children and adolescents with cancer. The same pattern occurs for males with testes that have been treated with these modalities.

Chemotherapy. Successful treatment of childhood acute lymphoblastic leukemia has become commonplace. Chemotherapy and radiation therapy to the CNS or ovaries exert damage in a dose-dependent manner.[680] Chemotherapy known to adversely affect ovaries carries about a recurrence rate of 6 for premature ovarian failure.[620]

Attempts to protect the gonads by suppressing the pituitary-gonadal axis with gonadal steroids or GnRH agonists are probably ineffective.[681] Oncofertility is a new field of investigation that aims to preserve fertility in children and teenagers subject to cancer therapy and is leading to improved methods of preservation.[682,683] A major problem is lack of discussion of possible

method of preservation by oncologists with the families. Careful endocrine follow-up of children and adolescents treated with chemotherapy or radiation therapy is essential.

Radiation Therapy. Ovarian transposition, moving the ovaries out of the radiation field if they are not the target of therapy, before radiation therapy is compatible with normal menses, pubertal development, and pregnancy in the few cases reported.[684] The uterus may be affected by radiation and may not expand normally during pregnancy. Hypothalamic-pituitary exposure to 30 Gy carries a recurrence rate of 6 for ovarian insufficiency.

Autoimmune Oophoritis. Premature menopause may occur at any age before the normal climacteric and has been reported in adolescent girls. Cessation of ovarian function usually manifests as secondary amenorrhea.[685] Autoimmune oophoritis can cause ovarian failure leading to primary amenorrhea, oligomenorrhea, arrest of puberty, and occasionally cystic enlargement of the ovaries. Most often it is associated with other autoimmune endocrinopathies, especially autoimmune Addison disease, in which it may precede the onset of adrenal insufficiency, but it rarely occurs in isolated premature ovarian failure. Autoimmune oophoritis occurs in more than 20% of patients with autoimmune adrenal insufficiency. Various autoantibodies have been detected in autoimmune oophoritis, including autoantibodies to cytochrome P450 steroidogenic enzymes; some are organ specific, whereas others react with antigens in more than one tissue and more than one cell type. Glucocorticoid therapy may improve, at least temporarily, ovarian function.

Type I autoimmune polyglandular insufficiency, also known as autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED), is a rare systemic autoimmune disorder with an array of clinical features, including hypoparathyroidism, adrenal insufficiency, gonadal failure, diabetes mellitus, pernicious anemia, hypothyroidism, chronic hepatitis, mucocutaneous candidiasis, dystrophic nail hypoplasia, vitiligo, alopecia, keratinopathy, and intestinal malabsorption. Thirty-six percent of women with APECED exhibited ovarian failure before age 20, whereas only 4% of affected men had testicular failure by that age. This autosomal recessive disorder is caused by more than 42 mutations in the *CDK14 (AIRE1)* gene at gene map locus 21q22.3.

Homozygous Galactosemia. Homozygous galactosemia due to mutation in the galactose-1-phosphate uridylyltransferase *(GALT)* gene is associated with primary ovarian failure, from failure to develop puberty to primary or secondary amenorrhea and premature menopause, but puberty is usually normal in males, and the risk of testicular dysfunction is low; compound heterozygotes have normal onset of puberty. Dietary restriction programs have not prevented the ovarian failure, nor are other means of avoiding ovarian failure effective.[686] The pathogenesis of galactose-induced ovarian toxicity remains unclear but probably involves galactose itself and its metabolites, such as galactitol and uridine diphosphate galactose. Most cases are detected by newborn screening programs.

Haploinsufficiency of the FOXL2 Gene. A rare autosomal dominant disorder involving eyelid dysplasia and premature ovarian failure is caused by haploinsufficiency of the *FOXL2* gene, a member of the winged helix/forkhead family of transcription factors.[687] The eyelid abnormalities include small palpebral fissures, ptosis, and a small skinfold extending inward and upward from the lower lid (i.e., epicanthus inversus). The gene is expressed in the follicular cells, and the mutations that lead to haploinsufficiency are associated with an increased rate of follicular atresia. The degree of ovarian failure varies from primary amenorrhea to irregular menses and premature ovarian failure, with ultrasound findings ranging from normal-appearing ovaries to streak gonads with an inconsistent number of primordial follicles found on ovarian biopsy. The infertility component of the syndrome is limited to females. Animal studies provide insights into other genetic mutations that may cause premature ovarian failure in humans, including mutations of *BMP15*, *FMR1*, *POF1B*, and *FOXO3A*.[688]

Congenital Disorders of Glycosylation-1: Carbohydrate-Deficient Glycoprotein Syndrome Type Ia. The congenital disorders of glycosylation-1 (i.e., carbohydrate-deficient glycoprotein syndrome type Ia) include an autosomal recessive disorder associated with circulating glycoproteins deficient in their terminal carbohydrate moieties, including a wide range of glycoproteins, enzymes, binding proteins, and coagulation factors.[689] A typical isoform pattern of serum transferrin detected by isoelectric focusing is used as a diagnostic test. The dominant clinical feature is the neurologic manifestations of involvement of the central and peripheral nervous system. Among the other organ systems affected is the pituitary-gonadal system.

The hypergonadotropic-hypogonadism is more severe in females because males virilize at puberty. The ovary and the pituitary are affected. Affected girls have sexual infantilism; the ovaries are hypoplastic or atrophic. High serum FSH and LH levels exhibited normal electrophoretic isoform patterns, but they appeared to have decreased but not absent FSH bioactivity in an FSH bioassay.

Follicle-Stimulating Hormone Receptor Resistance: Gene Mutations and Hypergonadotropic Hypogonadism. The FSH receptor is a member of the G protein–linked receptor, seven-transmembrane superfamily. It has a large, extended extracellular ligand-binding domain. An autosomal recessive disorder due to a mutation in the extracellular ligand-binding domain of the FSH receptor in affected females in six Finnish families mainly from the north central region resulted in delayed (40%) or normal puberty but primary amenorrhea, elevated gonadotropin levels, and hypergonadotropic ovarian dysgenesis with arrest of ovarian follicular development at the primary follicle stage and continued atresia.[642] The clinical features are very similar to the findings in FSH-deficient mice generated by targeted disruption of the gene encoding the FSHβ-subunit. This disorder likely is responsible for most cases of the resistant ovary syndrome. The FSH receptor gene contains nine small exons (1–9) that encode the extracellular ligand-binding domain and one large exon 10 that designates the remainder of the receptor, including the seven-transmembrane and intracellular domains. The Finnish mutation, an Ala1989Val substitution, is in the extracellular domain. Expression of the mutation in transfected cells indicated a small FSH effect on cAMP production, a striking reduction of FSH-binding capacity, but apparently normal binding affinity.

The FSH receptor mutation in the Finnish patients is not a null mutation. It remains to be determined whether the loss or complete inactivation of the FSH receptor leads to failure of puberty and sexual infantilism or to estrogen synthesis by the immature ovarian follicles described in the FSHβ-subunit knockout mouse. Affected males in these families are normally masculinized at puberty but tend to have small testes. They have a variable degree of spermatogenic insufficiency, but not azoospermia, increased plasma concentrations of FSH and LH, decreased inhibin B levels, and normal plasma testosterone values.[690]

Luteinizing Hormone and Human Chorionic Gonadotropin Resistance. LH/hCG resistance due to mutations in the gene encoding the seven-transmembrane LH-CGR is discussed in

Chapter 24. In the affected XY individual, this autosomal recessive disorder leads to various degrees of male pseudohermaphroditism; the mildest form is represented by an isolated micropenis.[691] Less severe mutations of the *LHCGR* may be associated with delayed puberty. In affected females, LH/hCG resistance does not affect pubertal maturation but does lead to amenorrhea with high serum LH levels but normal FSH and estradiol concentrations.

Polycystic Ovary Syndrome. PCOS, or functional ovarian hyperandrogenism, does not delay the onset of puberty but often delays menarche or causes menstrual abnormalities.[692] It can have serious long-term metabolic consequences such as dyslipidemia and insulin resistance over and above androgen excess and reproductive difficulties (see upcoming discussion).

Noonan Syndrome. Individuals with Noonan syndrome (i.e., pseudo-Turner syndrome, Ullrich syndrome) have webbed neck, ptosis, down-slanting palpebral fissures, low-set ears, short stature, cubitus valgus, and lymphedema, which explains why this phenotype has been called *pseudo-Turner syndrome*.[622] Features that differentiate these individuals from those with Turner syndrome include triangular facies, pectus excavatum, right-sided heart disease (e.g., pulmonary stenosis, often with valve dysplasia; atrial septal defect) compared with the left-sided heart disease in Turner syndrome, hypertrophic cardiomyopathy, varied blood clotting defects, and an increased incidence of developmental delay. Females with Noonan syndrome have normal ovarian function. Males have normal differentiation of external genitalia but may have undescended testes; germinal aplasia or hypoplasia and impaired Leydig cell function may be present. Puberty is often delayed as 35% of boys enter puberty after age 13.5 years and 44% of girls enter puberty after age 13 years.[693] Stature is decreased after normal birth length and weight, with a mean adult height of 162.5 cm (63.9 inches) for men and 152.7 cm (60.1 inches) for women, usually following the −2 SD curve. The pubertal growth spurt is often delayed or attenuated.

Noonan syndrome is inherited as an autosomal dominant trait.[622] A gene implicated in Noonan syndrome has been localized to the long arm of chromosome 12 (12q24.2-q24.31), and a mutation in *PTPN11* was identified, but at least three other gene mutations have been identified. Noonan syndrome is linked to the chromosomal band 12q24.1, and eight genes in the RAS-MAPK signaling pathway cause Noonan syndrome: *PTPN11, SOS1, KRAS, NRAS, RAF1, BRAF, SHOC2*, and *CBL*.[693] This disorder with a mutation in the (RAS) rat sarcoma-mitogen-activated protein kinase pathway is classified as one of the RASopathies.[694] The incidence is estimated at 1 case in 1000 to 1 in 2500 individuals. One parent may have features of the syndrome in 40% to 60% of cases. About 50% of patients are thought to have new mutations.

Administration of hGH is approved by the FDA for use in Noonan syndrome. Response to GH is decreased with *PTN11* mutations in some but not all[695] reports, and there is an increase in risk for neoplasia in this genotype as well.[696] GH therapy can allow affected children to reach the lower normal range of stature.

Frasier Syndrome. Germline mutations in exon 8 or 9, coding for zinc fingers 2 or 3 of the Wilms tumor suppressor gene, *WT1*, leads to Denys-Drash syndrome, which includes Wilms tumor, male pseudohermaphroditism, and early nephrotic syndrome with diffuse mesangial sclerosis. Frasier syndrome includes male pseudohermaphroditism, nephrotic syndrome with focal and segmental glomerular sclerosis, and the development of gonadoblastoma and is associated with mutations in the second splice donor site in intron 9 leading to a decrease in the KTS+ isoforms. Although most patients with Frasier syndrome present with ambiguous genitalia, this diagnosis should be considered for any phenotypic female with end-stage renal disease (due to focal segmental glomerulosclerosis) and sexual infantilism. The karyotype may be 46,XY or 46,XX.

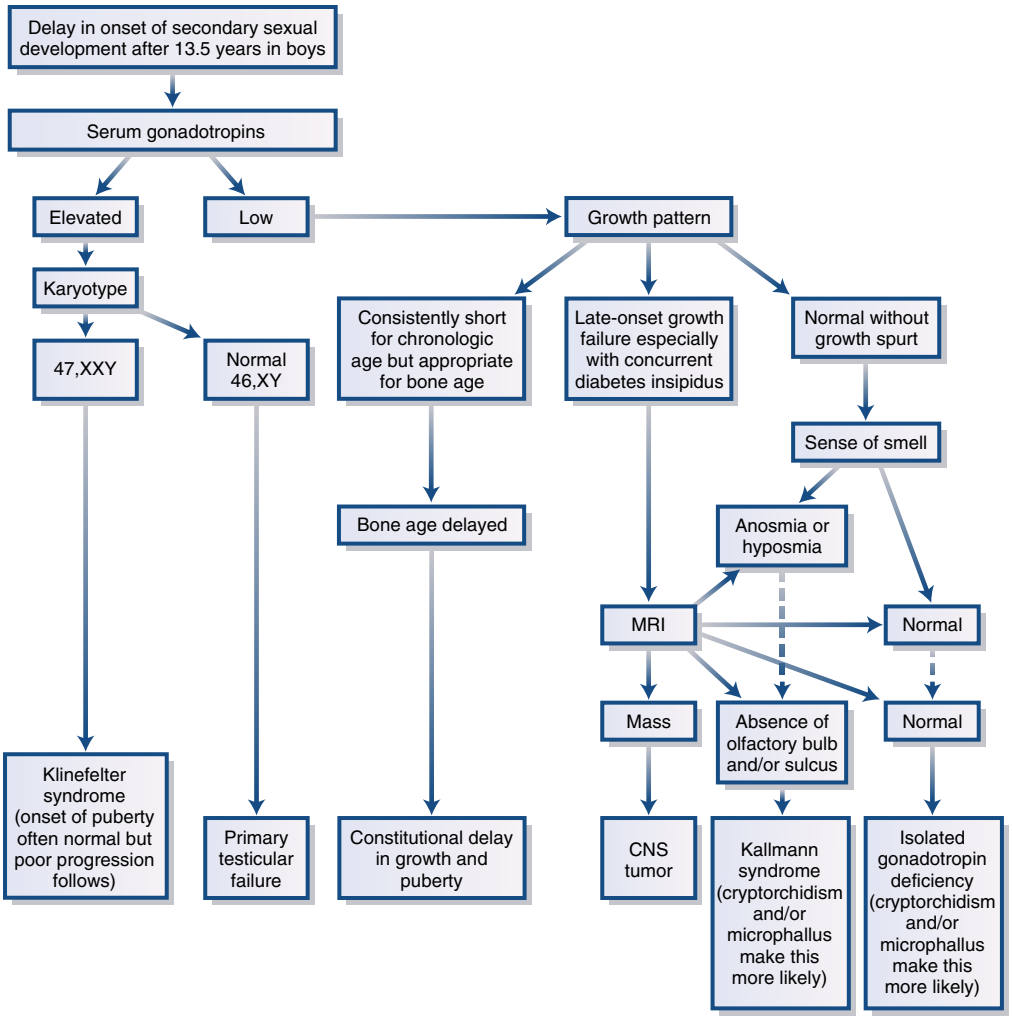
Williams-Beuren Syndrome. Williams-Beuren syndrome is a microdeletion disorder, or contiguous-gene-deletion disorder caused by deletion of the Williams-Beuren syndrome chromosome region; it was previously known as Williams syndrome. The prevalence is about 1 in 10,000 persons. While it is generally known for its characteristic facial appearance and unusual personality, many other features, including endocrine conditions, occur. While the guidelines of the Academy of Pediatrics state that precocious puberty is rare in this condition,[697] CPP is reported in about 18% of affected girls in a recent series of 24 patients, and these cases responded to GnRH agonist therapy.[698]

Diagnosis of Delayed Puberty and Sexual Infantilism

When girls remain prepubertal at 13 years or boys remain prepubertal at 14 years (although some say 13.5 years), the physician must make a clinical judgment about who are variants of the norm and who require extensive evaluation and treatment (Figs. 26.48 and 26.49; Tables 26.20 and 26.21). A boy who has not completed secondary sexual maturation within 4.5 years after onset of puberty or a girl who does not menstruate within 5 years after onset may have a hypothalamic, pituitary, or gonadal disorder. The diagnosis of hypergonadotropic hypogonadism is readily established by elevation of random plasma LH and FSH concentrations. However, differentiating the diagnosis of hypogonadotropic hypogonadism from constitutional delay in growth and adolescence remains difficult in spite of decades of study owing to the overlap in physical and laboratory findings for the two conditions (see Table 26.21).[699] Most boys with pubertal delay have a self-limited variant in the tempo of growth and pubertal onset, CDP.

Medical history must elicit all symptoms of chronic or intermittent illnesses and all details pertaining to growth and development. Questions about the patient's sense of smell are essential. Has puberty failed to occur, or did it begin but failed to progress or even regress? Disorders of pregnancy, abnormalities of labor and delivery, and birth trauma, if part of the patient's history, suggest that a congenital or neonatal event may be related to the delay in puberty. Poor linear growth and poor nutritional status during the neonatal period and childhood may reflect long-standing abnormalities of development. Family history may reveal disorders of puberty or infertility, anosmia, or hyposmia in relatives and delay in the age at onset of puberty in parents or siblings. Recalled age of pubertal onset is relatively reliable in women but less often accurate in men. A history of consanguinity is important in the detection of autosomal recessive disorders.

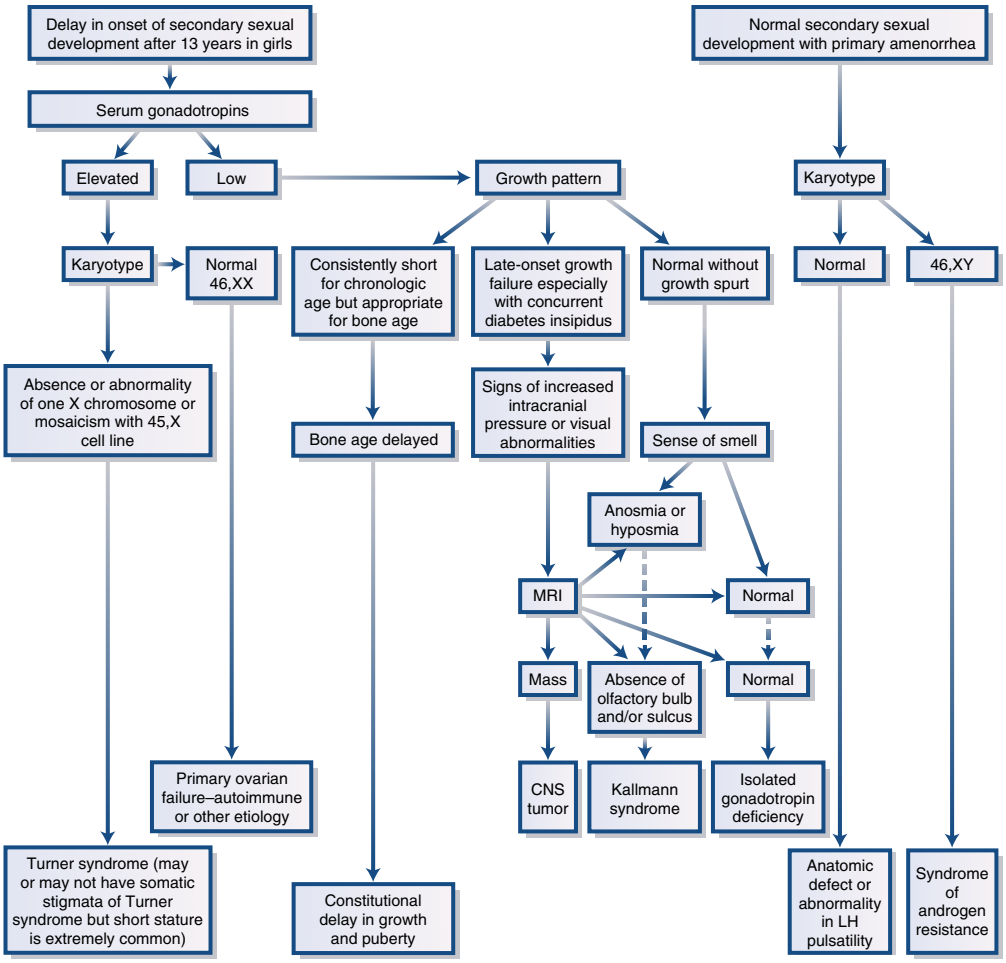
The physical examination starts with accurate determination of height, weight, and BMI. A growth chart is plotted to represent graphically growth velocity from birth (see Chapter 25). Late-onset growth failure usually indicates a serious condition requiring immediate evaluation. Weight is plotted to determine states of malnutrition. BMI should be calculated and plotted by age and gender in this era of epidemic obesity to further determine nutritional status. The height velocity should be documented over a period of at least 6 months, preferably 12 months. The U/L segment ratio and the arm span are measured



• **Fig. 26.48** Flow chart for the evaluation of delayed puberty in boys. *CNS,* central nervous system; *MRI,* magnetic resonance imaging.

and compared with the height. The signs of puberty are assessed, and the stage of secondary sexual development is determined by physical examination according to the standards presented earlier (see Figs. 26.5, 26.6, and 26.10). Questionnaires with pictures are used to allow a child to determine his or her own stage of puberty in some studies but do not replace the physical examination, as there is a tendency to overestimate development early in puberty and underestimate it late in puberty. The length and width of the testes are measured in boys, or the volume is assessed using an orchidometer. The length and diameter of the gently stretched penis are determined in boys, and the diameter of glandular breast tissue and areolar size are determined in girls. The presence or absence of galactorrhea is documented. Obese boys often appear to have a small penis because of excessive adipose tissue surrounding the phallus; only when the fat is retracted can the full extent of phallic development be assessed. This is among the most common causes of inappropriate referral for hypogonadism. The extent of pubic and axillary hair is assessed, as is the degree of acne or comedones. The possibility of cryptorchidism or retractile testes should be determined if no testes are palpated in the scrotum. Neurologic examination, including examination of the optic discs and visual fields by frontal confrontation perimetry, may reveal findings, suggesting the presence of a CNS neoplasm or a developmental defect, and may suggest that more accurate ophthalmologic evaluation is needed. Determination of olfaction is important because many patients with Kallmann syndrome wait years for the correct diagnosis to be made even in the presence of classic findings; physicians must remain alert to the possibility of this diagnosis and to the fact that congenital anosmia may not be noted by the patient or family for years. The stigmata of gonadal dysgenesis (i.e., Turner syndrome) or the small testes and gynecomastia of Klinefelter syndrome may suggest a karyotypic abnormality. Complete physical examination, including the lungs, heart, kidney, and gastrointestinal tract, is important in the search for a chronic disorder that may delay puberty.

Laboratory studies (Table 26.22) include determination of plasma LH and FSH concentrations by sensitive third-generation assays in pediatric endocrine laboratories, measurement of the rise in the LH level after GnRH or GnRH agonist administration, and determination of testosterone concentrations in boys and estradiol levels in girls in pediatric endocrine laboratories using HPLC-MS/MS, all with pediatric standards for that laboratory. One of the national endocrine laboratories should be used for determinations of the hormones of puberty, because most local laboratories are interested only in differentiating the normally higher adult values



• **Fig. 26.49** Flow chart for the evaluation of delayed puberty in girls. *CNS,* central nervous system; *LH,* luteinizing hormone; *MRI,* magnetic resonance imaging.

from inappropriately low levels, and they cannot determine the gradations of the low levels found in puberty.[265] Results of commercial immunochemiluminometric assays for LH and FSH are reported to be more sensitive for use in pediatrics than immunofluorometric assays (IFMA).[700] Several national laboratories began using liquid chromatography with tandem mass spectrometry methods for improved sensitivity and specificity and determinations in children (and women) for increased accuracy.[265] Newer ultrasensitive bioassays are not yet available commercially for the determination of low values of testosterone and estradiol or for total androgen or estrogen. Measurements of T_4 and TSH concentrations in boys and girls are usually necessary, and prolactin is often useful as well.

Genetic testing is available either by targeted evaluation or by panels developed by the commercial laboratories for hypogonadotropic hypogonadism. Targeted evaluation may be carried out by looking for mutations of FGF8 in affected patients with cleft palate or lip or skeletal abnormalities, signs of CHARGE syndrome in evaluating for mutations in CHD7, bimanual synkinesia or renal agenesis in looking for mutations of KAL1, or in those with severe obesity looking for mutations in leptin and leptin receptors or PCSK1.[374] Genetic counseling should be offered to the affected families. This is more easily carried out when there is an autosomal dominant, autosomal recessive, or X-linked condition than for oligogenetic conditions at present.

Radiographic examination may include bone age determination and, if the history or physical examination is consistent with a CNS lesion, an MRI of the brain, with specific attention to the pituitary and hypothalamic area using contrast. MRI (T2-weighted) coronal views of the olfactory tract will be useful in the diagnosis of Kallmann syndrome. CT can detect calcification, in contrast to standard MRI scans, although calcification can be found on plain radiographs, in some cases. Ultrasound evaluation of the uterus and ovaries provides useful information about the state of development of these structures but only if the ultrasonographer has experience with children and young adolescents. DXA evaluation of bone density should be considered in hypogonadotropic hypogonadism.

Assessment of karyotype should be considered for all undiagnosed short girls, even in the absence of somatic signs of Turner syndrome and especially if puberty is delayed or unexplained short stature is involved. Karyotype assessment should be performed for boys with suspected Klinefelter syndrome stigmata or behavior.

A presumptive diagnosis of constitutional delay in growth and adolescence is made if the history and growth chart reveal a history of short stature but a consistent growth rate for skeletal age (and no signs or symptoms of hypothalamic lesions), if the family history includes parents or siblings with delayed puberty, if the physical examination (including assessment of the olfactory threshold) is normal, if optic discs and visual fields are normal,

TABLE 26.20 Differential Diagnostic Features of Delayed Puberty and Sexual Infantilism

Condition	Stature	Plasma Gonadotropins	GnRHa Test LH Response	Plasma Gonadal Steroids	Plasma DHEAS	Karyotype	Olfaction
Constitutional delay in growth and adolescence	Short for chron. age, usually appropriate for bone age	Prepubertal, later pubertal	Prepubertal, later pubertal	Low, later normal	Low for chron. age, appropriate for bone age	Normal	Normal
Hypogonadotropic Hypogonadism							
Isolated gonadotropin deficiency	Normal, absent pubertal growth spurt	Low	Prepubertal or no response	Low	Appropriate for chron. age	Normal	Normal
Kallmann syndrome	Normal, absent	Low	Prepubertal or no response	Low	Appropriate for chron. age	Normal	Anosmia; pubertal growth spurt or hyposmia
Idiopathic multiple pituitary hormone deficiencies	Short stature and poor growth since early childhood	Low	Prepubertal or no response	Low	Usually low	Normal	Normal
Hypothalamic-pituitary tumors	Late-onset decrease in growth velocity	Low	Prepubertal or no response	Low	Normal or low for chron. age	Normal	Normal
Primary Gonadal Failure							
Syndrome of gonadal dysgenesis (Turner syndrome) and variants	Short stature since childhood	High	Hyperresponse for age	Low	Normal for chron. age	45,X or variant	Normal
Klinefelter syndrome and variants	Normal to tall	High	Hyperresponse at puberty	Low or normal	Normal for chron. age	47,XXY or variant	Normal
Familial XX or XY gonadal dysgenesis	Normal for age	High	Hyperresponse	Low	Normal for chron. age	46,XX or 46,XY	Normal

TABLE 26.21 Endocrine Diagnosis of Constitutional Delayed Adolescence and Hypogonadotropic Hypogonadism

No single test reliably discriminates between the two diagnoses.
Onset of puberty in boys is indicated by
- Testes >2.5 cm in diameter
- Serum testosterone concentration >50 ng/dL
- Pubertal LH response to GnRH bolus
- Pubertal pattern of LH pulsatility

GnRH, Gonadotropin-releasing hormone; *LH,* luteinizing hormone.

TABLE 26.22 Endocrine and Imaging Studies in Delayed Adolescence

Initial assessment
- Plasma testosterone or estradiol
- Plasma FSH and LH
- Plasma thyroxine (and prolactin)
- Bone age and lateral skull roentgenograph
- Test of olfaction

Follow-up studies
- Karyotype (short, phenotypic females)
- MRI with contrast enhancement
- Pelvic ultrasonography (females)
- GnRH test
- hCG test (males)
- Pattern of pulsatile LH secretion
- Visual acuity and visual fields

FSH, Follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *hCG,* human chorionic gonadotropin; *LH,* luteinizing hormone; *MRI,* magnetic resonance imaging.

and if the bone age is significantly delayed. In classic cases, MRI of the hypothalamic-pituitary region may not be necessary. The rate of growth in these patients is usually appropriate for bone age; a decrease in growth velocity occurs in some normal children just before the appearance of secondary sexual characteristics and may awaken concerns if such a pattern occurs in these subjects. The onset at puberty correlates better with bone age than with chronologic age in delayed puberty, although bone age is not any better at estimating the onset of puberty in normal boys than is chronologic age and cannot be considered a highly accurate test.[164] Elevated concentrations of gonadotropins and gonadal steroids to early pubertal levels precede secondary sexual development by several months; measurements of serum LH, FSH, estradiol, or testosterone levels in appropriate assays may help to predict future development. The GnRH stimulation test was the gold standard for the determination of whether a child is in puberty, but GnRH is not available in the United States. Under 3 years of age, children may have peaks of gonadotropins and sex steroids similar to pubertal subjects. In healthy Danish girls below 3 years of age LH increases up to 9.2 IU/L after GnRH test, and the stimulated LH/FSH ratio did not exceed 0.43. The third-generation LH assays are sufficiently sensitive to allow in most boys the determination of the onset of endocrine puberty with a single blood sample, but a dynamic GnRH test is still often performed using GnRH agonists. The measurement of gonadotropins 1 hour (or 4 hours in some reports) after a subcutaneous injection of GnRH agonist is the current method of testing dynamic secretion of gonadotropins in the absence of native GnRH supplies.

Measurement of an 8 AM serum testosterone level provides an accurate indication of impending pubertal development; a value of greater than 0.7 nmol/L (20 ng/dL) predicts enlargement of testes to greater than 4 mL by 12 months in 77% of cases and in 15 months in 100% of cases, whereas of those with a value less than 0.7 nmol/L, only 12% entered puberty in 12 months and only 25% entered puberty in 15 months. This technique may help predict spontaneous pubertal development, but it still requires considerable watching and waiting.[460] A single inhibin B value under 35 pg/mL holds promise in eliminating CDP in boys.[260,488] A method has been proposed to reliably separate constitutional delay in puberty from idiopathic hypogonadotropic hypogonadism in girls; a basal inhibin B value of less than 20 pg/mL or a GnRH agonist stimulated follicle-stimulating hormone less than 11 IU/L at 4 hours favors IHH.[701] For boys a method to reliably separate CDP from IHH is proposed to be a basal LH of less than 0.3 IU/L or a stimulated LH at 4 hours after GnRH agonist of less than 5.3 IU/L or an inhibin B less than 111 pg/mL.[702] A recent series of 174 boys with delayed puberty found that a history of cryptorchidism carried the highest risk of hypogonadism of all types and the combination of small testes (<1.1 mL) and low inhibin B (10–50 ng/L) carried the highest risk of CHH.[703] Low AMH values are found in severe IHH.[703] Functional hypogonadotropic hypogonadism or CDP were more likely if growth velocity was less than 3 cm per year. These methods require continued evaluation before they become standard clinically. Watchful waiting may remain the procedure of choice when a patient does not fulfill the delineated criteria and does not fall into a diagnosable grouping.

The presence of red flags is suggested to be a strong indication of gonadotropin deficiency rather than CDP. Thus lack of prior minipuberty of infancy (such as cryptorchidism or micropenis) or the presence of congenital defects, including anosmia, deafness, mirror movements, renal agenesis, dental/digital anomalies, clefting or coloboma, or findings of CHARGE syndrome, make the diagnosis of gonadotropin deficiency more likely.[704] Genetic testing for many of the genes that cause Kallmann syndrome is available; it is suggested that priorities for such testing may be best focused upon subjects with anosmia or hyposmia, synkinesia, dental agenesis, digital bony abnormalities, and hearing loss.[705] Genetic testing for *PROP* mutations is commercially available for combined hypopituitarism.

A typical patient with isolated gonadotropin deficiency is of average height for age and has eunuchoid proportions; has low plasma concentrations of gonadal steroids, LH, and FSH; and has no increase or a blunted response of LH after GnRH or GnRH agonist administration. The amplitude and usually the frequency of LH pulses are decreased when serial blood samples are studied over a 24-hour period. In some forms of Kallmann syndrome, the sense of smell is absent or impaired. However, as stated, differentiation of isolated gonadotropin deficiency in the absence of hyposmia or anosmia from CDP may be difficult at initial study. Gonadotropin-deficient patients may be as short as those with constitutional delay in growth and adolescence, and concentrations of LH and FSH in hypogonadotropic hypogonadism may be indistinguishable from those of normal prepubertal children or children with constitutional delay. Sometimes, years of observation are necessary to detect the appearance of spontaneous and progressive signs of secondary sexual development or to document rising concentrations of gonadotropins or gonadal steroids before the diagnosis is clear. There is a tendency for hypogonadotropic patients to undergo adrenarche at a normal age and to have higher DHEAS concentrations than those with constitutional delay in growth, and this pattern is helpful in making the differential diagnosis.[442] In most cases, absence of the first signs of sexual maturation or failure of a rise in gonadotropins or gonadal steroid levels by age 18 years in the presence of a normal concentration of serum DHEAS for chronologic age supports the diagnosis of isolated gonadotropin deficiency.

Patients with deficiency of gonadotropins combined with deficiency of other pituitary hormones require careful evaluation for a CNS neoplasm, especially if the defects are acquired. Visual field or optic disc abnormalities support the diagnosis of CNS tumor; even if these tests are normal, cranial MRI should be done to evaluate the pituitary gland and stalk and the hypothalamic region. MRI appears superior to CT for detecting mass lesions and developmental abnormalities of the hypothalamic-pituitary region.

Treatment of Delayed Puberty and Sexual Infantilism

Patients with constitutional delay in growth and adolescence ultimately have spontaneous onset and progression through puberty. Often, reassurance and continued observation to ensure that the expected sexual maturation occurs are sufficient. However, the stigma of appearing less mature than one's peers can cause psychologic stress. These individuals may be unable to participate in the dating activities their friends are starting; smaller size may lead them to avoid participation in athletics; immature appearance may lead to ridicule, especially in the locker room; and schoolwork may suffer because of their poor self-image. Some children feel such intense peer pressure and low self-esteem that only the appearance of signs of puberty can reassure them and enable them to participate in sports and social activities with their peers. Poor

self-image in late-maturing boys may carry into adulthood, even after normal puberty ensues. Growth retardation appears more often responsible for most of the stress rather than the delay in pubertal development itself.

For psychologic reasons, for boys 14 years old or older who show no signs of puberty, a 3-month to 6-month course of testosterone enanthate, cypionate, or cyclopropionate (50-mg dose given intramuscularly every 4 weeks) may be helpful. Because starting with the higher dose of 100 mg can lead to priapism in treatment-naïve boys, care, lower dosage, and short-acting preparations are advisable. Decades of experience confirm no effect on adult height of low dosages in the short term.[706] The low dose of testosterone enanthate is considered to be safe but can raise apolipoprotein B (apoB) and decrease HDL cholesterol and apoAI levels (estradiol increases HDL cholesterol and decreases triglycerides, LDL cholesterol, and apoB). Although the use of exogenous androgens may improve self-image and start the secondary sexual changes of puberty, low-dose androgen use does not increase final height. Low-dose estrogen may be invoked in the treatment of CDP in girls in a similar manner.

If during the 3 to 6 months after discontinuing gonadal steroid therapy spontaneous puberty does not ensue or the concentrations of plasma gonadotropins and plasma testosterone in boys or plasma estradiol in girls do not increase, the treatment may be repeated. Only one or two courses of therapy usually are necessary. When treatment is discontinued after bone age has advanced, for example, to 12 to 13 years in girls or 13 or 14 years in boys, patients with constitutional delay usually continue pubertal development on their own, whereas those with gonadotropin deficiency do not progress and may regress. Oral testosterone undecanoate was successfully used for less than 1 year in a large study of boys with constitutional delayed puberty with apparently no ill effects.[707]

Functional hypogonadotropic hypogonadism associated with chronic disease is treated by alleviating the underlying problem. Delayed puberty in this situation is usually a result of inadequate nutrition and low weight or excessive energy expenditure. When weight returns to normal values, puberty usually occurs spontaneously, although there will likely be months of delay. Treatment with T_4 allows normal pubertal development in hypothyroid patients with delayed puberty.

The transition of care from the range of age normally considered to be adolescence, administered by a pediatric practitioner, to adult life, administered by a practitioner experienced in adult endocrinology, presents important implications for a change in the manner in which medical care is presented. Changes in the individual's autonomy and implications of legal distinctions arise, and some have suggested that this transition period should be considered another stage of the life span.[708]

Congenital or acquired gonadotropin deficiency as a result of a lesion or surgery requires replacement therapy at an age approximating the normal age of onset of puberty (Tables 26.23 and 26.24). Present practice in hypogonadotropic hypogonadism is replacement with gonadal steroid therapy, but there is research into the use of gonadotropins or GnRH to stimulate the adolescent age gonad in a more physiologic manner; at present it is not clear which is the optimal approach in teenagers, but sex steroid replacement is most often used.

An exception may occur when GH deficiency coexists with gonadotropin deficiency; if bone age advancement and epiphyseal fusion are brought about by testosterone or estradiol replacement before therapy with GH causes adequate linear growth, adult height will be compromised. However, if puberty is not initiated early enough, the patient may suffer psychologic damage. It is advisable to initiate puberty in these patients with low-dose gonadal steroids by age 14 in boys and age 13 in girls, regardless of the definitive diagnosis of gonadotropin deficiency. Isolated GH-deficient patients may have a delayed onset of puberty; with GH administration, puberty usually occurs at an appropriate age but may progress faster than in normal individuals. Children with GH deficiency showed a correlation between the age of onset of induced puberty and adult height for those who were also gonadotropin deficient, whereas those who underwent spontaneous puberty, which occurred earlier than the age of hormone-induced puberty in the gonadotropin-deficient children, had a decreased adult height. This supports the advisability of waiting to initiate puberty in GH-deficient and gonadotropin-deficient children. Height at the onset of puberty is also correlated with adult height in GH-deficient children. However, artificially delaying puberty with a GnRH analogue to attempt to achieve a greater final height has been attempted in isolated cases of GH deficiency or with normal-variant short stature, but concern over decreased bone density seen in subjects treated with GnRH analogues led to warnings about the use of this agent in GH-deficient patients. There is inadequate evidence of efficacy to recommend this therapy.[470]

Microphallus due to hypothalamic deficiencies may be treated with one or two 3-month courses of testosterone enanthate, with 25 mg per month given intramuscularly to enlarge the size of the penis.[327] Although concern was raised that early testosterone therapy might not allow the attainment of a normal adult penile size, experience has shown otherwise. The concern that the penis might not respond to androgens later in life if exposed to testosterone in childhood, a pattern observed in the rat, proved incorrect. Positive psychologic outcomes and attainment of normal stretched penile

TABLE 26.23 Management and Treatment of Delayed Puberty

OBJECTIVE
Determine site and cause of abnormality.
Induce and maintain secondary sexual characteristics.
Induce pubertal growth spurt.
Prevent the potential short-term and long-term psychologic, personality, and social handicaps of delayed puberty.
Ensure normal libido and potency.
Attain fertility.
THERAPY
Concerned But Not Anxious or Socially Handicapped Adolescent
Reassurance and follow-up (tincture of time)
Repeat evaluation (including serum testosterone or estradiol) in 6 mo
Psychosocial Handicaps, Anxiety, Highly Concerned
Therapy for 4 mo
Boys: testosterone enanthate 100 mg IM q4wk at 14-14.5 yr of age, or overnight transdermal testosterone patch
Girls: ethinyl estradiol 5-10 mg/day PO or conjugated estrogens 0.3 mg/day PO or overnight ethinyl estradiol patch at 13 yr of age
No therapy for 4-6 mo; reevaluate status including serum testosterone or estradiol; if indicated repeat treatment regimen

IM, Intramuscularly; *PO*, orally; *q*, every.

TABLE 26.24 Hormonal Substitution Therapy in Hypogonadism

Boys

Goal: to approximate normal adolescent development when diagnosis is established

Initial therapy: at 13 yr of age, testosterone enanthate (or other long-acting testosterone ester) 50 mg IM every month for about 9 mo (6-12 mo)

Over the next 3-4 yr: gradually increase dose to adult replacement dose of 200 mg q2-3wk

Testosterone gel is coming into widespread use as discussed in the text

Begin *replacement therapy in boys with suspected hypogonadotropic hypogonadism* by bone age ≤14 yr

To induce fertility at appropriate time in hypogonadotropic hypogonadism: pulsatile GnRH or FSH and hCG therapy

Girls

With a firmly established diagnosis of hypogonadism (e.g., girls with 45,X gonadal dysgenesis), begin hormonal substitution therapy at 12-13 yr of age

Goal: to approximate normal adolescent development

Initial therapy: ethinyl estradiol 5 mg by mouth or conjugated estrogen 0.3 mg (or less) by mouth daily for 4-6 mo or preferably estradiol transdermally

After 6 mo of therapy (or sooner if breakthrough bleeding occurs), begin cyclic therapy:

- Estrogen: first 21 days of month
- Progestogen (e.g., medroxyprogesterone acetate 5 mg PO) 12th to 21st day of month
- Gradually increase dose of estrogen over next 2-3 yr to conjugated estrogen 0.6-1.25 mg or ethinyl estradiol 10-20 mg daily for first 21 days of month or estradiol patch

In hypogonadotropic hypogonadism, to induce ovulation at appropriate time: pulsatile GnRH or FSH and hCG therapy

FSH, Follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *hCG,* human chorionic gonadotropin; *PO,* orally; *q,* every.

length have been reported.[527,709] It is appropriate to treat male infants and children with micropenis due to gonadotropin or GH deficiency with short courses of androgens to enlarge the penis into the normal childhood range. Patients with isolated congenital GH deficiency occasionally have micropenis that may be successfully treated with GH replacement alone. It is not appropriate to sex reverse a male infant because of microphallus caused by fetal testosterone or GH deficiency.

Episodic administration of GnRH elicits pulsatile LH and FSH release and gonadal stimulation in prepubertal children or hypogonadotropic patients. Portable pumps are used to administer episodic GnRH over prolonged periods. Pulsatile GnRH therapy can induce puberty and promote the development of secondary sexual characteristics and spermatogenesis in men and ovulation in women,[710] but it is not practical for the routine induction of puberty in adolescent boys and girls with gonadotropin deficiency. Pregnancy can be achieved with this regimen in women and spermatogenesis in men with hypogonadotropic hypogonadism. A lower frequency of GnRH administration favors FSH secretion, whereas a faster frequency favors LH secretion and ultimately has been associated with a PCOS-like picture.

Human menopausal gonadotropin and hCG can be used as effective substitutes for recombinant human pituitary LH and FSH to produce full gonadal maturation, but this regimen is cumbersome and expensive. At present, long-term gonadal steroid replacement therapy is the treatment of choice for hypothalamic or pituitary gonadotropin deficiency until fertility is desired.

Hypergonadotropic hypogonadism is treated by replacement of testosterone in boys and estradiol in girls. For treatment of gonadal dysgenesis, estrogen therapy should be initiated when the patient is age 13 (bone age >11 years) to allow secondary sexual development at an appropriate chronologic age. Klinefelter syndrome is compatible with various degrees of spontaneous masculinization at puberty; some patients require testosterone replacement. The concentration of plasma testosterone and LH should be monitored every 6 months during puberty and yearly thereafter. If the LH level rises more than 2.5 SD above the mean value or the testosterone level decreases below the normal range for age, testosterone replacement therapy is indicated. FSH is increased due to lack of inhibin from affected testes and may not decrease with testosterone treatment.

Patients receiving gonadal steroid replacement follow the same treatment regimen whether the diagnosis is hypogonadotropic hypogonadism or hypergonadotropic hypogonadism (see Table 26.24). Various testosterone preparations are available with several routes of administration. Alkylated testosterone preparations should be avoided because of the risk of peliosis hepatis (i.e., hemorrhagic liver cysts), which is not related to dose or duration of treatment; although regression is possible with discontinuation of testosterone treatment, progression to liver failure can occur. Males may receive testosterone enanthate, propionate, or cypionate (50 mg every 4 weeks intramuscularly) at the start, although priapism has been reported with the higher starting dose (100 mg) in a testosterone-naïve boy; later, the dosage is gradually increased to 200 to 300 mg every 2 to 3 weeks. Low-dose replacement therapy is appropriate until well into the pubertal growth spurt.

Dermal preparations of testosterone have been used in studies of delayed puberty. Testosterone may be administered by cutaneous patch on nonsexual skin to cause secondary sexual development in hypogonadal adolescents; patches may be given at night to recreate the diurnal variation of testosterone seen in early puberty. Physiologic values of serum testosterone may be reached with these patches, along with secondary sexual development. A teenage boy may be less likely to apply a patch daily, and biweekly or monthly injections may allow better compliance; nonetheless, 2.5-mg and 5-mg dermal testosterone patches may be useful in motivated teenagers. Testosterone gel preparations, usually rubbed onto the forearms or shoulders, are approved for adults but not for adolescents. Contact with the skin, clothing, or towels used by a patient treated with androgen gel can cause virilization in young children or women. Testosterone ointment may be used as therapy for microphallus to enlarge the size of the phallus intentionally, but a normal infant or child contacting the skin of an individual treated with testosterone gel (before it is absorbed) runs the risk of unplanned testosterone effects.[711] A dose of 10 mg of 2% transdermal testosterone given for 6 months achieved similar effects to 50 mg of intramuscular testosterone in terms of height velocity, although the control group in comparison achieved testicular enlargement while the treated groups did not.[712] A 1% testosterone gel given daily to patients age 12 to 17 years with Klinefelter syndrome or anorchia raised their serum testosterone levels to the pubertal range over a 6-month period of treatment: Cough was the major adverse reaction.[713] Transdermal testosterone is not approved for use in teenagers with delayed puberty.

The type and route of estrogen administration for girls are being reconsidered. Many suggest the use of 17β-estradiol rather than ethinyl estradiol owing to more physiologic effects; there is evidence in the treatment of transgender individuals that the use of ethinyl estradiol or conjugated estrogen carries a higher risk for venous and arterial thrombosisis.[704] Transdermal estrogen administration is presently recommended to avoid the first pass effect and hepatic clotting factor production as injected estrogen transits the liver and stimulates the production of proteins such as C-reactive protein, angiotensin precursor, and activated protein C, which are involved in cardiac complications; adult women treated with injectable estrogen had experienced increased risk of deep vein thrombosis and pulmonary thromboembolism, breast cancer, decreased serum insulin-like growth factor-I concentrations, and reduced lean body mass but increased fat mass. This contrasts with dermal estrogen, which is administered in lower dosages and reaches its therapeutic targets relatively unchanged and in lower, more physiologic concentrations; there is no change in these proteins with dermal estrogen administration.[714,715] For girls 13 years of age or older, transdermal estrogen has been used in clinical trials for decades in the treatment of delayed puberty or hypogonadism with beneficial results on physical development and bone density and is entering widespread use.[716]

Initially, girls 12 to 13 years old are given estradiol alone in an attempt to mimic normal estrogen exposure characteristic of puberty. Estrogen patches, fractions of Evorel patches (0.05–0.07 μg/kg in younger girls or 0.08–0.12 μg/kg in older girls every night) where it is desirable to have more rapid breast development, demonstrate achievement of reasonable levels of serum estrogen.[716] Evorel patch is available in Europe; in the United States, one-sixth to one-eighth of a Vivelle-Dot patch is administered once or twice per week.[677] There is individual variation up to 10% in absorption, but in an individual similar plasma levels are achieved using 2 mg daily oral 17β-estradiol, 2 mg daily gel, and 100-mg patch.[704] However, these patches are not FDA approved for such use at this time. From a clinical experience 50 girls were given dosage that increased every 6 months until an adult dose of 100 to 200 μg daily or one to two pumps of 0.06% estrogen gel daily demonstrated efficacy. Estradiol gel in an increasing dose from 0.1 to 1.5 mg given over a 5-year period is reported to be safe and effective as replacement therapy in girls with Turner syndrome.[717] As with testosterone, children must not be in contact with the preparation because untoward estrogen effects may occur. However, it is important to note that to date dermal estrogen preparations are not approved for teenagers. If oral estradiol is used an initial dose might be 0.1 mg increasing toward adulthood to 1 to 2 mg daily.

Progestational agents are added after breakthrough bleeding occurs or when the girl reaches Tanner stage 4 after the start of cyclic estrogen therapy to avoid causing endometrial hyperplasia and to enhance artificially induced menstrual periods along with estradiol. Progestational agents may be initiated as 5 to 10 mg of progesterone first given 5 days per month increasing to 14 days per month toward adulthood. Estradiol might be administered the first 21 days of the cycle with progesterone added the last 14 days of the artificial cycle.

The maintenance dose should be the minimal amount to maintain secondary sexual characteristics, sustain withdrawal bleeding, and prevent osteoporosis. Undesirable effects are uncommon but may include weight gain, headache, nausea, peripheral edema, and mild hypertension.

There is a concern about the increased risk of endometrial and breast carcinoma in patients receiving chronic estrogen replacement therapy, including patients with Turner syndrome.[718] The use of progestational agents to antagonize the effect of estrogens reduces the risk of endometrial cancer, but the best answer about the optimal dose of estrogen, route of administration, and dose of progesterone to enhance development without unduly increasing the risk of cancer must come from future studies. Estrogen replacement is important for its antiosteoporosis action on bone. Bone density is decreased in Turner syndrome in part because of hypogonadism at puberty, and this tendency becomes more severe with age in patients who discontinue or do not receive estrogen replacement therapy. Transdermal estrogen can increase bone density in subjects with Turner syndrome who have finished statural growth.[719] We lack adequate controlled studies on optional sex steroid replacement regimens in young adolescent women.

Biosynthetic hGH therapy in Turner syndrome causes an increase in growth rate, with an increase in adult height approaching or reaching the lower range of the normal growth curves possible, as stated earlier.

Patients with hypopituitarism may complain of sparse pubic hair growth or, in girls, total absence of pubic hair. Pubic hair thickens further in affected males with hCG treatment, which adds the testicular contribution of testosterone to the exogenous testosterone therapy. GH therapy in GH-deficient and gonadotropin-deficient males enhances the steroidogenic response of the testes to hCG administration. Adolescent or young adult women have been given a low dose (25 mg) of long-acting intramuscular testosterone every 4 weeks to stimulate the growth of pubic hair without virilization. Oral DHEAS treatment is suggested to improve pubic hair growth in hypopituitary girls.[720] However, these androgens are not presently standard practice.

Aromatase inhibitors have been used to enhance growth in short children, including those with constitutional delay in puberty, by decreasing estrogen levels that would ordinarily advance bone age and limit future growth.[471] Unfortunately there are limited data on actual adult height achieved as most studies predict adult height at a point before the child actually ceases growth.[721]

As in the male, psychologic counseling is beneficial for girls to deal with the impact of chronic medical visits, infertility after an extensive medical treatment, and perhaps a less than ideal physical development compared to peers. Adults affected by hypogonadotropic hypogonadism comment that while their providers may attend to their medical treatment, they often do not address their emotional needs. Further problems occur when patients are lost to follow-up as they make the transition to adult care.[722]

Sexual Precocity[994]

If iso-sexual precocity results from premature reactivation of the hypothalamic GnRH pulse generator/pituitary gonadotropin-gonadal axis, the condition is GnRH dependent and is termed *CPP* (i.e., *central* [or previously, *complete* or *true*] *precocious puberty*). Pulsatile LH release has a pubertal pattern, and the rise in the concentration of LH after GnRH or GnRH agonist administration is indistinguishable from the normal pubertal pattern of serum LH. If extrapituitary secretion of gonadotropins or secretion of gonadal steroids independent of pulsatile GnRH stimulation leads to virilization in boys or feminization in girls, the condition is termed *incomplete, pseudoprecocious,* or *peripheral precocious puberty*. The production of excessive estrogens in males leads to inappropriate feminization, and the production of increased

androgen levels in females leads to inappropriate virilization; these conditions are termed *contrasexual precocity* or *heterosexual precocity*. Disorders causing sexual precocity are therefore separated into those in which the increased secretion of gonadal steroids depends on GnRH stimulation of pituitary gonadotropins and those in which it is unrelated to activation of the hypothalamic GnRH pulse generator.

In all forms of sexual precocity, increased gonadal steroid secretion increases height velocity, somatic development, and the rate of skeletal maturation; because of premature epiphyseal fusion, sexual precocity can lead to the paradox of tall stature in childhood but short adult height (Table 26.25). Untreated females with idiopathic CPP demonstrated a mean adult height of 151 to 155 cm.[723] In the few reports of adult height in boys with untreated precocious puberty, mean adult stature was 155.4 cm ± 8.3 SD, with all subjects well below midparental height and far below the father's height from the data available.[724,725]

Serum alkaline phosphatase reflects growth, and IGF1 concentrations reflect the degree of sexual development rather than chronologic age, as do most chemistry and hematology values. The serum concentrations of the propeptide of type III procollagen (P-III-NP) in normal puberty and in CPP parallel the normal pubertal growth curve and also parallel the changes in growth rate in children treated with GnRH agonists. Blood pressure matches that of normal subjects of the same height and gender after correcting for bone age rather than chronologic age according to the latest standards for blood pressure.[726]

In boys (Fig. 26.51), the testes usually enlarge under gonadotropin stimulation before any other signs of puberty are seen; in girls, an increase in the rate of growth, the appearance of breast development, enlargement of the labia minora, and maturational changes in the vaginal mucosa are the usual presenting signs, with variable manifestations of pubic hair depending on the age at onset. Progression of secondary sexual maturation may be more rapid than normal, but a waxing and waning course of development may occur. Spermatogenesis in males and ovulation in females often occur, and fertility is possible. The rapid growth is associated with the increased GH secretion and elevation of serum IGF1 levels resulting from stimulation by estradiol. The ratio of bone age to chronologic age and the rise of IGF1 above normal values for chronologic age are predictive of outcome: More mildly affected children progress less rapidly and tend to maintain their target height, and this may represent a benign entity.

Central Precocious Puberty: Complete Isosexual Precocity

As noted earlier, the classic lower age limit beneath which the diagnosis of precocious puberty is applied was 8 years in girls. However, this limit was reconsidered leading into the amended diagnosis of sexual precocity (Table 26.26) as the appearance of any sign of secondary sexual maturation before 7 years for white girls and 6 years for African-American girls. These newer lower cutoffs assume that there are no signs or symptoms of CNS disorders or other concurrent diseases that might cause sexual precocity, as evaluation is indicated in those cases regardless of age. Further, the newer lower limits usually applied to girls with elevated body mass index values and if the subject does not have an increased BMI evaluation may still be indicated. Thus careful evaluation is essential at these lower age ranges in girls who should have only minimal slowly progressive signs of sexual precocity. These newer limits remain controversial, so the cautions described must be heeded.

In the UCSF series of more than 200 patients with CPP, girls had true precocious puberty (i.e., GnRH-dependent CPP) five times more commonly than boys, and idiopathic CPP was eight times more common in girls than in boys (Table 26.27). Others reported a 10-fold increased prevalence of precocious puberty in girls compared with boys. CNS abnormalities occurred at least as often as idiopathic CPP in boys, whereas in girls neurologic lesions were one-fifth as common as idiopathic disorders. Therefore, it is essential to search for a CNS cause for CPP, especially in boys, because sexual precocity may be the only manifestation of a CNS tumor (Tables 26.28 and 26.29). However, most children referred for evaluation have the benign variants leading to premature thelarche or premature adrenarche.

TABLE 26.25 Historical Controls of Untreated Children With True Precocious Puberty

TABLE 26.26 Classification of Sexual Precocity

TRUE PRECOCIOUS PUBERTY OR COMPLETE ISOSEXUAL PRECOCITY (GNRH-DEPENDENT SEXUAL PRECOCITY OR PREMATURE ACTIVATION OF THE HYPOTHALAMIC GNRH PULSE GENERATOR)

- Idiopathic true precocious puberty
- CNS tumors
  - Optic glioma associated with neurofibromatosis type 1
  - Hypothalamic astrocytoma
- Other CNS disorders
  - Developmental abnormalities including hypothalamic hamartoma of the tuber cinereum
  - Encephalitis
  - Static encephalopathy
  - Brain abscess
  - Sarcoid or tubercular granuloma
  - Head trauma
  - Hydrocephalus
  - Arachnoid cyst
  - Myelomeningocele
  - Vascular lesion
  - Cranial irradiation
- True precocious puberty after late treatment of congenital virilizing adrenal hyperplasia or other previous chronic exposure to sex steroids
- True precocious puberty due to gain of function mutations:
  - in KISS1R/GRP54 gene
  - in *KISS1* gene

INCOMPLETE ISOSEXUAL PRECOCITY (HYPOTHALAMIC GNRH-INDEPENDENT)

Males

- Gonadotropin-secreting tumors
  - hCG-secreting CNS tumors (e.g., chorioepitheliomas, germinoma, teratoma)
  - hCG-secreting tumors located outside the CNS (hepatoma, teratoma, choriocarcinoma)
- Increased androgen secretion by adrenal or testis
  - Congenital adrenal hyperplasia (CYP21 and CYP11B1 deficiencies)
  - Virilizing adrenal neoplasm
  - Leydig cell adenoma
  - Familial testotoxicosis (sex-limited autosomal dominant pituitary gonadotropin-independent precocious Leydig cell and germ cell maturation)
  - Cortisol resistance syndrome

Females

- Ovarian cyst
- Estrogen-secreting ovarian or adrenal neoplasm
- Peutz-Jeghers syndrome

Both Sexes

- McCune-Albright syndrome
- Hypothyroidism
- Iatrogenic or exogenous sexual precocity (including inadvertent exposure to estrogens in food, drugs, or cosmetics)

VARIATIONS OF PUBERTAL DEVELOPMENT

- Premature thelarche
- Premature isolated menarche
- Premature adrenarche
- Adolescent gynecomastia in boys
- Macroorchidism

CONTRASEXUAL PRECOCITY

Feminization in Males

- Adrenal neoplasm
- Chorioepithelioma
- CYP11B1 deficiency
- Late-onset adrenal hyperplasia
- Testicular neoplasm (Peutz-Jeghers syndrome)
- Increased extraglandular conversion of circulating adrenal androgens to estrogen
- Iatrogenic (exposure to estrogens)

Virilization in Females

- Congenital adrenal hyperplasia
  - CYP21 deficiency
  - CYP11B1 deficiency
  - 3βHSD deficiency
- Virilizing adrenal neoplasm (Cushing syndrome)
- Virilizing ovarian neoplasm (e.g., arrhenoblastoma)
- Iatrogenic (exposure to androgens)
- Cortisol resistance syndrome
- Aromatase deficiency

CNS, Central nervous system; *CYP11B1*, 11-hydroxylase; *CYP21*, 21-hydroxylase; *GnRH*, gonadotropin-releasing hormone; *hCG*, human chorionic gonadotropin; *3βHSD*, 3β-hydroxysteroid dehydrogenase 4,5-isomerase; *KISS1R/GPR54*, kisspeptin/G protein–coupled receptor 54.

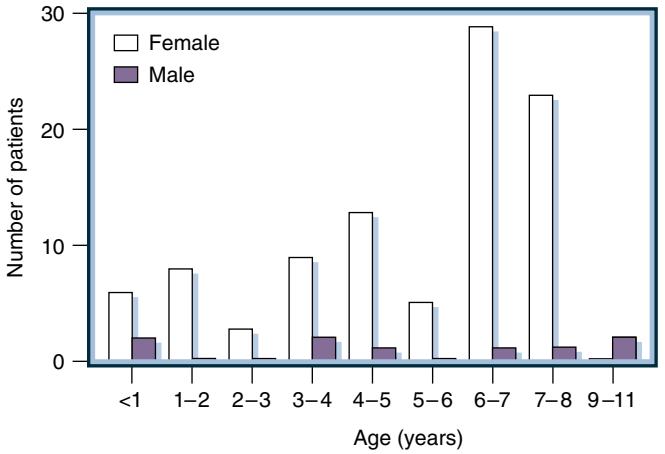
Modified from Grumbach MM. True or central precocious puberty. In: Kreiger DT, Bardin CW, eds. *Current Therapy in Endocrinology and Metabolism, 1985-1986*. Toronto, Canada: BC Decker; 1985:4–8.

Idiopathic True or Central Precocious Puberty[159,160,316,423,726,727]

In otherwise healthy girls, those with onset of puberty at 6 to 8 years of age often represent one end of the normal range of age at puberty onset; those with constitutional delay in growth and adolescence fall at the opposite end of the normal range of variation. These girls with low normal age of onset of puberty are often considered to have early puberty; a meta-analysis demonstrated that treatment with GnRH agonist is not needed to achieve mid-parental height.[728,729]

Children may develop CPP with no familial tendency and no signs of organic disease; these children have idiopathic CPP. This condition, which may manifest in infancy (see Table 26.27), is commonly associated with electroencephalographic abnormalities. The age at onset is 6 to 7 years (the new boundaries for age of onset of normal puberty suggest some of the 7-year-olds may be in the normal range) for about 50% of affected girls, 2 to 6 years for about 25%, and during infancy for 18% (Fig. 26.50). Patients with organic forms of CPP, especially if associated with hypothalamic hamartoma, have an earlier mean age at onset than those with the idiopathic form.

Many girls in this subset have clinical and hormonal features that fall between those of premature thelarche and CPP (e.g., more rapid growth rate) and are typical of neither condition[730]; this is



• **Fig. 26.50** Age at onset of idiopathic true precocious puberty in 106 children. At all ages, the frequency is greater in females than in males. The peak prevalence in girls is between ages 6 and 8 years. (From Kaplan SL, Grumbach MM. The neuroendocrinology of human puberty: an ontogenetic perspective. In: Grumbach MM, Sizonenko PC, Aubert ML, eds. *Control of the Onset of Puberty.* Baltimore, MD: Williams & Wilkins; 1990:1–68.)

denoted exaggerated thelarche. About 10% of girls with apparently classic premature thelarche progress to definite CPP, but there are no signs at the time of first presentation to differentiate them from girls who continue with the pattern of premature thelarche and even biochemical measurements may not define them.[731] In most patients in this situation, the onset of breast development was first noticed after 2 years of age. Therapy may not be indicated if a pubertal pattern of pulsatile LH secretion during sleep is not present or if the basal LH measured by ultrasensitive assay or the LH response to exogenous GnRH or GnRH agonist is prepubertal or the uterus on sensitive ultrasound is less than 34 mm. (The upper limit of uterine length in the prepubertal state is 35 mm, as stated later.) Regular follow-up is thus important.

The nature of the striking sex difference in the prevalence of idiopathic CPP (females > males), compared with that of constitutional delay in growth and puberty (males > females) is poorly understood, although genomic data are accumulating. There may be a history of early maturation in families of affected subjects. CPP may be transmitted as an autosomal dominant trait with incomplete dominance in boys and girls.[726]

Before beginning treatment, it is essential to establish the progressive nature of the sexual precocity. In a subset of girls, the tempo is relatively slow and the sexual precocity may not be sustained. A small proportion of patients with CPP proven by a pubertal response of LH to GnRH and increased pulsatile LH secretion at night may revert spontaneously to a more immature pubertal state, persist without further progression, or fluctuate between progression and regression. There is a continuum in girls with CPP from premature thelarche, through unsustained or slowly progressive precocious puberty, to the relatively rapid progression of sexual maturation once it has begun.[732] If the growth rate slows to normal for age, skeletal maturation progresses in accordance with chronologic age, and there is little to no risk of impairment of adult height[733]; estrogen and IGF1 concentrations are normal or only slightly elevated. If height prediction is normal at the time of diagnosis rather than reduced, the patient does not require therapy; the efficacy of treatment with GnRH in those with onset after 6 years of age is inconsistent and rarely leads to increased adult stature (some sources say the effects of GnRH treatment are decreased after initiation of treatment after 8 years).[470] In some girls, we have observed within a period of 1 to 2 months the return of a prepubertal pattern of LH pulsatility during sleep, a prepubertal LH response to GnRH, and a concentration of plasma estradiol equivalent to the prepubertal state. Unlike typical patients, such girls do not exhibit the initial hyperresponse of plasma estradiol and LH to the GnRH agonist or the physical changes of the estrogen effect, and they tend to have lower serum IGF1.

The uterus and ovaries increase in size in CPP. The ovaries also may develop a multicystic appearance (but not a polycystic appearance) that may remain even after successful treatment with a GnRH agonist. The pituitary gland undergoes hypertrophy in early infancy, puberty, and pregnancy and also increases in size on MRI imaging in patients with CPP (see later).

CPP in females does not lead to premature menopause. However, there is increased risk in girls for the development of carcinoma of the breast in adulthood as noted earlier.[734] Psychosexual development is advanced modestly in patients with sexual precocity (about 1.5 years in girls with idiopathic CPP).

The gonadotropin and gonadal steroid concentrations in plasma, the LH response to GnRH administration, and the amplitude and frequency of LH pulses are in the normal pubertal range in CPP (Figs. 26.52 and 26.53). The third-generation gonadotropin assays allow diagnosis of CPP by the determination in a single serum sample of LH in the basal state in most girls.[260] Gonadotropin determination 60 or 240 minutes after a single subcutaneous dose of GnRH or GnRH agonist can diagnose CPP with high specificity and sensitivity. Adrenarche usually does not accompany gonadarche in girls with CPP who are younger than 5 or 6 years of age[442]: Pubic hair is sparse or absent initially in such girls. When the onset of CPP occurs after age 6 years, it is usually associated with adrenarche that is early for chronologic age but not for bone age.

In the UCSF experience and that of others, normal pregnancies have occurred in women with idiopathic CPP, CPP triggered by a CNS abnormality, or premature menarche.[735] Pregnancy is reported in the lay press in a patient with CPP at 5 years of age, an unfortunate result of childhood sexual abuse and CPP.

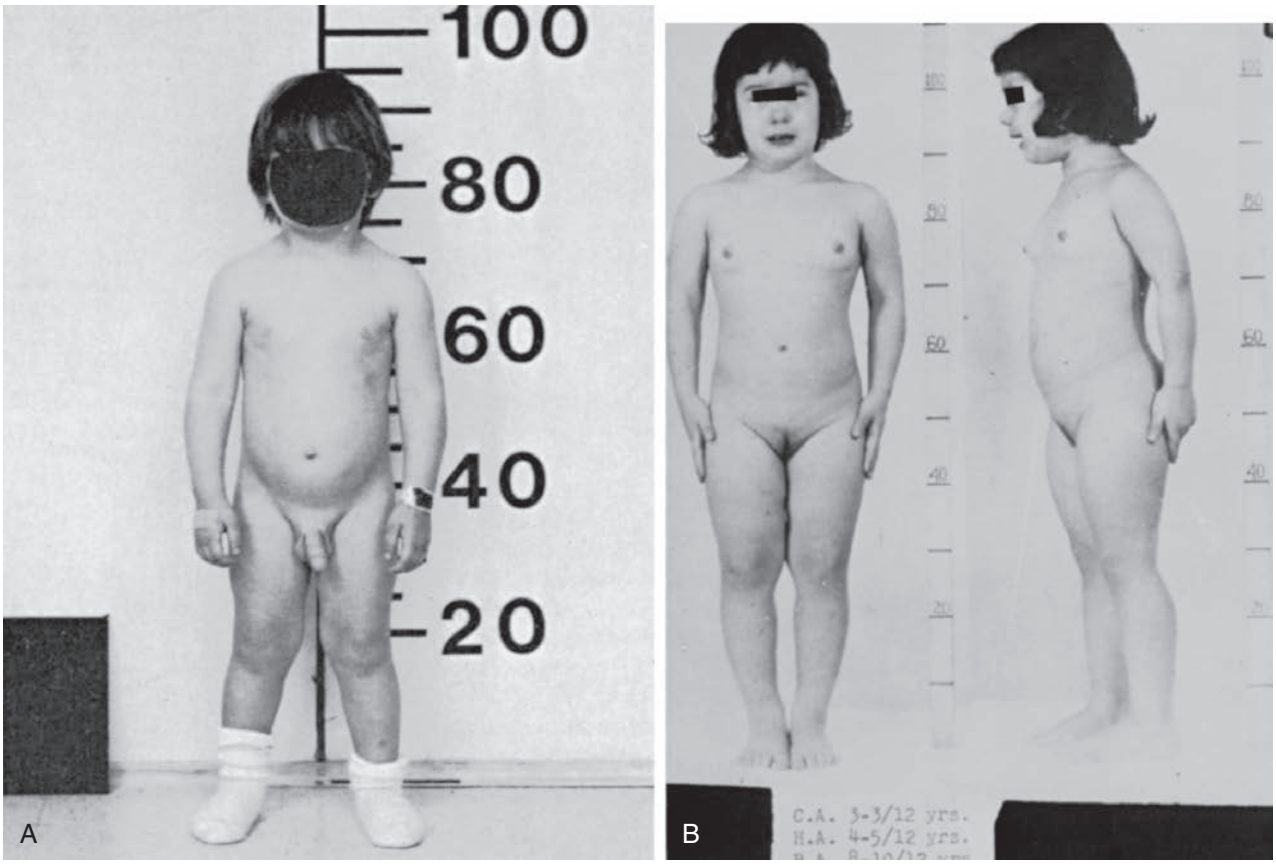
Long-term follow-up of 142 women up to 50 years of age who had central precocious puberty demonstrated no significant health conditions compared to the control population.[736] Treatment with gonadotropin-releasing hormone agonist or lack of treatment did not change this conclusion. In an upcoming discussion, however, a concern over the occurrence of PCOS is raised.

An increase in the prevalence of CPP girls in Korea between 2014 and 2010 is reported.[737] There was a lesser but measurable increase in prevalence in boys as well.

Gain-of-Function Mutations as Cause of Central Precocious Puberty

KISS and KISSIR/GRP54 Mutations

KISS Mutations. Whereas inactivating mutations in the KISS1R receptor cause hypogonadotropic hypogonadism, recently the first detected mutations in the gene encoding KISS and KISSR associated with precocious puberty were reported.[727] Two novel *KISS1* missense mutations were discovered in three children with idiopathic CPP; these mutations were absent in 400 control alleles. The first was an adopted Brazilian girl who had slowly progressing thelarche since birth, but acceleration of growth, bone age maturation, and secondary sexual development occurred at 7 years of age and was reversed with GnRH agonist treatment and had borderline pubertal GnRH-stimulated LH peak levels.[738] She had a



• **Fig. 26.51** (A) A boy aged 2 years and 5 months with idiopathic precocious puberty. He had pubic hair and phallic and testicular enlargement by 10 months of age. At 1 year, his height was 86 cm (+4 SD [standard deviation]); the phallus measured 10 × 3.5 cm, and the testes measured 2.5 × 1.5 cm. The plasma luteinizing hormone (LH) level was 1.9 ng/mL (LER-960); the follicle-stimulating hormone (FSH) level was 1.2 ng/mL (LER-869); and the testosterone level was 416 ng/dL. After 100 μg of gonadotropin-releasing hormone (GnRH), the plasma LH level increased to 8.4 ng/mL, and the FSH level increased to 1.8 ng/mL, a pubertal response. When photographed, the patient had been treated with medroxyprogesterone acetate for 1.5 years. His height was 95.2 cm (+1 SD), the phallus was 6 × 3 cm, and the testes were 2.4 × 1.3 cm. Basal concentrations of LH (LER-960) were 0.9 ng/mL; the FSH (LER-869) level was 0.8 ng/mL; and the testosterone level was 7 ng/dL. After 100 μg of GnRH, LH concentrations rose to 2.3 ng/mL, whereas FSH concentrations did not change when he was on treatment with medroxyprogesterone acetate. For conversion to SI units, see Figs. 26.19 and 26.20. (B) A girl aged 3 years and 3 months with idiopathic true precocious puberty had recurrent vaginal bleeding since she was 9 months old. Her height age was 4 years and 5 months; bone age was 8 years and 10 months. (A, from Styne DM, Grumbach MM. Puberty in the male and female: its physiology and disorders. In: Yen SCC, Jaffe RB, eds. *Reproductive Endocrinology*. 2nd ed. Philadelphia: WB Saunders; 1986:313–384.)

heterozygous activating mutation in the *KISS1R* (p.Arg386Pro), which led to prolonged activation of intracellular signaling pathways in response to kisspeptin.

A 1-year-old boy with CPP had a heterozygous missense mutation in *KISS1* and a c.C369T transition in exon 3 of the *KISS1* gene, resulting in substitution of a proline by a serine at position 74 of kisspeptin-1(1-145) (p.Pro74Ser). His *KISS1* product was thought to be more resistant to degradation, leading to greater kisspeptin bioavailability and leading to a greater capacity to stimulate signal transduction compared to the wild-type kisspeptin; there was no indication of a change of affinity for the receptor. Because his mother and maternal grandmother, who had normal pubertal development, also carried the p.Pro74Ser mutation in the heterozygous state, the mutation was thought to have incomplete sex-dependent penetrance.[727] Two unrelated girls with CPP had homozygous mutations in c.417 C3G in exon 3, leading to the substitution of a histidine by an aspartic acid at position 90 of kisspeptin-1 (p.H90D). It was not clear what biologic changes this mutation brought about to cause the precocious puberty, but heterozygous H90D mutations were previously found in rare patients with IHH. The prevalence of *KISS* mutations causing CPP in children previously thought to have idiopathic CPP remains to be determined but appears to be low. No new mutations of *KISS1* causing CPP have been found at this time.[428]

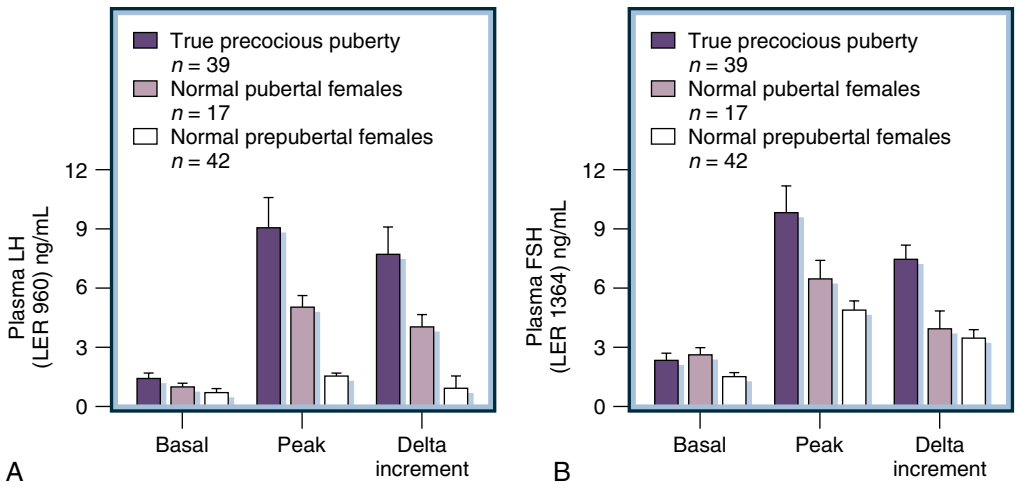
Loss-of-Function Mutations as Cause of Central Precocious Puberty

MKRN3. Ten different loss-of-function mutations of *MKRN3*, an imprinted gene located on the long arm of chromosome 15q11.2 in the Prader-Willi syndrome critical region, which encodes the makorin ring finger protein 3, was found in 22 patients, mostly girls, with CPP, all of whom inherited their mutation from their fathers as the maternal allele of this gene is silenced by methylation, a case of monoallelic expression.[428] No patient had findings of Prader-Willi syndrome. There was no family history reported in most cases in spite of the genetic inheritance of the trait; this is suggested to be an example of the underreporting of the familial nature of CPP in many cases as mothers more often are the parent to bring the child to the doctor. This mutation represents the most common cause of familial CPP. The age range of the onset of secondary sexual development in affected girls was 3 to 6.5 years with a mean of 5.9 years and median 6 years and in boys was 5.9 to 9.7 years with a mean of 8.5 years and median 8.8 years; this genetic dimorphism is reminiscent of the earlier age of normal puberty in girls compared to boys and demonstrates that girls are more affected by the mutation. A single girl diagnosed prepubertally had pubertal development by about 6 years.[739] These ages sometimes overlap with the new guidelines for precocious puberty in girls, which start at 7 years in white girls and 6 years in African-American girls with high BMI values, indicating that some girls starting puberty at these lower limits may have familial CPP. As the age of onset of puberty in affected patients was years after birth it is speculated that *MKRN3* does not play a role in suppression of pubertal development after the minipuberty of infancy but does play a role in the reactivation of the GnRH pulse generator closer to the normal age of pubertal onset. Affected patients are often but not always successfully treated with GnRH agonists. A single girl is described with a genetic alteration in the 4-nt proximal promoter region of *MKRN3*. Her mother had menarche at 10 years but did not have the same 4-nt mutation.[429] A boy and a girl with mutations in the *MKRN3* gene were asymptomatic carriers.[740] A normal-functioning *MKRN3* gene is considered to be a brake for the onset of puberty, and absence of this brake leads to precocious puberty.[425]

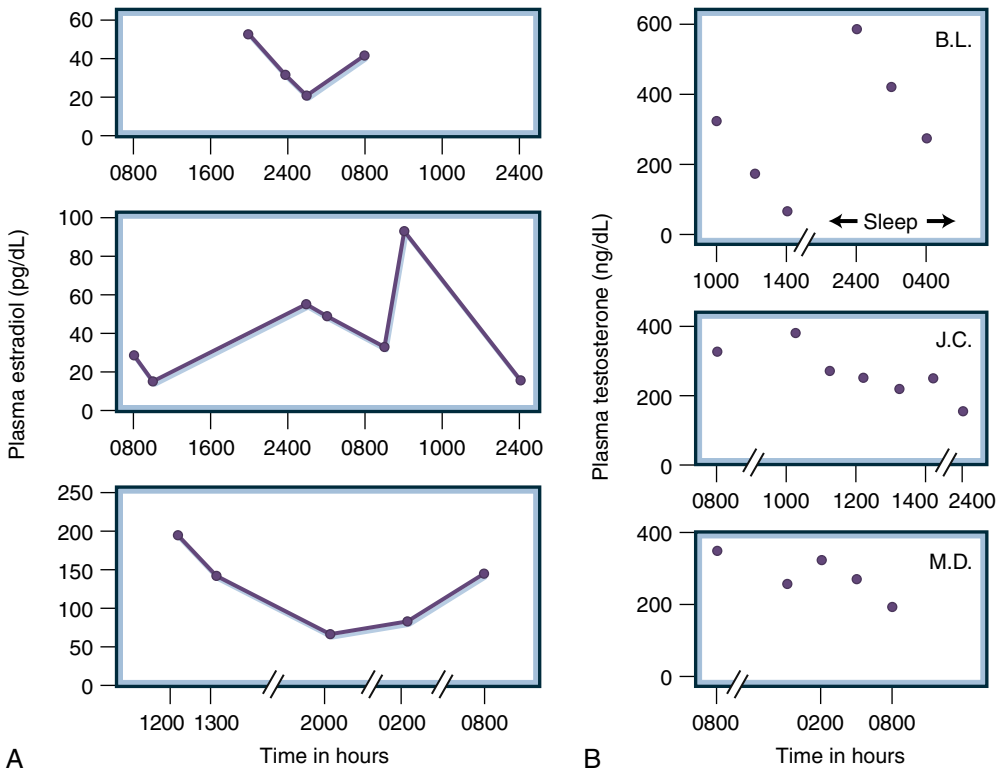
DLK1. Delta-like 1 homolog (DLK1) is another paternally imprinted gene recently reported to be associated with precocious puberty in girls.[741]

Central Nervous System Tumors Causing True Precocious Puberty

Sexual precocity may be the first manifestation of a hypothalamic tumor of any cell type when it arises in or impinges on the posterior hypothalamus. Neurologic symptoms such as headaches and



• **Fig. 26.52** (A) Mean basal plasma luteinizing hormone (LH) level (LER-960) and mean peak and increment after intravenous gonadotropin-releasing hormone (GnRH) (100 μg) in normal prepubertal and pubertal females and in females with idiopathic true precocious puberty. The mean peak and increments of plasma LH are higher in true precocious puberty than in normal puberty. (B) Basal follicle-stimulating hormone (FSH) level (LER-1364) and mean peak and increment after intravenous GnRH (100 μg) in normal prepubertal and pubertal females with true precocious puberty. The concentration of FSH and the response to GnRH were greater in females with true precocious puberty and normal puberty than in prepubertal females. (From Kaplan SL, Grumbach MM. Pathogenesis of sexual precocity. In: Grumbach MM, Sizonenko PC, Aubert ML, eds. *Control of the Onset of Puberty.* Baltimore, MD: Williams & Wilkins; 1990:620–660.)



• **Fig. 26.53** (A) Serial determinations of plasma estradiol in three girls with idiopathic true precocious puberty. Notice the striking fluctuations in values. (B) Serial determinations of plasma testosterone in three boys with true precocious puberty (B.L. and J.C. have a hypothalamic hamartoma; M.D. has the idiopathic form). For conversion to SI units, see Figs. 26.19 and 26.20. (From Kaplan SL, Grumbach MM. Pathogenesis of sexual precocity. In: Grumbach MM, Sizonenko PC, Aubert ML, eds. *Control of the Onset of Puberty.* Baltimore, MD: Williams & Wilkins; 1990:620–660.)

visual disturbances may develop, and children may have diabetes insipidus, hydrocephalus, or optic atrophy caused by an enlarging tumor in addition to precocious puberty. CPP resulting from CNS tumors (see Table 26.29) has about the same prevalence in boys as in girls in the population; however, boys have a lower overall prevalence of precocious puberty, and neurologic abnormalities account for two-thirds of those with CPP. It is more likely to find a CNS tumor in a boy with CPP than a girl. In the UCSF experience, a CNS tumor was present in at least half of this group.

A CNS neoplasm must be considered in the differential diagnosis of any patient with CPP. The location of CNS tumors causing CPP makes surgical removal difficult. A conservative approach calls for biopsy of the neoplasm and radiation or chemotherapy or both, depending on the pathologic findings. Optic and hypothalamic glioma (often associated with neurofibromatosis), astrocytoma, ependymoma, and, rarely, craniopharyngioma may cause CPP by impinging on the neural pathways that inhibit the GnRH pulse generator in childhood or as a consequence of cranial irradiation for treatment of a brain tumor. Pineal neoplasms may be associated with loss of upward gaze (Parinaud syndrome) due to brainstem compression.

The prevalence of CPP is increased after cranial irradiation for local tumors or leukemia even if radiotherapy targets the pituitary gland.[300] There is a 29% prevalence of CPP following cranial irradiation of the hypothalamic pituitary area for CNS tumors; there is a risk of decreased adult height, often due to delayed diagnosis and treatment.[742] Further, late onset gonadotropin deficiency is reported in about 33% of the irradiated subjects. The combination of GH deficiency and CPP can occur in children previously subjected to therapeutic irradiation of the CNS in association with a CNS neoplasm and in those with a variety of other CNS abnormalities, including developmental malformations and head trauma.[300] The lack of GH may not be apparent because of increased growth resulting from the elevated gonadal steroid levels; GH-deficient children with CPP grow more slowly than GH-sufficient children with CPP but faster than GH-deficient children without sexual precocity. GH-deficient children with CPP have IGF1 concentrations that are intermediate between the higher levels found in GH-sufficient children with sexual precocity and the lower levels found in prepubertal GH-deficient children.

GH deficiency and CPP can occur with CNS radiation doses of only 18 to 47 Gy, whereas gonadotropin deficiency, TSH deficiency, ACTH deficiency, and hypoprolactinemia usually occur with doses greater than 40 Gy.[743] The advance in the age of onset of puberty is positively correlated with the age of diagnosis of the condition for which the radiation therapy was given (i.e., earlier age at onset of puberty with earlier age at diagnosis) and is positively correlated with BMI at diagnosis. Newer radiation treatment regimens using lower doses of radiation for various malignancies may have less influence on advancing the age of menarche and may lead to less long-term morbidity. Treatment with a combination of GH and GnRH agonist is indicated in these patients and results in better growth and improved height prognosis when compared with the use of GnRH agonist alone. Because GH secretion is related to BMI, it is important to rule out a decrease in GH secretion caused by increased BMI in CPP before interpreting the decrease as evidence of GH deficiency.

Hamartomas of the Tuber Cinereum. Hamartomas are congenital malformations composed of a heterotopic mass of nervous tissue containing GnRH neurosecretory neurons, fiber bundles, and glial cells; they are frequently associated with CPP (Fig. 26.54), which usually manifests before the patient is 3 years of age (Table 26.30).[423,718,744] Hypothalamic hamartomas may be sessile or pedunculated and are usually attached to the posterior hypothalamus between the tuber cinereum and the mammillary bodies. These masses project into the suprasellar cistern, and the pedunculated hamartoma has a distinct stalk. They present a characteristic appearance that does not change with time. Hamartomas of the tuber cinereum are not true neoplasms,[395,396,744] as long-term follow-up demonstrated lack of growth on monitoring by periodic CT or MRI.[396,745,746] Hamartomas appear on CT or MRI scans as an isodense, abnormal fullness of the interpeduncular, prepontine, and posterior suprasellar cisterns, occasionally with distortion of the anterior third ventricle. Their appearance and location relate to the clinical manifestation, with distortion of the third ventricle more closely associated with the occurrence of seizures. There is no enhancement with contrast material, and T2-weighted MRIs provide the best visualization of the lesion (Fig. 26.55).[396] However, the solid component of hamartomas may be missed when associated with a subarachnoid cyst if lower resolution MRI studies are invoked.[747]

The etiologic development of the hypothalamic hamartoma may be the converse of the lack of migration of GnRH neurons in Kallmann syndrome due to absent production of adhesion molecules coded by the *KAL1* gene. We may postulate that in hypothalamic hamartoma, the KAL1 protein, among other axon-guiding factors, may cause most of the total complement of about 1500 GnRH neurons to migrate to the hamartoma; alternatively, there may be a stimulus to progenitor cells that are capable of synthesizing GnRH to do so while located in the hamartoma.

Hamartomas associated with CPP contain ectopic GnRH neurosecretory cells that are similar to the GnRH-containing neurons in the medial basal hypothalamus. This developmental abnormality exerts its endocrine effects through elaboration and pulsatile release of GnRH. GnRH-containing fibers have been identified passing from the hamartoma toward the median eminence. We have suggested that the GnRH-containing neurosecretory neurons in the tumor are unrestrained by the intrinsic CNS mechanism that inhibits the normal GnRH pulse generator and act as an ectopic GnRH pulse generator,[326] either independently or in synchrony with the GnRH neurosecretory neurons in the medial basal hypothalamus, to produce intermittent secretory bursts of GnRH[326] (see Fig. 26.29). The GnRH is transported to the pituitary by way of the portal circulation and elicits pulsatile release of LH. If the hamartoma were to secrete GnRH in a continuous fashion, CPP would not occur, because the GnRH receptors would be desensitized. About 10% of hypothalamic hamartomas are not associated with CPP. The hamartomas associated with CPP tend to be more likely to contact the infundibulum or tuber cinereum and less likely to distort the third ventricle and were larger than those that are not, but the size of the hamartoma is not related to the age of onset of puberty.[748]

Hypothalamic hamartomas are postulated to elicit their effects via neurons that are able to produce GnRH within the tumor, through the ability to control neurons synaptically connected to GnRH neurons, or through neuronal networks that include GnRH neurons in the hypothalamic hamartoma itself or signaling-competent astrocytic and ependymoglial cells.[749] The precocious sexual development can be controlled by treatment with GnRH agonist therapy.[750]

All hypothalamic hamartomas in a recent series contained GnRH, GnRHR, and TGFα, and some contained *KISS1, GPR54*, and *GRM1A* (which encodes the isoform of the

• **Fig. 26.54** (A) A 17-month-old male infant with hamartoma of the tuber cinereum and true precocious puberty. When the patient was 8 months of age, secondary sexual development was observed, and the patient was misdiagnosed as having congenital virilizing adrenal hyperplasia. He was treated with glucocorticoids, which slowed his growth but did not affect his sexual development and bone age advancement. When he was first seen at 17 months, his height was 84.2 cm, his weight was 14.8 kg, pubic hair was stage 2, penis was 10.4 × 2.2 cm, testes were 1.5 × 2.8 cm, and the scrotum was thinned and rugated. The bone age was 4.25 years. After gonadotropin-releasing hormone (GnRH) administration, the luteinizing hormone (LH) level rose from 0.5 to 3.1 ng/dL (LER-960), the follicle-stimulating hormone (FSH) level rose from 0.5 to 1.2 ng/mL (LER-869), and the testosterone level rose from 409 to 450 ng/dL. The dehydroepiandrosterone sulfate (DHEAS) was 17 μg/dL (preadrenarchal value). The patient was treated with a potent, long-acting LH-releasing hormone (LHRH) agonist, deslorelin (D-Trp^{6}Pro^{9}NEt-GnRH), which resulted in arrest of his pubertal advancement and a striking decrease in the plasma concentration of testosterone, LH pulses, and the response to exogenous GnRH. (B) Computed tomography demonstrated a 1.5-cm mass posterior and rostral to the dorsum sella, which depressed the flow of the third ventricle. For conversion to SI units, see Figs. 26.19, 26.20, and 26.30. (C) Sagittal, T1-weighted magnetic resonance image shows a hypothalamic hamartoma *(white arrow)* in a 4-year-old boy with true precocious puberty. The posterior pituitary hot spot is designated by the *black arrow*. (B, from Styne DM, Grumbach MM. Puberty in the male and female: its physiology and disorders. In: Yen SCC, Jaffe RB, eds. *Reproductive Endocrinology*. 2nd ed. Philadelphia: WB Saunders; 1986:313–384.)

metabotropic glutamate receptor 1A, which rises in the female monkey with puberty) with no relationship as to whether CPP occurred or not.[748] Earlier two young girls with rapidly progressive CPP did not contain immunoreactive GnRH neurons, but the mass showed a network of astroglial cells containing TGFα.[751] This suggests that some hypothalamic hamartomas, by virtue of increased production of TGFα and of neuregulins synthesized by hypothalamic and astroglial cells through paracrine mechanisms, effect the release of bioactive factors, including prostaglandin E_2, that act on GnRH neurons to increase GnRH secretion. However, these hamartomas were much larger than the typical hypothalamic hamartoma associated with CPP; the mass bulged into the third ventricle in one girl, and in the other girl, the pituitary gland was hypertrophic and bulged through the diaphragma sellae. Activation of the GnRH pulse generator through a mass effect and compromise of restraint mechanisms may be the mechanism of CPP rather than TGFα signaling in these cases.

Before 1980, only 37 patients were in the literature with hamartomas of the tuber cinereum, but many more have been reported since the advent of CT and MRI brain scans (see Fig. 26.54 and Table 26.30). Of girls with CPP studied at the National Institutes of Health, 16% had a hypothalamic hamartoma, 40% had other CNS abnormalities, and 60% had idiopathic CPP. Among boys with CPP, 10% had idiopathic CPP, 50% had a hypothalamic hamartoma, and the rest had other CNS abnormalities, including hypothalamic neoplasms.[752]

Hypothalamic hamartomas that cause CPP can be associated with laughing (gelastic), petit mal, or generalized tonic-clonic seizures; developmental delay; behavioral disturbances; and dysmorphic syndromes beginning as early as the neonatal period. Males are more likely to have seizures with these lesions, and seizures can be caused by a hamartoma in the absence of precocious puberty. The occurrence of seizure is uncommon when the mass diameter of the hamartoma is less than 10 mm, whereas a larger mass is associated with a higher risk.

Although some have advocated neurosurgical removal of these hamartomas because of the occurrence of precocious puberty alone, we do not recommend neurosurgical extirpation in the absence of strong evidence of growth of the mass or of an associated complication such as intractable seizures or hydrocephalus.[423,753] Gelastic seizures are less amenable to antiepileptic therapy than other hamartoma-related seizures and may require surgical treatment; endoscopic technique is increasingly used,[754,755] and Gamma Knife procedures are used, especially for small lesions.[756] Refractory seizures have replaced precocious puberty as the main reason to perform surgery in cases of hamartoma of the tuber cinereum. The endocrine result of surgery on these lesions is rarely reported, but in one series of 29 subjects, hypernatremia, low T_4, low GH, and weight gain were encountered.[757] Prior unsuccessful surgery may increase the risk for endocrinopathy in these patients. The postoperative endocrine disturbances appear to be transient and mild or asymptomatic, but increased appetite and weight gain appeared in 25% of the subjects and may present an enduring problem. Although there are cases in which removal of a hypothalamic hamartoma led to reversal of the pubertal process, deaths have been reported after attempted operative removal. Medical therapy with GnRH agonist in lieu of surgery is the optimal treatment of precocious puberty associated with these hamartomas if seizures are absent or under control.

The Pallister-Hall syndrome is associated with hypothalamic hamartomas, precocious puberty (but rarely) with or without seizures, polydactyly, imperforate anus, bifid epiglottis, and hypopituitarism with seizures.[758]

TABLE 26.30 Clinical and Laboratory Characteristics of Children With True Precocious Puberty Caused by Hypothalamic Hamartoma

• **Fig. 26.55** Pulsatile luteinizing hormone (LH) secretion before and during gonadotropin-releasing hormone (GnRH) agonist therapy in a boy (B) and a girl (A) with true precocious puberty resulting from a hypothalamic hamartoma. For conversion to SI units, see Fig. 26.19. *FSH,* follicle-stimulating hormone.

• **Fig. 26.56** A boy aged 8 years and 8 months with neurofibromatosis and precocious puberty resulting from a hypothalamic glioma. He had tonic-clonic seizures at 2.5 years and rapid growth starting at 4 years; an enlarged penis and testes and the presence of pubic hair were first noticed at 7.5 years. At this time, his height was 139.9 cm (+1.4 SD [standard deviation]); the phallus was 9 × 3 cm, the right testis measured 5.5 × 3.2 cm, and the left measured 5.4 × 2.9 cm. He had stage 3 pubic hair and 24 large café au lait spots. Computed tomography and pneumoencephalography revealed a 1.5 × 2.5–cm, hypothalamic mass, which was treated with irradiation. The plasma concentration of luteinizing hormone (LH) was 0.5 ng/mL (LER-960); the follicle-stimulating hormone (FSH) level was 0.4 ng/mL (LER-869); and the testosterone level was 221 ng/dL. After 100 μg of intravenous LH-releasing hormone (LHRH), the peak concentration of LH was 4.9 ng/mL, and that of FSH was 1.4 ng/mL, a pubertal response. For conversion to SI units, see Figs. 26.19 and 26.20. (From Styne DM, Grumbach MM. Puberty in the male and female: its physiology and disorders. In: Yen SCC, Jaffe RB, eds. *Reproductive Endocrinology*. 2nd ed. Philadelphia: WB Saunders; 1986:313–384.)

Neurofibromatosis Type 1. Neurofibromatosis type 1 (NF1 or von Recklinghausen disease) is associated with a propensity to develop the optic chiasmal tumors that are the most common cause (but not the only cause) of the development of CPP in a child with neurofibromatosis.[759] Most optic gliomas appear during the first decade of life, but only 20% to 30% become symptomatic; these tumors rarely progress in the years after diagnosis. The tumor suppressor *NF1* gene, located on the long arm of chromosome 17 (q11.2), which has a high mutation rate, encodes a 327-kDa protein, neurofibromin, that is widely expressed even though NF1 involves mainly tissues derived from the neural crest. A wide variety of mutations of the *NF1* gene are reported, especially deletions, nonsense mutations, and truncating mutations distributed over the coding region. In sporadic cases, the new mutation originates in the paternally derived *NF1* allele in most instances, suggesting a role for genomic imprinting. Concentrations of midkine (MK) and stem cell factor, but not epidermal growth factor, are substantially increased in the serum of NF1 patients compared with healthy control subjects and serve as a diagnostic feature.[760] Serum MK levels increase dramatically in patients older than 18 years of age, apparently as a feature of pubertal development. Because serum from patients with NF1 enhances proliferation of human neurofibroma-derived primary Schwann cells and endothelial cells, enhanced levels of circulating growth factors contribute to diffuse tumorigenesis in NF1.

NF1 is characterized by multiple pigmented areas and overgrowth of nerve sheaths and fibrous tissue elements (Fig. 26.56). Multiple café au lait spots are frequent and are smoother in outline (coast of California appearance) than those of the McCune-Albright syndrome (coast of Maine appearance). The diagnosis is made if two or more of the following are observed[761]:

1. Six or more café au lait macules, the greatest diameter being more than 5 mm in prepubertal subjects or more than 12.5 mm in postpubertal subjects
2. Two or more neurofibromas of any type or one plexiform neurofibroma
3. Freckling in the axillae or inguinal region
4. Optic glioma
5. Two or more iris Lisch nodules (ophthalmic hamartomas that occur more frequently after the onset of puberty)
6. A distinctive osseous lesion such as sphenoid dysplasia or pseudoarthrosis
7. A first-degree relative with NF1 according to the criteria described previously

Neurofibromas of the skin in neurofibromatosis may be subcutaneous, sessile or deep, plexiform masses in children; pedunculated lesions develop in later childhood. Internal neurofibromas cause most of the complications. Bone abnormalities such as cysts and pseudoarthrosis, hemihypertrophy, bowing, scoliosis, and skull and facial defects are common (20% of patients);

dumbbell-shaped tumors of spinal nerve roots may cause pain, sensory and motor dysfunction, and bone erosions; gliomas or neurofibromas of any part of the CNS, including the optic nerves and the hypothalamus, may calcify. Lisch nodules of the iris are frequent, particularly in adults. Sarcomatous degeneration occurs in 5% to 15% of patients. Other neoplasms include CNS astrocytomas that often involve the visual pathways, ependymomas, meningiomas, neurofibrosarcomas, rhabdomyosarcomas, and nonlymphocytic leukemias. Pheochromocytoma may develop in affected adults.

The clinical manifestations of neurofibromatosis include seizures, visual defects, and either delayed puberty or CPP, although many have growth hormone deficiency.[759] Although some manifestations of NF1 are quite common (e.g., café au lait spots, which were found in 99% of a series of 297 subjects), precocious puberty is rarer in some reports (found in 3.2% of that same series)[762] but found in about 33% in a report of 40 patients.[759] GH deficiency is possible at presentation, but after radiation therapy for associated optic glioma, GH, TSH, ACTH, and gonadotropin deficiency may develop. Developmental delay occurs more often in this population but usually is not severe; there is also an increased incidence of psychiatric disease. Most affected children have some manifestations of the disease by 1 year of age. Screening MRI scans are recommended for early detection of CNS tumors.

Other Central Nervous System Conditions

CPP may occur secondary to encephalitis, static cerebral encephalopathy, brain abscess, or sarcoid or tuberculous granulomas of the hypothalamus, with or without tuberculous meningitis. CPP can occur after severe head trauma (usually in girls), and it has been associated with cerebral atrophy or focal encephalomalacia occurring after cerebral edema (causing cerebral injury), complicating diabetic ketoacidosis. Children with nontumor hydrocephalus, even if shunted, experience earlier pubertal development, and those who have not been adequately treated may develop CPP. Delayed puberty is an alternative outcome in a minority of affected children. The growth pattern of children with severe hydrocephalus often includes poor prepubertal growth and an early pubertal growth spurt leading to decreased final height.

Arachnoid Cysts. Arachnoid cysts arising de novo, after infection or after surgery, can cause premature sexual development, possibly with associated GH deficiency.[326,763] Head nodding, abnormal gait, and abnormalities of visual fields are reported in 30% to 40% of cases. Erosion or enlargement of the sella turcica into a J shape may occur. Decompression and extirpation of a suprasellar arachnoid cyst can reverse the sexual precocity (see Fig. 26.30). Late endocrine effects such as growth hormone deficiency can be found after surgery to approach suprasellar arachnoid cyst.[764]

Other Central Nervous System Abnormalities. Other CNS abnormalities associated with CPP but without demonstrable lesions on imaging study include epilepsy, laughing seizures, developmental delay, cerebral palsy, and the posttraumatic state.[765] Septo-optic dysplasia (described earlier) may be associated not only with multiple pituitary hormone deficiencies and delayed puberty but also, rarely, with CPP.[546] There may be coexisting deficiencies of some pituitary hormones and excessive secretion of others, including prolactin.

Patients with myelomeningocele (myelodysplasia) have an increased prevalence of endocrine abnormalities, including hypothalamic hypothyroidism, hyperprolactinemia, and elevated gonadotropin concentrations, which in some patients is associated with CPP.

Miscellaneous Causes

Central Precocious Puberty in Children Adopted From Developing Countries. There was a 15-fold to 20-fold increased prevalence of CPP reported among children (with established birth dates) from developing countries who were adopted into Denmark, and other countries have reported similar tendencies. In Sweden, adopted Indian children had pubertal growth spurts similar to those of Swedish children, but adult height was decreased, with the loss of height in childhood and the early puberty apparently being responsible. Environmental influences, many related to the present obesity epidemic, are posited to exert effects in the reported decrease in age at menarche among children from the developing world. These children, who suffer poor prenatal nutrition and often are SGA, are adopted into families in developed countries, and in that environment of affluence they experience precocious puberty.[4,766]

It is not clear why adopted children may develop precocious puberty, and some even question this phenomenon itself; underreported age of adopted children fits an explanation of the tendency to ascribe precocious puberty to adoption and more critical analysis of the data is sought.[767] Foreign children who immigrated to Belgium with their biologic families from developing countries had greatly elevated concentrations of p,p′-DDE, a derivative of the organochlorine pesticide dichlorodiphenyltrichloroethane (DDT), raising the possibility of a role for endocrine disrupters in their CPP,[768] although this is contradicted in the experience of other counties. Older age at adoption and immigration are risk factors for precocious puberty. One study showed that children of immigrant groups who were born in their new country may have earlier puberty than children of the predominant ethnic group of that country; these influences might be genetic, or they might be related to cultural and dietary differences but could complicate the analysis.[31] However, a detailed analysis in Spain showed that the relative risk of CPP in domestic and internationally adopted children compared with those born in Spain was 27.82 (19.99 – 38.77), whereas the relative risk among immigrants was 1.55 (0.97 – 2.38); the authors suggest that psychologic factors may be the cause of this difference rather than immigration, nutrition, or pesticide exposure.[744] Remarkably, children adopted from South Korea do not appear to have the onset of puberty as early as those from other countries that were studied.[744]

The use of GnRH agonist in addition to GH treatment to increase adult height is reported in adopted children with CPP, but the combination is not supported by adequate evidence to recommend this combination in adopted children or any children with CPP.[470] The combination of adoption, living in a culture foreign to the background at birth, and precocious puberty makes these children vulnerable to psychic trauma, which must always be considered.

True Precocious Puberty After Virilizing Disorders. Correction of long-standing virilization may be followed by development of CPP with activation of the hypothalamic-pituitary gonadotropin-gonadal system. This secondary CPP occurs in congenital virilizing adrenal hyperplasia with advanced bone age when glucocorticoid replacement therapy starts after 4 to 8 years.[290,727] CPP has also been documented in children who received or were exposed to androgens or estrogens for long periods during early childhood for a variety of medical conditions.

TABLE 26.31 Objectives for the Management and Treatment of True Precocious Puberty

Detection and treatment of an expanding intracranial lesion
Arrest of premature sexual maturation until the normal age at onset of puberty
Regression of secondary sexual characteristics already present
Attainment of normal mature height; suppression of the rapid rate of skeletal maturation
Prevention of emotional disorders and handicaps and alleviation of parental anxiety; promotion of understanding by counseling, early sex education, and acceleration of social age
Reduction of risk of sexual abuse and early sexual debut
Prevention of pregnancy in girls
Preservation of future fertility
Diminishment of the increased risk of breast cancer associated with early menarche

From Grumbach MM. True or central precocious puberty. In: Krieger DT, Bardin CW, eds. *Current Therapy in Endocrinology and Metabolism, 1985-1986.* Toronto, Canada: BC Decker; 1989:4–8.

TABLE 26.32 Action of Gonadotropin-Releasing Hormone Agonists in True Precocious Puberty

A selective, highly specific pharmacologic clamp on the secretion of gonadotropin that produces a medical gonadectomy
- Chronic administration induces desensitization of the pituitary gonadotroph to the action of endogenous GnRH

As a consequence:
- Inhibition of pulsatile secretion of LH and FSH
- Inhibition of gonadotropin secretion results in a striking decrease in gonadal steroid output by testes or ovaries and reduction in gonadal size

FSH, Follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *LH,* luteinizing hormone.

Marfan Syndrome. Marfan syndrome may be associated with tall stature and early PHV and menarche compared with North American averages.[745]

Management of Central Precocious Puberty

Table 26.31 addresses the major psychosocial and clinical goals of therapy for CPP. Three principal agents were used in the medical treatment of idiopathic or neurologic CPP: medroxyprogesterone acetate, cyproterone acetate, and superactive GnRH agonists.

Medroxyprogesterone Acetate and Cyproterone Acetate. Medroxyprogesterone and cyproterone reversed or arrested the progression of secondary sexual characteristics but had no apparent effect or only a small effect on adult height, especially in affected girls.[622,746] Medroxyprogesterone acetate inhibits gonadotropin secretion by its action on the hypothalamic GnRH pulse generator/pituitary gonadotropin unit and has a direct suppressive effect on gonadal steroidogenesis through 3βHSD2. Medroxyprogesterone acetate has glucocorticoid action and can suppress ACTH and cortisol secretion, increase appetite and lead to excessive weight gain, and induce hypertension and a cushingoid facies and appearance.

Cyproterone acetate has been used outside the United States for the treatment of CPP with advantages and disadvantages similar to those of medroxyprogesterone acetate. Cyproterone acetate has antiandrogenic, antigonadotropic, and progestational properties. Cyproterone acetate suppresses the secretion of ACTH and the plasma concentration of cortisol. Fatigue and weakness are common side effects, probably as a consequence of secondary adrenal insufficiency. This agent lacks gluconeogenic activity and does not appear to produce cushingoid features.

The long-term effects of these agents on fertility are not known. For the treatment of CPP, medroxyprogesterone acetate and cyproterone acetate have now been replaced by the much more effective GnRH agonists; however, they may be used as backup agents for the occasional patients who develop untoward effects from GnRH agonist therapy.

Superactive Gonadotropin-Releasing Hormone Agonists. The GnRH agonists, synthetic analogues of the amino acid sequence of the natural GnRH decapeptide, are the treatment of choice for CPP of any cause (Tables 26.32 and 26.33). After initial stimulation, these pharmacologic agents suppress pulsatile LH and FSH release, gonadal steroid output, and gametogenesis, similar to the effects of continuous administration of natural GnRH, which suppresses gonadotropin secretion after an initial, brief stimulation of gonadotropin release.[336,747] The agonist binds to the GnRH receptor on gonadotrophs, and this is followed by desensitization of the gonadotroph to GnRH and downregulation and loss of receptors. Desensitization persists after receptor levels return to normal as a result of uncoupling of the receptors from the intracellular signaling effector pathway. This regimen functions as a selective, highly specific pharmacologic clamp on the secretion of gonadotropins without interfering directly with release of the other pituitary hormones. In essence, the regimen produces a reversible medical gonadectomy (see Table 26.32).

The superactive agonist analogues of GnRH have about 15 to 200 times the potency of the natural GnRH decapeptide, prolonged action, and low toxicity (see Table 26.33). Replacing the glycine-amide terminus of GnRH with alkyl amines (i.e., ethylamine [NEt]), as in (Pro^9-NEt)GnRH; substituting certain D-amino acids at position 6, as in (D-Trp^6)GnRH; or making bulky hydrophobic alterations at position 6, as in (D-Nal[2]^6)GnRH increases the potency and duration of action. These changes make the molecule more resistant to enzymatic degradation, increase the binding affinity of the analogue for the receptor on the pituitary gonadotroph, increase hydrophobicity, and, with some analogues, increase binding to plasma proteins.

The suppressive effects of the GnRH agonists on gonadotropin secretion make them useful in the treatment of CPP, and they are also used in endometriosis, prostatic carcinoma, and in delaying puberty during consideration of definitive treatment in transgender use. Every-4-week and every-12-week formulations of leuprorelin (leuprolide acetate) have been FDA approved for treatment of CPP.[769] Long-term studies have established the efficacy and safety of the every-4-week injection, but only short-term studies are available for the every-12-week version. Triptorelin has been recently approved for the treatment of central precocious puberty in children; it can be given as an injection every 6 months.[770] The bioavailability of agonists given intranasally is much reduced, as reflected in the need to use a high dose at more frequent intervals, and they are rarely used at present. A subcutaneous implant of histrelin was approved for 12-month treatment of CPP, and recent studies show efficacy in gonadotropin suppression for 2 years after implant.[771] Increased predicted adult height is demonstrated with this treatment.[772] The effectiveness of GnRH agonists in the

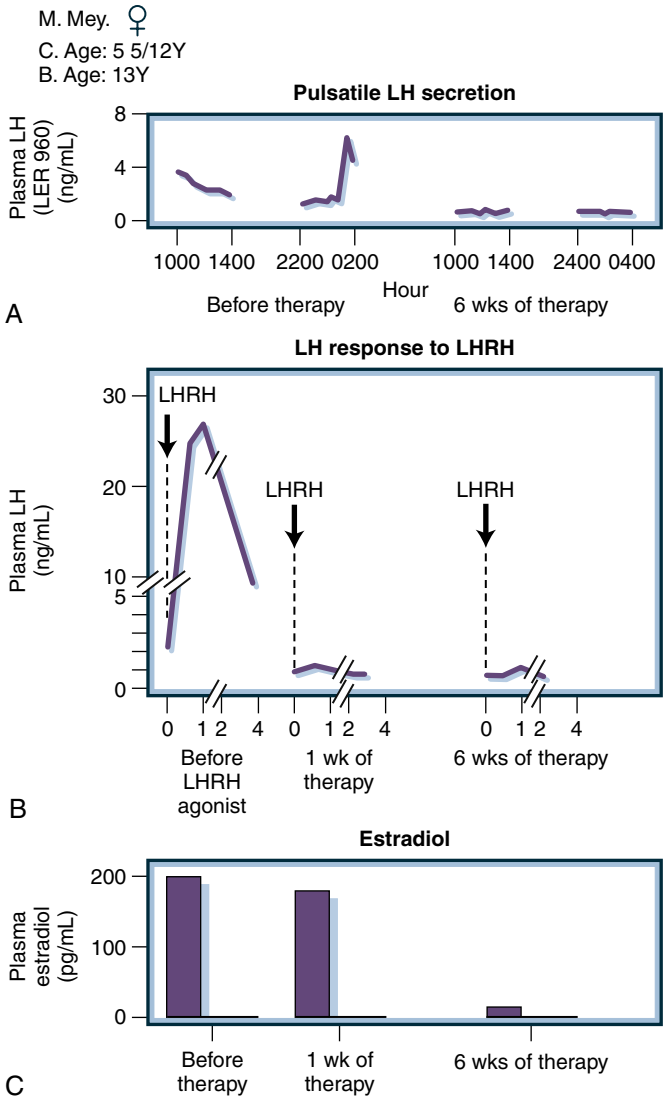
treatment of CPP varies with the potency of the analogue, dose, route of administration, and compliance.

Treatment of CPP with a potent GnRH agonist results in 1 to 3 days of increased FSH and LH release and a rise in circulating gonadal steroid levels, followed after 7 to 14 days of treatment by suppression of pulsatile secretion of LH and FSH and of the pubertal LH response to the administration of native GnRH (Figs. 26.57 and 26.58). The isoforms of gonadotropins tend toward a more basic charge. A plasma estradiol concentration of less than 18 pmol/L (5 pg/mL) in girls or a plasma testosterone level of less than 0.7 nmol/L (20 ng/dL) in pediatric assays using HPLC-MS/MS in boys indicates adequate gonadal suppression; this occurs within about 2 to 4 weeks in girls and 6 weeks in boys. GnRH agonist therapy does not affect the secretion of adrenal androgens or sexual hair growth.[750,773]

Changes in secondary sexual characteristics within the first 6 months of therapy (Fig. 26.59) include reduction in breast size and decrease in pubic hair, cessation of menses if present before treatment, and decreased size of the uterus and ovaries as assessed by pelvic sonography in girls. Some girls have recurrent episodes of hot flushes and moodiness. In boys, pubic hair thins, the testes decrease in size, acne and seborrhea regress, penile erections and masturbation become much less frequent, the high energy level and aggressive behavior diminish, and self-esteem improves.



• **Fig. 26.57** Effect of administration of the gonadotropin-releasing hormone (GnRH) agonist deslorelin (4 μg/kg/day subcutaneously) on pulsatile secretion of luteinizing hormone (LH) (A), LH response to GnRH (B), and plasma concentration of estradiol (C) in a 5-year, 1-month-old girl with idiopathic true precocious puberty. This patient, who had a bone age of 13 years when treatment was begun, has been administered deslorelin for 7 years. During this period, the estimated predicted final height increased by 15 cm. Surprisingly, the bone age advanced by only about 6 months on serial examinations for several years. *LHRH,* LH-releasing hormone. (Modified from Grumbach MM, Kaplan SL. Recent advances in the diagnosis and management of sexual precocity. *Acta Paediatr Jpn.* 1988;30:S155–S175.)

Height velocity decreases by about 60% during the first year of therapy, with greater decreases found in those with the most advanced bone age and taller relative height.[774] Skeletal maturation slows dramatically during the first 3 years, to a rate that often is less than the progression in chronologic age. From the second year on, height velocity for bone age is usually appropriate (Fig. 26.60). Bone age is suggested to represent a surrogate for growth plate senescence due to prior exposure to estrogens. Those with the longest courses before treatment commences, the most advanced physical findings, and the most rapid bone age advancement before therapy have the lowest growth velocities on treatment.

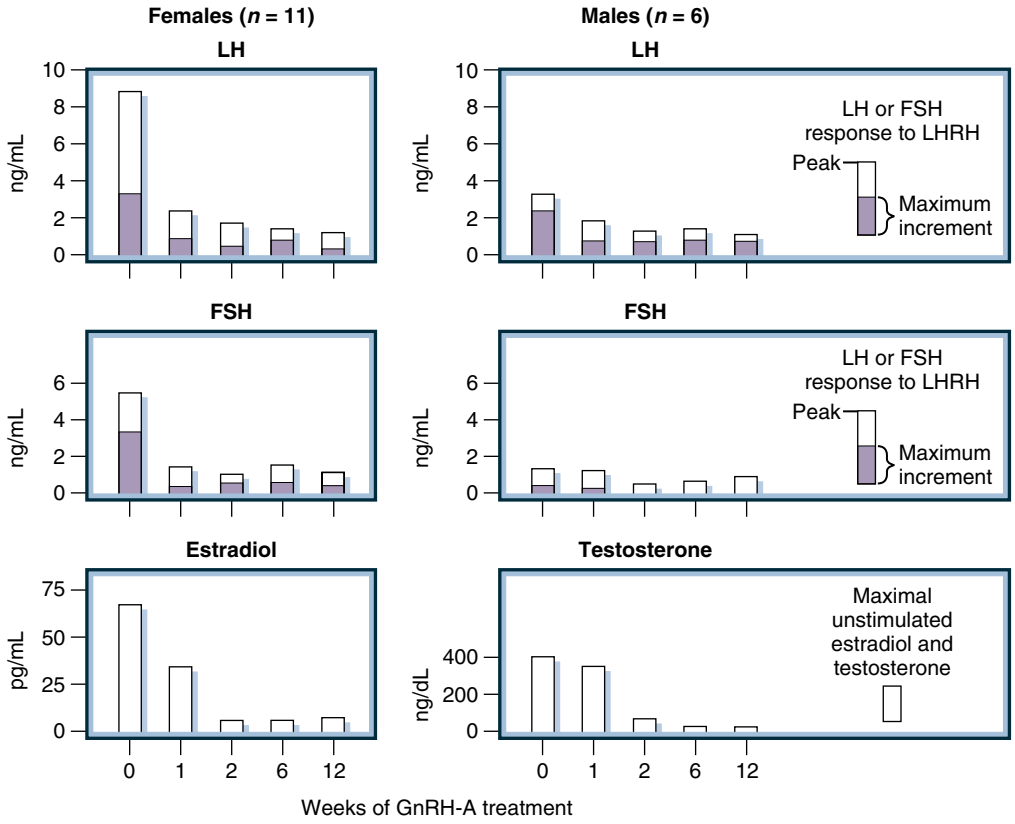
The rate of growth during treatment with GnRH agonists is inversely related to the bone age at the start of therapy[308]; best results occur when treatment is begun soon after the onset of precocity and when the bone age is advanced by only a few years.[775] There is a striking benefit for those children treated before 5 years of age (girls' height, 164.3 ± 7.7 cm) compared with those treated after age 5 years (157.6 ± 6.6 cm) or with untreated patients (152.7 ± 8.6 cm).[722] Adult height in children treated with GnRH agonists is improved, especially when therapy starts before 6 years of age rather than after 8 years of age[470,724,776] (Table 26.34). The literature on treatment in children with onset of puberty after 6 years of age varies but generally shows no proven efficacy in increasing adult height.[777] An adult height within the target height occurs with therapy in about 90% of girls and boys.[778] We recommend treatment of all affected children with onset of puberty before 6 years of age to ensure an optimal prognosis for adult height. The optimal age at which to discontinue therapy is undetermined because the posttreatment growth spurt is important in determining adult height.[470]

The addition of hGH treatment to the GnRH regimen is a consideration when growth velocity is reduced sufficiently over a 6-month period to compromise predicted final height but must be considered experimental.[779] This is in contrast to the concern raised regarding therapy with GnRH agonist and GH in normal variant short stature, which is not proved by evidence-based study.[470]

In a preliminary study, the GnRH antagonist, cetrorelix, appeared to bring about more rapid suppression of gonadotropin secretion and to eliminate the flare-up of gonadotropin secretion after administration of GnRH agonist; it is used in assisted reproductive treatment.[777] There are no reports at present concerning the use of cetrorelix as a sole treatment of precocious puberty, but in one unusual case, a girl with purported gonadotropin-independent precocious puberty responded to this treatment, bringing up a possible direct effect of the agent on ovarian function.[780] This agent suppresses ovarian but not adrenal function and was proposed to be useful as a test to differentiate the origin of severe hyperandrogenism in adolescence.

Girls with CPP have a tendency toward obesity that is unrelated to treatment with GnRH agonist.[470] Serum leptin values in patients with precocious puberty remain in line with the average for children of similar BMI and pubertal development.[781] There is conflicting data on weight gain while on treatment with GnRH agonists. A longitudinal study 101 girls, 23% obese at start of therapy, suggested that, with adequate gonadotropin suppression, BMI for age may improve after at least 2 years of therapy.[782] A study of 117 girls showed the increased BMI during treatment often reverted to normal after cessation of treatment.[783] However, a longitudinal study of 333 girls, some to adult height, demonstrated increasing BMI SDs with treatment continuing to adulthood.[784] These conflicting findings make it difficult to predict the effect of GnRH agonist on BMI in individuals.

The IGF1 concentration in CPP correlates best with the stage of puberty and the plasma concentration of testosterone or estradiol. Treatment with GnRH agonist reduces the level of IGF1 to the normal range for bone age but not for chronologic age.[316] Gonadal steroids increase plasma IGF1 concentrations in CPP, as in normal puberty. Secretion of GH is increased in CPP to a level comparable to that observed in normal puberty. Treatment with GnRH agonist usually results in decreased secretion of GH, most



• **Fig. 26.58** Deslorelin treatment (4 μg/kg/day subcutaneously) of girls and boys with true precocious puberty. Effects were seen during the first 12 weeks of treatment on the luteinizing hormone (LH) and follicle-stimulating hormone (FSH) response to a challenge with gonadotropin-releasing hormone (GnRH) (mean peak response and maximum increment) and on the maximal unstimulated concentration of plasma estradiol in the girls and of plasma testosterone in the boys. Notice the relatively rapid change from pubertal values to prepubertal values. For conversion to SI units, see Figs. 26.19 and 26.20. *LHRH,* LH-releasing hormone. (From Styne DM, Harris DA, Egli CA, et al. Treatment of true precocious puberty with a potent luteinizing hormone releasing factor agonist: effect on growth, sexual maturation, pelvic sonography, and the hypothalamic pituitary gonadal axis. *J Clin Endocrinol Metab.* 1985;61:142–181. Copyright by The Endocrine Society.)

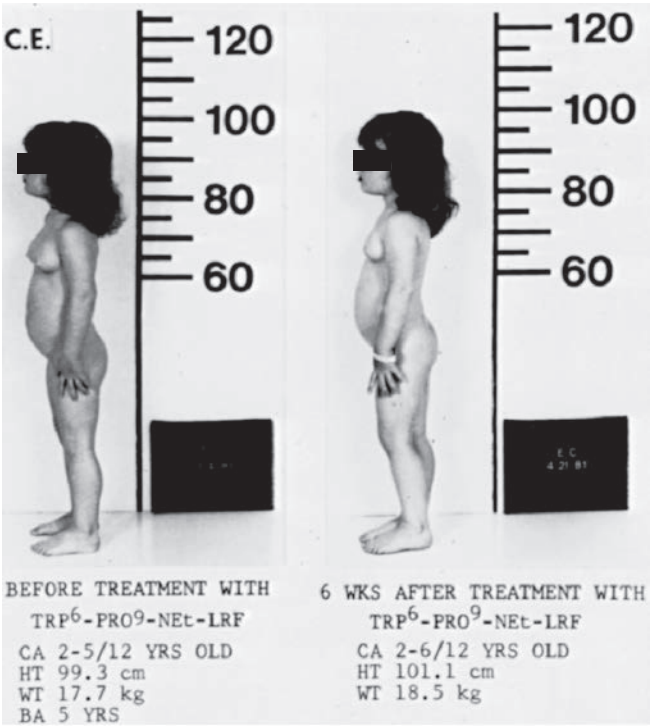
strikingly during sleep, and in a decreased GH response to provocative stimuli.

The depot formulations of GnRH agonists provide continuous exposure to the drug with a single intramuscular injection every 4 to 26 weeks (as described earlier) and minimize the problem of compliance. However, irregular or inadequate treatment or poor compliance results in persistent or intermittent increase in the concentration of plasma gonadal steroids, leading to decreased growth but advancing bone age.

Regular assessment is essential, initially at intervals of 3 to 6 months with the use of the injectable formulations, and should include periodic determinations of plasma testosterone levels in boys and estradiol levels in girls by HPLC-MS/MS; change in basal concentrations of LH and FSH as measured by third-generation assays with pediatric standards or in the LH and FSH response to exogenous GnRH or GnRH agonists; growth, bone age, and secondary sexual characteristics; and, in girls, serial evaluations of ovarian morphologic appearance and uterine size by pelvic sonography. A decrease in the size of the ovaries and uterus on pelvic sonography occurs with successful GnRH agonist treatment.[750] Because native GnRH is not available, the rise in serum LH and FSH is evaluated 60 or 240 minutes after administration of the GnRH agonist.[257–259] The LH and FSH responses to GnRH agonist are suppressed with effective therapy, but because standards differ among laboratories, actual cutoff values may differ in clinical practice, depending on location. A 1-year Silastic implant of the histrelin GnRH agonist, although it involves a surgical procedure, eliminates the need to titrate the dose and repeat testing for maximal effect; a second treatment year is reported to be effective.[771] There may be low pubertal values of LH even with successful suppression of advancement of puberty.[785]

Urinary excretion of LH correlates with the stage of pubertal development in normal subjects and is elevated in CPP; these methods are proposed as a noninvasive manner to monitor or diagnose CPP.[786]

When treatment is discontinued, even after 8 years, gonadal suppression is reversed within a few weeks to months, as manifested by a rise in the concentration of plasma gonadal steroids, progression of sexual maturation, and return of menses. Menarche occurred at an average of 1.2 to 1.5 years after discontinuation of therapy (range, 0–60 months). Ovulation had occurred in 50% of girls by 1 year after menarche and in 90% of those studied 2 or more years after menarche, and pregnancies are reported in GnRHA-treated girls.[735,787] Mean ovarian volume was found to remain greater than in normal subjects, and the LH response to GnRH was less than the normal response.

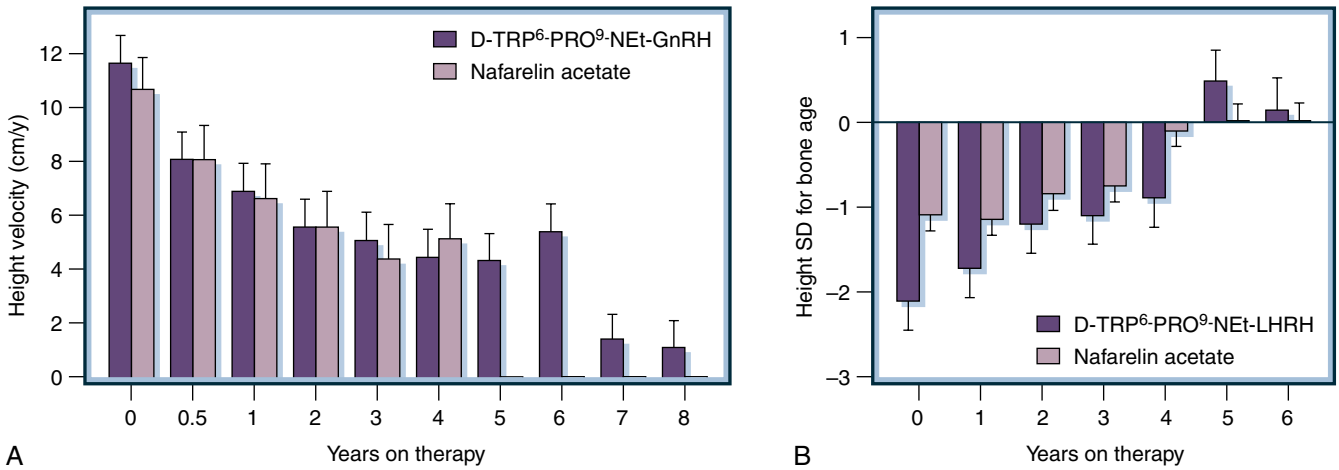


• **Fig. 26.59** A girl aged 2 years and 5 months with true precocious puberty after 6 weeks of deslorelin therapy (4 μg/day subcutaneously). Notice the regression in the size of the breasts; however, the rapid rate of growth had not decreased. At the end of 1 year of therapy, the growth rate was suppressed to 4 cm/year, and bone age advanced only 1 year. *BA,* bone age; *CA,* chronologic age; *HT,* height; *WT,* weight. (From Styne DM, Grumbach MM. Puberty in the male and female: its physiology and disorders. In: Yen SCC, Jaffe RB, eds. *Reproductive Endocrinology*. 2nd ed. Philadelphia: WB Saunders; 1986:313–384.)

The reversible nature of the therapy has also been confirmed in boys with CPP, because gonadotropins in the basal or GnRH-stimulated state return to normal pubertal values by 1 year after cessation of therapy.[788] Testicular size may take longer to reach normal values.

A report of 46 women studied 12.5 years after cessation of treatment with GnRH agonist revealed an adult height 1.6 cm, or 0.3 SD, below target height, with no evidence of reproductive impairment or apparent PCOS or hirsutism.[789] However, an increased prevalence of PCOS was reported in young women (mean age, 18.1 years) with a history of CPP, with onset at a mean age of 7.65 years.[790] Of the patients, 32% had PCOS according to the Rotterdam definition, and 30% had PCOS according to the Androgen Excess Society; the most common presentation was clinical or biochemical hyperandrogenism, or both, and polycystic ovarian morphologic appearance. The study authors did not find any other predictive factors for the development of PCOS when the diagnosis of CPP was made. These girls would not have qualified for the diagnosis of CPP based on the newest criteria, so it is of concern that these girls with early rather than precocious puberty had such a high prevalence of PCOS. GnRH agonist treatment may actually decrease the incidence of PCOS compared to the incidence in untreated patients.[735] Thus the prevalence of PCOS after Lupron for CPP is unclear.[777]

An international consensus conference convened by the Lawson Wilkins Pediatric Endocrine Society and the European Society for Pediatric Endocrinology reviewed the world literature on the use of GnRH to determine, in an evidence-based approach, the appropriate use of the agent in precocious puberty. However, few controlled prospective studies have been performed with GnRH analogues in children, so many of the conclusions relied



• **Fig. 26.60** Effect of gonadotropin-releasing hormone (GnRH) agonist therapy in true precocious puberty on growth. (A) Changes in mean height velocity (cm/year ± 1 SE [standard error]) after the initiation of GnRH agonist therapy with D-Trp^{6}Pro^{9}Net (deslorelin) *(darker bars)* or with nafarelin *(lighter bars)*. A sharp decrease in height velocity occurred within 1 year. (B) Mean (±1 SE) height for bone age before and during GnRH agonist treatment. The discrepancy between height and the more advanced bone age decreases (reverts to normal) with chronic GnRH agonist treatment. *SD,* standard deviation. (From Kaplan SL, Grumbach MM. in part on collective expert opinion. The major conclusions were as follows[451,470]:

- GnRH analogues exert benefit in increasing adult height in children with early-onset CPP (<6 years in girls) and are not routinely recommended after that age.
- The psychosocial effects of CPP and their alteration by GnRH analogues require additional study.
- The use of GnRH analogues does not appear to cause weight gain or long-term diminution of BMD.
- The use of GnRH analogues for conditions other than CPP, such as to increase adult height in children with idiopathic short stature or SGA, or with GH treatment in children, is not recommended.

Affected girls do not appear to manifest increased stress with this condition, although mothers do in preliminary studies.[791] Although psychosocial factors and parental anxiety that adversely affect the well-being of the child need to be assessed in the decision to initiate GnRH agonist treatment, this therapy cannot be routinely recommended for such concerns (Table 26.35).

Adverse Effects. Rare reactions to GnRH agonists include local and systemic allergic reactions, including asthmatic episodes when the agent is given intranasally. Rare cases of anaphylaxis occur in response to gonadotropin-releasing hormone agonist.[792] The prevalence of a sterile abscess at the site of intramuscular injection of long-acting repository preparations, including

TABLE 26.35 Indications for Therapy With Gonadotropin-Releasing Hormone Agonists in True or Central Precocious Puberty

In children with clinical and unequivocal endocrine features of idiopathic true precocious puberty:

- Rapid advancement over a period of 6-12 mo of secondary sex characteristics, height, height velocity, and bone age (increased >2.5 SD for chronologic age) in affected boys and girls
- A plasma testosterone concentration sustained >2.5 nmol/L (>75 ng/dL) in boys <8 yr of age determined by sensitive, specific immunoassay
- A plasma estradiol concentration, recurrently ≥36 pmol/L (≥10 pg/mL) determined by a sensitive, specific assay capable of quantifying low concentrations of estradiol
- Onset of menarche (and recurrent menses) in girls <9 yr of age
- Psychosocial factors and parental anxiety, including evidence that the child's psychosocial well-being is adversely affected

In children with neurogenic or organic true precocious puberty, especially those with associated GH deficiency, the course is almost invariably progressive and LHRH treatment should not be delayed.

GH, Growth hormone; *LHRH,* luteinizing hormone–releasing hormone; *SD,* standard deviation.

leuprorelin and triptorelin, is clearly increased (5–10%); these reactions are unpredictable and intermittent, and in most instances are related to the polylactic and polyglycolic polymer and not to the GnRH agonist itself. Switching to daily subcutaneous injections of nondepot preparations or to intranasal preparations is rarely associated with a recurrence. A small increase in serum prolactin above normal limits was described in girls after treatment with GnRH agonist, but galactorrhea was not observed. Volumetric BMD and peak bone mass are normal during and after discontinuation of GnRH therapy. Calcium and vitamin D intake must be ensured during treatment to achieve optimal skeletal health. However, high fruit and vegetable intake (defined as >3 servings per day, lower than the US government recommended intake of 3 vegetables and 2 fruit in younger children) is desirable in all children and may serve in early puberty as a factor to increase bone density, possibly because of decreasing calcium excretion in the urine.[793]

Four patients were reported to have developed slipped capital femoral epiphyses during or just after treatment of CPP with GnRH agonist.[794] Slipped capital epiphyses occur mostly during the earliest phase of puberty, when growth is beginning to increase, and not after fusion of the triradiate cartilage, so these cases may have a different etiologic course than that found in average pubertal children.

There is a concern over maintenance of bone density when sex steroids are reduced with the use of GnRH agonists. There is evidence, however, that adolescents previously treated with gonadotropin-releasing hormone agonist for precocious puberty have normal bone density.[795]

Recently, reports of young women complaining of various maladies who were previously treated for precocious puberty with GNRH agonist appeared. They speak of pain in the jaw, fibromyalgia, degenerative disc symptoms, thinning bones and depression, or other psychologic symptoms. These have generally appeared on lay websites but the FDA is gathering such reports for ongoing surveillance to determine whether these are long-term effects related to Lupron well after treatment.[796]

Other Treatment for Precocious Puberty. The GnRH agonists are useful in conjunction with GH in the management of organic or neurogenic CPP with associated GH deficiency (usually as a result of irradiation of the brain). However, the use of GnRh agonists has been advocated even in the absence of precocious puberty to allow a longer period of GH treatment before epiphyseal fusion. A few, usually short-term studies have evaluated the combination, with variable results. This regimen is experimental, and its cost effectiveness needs to be considered (see earlier discussion).[470]

Aromatase inhibitors (e.g., letrozole) decrease or eliminate the effect of estrogen on bone age advancement. They have been useful to increase height prognosis in familial sexual precocity in boys (see upcoming discussion).[787] A study of Greek girls with decreased predicted adult height due to early puberty demonstrated that the combination of an aromatase inhibitor with a gonadotropin-releasing hormone agonist will increase predicted adult height.[797] Long-term controlled studies are necessary to establish the safety and efficacy and, especially, the effects on adult bone density, which remains a worrisome subject in the use of aromatase inhibitors in children[475] (Table 26.36).

Psychosocial Aspects. Psychologic management is a critical aspect of the care of children with CPP. With the advanced physical maturation for chronologic age, these children tend to seek friends closer to their size, strength, and physical development. Difficulties may arise because they lack the social skills of older children. Sex education of the child and the family is essential and must be given in a skillful, sensitive, and explicit manner; the risks of sexual abuse (in both sexes) and of pregnancy need to be discussed.[798]

The parents need to be informed about the management of menses. The onset of sexual activity may be earlier than average but usually remains within the normal range. Menarche before or at 11 years increases the risk of higher delinquency rates and stronger negative peer influences.[799]

It is imperative to provide support in handling the increased height, the advanced sexual maturation, and the effects of gonadal steroids on behavior, activity, and emotional stability. The unrealistic demands and expectations that arise from the discrepancy between the child's physique and his or her chronologic, mental, and psychosexual age require wise counseling, as do the reactions to ridicule by peers and the concern about being different from age-mates. Some of these problems have been mitigated by school acceleration, in which the child is advanced by one or two grades, if this is consistent with the mental and emotional development. These comments are applicable to children with all forms of sexual precocity; the effectiveness of GnRH agonists has reduced but not eliminated many of these issues in CPP.

The psychological evaluation of the effects of precocious puberty children must take into account their family situation and other social stressors lest these factors create effects on the child and are incorrectly attributed to precocious puberty.[800] A series of 10 girls suggested an increased level of stress before treatment for central precocious puberty with a diminution of the stress with appropriate treatment.[801] However, one detailed study of 15 girls found remarkable similarity between girls with precocious puberty and controls, except that those with precocious puberty had some tendency to increased emotional lability.[802]

TABLE 26.36 Potential Use of Aromatase Inhibitors or Estrogen Receptor Antagonists in Disorders of Growth and Sexual Maturation

Growth Disorders or Variants of Normal Growth

Isolated growth hormone deficiency
- To restrain epiphyseal maturation

Genetic short stature/constitutional delay in growth
- To restrain epiphyseal maturation

Sexual Precocity

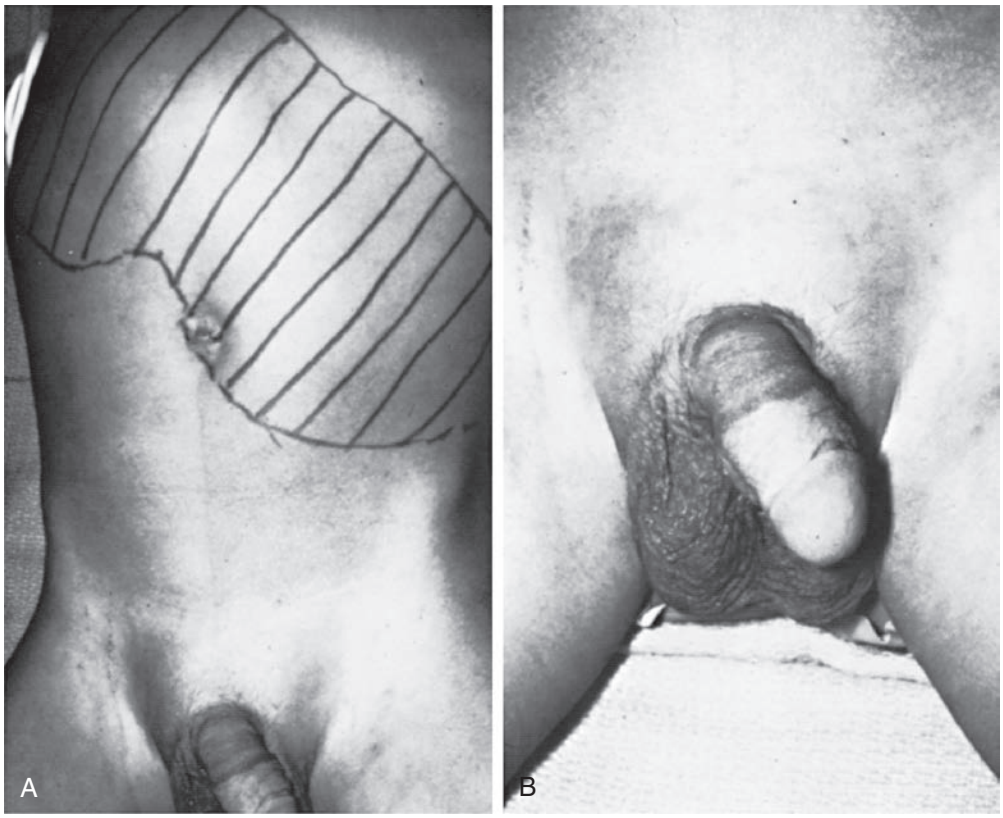
Congenital virilizing adrenal hyperplasia in male and female
- To reduce dose of glucocorticoid
- To inhibit conversion of C19 steroids to estrogens (or estrogen action)
- With or without use of 17,20-lyase inhibitor of antiandrogen

Testotoxicosis
- To inhibit conversion of C19 steroids to estrogens

McCune-Albright syndrome
- To inhibit conversion of C19 steroids to estrogens (or estrogen action)

Adolescent Gynecomastia
- To inhibit estrogen synthesis (or estrogen action)

From Grumbach MM. Estrogen, bone, growth, and sex: a sea change in conventional wisdom. *J Pediatr Endocrinol Metab.* 2000;13:S1439–S1455.



• **Fig. 26.61** A boy aged 1 year and 5 months with a human chorionic gonadotropin (hCG)–secreting hepatoblastoma. Notice the outline of the large liver (A) and the penile enlargement (B). The testes were 2 × 1 cm, and pubic hair was stage 2. The plasma hCG level was 50 mIU/mL; the plasma testosterone level was 168 ng/dL; and the plasma α-fetoprotein level was 160,000 ng/mL. Metastatic lesions in both lungs were seen on the chest radiograph. To convert testosterone values to SI units, see Fig. 26.19. To convert hCG values to international units per liter, multiply by 1.0. To convert α-fetoprotein values to micrograms per liter, multiply by 1.0. (From Kaplan SL, Grumbach MM. Pathogenesis of sexual precocity. In: Grumbach MM, Sizonenko PC, Aubert ML, eds. *Control of the Onset of Puberty.* Baltimore, MD: Williams & Wilkins; 1990:620–660.)

Peripheral Precocious Puberty or Incomplete Isosexual Precocity: Gonadotropin-Releasing Hormone–Independent Sexual Precocity[995]

In incomplete or peripheral forms of precocious puberty (IPP), such as GISP, the secretion of testosterone in boys and estrogen in girls is independent of the hypothalamic GnRH pulse generator (see Table 26.26). There is no pubertal LH response to GnRH or GnRHA, and there is no pubertal pattern of pulsatile LH secretion. Patients do not respond to chronic GnRH agonist therapy with suppression of gonadal steroid output. ISP is a consequence of gonadal or adrenal steroid secretion that is independent of GnRH, iatrogenic exposure to gonadal steroids, or, in boys, rare hCG-secreting or LH-secreting tumors. It can be considered a paraneoplastic syndrome caused by tumor production of hormones or a pathologic alteration of gonadotropin secretion.[803] Measures of tumor markers such as hCG or AFP may be helpful in the evaluation of peripheral precocious puberty but not of CPP.

Boys

Chorionic Gonadotropin–Secreting Tumors. Several types of germ cell tumors secrete hCG, which may cross-react in some polyclonal LH assays (although they are rarely used currently) and will lead to a positive pregnancy screen. Boys with hCG-secreting neoplasms have slightly enlarged testes (although not to a size consistent with the size of the phallus and other male secondary sex characteristics, because the seminiferous tubules are not affected), and it may be difficult to differentiate these patients from boys in the early stages of CPP on the basis of physical examination alone. However, plasma hCG levels are elevated without an increase in the concentration of FSH or LH measured in specific assays and will lead to a positive pregnancy screen.

Boys with hepatoma or hepatoblastoma present with hepatomegaly or firm, irregular liver nodules, anemia, and precocious puberty[804]; these are among the most serious of hCG-secreting tumors (Fig. 26.61). hCG is localized to multinucleated tumor giant cells; α-fetoprotein was found in the embryonal-type tumor cells of the hepatoblastoma in one case. The mean age at onset is 2 years, 8 months, but average survival time was only 10.7 months after diagnosis in previous series, but newer chemotherapy can lead to longer survival.[805]

Infantile choriocarcinoma is also associated with elevated hCG and is thought to originate in the placenta; infants may be diagnosed at 1 month of age, with a survival time of only 3 months.[806] About 20% of mediastinal germ cell tumors occur in boys with 47,XXY or mosaic Klinefelter syndrome, a prevalence 30 to 50 times more common than in unaffected boys. Plasma α-fetoprotein is a useful additional marker for yolk sac (endodermal sinus) or mixed germ cell tumors; the cells in the tumor that secrete α-fetoprotein appear to differ from those that secrete hCG. Rarely, the germ cells contain enough aromatase activity to convert

circulating C19 precursors (of adrenal origin after adrenarche) to estradiol, which in some instances is sufficient to induce breast development.[807]

Some teratomas, chorioepitheliomas, and mixed germ cell tumors in the hypothalamic region (or in the mediastinum, lungs, gonads, or retroperitoneum); certain pineal tumors (usually a germ cell tumor or mixed germ cell tumor); and, less commonly, a chorioepithelioma or its variants cause sexual precocity in boys by secreting hCG rather than by activating the pituitary gonadotropin-gonadal axis via the hypothalamic GnRH pulse generator.

Intracranial germ cell tumors account for 3% to 11% of malignant CNS tumors in children and adolescents, with a predominance in the Far East. Germ cell tumors of the hypothalamus or pineal region constitute fewer than 1% of primary CNS tumors in Western countries but account for 4.5% of such tumors in Japan. The prevalence of intracranial germ cell tumors is 2.6 times greater in males than in females, but germ cell tumors in the suprasellar-hypothalamic region do not exhibit a sex predominance and are generally associated with pituitary hormone deficiencies, including diabetes insipidus and delayed puberty.[481] Germ cell tumors do not cause gonadotropin-induced ISP in females because of the paucity of effects of hCG in prepubertal females. However, CPP may occur through disinhibition of the hypothalamic GnRH pulse generator by local mass effects.[808] Calcification of the pineal is found in 8% to 11% of children age 8 to 11 years, and by itself is not indicative of a germ cell tumor.

Germ cell tumors that secrete hCG are rarely located in the thalamus and basal ganglia. In "true" pure CNS germ cell tumors (germinomas), hCG cannot be readily detected in the circulation but may be detected in the cerebrospinal fluid.[481] In mixed germ cell tumors, hCG is commonly found in the blood as well as in cerebrospinal fluid. Extremely elevated levels of hCG in a CNS tumor suggest a primary intracranial choriocarcinoma or germ cell tumor with a high risk of tumor hemorrhage during biopsy, and surgical removal or debulking rather than diagnostic biopsy may be the initial operative approach.[809]

Mixed germ cell tumors and especially pure germinomas are radiosensitive, and if the bone age is less than 11 years, sexual precocity may regress, only to progress later into normal puberty. Long-term survival is reported in 88% of patients with CNS germ cell tumors after appropriate therapy. However, testicular germ cell tumors are occasionally found years after successful therapy for CNS germ cell tumors, so long-term surveillance is always indicated.[606]

Pineal cysts are a rare cause of CPP.[810] All pituitary adenomas, including gonadotropin-secreting pituitary adenomas, are exceedingly rare in children. An LH-secreting pituitary adenoma (basal serum LH of 900 IU/L with no rise after GnRH) and a prolactin-secreting pituitary adenoma (215 μg/L) caused sexual precocity in two boys with serum testosterone levels of 7 nmol/L (200 ng/dL).[811] Prepubertal values returned after removal of these chromophobe adenomas with suprasellar extension.

Precocious Androgen Secretion Caused by the Adrenal Gland

Virilizing Congenital Adrenal Hyperplasia. Virilizing CAH caused by a defect in 21-hydroxylation (CYP21 deficiency) leads to elevated androgen concentrations and masculinization and is a common cause of GISP in boys.[812] Approximately 75% of patients with CYP21 deficiency have salt loss resulting from impaired aldosterone secretion as well as low serum sodium and high serum potassium concentrations. Increased plasma concentrations of 17-hydroxyprogesterone, increased levels of urinary 17-ketosteroids and pregnanetriol, and advanced bone age and rapid growth are characteristic. Recent discovery of alternative steroidogenic pathways toward the production of virilizing androgens in this condition, the backdoor pathway, holds promise for new methods of evaluation of optimal treatment regimens.[813,814]

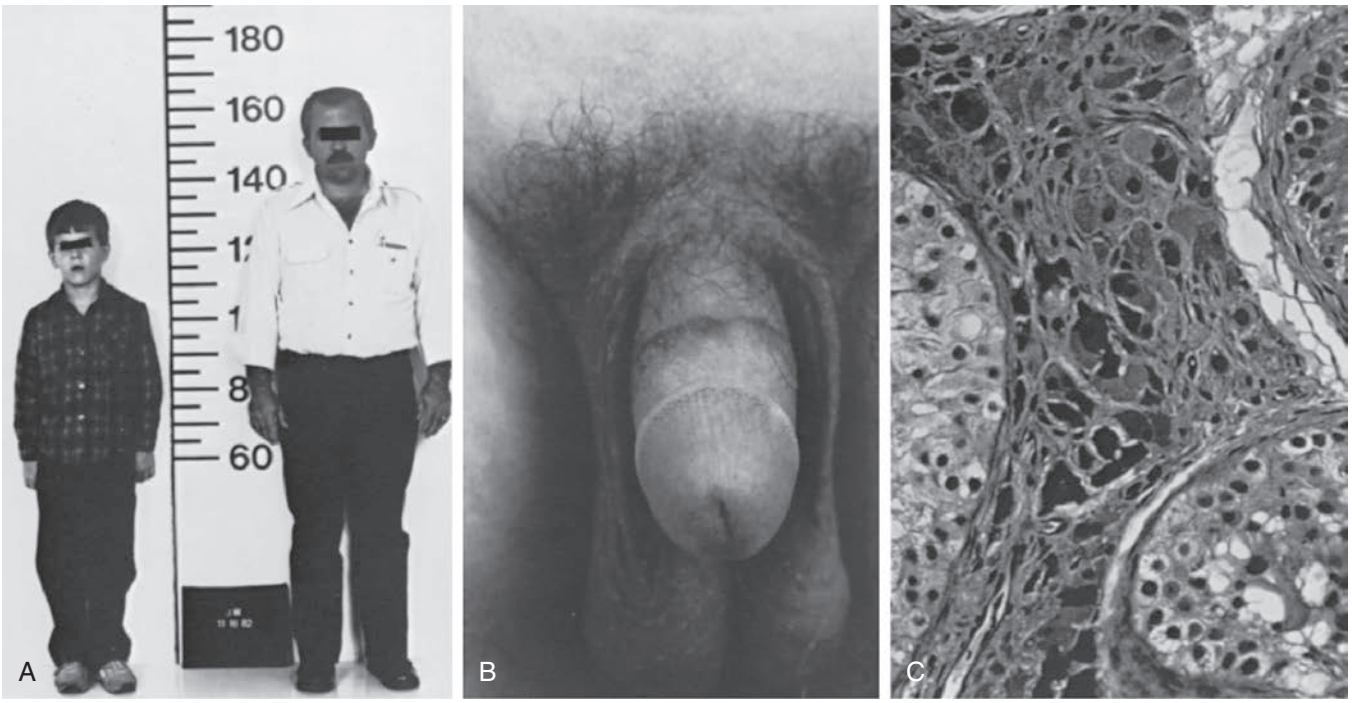
Treatment with glucocorticoids suppresses the abnormal androgen secretion and arrests virilization; treatment with mineralocorticoids, when necessary, corrects the electrolyte imbalance. Virilizing CAH accompanied by hypertension occurs in 11β-hydroxylase deficiency (CYP11B1 deficiency); the progressive virilization ceases and the blood pressure falls to normal with glucocorticoid therapy. All forms of CAH are inherited as autosomal recessive traits. Untreated virilizing CAH causes anovulatory amenorrhea in females and oligospermia in males; these conditions are reversible with treatment. Delayed treatment of virilizing CAH may reveal GnRH-dependent CPP (secondary CPP) as a consequence of the advanced somatic and hypothalamic maturation resulting from long exposure to adrenal androgen. Further difficulty is presented in the treatment of CAH during the pubertal years, when androgen secretion normally increases, and increased clearance of glucocorticoids at puberty in girls may alter dosing requirements.

Adrenal rests, or heterotopic adrenal tissue in the testes, are found in over 90% of boys with CAH. They may enlarge (sometimes to massive size) and may mimic bilateral or unilateral interstitial cell tumors. The size of these testicular adrenal rest tissues (TART) was thought to be related to poor control of CAH during childhood and adolescence, but recent evidence shows no relationship between biochemical control or plasma ACTH concentration and growth patterns, raising the likelihood that other control mechanisms perhaps originating in fetal life determine the size of these tumors.[815] MRI sonography, including Doppler flow studies of the testes, is useful to define the extent and nature of the testicular masses. These tumors can significantly decrease fertility, but surgical management, including enucleation of the tumor(s), has been useful to prevent further damage to the testes and improve the potential for fertility in some but not all studies.

As with most chronic diseases originating in childhood, transition of care to adult providers during late teenage years is essential. Comprehensive care clinics are suggested to offer the best method to provide care to children and adults with CAH.[816]

Virilizing Adrenal Tumor. Virilizing adrenal carcinomas or adenomas secrete large amounts of DHEA and DHEAS and, on occasion, testosterone. Glucocorticoids do not suppress the increased secretion of adrenal androgens to the normal range for age in carcinoma, as they do in CAH. Cushing syndrome resulting from adrenal carcinoma may cause ISP and growth failure in boys. Rarely, an adrenal adenoma produces both testosterone and aldosterone, leading to sexual precocity and hypertension with hypokalemia.

NR0B1 (DAX1) Gene Mutations. Two cases of *NR0B1* frameshift mutations demonstrated adrenal failure and GISP that were suppressible by glucocorticoid therapy but not by GnRH agonist. The exceedingly high ACTH levels, possibly acting through the human melanocortin 1 receptor present in human Leydig cells, may have been the underlying cause of the increased steroidogenesis and testosterone secretion that were reversed by glucocorticoid treatment. Because *NR0B1* inhibits transactivation of SF1, a regulator of steroidogenic genes, loss of *NR0B1* inhibition of SF1 transcriptional activity also may have had a role.[817,818]



• **Fig. 26.62** (A) A boy aged 5.5 years and his 28-year-old father with familial testotoxicosis. The boy exhibited signs of sexual precocity by 3 years of age. His height was 130.6 cm (+4.8 SD [standard deviation]), and his bone age was 12.5 years. The plasma testosterone level was 267 ng/dL; the dihydrotestosterone level was 46 ng/dL; and the dehydroepiandrosterone sulfate (DHEAS) level was 23 μg/dL. The plasma luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels were low, and neither rose after treatment. Pulsatile LH secretion was not demonstrable. Treatment with deslorelin, a gonadotropin-releasing hormone (GnRH) agonist, had no effect. The father had begun sexual maturation by 3 years of age and had reached a final height of 162.6 cm in his early teens. The plasma testosterone level was 294 ng/dL; the LH level was 0.5 ng/mL (LER-960); and the FSH level was 0.5 ng/mL (LER-869). The father had an adult-type LH and FSH response to GnRH; the LH level increased to 7.5 ng/mL, and the FSH level increased to 2 ng/mL. At least 28 male family members over nine generations are affected. To convert dihydrotestosterone values to nanomoles per liter, multiply by 0.03467. For other conversions to SI units, see Figs. 26.19 and 26.20. (B) External genitalia of the 5.5-year-old boy. The penis measured 12 × 2.8 cm, the right testis was 4 × 2 cm, and the left testis was 3.5 × 2.5 cm. (C) Testis of the boy showed Leydig cell maturation without Reinke crystalloids and spermatogenesis (Mallory trichrome stain).

Leydig Cell Tumor. Testicular tumors are rare in childhood, representing 1% to 2% of all pediatric solid tumors, and Leydig cell tumors make up only 1.5% of those.[819] Androgen-producing Leydig cell tumors rarely are malignant and are slow growing but must be treated or epiphyseal fusion will limit height and precocious puberty will affect social development. They derive from primordial mesenchyme, are classified as interstitial cell tumors, and occur most frequently around the age of 4 to 5 years. Unilateral enlargement (often nodular) of the testis usually occurs in boys with this neoplasm (although 5–10% of cases are bilateral); in contrast, both testes are usually of normal size (small) for chronologic age in boys with CAH or a virilizing adrenal tumor.[820] Although LH receptor–activating mutations were detected in several boys with sporadic Leydig cell adenomas,[779] no known mutations can be found in others. There is a trend toward testis sparing surgery or radiographic observation rather than orchidectomy in benign testicular lesions.[821]

Pituitary Gonadotropin–Independent Familial Premature Leydig Cell and Germ Cell Maturation: Familial or Sporadic Testotoxicosis.[331,779,822,823,997]. Pituitary gonadotropin–independent familial premature Leydig cell and germ cell maturation, or testotoxicosis,[822,824,825] causes boys to develop secondary sexual characteristics with penile enlargement, which may be present at birth, and bilateral enlargement of testes to the early or midpubertal range, although the testes often are smaller than expected in relation to penile growth and pubertal maturation (Fig. 26.62). Premature maturation of Leydig and Sertoli cells and spermatogenesis occur. Leydig cell hyperplasia may occur; the Leydig cells in affected boys produce dimeric inhibin B as well as testosterone, and Leydig cells and spermatogonia stain positively for the α and β_B segments of inhibin. The rate of linear growth is rapid, skeletal maturation is advanced, and muscular development is prominent. The presence of prepubertal basal and GnRH-stimulated gonadotropin concentrations, lack of a pubertal pattern of LH pulsatility (as measured by immunologic or bioassay techniques), and normal pubertal or adult testosterone levels and clearance of testosterone are characteristic (Table 26.37). The onset of adrenarche and its biochemical marker, serum DHEAS, correlate with bone age rather than chronologic age.

Treatment with an GnRH agonist does not suppress testicular function or maturation in the initial phase.[822] In late childhood or early adolescence, fertility is achieved and an adult pattern of LH secretion and response to GnRH is demonstrable[825]; secondary GnRH-dependent CPP may be superimposed on

TABLE 26.37 Testotoxicosis: Clinical and Laboratory Characteristics

Sex-limited autosomal dominant inheritance; activating mutation in the gene encoding the LH receptor
Early onset of sexual precocity in boys, with bilateral testicular enlargement
Prepubertal immunologic and biologic LH response to GnRH; prepubertal LH pulse secretory pattern
Concentration of plasma testosterone in pubertal range
Premature Leydig cell and seminiferous tubule maturation
No CNS, adrenal, or testicular abnormalities demonstrable by radiologic or hormonal studies
Lack of suppression of plasma testosterone or physical signs of puberty by GnRH agonist

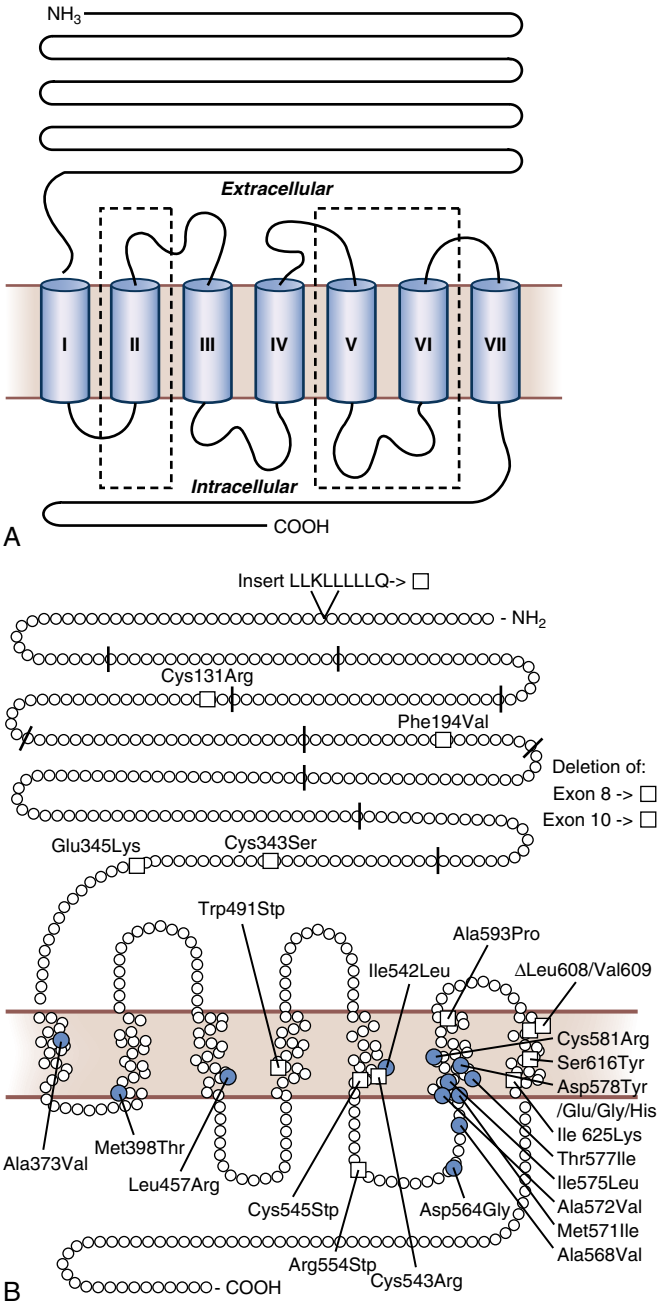
CNS, Central nervous system; *GnRH,* gonadotropin-releasing hormone; *LH,* luteinizing hormone.

the substrate of testotoxicosis. In some adults, impaired spermatogenic function is associated with elevated concentrations of plasma FSH. Testotoxicosis may occur sporadically, probably as a consequence of a germline mutation or even a postzygotic one, but it is usually inherited as a sex-limited autosomal dominant trait. A kindred with nine generations of affected males has been reported; obligatory female carriers of the trait were unaffected, because constitutional activation of the LH receptor on the ovary causes no ill effects.[826]

Heterozygous activating mutations of the heterotrimeric G_s protein–coupled LH-CGR that in concert transduce the LH/hCG signal to the main effector, adenyl cyclase, are the cause of testotoxicosis[827] (Fig. 26.63). The LH receptor cloned from the human is a glycoprotein of 80 to 90 kDa that belongs to a subfamily of the seven transmembrane–spanning, G protein–coupled receptors. The gene is localized to chromosome 2p21 (the same as for the FSH receptor); it spans at least 70 kilobases and contains 11 exons separated by 10 introns. The large glycosylated N-terminal extracellular hormone binding domain of the 701–amino acid LH-CGR is encoded by exons 1 through 10. A single exon, the large exon 11, encodes the entire G protein–linked transmembrane domain with its seven α-helic segments connected by alternating extracellular and intracellular loops, the intracellular domain, and the three untranslated regions—almost two-thirds of the receptor.[828]

Fourteen constitutive activating heterozygous missense mutations are reported in more than 60 patients[827] (see Fig. 26.63). Nine mutations were located between amino acid residues 542 and 581, suggesting a mutation hot spot. There appears to be a limited repertoire of mutations in American boys, consistent with a founder effect. European pedigrees are more diverse. A model of the transmembrane domain of the receptor provides novel suggestions for the structural and functional effects of these activating mutations.[829] Transfected cultured cells with these mutations exhibited increased basal cAMP production in the absence of agonist, observations consistent with a constitutive activating mutation.[823] Various possibilities for the conformational changes in the LH receptor that lead to its constitutive activation have been considered. Inactivating mutations of the LH-CGR and their clinical consequences are discussed earlier in this chapter.

Although affected boys do not respond to chronic administration of a GnRH agonist with suppression of testosterone



• **Fig. 26.63** (A) The serpentine, seven-transmembrane, G_s protein–coupled human luteinizing hormone/human chorionic gonadotropin (hLH/hCG) receptor with its large extracellular domain and the intracellular domain. The seven-helic transmembrane domains are indicated by roman numerals. (B) Mutations in the LH receptor protein are shown in the schematic structure of the LH receptor protein and localization of the inactivating *(open squares)* and activating *(blue-filled circles)* mutations in the human LH receptor. Notice the cluster of mutations in the VI transmembrane helix and third cytoplasmic loop. The Asx578Gly mutation is the most common activating mutation. The *short lines* across the amino acid chain separate the 11 exons. (A, redrawn from Yano K, Kohn LD, Saji M, et al. TABLE 26.38 Pharmacologic Therapy for Sexual Precocity

Disorder	Treatment	Action and Rationale
GnRH Dependent		
True or central precocious puberty	GnRH agonists	Desensitization of gonadotrophs; blocks action of endogenous GnRH
GnRH Independent		
Incomplete sexual precocity		
Girls		
Autonomous ovarian cysts	Medroxyprogesterone acetate	Inhibition of ovarian steroidogenesis; regression of cyst (inhibition of FSH release)
McCune-Albright syndrome	Medroxyprogesterone acetate[a]	Inhibition of ovarian steroidogenesis; regression of cyst (inhibition of FSH release)
	Third-generation aromatase inhibitor (e.g., letrozole)	Inhibition of P450 aromatase; blocks estrogen synthesis
Boys		
Familial testotoxicosis	Ketoconazole[a]	Inhibition of CYP17 (mainly 17,20-lyase activity)
	Flutamide or bicalutamide and letrozole or anastrozole	Antiandrogen Inhibition of aromatase; blocks estrogen synthesis
	Medroxyprogesterone acetate[a]	Inhibition of testicular steroidogenesis

[a]If true precocious puberty develops, an LHRH agonist can be added.

CYP17, Cytochrome P450 17α-hydroxylase/17,20-lyase; *FSH,* follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *LHRH,* luteinizing hormone–releasing hormone.

Modified from Grumbach MM, Kaplan SL. Recent advances in the diagnosis and management of sexual precocity. *Acta Paediatr Jpn.* 1988:30:S155–S175.

secretion, testosterone secretion, height velocity and rate of bone maturation, and aggressive and hyperactive behavior have reportedly been decreased by treatment with oral medroxyprogesterone acetate[822] (Table 26.38).

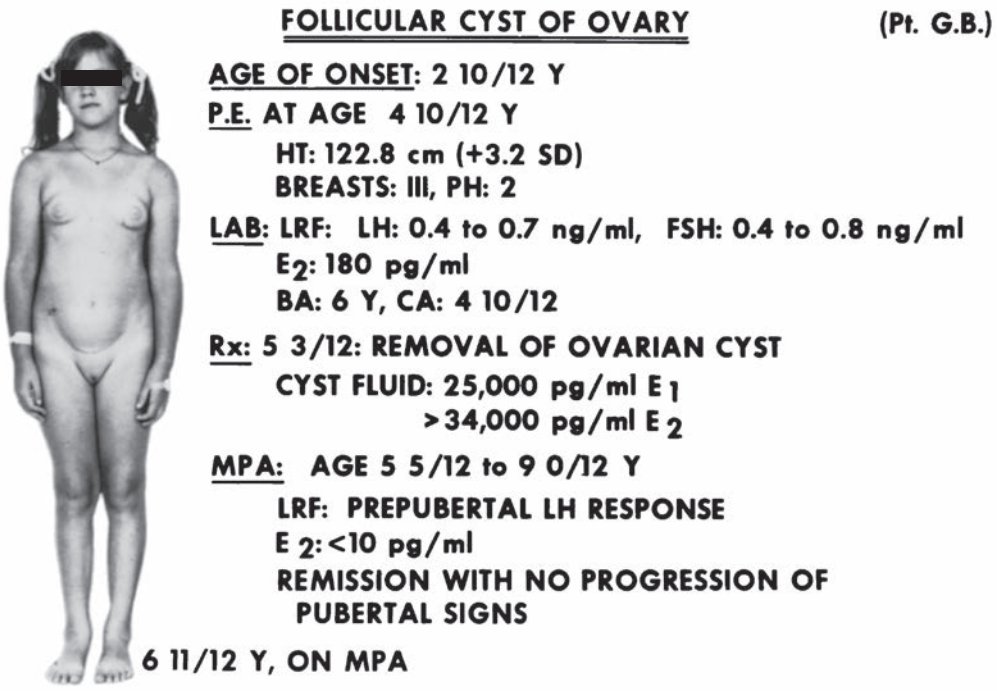
Ketoconazole, an orally active substituted imidazole derivative, suppresses gonadal and adrenal biosynthesis by inhibiting the enzyme CYP17, which regulates both 17-hydroxylation and the scission (17,20-lyase) of 17α-hydroxypregnenolone (Δ^5-17P) to DHEA (see "Nature and Regulation of Adrenal Androgens"). In the dosage used for treatment of testotoxicosis (median dose 16.2 mg/kg/day to a maximal dose of 700 mg/day[830]), the agent produces a mild transient decrease in cortisol secretion and interferes with binding of testosterone to TeBG. Secondary CPP often occurs when the bone age advances to or has already reached the pubertal range (usually >11.5 years), at which time the addition of a GnRH agonist is appropriate.[827] Ketoconazole can cause hepatic injury, which is usually mild and reversible, but in rare cases hepatotoxicity is severe. Reversible renal injury, rash, and interstitial pneumonia were reported in a patient who tolerated lower doses, suggesting a dose-response effect. Nonetheless, five patients treated with ketoconazole experienced no side effects other than one mild and transient elevation of liver enzymes; they had appropriate age of onset of true puberty and reached an adult height almost identical to the target height (a mean increase of 8 cm over the initially predicted height), suggesting great benefit of this therapy in this condition.[830,831]

The antiandrogen (and antimineralocorticoid) spironolactone, in combination with testolactone, an inhibitor of aromatase (CYP19), the key enzyme in the conversion of androgens to estrogens, is also used to treat testotoxicosis.[832] The addition of a GnRH agonist is a useful step to suppress pituitary gonadotropin secretion and secondary CPP that may later develop.[829] More potent nonsteroidal antiandrogens (e.g., flutamide, nilutamide) and aromatase inhibitors (e.g., letrozole) inhibit the rate of skeletal maturation and linear growth by suppressing estradiol synthesis, potentially with greater therapeutic efficacy.[159,160] The combination of bicalutamide and anastrozole is proposed as another approach.[833] Report of 20-year follow-up of these therapies demonstrated efficacy with few adverse effects. Table 26.38 lists the various agents used in the treatment of testotoxicosis.

A study of an untreated boy with testotoxicosis (GISP) had the expected pattern of rapid growth and early cessation, and the adult height of 174 cm was within target height range (171.5–188.5 cm), indicating the critical importance of individual approaches to affected boys when considering treatment to maximize height.[832]

Follow-up of boys with testotoxicosis indicates an increased risk of seminoma in adult life and Leydig cell adenoma in later childhood.[779,834] One boy with testotoxicosis developed nodular Leydig cell hyperplasia at 10 years of age.[835] These cases support a relationship between an activating mutation of the gene encoding the LH receptor and of Leydig cell tumors.[836]

Gonadotropin-Independent Sexual Precocity and Pseudohypoparathyroidism Type Ia. A mutation in $G_s\alpha$ can constitutively activate or inactivate adenyl cyclase.[837] Two boys who presented in infancy with classic pseudohypoparathyroidism type Ia (PHPIa), a disorder characterized by resistance to hormones whose action is mediated by cAMP, developed signs of sexual precocity with the hormonal characteristics of testotoxicosis (i.e., gonadotropin-independent sexual precocity) at about 24 months of age. Whereas the alanine residue is usually absolutely conserved in all heterotrimeric G pro-



• **Fig. 26.64** A girl aged 4 years and 10 months with recurrent, "autonomous" follicular cysts of the ovary. For conversion to SI units, see Fig. 26.19. *BA,* bone age; *CA,* chronologic age; E_2, estradiol; *FSH,* follicle-stimulating hormone; *LH,* luteinizing hormone; *LRF,* luteinizing hormone-releasing factor; *MPA,* medroxyprogesterone acetate (oral); *P.E.,* physical examination; Rx, treatment. (From Kaplan SL, Grumbach MM. Pathogenesis of sexual precocity. In: Grumbach MM, Sizonenko PC, Aubert ML, eds. *Control of the Onset of Puberty.* Baltimore, MD: Williams & Wilkins; 1990:620–660.)

teins, both of these patients had a unique Ala366Ser mutation in one allele of the $G_s\alpha$ gene. PHPIa is caused by a wide variety of inactivating mutations in $G_s\alpha$ that lead to an approximately 50% reduction in $G_s\alpha$ activity in functional assays.

The paradox of a $G_s\alpha$ mutation causing both inactivation with PHP and constitutive activation with testotoxicosis was resolved by the in vitro demonstration that, unlike other activating mutations of $G_s\alpha$, which involve mutations inhibiting its intrinsic GTPase activity and decreasing the rate of hydrolysis of GTP to GDP, the mutation in these two boys caused accelerated dissociation of GDP at 33°C in transfected Leydig cells but was rapidly degraded at 37°C in a lymphoma cell line[838] and at 33°C and 37°C in skin fibroblasts transfected with the mutation. These observations explain the clinical consequences of increased $G_s\alpha$ activity in the testis, which are 3°C to 5°C cooler than the body, and the tissue specificity and temperature dependency of the mutation. The mother of one patient appeared to be a mosaic for the $G_s\alpha$ mutation; in the other boy, a germline mutation was likely.

Girls

GISP in girls (see Table 26.26) is caused by autonomous estrogen secretion by an ovarian cyst or tumor or an adrenal neoplasm or by inadvertent exposure to estrogen. A series of 129 patients demonstrated that the prevalence of non-gonadotropin–dependent precocious puberty was 14 in 1000 children if congenital adrenal hyperplasia was excluded. Girls were affected four times more than boys due to the prevalence of ovarian cysts followed by McCune-Albright syndrome in girls.[837] Girls harboring a teratoma or teratocarcinoma (or a CNS germ cell tumor) that secretes hCG have experienced sexual precocity caused by concurrent estrogen secretion by the tumor but no effect from the hCG alone; these girls also may have galactorrhea, especially if chorionic somatomammotropin (hCS or hPL) is also secreted.

Autonomous Ovarian Follicular Cysts. The most common childhood estrogen-secreting ovarian mass and ovarian cause of sexual precocity is the follicular cyst.[838] Antral follicles up to about 8 mm in diameter are common in the ovaries of normal prepubertal girls and may be seen in third trimester fetuses and newborn infants.[839] They may appear and regress spontaneously. Larger follicular cysts may be discovered because of the presence of an abdominal mass or abdominal pain, especially after torsion or as an unexpected finding on pelvic sonography performed for other reasons. Occasionally, the antral follicles secrete estrogen and may form large masses, or the follicular cysts may recur and cause recurrent signs of sexual precocity and acyclic vaginal bleeding. Enlarged antral follicles or cysts occur in premature thelarche, CPP, and transient or incomplete sexual precocity. In some patients with ovarian follicular cysts, the transient or recurrent sexual precocity is GnRH independent (Fig. 26.64). The concentration of estradiol fluctuates, usually correlating with changes in the size of the follicular cyst(s) when monitored by pelvic sonography, and may increase to levels found in granulosa cell tumors, although values may also be in the pubertal range.

These patients do not have increased plasma granulosa cell tumor markers such as AMH or inhibin.[840] The concentration of LH is suppressed, a pubertal pattern of pulsatile LH secretion is absent, and the LH rise induced by GnRH is prepubertal. A constitutive activating mutation of the FSH receptor has not been described in a female, but a heterozygous mutation, Asp567Gly, was detected in the third intracellular loop of the FSH receptor in a hypophysectomized man who, despite the gonadotropin

deficiency, was fertile and had normal-size testes.[827] Accordingly, the possibility that some girls with recurrent ovarian cysts harbor an activating mutation of the FSH receptor seems worthy of study. The McCune-Albright syndrome may lead to recurrent ovarian cysts even in the apparent initial absence of other features of this disorder due to somatic activating mutations in the gene encoding the α-subunit of the heterotrimeric G_s protein. The luteinization of follicular cysts may be related to subtle elevations and increased pulses of plasma FSH. Ovarian cysts and sexual precocity have been associated with the fragile X syndrome in girls.[841]

Estradiol-secreting ovarian cysts occur in preterm infants born before 30 weeks of gestation; they are associated with edema of the labia majora and, in some instances, of the lower abdominal wall.[842] The LH and FSH response to GnRH in these patients suggests GnRH dependence, and treatment with medroxyprogesterone acetate is associated with regression of the cysts. A case of massive ovarian edema associated with ovarian cysts found in a 6-month-old with breast and pubic hair development has been reported.[843]

GnRH agonists are useful in the treatment of ovarian follicular cysts associated with CPP (GISP) but not of so-called autonomous cysts. However, autonomously functioning ovarian follicular cysts, whether recurrent or manifesting in an isolated episode, often respond to treatment with oral medroxyprogesterone acetate (or cyproterone acetate outside of the United States), which seems to prevent recurrence, to accelerate involution of the follicular cysts,[843] and to reduce the risk of torsion. The use of a potent aromatase inhibitor such as letrozole to reduce estradiol secretion is another potential approach to treatment and has been successfully used in girls with no stigmata of McCune-Albright syndrome other than autonomous ovarian cysts.[844,845] Surgical intervention is rarely indicated; a large or persistent cyst can be reduced by puncture at laparoscopy, and the size of the cyst can be monitored readily by pelvic sonography.

While it is a rare cause of ovarian tumors, an FSH-secreting and TSH-secreting adenoma of the pituitary gland led to extremely large cysts in a 9-year-old girl's ovaries but was only discovered after menopausal FSH levels led to the diagnosis of the tumor at 19 years of age.[846]

Ovarian Tumors. Ovarian tumors are the most common genitourinary tumors of girls,[847,848] accounting for about 1% of all tumors in girls younger than 17 years of age, but they are rare in the prepubertal period. Most are benign according to most reports,[849] but a referral center might find a majority of tumors are malignant.[850] Most ovarian tumors arise from germ cells or sex cord–stromal cells in childhood with fewer than 20% being of epithelial origin, whereas in adults, most are of epithelial origin.[851] Early diagnosis of most childhood tumors of the ovary allows successful cure, unlike ovarian cancer in adult women. Most of these girls present with pain or an abdominal mass. Tumors smaller than 5 cm at diagnosis are more likely to be nonneoplastic, and those larger than 10 cm are more likely to be neoplastic.[838,852] Malignant ovarian tumors evaluated by ultrasonography, computed tomography, or magnetic resonance imaging are mostly solid or heterogeneous and are larger than benign tumors.[853] The successful use of tumor markers for diagnosis varies by cause. For example, in one series, cystic teratomas resulted in lactate dehydrogenase (LDH) elevation and an increased erythrocyte sedimentation rate; immature teratomas produced elevated levels of LDH, α-fetoprotein, and cancer antigen 125 (CA125), and granulosa cell tumors had elevated sex steroids (estradiol or testosterone[850] or both).[854]

Granulosa cell tumor of the ovary is rare in childhood, although theca cell tumors are even less common.[855] Because most granulosa cell tumors produce estrogen, incomplete isosexual precocity occurs in the youngest girls affected. Characteristic histologic features of juvenile granulosa cell tumors include nodular architecture, follicle formation, abundant interstitial and intrafollicular acid mucopolysaccharide-rich fluid, irregular microcysts, individual cell necrosis, and high mitotic activity (mean activity, 11 mitotic figures per 10 high-power fields). Size can vary from 2.5 to 25 cm, with a mean diameter of 12 cm. The interstitial mucinous fluid consists predominantly of hyaluronic acid. Prognosis is good, with the mortality rate being about 3%, but delay in treatment leads to substantial complications. In one series, girls who presented with ISP and were correctly diagnosed had no intra-abdominal spread and had Federation of Gynecology and Obstetrics (FIGO) stage IA disease, whereas those who presented with acute abdominal symptoms had 50% prevalence of intra-abdominal spread and two recurrences after surgery. When the diagnosis was made after normal puberty had begun, some girls experienced virilization or abdominal symptoms; 80% had intra-abdominal spread, and 30% had recurrence with FIGO stage IIC.

Approximately 80% of granulosa cell tumors can be palpated on bimanual examination, whereas fewer than 5% are bilateral or clinically malignant. The concentration of plasma estradiol may increase to high levels, and serum FSH and LH concentrations are usually suppressed. AMH and inhibin are sensitive tumor markers and are used to screen for metastases especially if elevated at diagnosis[856]; an elevated estradiol concentration in an affected patient younger than 9 years of age or an abnormal rise in concentration of plasma AMH or inhibin at any age suggests recurrence or metastasis. Girls affected with stage I disease may be treated by surgery alone, but a more advanced grade will require chemotherapy.[857]

Occasionally, gonadoblastomas in streak gonads, rare lipoid tumors, cystadenomas, and ovarian carcinomas secrete estrogens, androgens, or both. Even with successful resection of a gonadal sex steroid–secreting neoplasm, the child is at risk for secondary CPP in the future. Gonadal tumors composed of a mixture of germ cells and sex cord–stromal cells are distinct from gonadoblastoma. They may be benign or malignant, with the Sertoli-Leydig cell tumors reported to be most aggressive.[858] α-Fetoprotein and other tumor markers aid in diagnosis. However, a 558-g ovarian dysgerminoma was found in a 7-year-old girl with precocious puberty and no elevation of serum tumor markers.[859]

Peutz-Jeghers Syndrome. Peutz-Jeghers syndrome, an autosomal dominant syndrome, is usually caused by mutations in the gene located on 9p13.3 that encodes a serine/threonine protein kinase, STK11, leading to haploinsufficiency of this novel tumor-suppressing gene.[88,860] This condition is characterized by mucocutaneous pigmentation of the lips, buccal mucosa, fingers, and toes; gastrointestinal hamartomatous polyposis; and a predisposition to malignancy.

It is associated with a rare, distinctive sex cord tumor with annular tubules in both boys and girls. Estrogen secretion by the tumor may lead to feminization in girls and incomplete sexual precocity in boys. Less frequently, a feminizing Sertoli-Leydig cell tumor has been found in patients with Peutz-Jeghers syndrome. The rare feminizing large-cell calcifying Sertoli cell tumors of the testes present with gynecomastia in boys and are found in Peutz-Jeghers syndrome and Carney complex, the latter of which is most often caused by *PRKAR1A* mutations, the gene encoding regulatory subunit type 1 of protein kinase A.

Sex cord–stromal cell tumors derive from the celomic epithelium or mesenchymal cells of the embryonic gonads and are composed of granulosa, theca, Leydig, and Sertoli cells. Estrogen secretion from these tumors can cause ISP in girls, and androgen secretion can cause virilization. Inhibin A and B activin are produced, as is AMH; all serve as useful tumor markers. Sex cord–stromal cell tumors not associated with Peutz-Jeghers syndrome are malignant in 25% of cases; these tumors can grow quite large, but those associated with Peutz-Jeghers syndrome are often small and multiple, and they contain calcifications.[861] Estrogen excess in Peutz-Jeghers syndrome[1008] has been treated with aromatase inhibitors.[474]

Girls with this disorder should be examined at regular intervals for the presence of gonadal tumors by pelvic sonography. Peutz-Jeghers syndrome should be considered in boys with unexplained gynecomastia, especially if in the prepubertal years.

Adrenal Tumors. Adrenocortical tumors are rare in childhood (0.6% of all childhood tumors and 0.3% of all malignant childhood tumors), but most produce steroid hormones, whereas those in adults usually do not. The median age at diagnosis is 4 years, but 41% of these tumors manifest before 2 years and 71% before 5 years of age. Most cause virilization or Cushing syndrome, but adrenal tumors may produce estrogen as well as androgens and can cause sexual precocity in a girl or gynecomastia in a boy.[862] One adrenal adenoma found in a 7-year-old girl expressed the gene for aromatase, demonstrating that the tumor could directly produce estrogen[863] to a level of 145 pg/mL, within the range found in adrenal carcinomas.

Boys and Girls

McCune-Albright Syndrome. McCune-Albright syndrome[846,1003] occurs about twice as often in girls than in boys; it is sporadic and is caused by somatic activating mutations (Cys or His to Arg201) in exon 8 of the gene *(GNAS1)* encoding the α-subunit of the trimeric GTP-binding protein ($G_s\alpha$) that stimulates adenyl cyclase.[864,865] This leads to a constitutive ligand-free activation of cellular function in a mosaic distribution, leading to a high variability of organ involvement and degree of severity.[474] It is characterized by the triad of irregularly edged hyperpigmented macules (café au lait spots of the coast of Maine type); a slowly progressive bone disorder, polyostotic fibrous dysplasia, that can involve any bone and is frequently associated with facial asymmetry and hyperostosis of the base of the skull; and, more commonly in girls, GISP (Fig. 26.65 and Table 26.39). At least two of the features must be present to consider the diagnosis.

Autonomous hyperfunction most commonly involves the ovary, but other endocrine involvement includes the thyroid gland (nodular hyperplasia with thyrotoxicosis or euthyroid status), adrenal gland (multiple hyperplastic nodules with Cushing syndrome that may occur in the neonatal period and may be followed by adrenal insufficiency),[866] pituitary gland (adenoma or mammosomatotroph hyperplasia with gigantism, acromegaly, and hyperprolactinemia), and parathyroid glands (adenoma or hyperplasia with hyperparathyroidism).[867,868] Hypophosphatemic vitamin D–resistant rickets or osteomalacia occurs either because of overproduction of a phosphaturic factor, phosphatonin, that is secreted by the bone lesions or because of an intrinsic renal abnormality leading to the excess generation of nephrogenous cAMP in the proximal tubule and, as a result, decreased reabsorption of phosphate. Hepatocellular dysfunction may occur due to expression of the mutant activating gene in liver cells, which leads to jaundice associated with hepatobiliary disease, and pancreatitis.

• **Fig. 26.65** A girl aged 7 years and 4 months with gonadotropin-releasing hormone (GnRH)–independent sexual precocity associated with McCune-Albright syndrome. She had breast development since infancy, and it increased noticeably at about 3 years of age; 6 months later, episodes of recurrent vaginal bleeding began. Growth of pubic hair was noticed at about 4 to 5 years. At age 5.5 years, the bone age was 6 years and 11 months; height was +1 SD (standard deviation) above the mean value for age. By 6.5 years, when she was seen at the University of California, San Francisco, the bone age had advanced to 9 years, and height was at +1 SD. Breasts were at Tanner stage 4, and pubic hair at stage 3. Extensive, irregular café au lait macules cover the right side of the face, left lower abdomen and thigh, and both buttocks. A bone survey showed widespread involvement of the long bones with typical polyostotic fibrous dysplasia, the floor of the anterior fossa of the skull was sclerotic, and the diploic space had widened. She has had two pathologic fractures through bone cysts in the right upper femur. Notice the osseous deformities. Plasma estradiol concentrations were consistently in the pubertal range; the luteinizing hormone (LH) response to GnRH was prepubertal. Results of thyroid function studies were normal, including the thyrotropin response to thyrotropin-releasing hormone administration, and antithyroid antibodies were not detected. Treatment with oral medroxyprogesterone acetate suppressed menses and arrested pubertal development but did not slow skeletal maturation. Her final height is 142 cm (–2.5 SD). Menstrual cycles are regular.

Another nonendocrine manifestation is cardiac disease, and patients carry the risk of cardiac arrhythmia and sudden death. This is a sporadic condition that can be concordant or discordant in monozygotic twins.

Considering children with at least one of the signs of McCune-Albright syndrome, 24% had the classic triad, 33%

TABLE 26.39 Clinical Manifestations of McCune-Albright Syndrome in 158 Reported Patients[a]

Manifestation	% OF PATIENTS			Mean Age at Diagnosis (yr) and Range	Comments
	Total (*N* = 158)	Male (*n* = 53)	Female (*n* = 105)		
Fibrous dysplasia	97	51	103	7.7 (0-52)	Polyostotic more common than monostotic
Café au lait lesion	85	49	86	7.7 (0-52)	Variable size and number of lesions, irregular border (coast of Maine)
Sexual precocity	52	8	74	4.9 (0.3-9)	Common initial manifestation
Acromegaly/gigantism	27	20	22	14.8 (0.2-42)	17/26 of patients with adenoma on MRI/CT
Hyperprolactinemia	15	9	14	16 (0.2-42)	23/42 of acromegalic patients with PRL
Hyperthyroidism	19	7	23	14.4 (0.5-37)	Euthyroid goiter is common
Hypercortisolism	5	4	5	4.4 (0.2-17)	All primary adrenal
Myxomas	5	3	5	34 (17-50)	Extremity myxomas
Osteosarcoma	2	1	2	36 (34-37)	At site of fibrous dysplasia, not related to prior radiation therapy
Rickets/osteomalacia	3	1	3	27.3 (8-52)	Responsive to phosphorus plus calcitriol
Cardiac abnormalities	11	8	9	(0.1-66)	Arrhythmias and CHF reported
Hepatic abnormalities	10	6	10	1.9 (0.3-4)	Neonatal icterus is most common

[a]Evaluations include clinical and biochemical data; other rarely described manifestations include metabolic acidosis, nephrocalcinosis, developmental delay, thymic and splenic hyperplasia, and colonic polyps.

CHF, Congestive heart failure; *CT,* computed tomography; *MRI,* magnetic resonance imaging; *PRL,* prolactin.

had two signs, and 40% had only one classic sign. The mutation was detected in 46% of blood samples from patients presenting the classic triad but in only 21% and 8% of samples from patients with two signs or one sign, respectively. If an affected tissue was available, the mutation was found in more than 90% of the patients no matter what the number of signs. The mutation was found in 33% of the 39 cases of isolated peripheral precocious puberty. Patients with monostotic fibrous dysplasia, isolated peripheral precocious puberty, neonatal liver cholestasis, or the classic McCune-Albright syndrome all had the same molecular defect.[818] Whereas most endocrine organs involved in McCune-Albright syndrome were not associated with parent specificity,[869] pituitary adenomas secreting GH expressed NESP55 transcripts, which are monoallelically expressed from the maternal alleles rather than from the exon 1A paternal allele. Mutation of *GNAS1* involving Arg201His replacement is associated with apparent premature or exaggerated thelarche and early menarche.[870,871]

Most patients have pigmented skin lesions in infancy that usually increase in size along with body growth.[872] The irregularly bordered café au lait macules usually do not cross the midline, but they may; they often are located on the same side as the main bone lesions and have a segmented distribution.

The skeletal lesions in the cortex are dysplastic and are filled with spindle cells with poorly organized collagen support; they take the form of scattered cystic areas of rarefaction on radiography and often result in pathologic fractures and progressive deformities (Fig. 26.66). Technetium bone scintigraphy has been the most sensitive approach to the detection of bone lesions before they are visible radiographically. Fractures are most common between the sixth and the tenth years but decline thereafter, and they are more frequent if phosphaturia is present.[873] Patients referred for fibrous dysplasia of the bone in one or more locations are often found to have endocrine or dermatologic manifestations of McCune-Albright syndrome as well as *GNAS1* mutations, so suspicion should be kept high when evaluating fibrous lesions.[874] If the skull is involved, there may be entrapment and compression of optic or auditory nerve foramina, which can lead to blindness, deafness, facial asymmetry, and ptosis. Asymmetry of the jaw is another manifestation of McCune-Albright syndrome. Fifty percent of affected children in one series manifested bone abnormalities by 8 years of age.[872] Increased serum GH

• **Fig. 26.66** Bone lesions in McCune-Albright syndrome. (A) The skull has severe thickening primarily at the base due to fibrous dysplasia. The auditory and optic nerves can be caught in narrowed foramina, but that is not the case in these patients. (B, C) Distortions of the long bones can develop into a "shepherd's crook" appearance. Notice the multiple bone cysts. (D) Bone scan shows the areas of remodeling that "light up," depending on the area affected in individual patients. There are examples of patients primarily affected in the craniofacial area or in the appendicular area, or both areas, and the axial skeleton. (Courtesy Michael T. Collins, M.D., National Institutes of Health, Bethesda, MD, and Sandra Gorges, M.D., University of California, Davis, CA.)

levels occur in up to 30% of cases and have an adverse effect on the skull deformities, depending on the age at onset; somatostatin analogues are usually effective in suppressing GH.[875,876] Irradiation of the hypothalamic-pituitary area may be invoked, but it carries a risk of later occurrence of sarcoma. Rapid control of elevated GH can be achieved by the use of long-acting somatostatin agonists such as pegvisomant, which is often but not always successful.[877]

The sexual precocity often begins during the first 2 years of life and is frequently heralded by menstrual bleeding; the cause is autonomously functioning luteinized follicular cysts of the ovary in girls (Table 26.40).[865] The ovaries contain no corpora lutea and commonly exhibit asymmetric enlargement as a result of a large solitary follicular cyst that characteristically enlarges and then spontaneously regresses, only to recur (Fig. 26.67).[865] Serum estradiol is elevated (at times to extraordinary levels); in contrast, the LH response to GnRH is prepubertal, and the pubertal pattern of nighttime LH pulses is absent at the onset and during the initial years. Later in the course of the sexual precocity, when the bone age approaches 12 years, the GnRH pulse generator becomes operative and ovulatory cycles ensue. However, adults carry the risk of acyclic hyperestrogenemia, infertility, and a potential risk of estrogen-dependent cancer, including breast cancer.[878]

An affected girl may progress from GnRH-independent puberty to GnRH-dependent puberty (see Table 26.40). GnRH agonists are not effective for treatment in the GnRH-independent stage. Testolactone, fadrozole, and anastrozole have had equivocal or no success in controlling manifestations in initial studies.[475] After a single case report of treatment with tamoxifen, an antiestrogen, showed decreases in bone age advancement, growth rate, menses, and pubertal development, a multicenter trial demonstrated the utility of this agent in decreasing vaginal bleeding and decreasing the rate of bone age advancement and growth rate in

TABLE 26.40 A Patient With McCune-Albright Syndrome and Recurrent Ovarian Cysts

Chronologic Age (yr)	Bone Age (yr)	Height (cm)	Physical Signs	Basal and Post-LHRH (ng/mL)[a,b]	Plasma Estradiol (pmol/L [pg/mL])	Radiography (Long Bones)
$1^{4}/_{12}$	$1^{3}/_{12}$	81.1	Café au lait pigmentation, B2, PH1	LH 0.6-1.3 FSH 1.9-3.2	40 (11)	Normal

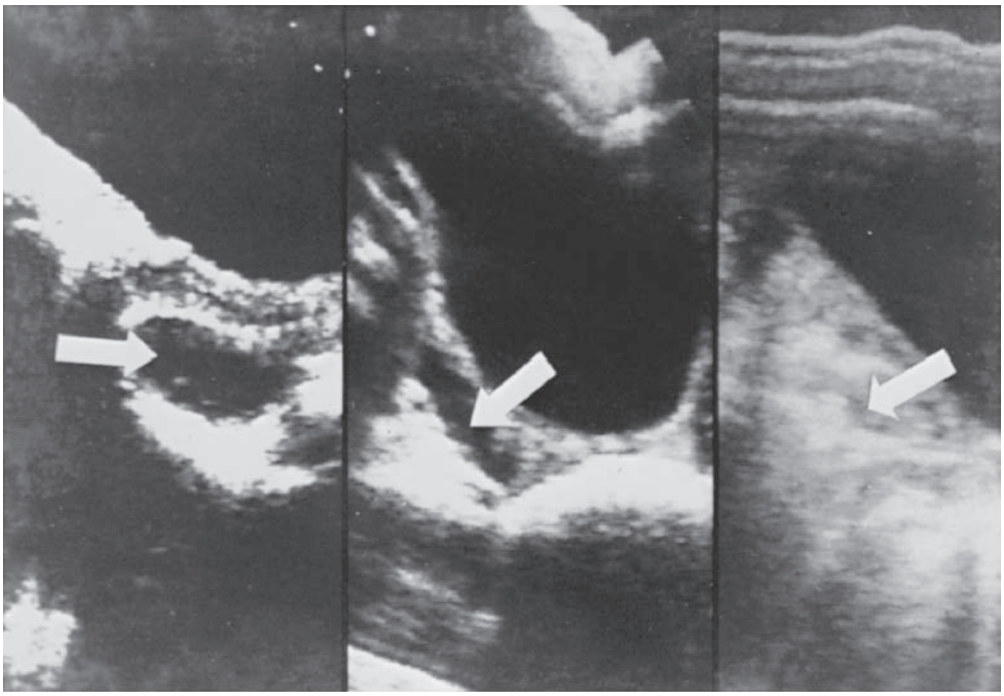
affected girls.[879] However, ovarian and uterine volumes remained elevated. The longest term study demonstrated that letrozole can suppress bone age advancement and preserve adult height far over controls.[880]

Sexual precocity is rare in boys with McCune-Albright syndrome[865]; however, testicular disease occurs as frequently in affected boys as ovarian disease in girls.[881] Affected boys may have asymmetric enlargement of the testes in addition to signs of sexual precocity. The histologic changes and hormonal findings are reminiscent of those observed in testotoxicosis: The seminiferous tubules are enlarged and exhibit spermatogenesis, and Leydig cells may be hyperplastic, the most common histologic finding.[865,881] A 3.8-year-old boy with McCune-Albright syndrome (several café au lait lesions on the back and polyostotic fibrous dysplasia) had an Arg201His mutation detected in bone and testis tissue and the unusual feature of macroorchidism (right testis, 9 mL; left testis, 7 mL), but sexual precocity was absent. Basal and GnRH-stimulated gonadotropins and sex steroid levels were prepubertal, but serum inhibin B and AMH concentrations were strikingly elevated. On histologic examination of the testes, most of the seminiferous tubules were slightly increased in diameter and filled with Sertoli cells but lacked a lumen. The tubules stained intensively for inhibin β_B-subunit; mature Leydig cells were absent.[882] An increased incidence of the rare condition testicular microlithiasis was described in boys with McCune-Albright syndrome evaluated by ultrasonography.[883,884]

McCune-Albright syndrome may occur concordantly or discordantly in monozygotic twins; familial cases have not been convincingly described. In 1986, Happle[885] posited that the disorder

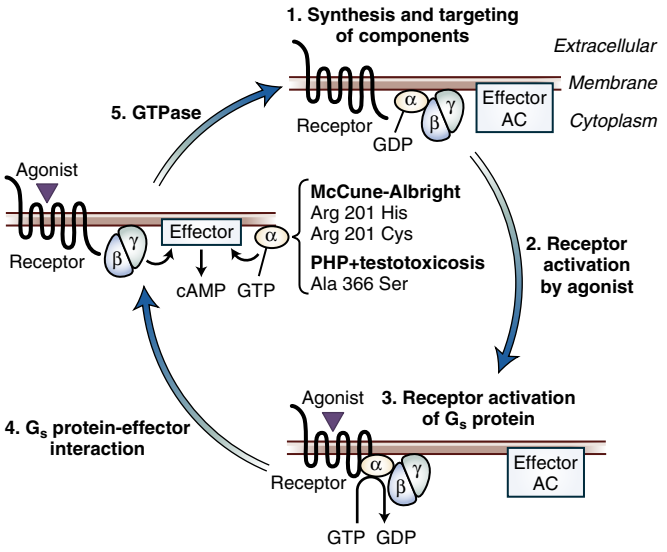


• **Fig. 26.67** Serial pelvic ultrasonograms at 2-week intervals of a 6-year-old girl with McCune-Albright syndrome. Breast development and vaginal bleeding coincided with the enlargement of the ovarian cyst; *white arrows* denote the decreasing size of the cyst. With the spontaneous regression of the large ovarian cyst, the breasts regressed in size, and vaginal bleeding ceased. (From Kaplan SL, Grumbach MM. Pathogenesis of sexual precocity. In: Grumbach MM, Sizonenko PC, Aubert ML, eds. *Control of the Onset of Puberty.* Baltimore, MD: Williams & Wilkins; 1990:620–660.)

is caused by an autosomal dominant lethal gene that results in loss of the zygote in utero and that cells bearing this mutation survive only in embryos mosaic for the lethal gene. Early somatic mutation would lead to a mosaic cell pattern of the distribution of cells containing the mutation. The severity of the disorder would depend on the proportion of mutant cells in various embryonic tissues. The description of somatic mutations in human endocrine tumors that convert the peptide chain of the G_s protein into a putative oncogene (referred to as a *gsp* mutation) raised the possibility of a similar defect in McCune-Albright syndrome that both affects a differentiated function such as a signaling pathway and mediates the regulation of proliferation. These hypotheses are now established, because mutations in the gene encoding the α-subunit of the stimulatory G protein for adenyl cyclase was identified in the tissues of children with the McCune-Albright syndrome.

The heterotrimeric guanine nucleotide–binding proteins (G proteins) are a subfamily within the large superfamily of GTP-binding proteins and serve to transduce signals from a large number of cell surface receptors with a common structural motif of seven-transmembrane–spanning domains to their intracellular effector molecules, including enzymes and ion channels; in essence, they couple serpentine cell surface receptors to effectors (Fig. 26.68). For G_s, the stimulatory G protein, the effector is adenyl cyclase, which is controlled by G_s and an inhibitory G protein,[836] G_i. The heterotrimer is composed of an α-subunit (39–45 kDa) that binds GTP, has intrinsic GTPase activity, and converts GTP to GDP; a β-subunit (35–36 kDa); and a smaller β-subunit (7–8 kDa). The latter two subunits are tightly but noncovalently associated with each other. Each of the subunits is encoded by a distinct gene. The G proteins function as conformational switches. The GDP-liganded α-subunit is bound to the βγ-subunits and is in an inactivated state. When the cell surface receptor is activated by its ligand or agonists, the GDP is catalytically released from the α-subunit, enabling GTP to bind. This leads to dissociation of the GTP-activated α-subunit from the bound βγ-subunits and activation of the effector, adenyl cyclase. When GTP is hydrolyzed by the intrinsic GTPase activity of $G_s\alpha$, the α-subunit and βγ-subunit reassociate, and the α-subunit is in the off or inactive conformation. The three-dimensional structure of the heterotrimeric G proteins has been determined.

Activating heterozygous mutations in the $G_s\alpha$-subunit that occurred as an early postzygotic event are described in the McCune-Albright syndrome. The somatic constitutive activating mutation, which leads to excess cAMP production and, in some tissues, cAMP-induced hyperplasia, has a mosaic pattern; the proportion of the hyperactive mutant compared with normal cells varies in different tissues, contributing, at least in part, to the varied clinical findings, the severity, the sporadic nature of the syndrome, and the discordant occurrence in monozygotic twins. A germline mutation is presumed to be lethal to the embryo. Two gain-of-function somatic missense mutations have been described in this disorder, both of which involve the arginine 201 residue of the α-subunit.[836] This is the site of covalent modification by cholera toxin: Either a cysteine or a histidine is substituted for arginine 201 (see Fig. 26.68). The arginine 201 residue is critical for α-subunit GTPase activity, and each of these two mutations decreases the GTPase activity of the $G_s\alpha$-subunit, leading to constitutive activation. These activating mutations have been found in all tissues affected by the syndrome, including bone lesions.



• **Fig. 26.68** The G protein guanosine triphosphatase (GTPase) cycle. The heterotrimeric guanine nucleotide-binding proteins (G proteins), which are composed of three subunits (α, β, γ), couple cell surface receptors consisting of a single serpentine polypeptide having seven-helic membrane-spanning domains with an effector. In this instance, adenylate cyclase (AC) catalyzes the transformation of adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP). The G protein stimulation subunit α (G_s) mediates the stimulation of cAMP generation. In the inactive, unstimulated state, the G protein is a heterotrimer, and guanosine diphosphate (GDP) is tightly bound to the α-subunit. When the cell surface receptor is activated by its cognate agonist, the receptor catalyzes the release of the tightly bound GDP, which enables GTP to bind to the α-subunit. The GTP-bound α-subunit (αGTP) dissociates from the tightly bound βγ dimer, and both play a role in the G protein activation of the effector, adenylate cyclase. The intrinsic GTPase activity of the α-subunit ends the stimulation of the effector by converting the bound αGTP to αGDP; as a consequence, the α-subunit again returns to its inactive state and reassociates with high affinity with the βγ subunit, yielding the α, β, γ heterotrimer. Disorders of signal transduction can arise from germ cell or somatic mutations at any of the five stages of the cycle. The gain-of-function, activating somatic mutations in the *GNAS1* gene that encodes the G G_sα-subunit and leads to McCune-Albright syndrome *(shown in the bracket),* involves the highly conserved arginine 201 residue. These mutations inhibit the intrinsic GTPase activity of the α-subunit and therefore the conversion of the bound GTP to GDP. The Ala366Ser mutation *(shown in the bracket)* was detected in two boys, both of whom had pseudohypothyroidism 1a (PHP1a) and testotoxicosis. The mutant protein was constitutively activated in the Leydig cells at the scrotal temperature (32–33°C), leading to testotoxicosis, but it was rapidly degraded at body temperature, 37°C, which led to PHP1a. (Modified from Spiegel AM. Mutations in G proteins and G protein-coupled receptors in endocrine disease. *J Clin Endocrinol Metab.* 1996;81:2434–2442.)

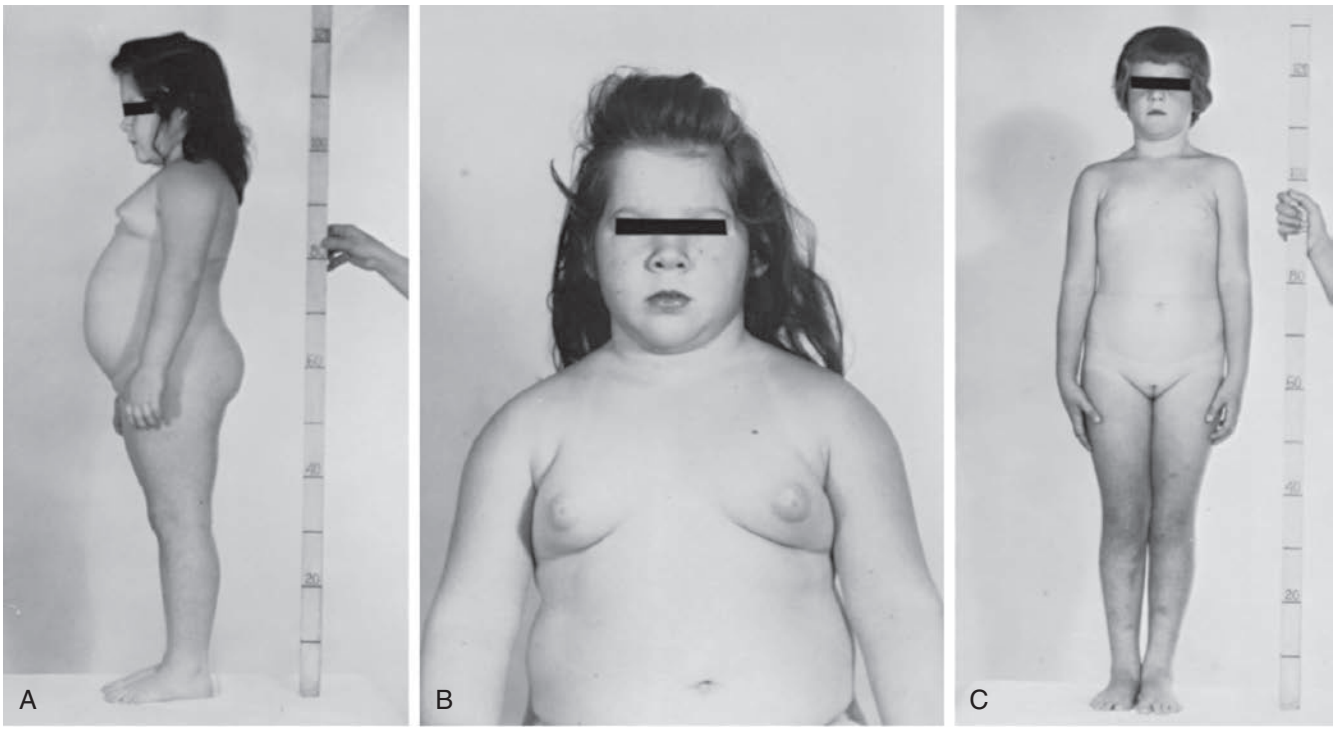
Adults with this syndrome have continued hyperfunction of the endocrine organs, but other comorbidities are reported. For example, a GNAS-positive breast cancer is reported in a woman, two GNAS-positive muscle myomas, platelet dysfunction in four, and various types of respiratory and cardiovascular complications were found in a series of 16 affected adults.[886] There are reports of fertility in adults with McCune-Albright syndrome.

Juvenile Hypothyroidism. Long-standing untreated primary hypothyroidism, usually a consequence of Hashimoto thyroiditis, is an uncommon cause of incomplete ISP in both girls and boys and occurs in association with impaired growth and delayed skeletal maturation.[323] If the concentration of plasma prolactin is elevated, galactorrhea may be demonstrable, more commonly in affected girls than boys (Figs. 26.69 and 26.70). Girls have breast development, enlarged labia minora, and estrogenic changes in the vaginal smear, usually without the appearance of pubic hair; some girls have irregular vaginal bleeding that could proceed to metrorrhagia, and solitary or multiple ovarian cysts may be demonstrable by pelvic sonography or on physical examination.[887] It is important to recognize the condition to avoid unnecessary surgery for the ovarian cysts or the accompanying pituitary enlargement, which would be a tragic mistake in view of the success of medical management. In about 80% of boys with juvenile hypothyroidism, the testes are enlarged because of an increase in the size of the seminiferous tubules, but signs of virilization and Leydig cell maturation are absent, and the plasma concentration of testosterone is prepubertal. Enlargement of the sella turcica and the pituitary gland in the face of hypersecretion of TSH (see Fig. 26.70) as well as associated galactorrhea has led to the misdiagnosis of a pituitary neoplasm. The hypothyroidism, incomplete sexual maturation, galactorrhea, and pituitary enlargement are reversed or corrected by levothyroxine therapy within a few months.

In 1960, Van Wyk and Grumbach[323] suggested that the syndrome resulted from hormonal overlap in negative feedback regulation with increased secretion of gonadotropins, prolactin, and TSH as a consequence of the chronic hypothyroidism. With the advent of radioimmunoassays for pituitary hormones, increased prolactin secretion was documented in children and adults with primary hypothyroidism and in affected girls with the syndrome. GH release is usually decreased, as in uncomplicated primary hypothyroidism.

However, the explanation for the sexual maturation remains uncertain. Pubertal development in primary hypothyroidism is usually delayed and is only rarely advanced for chronologic age. By the use of radioimmunoassays or other methods for FSH and LH in which the cross reaction with TSH is negligible, an increased (pubertal) concentration of plasma immunoreactive and bioactive FSH, but not LH, has been detected. Bioactive LH activity is also low. Increased FSH pulsatility, mainly at night, but not LH release was demonstrated in patients with the syndrome and in some children with primary hypothyroidism who did not exhibit premature sexual maturation. The increased FSH release[888] and the high FSH/LH ratio (in contrast to that observed in normal puberty) seem to account for the increased ovarian estrogen secretion in girls and for the enlarged testes without signs of virilization in affected boys; the suggestion is that FSH-induced Sertoli cell proliferation is an important determinant of mature testis size. Prolactin is postulated to suppress LH in this condition.

Pulsatile TSH release is increased at night, and administration of TRH appears to increase FSH release in normal children (but not in adults). Moreover, the FSH response to TRH, but not GnRH, is augmented in primary hypothyroidism, and this response can occur in gonadotropin-secreting pituitary adenomas. It is likely that the incomplete sexual precocity and the increased prolactin secretion and galactorrhea are a consequence of the increased release of TRH, the increased sensitivity of the mammotrophs and gonadotroph to TRH, or both.[323] This mechanism, which has gained support, would explain the relatively rapid and complete reversal of the syndrome by levothyroxine treatment. Human recombinant TSH at a dose about 1000-fold greater than that of human FSH evoked a dose-dependent cAMP response in COS7 cells transfected with the



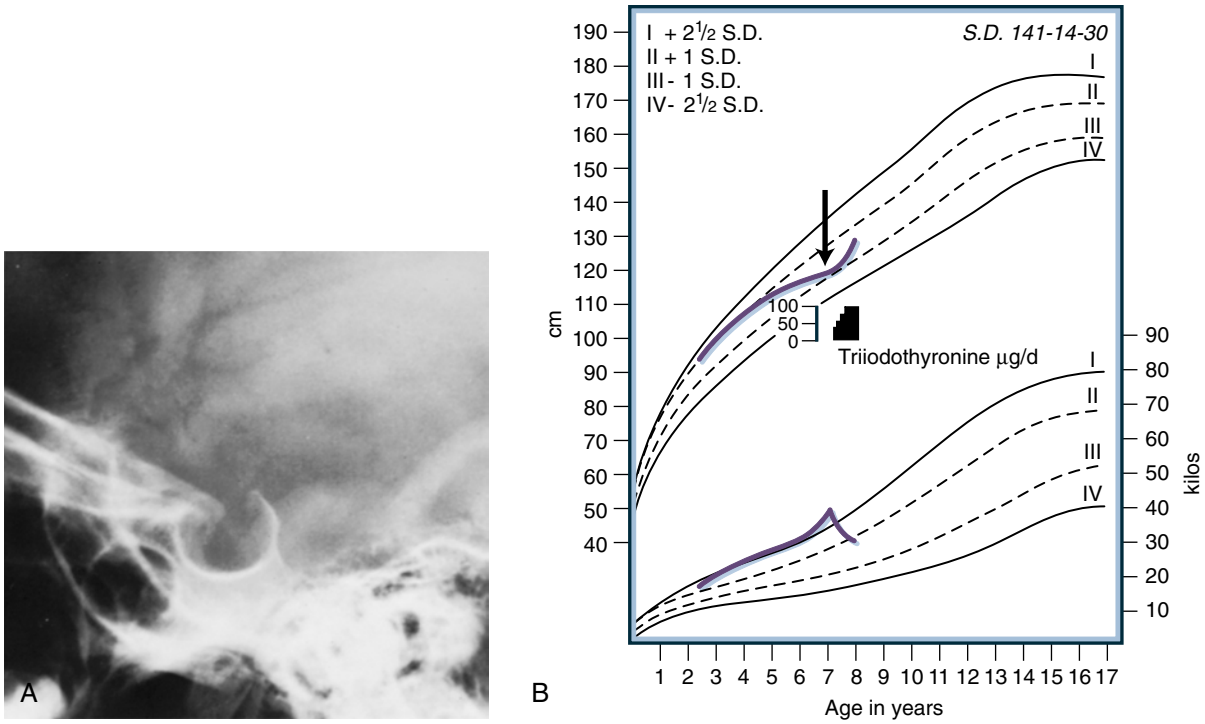
• **Fig. 26.69** (A, B) Severe, chronic hypothyroidism of Hashimoto thyroiditis in a girl aged 7 years and 1 month with sexual precocity (without pubic or axillary hair), episodic vaginal bleeding, and galactorrhea. She had symptoms of hypothyroidism and a sharply decreased rate of growth over the previous 2 years (height, −1 SD [standard deviation]; bone age, 5 years and 3 months). Breast development was Tanner stage 3, the labia minora were enlarged, and the vaginal mucosa was dull pink, thickened, and rugated, with evidence of an estrogenic effect. No acne, seborrhea, or hirsutism was present. The uterus was of adolescent size, and the endometrial mucosa was in a proliferative phase. Urinary gonadotropins were barely detectable by bioassay. (C) Striking change in appearance after 8 months of thyroid hormone treatment. She had grown 7 cm in height and lost 8.1 kg in weight. The breasts had decreased in size, galactorrhea was no longer demonstrable, the labia minora had regressed, and the vaginal mucosa was pink and glistening (no estrogen effect). Ten weeks after the initiation of thyroid hormone replacement therapy, she developed a right slipped capital femoral epiphysis that was repaired surgically; recovery was uneventful.

human FSH receptor, which suggests another possible but less likely mechanism for the FSH-dependent (or FSH-like–dependent) but GnRH-independent sexual precocity.[889] A direct effect of severe hypothyroidism on the prepubertal testis that leads to overproliferation of Sertoli cells also has been advanced as an explication of the macroorchidism.

The syndrome is rare but a few cases combine the Van Wyk-Grumbach syndrome with the Kocher-Debre-Semelaigne syndrome, which manifests as lower extremity muscle pseudohypertrophy, elevation of serum creatinine and creatinine kinase concentrations, delayed contraction and relaxation of reflexes, and myxedema; both manifestations of hypothyroidism can be treated with appropriate doses of thyroxine.[890,891]

Iatrogenic Sexual Precocity and Endocrine Disruptors. Prepubertal children are remarkably sensitive to exogenous gonadal steroids and may show signs of sexual maturation resulting from overlooked sources of androgens or estrogens, such as ingested or absorbed tonics, lotions, or hair creams or hair straighteners that contain or are inadvertently contaminated with an estrogen.[892] Dermal exposure to estrogen may add up to more than 300 μg, far in excess of a therapeutic dose and possibly greater in infants and children exposed to estrogen dermal gel. Compounds containing tea tree and lavender oils caused gynecomastia in three prepuberal boys and demonstrated estrogenic activity in vitro.[893,894] A short course of application of estrogen cream is used to treat labial adhesions, but long courses may lead to breast development or even withdrawal bleeding. In addition to breast development, pigmentation of the areolae and the linea alba and the appearance of pubic hair may be seen in children exposed to dermal estrogen. Children who touch the skin or the towels of men using androgen gel therapy may themselves develop virilization.[895] The administration of hCG to boys with undescended testes may induce secretion of testosterone sufficient to cause incomplete sexual precocity.

FDA guidelines define a limit of not more than 1% of normal daily estrogen production in prepubertal children as a safe intake of estrogen[835]; this is equivalent to 0.43 ng/day for boys and 3.24 ng/day for girls, based on data from extremely sensitive estrogen assays, but food is still a suspected source of endocrine disruptors.[835,892] Epidemics of gynecomastia in boys and thelarche in girls among schoolchildren in Italy were suspected to be caused by contaminated meat. During a 10-year period, more than 600 cases of gynecomastia in boys and premature thelarche or incomplete sexual precocity in girls were discovered in Puerto Rico; this is the highest prevalence reported in the world, about 10 to 15 times higher than that measured in a survey in Olmsted, Minnesota.[896,897] Maternal ovarian cysts were demonstrated in two-thirds of affected Puerto Rican girls. The clandestine use of



• **Fig. 26.70** (A) Radiograph of the skull of a patient with hypothyroidism shows an enlarged pituitary fossa in the lateral view. The dorsum sellae was thin and demineralized, and the floor had a double contour line. The area of the sella turcica was 150 mm^2. Pneumoencephalography showed a suprasellar mass impinging on the cisterna chiasmatica. After thyroid hormone treatment for 8 months, the volume of the sella had decreased 30% to 100 mm^2, the dorsum sellae had remineralized, and the double floor was no longer evident. (B) Growth curve illustrates the decrease in growth rate despite sexual precocity and the catch-up growth induced by thyroid hormone therapy. (From Van Wyk JJ, Grumbach MM. Syndrome of precocious menstruation and galactorrhea in juvenile hypothyroidism: an example of hormonal overlap in pituitary feedback. *J Pediatr.* 1960;57:416–435.)

estrogen preparations in animals to stimulate weight gain, leading to ingestion of estrogen-contaminated meat from these animals, was raised as a possible cause, but this was neither confirmed nor excluded by selected analyses of meat, poultry, and milk in Puerto Rico by the US Department of Agriculture.

There are rising concerns that endocrine-disrupting chemicals (EDCs), defined as "an exogenous substance that causes adverse health effects in an intact organism, or its progeny, secondary to changes in endocrine function" exert many effects on growth and development of children, including pubertal development.[852,898] Far more conclusive evidence of an adverse effect of EDCs comes from animal, rather than human, studies, and some of the data on human beings derive from industrial accidents and very high-level exposure rather than the lower level exposures most individuals experience, so EDCs must be studied in more detail in human beings. Method of ascertainment, laboratory methods, activity and half-life of various molecules of interest, and the frequent difficulties in drawing conclusions from associations rather than controlled studies present complexities in interpreting data.

Girls who were breastfed or exposed during intrauterine life to polybrominated biphenyls (PBBs) after an accidental exposure of their mothers in Michigan experienced early menarche (by about 1 year of age) and early appearance of pubic hair but not breast development, compared with girls who were not exposed or breastfed.

The NHANES 2003-2004 data demonstrate a slightly lower age at menarche with higher serum polybrominated diphenyl ether (PBDE, a flame retardant) concentrations.[899,900] On the contrary, a recent longitudinal study in Hispanic American children demonstrated a later age of menarche while boys had an earlier onset of pubic hair development with in utero exposure to PBDE.[901]

Exposure to polychlorinated biphenyls (PCBs) in inner-city girls with reduced BMI values reportedly delayed thelarche.[63] There was a 9.56 increase in relative risk for precocious puberty treated by GnRH agonist in a localized area in Italy, compared with surrounding areas, suggesting the presence of an endocrine disruptor in the area.[902] Recent longitudinal studies demonstrate no effect on secondary sexual development in girls with a slight decrease in the age of puberty in boys by elevated levels of phthalate excretion in urine.[900] A Chinese study found elevated levels of LH which corresponded to decreased levels of testosterone in children with constitutional delay in puberty who had elevated phthalates.[903]

Widespread exposure to 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), an extremely potent antiestrogenic xenobiotic, in Italy revealed that girls younger than 8 years of age at the time of exposure, who presumably had the highest dose per BMI compared with older girls, showed a tendency for a decrease in age at menarche, suggesting that age of exposure to environmental endocrine disruptors modulates their effects.[904] Blood concentrations of the phenols, 2,5-dichlorophenol and 2,4-dichlorophenol, were inversely proportional to the age of menarche in 440 girls included in the NHANES for 2003 to 2008.[904] Follow-up of adolescents

who were exposed to di-(2-ethylhexyl)-phthalate (DEHP), a component of polyvinyl chloride (PVC) that is used in plastic tubing and medical devices, when they underwent extracorporeal membrane oxygenation (ECMO) as neonates, demonstrated no effects on pubertal development despite findings of disruption of development in animals exposed to this substance, demonstrating difficulties in translating animal data to human beings.[905]

Increased lead levels in Mohawk girls living near the border of New York and Canada delayed the age of menarche, whereas increased levels of PCB promoted it[906]; surprisingly, variations in BMI exerted no effect of these toxic substances, which are concentrated in adipose tissue. In the NHANES III survey, a serum lead level of 0.7 to 2.0 μg/dL delayed menarche and pubic hair development, and African Americans exposed to 3 μg/dL also experienced delay in breast development.[908] A long-term study of puberty in Chapaevsk, Russia, an area highly contaminated with industrial waste, demonstrated 43% reduced odds of entering stage 2 genitalia among boys age 8 to 9 years with serum lead levels equal to or greater than 5 μg/dL.[909]

There is a high frequency of reproductive problems among adult Danish men, including impaired semen quality, testicular cancer, and increased rate of infantile testicular cancer; these disorders occur in a pattern that is attributed to environmental disruptors, described in the testicular dysgenesis syndrome.[669] A higher rate of hypospadias in Danish newborns and smaller testes with lower serum inhibin B, compared with Finnish infants, suggested that environmental agents played a role. Phthalates were found in the breast milk of mothers from both countries, and although there was no relationship to the finding of hypospadias, there was an indication of altered reproductive hormones in the boys in a pattern suggesting effects on Leydig cells. There may be a genetic component to susceptibility to the TDS based upon GWAS analysis, indicating a gene X environment basis for the disorder.[848]

Insulin-like peptide 3 (INSL3) is a testicular product associated with testicular descent in a chronologic pattern; amnionic values of INSL3 during the development of normal genitalia are affected by exposure to phthalates, which is postulated to offer a potential mechanism of the etiology of TDS, although this is not proven to date.[910,911]

Longitudinal observation of girls in Copenhagen, Denmark, using physical examination of breast tissue, showed a significant decline in the age of Tanner stage 2 breast development (estimated mean age, 9.86 years in 2006–2008 vs 10.88 years in 1991) and the age at menarche (13.13 vs 13.42 years, respectively); there was no change in serum gonadotropins, but the serum estradiol concentration was decreased in 2006.[54] Changes in BMI did not occur in this study between the cohorts, leaving open the possibility of endocrine-disrupting chemicals as an explanation.

Boys exposed to PCBs and polychlorinated dibenzofurans (PCDFs) in utero from contamination of rice ingested by their mothers had decreased testosterone and defects in postpubertal sperm production in a preliminary study, as well as increased estrogen compared with control subjects, although there was no difference on physical examination or in age at onset of puberty.[912] Boys exposed to DDT in utero did not demonstrate any abnormalities in puberty in a study from Philadelphia, Pennsylvania.[854]

Proximity to traffic in a longitudinal cohort study of 437 girls found an earlier onset of signs of puberty of 2 to 9 months compared to unexposed girls. This suggests exposure to air pollutants affects the onset of puberty, although no pollutants were measured in this study.[913] The complexities of the study of endocrine disrupters on pubertal timing are complicated by type, amount, developmental age at exposure, and other factors that are difficult to tease apart.[914] In the United States, chemicals can enter the environment before their safety is proved, leading to an ever-expanding list of potential EDCs without data to prove their effects. Environmental disrupters have a wide range of deleterious effects upon neurodevelopment as well as the endocrine system.[915]

Well-designed longitudinal studies are needed in this area.[910]

Diagnosis of Sexual Precocity

As with delayed puberty the majority of patients referred for precocious puberty will prove to have variations of normal development or to be inappropriately referred due to a misinterpretation of the normal ages of puberty by the referring physicians. However, precocious puberty can certainly be the outward sign of a serious condition. Thus the separation of patients with self-limited benign disorders, such as premature adrenarche, premature thelarche, or normal but early puberty, from those with serious or even potentially fatal disorders is the first step in evaluation (Figs. 26.71, 26.72, and 26.73; Table 26.41). The history may reveal symptoms suggesting perinatal CNS abnormalities or injuries, previous infections, adventitious ingestion of or exposure to gonadal steroids, or the presence of similar conditions in family members. Previous measurements should be plotted on a growth chart to determine height velocity and the age at onset of any increase in the rate of growth.

Important aspects of the physical examination include description of the secondary sexual development according to Tanner (sexual maturation) stages; measurement of the penis (length gently stretched and width) and the testes in boys (greatest diameter without the epididymis or volume by comparison with an orchidometer) and of the breast tissue in girls (areolar and glandular diameters); and examination for comedones and acne, oily skin, facial and body hair, pubic and axillary hair development, axillary apocrine gland odor, muscular development, and galactorrhea. A careful examination of the external genitalia should be done with a nonrelated chaperone present. A thorough neurologic examination is indicated, with emphasis on assessment of the visual fields and optic discs in a search for signs of increased intracranial pressure; evaluation for skin lesions associated with the McCune-Albright syndrome or neurofibromatosis; and examination for abdominal, gonadal, or adnexal masses and for coexisting endocrine disease. Bone age is determined in all cases, although it is an imperfect measure and the reader must be experienced. Dental development can be determined as a rough index of pubertal development[916] but is rarely invoked clinically except in forensic cases.[917]

Ultrasonography of the ovary and uterus is exceedingly useful in the evaluation of affected girls, because standards are available for shape and volume of the uterus and the ovaries.[918] The largest measurements of uterine size by sonography in infants and children are found at puberty and in the neonatal period. The upper limit of uterine length in the prepubertal state is 3.5 cm. A uterine volume of greater than 1.8 mL is specific for the onset of normal puberty, but increased ovarian volume is less specific. Patients with premature thelarche were indistinguishable from age-matched control subjects when this sonographic standard was used.[128] The presence of microcysts and macrocysts of the ovary also can be detected on ultrasound examination. Cysts may be found in the ovaries in patients with CPP or

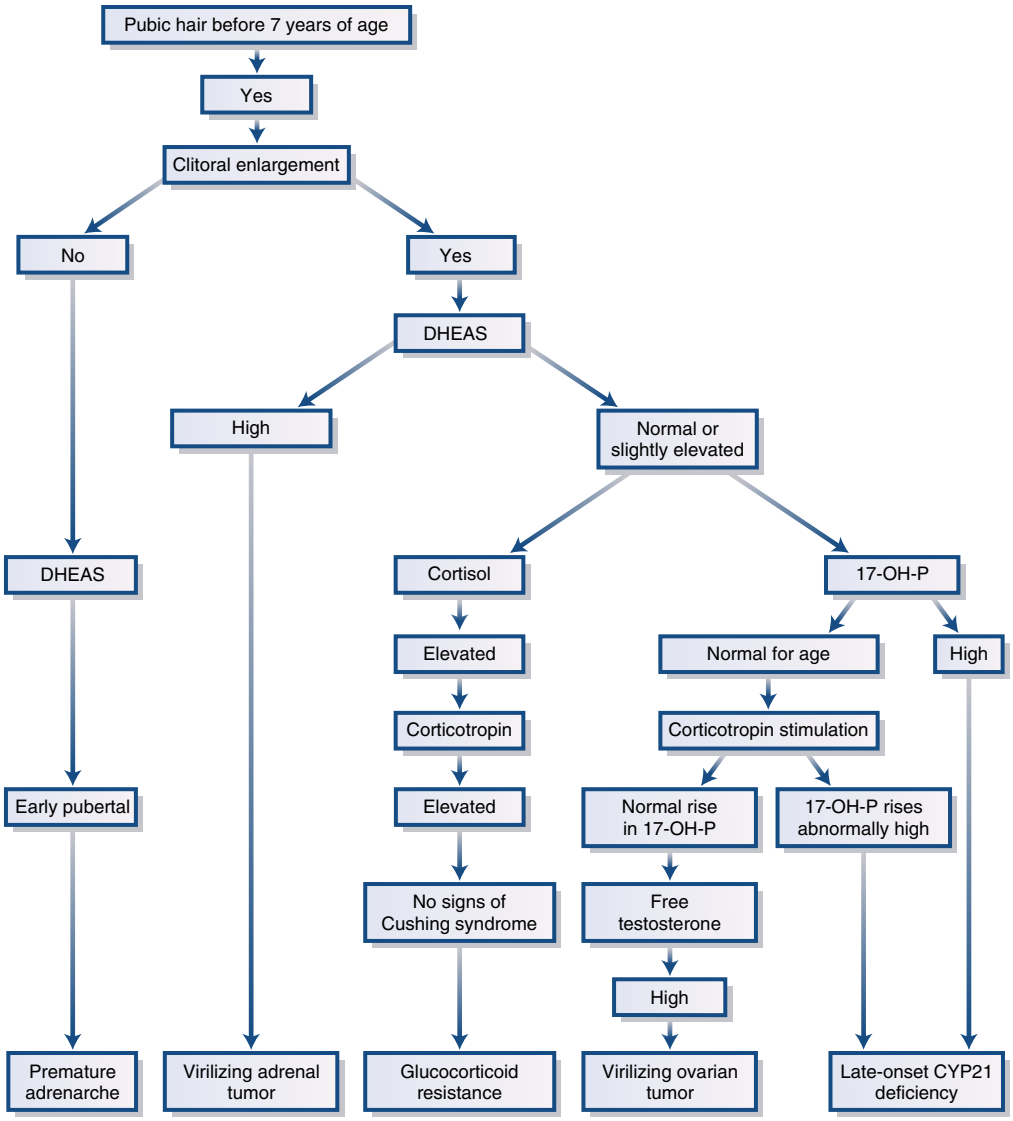
GnRH-independent ISP; they usually are smaller than 9 mm in the former and larger than 9 mm in the latter[919] condition. Ovarian volume is reportedly the best indicator of precocious puberty, and uterine length was best for the differentiation of premature thelarche from premature puberty.[920] However, in the earliest stages of pubertal development ultrasonography of the pelvis may not differentiate the patient from the prepubertal state, although gonadotropin values will do so.[921] The presence of an endometrial stripe was indicative of precocious puberty.[128] Ultrasonography of the breast is reported as a method of determining rapidly progressive versus slowly progressive or transient precocious puberty; accuracy is increased when breast ultrasound findings are added to those of uterine ultrasound and the other factors discussed previously.[922]

CPP in males usually begins with enlargement of the testes, followed by other signs of secondary sexual maturation. A Leydig cell tumor usually causes asymmetric enlargement of the testes, whereas an extragonadal hCG-secreting tumor is associated with less marked testicular enlargement than occurs at the same stage of masculinization in CPP. Testicular adrenal rest tissues may enlarge in boys with CAH and may be bilateral, although they are unlikely to closely mimic normal pubertal testicular development. An elevated hCG level with prepubertal gonadotropin values or GnRH test indicates an ectopic, autonomous, gonadotropin-secreting tumor. If this tumor is in the CNS, abnormalities will likely be present on MRI or CT brain scans. Enlargement of the liver or a mediastinal, retroperitoneal mass in boys with sexual precocity suggests an hCG-producing hepatic or germ cell tumor; the possibility of Klinefelter syndrome needs to be considered in the latter case.

It is essential that laboratory tests for sex steroids and gonadotropin be carried out by appropriate methods in the experienced laboratories. Simply ordering LH or FSH levels in a standard laboratory will usually lead to a determination of whether there are high levels with gonadal failure such as menopause or normal levels for adults, but rarely can such an assay determine subtle changes that are characteristic of childhood and adolescence. A highly sensitive third-generation assay with pediatric standards

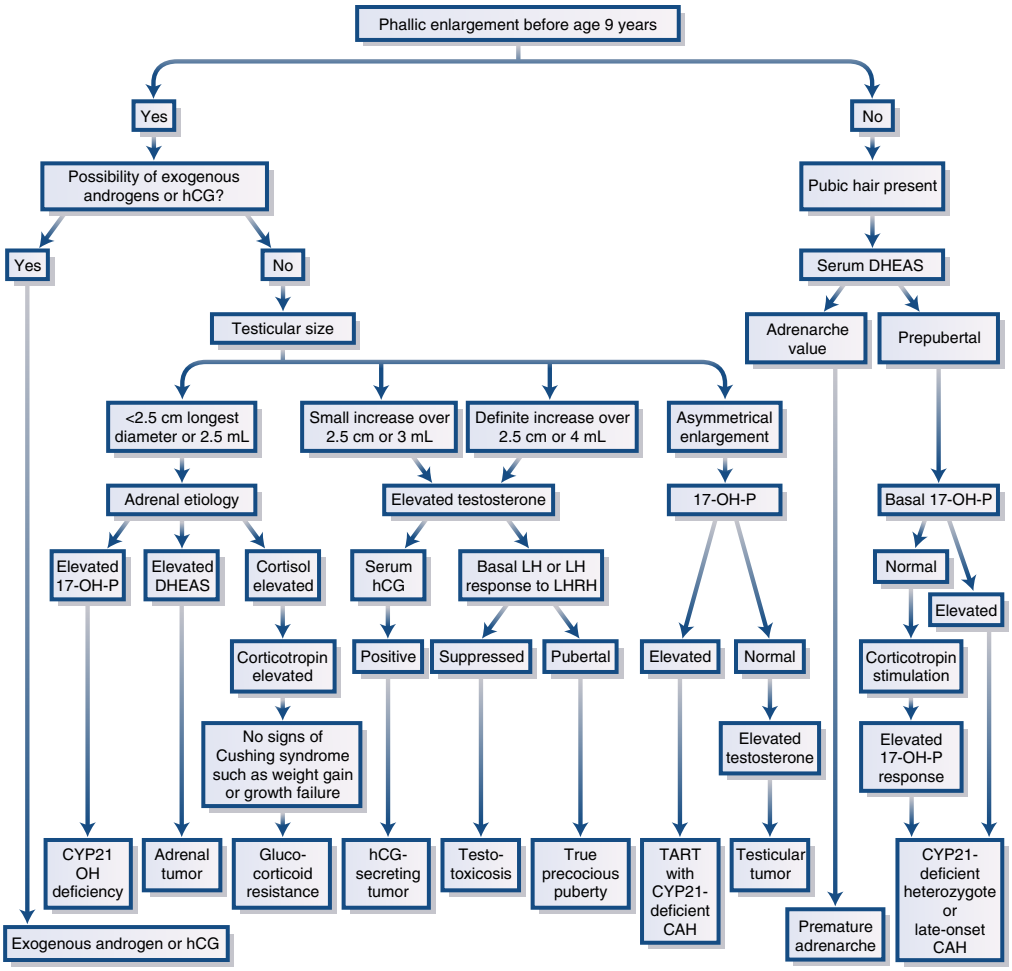


• **Fig. 26.72** Flow chart for the evaluation of pubic hair in normal phenotypic girls before 7 years. *DHEAS,* dehydroepiandrosterone sulfate; *17-OH-P,* 17-hydroxyprogesterone.

must be ordered. Further, standard testosterone assays can differentiate between a normal male and one with gonadal failure but cannot determine the low levels characteristic of the early stages of puberty. For children and adolescents (and indeed for women) an HPLC-MS/MS method with pediatric standards is necessary; the same type of assay must be used for the determination of estradiol levels in girls.[266]

Measurements of basal plasma gonadotropin concentrations and the LH response to administration of GnRH (presently not available) or GnRH agonist or the amplitude and frequency of LH pulses, especially at night, using third-generation assays with pediatric standards, as well as measurements of the plasma concentration of testosterone in boys or of estradiol in girls using LC/MS-MS assays, are of primary importance in diagnosis. Patients with a basal LH level 0.3 IU/L or higher had subsequent pubertal progression, whereas 39 of 41 patients with a basal LH 0.2 IU/L or lower did not progress, resulting in 100% specificity (95% CI 92–100%) and 90.5% sensitivity (69.6–98.8%) in one report.[261] Girls early in the course of CPP may have elevation of estradiol (this is not always noted, however) associated with increasing LH levels but not necessarily an increase in the concentration of FSH. Boys will have rising values of testosterone as puberty commences. Pubertal concentrations of LH and FSH, a pubertal mode of pulsatile LH secretion (initially during sleep), or pubertal LH response to GnRH or GnRH agonist confirms the diagnosis of CPP (and in boys differentiates CPP from familial testotoxicosis). Determination of T_4 concentration (usually free T_4) is indicated when hypothyroidism as a cause of sexual precocity is suspected.

A CNS tumor must be considered as a potential cause of premature activation of the hypothalamic GnRH pulse generator, especially in boys. The evaluation for a CNS tumor as a cause of CPP is similar to the investigation of an hCG-secreting tumor of the CNS.[923] Although CT scanning is a well-established procedure for determining the presence of a CNS abnormality, MRI with contrast is more sensitive for the detection of small tumors in the hypothalamus, such as a hamartoma of the tuber cinereum (see Fig. 26.55). The use of contrast adds to diagnostic certainty and is recommended for MRI of the CNS. All boys with CPP



• **Fig. 26.73** Flow chart for diagnosing sexual precocity in a phenotypic male. *CAH,* congenital adrenal hyperplasia; *DHEAS,* dehydroepiandrosterone sulfate; *hCG,* human chorionic gonadotropin; *LH,* lutein-izing hormone; *LHRH,* LH-releasing hormone; *17-OH-P,* 17-hydroxyprogesterone; *TART,* testicular adrenal rest tissue.

should have CNS MRI evaluation, but girls do not always receive the same recommendation because a CNS tumor is less likely in girls than in boys to be the cause of CPP. However, studies using MRI or CT brain scans indicate that the hypothalamic hamartoma is more prevalent in both boys and girls with so-called idiopathic CPP than was previously suspected. An unselected group of girls with precocious puberty and no other symptoms underwent CNS MRI; 15% were found to have intracranial trauma, and the investigators found no clinical difference between those girls and the other 85% of girls studied, supporting the use of CNS MRI for girls with precocious puberty.[924]

The height of the pituitary gland on MRI correlates with advancing age and with pubertal development[925]; patients with CPP had pituitary heights exceeding 6 mm on average, whereas those with precocious thelarche had lower heights. The shape of the pituitary gland is also of importance: A convex appearance rather than a flat top is associated with CPP of any cause.[749] Physiologic enlargement of the pituitary gland characteristic of puberty is the source of many needless neurosurgery referrals.[926] The size and shape of the pituitary gland do not decrease with successful GnRH therapy.

T1-weighted images indicate a convex upper border of the pituitary gland in both normal patients and those with CPP, indicating the similarity in the physiologic changes in both pubertal conditions. Pituitary gland hyperplasia (height >1 cm) is a rare finding reported in CPP. The empty sella syndrome is less frequently observed in patients with CPP than in patients with pituitary hypofunction. Empty sella is found in 10% of children who are imaged for suspected hypothalamic-pituitary disorders, including hypogonadotropic hypogonadism.[927]

The premature appearance of pubic hair, phallic enlargement, and other signs of virilization in a male without enlargement of the testes or the liver suggests the diagnosis of virilizing CAH, virilizing adrenal tumor, or, more rarely, Cushing syndrome. Measurement of plasma 17-hydroxyprogesterone and DHEAS concentrations and their suppressibility with glucocorticoids will distinguish 21OH-deficient CAH from a virilizing adrenal tumor. If growth rate is suppressed, the possibility of primary hypothyroidism or Cushing syndrome is raised; elevated plasma concentrations of cortisol, urinary free cortisol, 17-hydroxycorticosteroid, or salivary cortisol after suppression with dexamethasone confirm the latter diagnosis. The appearance in a girl of pubic hair and other signs of virilization, such as clitoral enlargement, acne, deepening voice, muscular development, or growth spurt, is caused by virilizing CAH, virilizing adrenal tumor, or virilizing ovarian tumor. Cushing syndrome caused by an adrenocortical

TABLE 26.41 Differential Diagnosis of Sexual Precocity

Disorder	Plasma Gonadotropins	LH Response to GnRHa	Serum Sex Steroid Concentration	Gonadal Size	Miscellaneous
Gonadotropin Dependent					
True precocious puberty	Prominent LH pulses (premature reactivation of GnRH pulse generator)	Pubertal LH response initially during sleep	Pubertal values of testosterone or estradiol	Normal pubertal testicular enlargement or ovarian and uterine enlargement	MRI of brain to rule out CNS tumor or other abnormality; skeletal survey for McCune-Albright syndrome (by US)
Incomplete Sexual Precocity (Pituitary Gonadotropin-Independent)					
Males					
Chorionic gonadotropin-secreting tumor in males	High hCG, low LH	Prepubertal LH response	Pubertal value of testosterone	Slight to moderate uniform enlargement of testes	Hepatomegaly suggests hepatoblastoma; CT scan of brain if chorionic gonadotropin-secreting CNS tumor suspected
Leydig cell tumor in males	Suppressed	No LH response	Very high testosterone	Irregular, asymmetric enlargement of testes	
Familial testotoxicosis	Suppressed	No LH response	Pubertal values of testosterone	Testes symmetric and >2.5 cm but smaller than expected for pubertal development; spermatogenesis occurs	Familial; probably sex-limited, autosomal dominant trait
Virilizing congenital adrenal hyperplasia	Prepubertal	Prepubertal LH response	Elevated 17-OHP in CYP21 deficiency or elevated 11-deoxycortisol in CYP11B1 deficiency	Testes prepubertal	Autosomal recessive, may be congenital or late-onset form, may have salt loss in CYP21 deficiency or hypertension in CYP11B1 deficiency
Virilizing adrenal tumor	Prepubertal	Prepubertal LH response	High DHEAS and androstenedione values	Testes prepubertal	CT, MRI, or US of abdomen
Premature adrenarche	Prepubertal	Prepubertal LH response	Prepubertal testosterone, DHEAS, or urinary 17-ketosteroid values appropriate for pubic hair stage 2	Testes prepubertal	Onset usually after 6 yr of age; more frequent in CNS-injured children
Females					
Granulosa cell tumor (follicular cysts may present similarly)	Suppressed	Prepubertal LH response	Very high estradiol	Ovarian enlargement on physical examination, CT, or US	Tumor often palpable on physical examination
Follicular cyst	Suppressed	Prepubertal LH response	Prepubertal to very high estradiol	Ovarian enlargement on physical examination, CT, or US	Single or recurrent episodes of menses and/or breast development; exclude McCune-Albright syndrome
Feminizing adrenal tumor	Suppressed	Prepubertal LH response	High estradiol and DHEAS values	Ovaries prepubertal	Unilateral adrenal mass
Premature thelarche	Prepubertal	Prepubertal LH, pubertal	Prepubertal or early estradiol response	Ovaries prepubertal	Onset usually before 3 yr of age

TABLE 26.41 Differential Diagnosis of Sexual Precocity—cont'd

Disorder	Plasma Gonadotropins	LH Response to GnRHa	Serum Sex Steroid Concentration	Gonadal Size	Miscellaneous
Premature adrenarche	Prepubertal	Prepubertal LH response	Prepubertal estradiol; DHEAS or urinary 17-ketosteroid values appropriate for pubic hair stage 2	Ovaries prepubertal	Onset usually after 6 yr of age; more frequent in brain-injured children
Late-onset virilizing congenital adrenal hyperplasia	Prepubertal	Prepubertal LH response	Elevated 17-OHP in basal or corticotropin-stimulated state	Ovaries prepubertal	Autosomal recessive
In Both Sexes					
McCune-Albright syndrome	Suppressed	Suppressed	Sex steroid pubertal or higher	Ovarian (on US); slight testicular enlargement	Skeletal survey for polyostotic fibrous dysplasia and skin examination for café au lait spots
Primary hypothyroidism	LH prepubertal; FSH may be slightly elevated	Prepubertal FSH may be increased	Estradiol may be pubertal	Testicular enlargement; ovaries cystic	TSH and prolactin elevated; T_4 low

carcinoma can result in virilization associated with growth failure, and a virilizing adrenocortical carcinoma can manifest with so much androgen effect that the signs of Cushing syndrome are not apparent, as rapid growth and virilization are first noted; estradiol may be secreted by these tumors as well as androgens. Virilizing ovarian tumors may be detected by pelvic ultrasonography.

The appearance of pubic hair without other signs of puberty in boys or girls is usually a result of premature adrenarche but may alternatively be the first sign of sexual precocity or of adrenal virilism from other causes.

In a girl, breast development associated with dulling and thickening of the vaginal mucosa leading to a more pink than red appearance and enlargement of the labia minora indicate significant estrogen secretion or iatrogenic exposure to estrogen. The differential diagnosis includes CPP, an estrogen-secreting neoplasm, aromatase excess, and a cyst of the ovary. If the plasma concentrations of gonadotropins are in the pubertal range, if LH pulses of pubertal amplitude are detected, or if a pubertal LH response to GnRH or GnRH agonist is elicited, CPP is present. In one report, a child had pubertal-level serum LH due to heterophile antibodies that interfered with the LH assay and fallaciously elevated the values in the basal and stimulated state; after addition of antimouse antibody, LH values decreased.[928] As always, clinical observation should be congruent with laboratory findings, and the assays should be highly sensitive and associated with valid pediatric standards. Estradiol concentrations in girls early in normal puberty or CPP are in the prepubertal range for much of the day, and a single determination may be inadequate to reflect ovarian function.[160]

If the concentration of plasma estradiol is elevated but gonadotropin levels are low, an estrogen-secreting cyst or neoplasm is present or exogenous estrogens are the cause. Ovarian tumors of moderate size can be palpated by bimanual examination. Advances in pelvic sonography allow the delineation of ovarian cysts or tumors and the determination of uterine size and the size of the endometrial stripe.[128] An estrogen-secreting neoplasm of the ovary is usually accompanied by high estradiol concentrations, but some ovarian cysts are associated with concentrations of estradiol as high as those in granulosa cell tumors; the differential diagnosis between these cysts and ovarian neoplasms rarely requires exploratory laparotomy or laparoscopy and usually can be resolved by pelvic sonography and the use of tumor markers. Breast development in the absence of other estrogen effects is almost always a result of premature thelarche.

Contrasexual Precocity: Feminization in Boys and Virilization in Girls

Boys

Feminization in a boy before the age of puberty is rare. Rarely, an estrogen-secreting adrenal adenoma or a chorionepithelioma causes gynecomastia. Gynecomastia has been reported in a 1-year-old boy with 11β-hydroxylase deficiency and in boys with late-onset CAH.[929]

Aromatase Excess Syndrome. Gynecomastia in prepubertal boys can be caused by increased extraglandular aromatization of C19 steroids of adrenal origin, such as androstenedione, and subsequent increased extraglandular estrogen production in sporadic or familial cases. The autosomal dominant form leads to excess estrogen synthesis from C19 precursors due to aromatase overexpression, especially in fat and skin; it is a consequence of gain-of-function mutations of *CYP19*, the gene that encodes aromatase, resulting from a chromosome arrangement that gives rise to a cryptic promoter.[930] An autosomal dominant pattern of prepubertal gynecomastia and adult hypogonadism but not short stature in the presence of elevated serum estrone (with little or no elevation of estradiol) has been reported; the mutations in the *CYP19* gene in these patients appeared to be different from those in the families described earlier with gain-of-function mutations resulting from gene inversions.[931] In a Turkish kindred, there was a potential rearrangement between *CYP19* and *TRPM7* genes on chromosome 15q21.2 as a cause of aromatase excess syndrome. Aromatase excess syndrome is caused by duplications involving *CYP19A1* and simple and complex rearrangements generated by

both recombination-mediated and replication-mediated mechanisms, independent of the known rearrangement-inducing DNA features or late-replication timing.[932]

Feminizing Testicular Tumors. Feminizing testicular tumors may cause gynecomastia in boys younger than 6 years of age who have the Peutz-Jeghers syndrome.[860,933] Aromatase is absent or is present in barely detectable amounts in prepubertal testes, but maximal amounts appear in late puberty. In normal testes, aromatase is predominantly present in the Leydig cells, but in testicular tumors of Sertoli cells or Leydig cells (e.g., associated with the Peutz-Jeghers syndrome), the Sertoli cells of the tumor express aromatase. Both testes may be enlarged, and the histologic examination indicates sex cord or Sertoli cell tumors that form annular tubules and often have areas of calcification; increased estradiol secretion is noted in the basal state, and a further rise occurs after hCG administration. Otherwise, feminizing Sertoli cell tumors are very rare in boys.[934] Sonography or MRI of the testes may be useful in making the diagnosis.

In one series, 5% of 581 boys referred for evaluation of gynecomastia were prepubertal at diagnosis (mean age, 9 years), and in 93% no underlying cause was identified.[935] Spontaneous resolution was recorded in 6 boys, no change was found in 15, and further breast enlargement was found in 6. Prepubertal gynecomastia can also be caused by neurofibromatosis.

Girls

Adrenal Causes of Virilization. CAH resulting from 21-hydroxylase or 11β-hydroxylase deficiency or from androgen-producing tumors of the adrenal can cause virilization (see earlier discussion of their occurrence in males). Nonclassic or late-onset forms of CAH do not demonstrate ambiguous genitalia, but there is evidence of androgen effect in prepuberty or the teenage years. The etiology is usually 21OH deficiency. 3βHSD/$\Delta^{4,5}$-isomerase deficiency is a rare type of CAH characterized by elevated levels of Δ^5-17P, DHEA, and DHEAS, as well as decreased secretion of aldosterone and cortisol in the severe form. Severely affected patients have mineralocorticoid and glucocorticoid deficiencies and may die in infancy. Excess adrenal androgens lead to virilization in utero and to ambiguous external genitalia, including clitoral enlargement in females with continued virilization after birth. Milder forms of this disorder can cause hirsutism in women. Women with a 46,XY phenotype and incomplete forms of androgen resistance syndrome or 17βHSD3 deficiency may have virilization as well as breast development at the time of expected puberty. Aromatase deficiency due to mutations in the *CYP19* gene, which encodes aromatase, is associated with intrauterine masculinization of the external genitalia in affected 46,XX individuals and with progressive virilization, lack of female secondary sex characteristics, multicystic ovaries at the age of puberty, tall stature, and osteopenia.[272,274,301,303]

Cushing syndrome resulting from adrenal carcinoma usually manifests as growth failure with or without virilization, obesity, and moon facies; striae may not appear until months to years later.

Syndrome of Glucocorticoid Resistance. The syndrome of glucocorticoid resistance has variable manifestations. Some patients demonstrate hyperandrogenic signs such as acne, hirsutism, male-type baldness, menstrual irregularities, and oligoanovulation and infertility.[936] Dexamethasone decreases the excessive adrenal androgen secretion, virilization, and advancing bone age found in general glucocorticoid resistance.

Virilizing Ovarian Tumors. Arrhenoblastoma, also called Sertoli tumor of the ovary, is the most common virilizing ovarian tumor, but it is rare in children.[871] Recently somatic missense mutations affecting the RNase IIIb domain of DICER1 that alter DICER1 function in a manner that perturbs microRNA processing to become oncogenic are common in these nonepithelial ovarian tumors.[937] Lipoid-cell tumors of the ovary and gonadoblastomas of the ovary are even more unusual sources of androgens.

Variations of Pubertal Development

Premature Thelarche

Unilateral or bilateral breast enlargement without other signs of sexual maturation (e.g., sexual hair, growth of the labia minora, growth of the uterus) is not uncommon in infancy and childhood and is termed *premature thelarche*. The disorder usually occurs by age 2 (>80% of cases) and rarely after age 4.[938] In a retrospective study in Minnesota, the incidence of premature thelarche was 21.2 per 100,000 patient-years, 60% of cases were identified in patients between 6 months and 2 years of age, and most cases regressed within 6 months to 6 years after diagnosis, although a few persisted until puberty. The prevalence of premature thelarche appears to be increasing in Denmark.[940] When 10-year to 35-year follow-up of premature thelarche was available, no untoward effects on later health, growth, or fertility were evident.[897] Breast enlargement usually regresses after a few months but occasionally persists for years or until the onset of normal puberty; in about half of affected girls, the breast development, which is characteristically cyclic, lasts 3 to 5 years, and this is found with age of onset over 2 years.[939] Usually significant nipple and areola development is absent, and estrogen-induced thickening and dulling of the vaginal mucosa is uncommon. Enlargement of the uterus on ultrasonography (volume >1.8 mL, length >36 mm) is rare. Measurement of the ellipsoid volume of the uterus (V = longitudinal diameter × anteroposterior diameter × transverse diameter × 0.523) is the most sensitive and specific discriminator between premature thelarche and early[128] CPP and provides better early discrimination than the LH response to GnRH or GnRH agonist. Growth in stature is normal.

This is a benign, self-limited disorder that is compatible with normal pubertal development at an appropriate age; usually, only reassurance and follow-up are necessary. However, the appearance of premature thelarche can be the harbinger of further sexual maturation in a minority of cases. Although onset occurring soon after birth and before 2 years of age carries a higher prognosis for regression, 14% of two large series did progress no matter the age of onset of premature thelarche.[940] Because the breast development may be unilateral, it is important to consider the condition in girls who have unilateral breast development so that needless worry about a breast neoplasm is not stimulated in the parents and no unnecessary surgical procedure is carried out. Removal of tissue in premature thelarche may leave the child with no possibility of future breast development. In selected instances, sonography of the breast is useful to distinguish unilateral premature thelarche from less benign conditions but is of limited value in differentiating premature thelarche from precocious puberty.[941] The most common cause of a breast mass in a pubertal girl is fibroadenoma, and although metastatic disease may locate in the pubertal breast, breast carcinoma is exceedingly rare in young patients. Plasma estradiol levels are prepubertal in most standard assays but were slightly higher for age in patients with premature thelarche determined by a highly sensitive estrogen bioassay.[942,943] However, there is usually no significant increase in plasma levels of TeBG or in

thyroxine-binding globulin, which are indicators of estrogen action on circulating plasma proteins, and TeBG is suggested as one method of differentiating premature thelarche from PP.[940]

The urocytogram often reveals an estrogen effect on squamous epithelial cells in the urine in premature thelarche.[840,944]

Some endocrine measurements are proposed to differentiate PT from CPP. The concentration of serum FSH may be in the pubertal range, nocturnal FSH pulsatility has been detected, and the rise in FSH elicited by administration of GnRH may be augmented for chronologic age, with an FSH/LH ratio higher in precocious thelarche than in normal individuals or in girls with CPP. Girls under 48 months with mild premature thelarche had $17\beta E_2$ levels below 32 pmol/L using extraction RIA, while those with CPP have values over 70.[935] However, these methods are not infallible in differentiating the two conditions.

As postulated for some recurrent ovarian cysts, premature thelarche appears to result from the ovarian response to transient increases in FSH levels and possibly from variations in ovarian sensitivity to FSH. The LH response to GnRH is prepubertal in all cases.[437,945] Plasma inhibin B and FSH levels are higher in girls with precocious thelarche than in control subjects, in a range similar to that observed in patients with precocious puberty. Activin concentrations have not been reported. The possible role of a paracrine-acting pituitary factor in stimulating FSH independent of GnRH is not known.

Sonograms of the ovary may show one or several cysts larger than 0.5 cm that disappear and reappear, usually correlating with changes in the size of the breasts, but the volume of the ovary and uterus is prepubertal.[128] In clinical practice, it is rare to find a cyst at the time of presentation and on ultrasonic study.

Exaggerated thelarche is described as premature thelarche with the added findings of advanced bone age and increased growth rate, which are estrogen effects. The endocrine measurements in the basal state are in the normal prepubertal range, but after GnRH agonist stimulation, the level of FSH (but not of LH) rose higher than in control subjects or in patients with CPP. Mutation of *GNAS1* involving Arg201His is associated with apparent premature or exaggerated thelarche and early menarche.[730]

Unfortunately, there are no guidelines that can determine which girl will undergo progression from premature thelarche to precocious puberty. Clinical follow-up is essential to determine which course will occur.

Premature Isolated Menarche

Rarely, girls begin periodic vaginal bleeding at between 1 and 9 years of age without any other signs of secondary sexual development. The bleeding can recur for 1 to 6 years and then cease. At the normal age of puberty (3–11 years later), secondary sexual development and menses ensue and follow a normal pattern, as does stature.[946]

Fertility was later demonstrated after a normal onset of puberty in women with this variant of pubertal development. The cause is uncertain, but it may be a counterpart of premature thelarche. There is a predominance of FSH secretion, but the gonadotropin secretion pattern is not characteristic of CPP.[947] Isolated menarche may appear before other manifestations of sexual precocity in patients with the McCune-Albright syndrome and in those with the premature sexual maturation that can occur in juvenile hypothyroidism.

Before the diagnosis of premature menarche is accepted, all other causes of vaginal bleeding and precocious estrogen secretion and of exposure to exogenous estrogens should be excluded, including neoplasms, granulomas, infection of the vagina or cervix, and presence of a foreign body. A careful examination for trauma, such as that caused by sexual abuse, is indicated. Urethral prolapse may be misdiagnosed as vaginal bleeding.

Premature Adrenarche

Premature adrenarche causes the precocious appearance of pubic hair (i.e., pubarche), axillary hair and apocrine axillary odor, comedones, and acne, without other signs of puberty or virilization. It is characterized by premature and mild adrenal hyperandrogenism.[444,948] The term *premature adrenarche* refers to the rise in serum concentrations of adrenal androgens that cause the appearance of the pubic hair, which is termed *premature pubarche*. In the past, this designation was assigned when these clinical features appeared before age 8 years in girls or 9 years in boys. Although in boys the 9 years still seems appropriate as a cutoff point, the age of 8 years may no longer be appropriate for girls, according to the results of previously quoted studies showing earlier onset of puberty in recent years (mean ages are shown in Table 26.1). We recommend that the diagnosis of premature pubarche should be limited to African-American girls younger than 6 years of age and Caucasian American girls younger than 7 years, which should affect the age at which laboratory studies are initiated unless there are other signs of virilization, such as clitoromegaly or rapid growth.

Premature adrenarche is about 10 times more common in girls than in boys.[289,949,950] The prevalence is increased in children with CNS abnormalities without a clear sex difference; the electroencephalogram may be abnormal in the absence of other neurologic findings. Familial transmission is uncommon. Premature adrenarche is commonly slowly progressive and does not have an untoward effect on either the onset or the normal progression of gonadarche or final adult height.[444] Nonetheless, there is a relationship between reduced fetal growth leading to intrauterine growth retardation and subsequent SGA and the increased prevalence of premature adrenarche, and probably ovarian hyperandrogenism in life, although the relationship may vary among different ethnic groups.[951]

Plasma concentrations of DHEA, DHEAS, androstenedione, testosterone, 17-hydroxyprogesterone, and Δ^5-17P are usually comparable to values normally found in pubic hair stage 2. However, some patients have low concentrations of adrenal androgens, indicating that conversion of these molecule to more active androgens or a rise in androgen receptor activity is as important in the development of premature pubarche as the adrenal androgen secretion itself.[444] An ACTH stimulation increases serum DHEA and DHEAS concentrations and the excretion of urinary 17-ketosteroids, but the concentrations of plasma 17-hydroxyprogesterone and Δ^5-17P do not increase to the levels found in individuals with virilizing forms of CAH.[884] Shorter *AR* gene CAG number, indicative of increased androgen sensitivity, is reported in some girls with precocious adrenarche, suggesting that increased sensitivity to low androgen levels may be the basis rather than high androgen values per se. As in CAH, dexamethasone suppresses adrenal androgen and androgen precursor secretion.[952]

Serum gonadotropin levels in the basal state and after GnRH are in the prepubertal range in patients with premature adrenarche.[437] Premature adrenarche occurs independently of gonadarche and results from some unknown factor other than increased secretion of GnRH or ACTH. Bone age, height, and weight gain are slightly advanced for chronologic age, but normal adult height is commonly achieved, except, rarely, in some individuals with unusually high levels of adrenal androgens, hirsutism, acne, and a

bone age more than 2 years advanced or 2.5 SD above the mean value for chronologic age.[953] In a follow-up study of 20 girls, the functional adrenal hyperandrogenism in premature adrenarche was limited to childhood.

Premature adrenarche may be considered to be a developmentally regulated, normal variation in the differentiation, growth, and function of the zona reticularis of the adrenal cortex, marked biochemically by the precocious increase in the concentration of plasma DHEAS to more than 40 μg/dL.[290] The latter is probably related to the independent increase of 17,20-lyase activity in the developing zona reticularis, which is mediated by increased phosphorylation of serine and threonine residues on the CYP17 enzyme, and the increased abundance of cytochrome b_5 and of electron-donating redox partners such as cytochrome P450 oxidoreductase and cytochrome b_5, which are essential for the 17,20-lyase activity of this functional microsomal enzyme (see Fig. 26.36).[884] A rise in intra-adrenal cortisol may inhibit 3βHSD activity, thereby increasing DHEA according to in vitro evidence.[948] Nonetheless, the factors stimulating development and function of the zona reticularis, independent of ACTH, remain elusive.

The appearance of premature pubarche can be a manifestation of nonclassic 21-hydroxylase deficiency CAH caused by homozygous or compound heterozygous missense mutations in the *CYP21* gene.[954] This condition can readily be detected by a plasma 17-hydroxyprogesterone above 200 ng/dL (6 nmol/L) in the basal state or above 2000 ng/dL or 72 nmol/L in response to ACTH, which is at least 10 SD above the mean value for age. The prevalence of nonclassic 21-hydroxylase deficiency in children apparently presenting with premature adrenarche is low except in some ethnic groups (e.g., Hispanics, Italians, Ashkenazi Jews), in which the prevalence may be as high as 20% to 30%.

The cause of the observed mild deficiency in 3βHSD activity is unknown, but it may be multifactorial and may lead to a wide range in secretory capacity of the zona reticularis. A family constellation was described with a dominant pattern of inheritance of elevated adrenal androgens and androgen precursors that manifested as premature pubarche[949]; later-affected individuals developed hirsutism and anovulation. Several investigators joined to propose hormonal standards for the diagnosis of 3βHSD deficiency in cases of apparent premature pubarche and stated that ACTH-stimulated Δ^5-17P values must exceed 294 nmol/L for Tanner stage 2 (17 ± 5 nmol/L) or the ratio of Δ^5-17P to cortisol (F) must be at least 363. Studies relating genotype and hormonal analyses in basal and ACTH-stimulated conditions have confirmed that significant elevations of the Δ^5-17P-to-F ratio are necessary to prove true 3βHSD deficiency in genetically proven disease and that this is a rare disorder in patients presenting with putative premature adrenarche.[955] However, patients with a constellation of findings indicating PCOS may have subtler elevations of these values and present a picture of adrenal impairment of 3βHSD activity in the absence of mutations in the gene coding for the enzyme; these children presenting with premature pubarche are postulated to develop clinical PCOS at a later age.

The phenotype of premature pubarche is also associated with the rarer nonclassic 11β-hydroxylase deficiency. Mutation of *HSD3B2* or *HSD3B1* is an uncommon cause of premature pubarche, exaggerated adrenarche, and hirsutism in adolescent girls and women.

DHEA stimulates sebaceous gland activity,[956] and prepubertal acne or comedones may appear in association with elevated serum DHEAS concentrations in some children without the appearance of pubic hair, suggesting that a variant of premature adrenarche may manifest in this manner.[145] More significant androgen effects (e.g., clitoral or penile enlargement, rapid growth, hirsutism, deepening of the voice) exclude premature adrenarche and indicate a more severe form of hyperandrogenism.

Although premature adrenarche was usually considered to be a benign condition with no substantial long-term risk, accumulating observations indicate that girls with premature adrenarche are at increased risk of developing functional ovarian hyperandrogenism and PCOS, hyperinsulinism, acanthosis nigricans, and dyslipidemia in adolescence and adult life, especially if fetal growth was reduced and the birth weight was low.[950] Affected girls have BMI values similar to those of control subjects but differing distribution of fat; they are more likely to have increased waist circumference along with measures of insulin resistance.[957]

The concept of exaggerated adrenarche was first advanced in relation to a postulated childhood antecedent of PCOS. It has been extended to include rare instances of premature adrenarche associated with excessive responses of Δ^5-17P, DHEAS, and androstenedione to ACTH found in women with functional adrenal hyperandrogenism.

A report of a patient with premature adrenarche, advanced bone age, excessive acne, hyperandrogenic anovulation, very low DHEAS levels, and increased androgen levels demonstrated a mutation in PAPSS2, an enzyme that generates the sulfate donor 3′-phosphoadenosine-5′-phosphosulfate (PAPS), which is required for conversion of DHEA to DHEAS by the enzyme SULT2A1. Although the child was described as having premature pubarche, the androgen effects were greater than those usually encountered in this condition. The DHEA level was not elevated for age, but androstenedione was high owing to inadequate formation of DHEAS that decreases the conversion of DHEA to androstenedione. This presentation would ordinarily suggest an ovarian cause of the virilization. This monogenetic defect must be added to the differential diagnosis of premature adrenarche.[292]

Polycystic Ovary Disease[958,959]

PCOS is the most common endocrine disease of reproductive age women; it is estimated to affect 10% of women.[960] The hallmarks of this condition are hyperandrogenism, hirsutism,[961] anovulation, amenorrhea or oligomenorrhea, and insulin resistance; there is compensatory hyperinsulinemia, with its attendant risk of major metabolic sequelae, including type 2 diabetes mellitus, dyslipidemia, an increased propensity to coronary heart disease, and, in about 50% of affected women, obesity. PCOS is considered to be equivalent to the metabolic syndrome in men with its many manifestations in females. A 2013 review of diagnostic criteria supports the use of the Rotterdam criteria for diagnosis, noting the weakness of the method as well. Thus diagnosis rests upon the presence of two of the following criteria: androgen excess, ovulatory dysfunction, or polycystic ovaries.[691] Some prefer *hyperinsulinemic androgen excess* as a better indicator of the basis of the disorder in view of the fact that polycystic ovaries are not required for diagnosis.[950] Indeed criteria for the diagnosis of polycystic ovary morphologic appearance may require a greater number of follicles (>25 on ultrasound) than recommended by the Rotterdam criteria, and standards may yet change.[933] The use of AMH in the diagnosis of PCOS is under consideration but remains controversial owing to differences in study criteria and in the assays used to report AMH values.[962] At least it can be said

that AMH appears to correlate with polycystic appearance and androgen manifestations in many studies and in the future may become a diagnostic criterion.

Premature adrenarche in some populations is a risk factor for the later development of the PCOS and functional ovarian hyperandrogenism in adolescent and adult women; the magnitude of this risk is unknown, but it appears to be rare, except in girls with a history of SGA.[963] However, catch-up growth after SGA may be as important a factor in the development of PCOS, and even prematurity may be a risk. In an 880-member cohort of 8-year-olds, serum androstenedione and DHEAS levels were directly related to weight gain between 1 and 3 years and current weight and inversely related to birth weight.[878] However, a Dutch study could not confirm such a relationship between increase in premature adrenarche and SGA birth weight in 181 subjects born SGA compared with 170 subjects born with AGA.[964]

In certain ethnic groups, and especially in African-American and Hispanic girls, there is a greater association of premature adrenarche with the metabolic syndrome (obesity, hyperinsulinism, dyslipidemia, and other factors that increase the risk of later coronary heart disease) and the development of PCOS in late adolescence and early adulthood, especially if decreased insulin sensitivity and acanthosis nigricans accompany the premature adrenarche.[965]

As discussed earlier, hyperinsulinism is associated with many metabolic and endocrine conditions and functional ovarian hyperandrogenism that, in some cases, is heralded by premature adrenarche. Lifestyle modification is the primary approach to the treatment of PCOS and although success is achievable,[966] the failure rate is substantial. Oral contraceptives are often invoked but may be considered to treat the effects rather than the cause based on insulin resistance and excessive adiposity; nonetheless, the use of oral contraceptives with progestational and antiandrogen effects can regulate menstrual periods,[951] although long-term studies of progestation-only contraceptives in teenagers with PCOS are lacking.[967] Therapeutic approaches to reduce insulin resistance, especially the use of insulin sensitizers, have been introduced into the therapy for PCOS. The most widely used drug is metformin because of its low prevalence of adverse effects and therapeutic efficacy. Substantial data support the safety and efficacy of its use in adolescents with insulin resistance,[951] although metformin is not FDA approved for such use. Although flutamide in higher doses has caused hepatotoxicity, low-dose flutamide (1 mg/kg) is reportedly safe and effective in hirsute young women (but has not been proved to have such a safety profile in obesity or steatohepatitis)[968]; abstinence or contraception is essential when using this teratogenic agent. Thiazolidinediones are not recommended because of safety concerns.[691]

In a trial involving girls just past menarche who had a history of low birth weight and premature adrenarche and were therefore at risk for development of PCOS, metformin prevented this predicted course.[963] Treatment of 8-year-old girls who had similar risk factors appeared to diminish the risk during short-term studies. The beneficial effects on body composition, dyslipidemia, insulin resistance, and other parameters were present only during therapy; they reverted to increased risk factors after discontinuation of metformin. Weight loss is documented with the combination of metformin and oral contraceptives.[969]

The Endocrine Society recommends the oral contraceptives pill (OCP) as the first-line treatment for PCOS.

Adolescent Gynecomastia[970]

Normal boys, usually in the early stages of puberty, may have either unilateral breast enlargement (~25% of boys)[971] or bilateral breast enlargement (~50–65% of boys to varying degrees); this commonly occurs between chronologic ages 14 and 14.5 years or with pubic hair stages 3 and 4.[972] The physical exam aims to detect glandular tissue, but due to the epidemic of childhood and adolescence obesity differentiation of glandular tissue from adipose tissue has become more difficult. "Pinching" the tissue under the areole between the thumb and forefinger and comparing this to other areas of the chest helps in the determination of glandular tissue.[973] After such palpation, determination of serum prolactin might be misleading high, so blood samples must be taken before or well after.

In affected boys, the plasma concentrations of testosterone and estrogen are normal for their stage of puberty. Some have suggested that the ratio of estrogen to androgen or an increase in the ratio of testosterone to dihydrotestosterone is a cause. In a prospective study, adolescent boys with gynecomastia had a lower mean free testosterone concentration, lower weight, higher plasma TeBG levels, and a tendency toward earlier onset of puberty and more rapid progression through puberty.[971] In one study, a significant decrease in the concentration ratio of plasma androstenedione to estrone and estradiol and a similarly low ratio of DHEAS to estrone and estradiol were described in boys with pubertal gynecomastia who had normal ratios of plasma estrone and estradiol to testosterone. It was postulated that decreased adrenal production of androgens or (more likely) increased peripheral conversion of adrenal androgens to estrogens was a factor in the development of pubertal gynecomastia.[974]

Trials of estrogen receptor antagonists (e.g., tamoxifen, raloxifene) show promise, but more study is required.[975,976] Aromatase inhibitor administration had mixed results in gynecomastia. One study of boys (average age, 13 years) with gynecomastia involving a mean of 7 months of treatment with anastrozole demonstrated a substantial decrease in breast area (63%) and volume (53%), as measured manually and by ultrasonography, compared with watchful waiting[977]; however, larger studies are recommended to prove the utility of this approach because another study found no such result.

Pubertal gynecomastia is due to ductular proliferation in fibrous connective tissue.[978] The condition usually resolves spontaneously within 1 to 2 years after onset,[972] and reassurance and continued observation are often adequate treatment. Nevertheless, some boys have conspicuous gynecomastia, and if it lasts longer than 2 years (5–20% in various studies), it is likely to become permanent. These children may have sufficient psychologic distress to warrant a reduction mammoplasty. Indeed the psychologic stress appears unrelated to the duration or severity, and counseling should be considered in appropriate boys.[979] Liposuction is an alternative approach, but its efficacy in adolescent gynecomastia remains to be established. Untreated persistent gynecomastia persists into adulthood. The histologic examination of physiologic gynecomastia tissue rarely reveals carcinoma, so routine disease examination may be unnecessary.[980]

Gynecomastia is a component of Klinefelter syndrome, anorchia, primary and secondary hypogonadism, biosynthetic defects in testosterone synthesis, increased aromatase activity in adipose and other tissues (aromatase excess syndrome),[1008] Sertoli cell tumors, adventitious exposure to estrogens in meat or cosmetics, and variants of the androgen resistance syndromes, including Rosewater syndrome (familial hypogonadism and gynecomastia)

and Reifenstein syndrome (hypospadias, hypogonadism, and gynecomastia). These disorders usually have characteristic findings or environmental circumstances that allow ready differentiation from the normal gynecomastia of puberty.[622] Gynecomastia has been described in association with the administration of drugs such as cimetidine, spironolactone, digitalis, atypical antipsychotics, and phenothiazines; with GH therapy; and with the use of marijuana. The aromatase excess syndrome is described earlier.

Macroorchidism

Macroorchidism is defined as testes twice the normal size for age without androgenization. It is a rare manifestation of the McCune-Albright syndrome[884] and an occasional finding in prepubertal boys with long-standing primary hypothyroidism (see Van Wyk-Grumbach syndrome). This form of testicular enlargement appears to result from increased FSH secretion, independent of a pubertal increase in LH secretion or a pubertal LH response to GnRH. Testicular adrenal rests in CAH can cause bilateral macroorchidism, usually with nodules, as can lymphoma. In the McCune-Albright syndrome, an activating mutation in the $G_s\alpha$ gene primarily expressed in the Sertoli cells can cause macroorchidism due to Sertoli cell proliferation and hyperfunction with increased concentration of serum inhibin B and AMH but without increased testosterone levels due to Leydig cell hyperplasia, elevated gonadotropins, or signs of puberty.[327] Macroorchidism is a feature of severe aromatase deficiency in young male adults[303] and in men with an FSH-secreting pituitary macroadenoma. Bilateral megalotestis (testicular volume, 26 mL) in adults can occur as a normal variant.[981] One may speculate that some instances of bilateral macroorchidism are the result of a heterozygous constitutive activating mutation of the FSH receptor. As noted earlier, prepubertal enlargement of the testes was reported with a single-base-pair deletion at codon 434 (1301delT) of the *NR0B1/DAX1* gene and led to prepubertal testosterone and gonadotropin values.[818]

Immunoglobulin superfamily 1 *(IGSF1)* gene stimulates transcription of the thyrotropin-releasing hormone receptor by decreasing activity of the TGFβ1-Smad signaling pathway while increasing synthesis and biopotency of TSH; it also downregulates the activin-Smad pathway so that FSHB decreases. Thus with mutation in the *IGSF1* gene, central hypothyroidism and macroorchidism develop.[982]

Testes may enlarge during treatment with aromatase inhibitors.

The fragile X syndrome is associated with developmental delay, a long face and large prominent ears, and macroorchidism in 80% of affected pubertal boys. Macroorchidism may be evident only after careful measurements. The enlarged testes are caused by increased interstitial volume and excessive connective tissue, including increased peritubular collagen fibers, rather than by an increase in the seminiferous tubules. Enlargement of the testes is demonstrable in the prepubertal period in most patients with fragile X syndrome, but the onset of true macroorchidism (>4 cm) occurs only in the later prepubertal period.[983]

27 Hormones and Athletic Performance

FABIO LANFRANCO, EZIO GHIGO, AND CHRISTIAN J. STRASBURGER

CHAPTER OUTLINE

KEY POINTS

- Physical activity exerts an important influence on the endocrine system, modulating synthesis and secretion of several hormones. Almost every organ and system in the body is affected by physical activity and exercise, mainly mediated through the endocrine and neuroendocrine system.
- Exercise mode, intensity, and duration, age, gender, and individual fitness level, and environmental and psychological factors may affect endocrine responses to physical activity.
- Several hormones influence physical performance and body composition, with a bidirectional interrelationship between exercise and hormones.
- Hormone abuse has become a widespread habit among professional and recreational athletes. Anabolic androgenic steroids, growth hormone and growth hormone secretagogues, insulin-like growth factor 1, insulin, erythropoietin, and glucocorticosteroid properties are used and misused in sports. Specific methods to detect hormone abuse are described.
- Professionals involved in sports medicine and in endocrinology are presented with an elucidation of the complex interactions between physical activity and the endocrine system. Hormone abuse in competitive and recreational sports exerts negative consequences for long-term health.

Effect of Athletic Performance on Hormonal Systems

Catecholamines

Norepinephrine and epinephrine are closely coupled in their actions and respond rapidly to exercise to redistribute blood flow to meet metabolic demands. Norepinephrine increases from a resting level of 1.2 to 3.0 nmol/L to levels as high as 12.0 nmol/L at maximal exercise. Resting concentrations of epinephrine are 380 to 655 pmol/L. With maximal exercise, epinephrine concentrations can increase up to 3300 pmol/L. Both of these hormones progressively increase as workload increases.[1] Following exercise, plasma levels of catecholamines return to resting levels in a matter of minutes.

Mild exercise produces little or no response in catecholamines, whereas at moderate exercise levels norepinephrine significantly increases with minimal change in circulating epinephrine. At intense or prolonged exercise levels, both hormones increase significantly. Acute, short-duration maximal exercise can significantly increase norepinephrine and epinephrine levels. This rapid response suggests that the levels are primarily regulated via neural release mediated by activation of the sympathetic nervous system. Spillover from active muscle during exercise appears to be the primary contributor, but the kidneys are a possible other source.[1] Moreover, alteration in the ratio of norepinephrine to epinephrine, with a greater increase in the release of epinephrine from the adrenal medulla during exercise, suggests a possible hypothalamic mediation in the response to exercise.

Graded exercise produces a lower catecholamine response than continuous prolonged exercise. The responses are directly related to workload and oxygen uptake, and they are greater with small muscle groups than with large muscle groups.

Many studies report a higher adrenaline response to exercise in endurance-trained subjects compared with untrained subjects in response to intense exercise at the same relative intensity as all-out exercise. This higher capacity to secrete adrenaline was observed both in response to physical exercise and to other stimuli such as hypoglycemia and hypoxia.[2] This phenomenon can partly explain the higher physical performance observed in trained subjects compared with untrained subjects. More recently, these findings have also been reported in anaerobic-trained subjects in response to supramaximal exercise.

The combination of mental and physical challenges can elicit exacerbated catecholamine responses above that of a single challenge alone. Webb and colleagues[3] demonstrated that acute mental challenges and

physical stress together elicit a greater catecholamine and cardiorespiratory response than a single challenge, and this response is affected by fitness level (being higher in individuals with higher fitness levels). These findings suggest that fitness may be of benefit to those engaged in situations where dual-stressors are common (emergency responders, military personnel, etc.), as greater activation of the sympathoadrenal axis may be essential to safety and survival.

Interestingly, studies in women remain scarce; the results are more conflicting than in men, and the physical training type (aerobic or anaerobic) effects on catecholamine response remain to be specified.

Epinephrine and norepinephrine are responsible for many adaptations both at rest and during exercise. These include cardiovascular and respiratory adjustments and substrate mobilization and utilization.[2] Redistribution of circulation to working muscles and to the skin for heat loss and sweating is mediated through changes in catecholamines directly or indirectly via other intermediate hormones. Moreover, catecholamines may mediate mental performance improvement that occurs through exercise.[2]

Fluid Homeostasis–Vasopressin–Renin-Angiotensin-Aldosterone System

During physical exercise, there is considerable loss of water and electrolytes in sweat, which is necessary to maintain body temperature by dissipating heat generated from muscle use. The rate of fluid loss owing to sweating may be as high as 1500 mL/hour. The loss of fluids is replaced by the subsequent ingestion of liquids, which is modulated by thirst. The replacement of electrolyte is the result of the normal intake of food. Renal function is the major mechanism by which electrolytes are conserved following exercise.

The maintenance of fluid and electrolyte homeostasis during physical exercise depends on the action of arginine vasopressin (AVP), natriuretic peptides, the renin-angiotensin-aldosterone (RAA) axis, and catecholamines. These hormonal systems are modified in response to exercise, with different patterns depending on the amount of relative work performed, the duration of exercise, and the training status. Other factors influencing the response of hormones to exercise include the mode of exercise, environmental factors, age and gender of the subjects, and several medical/physiologic conditions.[1,4] Hormones involved in the regulation of fluid and electrolyte homeostasis show a relatively consistent response among individuals.

AVP concentrations increase during exercise up to 24 pg/mL, and elevated levels persist for more than 60 minutes following maximal exercise. The stimulus for the increase in AVP during exercise is the increase in plasma osmolality and reduction in blood volume. Animal experiments have demonstrated an increase in activation of hypothalamic neurons indicating an increased vasopressin content and performance above the anaerobic threshold.[5] Thus, the response of vasopressin appears to be associated with the onset of anaerobic metabolism, which is also related to increases in stress hormones such as cortisol and adrenocorticotropic hormone (ACTH).

A study in runners using pharmacologic manipulation with a receptor-specific agonist and antagonist to activate and inhibit the vasopressin type 2 receptor (V2R) has provided indirect evidence that AVP response during exercise regulates water losses from body fluids only in the kidney with no effects on sweat and salivary glands.[6]

Atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP), which may be altered by exercise,[1] also elicit a natriuretic effect. ANP is increased with exercise in a linear response. In case of prolonged exercise, ANP undergoes an initial increase, a subsequent fall, and then a re-elevation of levels, persisting until completion of the exercise.[1] The increase in ANP with exercise appears to be related to stretch of the atrium due to volume changes, neurologic inputs, and sodium intake.[1] BNP response to exercise is modulated by sodium intake, hydration status, and hypoxia.[1,7] BNP is not consistently altered in normal subjects in response to acute exercise except under conditions of high altitude/hypoxia, whereas it increases with long-duration exercise such as a 100-km ultramarathon.[7]

The RAA system responds to acute exercise with a significant increase of activity. In fact, increased values of plasma renin activity (PRA) are reported following maximal exercise.[1] The increase in PRA occurs at submaximal workloads of more than 60% to 70%. With the increase in PRA during exercise, there is a concomitant increase in angiotensin II (A-II), which partially mediates the increase in circulating aldosterone concentrations up to 250 to 3300 pmol/L. Elevated levels of aldosterone may persist for days after the end of exercise, depending on water and sodium intake. The primary activator of the RAA system during exercise is the sympathetic nervous system. Stimulation of the release of renin is modulated by changes in renal sympathetic nerve activity resulting in an increase in local norepinephrine. The increase in aldosterone with exercise is assumed to be mediated by the increase in A-II in response to activation of the RAA system. However, inhibition of angiotensin-converting enzyme does not attenuate the increase in aldosterone with maximal exercise in healthy subjects.[8] Other factors involved in the activation of aldosterone production include sodium intake, potassium balance, and levels of ACTH. Elevated levels of aldosterone may persist for days after the end of exercise depending on water and sodium intake.[1]

The persistent increase of aldosterone long after the end of exercise may be associated with reductions in plasma osmolality and sodium concentrations due to ingestion of water to replace total body water losses.[1] Thus, the interaction of several regulating factors is involved in mediating the response of aldosterone.

In contrast with acute exercise, PRA is reduced after exercise training, whereas no effect is observed on serum aldosterone or A-II. Significant reductions in systolic and diastolic blood pressure following exercise training have been observed with no relation between PRA changes and changes in blood pressure.[4]

Hypothalamus-Pituitary-Adrenal Axis

Glucocorticoids

Since the pioneering studies of Davies and Few,[9] it has been known that exercise of an appropriate intensity is a potent stimulus for cortisol secretion. Glucocorticoids exert many beneficial effects in exercising humans, increasing the availability of metabolic substrates for the need of energy of muscles, maintaining normal vascular integrity and responsiveness, and protecting the organism from an overreaction of the immune system in the face of exercise-induced muscle damage.[10]

During acute exercise, the hypothalamus-pituitary-adrenal (HPA) axis responds to numerous stimuli demonstrating the regulatory and integrative functions of the HPA axis: neuronal homeostatic signals (chemoreceptor, baroreceptor, and osmoreceptor stimulation), circulating homeostatic signals (glucose, leptin, and ANP), and inflammatory signals (interleukin 1, interleukin 6, and tumor necrosis factor α).[11,12]

In humans, repeated brachial blood samplings have shown that the dynamics of HPA axis activation during exercise associate

stimulation of hypothalamic corticotropin-releasing hormone and AVP secretion (with a prominent role of corticotropin-releasing hormone), synthesis, and release of ACTH from pituitary corticotroph cells preceding the increase of cortisol.[13]

Response to Endurance Exercise

Two major factors modulate the HPA axis response to endurance exercise: the intensity and the duration of exercise.[10,13] The minimum intensity of exercise necessary to produce a cortisol response from the HPA axis is 60% of maximal oxygen uptake ($\dot{V}O_2max$), with a linear increase between the intensity of exercise and the increase in plasma cortisol concentrations for exercises above 60% $\dot{V}O_2max$.[13,14] Below this intensity threshold, such as during light and prolonged exercise (<60% $\dot{V}O_2max$), ACTH and cortisol concentration may increase, with a duration threshold around 90 minutes of exercise at 40% $\dot{V}O_2max$.[14] These thresholds are independent of training.

Several other factors modify the response of the HPA axis to physical activity. The cortisol response to exercise is modulated by hypohydration, meals, and time of day. Independently of external thermal stress, hypohydration (up to 4.8% body mass loss) greatly amplifies the exercise-induced cortisol response to exercise. This enhancement probably results from an increased core temperature and cardiovascular demand consecutive to decreased plasma volume.[15] Meals also stimulate cortisol release in humans. Exercise performed immediately after food ingestion results in a blunted cortisol response to the exercise stimulus. Finally, the cortisol response to exercise is significantly modulated by time of day, which influences the incremental response to exercise (greater increase in the evening than in the morning) but not the peak response to exercise.[13]

Endurance training has been compared with chronic stress in humans. When the HPA axis is repeatedly challenged by exercise, humans demonstrate modifications in the activity of the HPA axis suggesting an adapting process to endurance training. Several studies have shown that in endurance-trained subjects, the HPA axis activity in resting conditions is similar to that of healthy sedentary subjects.[14,16] Accordingly, plasma cortisol at 0800 hours, nycthemeral cortisol rhythm, overnight and 24-hour urinary free cortisol, seasonal rhythmicity of cortisol excretion, and cortisol response to the dexamethasone suppression test in resting endurance-trained subjects are similar to those of age-matched untrained subjects.[13,14,16]

However, when the HPA axis is challenged, endurance-trained subjects demonstrate a decreased pituitary sensitivity to the negative feedback of glucocorticoids, which explains their capacity to successfully achieve a second bout of exercise separated by a short rest period.[14] Different mechanisms can be involved in this adaptation. At the central nervous system level, neuropeptides and corticosteroid receptors (glucocorticoid receptors, mineralocorticoid receptors) in the brain and anterior pituitary play a major role in the regulation of circulating cortisol levels. At the peripheral level, tissue sensitivity to glucocorticoids may also be different between endurance-trained and sedentary subjects.[17] Altogether, these adaptation processes are finalized to protect the body from the severe metabolic and immune consequences of increased cortisol levels.

Response to Resistance Exercise

Resistance (strength) exercise is also a potent stimulus to the HPA axis. In humans, a bout of resistance exercise acutely increases cortisol secretion and then plasma cortisol concentrations.[18]

Two major factors modulate HPA axis response to resistance exercise: the intensity and the volume (sets × repetitions × intensity) of the exercise performed. Resistance protocols of moderate to high intensity, high in volume, stressing large muscle mass, and using short rest intervals produce the greatest acute hormonal elevations (ACTH and cortisol).[18]

Cortisol has multiple roles during resistance exercise: meeting the greater metabolic demand of resistance training; remodeling of muscle in response to a bout of exercise, as cortisol regulates muscle protein content by inhibiting muscle protein synthesis; and stimulating protein degradation likely via activation of the ubiquitin pathway.[13] Moreover, cortisol can also influence neuromuscular function (i.e., neuronal activity, intracellular signaling, muscle force) through various rapid or short-term mechanisms. Cortisol may contribute to the muscular properties of the peripheral nervous system by rapidly modulating calcium influx in skeletal muscle cells.[19]

Mineralocorticoids

The RAA system is closely coupled and responds to acute exercise. PRA values increase following maximal exercise.[1] Progressively higher increases in aldosterone levels have been observed with increasing degrees of exertion. Elevated levels of aldosterone may persist for days after the end of exercise depending on water and sodium intake.[1] The interaction of several regulating factors is involved in mediating the response of aldosterone. These include the sympathetic nervous system, renin activity, A-II, sodium intake, potassium balance, blood volume reductions, and levels of ACTH.[1] In contrast with acute exercise, PRA is reduced after endurance training, whereas no effect is observed on serum aldosterone or A-II.[4]

Endorphins

Exercise influences the release of β-endorphins depending on intensity and duration of the physical activity. If a threshold intensity is exceeded, endogenous opiate levels start to increase. Incremental graded exercise tests elevate β-endorphin levels 1.5- to 7-fold.[20] Several studies suggest that circulating β-endorphins can increase with an appropriate minimal intensity of exercise (>60% $\dot{V}O_2max$) but this is not always the case.[20] Instead of a critical intensity related to aerobic capacity, other studies related the increase in β-endorphins to the lactate threshold.[20] Moreover, other factors, such as diet and immune function, can influence the β-endorphin response. Very little is known about the influence of training status on the release of β-endorphins, and study results are often inconsistent.

Interestingly, the psychological and physiologic stress related to competitive practice has been proposed to stimulate the secretion of endorphins to counter the negative effects of competitive stress.[21] A physiologic purpose of endogenous opiate increase in athletes can be the modulation of pain and the improvement of mood.[22] Altogether, the action of endogenous opiates can be described as a rewarding system that makes the athlete continue physical activity.

Hypothalamic-Pituitary-Gonadal Axis

Male Gonadal Axis

The effects of physical activity on the hypothalamic-pituitary-gonadal (HPG) axis in males vary with the intensity and duration of the activity, the fitness level of the individual, and his nutritional-metabolic status. Relatively short, intense exercise usually

increases serum testosterone levels, whereas more prolonged exercise usually decreases them.[23-25] Increased serum testosterone levels have been reported during relatively strenuous free and treadmill running, weight training, rock climbing, and ergometer cycling.[26]

The testosterone response increases with increased exercise load.[27] Similar workloads produce similar responses regardless of whether the load is aerobic or anaerobic.[28] Increased and decreased ambient temperature, altitude, and dehydration have no effect on testosterone response to intense exercise.[29] Acute exercise-induced testosterone increments are also seen in older men despite their different hormonal milieu.[30]

Exercise-associated increase in circulating testosterone is considered not to be mediated by luteinizing hormone (LH) due to the inconsistent LH response and to the evidence that testosterone levels increase more quickly than LH in response to exercise. Possible mechanisms such as hemoconcentration, reduced clearance, and/or increased testosterone synthesis may be involved.[26] However, the timing of testosterone response differs from that of other circulating steroids (e.g., androstenedione and dehydroepiandrosterone increase simultaneously with cortisol), thus suggesting that specific testicular mechanisms are involved.[31] These mechanisms may include the activation of the sympathetic system, which stimulates testicular testosterone production during exercise via a direct neural pathway in some species.

In contrast to the short-term testosterone increment, a suppression of serum testosterone levels occurs during and subsequent to more prolonged exercise, and to some extent in the hours following intense short-term exercise.[32,33] A variety of systems could influence the decrease of testosterone synthesis during and subsequent to prolonged exercise. A lack of significant elevation in basal LH, coupled with a reduced testosterone concentration, has been reported, reflecting hypogonadotrophic-hypogonadism characteristics.[34,35] Moreover, altered basal prolactin has been described in response to prolonged exercise.[34,36]

Leptin and ghrelin levels, which may be influenced by physical exercise, have been suggested to be altered in exercise-hypogonadal men. Leptin is an adipocyte-released hormone associated in part with communicating satiety and energy reserve status to the hypothalamus.[37] It is also linked to reproductive function in both women and men. Acute and chronic exercise can reduce leptin concentrations independent of changes in body adiposity.[38,39]

Ghrelin is another hormone associated with appetite regulation. Evidence from several experimental studies in animals and in humans suggests that ghrelin may function as a metabolic modulator of the HPG axis, with predominant inhibitory effects in line with its role as a signal of energy deficit.[40] Acute and chronic exercise has been shown to increase ghrelin concentration levels.[38,41] However, no research has yet examined whether ghrelin levels in exercise-hypogonadal men are normal.

Another potential disruptive hormone to the HPG axis is cortisol. Cumming and associates[42] have demonstrated that the direct infusion of cortisol in men results in concurrent declines in testosterone levels. However, in the hormonal profile studies reporting the existence of low testosterone in trained men, none have reported elevated resting cortisol levels.[26] Thus, at this time, the role of cortisol in the changes found in the gonadal axis of trained men is in need of further study.

Reductions in testosterone levels, if extensive and prolonged, can compromise a person's health status. Relative to athletes, these reductions can negatively impact on the adaptation process associated with skeletal muscle (i.e., myoplasticity), which is fundamental to the exercise training progression and improvement in performance.[43,44]

It is important to note that hormonal changes involved in overtraining and/or decreased energy availability can decrease the production of testosterone. Participation in sports where leanness is considered a competitive advantage, such as running, cycling, wrestling, lightweight rowing, and gymnastics, has been linked to lower body mass index, eating disorders, and low energy availability.[33,45] Low energy availability in the context of anorexia nervosa has been associated with low testosterone levels in males.[46] Hagmar and associates[47] evaluated athletes from 26 different sports and divided them into those who participated in leanness sports and those who did not. The leanness sport athletes had lower body fat, higher spinal bone mineral density (BMD), lower serum free testosterone and leptin, and higher insulin-like growth factor 1 (IGF1) binding protein.

Research in exercising men demonstrates the existence of a select group who, through chronic exposure to endurance exercise training, developed alterations in their reproductive hormonal profile (i.e., persistently low basal resting testosterone concentrations).[34] In particular, the majority of these men exhibit clinically "normal" testosterone concentrations, but these concentrations are at the low end of the normal range or even reach subclinical status. The health consequences of such hormonal changes are increased risk of abnormal spermatogenesis, male infertility problems, and compromised bone mineralization.[34] The prevalence of such health problems seems low, but investigative studies examining this condition and its consequences are few in number.[34] The specific terminology used to refer to this condition has not been universally agreed on. In 2005, Hackney and associates[48] proposed use of the phrase "the exercise-hypogonadal male" as a label for this condition.

The effects of intense training on male fertility are controversial. Some studies have found changes in semen from exercise, noting decreases in sperm motility, quality, and number,[49-51] whereas others have not found such alterations.[52,53] Several studies, however, did not control for energy availability. Thus, like much of the work in female athletes, research in male athletes will be more easily interpretable in the future if energy availability is accurately quantified and factored into the analysis.[33]

Female Gonadal Axis

The endocrine equilibrium that regulates the reproductive function in women can be affected by physical and psychological factors. In females, short-term consequences of physical exercise on the HPG axis have not been as widely studied as in males. Differences in hormonal responses between the sexes are believed to be dependent on basal hormone concentrations (i.e., sex differences in basal estradiol and testosterone).[33] A few studies have demonstrated increases in total testosterone after acute bouts of resistance and endurance training in women.[54-57] Studies evaluating acute changes in estradiol are challenging given that estradiol levels change widely during a typical menstrual cycle. Nevertheless, multiple investigations have found an acute increase in estradiol immediately after exercise.[54,58] This increase in estradiol seems to be responsible for greater lipid and less carbohydrate oxidation in women compared with men during exercise and seems to be protective for muscle during the stress of exercise.[33]

The long-term impact of exercise and training on hormone levels has been more widely studied in females, particularly in the setting of decreased energy availability. Women who engage in regular high-intensity exercise may be at risk of developing menstrual disturbances such as delayed menarche, oligomenorrhoea, amenorrhea, and luteal phase defects.[59]

Although factors such as physical and/or psychological stress of competition have been postulated to underlie exercise-induced reproductive disorders, evidence accumulated to date indicates that negative energy balance is the primary cause of the impairment of normal reproductive function commonly observed in female athletes.[60,61] In 1939, Selye[62] reported that "the ovaries undergo atrophy and more or less permanent anestrus ensues" when young female rats were forced to exercise for prolonged periods. Earlier, Selye[63] observed a *general adaptation syndrome* also involving hypertrophy of the adrenal glands, cessation of growth and lactation, shrinkage of the liver, loss of muscular tone, a fall in body temperature, and the disappearance of adipose tissue. In 1980, Warren[60] was the first to suggest that menstrual disorders in dancers are disrupted by an "energy drain." In 1984, Winterer and associates[64] hypothesized that lack of sufficient metabolic fuels to meet the energy requirements of the brain causes an alteration in brain function that disrupts the gonadotropin-releasing hormone (GnRH) pulse generator, although the mechanism of this alteration was unknown. The energy availability hypothesis is supported by endocrine observations of athletes. Amenorrheic athletes display low 24-hour blood glucose, low 24-hour insulin, and high 24-hour insulin-like growth factor binding protein 1 (IGFBP1),[65] loss of the leptin diurnal rhythm,[66] and low T3 levels in the morning.[67] Loucks and associates[68] found that low energy availability reduced LH pulse frequency and increased LH pulse amplitude, and that exercise stress had no suppressive effect on LH pulsatility beyond the impact of the energy cost of exercise on energy availability. LH pulsatility was disrupted regardless of whether energy availability was reduced by extreme energy restriction alone, by extreme exercise energy expenditure alone, or by a combination of moderate dietary energy restriction and moderate exercise energy expenditure. Dietary supplementation prevented the suppression of LH pulsatility by exercise energy expenditure.

To investigate the dose-response relationship between energy availability and LH pulsatility in exercising women, Loucks and Thuma[69] manipulated the energy availability of 29 regularly menstruating, habitually sedentary, young women, administering a clinical dietary product to set energy availability at 45 and 10, 20, or 30 kcal/kg fat-free mass (FFM) for 5 days. LH pulsatility was disrupted only below 30 kcal/kg FFM per day. This was consistent with many studies of amenorrheic runners, all of which indicated energy availabilities less than 30 kcal/kg FFM per day,[70] and with the only prospective study of the refeeding of amenorrheic athletes, in which menstrual cycles were restored in runners by increasing energy availability from 25 to 31 kcal/kg FFM per day.[71]

In female athletes, low energy availability is a component of the *female athlete triad*, a term used to describe the interrelationship of decreased energy availability, subsequent HPG axis inhibition leading to menstrual irregularity, and decreased BMD.[45] The triad was first described by the American College of Sports Medicine in the 1990s. In 2007, the American College of Sports Medicine published a revised position stand on the female athlete triad,[72] correcting the former misunderstanding of the triad as a narrow syndrome consisting of disordered eating, amenorrhea, and osteoporosis by describing the triad more broadly as the harmful effects of low energy availability on menstrual function and BMD.[61] The International Olympic Committee (IOC) proposed an expansion of the concept of the female athlete triad to include males and coined the term *relative energy deficiency in sport*.[73] The development of that term had three main purposes: (1) to draw awareness to the fact that energy restriction can have negative consequences in men in addition to women; (2) to highlight other potential negative health and performance consequences of low energy availability in athletes besides bone problems; and (3) to encourage expansive research into the potential myriad effects of low energy availability in various populations, including Paralympic athletes.

The discovery of leptin in 1994 was fundamental in clarifying the relationship between negative energy balance and reproductive dysfunction. Various sets of data suggest that leptin may serve as a signal to the CNS with information on the critical amount of adipose tissue stores necessary for GnRH secretion and pubertal activation of the HPG axis. Several unfavorable metabolic situations are associated with low plasma leptin, increased secretion of hypothalamic neuropeptide Y, and hypogonadism, and a causal relationship has been evoked. Severe dietary restriction in juvenile female rats is associated with low plasma leptin and sexual immaturity. Cessation of food restriction leads to immediate increase in plasma leptin followed by sexual maturation.[74] Leptin administration for the relative leptin deficiency in women with hypothalamic amenorrhea improves reproductive, thyroid, and growth hormone (GH) axes and markers of bone formation, confirming that leptin is required for normal reproductive and neuroendocrine function[75] and can restore ovulatory cycles.[76]

Impaired production of gonadotropins, which leads to luteal phase deficiency and anovulation, is a common hormonal finding with exercise-induced menstrual disturbances, but several other hormones may show significant alterations.

The HPA axis activation may be involved in the gonadal axis functional disruption during physical exercise. The so-called stress hypothesis holds that exercise activates the HPA axis, which disrupts the GnRH pulse generator by another unknown mechanism. Amenorrheic athletes may display mildly elevated cortisol levels, and this observation is the basis for attributing their amenorrhea to stress. However, since cortisol is a glucoregulatory hormone activated by low blood glucose levels, the mild hypercortisolism observed in amenorrheic athletes may reflect a chronic energy deficiency rather than exercise stress.[61]

The involvement of endogenous opioid peptides and catecholestrogens in provoking menstrual irregularities in women athletes has been also suggested.[77] In basal circumstances, β-endorphins may decrease LH levels by suppressing hypothalamic GnRH; some catecholestrogens may suppress LH levels, whereas others seem to potentiate and induce LH surge. The activities of both β-endorphins and catecholestrogens depend on the essential presence of a sufficiently estrogenic environment. In addition, both endogenous opioid peptides and some of the catecholestrogens appear to be able to suppress prolactin release, probably by interfering with its inhibiting factor, dopamine. The increased plasma concentrations of β-endorphin, which are found after physical exercise, give rise to speculations as to their involvement in the frequently appearing menstrual irregularities in female athletes.[77]

Hyperandrogenism has been suggested as a possible alternative mechanism underlying oligomenorrhea or amenorrhea in some female athletes with menstrual disturbances.[78-80] Sports that emphasize strength over leanness, such as swimming and rowing, are not associated with low weight and restrictive eating patterns, yet athletes engaged in these sports are vulnerable to menstrual irregularities as well. The endocrine profile of athletes engaged in these sports is characterized by mildly elevated LH levels, elevated LH/follicle-stimulating hormone ratios, and mild hyperandrogenism rather than hypoestrogenism. Interestingly, hyperandrogenic female athletes have a more anabolic body composition and higher $\dot{V}O_2$max and performance values than female athletes with menstrual disturbances but normal androgen concentrations.[78]

Prolactin

Blood prolactin levels increase during exercise, and this response appears proportional to the exercise intensity.[36] Provided that the intensity is adequate, the increase in prolactin is quite rapid. Nonetheless, short-term, graded exercise may result in a peak hormonal response after the exercise ends. In a prolonged exercise session, the prolactin response is proportional to the intensity at which it is performed. However, extending the duration of exercise can augment the magnitude of the prolactin response.[36]

The mechanisms by which prolactin increases with exercise are unclear. Prolactin levels may increase when the anaerobic threshold is reached, perhaps concomitantly with a GH increase.[81] In some situations, such as competitive sports, excessive emotional stress can cause an anticipatory increase in prolactin even before the initiation of exercise.[82] Moreover, the prolactin increase may be related to changes in body temperature and dehydration, is reduced with habituation and hypoxia, and is unresponsive to metabolic events.[83]

Vigorous, high-intensity anaerobic exercise results in greater prolactin response than that typically seen in submaximal steady-state aerobic exercise.[28] The effect of resistance exercise, which is intermittent in nature, on prolactin has not been studied extensively.

The chronic effects of exercise training on basal, resting prolactin levels are yet unclear and in need of further research. Some studies have found increases in resting levels, whereas others have found decreased levels.[36] These contradictions seem to be related to differences in training protocols (intensity, frequency, and duration of training sessions).

GH/IGF1 Axis

In 1963, Roth and associates[84] demonstrated that plasma levels of GH increase during exercise, and it was later shown that exercise is the most potent physiologic stimulus to GH release.[85] Most of the current knowledge regarding the GH response to exercise is based on studies of the effect of aerobic-type exercise.

The GH response to exercise is dependent on the duration and intensity of the exercise bout, the fitness level of the exercising subject, the refractoriness of pituitary somatotroph cells to the exercise stimuli, and other environmental factors.[86] Lactate and nitric oxide are suggested to be afferent stimulation for the exercise-induced GH response.[87] A linear dose-response relationship between exercise intensity and the GH secretory response was demonstrated, with escalating GH release across the range of exercise intensities (25–175% of lactate threshold).

The exercise duration should be at least 10 minutes, because exercise of shorter duration both below and above the lactate threshold was not accompanied by increases in circulating GH levels.[86] Exercise-induced GH peak occurs 25 to 30 minutes after the start of exercise, irrespective of the exercise duration.[86] Thus, when the task is brief, a peak may be reached after its cessation, but when the task is long (e.g., 45 minutes), the GH peak occurs while the individual is still exercising.

The nature of the exercise may also influence the GH response. Although the continuous exercise protocols may be comparable to competition events, the endurance-type training undertaken by many athletes involves intermittent or interval exertion. Comparing exercise at equivalent total workloads, GH levels are lower with continuous protocols (40–45% $\dot{V}O_2$max) as opposed to interval protocols, with twice the work rate for half the time, reflecting the greater metabolic stress and lactate levels in the latter.[88] With resistance exercise, incremental GH responses have also been described.[89] The important determinants appear to be the relationship between load and frequency of individual repetitions. Greater GH increments have been reported following "hypertrophy" protocols (moderate loads, high number of repetitions) than "strength" protocols (heavy loads, low repetitions) in both men and women.[90]

There is conflicting evidence regarding the neuroendocrine pathways that regulate GH secretion during exercise. Mechanisms involving cholinergic, serotoninergic, α-adrenergic, dopaminergic, and opioidergic pathways have been proposed.[91] There may be interactions among the pathways, and they may operate at different exercise intensities. In young males, regular but not acute exercise is associated with higher GH production and also augments GH stimulation of GH release by GH-releasing hormone.[92] It has been hypothesized that this is due to decreased hypothalamic somatostatinergic activity and higher GH pulsatility.

The GH response to exercise is greater in women than in men—as is the unstimulated GH output over time—and declines with aging.[91] In fact, even in early middle age (mean age, 42 years), the GH response to exhaustive exercise is greatly attenuated compared with younger subjects (mean age, 21 years).[93] However, it is difficult to separate the effects of aging from changes in body composition, because body fat increases with aging and GH secretory rates are reduced in overweight subjects.[94]

Environmental and nutritional factors, as well as some pathologic states, may interfere with the GH response to exercise. Cappon and associates[95] showed that a high-fat meal could inhibit the magnitude of GH response to exercise, the inhibition of the exercise-induced GH response being correlated with circulating levels of somatostatin.

High ambient temperature may increase circulating GH levels,[96] whereas low temperature attenuates GH release.[97] Obesity and/or polycystic ovarian syndrome are characterized by attenuated GH response to exercise.[98]

Exercise exerts acute effects on other components of the GH/IGF1 axis. The effect of exercise on circulating IGF1 has been examined by several investigators with differing results depending on the intensity, duration, and type of exercise performed. Schwarz and associates[99] demonstrated IGF1 increases following 10 minutes of exercise of both below and above the lactate/anaerobic threshold. This study suggests that the increase in IGF1 accompanying exercise is not related to GH.

The transient nature of IGF increases suggests that hemodynamic or metabolic effects of exercise per se might play a role. Exercise in humans is accompanied by the rapid "hemotransfusion" of hemoconcentrated blood from the spleen into the circulation by increased blood flow to the exercising muscle and by loss of plasma water. These phenomena might explain, at least in part, an increased IGF concentration by changes in IGF flux and/or volume of distribution.

Longer periods of exercise training, however, stimulate *IGF1* gene expression both in the central neuroendocrine and local tissue components of the GH-IGF1 system. Eliakim and associates[100] showed that muscle IGF1 protein concentrations in rats can increase with endurance training despite the lack of change in muscle IGF1 mRNA or serum IGF1.

Few studies have investigated the response of IGFBPs to exercise. IGFBP1 levels have been shown not to change during 30 minutes of moderate exercise[90] but to increase transiently after acute exercise.[101] The physiologic role of the postexercise increase in IGFBP1, given IGFBP1 inhibition of IGF1 metabolic actions, may be to prevent late hypoglycemia.

Schwarz and associates[99] have demonstrated that IGFBP3 levels increased with both low- and high-intensity exercise and that high-intensity exercise increased IGFBP3 proteolysis. A transient increase in IGFBP3 levels in response to an acute exercise has also been confirmed by Wallace and associates,[101] who described an acute increase of all components of the ternary complex, IGF1, IGFBP3, and the acid-labile subunit.

Eliakim and associates[102] have described that functional and structural indices of fitness were correlated with mean overnight GH levels, growth hormone–binding protein (GHBP), and serum IGF1 levels in late pubertal adolescent girls. Moreover, thigh muscle volume was inversely correlated with IGFBP2 and IGFBP4.

The acute increase in serum GHBP in response to acute exercise has also been described by Wallace and associates[101]; considering that GHBP at rest acts as a damper on GH oscillation, these authors speculate that the postexercise GHBP increase may prolong the GH signal, increasing the GH-mediated signal for postexercise protein synthesis, tissue repair, and muscle glycogen replenishment. The increment in the serum GHBP concentration may represent either increased synthesis from the liver or reduced clearance.[101]

Hypothalamus-Pituitary-Thyroid Axis

Exercise has effects on thyroid function, which can be viewed as an adaptive mechanism associated with enhanced performance possibly serving to provide a better balance between energy consumption and expenditure.[103] Short-term incremental exercise (≤20 minutes) increases blood TSH (thyroid-stimulating hormone, or thyrotropin) levels, with a critical intensity threshold of approximately 50% or more of $\dot{V}O_2max$ necessary to induce significant changes.[36] Even though TSH is elevated, most research involving short-term exercise indicates that total and free thyroxine (T_4) and T_3 are not immediately affected.[36] However, total T_4 and T_3 levels can increase following such exercise, although these findings appear primarily due to exercise-induced hemoconcentration.[104]

The influence of more prolonged submaximal exercise (approaching 60 minutes) on thyroid hormones is controversial. Some investigations report no effect on blood TSH levels, whereas others have found TSH and/or free T_3 to increase progressively with high-intensity steady-state workloads.[36] These divergent findings are difficult to interpret due to the highly variable exercise sessions (i.e., different durations and intensities of exercise) and the varying blood sampling protocols employed.

Energy balance plays an important role in the body's thyroid hormone response to exercise. Loucks and Heath[105] found a decrease in T_3 and free T_3 along with an increase in reverse T_3 in healthy women undergoing aerobic exercise testing with low caloric intake. This "low T_3 syndrome" was not seen in individuals receiving a higher caloric diet. An increase in reverse T_3 concentrations has been described as one of the more consistent findings, particularly when a caloric energy deficiency is associated with exercise.[103]

Insulin and Glucose Metabolism

Physical activity affects the metabolism of glucose and other intermediate substrates in normal subjects and in subjects with diabetes. The effects of exercise on carbohydrate metabolism are complex and involve type, intensity, and duration of exercise; changes in body composition; alterations in other behaviors, such as food intake; degree of insulin deficiency; and a complex time course of the glucose-insulin response.[106]

In healthy individuals, no major alterations in blood glucose levels are usually seen during exercise, despite the increase in glucose utilization by skeletal muscle. With the onset of activity, activation of the α-adrenergic system results in inhibition of insulin release from the pancreas. This results in an increased rate of lipolysis in the periphery, as well as a stimulation of hepatic glucose output. As glucose levels begin to fall, glucagon levels rise, further stimulating hepatic glucose output. Finally, as plasma glucose drops toward hypoglycemic levels, epinephrine is released, further stimulating hepatic glucose production and increasing lipolysis in the periphery. The increased availability of free fatty acid for muscle metabolism helps to restrain the rate of glucose utilization. It has been shown that when one of these mechanisms fail, the others can largely compensate, avoiding the development of hypoglycemia.[106]

Training induces a reduction in basal insulin levels and in exercise-associated changes in glucagon and insulin, increases insulin sensitivity at rest and in response to a glucose load, and reduces insulin decline during acute exercise.[107] Regular exercise has become an integral part of the treatment recommendations for patients with type 2 diabetes, because it improves insulin sensitivity and reduces average blood glucose concentrations.[108,109] Physical training results in an increase in insulin-stimulated glucose disposal and improves glucose control in type 2 diabetes. However, the increase in insulin sensitivity is rapidly lost if exercise is not performed on a regular basis. Exercise may also be effective in delaying or preventing the development of type 2 diabetes.[109,110]

Erythropoietin

Plasma erythropoietin (EPO) levels are not usually affected by single bouts of strenuous exercise at sea level. The lack of major effects of normoxic exercise on EPO production is plausible, because the oxygen sensor in control of EPO synthesis is not located in the skeletal muscle or the heart but in the kidneys.[111] Generally, there are no major differences in basal red blood cell (RBC) count, hematocrit, blood hemoglobin concentration, and mean corpuscular hemoglobin concentration values in athletes compared with nonathletes. Hemoglobin mass has been described to be increased in elite endurance athletes.[112] However, sportsmen, particularly those in endurance sports, may present with relatively low hemoglobin concentrations and hematocrit values. This "sports anemia" is usually a pseudoanemia due to an enlarged plasma volume. If there is an increased rate of intravascular hemolysis caused by compression, the RBC lifespan will be reduced.[111]

Performance-Enhancing (Ab)use of Hormones

Anabolic Androgenic Steroids

The use of ergogenic (performance-enhancing) substances by athletes continues to be a growing problem, and androgens are among the most frequently abused drugs.[113] The global lifetime prevalence rate of using anabolic-androgenic steroids (AASs) is 6.4% for males and 1.6% for females.[114] Classical sport disciplines are not the only ones involved; the phenomenon is similarly widespread among bodybuilders, and thus the drugs used have been collectively classified as appearance- and performance-enhancing drugs (APEDs).

Although doping has been practiced since antiquity, often with placebo or toxic effects, truly effective APEDs only became available with the rise of modern pharmacology, and particularly following the isolation and synthesis of testosterone and AASs. Testosterone came into clinical use shortly after its synthesis in 1935,[115] and its first documented use for doping was by German rowers in 1952 (to maintain their marital duties during exhausting training) and by Russian weight lifters in 1954 to enhance their power.[116]

The IOC introduced antidoping regulations for the first time in 1967 and performed the first antidoping testing in the 1972 Munich Olympics. In 1976, androgens were placed on the IOC doping list.[113]

Interestingly, an early and comprehensive review of previous results concluded that there was little evidence for supraphysiologic doses of testosterone or synthetic AASs having any appreciable effect on muscle size or strength in healthy men.[117] However, many of the studies reviewed had a lack of adequate control and standardization. Conclusions from more recent reviews suggested that the administration of AASs could consistently result in significant increases in strength if male athletes satisfied certain criteria, including the timing of doses and dietary factors.[118,119] In 1996, Bhasin and associates[120] demonstrated that the administration of supraphysiologic doses of testosterone in combination with exercise in male weight lifters induces a greater increase in muscle size and strength than exercise alone or testosterone treatment alone (i.e., the effects of combining supraphysiologic doses of testosterone with exercise are additive). Subsequent work showed that increases in FFM, muscle size, strength, and power are highly dose dependent and correlated with serum testosterone concentrations.[121,122] In fact, significant increases in muscle size and strength occur only with doses of 300 mg per week and higher.[121] The increase in muscle size is due to a hypertrophy that results from an increase in cross-sectional areas of both type I and type II muscle fibers and an increase in myonuclear number.[123]

The anabolic effects of androgens are primarily mediated through androgen receptor signaling. Androgen receptors are expressed in the satellite cells and other stem-like cells in the interstitium of the skeletal muscle fibers.[124] A growing body of evidence supports the hypothesis that testosterone and dihydrotestosterone promote myogenic differentiation of mesenchymal, multipotent stem cells and inhibit their differentiation into the adipogenic lineage.[125,126]

The AASs used for nontherapeutic purposes are endogenous androgens (e.g., androstenedione, dehydroepiandrosterone [DHEA]), 17β-esters of testosterone (e.g., cypionate, enanthate, heptylate, propionate, undecanoate, buciclate), 17α-alkyl derivatives of testosterone (e.g., methyltestosterone, fluoxymesterone, oxandrolone, stanozolol), 19-nortestosterone (nandrolone), 17β-esters of 19-nortestosterone (e.g., decanoate, phenpropionate), 19-norandrostenedione and 19-norandrostenediol, and tetrahydrogestrinone. More than 100 different AASs have been developed, with most of them being used illegally, synthesized in clandestine laboratories, commercialized without medical prescription or safety controls, and sometimes unknown to the scientific world[127] (Table 27.1).

The updated list of AASs is available on the following website: https://www.wada-ama.org/en/prohibited-list.[128]

Intramuscular injections are used far more frequently than oral formulations. The dose of AASs used by athletes varies considerably and is often thought to exceed 10 to 40 times the recommended therapeutic dose. In addition, combinations of androgens are used more frequently than single agents. Multiple androgens may be combined in a practice known as stacking, in which two or more androgens are added in progressively increasing doses over a period of several weeks. Athletes also often use a practice called *cycling*, in which weeks of androgen use are followed by periods of drug holiday; this routine is based on the unproven premise that cycling prevents desensitization to massive doses of androgen. The phrase "building a pyramid" refers to the progressive increase in the doses of androgens during a cycle. Toward the end of a cycle, athletes may reduce the doses of androgens or switch to other drugs (e.g., human chorionic gonadotropin or aromatase inhibitors or estrogen antagonists) that they believe will reduce the likelihood of testicular suppression. In most surveys, the duration of steroid administration or steroid cycle lasts between 4 and 12 weeks.[129]

TABLE 27.1 Performance-Enhancing Hormones

Anabolic Androgenic Steroids

17β-Esters of testosterone (cypionate, enanthate, heptylate, propionate, undecanoate, buciclate)
17α-Alkyl derivatives of testosterone (methyltestosterone, fluoxymesterone, oxandrolone, stanozolol)
19-Nortestosterone (nandrolone)
17β-Esters of 19-nortestosterone (decanoate, phenpropionate)
19-Norandrostenedione
19-Norandrostenediol
Tetrahydrogestrinone

Peptide Hormones

Growth hormone

Insulin
Erythropoietin

Adverse Effects

The side effects associated with AAS use are numerous and involve multiple organ systems[113,116,130] (Table 27.2). Systematic investigations of the adverse effects of androgens in athletes and recreational body builders have been difficult for many reasons. With the exception of the association between hepatic dysfunction and the use of some oral AASs, many of the reports of serious side effects in otherwise healthy individuals have come from anecdotal case studies or small retrospective studies based largely on self-reported data.[130] Confounding factors, such as undiagnosed preexisting conditions, family history, and concurrent use of other drugs, further dampen the credibility of case reports. Moreover, because most anabolic steroids are obtained on the black market and are of dubious quality, there is potential for adverse medical events independent of steroid use. However, data from larger observational studies suggest that the majority (88–96%) of AAS users experience at least one minor subjective side effect, including acne (40–54%), testicular atrophy (40–51%), gynecomastia (10–34%), cutaneous striae (34%), and injection site pain (36%).[131]

AAS-induced hypogonadism (ASIH) is common among former AAS abusers and usually presents as hypogonadotropic hypogonadism due to abrupt decreases in plasma androgen levels following AAS cessation.[132] Scientific data on ASIH are limited, but the condition is characterized by symptoms and signs of hypogonadism (e.g., testicular atrophy, low plasma testosterone levels, impaired spermatogenesis, erectile dysfunction, fatigue, decreased libido, and depressive symptoms) and is considered to resolve spontaneously within 6 to 12 months.[116,133] However, studies investigating the recovery phases of young men with ASIH are scanty. A growing number of studies reporting cases in which ASIH manifestations persisted years after AAS cessation suggest that ASIH is a more permanent condition in a substantial proportion of former AAS abusers.[132] This emerging group of young men may become a considerable public health concern in the coming years.

TABLE 27.2 Side Effects of Anabolic Androgenic Steroids

Cardiovascular
Cardiomyopathy
Lipid disorders (decreased HDL, increased LDL)
Increased platelet aggregation
Increased hematocrit
Elevated blood pressure

HDL, High-density lipoprotein; *LDL,* low-density lipoprotein.

In a recent cross-sectional case-control study involving 37 current AAS abusers, 33 former AAS abusers, and 30 healthy control participants, Rasmussen and associates[132] demonstrated that the group of former AAS abusers exhibited significantly lower plasma total and free testosterone, had smaller testicular sizes, and featured a higher proportion of participants with depressive symptoms, fatigue, erectile dysfunction, and decreased libido than the control group more than 2 years after AAS cessation.

AASs may also induce dyslipidemia, cardiovascular disease, insulin resistance, glucose intolerance, diabetes mellitus, and liver disease.[113,130] In general, the ingestion of oral C17α-alkylated anabolic steroids causes an average 30% decrease in high-density lipoprotein and an average 30% increase in low-density lipoprotein.[134] The mechanisms for this effect are unknown but apparently include an increase in the activity of hepatic triglyceride lipase that catabolizes high-density lipoprotein particles. Most studies indicate that injectable non-C17α-alkylated anabolic steroids, such as testosterone and nandrolone esters, exert minimal adverse effects on blood lipids.[129,134] It is unclear if the adverse changes in blood lipids as a function of testosterone use actually lead to an increase in the incidence of coronary artery disease.

AASs may also influence platelet aggregation and the myocardium, although the relationship between these effects and cardiovascular disease is unclear. Occasional reports of cardiomyopathies and arrhythmias associated with steroid use have been published, and several mechanisms have been proposed.[130]

Liver disease is a well-documented side effect of most, but not all, C17α-alkylated AASs, the exception being oxandrolone. In contrast, most non-C17α-alkylated steroids exert minimal hepatoxicity. Liver pathologies associated with anabolic steroids include cholestasis, peliosis hepatis, hepatocellular adenoma and carcinoma, and hepatic angiosarcoma and cholangiocarcinoma.[113,130]

Potential effects on the reproductive system include infertility and testicular atrophy in men, and menstrual and genital tract alterations and infertility in women.[116] Although all AASs suppress the hypothalamic-pituitary axis to some extent, the resulting infertility in males is generally reversible. The effects of AAS use on fertility in women is unknown.[116] Menstruation is either diminished or absent in steroid users, but ovulation may occur.[135]

Balding is common in those who use AASs that undergo 5α reduction to potent androgens. In some male steroid users, gynecomastia may be caused by increased circulating estrogen associated with the use of aromatizable androgens and/or human chorionic gonadotropin, with decreased clearance of circulating estrogens as a result of impaired hepatic function, and/or with a temporary state of hypotestosteronemia following AAS withdrawal.[130]

Several studies have suggested that AAS use may lead to significant psychological morbidity. Anxiety, psychosis, irritability, increased aggression, and antisocial and violent behavior have been described to be associated with AASs. In addition, dependence, withdrawal symptoms, and depression may accompany or follow the nonmedical use of AASs.[130]

Finally, there are concerns about potential effects of androgens on the risk of prostate disease, although the long-term effects of supraphysiologic doses of androgens on the risk of prostate cancer, benign prostatic hypertrophy, and lower urinary tract symptoms remain unknown.[116]

Detection

All known AASs can be detected via urinalysis for a period of time following the last dose. Detection of the misuse of exogenous substances is preferably done using gas chromatography/mass spectrometry (GC-MS) complemented by liquid chromatography/tandem mass spectrometry.[136] To improve the selectivity and sensitivity, traditional GC-MS methods are accompanied by high-resolution mass spectrometry and/or tandem mass spectrometry techniques.[137]

Endogenous androgens and their metabolites occur naturally in the human body, and thus specific indicators for the detection

of the exogenous administration of these steroids are required.[137] For screening purposes, a set of urinary concentrations of several endogenous steroids or metabolites is determined by the GC-MS method used for the detection of steroid abuse. The method of steroid profiling was first introduced into routine doping control by Donike and associates[138] in 1983 (testosterone to epitestosterone ratio). The most important steroid profile parameters in doping control are the ratios of testosterone/epitestosterone, androsterone/etiocholanolone, androstane/testosterone, and 5α/5β forms of androstane-3,17-diol. The administration of steroids like testosterone or its precursors (e.g., androstenediol, androstenedione, or DHEA) or metabolites (e.g., dihydrotestosterone or epitestosterone) has been proved to alter one or more of the parameters of the urinary steroid profile.[138] Consequently, monitoring the steroid profile parameters allows to screen for potential misuse.

Growth Hormone

GH has been used as a drug of abuse in sport since the early 1980s, although the first scientific studies demonstrating a clear-cut physiologic role for GH in adults were only published in the peer-reviewed medical literature in 1989.[139,140]

Human GH (hGH) misuse in sports predates its use in adult endocrinology by 10 years, although cadaveric GH had been used in children since the 1950s. This practice was stopped by clinicians (but not athletes) when cases of Creutzfeldt-Jakob disease were discovered in patients who had previously received hGH. The clinical use of GH resumed following US Food and Drug Administration approval of the first synthetic recombinant hGH (rhGH) in 1985. Other formulations subsequently followed.[141]

GH has several properties that are attractive to athletes wishing to improve their performance, but it is mainly misused because of its anabolic and lipolytic effects. GH administration leads to increased muscle mass and a decrease and redistribution of body fat from central to peripheral depots, thereby potentially improving the power to weight ratio of an athlete.[141]

In 2008, Liu and associates[142] completed a systematic review of 44 randomized controlled trials that compared GH treatment with no GH treatment in healthy adults. Their review suggests that although GH administration may increase FFM, strength and exercise performance did not improve with GH, and edema and fatigue were more common in the GH-treated subjects. The authors concluded that claims that GH improves athletic performance are not supported by the available scientific literature.

Graham and associates[143] performed a well controlled study that showed an effect on strength and peak power output in a group of well-defined abstinent steroid abusers using rhGH. A study in recreational athletes demonstrated that in the short term, GH significantly increased lean body mass, reduced fat mass, and improved sprint capacity but not strength, power, or endurance.[144]

Because GH is a banned substance, the doses that athletes use are difficult to evaluate. It has been suggested that athletes abusing GH take rhGH three to four times per week at a dose of 10 to 25 IU per day to increase their lean body mass.[145]

GH abuse extends beyond professional sports and is also present among adolescents engaged in sports in schools. This widespread use presents a public health problem because GH use is accompanied by adverse effects, and long-term use can lead to serious morbidity.[146]

Adverse Effects

The side effects of GH treatment in GH-deficient adults are well documented and include edema, arthralgias, myalgias, sweating, fatigue, and dizziness.[141,147] Athletes typically take pharmacologic doses that are likely 10 or more times greater than typical replacement doses. Although the long-term adverse effects of these megadoses are not known at present, some insight may be obtained from patients with acromegaly. Acromegalic patients have an increased risk of insulin resistance and diabetes, hypertension, cardiomyopathy, and certain forms of cancer (colorectal, thyroid, breast, and prostate).[148]

Finally, the risk of infections such as human immunodeficiency virus/acquired immunodeficiency syndrome or hepatitis due to the use of nonsterile or contaminated syringes[145] and the availability on the black market of GH that comes from extracts of human pituitary glands and represents a source for Creutzfeldt-Jakob disease must be taken into account.

Detection

Two different strategies have been proposed to detect GH doping in sports.[149] For the marker method "pharmacodynamic endpoints of GH use," the GH-2000 and GH-2004 consortiums identified biochemical parameters of the IGF system, such as IGF1, IGFBP3, and the acid-labile subunit, as suitable markers of GH use in combination with procollagen cleavage products that also show a clear-cut increase following GH use. The combination of IGF1 and the procollagen III N-terminal extension peptide is proposed to provide a set of markers that allow the detection of GH abuse in athletes for up to 2 weeks after the last application.

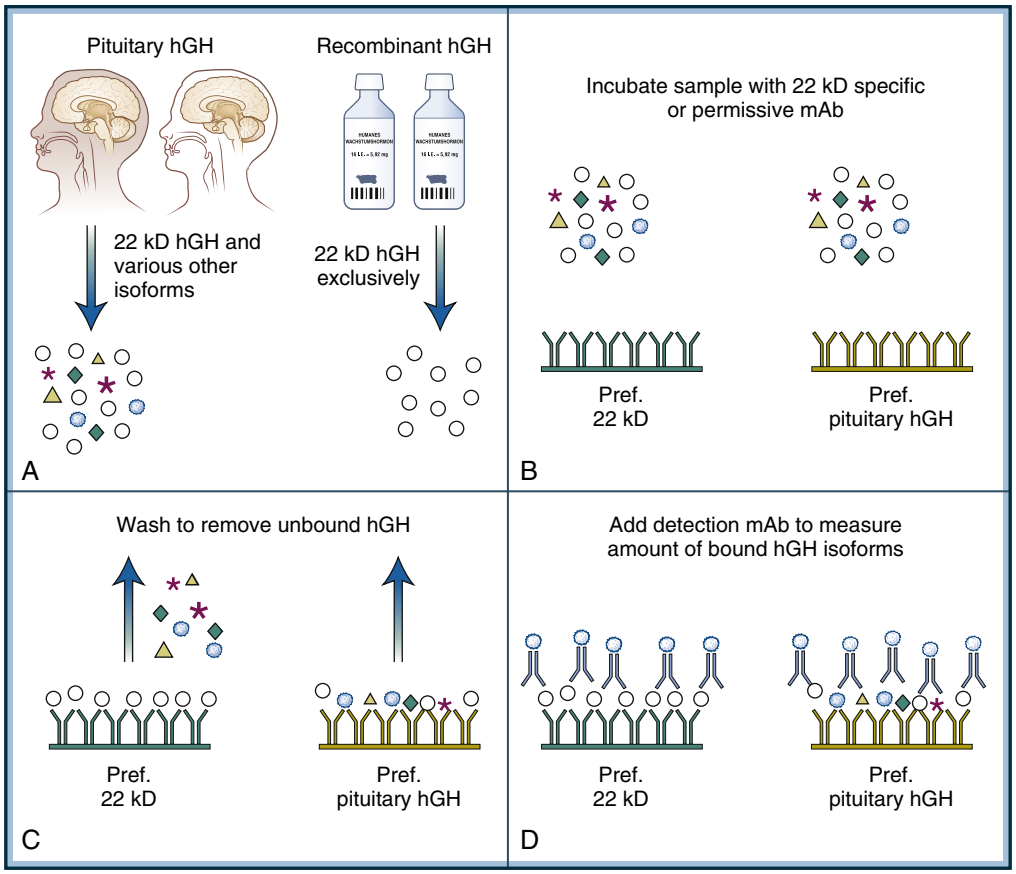
The "GH-isoform method" exploits the difference in isoform composition between recombinant GH consisting mostly of monomeric 22-kilodalton (kDa) hGH while the pituitary secretes a variety of GH isoforms including a 20-kDa form lacking 14 amino acids, as well as amidated and acylated isoforms, and dimers, oligomers, and fragments of GH. After peripheral injection of recombinant 22-kDa hGH, the pituitary's production of GH isoforms is reduced by negative feedback via IGF1. Subjecting serum samples to two immunoassay analyses—one of which is specific for 22-kDa monomeric hGH, whereas the other recognizes the majority of isoforms released from the pituitary—allows the calculation of an isoform ratio (Fig. 27.1).

The isoform test is an excellent strategy to detect GH doping, provided that it is administered shortly after the last GH dose (within 24–36 hours, depending on the dose),[150] realistically probably within 12 to 24 hours.[146] Due to this short window of opportunity, the test is not well suited for in-competition testing. Its use in unannounced out-of-competition testing, however, should be more successful in catching GH abusers, and recently it has been used mostly in that setting.[146]

GH Secretagogues

GH secretagogues are peptides or nonpeptidic agents that act to release GH from the pituitary. There is evidence that they are being used by athletes as an indirect method for GH doping. Secretagogues include GH-releasing hormone and its analogues, ghrelin analogues (known as GH-releasing peptides) or GHSs (GH secretagogues in a narrower sense), and amino acids (e.g., arginine or ornithine). GHSs have short-lived effects and provide a relatively weak boost in GH exposure compared with what can be achieved by direct GH administration.[146] Nevertheless, GHSs may be attractive to athletes who want to avoid detection because the GH released is endogenous and therefore not detectable by the GH isoform test.[146]

Currently, there are no published studies of the effects of GHSs on performance, but investigations have shown that they increase GH secretion and potentially could improve athleticism through this mechanism.[141]



• **Fig. 27.1** (A) While the pituitary gland secretes a variety of molecular forms of growth hormone (GH), recombinant GH consists predominantly of monomeric 22 kD GH. (B) Serum samples are incubated with immobilized monoclonal antibodies (mAbs) against GH preferentially binding to either 22 kD GH *(left)* or the other pituitary-derived molecular forms *(right)*. (C) Unbound GH forms and other sample constituents are washed away before (D) incubation with an independently labeled anti-GH antibody binding to all GH molecular forms. The result of the differential immunoassay is then expressed as the ratio between the two different isoform measurements. *hGH,* human growth hormone.

Insulin-like Growth Factor 1

Recombinant human IGF1 (rhIGF1) is used in clinical practice, but a variety of IGF1 compounds and IGF1 analogues are also advertised on the internet, and many have been available on the black market for several years.[151] The rationale for using rhIGF1 as an ergogenic aid differs little from that of rhGH. The potential benefits include increased muscle protein synthesis, increased glycogen synthesis, and free fatty acid availability,[152] but in contrast to GH, IGF1 is not lipolytic.

Abuse of IGF1 is more recent than that of rhGH. In fact, until recently, IGF1 was only available in limited supply, partly because there is no natural source for this hormone and partly because there were no pharmaceutical preparations. This situation changed with the development of two compounds, mecasermin (Increlex) by Tercica (Brisbane, CA) and mecasermin rinfabate (iPLEX) by Insmed (Richmond, VA). Both preparations received US Food and Drug Administration approval for clinical use in the treatment of growth failure in children with severe primary IGF1 deficiency or with GH gene deletion who have developed neutralizing GH antibodies.[153] Although there are no confirmed cases of IGF1 misuse by athletes, the drug seems to be already popular among amateur bodybuilders. IGF1 is extensively discussed on internet bodybuilding forums. The list of purported benefits include increases in muscle size and strength, improvements in energy and endurance, benefits to the immune system, and increased bone density.[151]

Very few studies have been undertaken to examine the effects of IGF1 on performance. Guha and associates[154] demonstrated a 9% increase in $\dot{V}O_2$max in recreational athletes following 28 days of administration of rhIGF1/rhIGFBP3 despite no change in body composition. The mechanism underlying this change is unknown, but previous studies have shown that the intravenous administration of rhIGF1 caused an increase in cardiac output, heart rate, and stroke volume in healthy adults.[155] IGF1 may have a role in the regulation of vascular tone through alterations in nitric oxide synthesis, allowing improved intramuscular blood flow. Serum IGF1 correlates positively with hemoglobin concentration, which may enhance oxygen delivery to exercising muscle. Finally, an anabolic effect on respiratory muscle strength may improve inspiratory effort.[141]

Adverse Effects

The adverse effects that have been reported with Increlex include hypoglycemia, jaw pain, headache, myalgias, and fluid retention.[156] The most common adverse effects observed so far with the use of mecasermin rinfabate include local injection site erythema and lipohypertrophy, although headaches, increased liver and kidney size, and altered liver function tests have also been reported.[153]

It also seems reasonable to hypothesize that IGF1 could result in adverse effects similar to acromegaly.[152]

Detection

At present, there is no specific test to detect IGF1 abuse, and detection of this form of doping poses many challenges. IGF1 is excreted in urine at low concentrations, and methods for measuring urinary

IGF1 are complex and time consuming. Several factors contribute to renal clearance of IGF1: a significant increase in urinary IGF1 concentration is observed as part of the proteinuria that occurs in response to exercise. Blood sample collection, rather than urine, will thus be required for IGF1 doping tests.[151]

The GH-2004 research group has been investigating methods for detection of IGF1 misuse, and a test is being developed based on principles of the successful GH-2000 marker method. Commercial immunoassays for these markers have been validated for antidoping purposes, but new methods, including IGF1 measurement by use of mass spectrometry, are hoped to improve the performance of the tests and to help in the detection of athletes who are doping with these peptide hormones.[151,157]

Insulin

Insulin stimulates the uptake of glucose into muscle and fat by making available an increased number of glucose transporters (Glut-4) at the cell membrane. However, its main effect is inhibitory to lipolysis, glycolysis, gluconeogenesis, ketogenesis, and proteolysis.[158]

Insulin regulates hepatic glucose output by inhibiting gluconeogenesis and promoting glycogen storage. Similarly, in muscle cells, insulin-mediated glucose uptake enables glycogen to be synthesized and stored, and for carbohydrates, rather than fatty acids or amino acids, to be utilized as the immediately available energy source for muscle contraction. Although insulin stimulates the uptake of amino acid into cells and promotes protein synthesis in a range of tissues at high insulin concentrations, the major action of insulin is to inhibit proteolysis, which occurs at lower insulin concentrations.[152]

The theoretic performance benefits of insulin are mediated by an increase in muscle glycogen storage and the inhibition of proteolysis but have not been demonstrated in clinical or scientific trials.[152] The first suggestions of insulin as an anabolic agent were published in two bodybuilding magazines in 1996, which were commented on in the *British Journal of Sports Medicine* in 1997.[159] At the Winter Olympic Games in Nagano in 1998, a Russian medical officer inquired as to whether the use of insulin was restricted to type 1 diabetes.[160] This drew attention to its role as a potential performance-enhancing drug and led to its ban in 1999 by the IOC.[153]

Various reports since then have described the misuse of insulin to improve performance and muscle strength, and synthetic analogues were the subject of several studies describing the beneficial effects of biotechnologically modified insulins.[161]

Adverse Effects

The most common adverse effect of insulin use is hypoglycemia. Most athletes who abuse insulin usually balance the ingestion of carbohydrate when injecting rapidly acting insulin analogues. Another problem associated with insulin is weight gain, although most competitive athletes are accustomed to diet and follow training regimens that allow them to have strict control over weight gain.[152,153]

Detection

So far, no screening tool is available providing fast and reliable information on possible insulin misuse. Only sophisticated procedures including immunoaffinity purification followed by liquid chromatography and tandem mass spectrometry have enabled the detection of synthetic insulins in doping control blood or urine samples.[162] Insulin analogues have been designed to alter their pharmacokinetics by genetic substitutions of one or two amino acids from human insulin. These small differences can be utilized to differentiate between native and exogenous insulin.[153]

Erythropoietin and the Erythropoietin System

EPO, a glycoprotein hormone naturally produced in the kidney and the liver, is an essential growth factor for the erythrocytic progenitors in the bone marrow. Tissue hypoxia is the physiologic stimulus for EPO expression and erythropoiesis. Once released, it serves to stimulate an increase in hemoglobin. In this way, it increases the oxygen-carrying capacity of the blood.[111]

Successful cloning of the human *EPO* gene allowed for the production of recombinant human EPO (rhEPO) and later the approval to treat patients with anemia. More recently, several newer generations of EPO analogues have been produced.[163]

Because hemoglobin mass correlates with the aerobic capacity, some athletes seek to increase erythropoiesis by pharmacologic means. Treatment with rhEPO may enhance performance by raising hemoglobin concentration. Studies show that when rhEPO is applied to healthy volunteers in low dosages, $\dot{V}O_2$max is increased by 6% to 12% when the hematocrit is raised to approximately 0.50. In addition, the time to exhaustion (in the laboratory) is increased by up to 50% at a given level of $\dot{V}O_2$max.[164] When rhEPO administration is discontinued, $\dot{V}O_2$max remains elevated for at least 3 weeks.[111]

Apart from rhEPO, several other erythropoiesis-stimulating agents have been developed. Darbepoetin alfa is an rhEPO glycosylation analogue approved for use in 2002 in the European Union and United States. It has the same mechanism of action as rhEPO—binding and activation of the EPO receptor—but it has a longer serum half-life and an increased in vivo potency. Another long-acting erythropoiesis-stimulating agent is methoxy polyethylene glycol-epoetin beta (methoxy PEG-epoetin beta). The half-life of methoxy PEG-epoetin beta amounts to 130 to 140 hours on intravenous injection. The prolonged in vivo survival of darbepoetin alfa and methoxy PEG-epoetin beta is in part due to a reduced EPO-R binding affinity.[111]

EPO mimetic peptides are synthetic cyclic peptides of about 20 amino acids that signal through the EPO-R but show no sequence homology to EPO. The clinically most advanced product was peginesatide, a pegylated homodimer of two EPO mimetic peptides, which was initially approved in the United States for treatment of anemic patients with chronic renal failure but subsequently recalled after lethal acute hypersensitivity reactions occurred in several patients.[165]

Sotatercept (ACE-011) is a novel recombinant erythropoietic protein. It is composed of the extracellular part of the activin type II receptor and the Fc domain of human immunoglobulin G1. In a clinical phase I study, single intravenous injections of sotatercept proved to increase blood hemoglobin levels, RBC numbers, and the hematocrit.[166] However, the mechanisms underlying the effect of sotatercept or of analogue compounds on erythropoiesis are still poorly understood.[111]

The expression of the *EPO* gene (chromosome 7q22) is under the control of several transcription factors, including GATA-2, which inhibits EPO expression. GATA antagonists are organic small molecule compounds that prevent GATA-2 from suppressing the EPO promoter. GATA antagonists may be misused in sports, because they have been shown to increase EPO concentrations, hemoglobin levels, and endurance performance in mice, although human studies have not yet been reported.[111,167]

Hypoxia-inducible factor (HIF) stabilizers, such as α-ketoglutarate competitors, stimulate erythropoiesis by increasing EPO expression in the kidneys and at extrarenal sites. Advantages of HIF stabilizers—compared with recombinant proteins—include the oral

route of administration. However, the HIFs can activate more than 1000 genes apart from EPO, including genes for proteins that are involved in tumor growth, such as vascular endothelial growth factor. However, some of the HIF-activated genes encode proteins that may increase physical performance independent from the stimulation of erythropoiesis.[111]

EPO gene transfer is theoretically possible but medically little advanced. In vivo allogeneic EPO transfer can cause immune reactions. Furthermore, antidoping research has provided techniques to specifically amplify intronless DNA sequences allowing the detection of small amounts of transgenic DNA in blood.[168] Ex vivo EPO transfer is performed by use of transfected autologous or allogeneic cells that are transferred from in vitro cultures into the individual. The autologous ex vivo approach has been investigated in clinical trials.[169] However, the method has made little progress and has not stepped beyond the clinical trial phase, even after many years of study. Taken together, for technical difficulties, gene doping with EPO is probably not applied in sports, at least not yet.[111]

Adverse Effects

Artificially raising hemoglobin levels can have dangerous consequences. In contrast to the effect of endurance training, which results in an increased plasma volume, the administration of rhEPO produces a selective increase in red cell mass. If the hematocrit exceeds 0.50, blood viscosity and cardiac afterload increase significantly. The main risk of erythrocytosis with a hematocrit greater than 0.55 include heart failure, myocardial infarction, seizures, peripheral thromboembolic events, and pulmonary embolism.[170] Moreover, EPO withdrawal may be implicated in neocytolysis—that is, the hemolysis of young red blood cells in the presence of an increased hematocrit.[171]

Detection

The authorities of sports forbade the use of EPO in 1990, and now any analogue or mimetic is also included in the list of prohibited substances of the World Anti-Doping Agency (WADA). The challenge of detecting the misuse of EPO has given strength to the proposal of several strategies.[172] The marker methods rely on the measurement of some hematologic and serum parameters, and their comparison with populational or individual limit values.[173] An indirect test based on the measurement of five blood parameters, including reticulocyte hematocrit, serum EPO, hematocrit, soluble transferrin receptor, and the percentage macrocytes, was developed by Parisotto and associates.[174] Two models were developed. The "on" model used all parameters to detect recent use of EPO. The "off" model used three parameters to detect EPO use with more retrospectivity.[173] An advantage of indirect methods to detect rhEPO is its universal coverage of different types of analogues and mimetics, a field in clear expansion.

The most powerful way to directly discriminate between endogenous and rhEPO is probably based on the glycosylation differences existing between both types of molecules.[175] In 1995, Wide and colleagues[176] proposed, for the first time, a method able to separate both types of molecules in blood and urine. This technique was reliable, as it allowed to clearly identify the presence of rhEPO in urine and blood. However, although the proposed method was powerful as long as the biologic samples were collected within 24 hours after the last rhEPO injection, it appeared to be far less sensitive on samples collected later after injection.

In June 2000—a few weeks before the Sydney Olympic Games—Lasne and de Ceaurriz[177] presented in *Nature* an innovative test based on the isoelectric separation of urinary EPO isoforms on a polyacrylamide gel followed by a double blotting process.[178] In the past 10 years, this test has been adapted to several recombinant EPO forms, such as darbepoetin-α, whose isoforms are located in the most acidic part of the gel, epoetin-δ, or more recently, generic (biosimilar) or "copy" EPOs.

Glucocorticosteroids

Glucocorticosteroids (GCs) were first purified and manufactured in the 1930s and 1940s following the discovery of their potent anti-inflammatory actions.[179] GCs are widely used in medicine and have shown unchallenged therapeutic potential in several chronic inflammatory and other diseases.

GCs are also widely used in sports medicine for the treatment of conditions such as asthma and acute injuries. Nevertheless, their beneficial effect in certain conditions in sports, where inflammation is only a secondary reaction, remains to be validated.[180]

According to the World Anti-Doping Code, all orally, rectally, intravenously, and intramuscularly administered GCs are prohibited, and their medical use requires a standard therapeutic use exemption. Administration of GCs by all other routes requires an abbreviated therapeutic use exemption, except dermatologic preparations, which are not prohibited.[180] Because of the complexity of GCs, determining the boundaries between their medical use and abuse is a constant challenge for antidoping organizations.

The first use of GCs as performance-enhancing drugs was described in the 1960s.[179] With regard to athletes, the most interesting systemic effect of GCs is energy production by stimulation of gluconeogenesis and mobilization of amino acids and fatty acids. A possible increase in cardiovascular performance is a matter of debate, as there is no evidence for such effects. As a consequence, systemic GCs have been misused for decades to enhance performance, and they once belonged to the group of most commonly used doping substances in sports.[180] Indeed, the expected effects of the use and abuse of GCs are numerous: neurostimulatory effects at cerebral GC receptors could attenuate central impressions of fatigue, and anti-inflammatory and analgesic effects could inhibit sensations of muscle pain on effort and raise the fatigue threshold.[181]

Few studies have examined the effects of GCs on exercise performance. An extensive review of the scientific literature performed by Duclos[182] showed two types of results: studies supporting the hypothesis that there is no relationship between performance and corticosteroid use in humans (negative studies) and studies supporting the hypothesis that there are relationships between performance and corticosteroid use in humans (positive studies).

Inconsistencies found regarding the ergogenic effect of GC administration in humans may be attributed to (1) the GC administration dosage, route, and mode (acute or short term); (2) the type, duration, and intensity (submaximal, maximal) of exercise tested; (3) the participants (highly trained or professional vs. recreational trained); (4) the differences in diet, such as whether or not experiments are food controlled and whether or not subjects fasted; and (5) GC intake coupled or not with intensive training.[182]

It is noteworthy that data reported by the "negative studies" mainly was derived from acute administration of GCs. Animal and human studies performed using higher doses of GCs and/or longer periods of administration (positive studies) clarified the effects of GC based on scientific evidence and clearly demonstrated that GCs have ergogenic effects in both animals and humans.[182]

Adverse Effects

GCs have pleiotropic effects, causing several adverse effects, especially at higher doses and for long periods, such as osteoporosis, insulin resistance, and cardiovascular conditions (e.g., hypertension and atherosclerosis).[183] Moreover, a major (possibly life-threatening) complication can arise on the withdrawal of GCs: acute adrenal insufficiency.

Detection

The detection of the administration of GCs is complicated by the fact that the human body produces these steroids naturally. Several groups have described protocols and screening methods for the analysis of endogenous GC urinary metabolites using liquid chromatography/mass spectrometry. Some methods allow for the analysis of a large number of analytes from most of the classes in the WADA Prohibited List, including anabolic agents, β2-agonists, hormone antagonists and modulators, diuretics, stimulants, narcotics, glucocorticoids, and β-blockers, and do so while meeting the WADA sensitivity requirements.[184]

Endocrinology and Aging

ANNEWIEKE W. VAN DEN BELD AND STEVEN W.J. LAMBERTS

CHAPTER OUTLINE

KEY POINTS

- Treatment of subclinical hypothyroidism in older individuals is not associated with clinical benefits. In younger individuals, it is associated with fewer ischemic heart disease events, but this is not evident in older people (>70 years).
- Subclinical hyperthyroidism is associated with an increased risk of total and ischemic heart disease mortality, as well as incident atrial fibrillation. Currently, treating subclinical hyperthyroidism is recommended when the thyroid-stimulating hormone level is <0.1 mU/L, and confirmed after a 3- to 6-month period, in all individuals 65 years of age or older; postmenopausal women not on bisphosphonates or estrogen; and patients with cardiac risk factors, heart disease, or osteoporosis. At a thyroid-stimulating hormone level between 0.1 and 0.5 mU/L, treatment should be considered only for individuals 65 years of age or older and in patients with cardiac disease or hyperthyroid symptoms.
- Aging is associated with late-day and evening increases in cortisol levels; earlier morning cortisol maximum (phase advance)—for example, 6:30 AM (older) versus 9:00 AM (younger); lower circadian amplitude; and more irregular cortisol secretion patterns.
- Estrogen hormone therapy is currently only recommended in the perimenopausal period in those women suffering from menopausal symptoms. Hormone therapy is not indicated for cardioprotection for women in their 70s.
- The current recommendation is not to treat asymptomatic older men with age-related decline in testosterone levels. Clinicians can consider offering testosterone therapy on an individualized basis to older men with low testosterone levels and clinically significant symptoms of androgen deficiency. Control of prostate size, prostate-specific antigen levels, and hematocrit is mandatory.
- During the aging process, growth hormone–insulin-like growth factor 1 axis activity declines. At present, there is no evidence to recommend medical intervention in the growth hormone–insulin-like growth factor 1 axis as an antiaging effort to prolong life or rejuvenate healthy elderly people.

Global life expectancy at birth is currently 69.1 years for men and 73.8 years for women.[1] Twenty-nine countries have an average life expectancy of 80 years or higher. Life expectancy increases accelerated in most regions from 2000 onward, and overall there was a global increase of 5 years in life expectancy between 2000 and 2015. Average global life expectancy at birth is predicted to further increase by 4 years by 2030.[1] Between 1950 and 2050, the number of people in the world older than 80 years is expected to increase from 14.5 million to 394.7 million.[2]

It is not clear, however, whether these additional years will be satisfactory. Healthy life expectancy in high-income countries at birth in 2015 for males and females combined was 69.8 years, 8.9 years lower than total life expectancy at birth. In general, healthy life expectancy is on average 11.7% shorter than life expectancy (ranging from 9.3–14.7% between countries).[1] Most data indicate a modest gain in the number of healthy years lived but a far greater increase in years of compromised physical, mental, and social function.[3] The number of days with restricted activity and admissions to hospitals and nursing homes increases sharply after 70 years of age.[4] The compression-of-morbidity hypothesis[5] suggests that it may be possible to reduce cumulative lifetime morbidity. Since chronic illness and disability usually occur late in life, cumulative lifetime disability could be reduced if primary prevention measures postpone the onset of chronic illness. Indeed, smoking, body mass index, and exercise patterns in midlife and late-adulthood are important predictors of subsequent disability.[6] Not only do persons with better health habits live longer, but in such persons, disability is postponed and compressed into fewer years at the end of life.

Aging and Physical Frailty

Throughout adult life, all physiologic functions start to decline gradually.[7] There is a diminished capacity for cellular protein synthesis, a decline in immune function, an increase in fat mass, a loss of muscle mass and strength, and a decrease in bone mineral density.[7] Most older adults die of atherosclerosis, cancer, or dementia, but in an increasing number of the "healthy" oldest old, loss of muscle strength is the limiting factor that determines their chances of an independent life until death.

Age-related disability is characterized by generalized weakness, impaired mobility and balance, and poor endurance. In the oldest old, this state is termed *physical frailty*, defined as "a state of reduced physiological reserves associated with increased susceptibility to disability."[8] Clinical correlates of physical frailty include falls, fractures, impairment in activities of daily living, and loss of independence. Falls contribute to 40% of admissions to nursing homes.[9]

Loss of muscle strength is an important factor in the development of frailty. Muscle weakness can be caused by aging of muscle fibers and their innervation, osteoarthritis, and chronic debilitating diseases.[10] A sedentary lifestyle, decreased physical activity, and disuse, however, are also important determinants of the decline in muscle strength.

In a study of 100 frail nursing home residents (average age 87 years), lower extremity muscle mass and strength were closely related.[11] Supervised resistance exercise training (45 minutes three times a week for 10 weeks) doubled muscle strength and significantly increased gait velocity and stair-climbing power. This finding demonstrates that frailty in the elderly population is not an irreversible effect of aging and disease but can be influenced and perhaps even prevented.[11] Further, in nondisabled elderly persons living in the community, objective measures of lower extremity function are highly predictive of subsequent disability.[12] Prevention of frailty may be achieved by caloric and protein support, vitamin D supplementation, reduction in polypharmacy, and working (training).[13] However, exercise is difficult to implement in the daily routine of the aging population, and the number of dropouts from exercise programs is very high.

Part of the aging process involving body composition (i.e., loss of muscle [strength] and bone, increase in fat mass) might also be related to changes in the endocrine system.[14] Current knowledge has shed light on the effects of long-term hormone replacement therapy on body composition, as well as on atherosclerosis, cancer formation, and cognitive function.

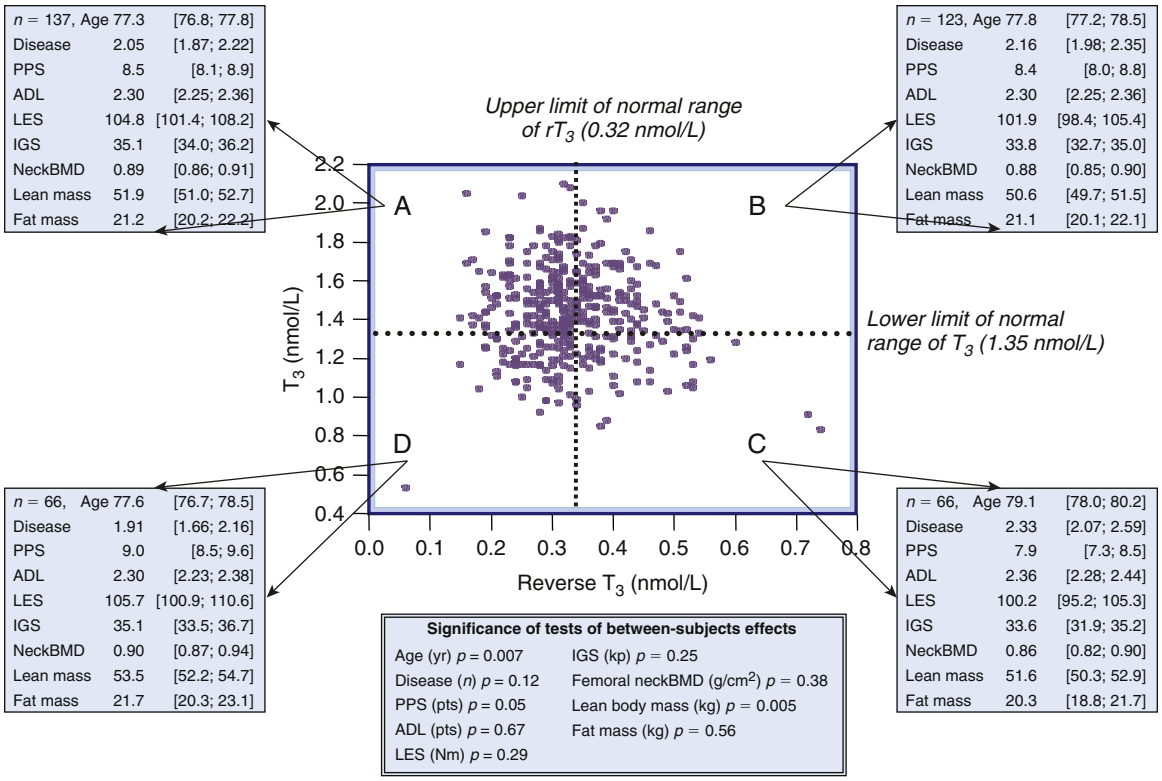
The Endocrinology of Aging

The two most important clinical changes in endocrine activity during aging involve the pancreas and the thyroid gland. Approximately 40% of individuals age 65 to 74 years and 50% of those older than 80 years have impaired glucose tolerance or diabetes mellitus, and in nearly 50% of elderly adults with diabetes, the disease is undiagnosed.[15] These adults are at risk for development of secondary, mainly macrovascular, complications at an accelerated rate. Pancreatic, insulin receptor, and postreceptor changes associated with aging are critical components of the endocrinology of aging. Apart from decreased (relative) insulin secretion by the beta cells, peripheral insulin resistance related to poor diet, physical inactivity, increased abdominal fat mass, and decreased lean body mass contributes to the deterioration of glucose metabolism.[16] Dietary management, exercise, hypoglycemic agents, and insulin are the four components of treatment for these patients, whose medical care is costly and intensive (see Chapter 27).

Age-related thyroid dysfunction is also common.[17] Lowered plasma thyroxine (T_4) and increased thyrotropin concentrations occur in 5% to 10% of elderly women.[17] These abnormalities are primarily caused by autoimmunity and are thus an expression of age-associated disease rather than a consequence of the aging process. Normal aging is accompanied by an increase in serum thyrotropin levels and seems to be dependent on the regional iodine intake.[18-21] Serum free T_4 levels remain largely unaffected during aging, but decreased peripheral degradation of T_4 results in a gradual age-dependent decline in serum triiodothyronine (T_3) concentrations.[17,22] The magnitude and pattern of changes in thyroid function during aging, however, are highly variable among individuals.[21,23] This slight decrease in plasma T_3 concentrations occurs largely within the broad normal range of the healthy elderly population and has not been convincingly related to functional changes during the aging process. It remains to be clarified why serum thyroid-stimulating hormone (TSH) levels increase with advancing age. Several mechanisms, like a changed pituitary sensitivity or affected TSH glycosylation and thus TSH bioactivity, have been proposed.[19] The detrimental effects of overt thyroid dysfunction in elderly individuals are clearly recognized. However, the clinical relevance of mild forms of hypo- and hyperthyroidism are a matter of debate.

Subclinical hypothyroidism (SCH) is present in about 4% to 8.5% of adults in the United States without known thyroid disease.[24] Subtle thyroid dysfunction in the oldest-old fraction of the elderly population (i.e., those >85 years) is often present. Although SCH in younger individuals is associated with an increased risk of atherosclerosis,[25] such an association is not present in elderly subjects older than 65 years.[26,27] In addition, an observational study of real-life practice performed from data obtained from the United Kingdom General Practitioners Research Database showed that treatment of SCH with levothyroxine was associated with fewer ischemic heart disease events in younger individuals, but this was not evident in older people (>70 years).[26] Treatment with levothyroxine in persons with SCH older than 65 years for 1 year did not provide improvement of hypothyroid symptoms or tiredness.[28] In fact, in 85-year-old "healthy" individuals, hypothyroidism was, in the subsequent 4 years, accompanied by lower all-cause and cardiovascular mortality when compared with euthyroid individuals.[29] In a group of 400 males with a mean age of 78 years, low serum free T_4 and T_3 (with normal reverse T_3 [rT_3]) concentrations were associated with better physical performance and 4-year survival, whereas subjects with low serum T_3 and high rT_3 concentrations (i.e., fulfilling the criteria for "low T_3 syndrome") did not show a survival advantage and had lower physical activity[23] (Fig. 28.1). These findings were confirmed in other studies that link lowered thyroid hormone levels to less frailty.[30,31] These studies support the concept that some degree of physiologically decreased thyroid activity at the tissue level might even have favorable effects in the oldest-old subjects, but caution should be exercised when interpreting the predictive value of thyroid dysfunction in old subjects, which may give a double-faced "Janus response" if not considered in the appropriate context.[32,33]

Subclinical hyperthyroidism seems to be associated with an increased risk of total and ischemic heart disease mortality, and incident atrial fibrillation, as was concluded by recently pooled individual data from 10 prospective cohort studies.[34] In addition, subclinical hyperthyroidism is associated with an increased



• **Fig. 28.1** Overview of the values of triiodothyronine (T_3) and reverse T_3 (rT_3) within a population of 403 elderly men. The *spotted lines* indicate the normal values of T_3 and reverse T_3. *PPS*, physical performance score; *ADL*, number of problems in activities of daily living; *LES*, maximum leg extensor strength; *IGS*, isometric grip strength; *BMD*, bone mineral density. (From van den Beld AW, Visser TJ, Feelders RA, et al. Thyroid hormone concentrations, disease, physical function, and mortality in elderly men. *J Clin Endocrinol Metab.* 2005;90[12]:6403–6409.)

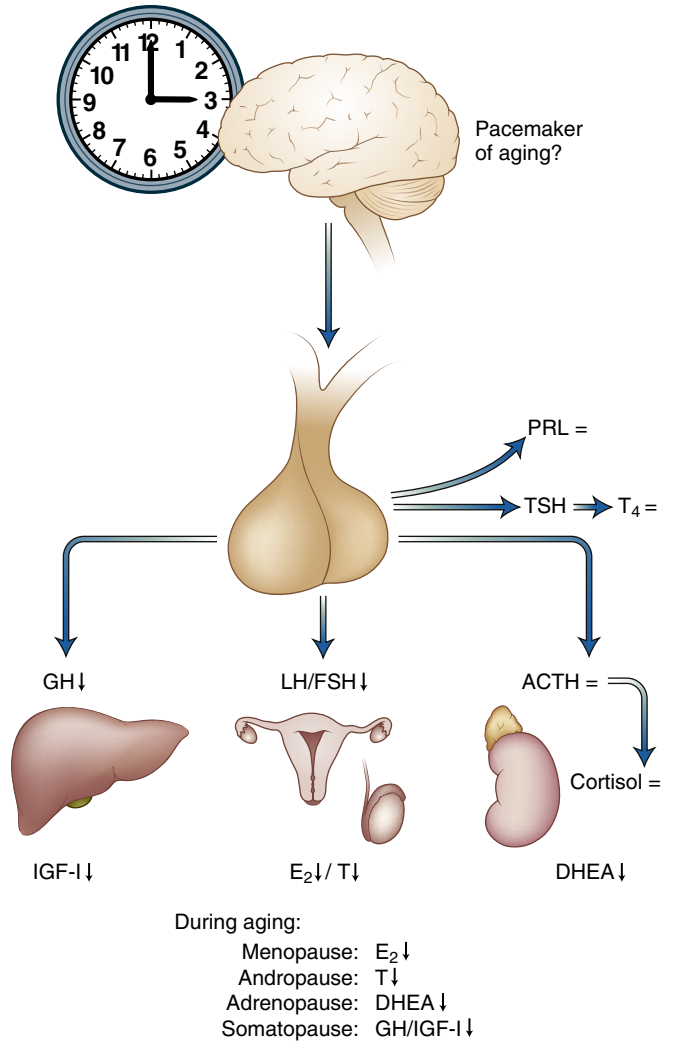
fracture risk.[35] Controversy persists about whether treatment is warranted. The latest consensus guidelines recommend treating subclinical hyperthyroidism after diagnosing the underlying disorder, based on the level of TSH suppression. When the TSH is less than 0.1 mU/L, and confirmed after a 3- to 6-month period, treatment is advised in individuals with hyperthyroid symptoms; all individuals 65 years of age or older; postmenopausal women not on bisphosphonates or estrogen; and patients with cardiac risk factors, heart disease, or osteoporosis. At a TSH level between 0.1 and 0.5 mU/L, treatment should be considered only for individuals 65 years of age or older and in patients with cardiac disease, osteoporosis, or hyperthyroid symptoms.[36] Furthermore, a recent systematic review concluded that there is a substantial body of evidence to support the association between subclinical hyperthyroidism and cognitive impairment. There is, however, lack of evidence to suggest that antithyroid treatment might delay the development of dementia.[37]

In addition, cortisol homeostasis is influenced by age, mostly via unknown mechanisms. Most clinical studies show circadian cortisol changes with age (reviewed by Veldhuis and colleagues[38]). Aging is associated with late-day and evening increases in cortisol levels; earlier morning cortisol maximum (phase advance)—for example, 6:30 AM (older) versus 9:00 AM (younger); lower circadian amplitude (24-hour decrement for peak minus nadir or attenuated wake-evening slopes); and more irregular (less orderly) cortisol secretion patterns.

The question remains to which degree these alterations reflect or cause aging-associated changes in functional ability, cognition, and possibly depression. A few studies have investigated associations between parameters of the hypothalamic-pituitary-adrenal axis and functional parameters. More dynamic activity of the hypothalamic-pituitary-adrenal axis (i.e., a greater diurnal decline) seems to be associated with better physical performance in later life,[39] as well as better cognitive function.[40] In a longitudinal setting, higher urinary cortisol levels are associated with an increased risk in Alzheimer disease pathology.[41] Further, data from a prospective cohort study of more than 400 men and women, with a mean age of 61 years, demonstrated that a flatter slope in cortisol levels across the day was associated with increased risk of all-cause 6-year mortality.[42] Results from the Longitudinal Amsterdam Study of Aging showed that higher morning salivary cortisol levels were associated increased mortality in men, and that higher nighttime salivary cortisol levels were associated with increased mortality in women.[43] Future clinical research is necessary to determine whether measuring diurnal cortisol measures is relevant in identifying those who might benefit from intervention therapies.

Three other hormonal systems exhibit lowered circulating hormone concentrations during normal aging, and these changes have thus far been considered mainly physiologic (Figs. 28.2 and 28.3). Hormone replacement strategies have been developed, but many aspects remain controversial, and replenishing hormone blood levels to those found in 30- to 50-year-old patients has not yet uniformly proved to be beneficial and safe.

The most dramatic and rapidly occurring change in women around age 50 years is *menopause*.[44] Cycling estradiol production during the reproductive years is replaced by very low, constant



• **Fig. 28.2** During aging, declines in the activities of several hormonal systems occur. *PRL*, prolactin; T_4, thyroxine; *TSH*, thyroid-stimulating hormone. *Left*. A decrease in growth hormone (GH) release by the pituitary gland causes a decrease in the production of insulin-like growth factor 1 (IGF1) by the liver and other organs (somatopause). *Middle*. A decrease in release of gonadotropin luteinizing hormone (LH) and follicle-stimulating hormone (FSH) and decreased secretion at the gonadal level (from the ovaries, decreased estradiol [E_2] from the testicle, decreased testosterone [T]) cause menopause and andropause, respectively. (Immediately after the initiation of menopause, serum LH and FSH levels increase sharply.) *Right*. The adrenocortical cells responsible for the production of dehydroepiandrosterone (DHEA) decrease in activity (adrenopause) without clinically evident changes in corticotropin (adrenocorticotropic hormone [ACTH]) and cortisol secretion. A central pacemaker in the hypothalamus or higher brain areas (or both) is hypothesized, which together with changes in the peripheral organs (the ovaries, testicles, and adrenal cortex) regulates the aging process of these endocrine axes.

estradiol levels. For many years, the prevailing view was that menopause resulted from exhaustion of ovarian follicles. An alternative perspective is that age-related changes in the central nervous system and the hypothalamic-pituitary unit initiate the menopausal transition. The evidence that both the ovary and the brain are key pacemakers in menopause is compelling.[44]

Changes in the activity of the hypothalamic-pituitary-gonadal axis in men are slower and more subtle. During aging, a gradual decline in serum total and free testosterone levels occurs.[45] *Andropause* is characterized by a decrease in testicular Leydig cell numbers and their secretory capacity, as well as by an age-related decrease in episodic and stimulated gonadotropin secretion.[46,47] The primary site of the aging effect appears to be the Leydig cell's ability to respond to luteinizing hormone (LH) with increased testosterone production.

The second hormonal system demonstrating age-related changes is *adrenopause*, a term that describes the gradual decline in circulating levels of dehydroepiandrosterone (DHEA) and its sulfate (DHEAS).[48,49] Adrenal secretion of DHEA gradually decreases over time, whereas corticotropin secretion, which is physiologically linked to plasma cortisol levels, remains largely unchanged. The decline in DHEA and DHEAS levels in both sexes therefore contrasts with the maintenance of plasma cortisol levels and seems to be caused by a selective decrease in the number of functional zona reticularis cells in the adrenal cortex instead of being regulated by a central (hypothalamic) pacemaker of aging.[50]

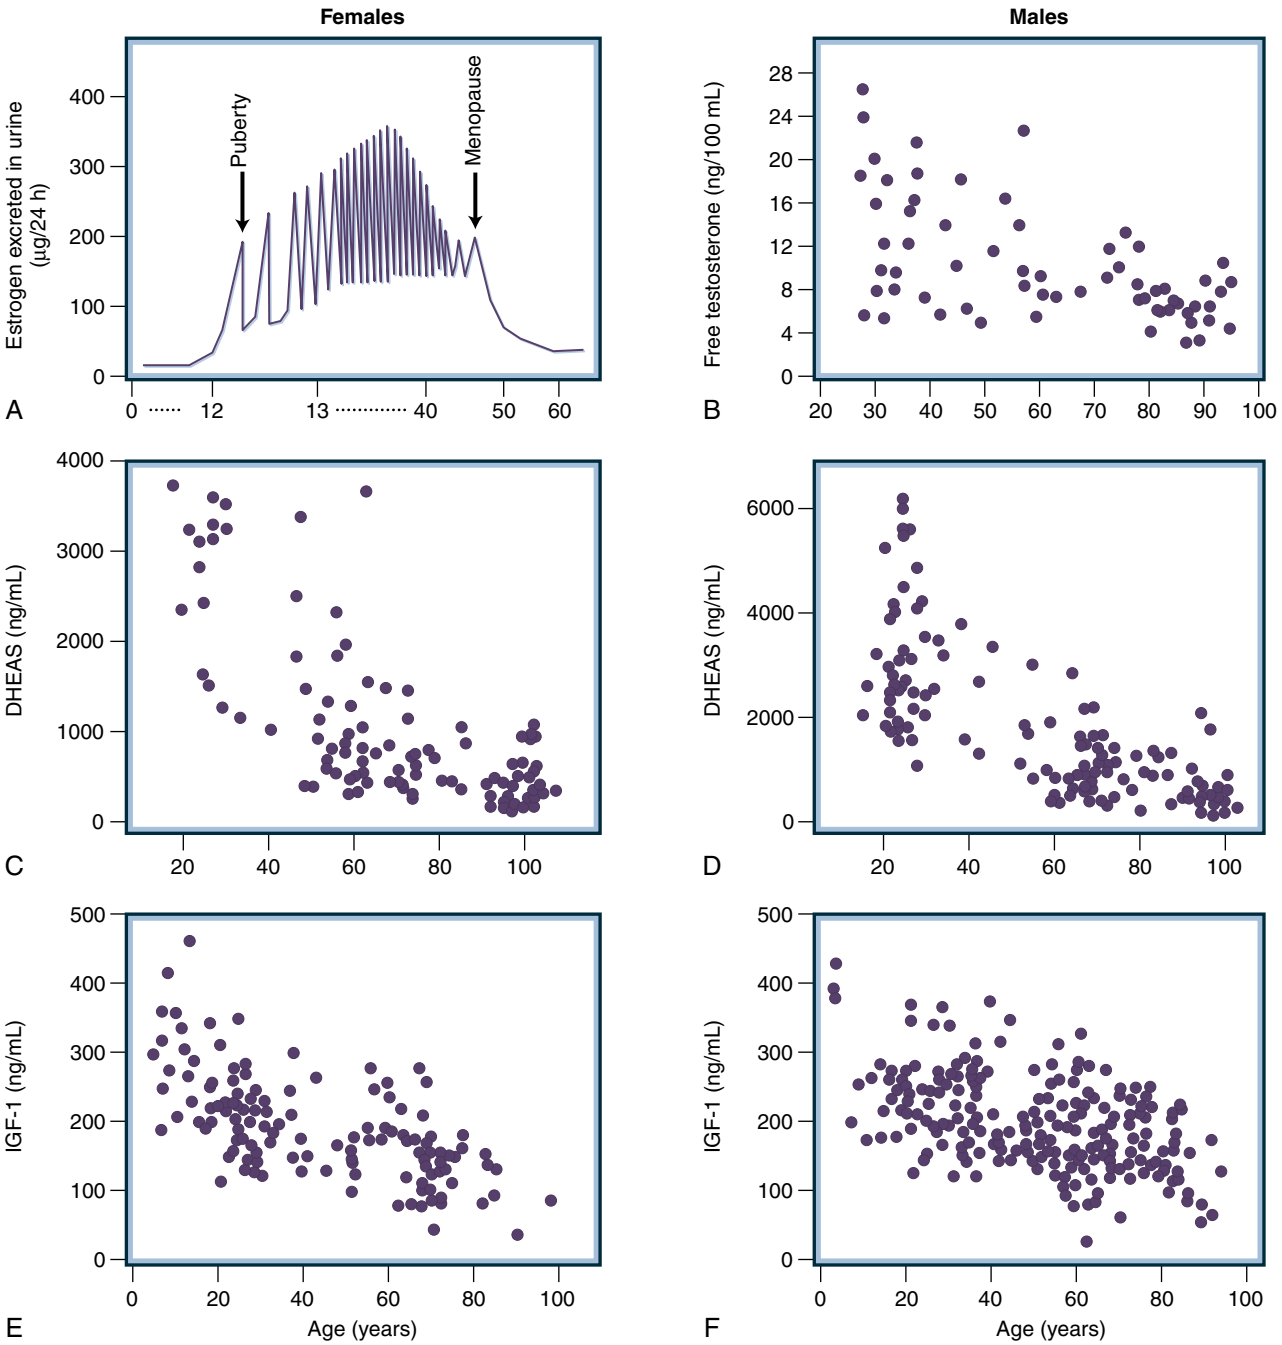
The third endocrine system that gradually declines in activity during aging is the growth hormone (GH)–insulin-like growth factor 1 (IGF1) axis[51] (see Fig. 28.3[219]). Mean pulse amplitude and duration and fraction of GH secreted, but not pulse frequency, gradually decrease during aging. In parallel, a progressive drop in circulating IGF1 levels occurs in both sexes.[51,52] There is no evidence for a peripheral factor in this process of *somatopause*, and its triggering pacemaker seems mainly localized in the hypothalamus because pituitary somatotropes, even in the oldest old, can be restored to their youthful secretory capacity by treatment with GH-releasing peptides (see later discussion).

It is unclear whether changes in gonadal function (menopause, andropause) are interrelated with the processes of adrenopause and somatopause, which occur in both men and women. In addition, functional correlates (decrease in muscle size and function and in fat and bone mass, progression of atherosclerosis, and decline of cognitive function) have not been demonstrated to be directly causally related to these changes in endocrine activity. However, several effects of normal aging closely resemble features of (isolated) hormonal deficiency (hypogonadism, GH deficiency), which in subjects in middle adulthood are successfully reversed by replacement of the appropriate hormone.[53,54] Although aging does not simply result from a variety of hormone deficiency states, medical intervention in the processes of menopause, andropause, adrenopause, or somatopause might prevent or delay some aspects of the aging process.

Menopause

Menopause is the permanent cessation of menstruation resulting from the loss of ovarian follicular function and is diagnosed retrospectively after 12 months of amenorrhea. In most women, vasomotor reactions, depressed mood, and urogenital complaints accompany this period of estrogen decline. In the subsequent years, the loss of estrogens is followed by a high incidence of cardiovascular disease, loss of bone mass, and cognitive impairment. The average age of menopause (51.4 years) has not changed over time and seems to be largely determined by genetic factors.

In the past decade, antimüllerian hormone (AMH) has been proposed as a marker to predict age at natural menopause. In women, AMH is exclusively produced by granulosa cells of ovarian follicles during the early stages of follicle development. After an initial increase until early adulthood, AMH concentrations slowly decrease with increasing age until becoming



• **Fig. 28.3** Changes in the hormone levels of normal women (*left*) and men (*right*) during the aging process. A and B, Estrogen secretion throughout an individual normal woman's life (expressed as urinary estrogen excretion) (A) and mean free testosterone (T) index (the ratio of serum total testosterone to sex hormone–binding globulin levels) during the life span of healthy men (B). C and D, Serum dehydroepiandrosterone sulfate (DHEAS) concentrations in 114 healthy women (C) and 163 healthy men (D). E and F, The course of serum insulin-like growth factor 1 (IGF1) concentrations in 131 healthy women (E) and 223 healthy men (F) during aging. Note the difference in the distribution of ages in the different panels. (A and B from Guyton A. *Textbook of Medical Physiology,* 8th ed. Philadelphia: Saunders; 1991:899. C and D modified from Ravaglia G, Forti P, Maioli F, et al. The relationship of dehydroepiandrosterone sulfate [DHEAS] to endocrine-metabolic parameters and functional status in the oldest-old. Results from an Italian study on healthy free-living over-ninety-year-olds. *J Clin Endocrinol Metab*. 1996;81[3]:1173–1178. E and F modified from Corpas E, Harman SM, Blackman MR. Human growth hormone and human aging. *Endocr Rev.* 1993;14[1]:20–39.)

undetectable about 5 years before menopause when the stock of primordial follicles is exhausted.[55] In a long-term follow-up study, 257 women were followed for 11 years. It was demonstrated that using age and AMH, the age range in which menopause will subsequently occur can be individually calculated.[56,57] A study of 401 women participating in the Penn Ovarian Aging Study demonstrated that in women with a baseline AMH level below 0.20 ng/mL, the median time to menopause was 5.99 years (95% confidence interval [CI], 4.20–6.33) in the 45- to 48-year age group and 9.94 years (95% CI, 3.31–12.73) in the 35- to 39-year age group. With higher baseline AMH levels above 1.50 ng/mL, the median time to menopause was 6.23 years in the oldest age group and more than 13.01 years in the youngest age group. Smoking significantly reduced the time to menopause.[58]

Perimenopausal Use of Hormone Therapy

Typical symptoms that result from the sudden decrease in estrogen production around menopause are menstrual cycle disorders, vasomotor changes (hot flushes, night sweats), and urogenital complications (atrophic vaginal irritation and dryness, dyspareunia, atrophic urethral epithelium leading to micturition disorders). Additional symptoms are irritability, mood swings, joint pain, and sleep disturbances. Frequency, severity, onset, and duration of symptoms vary widely between individuals and between ethnic groups. About 75% of women in Western societies experience so few troublesome symptoms during the menopausal transition that hormone therapy (HT) is not needed or requested.[59] HT rapidly alleviates the symptoms of menopause. Hot flushes and vasomotor instability, as well as symptoms of urogenital atrophy, rapidly disappear on the start of HT.

Long-Term Hormone Replacement Therapy

Because life expectancy is increasing, the time a woman spends after menopause constitutes more than one third of her life. A decade ago, long-term use of HT (5–10 years) was considered to offer advantages with regard to the prevention of the three chronic disorders most common in the elderly: cardiovascular diseases, osteoporosis, and dementia. In the early 1900s, several cross-sectional and prospective studies demonstrated a statistically significant reduction in coronary heart disease in menopausal women taking HT. Grady and colleagues[60] presented a meta-analysis of published observational studies and reported that HT was associated with a reduction in fatal coronary heart disease by one third. A meta-analysis of 25 observational studies conducted between 1976 and 1996 showed that the relative risk for coronary heart disease in women who ever used HT compared with never users was 0.70.[61]

The Nurse's Health Study was a comprehensive investigation conducted in 121,700 female nurses age 30 to 55 years. In the latest report, compiled with data from 70,533 postmenopausal nurses followed for 20 years, the overall risk of coronary heart disease in current users of HT was reduced, with a relative risk of 0.61.[62]

Over the past 15 years, however, findings from several prospective randomized controlled trials (RCTs) have fully changed the attitudes concerning the benefits and harms of HT. The Women's Health Initiative (WHI) trial comprised two large, randomized, placebo-controlled clinical trials, including estrogen-only and combined estrogen-progestin studies in more than 161,000 "healthy" postmenopausal women, age 50 to 79 years.[63] It was expected that the WHI would definitively answer whether or not estrogen is cardioprotective. However, the estrogen-progestin versus placebo trial, which involved more than 16,000 women, was discontinued early because of an increase in cardiovascular complications (coronary heart disease, stroke, and venous thromboembolism) and increased incidence of breast cancer in the treatment group.[63] Although important benefits were also seen (risk reduction for fractures and colon cancer), there was concern that the risks of combined estrogen-progestin outweighed the benefits. The estrogen-only versus placebo trial included nearly 11,000 women who had undergone hysterectomy and therefore did not require a progestin. This trial was also stopped early because a small increase in breast cancer and coronary heart disease risk was seen, although hip fracture risk was reduced.[64]

Three other RCTs supported the absence of benefit of HT for prevention of coronary heart disease and ischemic stroke.[65,66] These studies were carried out in postmenopausal women with documented ischemic stroke or transient ischemic attack,[67] in women after documented myocardial infarction,[65] or in women with documented coronary heart disease.[66]

Taken together, the WHI, which studied women presumed healthy at recruitment, and the 3 other trials carried out in women with documented cardiovascular disorders argue strongly against the earlier assumptions made on the basis of observational studies that estrogen users had a 30% to 40% reduced risk of coronary heart disease mortality and morbidity relative to nonusers.

A series of commentaries has addressed the differences in outcome between the observational studies and the randomized trials.[68,69] Healthy user bias, the age at which study participants started HT, the different estrogen and progestin preparations, and dose all have been mentioned as possible confounders.

Subsequently, reassessment of the data from the WHI and other studies has led to a different interpretation of the data, in that groups of peri- and early postmenopausal women may in fact derive cardiovascular benefits from hormone replacement therapy. In this regard, much interest has been focused on the "timing hypothesis," which states that estrogens are atheroprotective if used in an early phase of atherosclerosis development. In an arm of the WHI in which 50- to 59-year-old women were treated with conjugated estrogens, coronary artery calcium scores were slightly but significantly lower.[70] The timing hypothesis is also supported by a recent Danish study in which it was shown that participants who were assigned to HT and were younger than 50 years at baseline had a 65% lower risk of a combined outcome of all-cause mortality, heart failure, or myocardial infarction. Unfortunately, there was no placebo, and the trial was not blinded.[71] Further, an independent subanalysis from the WHI also supported the timing hypothesis. This study also demonstrated that the duration of treatment is of importance. Comparison of the rate ratios for years 1 through 6 versus years 7 through 8 showed a statistically significant (p = 0.003) reduction in cardiovascular disease risk after more than 6 years of use of conjugated equine estrogens (CEE) versus placebo.[72] In summary, the majority of long-term large observational studies and several small RCTs strongly suggest that menopausal HT should be protective against atherosclerosis if initiated early but is potentially harmful if administered to women who already have mature at-risk plaque.[73]

Subsequently, several studies have confirmed the risk of breast cancer, which increases with longer duration of HT.[74-76] In the Million Women Study, current users of estrogen had an increased

TABLE 28.1 Absolute Risks and Benefits of Clinical Events With Estrogen-Progestin and Estrogen-Only Therapy Compared With Placebo in the Women's Health Initiative Trial.[a]

	ESTROGEN-PROGESTIN THERAPY		ESTROGEN THERAPY

Modified from Hodis HN. Assessing benefits and risks of hormone therapy in 2008: new evidence, especially with regard to the heart. *Cleve Clin J Med.* 2008;75 Suppl 4:S3–S12.

risk of incident invasive breast cancer of 30%, whereas in women using estrogen plus progestin, this risk had doubled. Breast cancer risk was unchanged in both the older and younger women with a prior hysterectomy treated with estrogen only. Past users of HT also had no increased risk.[77]

In addition, the earlier expectations from observational studies that estrogen use might prevent cognitive decline were not confirmed by randomized, placebo-controlled trials. Estrogen therapy alone did not reduce dementia or mild cognitive impairment in women 65 years of age or older, but the estrogen-progestin combination resulted in slightly increased risks for both end points.[78]

The efficacy of HT in the prevention of osteoporotic fractures remains undisputed with regard to both hip and other fractures[79] (Table 28.1).

The findings of the WHI trial are so important and have been so broadly publicized that they have created the perception that HT, in general, always carries risks that exceed its benefits. Interestingly, recently, data have been published presenting the analysis of two combined studies of the WHI with extended duration of follow-up of 18 years. Compared with placebo, no differences were found in all-cause mortality (cardiovascular and cancer related) in the CEE plus medroxyprogesterone acetate treated group (treated for a mean of 5.6 years) nor in the CEE trial only (treated for a mean of 7.2 years). Mortality risk is similar compared with the placebo group despite an increased risk of breast cancer in the CEE plus medroxyprogesterone acetate treated group.[80] However, it remains unclear whether longer duration of treatment would be of benefit and outweigh the risks.

Given the noted uncertainties, HT can be considered in the perimenopausal period in those women suffering from menopausal symptoms.[81] For menopausal women older than 60 years or more than 10 years past menopause with bothersome vasomotor symptoms who do not have contraindications or excess cardiovascular or breast cancer risk, it is suggested to initiate estrogen therapy for those without a uterus and estrogen plus progesterone for those with a uterus. An association between endometrial cancer and estrogen use was observed many years ago. Ten years of unopposed estrogen use increases the risk for endometrial cancer 10-fold.[60] For this reason, the HT regimens were supplemented with progestogens, which almost completely prevented this excess risk for endometrial cancer.

Presently advised doses of estrogen were originally designed to prevent bone loss, and progestogen regimens were opposed to prevent endometrial cancer. Several estrogen and progestogen preparations are available for HT.[59] Components of available preparations vary in their effects on different target tissues. Commercial preparations differ in their clinical effect by design, and individual women differ in their responses. HT can be administered orally, transdermally, topically, intranasally, or as subcutaneous implants.

Although HT in the perimenopausal state can cause some symptoms (e.g., vaginal discharge, uterine bleeding, and breast tenderness), it relieves many other symptoms, including hot flushes and the severity of night sweats.[82] Grady has estimated that about one serious adverse event will occur among every thousand 50-year-old women using HT for 1 year. The HT regimen used in the WHI trial combined 0.625 mg/day of CEE and 2.5 mg/day of medroxyprogesterone acetate. The dose of estrogen necessary to diminish perimenopausal symptoms, however, can be lower in many women. A dose of 0.3 or 0.45 mg/day of CEE is effective at diminishing the number and the intensity of hot flushes as well.[83]

Selective Estrogen Receptor Modulators

In the search for optimal hormone replacement therapy during menopause, it was observed that tamoxifen has variable antiestrogenic and estrogenic actions in different tissues.[84,85] Tamoxifen suppresses the growth of estrogen receptor–positive breast cancer cells. Long-term treatment of menopausal patients with breast cancer with tamoxifen also lowered the incidence of new (contralateral) breast cancer by 40%. In addition, the number of cardiovascular incidents decreased by 70%, and the age-related decrease in bone mineral density was partially prevented.[86]

These initially puzzling observations were explained by the fact that tamoxifen and other compounds such as raloxifene have selective estrogen receptor–modulating effects, exerting antiestrogenic actions on normal and cancerous breast tissue but agonistic actions on bone, lipids, and blood vessel walls.[87] These effects of tamoxifen and raloxifene may be explained by differential stabilization of the conformation of the estrogen receptor, which facilitate interactions with coactivator or corepressor proteins, and subsequently initiate or suppress transcription of target genes. These specific interactions in the target cell lead to tissue selective actions.[88] Several other selective estrogen receptor modulators (SERMs) have been evaluated for the treatment of breast cancer, osteoporosis, and menopausal symptoms.[89]

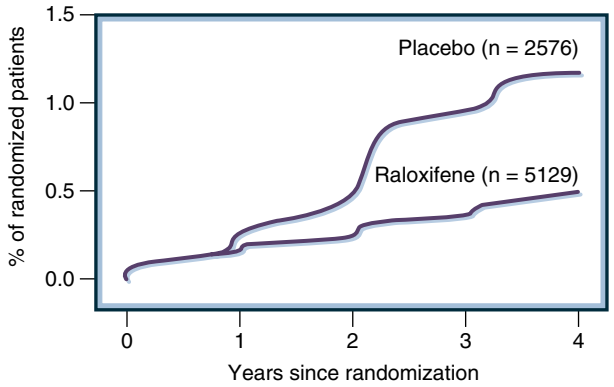
The efficacy and safety of raloxifene for the prevention of osteoporosis in postmenopausal women were demonstrated in a study that found a 2.5% increase in bone mineral density in the lumbar spine and hip in a group of postmenopausal nonosteoporotic women treated with raloxifene for 2 years.[90] A significant reduction of vertebral fracture risk by raloxifene was subsequently demonstrated.[91] A meta-analysis confirmed the effects of raloxifene treatment on reduction of vertebral fracture risk in postmenopausal women without an effect on nonvertebral fracture risk.[92]

In a placebo-controlled clinical trial of 10,000 postmenopausal women with an increased risk of coronary heart disease followed for 5 or 6 years, raloxifene had an overall neutral effect on the incidence of cardiovascular events.[93] The incidence of all strokes did not differ between the raloxifene participants and placebo-treated participants. However, in the raloxifene-treated individuals, there was a higher incidence of fatal stroke, especially in smokers, as well as venous thromboembolic events (incidence rates per 100 women-years 0.22 vs. 0.15 [$p < 0.05$] and 0.39 vs. 0.27 [$p = 0.02$], respectively).[94] Raloxifene, in contrast to tamoxifen and estrogen, does not stimulate endometrial thickness or vaginal bleeding.[90] With regard to side effects, raloxifene causes an increased incidence of leg cramps and hot flushes.[95]

Endocrine approaches to breast cancer prevention have been increasingly successful in recent years. Four trials of tamoxifen administration for 5 years or longer in women at increased risk of breast cancer showed an about 50% reduction in breast cancer, but only for estrogen receptor–positive disease (Fig. 28.4[220]) (refer to Howell[96] for further discussion). Follow-up indicates that there was a carryover effect of tamoxifen after the completion of treatment at 5 years, so the preventive effect at 10 years is significantly greater than at 5 years.

Raloxifene has been compared with placebo in three trials: one in women with osteoporosis,[91,97] one in women with or at risk of cardiac disease,[93] and one in which raloxifene was compared with tamoxifen in women at high risk of breast cancer[98]: a 66%, a 44%, and a 50% risk reduction of breast cancer was noted after 4 to 5 years of raloxifene therapy, respectively. The last trial showed that raloxifene was as effective as tamoxifen.[98] As with the previous tamoxifen studies, raloxifene was only reducing the risk of estrogen receptor α–positive tumors.

In the United States, a 60-mg dose of raloxifene is now indicated for the treatment and prevention of osteoporosis in postmenopausal women, for reduction in risk of invasive breast cancer in postmenopausal women with osteoporosis, and in postmenopausal women at high risk for invasive breast cancer.[99,100] Although approved for use in the European Union for the prevention of vertebral fractures, lasofoxifene was never marketed. In addition, bazedoxifene is approved for use in the European Union. Four RCTs show that bazedoxifene decreases the incidence of new vertebral fractures (relative risk, 0.69: 95% CI, 0.52–0.93). Bazedozifene treatment was not associated with an increased risk of breast cancer or with increases in endometrial thickness or carcinoma.[101-103] Tibolone is a compound that also regulates estrogen activity selectively at different tissues. It has a high efficacy in the treatment of climacteric symptoms and the prevention of bone loss. The compound is approved in many countries but not in the United States. In a 5-year trial, tibolone (2.5 mg/day) was associated with a 45% decrease in vertebral fractures, a 26% decrease in nonvertebral fractures, a 68% decrease in invasive breast cancer, and a 69% decreased risk of colon cancer.[104] However, the tibolone-treated group had an increased risk of stroke (relative hazard, 2.19 [$p = 0.02$]).



• **Fig. 28.4** Effect of raloxifene administration (60–120 mg/day) on the cumulative incidence of breast cancer in 7705 postmenopausal women (mean age, 66.5 years) with osteoporosis. Statistical significance of the difference between the groups was $p < 0.001$. (Modified from Cummings SR, Eckert S, Krueger KA, et al. The effect of raloxifene on risk of breast cancer in postmenopausal women: results from the MORE randomized trial. Multiple Outcomes of Raloxifene Evaluation. *JAMA*. 1999;281[23]:2189–2197.)

Androgen Replacement

In premenopausal women, androgen production originates equally from the adrenal glands and the ovaries. Androgen production in women declines with aging. After menopause, circulating androgen levels decrease by more than 50%.

At present, there is increasing awareness of the impact of low androgen levels on emotional and sexual well-being in perimenopausal women. No single androgen level is predictive of low female sexual function, and the majority of 1423 women age 18 to 75 years with low DHEAS levels had normal sexual function.[105]

The efficacy and safety of testosterone treatment for hypoactive sexual desire disorder in postmenopausal women was studied in a double-blind, placebo-controlled, 52-week trial in which more than 800 women participated.[106] Treatment with a patch delivering 300 μg of testosterone per day resulted in a modest but meaningful improvement in sexual function. Similar results were found in a smaller study among 272 women treated with a testosterone patch for 6 months.[107] The long-term effects of testosterone, including effect on the breast, remain uncertain.

HT, SERMs, or No Treatment?

The issue of hormonal therapy in postmenopausal women is controversial, and many aspects remain unresolved. The idea that HT is a global risk reduction strategy has been abandoned.

Although the general benefits of HT in the short term during and after the menopausal transition are evident in women suffering from estrogen withdrawal symptoms, the balance of the effects of long-term HT after menopause points in general to a negative outcome with more harm than benefits. The evolution of the association of HT and cardiovascular risk from protection to harm and now to possible protection again has resulted in controversy and confusion.[108,109]

HT is usually prescribed for women 45 to 60 years of age who are experiencing vasomotor symptoms. HT is not indicated for cardioprotection for women in their 70s or for women who do not suffer from vasomotor symptoms or urogenital atrophy. Data clearly demonstrate, however, that clinicians can prescribe and women can use (low-dose) HT confidently during the time when therapy is most needed. The debate regarding the potential benefits of HT on cardiovascular risk and/or mortality for women who start therapy in proximity to the menopausal transition is not resolved. The benefit and risk of any therapy, including HT, should be reassessed periodically in each individual based on future scientific evidence.[109]

Currently, a vast armamentarium of other pharmacologic treatments to reduce cardiovascular and bone risks is available; these include cholesterol-lowering statins, β-blockers, SERMs, and bisphosphonates. An optimal choice of these different lifestyle drugs for menopausal women requires individualization of the treatment decision. Coronary artery disease, for example, is a complex disorder resulting from an interaction of genetic predisposition and environmental factors. Risk factor modification (diet, smoking, physical activity) should be advised. Secondary prevention of coronary artery disease and atherosclerosis includes lipid-lowering drugs, aspirin, nitrates, and β-blockers.[110] For women with existing osteoporosis, HT is effective. However, SERMs and especially bisphosphonates come close or are better in their fracture-reducing effects. Recognition of an increased risk for breast cancer in menopausal women is an important consideration in the choice for SERMs. Chemoprevention of breast cancer with raloxifene has become a major consideration in the pharmacologic choice for risk reduction in the long-term preventive treatment of postmenopausal women.

Andropause Versus Late-Onset Hypogonadism

Role of Testosterone During Aging

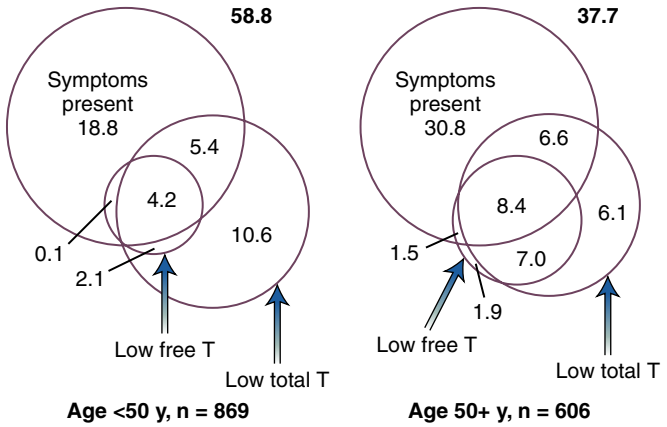
Age-associated hypogonadism does not develop as clearly in men at andropause as in women at menopause. The key difference is the gradual, often subtle change in androgen levels in men versus the precipitate fall of estrogen production in women. It is generally agreed that as men age, there is a decline in serum total testosterone concentration that begins after the age of 40 years. In cross-sectional studies, the annual decline in total and free testosterone is 1.0% and 1.2%, respectively. The higher decline in free testosterone levels is related to the increase in sex hormone–binding globulin (SHBG) levels with age.[45,111] Part of these changes attributed to aging may be confounded by health-related factors such as obesity. It was also reported that serum testosterone was stable across age strata among men self-reporting very good health.[112] It remains unclear whether the well-known biologic changes occurring during aging in men (e.g., reduced sexual activity, muscle mass and strength, and skeletal mineralization) are causally related to these changes in testosterone bioactivity. The gradual decline in testosterone levels is called *late-onset hypogonadism* (LOH). In recent years, there has been major disagreement on how to define androgen deficiency in the elderly man. According to practice guidelines,[113-115] the diagnosis of androgen deficiency in the elderly or LOH, for which testosterone treatment might be considered, should be based on the concurrent presence of consistent symptoms of hypogonadism and unequivocally low serum (free) testosterone.

The biochemical part consists of measuring morning serum total testosterone levels (two times) or determining a "free" testosterone concentration by additionally measuring SHBG levels. Most elderly men have testosterone levels within the normal range, with prevalence estimates of "low" (e.g., <10.4 nmol/L = <300 ng/dL) serum testosterone concentrations generally between 10% and 25%.[116,117] Most of these men with low testosterone levels will not come to clinical attention because testosterone levels are not routinely measured in clinical practice.[118] An important problem with a biochemical approach of the diagnosis of LOH in elderly men is that men with low testosterone may not exhibit clinically significant symptomatology, raising the possibility that large numbers of men, simply by virtue of falling below an arbitrary threshold, are diagnosed as needing testosterone replacement therapy.

In addition, the clinical part to the diagnosis of androgen deficiency of the aging male has important drawbacks.[119] All symptoms and signs of androgen deficiency are nonspecific and readily accounted for or modified by comorbidities and medications. Lethargy, reduced concentration, sleep disturbance, irritability, and depressed mood may relate to physical illness (and side effects of treatment), obesity, and/or lack of physical exercise and other lifestyle issues (e.g., alcohol or drug use), relationship difficulties, and occupational or financial stresses. Indeed, existing screening tools for androgen deficiency lack adequate specificity and sensitivity to be reliably employed in directing clinical diagnosis and treatment.

Araujo and colleagues[118] defined the prevalence of symptomatic androgen deficiency in men by studying the association between symptoms of androgen deficiency (low libido, erectile dysfunction, osteoporosis or fracture, or two of the following symptoms: sleep disturbance, depressed mood, lethargy, or diminished physical performance) and low serum total (<10.4 nmol/L = <300 ng/dL) and free (<0.17 nmol/L = <5 ng/dL) testosterone concentrations. In nearly 1500 men (age 30–79 years), they found 24% with total testosterone less than 10.4 nmol/L and 11% with free testosterone levels less than 0.17 nnol/L. The prevalence of symptoms was as follows: low libido (12%), erectile dysfunction (16%), osteoporosis/fracture (1%), and two or more of the nonspecific symptoms (20%). Although low testosterone levels were associated with symptoms, many men with low testosterone levels were asymptomatic (e.g., in men older than 50 years: 47.6%). In Fig. 28.5, the interrelationships are shown: symptomatic androgen deficiency with low serum testosterone levels (<10.4 nmol/L) was observed in 4.2% of men younger than 50 years and in 8.4% of men older than 50 years. This prevalence rapidly increases with age, amounting to 18.4% among 70-year-old men.

In addition, Wu and colleagues[120] tried to better identify elderly men with LOH. They surveyed a random population sample of 3369 men between the ages of 40 and 79 years (the European Male Aging Study). They proposed minimal diagnostic criteria, consisting of the "syndromic" simultaneous presence of three sexual symptoms (i.e., poor morning erections, decreased sexual interest, and erectile dysfunction), together with a serum



• **Fig. 28.5** Venn diagrams showing the interrelationships among symptoms, low total testosterone (<10.4 nmol/L [<300 ng/dL]), and low free testosterone (<0.17 nmol/L [<5 ng/dL]) among men younger than 50 years (*left*) and those 50 years of age or older (*right*). Numbers displayed are percentages within each area. Positive symptom reports and low total and free testosterone were more common in older men. The presence of symptoms was related more strongly to testosterone levels in older as compared with younger men as indicated by a greater degree of overlap between symptom presence and low total and free testosterone among older (52.4% of men with low total or free testosterone had symptoms) compared with younger (43.1% of men with low total or free testosterone had symptoms) men. The intersection of symptoms and low total and free testosterone levels was more common in older men (prevalence of symptomatic androgen deficiency was 4.2% among men <50 years of age and 8.4% among men 50 years of age or older). Note: Circles for the Venn diagrams are proportional within age strata. *T*, testosterone. (From Araujo AB, Esche GR, Kupelian V, et al. Prevalence of symptomatic androgen deficiency in men. *J Clin Endocrinol Metab*. 2007;92[11]:4241–4247.)

total testosterone levels less than 11 nmol/L (320 ng/dL) and free testosterone levels less than 0.22 nmol/L (6.4 ng/dL); men fulfilling these criteria with serum total testosterone levels less than 8 nmol/L (230 ng/dL) are considered to have severe LOH. Prevalence of such defined LOH in the European Male Aging Study population increased with age, body mass index, and number of coexisting illnesses and was 5.1% in men 70 to 79 years of age.[120] Men with LOH had lower hemoglobin and muscle and bone mass and poorer physical performance and general health compared with their peers; men with low testosterone only, irrespective of sexual symptoms, showed lesser magnitude of associations with the same end points.[121]

In recent years, it has become clear that an association exists between LOH and adverse metabolic conditions, such as obesity, metabolic syndrome, and type 2 diabetes mellitus.[122-124] An obesity-induced estrogen increase seems to play a major role in determining the negative feedback at the pituitary level, therefore inducing hypogonadotropic hypogonadism with low, or inappropriately normal, gonadotropin levels. In addition, insulin resistance may contribute to the low testosterone levels seen in obese men.[122] Comorbidity was also associated with a lower total testosterone level. Three independent meta-analyses published in 2011, as well as a recent large observational study of nearly 2600 men participating in the European Male Aging Study, demonstrated an association between hypogonadism and overall and cardiovascular mortality, but they failed to find any statistical association with incident cardiovascular events.[124-127] These findings support the concept that cardiovascular disease is associated with male hypogonadism.

Testosterone Replacement Therapy

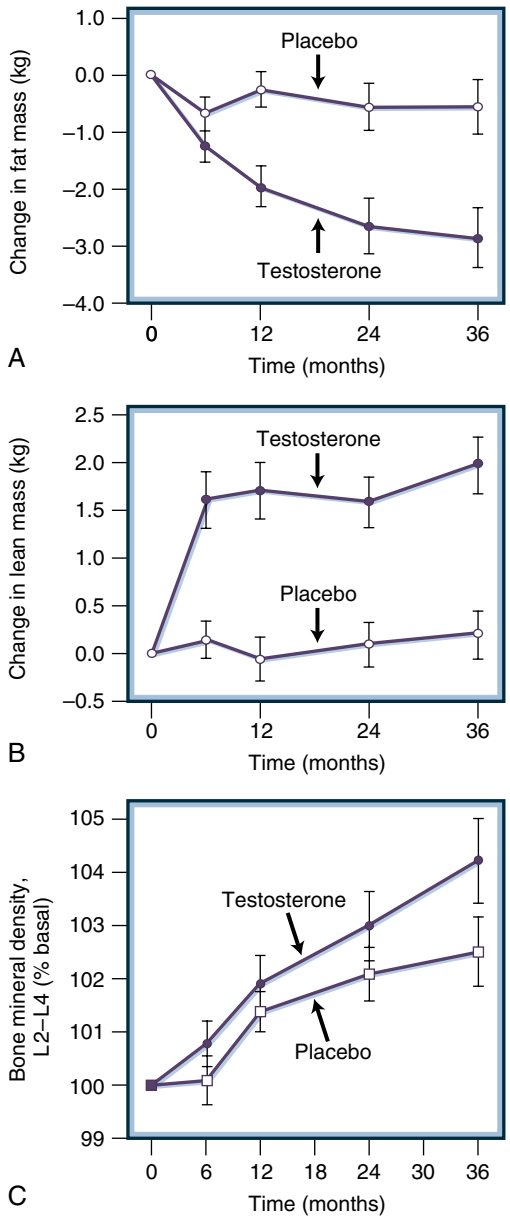
Many persuasive reports in the literature demonstrate that testosterone replacement in men of all ages (young, adult, and old) with clear clinical and severe biochemical hypogonadism instantly reverses vasomotor activity (flushes and sweats); improves libido, sexual activity, and mood; increases muscle mass, strength, and bone mineralization; prevents fractures; decreases fat mass; and decreases fatigue and poor concentration.[54,111,128] In addition, the treatment of normal adult men with supraphysiologic doses of testosterone, especially when combined with resistance exercise training, increased fat-free mass and muscle size and strength.[129]

Most studies reporting the results of androgen therapy in older men were small, short term, noncontrolled, and without uniform end points. The results of one of the first large randomized studies in healthy elderly men seem representative for effects expected of androgen therapy.[130,131] Ninety-six men (mean age 73 years) wore a testosterone patch on their scrotum (6 mg of testosterone per 24 hours) or a placebo patch for 36 months. Mean serum testosterone concentrations in the men treated with testosterone increased from 12.7 ± 2.9 nmol/L (367 ± 7.9 ng/dL) before treatment to 21.7 ± 8.6 nmol/L (625 ± 249 ng/dL; $p < 0.001$) at 6 months of treatment and remained at that level for the duration of the study. The decrease in fat mass (–3.0 ± 0.5 kg) in the testosterone-treated men during the 36 months of treatment was significantly different from the decrease (–0.7 ± 0.5 kg) in the placebo-treated men ($p < 0.001$) (Fig. 28.6A). The increase in lean mass (1.9 ± 0.3 kg) in the testosterone-treated men was significantly different from that in the placebo-treated men (0.2 ± 0.2 kg; $p < 0.001$).

Changes in knee extension and flexion strength, hand grip, walking speed, and other parameters of muscle strength and function were not significantly different in the two groups. Bone mineral density in the lumbar spine increased in both the testosterone-treated (4.2% ± 0.8%) and placebo-treated (2.5% ± 0.6%) groups, but mean changes did not differ between groups (see Fig. 28.6C). However, the lower the pretreatment serum testosterone concentration, the greater the effects of testosterone treatment on lumbar spine bone density after 36 months ($p = 0.02$). A minimal effect (0.9 ± 1.0%) of testosterone treatment on bone mineral density was observed in men with a pretreatment serum testosterone concentration of 13.9 nmol/L (400 ng/dL), but an increase of 5.9% ± 2.2% was found in men with a pretreatment testosterone concentration of 6.9 nmol/L (200 ng/dL).

The subjective perception of physical functioning decreased significantly during the 36 months of treatment in the placebo-treated group ($p < 0.001$) but not in the testosterone-treated group. Interestingly, the effect of testosterone treatment on the perception of physical functioning varied inversely with the pretreatment serum testosterone concentration ($p < 0.01$). There was no significant difference between the two treatment groups with regard to the subjective perception of energy or sexual functions.

To determine definitively whether testosterone treatment of elderly men with low testosterone is efficacious in improving symptoms and objective measures of age-associated conditions, a coordinated set of seven clinical trials were designed. The seven trials included 790 men with measurements of physical function, sexual function, vitality, cognitive function, anemia,



• **Fig. 28.6** A to C, Mean (± standard error) change from baseline in fat mass, lean mass, and bone mineral density of the lumbar spine (L2–L4) as determined by dual-energy x-ray absorptiometry in 108 men older than 65 years who were treated with either testosterone or placebo (54 men each). The decrease in fat mass ($p < 0.005$) and the increase in lean mass ($p < 0.01$) in the testosterone-treated subjects were significantly different from those in placebo-treated subjects at 36 months. Bone mineral density increased significantly in both groups. (A and B from Snyder PJ, Peachey H, Hannoush P, et al. Effect of testosterone treatment on body composition and muscle strength in men over 65 years of age. *J Clin Endocrinol Metab.* 1999;84[8]:2647-2653; C from Snyder PJ, Peachey H, Hannoush P, et al. Effect of testosterone treatment on bone mineral density in men over 65 years of age. *J Clin Endocrinol Metab*. 1999;84[6]:1966–1972.)

cardiovascular, and bone parameters.[132] These trials show that in treatment of men younger than 65 years for 12 months with testosterone levels below 9.5 nmol/L (275 ng/dL) with a testosterone gel in an adjusted dose to maintain testosterone levels in the normal range of young men, self-reported sexual function increased more with testosterone treatment than with placebo. There was a small difference between the testosterone group and the placebo group in the percentage of men whose 6-minute walking distance increased by at least 50 m[131] (Fig. 28.7). Further, testosterone treatment showed no significant benefit over placebo with respect to vitality, as determined by an increase of at least 4 points in the FACIT-Fatigue score[131] (Fig. 28.8).

With regard to the potential adverse effects of testosterone treatment in healthy elderly men, the studies by Snyder and colleagues[131,133] seem representative. The mean serum prostate-specific antigen concentration did not change during treatment in the placebo-treated group but increased by a small but statistically significant ($p < 0.001$) amount in the testosterone-treated group. Three cases of prostate cancer were observed in the testosterone-treated group versus one in the placebo group. The urine flow rate and volume of urine in the bladder after voiding were similar in the two groups. Hemoglobin and hematocrit did not change in the placebo-treated group, but both increased significantly ($p < 0.001$) in the testosterone-treated group. Seven men treated with testosterone developed persistent erythrocytosis (hemoglobin >17.5 g/dL; hematocrit >52%) during treatment.

Numerous studies of large populations of healthy men have shown a marked rise in the incidence of impotence to more than 50% in men 60 to 70 years old.[134] Although this increased rate occurs in the same age group who show a clear decline in serum (free) testosterone levels, no causal relationships have been demonstrated. A systematic review and meta-analysis of randomized, placebo-controlled trials concluded that testosterone use in normal men is associated with a small improvement in satisfaction with erectile function and moderate improvements in libido.[135] Other factors, such as atherosclerosis, alcohol consumption, smoking, and the quality of personal relationships, seem to be more important.[136,137] Only in the case of clear hypogonadism is the decrease in libido and potency restored by testosterone replacement therapy.[114,128,133]

No RCTs have been large enough or long enough to determine the effects of testosterone replacement therapy on major adverse cardiovascular events. A meta-analysis suggested that testosterone therapy increases cardiovascular-related events among men. The risk of testosterone therapy was particularly marked in trials not funded by the pharmaceutical industry.[138] The Testosterone Trials,[132] which were published after this meta-analysis, have investigated the effects of testosterone therapy in older men on cardiovascular-related parameters. Treatment with testosterone gel for 1 year in 394 men with symptomatic hypogonadism and testosterone levels less than 275 ng/dL was associated with small reductions in cholesterol and insulin but not with glucose markers or markers of inflammation or fibrinolysis or with troponin compared with placebo.[139] However, testosterone treatment in a subset of 73 men was associated with a significantly greater increase in coronary artery noncalcified plaque volume compared with placebo.[140] In addition, in the Testosterone Effects on Atherosclerosis in Aging Men Trial, a placebo-controlled, randomized, double-blind trial among 308 community-dwelling men older than 60 years, insulin sensitivity did not improve in a subset of 134 nondiabetic men treated with testosterone for 36 months.[141]

The Endocrine Society Clinical Practice Guideline on testosterone therapy in adult men with androgen deficiency syndromes summarized the observed effects and the adverse outcomes of randomized, placebo-controlled trials of testosterone administration over 1 to 3 years in older men with low-normal to low testosterone concentrations.[115]

Which Elderly Men Should Be Treated?

A key lesson from the Heart and Estrogen/Progestin Replacement and WHI studies is that conventional medical practice should not precede substantiation with reliable clinical evidence of safety and efficacy.[142] Androgen replacement in older men is the male counterpart of hormonal therapy in postmenopausal women but differs crucially in that a clear syndrome of androgen deficiency is lacking. On the basis of several suggestive clinical features collected from the history, symptoms, or signs of an elderly man, the biochemical confirmation of androgen deficiency

is sought. In previous discussions of testosterone replacement in older men,[136,143] it was suggested that the biochemical diagnosis of "true" hypogonadism seems certain if the serum total testosterone concentration is less than 6.9 nmol/L (200 ng/dL). This cutoff remains arbitrary and does not answer the question whether healthy elderly men with testosterone levels between 6.9 and 10.4 nmol/L are hypogonadal, or whether such men would benefit from replacement therapy with testosterone. There are not enough data to determine whether low testosterone levels in the elderly are just a marker of poor health and should be treated with testosterone replacement. It has been demonstrated that intercurrent diseases frequently result in a transient, sharp drop in serum testosterone concentrations,[144] whereas frail, elderly men generally tend to have testosterone levels 10% to 15% lower than those of healthy, age-matched control subjects.[145] In addition, functional hypogonadism in the elderly is potentially reversible.[146] Lifestyle modifications, particularly weight loss, as obesity is the strongest risk factor for low testosterone levels in older adults, can lead to higher testosterone levels.[147]

The current recommendation[115] is not to treat asymptomatic older men with age-related decline in testosterone levels. The guideline suggests that clinicians consider offering testosterone therapy on an individualized basis to older men with low testosterone levels measured on more than one occasion and clinically significant symptoms of androgen deficiency, after explicit discussion of uncertainty about the risks and benefits of testosterone therapy. Among experts, there is disagreement on serum levels below which testosterone therapy should be offered to older men with symptoms. When a serum testosterone concentration is found to be low, an additional evaluation with measurements of serum gonadotropins and prolactin is mandatory to exclude pituitary pathology.

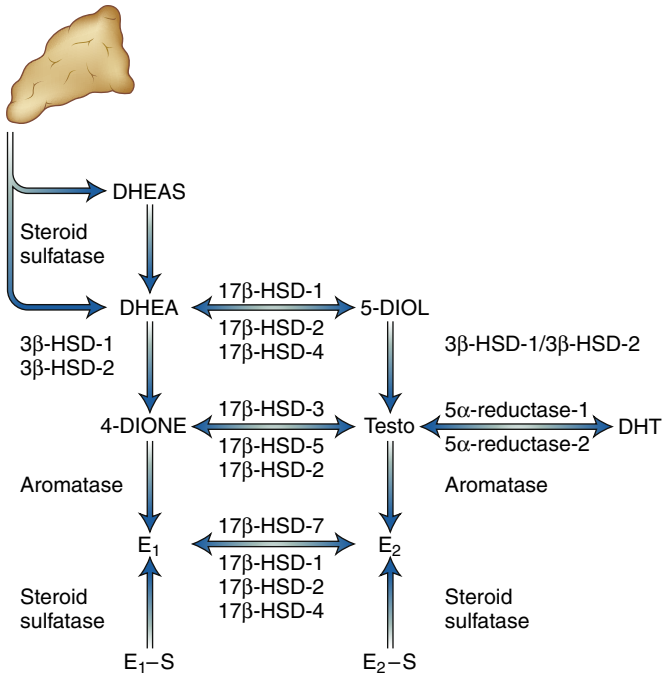
If one decides to start testosterone replacement, the guideline suggests that clinicians aim at achieving total testosterone levels in the lower part of the normal range of young men (400–500 ng/dL (14.0–17.5 nmol/L). The dose should thus be titrated according to serum levels. Considerations concerning the choice of testosterone preparation, as well as the route of administration (oral, injectable, implantable, or transdermal), are discussed in Chapter 8.

At present, the duration of testosterone administration is uncertain. Control of prostate size, prostate-specific antigen levels, and hematocrit is mandatory. The identification of elderly men who might benefit most from testosterone treatment remains uncertain, and the risks to the prostate and increased blood viscosity require further study.

Adrenopause

Role of DHEA During Aging

Humans are unique among primates and rodents because the human adrenal cortex secretes large amounts of the steroid precursor DHEA and its sulfate derivative DHEAS.[148] Serum DHEAS concentrations in adult men and women are 100 to 500 times higher than those of testosterone and 1000 to 10,000 times higher than those of estradiol. In normal subjects, serum concentrations of DHEA and its sulfate are highest in the third decade of life, after which the concentrations of both gradually decrease; therefore, by the age of 70 to 80 years, the values are about 20% of peak values in men and 30% of peak values in women[49] (see Fig. 28.3).



• **Fig. 28.9** Human steroidogenic enzymes in peripheral intracrine tissues. *DHEA*, dehydroepiandrosterone; *DHEAS*, DHEA sulfate; *DHT*, dihydrotestosterone; *5-DIOL*, androsterone-5-ene-3β,17β-diol; *4-Dione*, androstenedione; E_1, estrone; E_2, estradiol; *3β-HSD*, 3β-hydroxysteroid dehydrogenase; *17β-HSD*, 17β-hydroxysteroid dehydrogenase; *Testo*, testosterone. (Modified from Labrie F, Luu-The V, Lin SX, et al. Intracrinology: role of the family of 17 beta-hydroxysteroid dehydrogenases in human physiology and disease. *J Mol Endocrinol.* 2000;25[1]:1–16.)

DHEA and DHEAS seem to be inactive precursors that are transformed within human tissues by a complicated network of enzymes into androgens or estrogens, or both (Fig. 28.9). The key enzymes are aromatase, steroid sulfatase, 3β-hydroxysteroid dehydrogenases (3β-HSD-1 and 3β-HSD-2), and at least seven organ-specific 17β-hydroxysteroid dehydrogenases (17β-HSD-1 to 3β-HSD-7). Labrie and colleagues[148] introduced the term *intracrinology* to describe this synthesis of active steroids in peripheral target tissues in which the action is exerted in the same cells in which synthesis takes place, without release into the extracellular space and general circulation.

In postmenopausal women, nearly 100% of sex steroids are synthesized in peripheral tissues from precursors of adrenal origin, except for a small contribution from ovarian or adrenal testosterone and androstenedione. Thus, in postmenopausal women, virtually all active sex steroids are made in target tissues by an intracrine mechanism. In elderly men, the intracrine production of androgens is also important; less than 50% of the androgen supply is derived from testicular production.

The high secretion rate of adrenal precursor sex steroids in men and women differs from that in laboratory animal models, in which the secretion of sex steroids occurs exclusively in the gonads. In rats and mice, long-term administration of DHEA prevented obesity, diabetes mellitus, cancer, and heart disease, and enhanced immune function as well.[48,50,149]

These experimental animal data have been used to argue that DHEA administration in adult or elderly individuals prolongs the life span and might be an "elixir of youth." Supportive data in humans are few, however, and highly

controversial (see the following). Epidemiologic studies indeed point to a mild cardioprotective effect of higher DHEAS levels in both men and women.[150] In the Rotterdam study, DHEA and DHEAS concentrations are inversely associated with the risk of diabetes.[151] Functional parameters of activities of daily living in men older than 90 years were lowest in those with the lowest serum DHEAS concentrations[49]; in healthy elderly individuals, there was an association between the ratio of cortisol to DHEAS levels and cognitive impairment.[152]

CYP3A7, expressed in the human fetal liver and normally silenced after birth, plays a major role in the 16α-hydroxylation of DHEA, DHEAS, and estrone. A common polymorphism in the *CYP3A7* gene (CYP3A7*1C) causes persistence of the enzymatic activity of the gene during adult life. Between 6% and 8% of the population are heterozygous carriers of this polymorphism, resulting in almost 50% lower DHEAS levels compared with homozygous carriers of the reference allele.[153] Interestingly, no evidence was found that such lowered levels are associated with an acceleration of the aging process.

DHEA Replacement Therapy

A physiologic functional role of DHEA in women has been ascertained in a careful double-blind study. In women with adrenal insufficiency,[154] DHEA administration (50 mg/day) normalized serum concentrations of DHEA, DHEAS, androstenedione, and testosterone. DHEA significantly improved overall well-being, as well as scores for depression and anxiety, the frequency of sexual thoughts, sexual interest, and satisfaction with both mental and physical aspects of sexuality.

Several short controlled trials with DHEA in small groups of elderly individuals provided ambiguous results.[155,156] A 2-year placebo-controlled trial showed no effect of the oral administration of DHEA (at a dose of 75 mg/day in men and 50 mg/day in women) on body composition, muscle strength, or insulin sensitivity, as compared with placebo.[157] In this study involving 87 elderly men with low levels of DHEAS and bioavailable testosterone and 57 elderly women with low levels of DHEAS, DHEA levels increased in both sexes during DHEA administration by about 9.5 μmol/L.

These results are in line with a previous study[158] in 280 healthy subjects 60 to 79 years of age, in which 50 mg of DHEA daily for 1 year did not improve body composition or muscle strength, although in women an increase in libido was noted. In addition, a double-blind RCT with 50 mg of DHEA for 36 weeks in 50 elderly men, 70 years of age or older, with low scores on muscle strength tests did not improve isometric grip strength, leg extensor power, and physical performance.[159]

With regard to one beneficial effect of DHEA administration, the results seem rather consistently positive: increases in bone mineral density in women were repeatedly reported.[157,158,160,161] These positive effects, however, were very small and not more than approximately half those observed with current osteoporosis therapies, such as estrogens and bisphosphonates, and therefore they are unlikely to have a significant effect on the risk of fracture.[157] Review of placebo-controlled RCTs does not show benefits of oral DHEA in postmenopausal women for impaired sexual function, well-being, and cognitive performance, nor does it show favorable effects on lipids and carbohydrate metabolism.[162,163] A study from Weiss and colleagues,[164] however, of both elderly men (n = 92) and women (n = 51) showed that DHEA supplementation in a dose of 50 mg/day with a follow-up of 12 months reduces arterial stiffness.

Results from a meta-analysis showed that among the 644 elderly men enrolled in 8 RCTs measuring bone parameters, DHEA supplementation with a mean follow-up of 52 weeks did not improve lumbar or femoral bone mineral density nor formation or resorption of bone turnover markers.[165] The same meta-analysis including a total of 25 RCTs with 1353 elderly men with a mean follow-up of 36 weeks showed that DHEA supplementation of 50 to 100 mg/day was associated with a reduction of fat mass. No effect was observed for lipid and glycemic metabolism, sexual function, or quality of life.

Local delivery of DHEA, however, may be beneficial, because daily intravaginal administration of 0.50% (6.5 mg) DHEA has shown to improve moderate to severe vaginal dryness at 12 weeks and decrease pain at sexual activity.[166]

Conclusions

DHEAS is a universal precursor for the peripheral local production and action of estrogens and androgens in target tissues such as brain, bone, skin, and adipose tissue. However, the importance of these pathways remains undefined, particularly in men, who have a relatively much higher production of testosterone from testicular origin. DHEA administration in the elderly, compared with placebo, increases serum DHEAS, testosterone, free testosterone, estrone, estradiol, and IGF1 concentrations, and lowers SHBG levels.[157,159,160] It is not known whether this increase in sex steroid levels induced by DHEA administration in the long term is safe with regard to the development or growth of ovarian, prostate, or other types of steroid-dependent cancers. The addition of DHEA (50 mg/day) to the existing large pool of DHEA and DHEAS in elderly individuals, even if they have been selected on the basis of low(ered) circulating levels of these steroids, has very limited clinically meaningful effects, if any.

DHEA, which is currently available as a dietary supplement, is widely used within the United States as an unapproved preventive treatment against aging. There are no convincing arguments at present to recommend the (routine) use of DHEA for delaying or preventing the physiologic consequences of aging, and its safety is unknown.[167,168]

Somatopause

Role of GH and IGF1 During Aging

Elderly men and women secrete GH less frequently and at lower amplitude than do young people.[20] In fact, GH secretion declines approximately 14% per decade in normal individuals.[169,170] In parallel, serum levels of IGF1 (see Fig. 28.3) are 20% to 80% lower in healthy elderly individuals than in healthy young adults.[171] However, whether this decline has adverse or beneficial effects is controversial. In invertebrates and rodents, an attenuation of the insulin/IGF signaling pathway has led to an extension of the life span.[172] In addition, in humans, genetic defects in the somatotropic axis resulting in lower or a decreased IGF1 signaling may be associated with increased survival.[173] Paradoxically, low IGF1 concentrations in humans have been associated with increased risk for cardiovascular disease, stroke, type 2 diabetes mellitus, and osteoporosis. Many studies over the past decade have looked for associations between IGF1 levels and mortality risk. Some studies have found no association[174-176]; however,

other studies have found that lower levels of serum IGF1[177-179] or serum IGF1 bioactivity[180] were associated with greater all-cause mortality, whereas still others found that low IGF1 levels were predictive of extended survival.[181] One study found that higher IGF1 levels were associated with a higher mortality risk,[182] and two studies found a higher risk in subjects with both high and low IGF1 levels.[183,184] A meta-analysis indicated that both high and low IGF1 concentrations are associated with increased cancer and cardiovascular-related mortality in the general population.[185]

IGF1 and IGF2 actions can be modulated by IGF binding proteins (IGFBPs). IGFBP2 is the second most abundant IGFBP in the circulation. This protein has received a lot of attention over the past decade due to its potential role in metabolic syndrome and several forms of cancer. IGFBP2 levels increase with increasing age and decrease with increasing body mass index (BMI).[186,187] A strong association between low IGFBP2 levels and metabolic syndrome and low insulin sensitivity has been identified.[187-190] Surprisingly, however, although it was found that higher IGFBP2 was associated with favorable risk factors, including lower fasting glucose and lower fasting insulin, two studies found a strong association between higher IGFBP2 and mortality in older adults.[187,189] In both studies, the association appeared to be independent of acute-phase reactants (C-reactive protein and interleukin 6). Earlier, it was published that high serum IGFBP2 concentrations were associated with worse physical function, low muscle mass, and low bone density in a population of elderly men.[191] The association of high IGFBP2 concentrations and increased 8-year mortality was independent of physical function. The clinical features of subjects with high IGFBP2 levels are similar to subjects with protein energy malnutrition. Interestingly, these associations were, however, present in a population with a normal BMI and in subjects who lived independently.

IGFBP2 concentrations are overexpressed in several forms of malignancies.[192] Thus far, it is unclear what role IGFBP2 plays in the development and progression of human cancers.[192] In the studies mentioned previously, the associations between high IGFBP2 levels and increased mortality were independent of the presence of malignancy. The role of IGFBP2 in the aging process remains to be elucidated. The concept that this decline in GH and IGF1 secretion contributes to the decline of functional capacity in elderly people (somatopause) is mainly derived from studies in which GH replacement therapy in GH-deficient adults was shown to increase muscle mass, muscle strength, bone mass, and quality of life. A beneficial effect on the lipid profile and an important decrease in fat mass were also observed in these patients.[53,193,194] As in hypogonadal individuals, adult GH deficiency can thus be considered a model of normal aging because several catabolic processes that are central in the biology of aging can be reversed by GH replacement.

GH Therapy

Rudman and colleagues,[195] after a ground-breaking RCT of healthy men, 61 to 81 years old, with serum IGF1 concentrations in the lower third for their age, reported in 1990 that GH treatment (30 mg/kg three times weekly for 6 months) restored the men's IGF1 levels to "normal." In the treatment group, lean body mass rose by 8.8% and lumbar vertebral density increased by 1.6%. The magnitudes of these initial changes were equivalent to a reversal of the age-related changes by 10 to 20 years. However, during continuation of this study to 12 months, the significant positive effect on bone mineral density at any site was lost.[196]

In the subsequent years, it became clear that GH administration in healthy elderly individuals frequently caused acute adverse effects, such as carpal tunnel syndrome, gynecomastia, fluid retention, and hyperglycemia, which were severe enough for an appreciable number of individuals to drop out of these studies. The most disappointing aspect, however, was that no positive effects of GH administration were observed on muscle strength, maximal oxygen consumption, or functional capacity. In contrast, when GH was administered in combination with resistance exercise training, a significant positive effect on muscle mass and muscle strength was recorded that did not differ from that seen with placebo treatment, which suggests that GH does not add to the beneficial effects of exercise.[197,198] A representative example of a well-controlled study[199] of GH administration in unselected elderly men is given in Table 28.2.

In a systematic study of 31 articles describing 18 unique well-defined study populations, the safety and efficacy of GH in the healthy elderly were reviewed.[200] A total of 220 participants who received GH for 107 person-years completed the study. Participants' mean age was 69 years, and they were overweight (mean BMI, 28 kg/m^2). Initial daily GH dose (mean, 14 μg/kg body weight) and treatment duration (mean, 27 weeks) varied. Overall fat mass decreased by 2.1 kg and lean body mass increased by 2.1 kg in those treated with GH, whereas total cholesterol levels decreased by 0.29 mmol/L. Disappointingly, no consistent changes in muscle strength, physical activity, or psychosocial outcomes were observed.

GH is associated with substantial adverse effects.[200] To obtain insights into what can be expected, the details of one particularly well carried out placebo-controlled study in healthy women (n =

TABLE 28.2 Effects of Growth Hormone Administration in Healthy Older Men.

	MEAN CHANGE IN VARIABLE

GH, 30 μg/kg three times a week, was administered for 6 months to 52 healthy 69-year-old men with well-preserved functional ability but low levels of IGF1.

GH, Growth hormone; *IGF1*, insulin-like growth factor 1.

From Papadakis MA, Grady D, Black D, et al. Growth hormone replacement in healthy older men improves body composition but not functional ability. *Ann Intern Med.* 1996;124:708–716.

57) and men (n = 74) 65 to 88 years of age is presented[201]: GH administered subcutaneously at an initial dose of 30 μg/kg, three times per week, then reduced to 20 μg/kg for 26 weeks, was associated with carpal tunnel syndrome in 38% of women versus 7% of those taking placebo, and in 24% of men versus 0% taking placebo; edema in 39% of women (0% for placebo) and 30% of men (12% for placebo); and arthralgias in 46% of women (7% for placebo) and 41% of men (0% for placebo). Troublesome was the report that 18 men treated with GH developed glucose intolerance or diabetes compared with 7 men in the nontreatment group.[201]

In an RCT, Blackman and colleagues[201] studied the synergetic effects of a combination of GH and sex steroids in healthy elderly women and men. A slight increase in lean body mass and muscle strength was observed in elderly men treated with GH and testosterone but not in women who received GH and estrogen. In a study of healthy elderly men, coadministration of low-dose GH with testosterone resulted also in slightly beneficial changes (muscle strength, quality of life) compared with GH or testosterone alone.[202] In a partially placebo controlled trial of 112 older men, testosterone and recombinant human GH administration appeared not to worsen cardiometabolic risk in healthy older men after 4 months.[203] Earlier studies demonstrated that pharmacologic doses of GH prevent the *autocannibalistic* effects of acute diseases on muscle mass.[204] Confirmation is needed, however, before GH can gain a place in the treatment of acute catabolic states in frail elderly people.

Other components in the regulation of the GH–IGF1 axis are effective in activating GH and IGF1 secretion. Long-acting derivatives of the hypothalamic peptide growth hormone–releasing hormone, given twice daily subcutaneously for 14 days to healthy 70-year-old men, increased GH and IGF1 levels to those encountered in 35 year olds.[51] These studies suggest that somatopause is driven primarily by the hypothalamus and that pituitary somatotropes retain their capacity to synthesize and secrete high levels of GH.

Two ghrelin-mimetic GH secretagogues (GHSs) have also been demonstrated to be able to restore levels of GH and IGF1 in elderly individuals to those of young adults.[205] Ghrelin, an octanoylated 28–amino acid peptide, stimulates GH secretion via a distinct, endogenous GHS receptor but also has appetite-stimulating activity.[206] These GHSs slightly increased fat-free mass without changing fat mass, muscle strength, and function or quality of life,[207] and changed body composition and increased appetite that was accompanied by small but significant improvements in some measures of physical function[208] in older adults.

The long-term safety of activating GH and IGF1 levels in older people has become a concern because of reports of an association between serum IGF1 concentrations and cancer risk. Individuals with high IGF1 levels (or low IGFBP3 levels) within the broad normal range have an increased risk of prostate, colon, and breast cancer.[209-211] These epidemiologic studies, together with experimental data, suggest that the IGF1 system is involved in tumor development and progression. However, no causal relationship between IGF1 levels and cancer risk has yet been established, and possible medical intervention directed at increasing IGF1 bioactivity in elderly people will in most instances be given toward the end of life, presumably not allowing enough time to affect tumor development or progression.

Conclusions

During the aging process, GH–IGF1 axis activity declines. It is unclear whether changes in body composition and functional capacity are directly related. GH administration in older adults causes an increase in lean body mass and an appreciable loss of fat mass. However, GH treatment does not improve muscle strength and functional capacity in elderly people, despite restoration of circulating IGF1 concentrations to young adult levels. Furthermore, most dose regimens of GH cause appreciable adverse effects, and long-term safety with regard to tumor development and progression remains uncertain. Oral ghrelin mimetics are also capable of restoring GH and IGF1 levels in the elderly population, together with an increase in appetite. Modest functional improvement was observed in one study after 2 years administration.

In the near future, clinical trials with such orally active molecules in frail elderly people or in elderly individuals with clearly lowered IGF1 levels, or both, should be able to delineate the precise role of the GH–IGF1 axis in the aging process. In such trials, much emphasis must be given to safety aspects. At present, there is no evidence to recommend medical or other intervention in the GH–IGF1 axis as an antiaging effort to prolong life or rejuvenate healthy elderly people.[212,213] Only elderly patients with GH deficiency caused by organic diseases, such as pituitary adenomas, clearly benefit from GH replacement therapy.[214]

The Concept of Successful Aging

There is considerable variation in the effects of aging on healthy individuals, with some people exhibiting greater and others exhibiting few or no age-related alterations in physiologic functions. It has been suggested that it might be useful to distinguish between usual and successful patterns of aging.[215] Genetic factors, lifestyle, and societal investments in a safe and healthful environment are important aspects of successful aging.[216] Traditionally, the aging process, including the development of physical frailty toward the end of life, has been considered physiologic and unavoidable.

It has recently become evident, however, that it might not be necessary to accept the grim stereotype of aging as an unalterable process of decline and loss.[215] As life expectancy rises further in the coming decades, the overarching goal should be "an increase in years of healthy life with a full range of functional capacity at each stage of life."[217] Such a compression of morbidity can be achieved by adapting lifestyle measures, but several aspects of the aging process of the endocrine system invite the development of routine medical intervention programs offering long-term replacement therapy with one or more hormones to delay the aging process and to allow humans to live for a longer period in a relatively intact state.[218] However, unfortunately, it should be concluded at present that hormonal interventions with sex steroids, DHEA, GH, and/or oral ghrelin agonists have very limited effects on physical capacity in elderly individuals, whereas adverse effects are often considerable.

Hormones and Disorders of Mineral Metabolism

F. RICHARD BRINGHURST, MARIE B. DEMAY, AND HENRY M. KRONENBERG

CHAPTER OUTLINE

KEY POINTS

- Parathyroid hormone (PTH), vitamin D, and fibroblast growth factor 23 (FGF23) together regulate the levels of calcium and phosphorus in the bloodstream to keep them relatively constant and slightly above the inherent solubility product of calcium and phosphate. These hormones act largely on cells in intestine, kidney, bone, and parathyroid gland.
- Primary hyperparathyroidism and malignant hypercalcemia are the commonest causes of hypercalcemia. All causes of hypercalcemia can be grouped as either PTH dependent or PTH independent.
- Hypocalcemic disorders can be usefully organized as PTH-related, vitamin D–related, or miscellaneous disorders.
- Disorders associated with abnormal levels of phosphate in the blood are usually caused by diseases of the kidney.
- Magnesium disorders usually reflect abnormalities of influx of magnesium across the intestine, excretion of magnesium by the kidney, or shifts among the intracellular and extracellular compartments.

Basic Biology of Mineral Metabolism: Roles of the Mineral Ions

Calcium (Ca) and phosphorus (P) are the principal constituents of bone, and together they compose 65% of its weight. Bone, in turn, contains nearly all of the calcium and phosphorus and over half of the magnesium in the human body. The quantitatively minor amounts of each of these ions in the extracellular fluid and within cells play crucial roles in normal physiology (Fig. 29.1).

Ninety-nine percent of total body calcium resides in bone, of which 99% is located within the crystal structure of the mineral phase. The remaining 1% of bone calcium is rapidly exchangeable with extracellular calcium; this calcium is equally distributed between the intracellular and extracellular fluids. Extracellular calcium is the principal substrate for the mineralization of cartilage and bone, but it also serves as a cofactor for many extracellular enzymes, most notably the enzymes of the coagulation cascade, and as a source of calcium ions that serve as signaling molecules for a great diversity of intracellular processes. These processes include automaticity of nerve and muscle; contraction of cardiac, skeletal, and smooth muscle; neurotransmitter release; and various forms of endocrine and exocrine secretion.

In blood, approximately 50% of total calcium is bound to proteins, mainly albumin and globulins. The ionized calcium concentration in serum is approximately 1.2 mmol/L (5 mg/dL), and it is this ionized fraction that is biologically active and that is tightly controlled by hormonal mechanisms. Because intracellular cytosolic free calcium concentrations typically are in the range of only 100 nM, a very large chemical gradient (i.e., 10,000:1), augmented by the large negative electrical potential, favors calcium entry into cells through calcium channels. This gradient is maintained by the limited conductance of resting calcium channels and

	Calcium ions	Phosphate ions

by the energy-dependent extrusion of calcium into the extracellular fluid via high-affinity Ca^{2+}-adenosine triphosphatases and H^+-adenosine triphosphatases (ATPases) and low-affinity sodium-calcium (Na^+-Ca^{2+}) exchangers.

More than 99% of intracellular calcium exists in the form of complexes within the mitochondrial compartment, bound to the inner plasma membrane, or associated with the inner membranes of the endoplasmic reticulum and other compartments. Release of calcium from membrane-bound compartments transduces cellular signals and is tightly regulated. The mechanisms responsible for translocations of intracellular calcium between the cytosol and these sequestered regions have become better understood with the identification of specific receptors for calciotropic signaling molecules such as the inositol triphosphate (IP_3) receptor and ryanodine receptors.

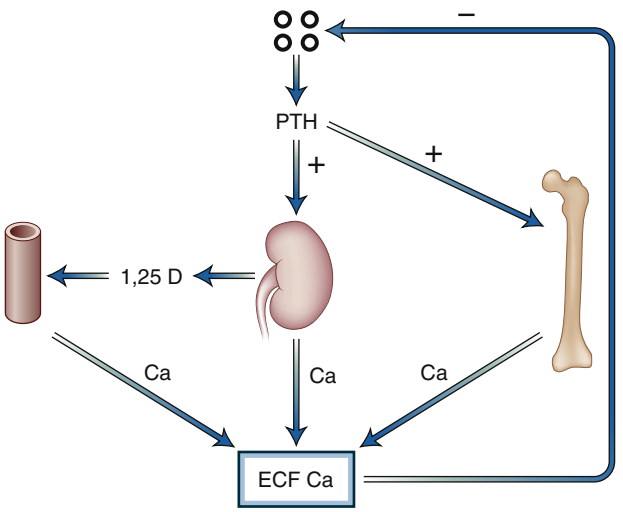
Phosphate is more widely distributed to nonosseous tissues than is calcium. Eighty-five percent of body phosphate is in the mineral phase of bone, and the remainder is located in inorganic or organic form throughout the extracellular and intracellular compartments. In human serum, inorganic phosphate (P_i) is present at a concentration of approximately 1 mmol/L and exists almost entirely in ionized form as either $H_2PO_4^-$ or HPO_4^{2-}. Only 12% of serum phosphate is protein bound, and an additional small fraction is loosely complexed with calcium, magnesium, and other cations. Intracellular free phosphate concentrations are generally comparable to those in the extracellular fluid (i.e., 1–2 mmol/L), although the inside-negative electrical potential of the cell creates a significant energy requirement for translocation of phosphate into cells. This process generally is accomplished through sodium-phosphate cotransport driven by the transmembrane sodium gradient. A number of sodium-phosphate cotransporters have been cloned; various cells and tissues use different species of such transporters with distinctive regulatory characteristics.

Organic phosphate is a key component of virtually all classes of structural, informational, and effector molecules that are essential for normal genetic, developmental, and physiologic processes. Phosphate is an integral constituent of nucleic acids; phospholipids; complex carbohydrates; glycolytic intermediates; structural, signaling, and enzymatic phosphoproteins; and nucleotide cofactors for enzymes and G proteins. The need for the large amounts of phosphate incorporated into cellular constituents during cell proliferation explains why phosphate levels in the blood are regulated by insulin-like growth factor 1 (IGF1), in addition to regulation by hormones of bone mineralization. Of particular importance are the high-energy phosphate ester bonds present in molecules such as adenosine triphosphate (ATP), diphosphoglycerate, and creatine phosphate that store chemical energy. Phosphate plays a particularly prominent role as the key substrate or recognition site in numerous kinase and phosphatase regulatory cascades. Cytosolic phosphate per se also directly regulates a number of crucial intracellular reactions, including those involved in glucose transport, lactate production, and synthesis of ATP. In light of these diverse roles, it is not surprising that disorders of phosphate homeostasis associated with severe depletion of intracellular phosphate lead to profound and global impairment of organ function. Note that none of these roles for intracellular phosphate involves actions of intracellular calcium; the reason we are discussing these together results solely from their intimate relationship in regulating bone mineralization outside cells.

Magnesium is the fourth most abundant cation in the body. Roughly half is found in bone and half in muscle and other soft tissues. As much as half of the magnesium in bone is not sequestered in the mineral phase but is freely exchangeable with the extracellular fluid and therefore may serve as a buffer against changes in extracellular magnesium concentration. Less than 1% of all magnesium in the body is present in the extracellular fluid, where the magnesium concentration is approximately 0.5 mmol/L. The concentration of magnesium in serum normally is 0.7 to 1 mmol/L, of which roughly one-third is protein bound, 15% is loosely complexed with phosphate or other anions, and 55% is present as the free ion. Over 95% of intracellular magnesium is bound to other molecules, most notably ATP, the concentration of which is approximately 5 mmol/L. The intracellular cytosolic free magnesium concentration is approximately 0.5 mmol/L (i.e., 1000-fold higher than that of calcium) and is maintained by an active sodium-magnesium antiporter. The mechanism(s) whereby magnesium enters cells, presumably down a favorable electrochemical gradient, is unknown, although some evidence for regulated channels has been obtained.[1]

Intracellular magnesium, like phosphate, is necessary for a wide range of cellular functions. It is an essential cofactor in enzymatic reactions, including most of the same glycolytic, kinase, and phosphatase pathways that also involve phosphate. Magnesium serves to directly stabilize the structures of a variety of macromolecules and complexes, including deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and ribosomes; is a key activator of the many ATPase-coupled ion transporters; and plays a direct role in mitochondrial oxidative metabolism. As a result, magnesium is critical for energy metabolism and the maintenance of a normal intracellular environment. Extracellular magnesium is crucial for normal neuromuscular excitability and nerve conduction, and many of the clinical consequences of magnesium deficiency or excess reflect abnormalities in this sphere.

The levels of extracellular calcium and phosphate are regulated in a coordinated way that reflects the roles of calcium and phosphate in mineralization of bone. The concentrations of these ions in body fluids are together close to the concentrations that could lead to spontaneous precipitation in soft tissues. In fact, elaborate mechanisms, most poorly understood, have evolved to prevent calcium phosphate precipitation in tissues and yet to allow the controlled deposition of calcium and phosphate in



• **Fig. 29.2** Parathyroid hormone (PTH)–calcium feedback loop that controls calcium homeostasis. Four organs—the parathyroid glands, intestine, kidney, and bone—together determine the parameters of calcium homeostasis. *ECF,* extracellular fluid; *1,25 D,* 1,25-hydroxyvitamin D; –, negative effect; +, positive effect.

bone.[2] The importance of the mineral ions for normal cellular physiology as well as skeletal integrity is reflected in the powerful endocrine control mechanisms that have evolved to maintain their extracellular concentrations within relatively narrow limits. The following sections describe the structures, secretory controls, actions, and interactions of parathyroid hormone, calcitonin, 1,25-dihydroxyvitamin D ($1,25[OH]_2D_3$ or calcitriol), and fibroblast growth factor 23 (FGF23)—the major hormones involved in mineral ion homeostasis. Subsequent sections cover the wide variety of clinical disorders that accompany abnormalities in this hormonal network.

Parathyroid Hormone

Parathyroid hormone (PTH) is the peptide hormone that controls the minute-to-minute level of ionized calcium in the blood and extracellular fluids. PTH binds to cell surface receptors in bone and kidney, thereby triggering responses that increase blood calcium (Fig. 29.2). PTH also increases renal synthesis of $1,25(OH)_2D_3$, the hormonally active form of vitamin D, which then acts on the intestine to augment absorption of dietary calcium, in addition to promoting calcium fluxes into blood from bone and kidney. The resulting increase in blood calcium (and in $1,25[OH]_2D_3$) feeds back on the parathyroid glands to decrease the secretion of PTH. The parathyroid glands, bones, kidney, and gut are thus the crucial organs that participate in PTH-mediated calcium homeostasis.

Parathyroid Gland Biology

Parathyroid glands first appeared in evolutionary history with the exit of amphibians from the sea and a switch from dependence on gills to sole dependence on bone, intestine, and kidney to maintain extracellular calcium homeostasis. Reptiles, birds, and mammals all have parathyroid glands that develop as epithelial specializations from the endoderm of the pharyngeal pouches. Though fish have no discrete parathyroid glands, they do have several PTH-related genes, including two or more that can influence calcium homeostasis.[3]

Parathyroid chief cells have three properties vital to their homeostatic function: First, they rapidly secrete PTH in response to changes in blood calcium. Second, they can synthesize, process, and store large amounts of PTH in a regulated manner. Third, parathyroid cells replicate when chronically stimulated. These functional attributes allow for short-term, intermediate-term, and long-term adaptation, respectively, to changes in calcium availability.

Parathyroid Hormone Biosynthesis

PTH, a protein of 84 amino acids in mammals, is synthesized as a larger precursor, pre-proparathyroid hormone (pre-pro-PTH); with the explosion of genome sequencing in the past decade, the gene has been sequenced in a large number of species (see sequences in Genbank: http://www.ncbi.nlm.nih.gov/gene/5741) from fish to humans. Fig. 29.3 illustrates representative pre-pro-PTH sequences. These pre-pro-PTH sequences share a 25-residue "pre" or signal sequence and a 6-residue "pro" sequence. The signal sequence, along with the short pro sequence, functions to direct the protein into the secretory pathway (Fig. 29.4). During transit across the membrane of the endoplasmic reticulum, the signal sequence is cleaved off and rapidly degraded. The importance of the signal sequence for normal secretion of PTH is illustrated by the hypoparathyroidism inherited in families carrying mutations in the signal sequence of pre-pro-PTH.[4–6]

The role of the short pro sequence is not completely understood; it may help the signal sequence work efficiently and ensure accurate cleavage of the precursor.[7] After cleavage of the pro sequence, the mature PTH(1-84) is concentrated in secretory vesicles and granules. One morphologically distinct subtype of granule contains both PTH and the proteases cathepsin B and cathepsin H. This co-localization of proteases and PTH in secretory granules probably explains the observation that a portion of the PTH secreted from parathyroid glands consists of carboxy-terminal PTH fragments. No amino-terminal fragments of PTH are secreted. Although the possible functions of carboxy-terminal fragments of PTH are still poorly characterized, these fragments do not activate the PTH/PTHrP (PTH-related protein) receptor and may even block bone resorption[8] (see later discussion). The intracellular degradation of newly synthesized PTH thus may provide an important regulatory mechanism. Under conditions of hypercalcemia, the secretion of PTH is substantially decreased, and most of what is secreted consists of carboxy-terminal fragments.[9]

Parathyroid Hormone Secretion

Although catecholamines, magnesium, and other stimuli can affect PTH secretion, the major regulator of PTH secretion is the concentration of ionized calcium in blood. Increased serum ionized calcium leads to a decrease in PTH secretion (Fig. 29.5A). The shape of the dose-response curve is sigmoid. Properties of the parathyroid cell determine the conformation of the sigmoid curve but do not alone determine the point on the curve that represents a physiologic steady state for an individual. This point, usually between the midpoint and the bottom of the curve, is determined by how vigorously target organs respond to PTH.[10] Fig. 29.5C *(solid line)* shows how an individual's calcium level rises in response to increases in PTH; the parathyroid gland's sigmoid curve is the *dotted line*. In the steady state, an individual's blood levels of PTH and calcium represent the intersection of the two lines.

The sigmoid curve reveals several important physiologic properties of the parathyroid gland. The minimal secretory rate is low,

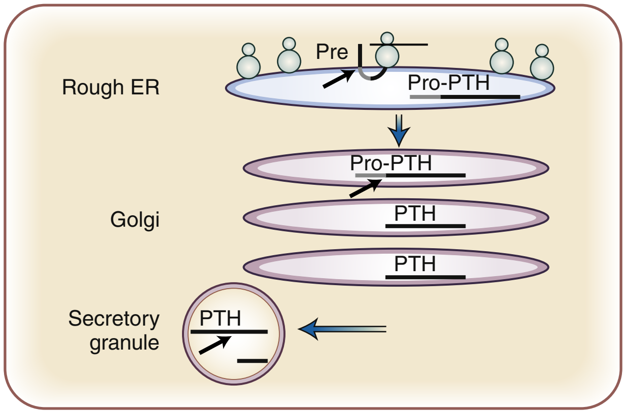
• **Fig. 29.3** Sequences of pre-proparathyroid hormone from six species. Completely conserved residues are in **boldface**. *Arrows* indicate the sites of signal sequence ("pre") and "pro" sequence cleavage. Numbers start at residue +1 of mature parathyroid hormone (PTH); because of gaps, the numbers correspond only to the mammalian and not to the chicken sequence. Amino acids are indicated by the single-letter code: *A,* Ala; *R,* Arg; *N,* Asn; *D,* Asp; *C,* Cys; *Q,* Gln; *E,* Glu; *G,* Gly; *H,* His; *I,* Ile, *L,* Leu; *K,* Lys; *M,* Met; *F,* Phe; *P,* Pro; *S,* Ser; *T,* Thr; *W,* Trp; *Y,* Tyr; *V,* Val.



• **Fig. 29.4** Intracellular processing of pre-proparathyroid hormone (pre-pro-PTH). *Diagonal arrows* indicate sites of cleavage by enzymes that generate pro-PTH in the rough endoplasmic reticulum (ER), PTH in the Golgi, and carboxy-terminal fragments of PTH in the secretory granule.

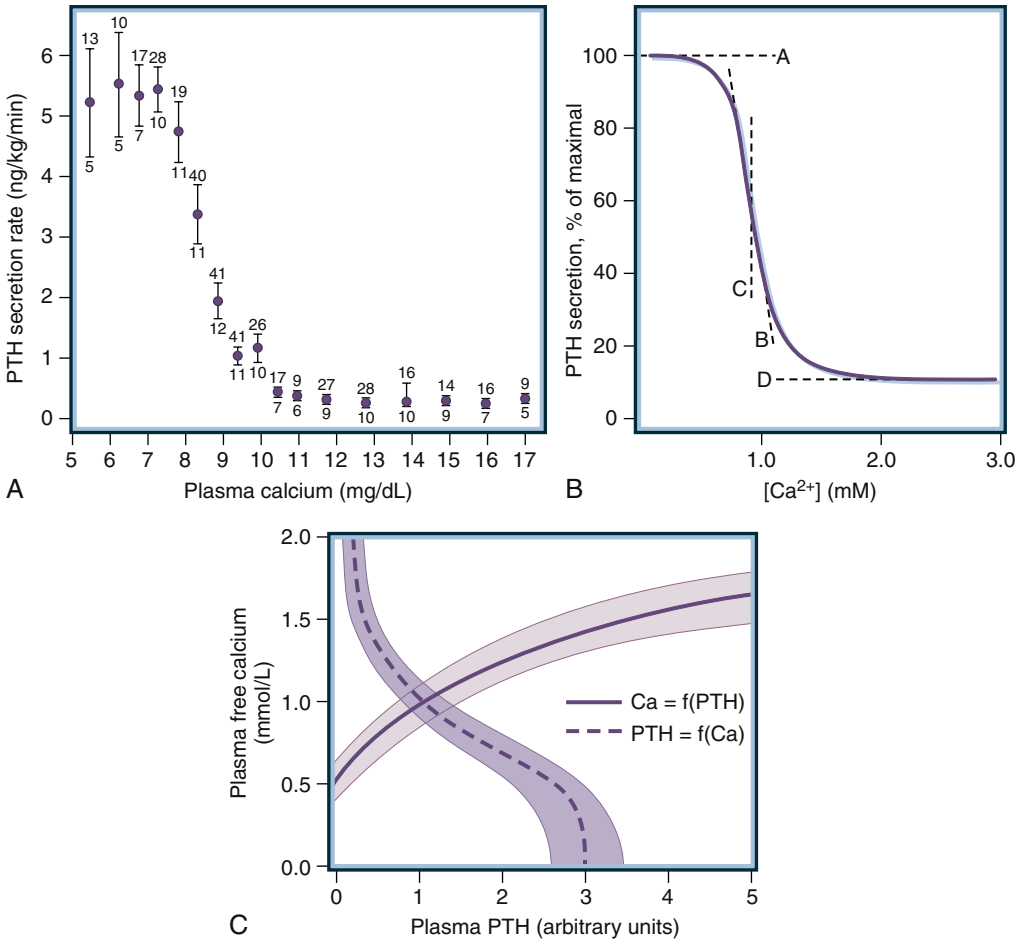
but not zero. The maximal secretory rate represents the reserve of the parathyroid's capacity to respond to hypocalcemia. Because values from normal persons in the steady state are located in the lower portion of the sigmoid curve, the system seems designed to respond more dramatically to hypocalcemia than to hypercalcemia.

Physiologic studies in humans confirmed this sigmoid relationship and have revealed that the parathyroid cell responds both to the absolute level of blood calcium and to the rate of fall of calcium level. Thus PTH levels briefly rise higher during a sudden drop in blood calcium than they do during a more gradual fall in calcium. This property of the parathyroid cell offers an additional protection against sudden hypocalcemia.

The biochemical and cellular determinants of the parathyroid gland's sigmoid response curve are beginning to be defined. A parathyroid calcium-sensing receptor (CaSR) on the parathyroid cell surface is a member of the G protein–coupled family of receptors.[11] The sequence of the receptor suggests that it spans the plasma membrane seven times, like other receptors in the G protein–linked receptor family (Fig. 29.6). A large extracellular domain resembles similar domains in brain metabotropic glutamate receptors as well as bacterial periplasmic proteins designed to bind small ligands, including cations. This domain has been crystalized, and binding sites for calcium, phosphate, and other ligands have been identified.[12] The receptor has been expressed in a number of cell types and has been shown to activate phospholipase C (PLC) and to block stimulation of cyclic adenosine monophosphate (cAMP) production, just as it does in normal parathyroid cells.

The most convincing proof of the identity of the parathyroid CaSR has been the observation that mutations in the receptor gene cause characteristic human diseases. Inactivating mutations cause familial hypocalciuric hypercalcemia (FHH), a disease of defective calcium sensing (see later discussion),[13] whereas activating mutations cause familial hypoparathyroidism with hypercalciuria.[14] Furthermore, mice genetically engineered to have only one functioning copy of the *CASR* gene also have the expected defects in parathyroid calcium sensing.[15] Of importance, calcimimetic compounds that activate the cloned CaSR have been shown to inhibit PTH secretion in humans and are useful in the treatment of secondary hyperparathyroidism.[16,17] Despite the enormous increase in understanding how extracellular calcium activates the parathyroid CaSR, the mechanism whereby this activation leads to a decrease in PTH secretion is poorly understood.

The CaSR is expressed widely. Expression in the renal tubules and calcitonin-producing cells of the thyroid contributes to calcium homeostasis, whereas expression in organs such as the brain points to multiple roles for calcium signaling. Knockout of the CaSR in osteoblasts of mice shows that this receptor regulates osteoblast differentiation and mineralization.[18] The observation that the CaSR also responds to physiologic levels of certain amino



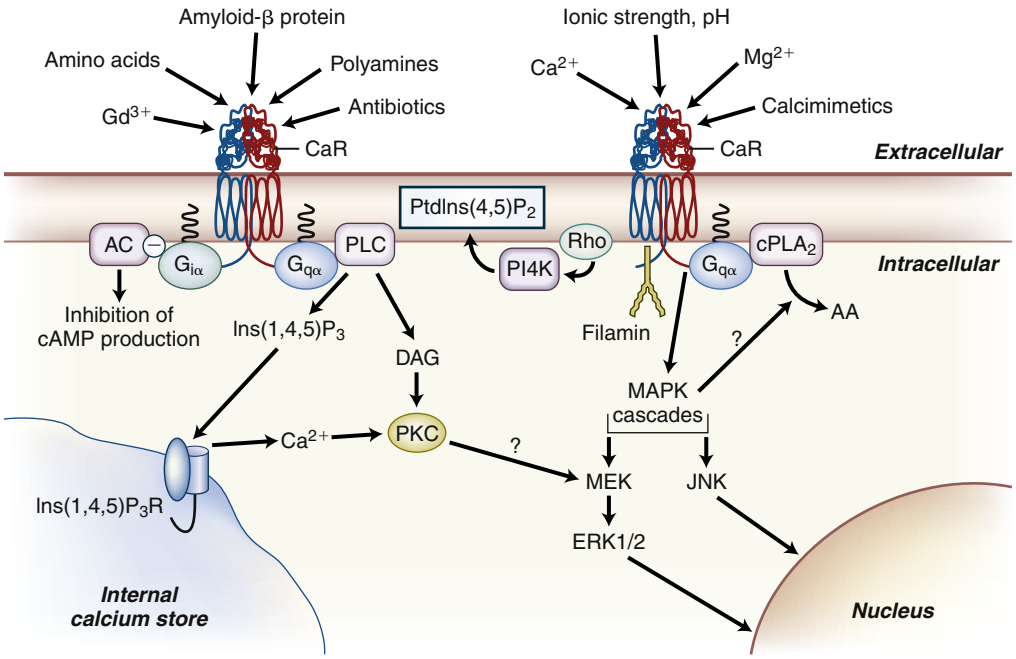
• **Fig. 29.5** Parathyroid hormone *(PTH)* secretion. (A) Secretory response of bovine parathyroid glands to induced alterations of plasma calcium concentration. Calves were infused with calcium chloride or ethylenediaminetetraacetic acid (EDTA), and PTH secretion was assessed by measuring PTH levels in the parathyroid venous effluent. The symbols and *vertical bars* indicate the secretory rate (mean ± SE) in calcium concentration ranges of 1 or 0.5 mg/100 mL. The number of calves and samples are indicated, respectively, by numbers below and above the bars. (B) Sigmoidal curve generated by the equation $Y = ([A - D]/[1 + (X/C)^B]) + D$. Such a curve can be defined by four parameters: the maximal secretory rate *(A)*, the slope of the curve at its midpoint *(B)*, the level of calcium at the midpoint (often called the set-point) *(C)*, and the minimal secretory rate *(D)*; the significance of *A*, *B*, *C*, and *D* is described in the text. (C) Relationships between calcium and PTH levels when each in turn is treated as an independent variable. The *dashed line* represents the sigmoidal relationship between calcium and PTH, when calcium is the independent variable. This curve is the same as that in (A) and (B), but it is turned on its side because the axes are reversed. The *solid line* represents the relationship between calcium and PTH when PTH is considered the independent variable; values for this curve result from measurements made during PTH infusion into parathyroidectomized animals. Actual data are limited, thus the curves should be viewed as illustrative. (A, from Mayer GP, Hurst JG. Sigmoidal relationship between parathyroid hormone secretion rate and plasma calcium concentration in calves. *Endocrinology*. 1978;10:1037–1042; B, modified from Brown EM. Four-parameter model of the sigmoidal relationship between parathyroid hormone release and extracellular calcium concentration in normal and abnormal parathyroid tissue. *J Clin Endocrinol Metab*. 1983;56:572–581; C, from Parfitt AM. Calcium homeostasis. In Mundy GR, Martin TJ, eds. *Physiology and Pharmacology of Bone*. Berlin: Springer-Verlag; 1993.)

acids[19] suggests that the expression of the CaSR in the gut, parathyroid, and other sites may facilitate the assimilation of multiple nutrients.

Regulation of the Parathyroid Hormone Gene

The minute-to-minute regulation of PTH blood levels can be explained by the two mechanisms already discussed—regulation of PTH secretion by the CaSR and amplification of this regulation by intracellular degradation of stored hormone. Over a longer time frame, the parathyroid cell regulates the expression of the PTH gene as well.

Although $1,25(OH)_2D_3$—the active form of vitamin D—has no direct effect on PTH secretion, it dramatically suppresses PTH gene transcription.[20] This suppression of transcription does not occur when $1,25(OH)_2D_3$ is administered to chronically hypocalcemic animals, however, perhaps because hypocalcemia leads to a fall in parathyroid cell vitamin D receptors (VDRs) or because hypocalcemia increases the expression of calreticulin



• **Fig. 29.6** Signaling by the calcium-sensing receptor. (From Hofer AM, Brown EM. Extracellular calcium sensing and signaling. *Nat Rev Mol Cell Biol*. 2003;4:530–538.)

in the parathyroid.[21] The capability of hypocalcemia to override the effects of high levels of 1,25(OH)$_2$D$_3$ represents an important defense because it provides a way for the parathyroid cell to synthesize large amounts of PTH and 1,25(OH)$_2$D$_3$ at the same time, when both are needed.

Calcium also regulates the biosynthesis of PTH. In vivo studies show that acute hypocalcemia in rats leads, within an hour, to an increase in PTH messenger RNA (mRNA). In contrast, hypercalcemia leads to little or no change in PTH mRNA. Thus under normal conditions the inhibition by calcium of PTH biosynthesis already is nearly maximal, just as it is for PTH secretion. The parathyroid gland is poised to respond to a fall in calcium much more readily than to a rise. The mechanism for the increase in PTH mRNA in response to hypocalcemia is uncertain; differing experimental paradigms suggest regulation at the levels of gene transcription, mRNA translation, and mRNA stability. The latter mechanism is the one best understood at the molecular level.[22] In the parathyroid cell, peptidylprolyl isomerase Pin1 binds to and leads to the activation of K-homology splicing regulator protein (KSRP), an RNA-binding protein that destabilizes PTH mRNA. Mice without Pin1 have high PTH and PTH mRNA levels, and hypocalcemic rats and rats with chronic kidney disease have low Pin1 levels. Thus Pin1 and KSRP regulate PTH mRNA levels in normal physiology and disease and mediate the effects of calcium and phosphate on PTH mRNA stability.[23]

For decades it has been known that phosphate elevation stimulates PTH secretion largely by lowering blood calcium and 1,25(OH)$_2$D$_3$ levels. Furthermore, a series of studies in vitro[24,25] and in vivo[26] have demonstrated that phosphate can increase PTH secretion directly, independent of effects on blood calcium and 1,25(OH)$_2$D$_3$. Phosphate increases PTH secretion acutely only after a delay and probably works largely through regulation of PTH mRNA levels. The mechanisms that parathyroid cells use to sense phosphate are unknown, but the effect of hypophosphatemia and hyperphosphatemia on PTH mRNA occurs through regulation of PTH mRNA stability through changes in protein binding to the 3′ noncoding region of the mRNA by mechanisms that closely parallel those used by calcium.[27] FGF23, an important phosphate-regulating hormone (see later), activates FGF receptor 1 and its coreceptor, Klotho, on parathyroid cells and thereby suppresses PTH synthesis,[28] though Klotho-independent signaling by FGF23 may be important as well.[29] In renal failure, both FGF23 levels and PTH levels are elevated. This paradoxic observation (given the role of FGF23 to suppress PTH secretion) may be explained by the downregulation of parathyroid cell FGF receptor 1 and Klotho in renal failure.[30,31]

Regulation of Parathyroid Cell Number

Parathyroid cells divide during the growth of young animals but replicate little in adulthood.[32] Parathyroid cell number can dramatically increase, however, in the setting of hypocalcemia, low levels of 1,25(OH)$_2$D$_3$, hyperphosphatemia, or uremia, or during neoplastic growth.

Calcium, acting through the parathyroid CaSR, restrains parathyroid proliferation. The behavior of the parathyroids in patients who lack both copies of the *CASR* gene is consistent with this hypothesis. These neonates exhibit severe primary

hyperparathyroidism with large, diffusely hyperplastic glands that presumably have developed because of insufficient activation of the parathyroid CaSR by extracellular calcium. Furthermore, administration of the calcimimetic compound NPS R-568, which activates the CaSR directly, prevents parathyroid cell proliferation in experimental uremia.

The role of $1,25(OH)_2D_3$, independent of blood calcium, in regulating parathyroid cell proliferation is less well established than that of calcium. That $1,25(OH)_2D_3$ can dramatically affect parathyroid cell number has been shown in vivo in many settings, but such studies cannot rigorously eliminate effects of transient changes in blood calcium. The suppression of proliferation of cultured parathyroid cells by $1,25(OH)_2D_3$[33] suggests that $1,25(OH)_2D_3$ can directly inhibit parathyroid cell replication. In experimental renal failure, the action of $1,25(OH)_2D_3$ to suppress the increase in parathyroid cell transforming growth factor-α (TGFα) and epidermal growth factor (EGF) receptor expression that otherwise would occur may partly explain the dampening of parathyroid cell proliferation.[34] Nevertheless, vitamin D action through the VDR is not essential for control of parathyroid cell number, because calcium alone can prevent parathyroid cell hyperplasia in mice engineered to lack VDRs.[35] Hypocalcemia and experimental renal failure activate the mTORC1 complex, and this increased signaling by mTOR is required for the parathyroid cell proliferation observed.[36]

Although the ability to increase parathyroid cell number in response to physiologic challenge represents an important defense against hypocalcemia, it is a slow response that is not easily reversible. When the need for an increased number of parathyroid cells disappears (e.g., after renal transplantation for uremia), persistent hyperparathyroidism can cause vexing clinical problems for months and years thereafter. The mechanisms for decreasing parathyroid cell number are poorly understood.

Parathyroid Gland Development

Genes involved in making parathyroid cells during development may also regulate PTH synthesis and parathyroid cell number throughout life and may be mutated in human inherited hypoparathyroidism[37]; thus an understanding of parathyroid cell development may have broad clinical implications. Although the genetic mechanisms used to generate parathyroid chief cells during development are largely unknown, the importance of several specific genes has become clear. Studies of gene knockout mice have shown that the hoxa3,[38] pax1,[39] pax9,[40] and Eya1[41] transcription factors are needed to form parathyroid glands as well as many other pharyngeal pouch derivatives, such as the thymus, as reviewed in Liu and associates.[42] Another transcription factor, Tbx1, regulated by the developmental paracrine factor, sonic hedgehog, is expressed early in parathyroid development and is essential for parathyroid cell development. In humans and mice, haploinsufficiency for the transcription factor Tbx1 is likely to be responsible for many of the abnormalities found in DiGeorge syndrome, including hypoparathyroidism.[43] Even though these transcription factors together are essential for the early generation of parathyroid cells, another transcription factor, gcm2 in mice and GCMB in humans, is needed for the continued survival of parathyroid cells.[42] Furthermore, mice or humans[44] missing the *gcm2* and *GCMB* genes, respectively, have no parathyroid glands. In both species, the deletion of *gcm2* or *GCMB* (the human equivalent) is very specific for controlling parathyroid development because no abnormalities in other tissues have been noted. Studies of human hypoparathyroidism have led to the discovery of the likely roles of other transcription factors in parathyroid development. Another transcription factor, MafB, is dependent on GcmB expression and is also important for parathyroid function.[45] Deletion of one copy of MafB in the mouse leads to ectopic parathyroid glands and, in adulthood, suppression of secondary hyperparathyroidism in a renal failure model.[46] Sox3 is a transcription factor expressed in the pharyngeal pouches that give rise to parathyroid cells. Humans with X-linked hypoparathyroidism manifest a deletion-insertion near the end of the *SOX3* gene, a finding that suggests an important role for Sox3 in parathyroid development.[47] People with mutations in the gene encoding the transcription factor GATA3 exhibit a syndrome of hypoparathyroidism, sensorineural deafness, and renal anomalies when only one copy of the gene is mutated.[48] GATA3 synergizes with GcmB and MafB in stimulating PTH gene expression.[49]

Metabolism of Parathyroid Hormone

The earliest radioimmunoassays for PTH demonstrated that the molecular forms of PTH in the circulation differ from those in the parathyroid gland. Characterization of the metabolism of PTH and its fragments has clarified the origins and significance of immunoreactive PTH (iPTH) molecules in the bloodstream.[50] As noted previously, both PTH(1-84) and carboxy-terminal fragments of PTH are secreted from the parathyroid gland; the ratio of inactive PTH to active PTH secretion increases with increasing blood calcium. Secreted intact PTH(1-84) is extensively metabolized by liver (70%) and kidney (20%) and disappears from the circulation with a half-life of 2 minutes. This rapid peripheral metabolism of PTH is unaffected by widely varying levels of blood calcium or $1,25(OH)_2D_3$. Less than 1% of the secreted hormone finds its way to PTH receptors on physiologic target organs. These features of PTH metabolism ensure that the blood level of PTH is determined principally by the activity of the parathyroid glands and that the PTH level can respond rapidly to small changes in the rate of secretion of the hormone.

In the liver, a small amount of PTH binds to physiologically relevant PTH receptors, but most of the intact PTH is cleaved, initially after residues 33 and 36, probably by cathepsins. In the kidney, a small amount of intact PTH binds to physiologic PTH receptors, but most of the intact PTH is filtered at the glomerulus and subsequently bound by a large, membrane-bound luminal protein, megalin[51]; this binding leads to internalization and degradation of PTH by the tubules.[52] Carboxy-terminal fragments are also cleared efficiently by glomerular filtration. In fact, the kidney is the only known site of clearance of carboxy-terminal PTH fragments; these fragments thus accumulate dramatically when the glomerular filtration rate (GFR) falls. Even in the presence of normal renal function, the half-life of carboxy-terminal fragments of PTH exceeds that of PTH(1-84) by several-fold. Consequently, the concentration of carboxy-terminal fragments in the circulation exceeds that of intact PTH, even though intact PTH usually is the major form of PTH secreted from the parathyroid gland.

Careful analysis of PTH fragments using high-performance liquid chromatography (HPLC) and immunologic methods has revealed almost full-length PTH fragments missing the first several amino acids of the hormone, but containing most or all of the remaining hormone sequence.[53] These still incompletely characterized fragments are both secreted from the parathyroid gland and generated by peripheral metabolism of the hormone. Because

they are missing the amino-terminal portion of PTH, they cannot stimulate cAMP production by the PTH/PTHrP receptor, and except in renal failure, they circulate in small amounts. Nevertheless, the possible biologic activity of these and other PTH fragments, possibly through novel receptors, remains an area of active investigation. Experiments with PTH(7-84) suggest that such extended carboxy-terminal fragments may exert potent effects in vivo, opposing those of intact PTH (see later discussion).[8,54,55]

Actions of Parathyroid Hormone

Actions of Parathyroid Hormone on the Kidney

Stimulation of Calcium Reabsorption

Almost all of the calcium in the initial glomerular filtrate is reabsorbed by the renal tubules. Sixty-five percent or more is reabsorbed by the proximal convoluted and straight tubules via a passive, paracellular route.[56] Changes in the transepithelial voltage gradient, determined largely by the rate of sodium reabsorption, control the rate of calcium transport in the proximal tubule, and PTH does little to affect calcium flux in this region. The remaining calcium is largely reabsorbed more distally—20% of the initial filtrate in the cortical thick ascending limb (cTAL) of Henle loop and 10% in the distal convoluted and connecting tubules. In the cTAL, calcium reabsorption also is mainly passive and paracellular, although some transcellular, active calcium transport may occur as well. Efficient paracellular calcium and magnesium movement requires expression of a unique tight-junction protein, paracellin-1, also called claudin-16; mutant paracellin-1 genes underlie a rare renal calcium-wasting and magnesium-wasting disorder.[57] Because paracellular cation transport in the cTAL is driven by the lumen-positive transepithelial voltage gradient that is established by active Na-K-Cl_2 reabsorption, calcium reabsorption there is strongly inhibited by loop diuretics such as furosemide. The CaSR, initially characterized in the parathyroid, also is expressed in the cTAL. When activated by high blood calcium or magnesium, this receptor inhibits Na-K-Cl_2 reabsorption in the cTAL and, thereby, paracellular calcium reabsorption as well. This provides a parathyroid-independent mechanism for controlling renal calcium handling in direct response to changes in blood calcium concentration.

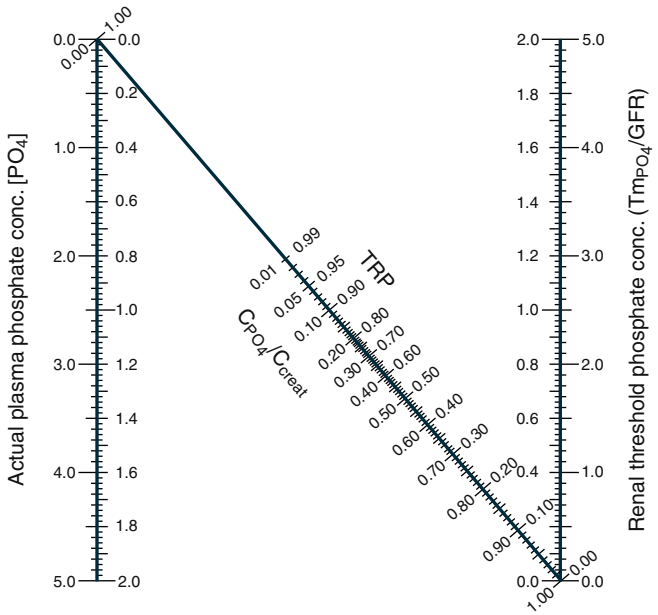
Although PTH modestly stimulates paracellular calcium reabsorption in the cTAL, the primary site for hormonal regulation of renal calcium reabsorption is the distal nephron, which normally reabsorbs nearly all of the remaining 10% of filtered calcium by a unique transcellular active transport mechanism. As depicted in Fig. 29.1, the intracellular level of calcium is extremely low, about 150 nM, compared with the millimolar levels in the glomerular filtrate and the blood. Calcium enters distal tubular cells from the tubular lumen down a highly favorable electrochemical gradient via selective channels (TRPV5 and TRPV6) present on the apical membrane of cells in the distal convoluted tubule (DCT) and connecting tubule (CNT). Intracellular calcium inhibits the activity of these channels, but this is minimized by the avid binding of calcium to calbindin-D28K, which effectively buffers cytosolic calcium and transports it to the basolateral membrane. There, calcium is ejected via active processes involving mainly the sodium-calcium exchanger NCX1 and an ATP-driven calcium pump (PMCA).[58] PTH stimulates DCT and CNT active calcium transport by upregulating several of these components, including TRPV5, calbindin-D28K, and NCX1, both directly and indirectly, via increased synthesis of $1,25(OH)_2D$.[58] PTH acutely increases the flux of calcium through TRPV5 by leading to protein kinase A (PKA) phosphorylation of a residue of TRPV5 that otherwise would bind calmodulin and thereby close the channel.[59]

The amount of calcium in the final urine reflects all of the tubular reabsorption processes just enumerated but also depends crucially on the initial filtered load of calcium. All of PTH's actions serve to raise the blood calcium level so that the filtered load of calcium is high in states of PTH excess. In that setting, even though the rate of distal tubular calcium reabsorption is increased by PTH, the total amount of calcium in the final urine is likely to be high, because of the high initial filtered load.

Inhibition of Phosphate Transport

Phosphate reabsorption occurs mainly in the proximal renal tubules, which reclaim roughly 80% of the filtered load. Some additional phosphate (8–10%) is reabsorbed in the distal tubule (but not in Henle loop), leaving about 10% to 12% for excretion in the urine. The normal overall fractional tubular reabsorption of phosphate (TRP), therefore, is about 90%, although a more reliable measure of renal phosphate handling is the *phosphate threshold* (TmP/GFR), which can be derived from the TRP through the use of a nomogram (Fig. 29.7) based on studies of experimental phosphate infusions in healthy persons and in patients with a variety of diseases that affect phosphate excretion.[60]

Phosphate reabsorption in both proximal and distal tubules is strongly inhibited by PTH, although the proximal effect is quantitatively most important. Phosphate is reabsorbed by a transepithelial route. Transport from the glomerular filtrate into the cell is mediated by specific sodium phosphate (NaPi) cotransporters, several types of which have been cloned and extensively



• **Fig. 29.7** Nomogram for determining renal threshold phosphate concentration *(Tm_{PO4}/GFR)* from the plasma phosphate concentration and the fractional reabsorption of filtered phosphate *(TRP)* or fractional excretion of filtered phosphate (1 – TRP, or C_{PO4}/C_{creat}). Because the blood level of phosphate influences the renal handling of phosphate, the renal threshold phosphate concentration best separates normal from abnormal renal phosphate handling. *C,* clearance; *creat,* creatinine; *GFR,* glomerular filtration rate; *TRP,* tubular resorption of phosphate. (From Walton RJ, Bijvoet OLM. Nomogram of derivation of renal threshold phosphate concentration. *Lancet*. 1975;2:309–310.)

characterized.[61] The low level of sodium within the cell drives the cotransport of sodium and phosphate, even though the phosphate travels up an electrochemical gradient. In response to PTH, the maximum velocity (V_{max}) for sodium phosphate cotransport decreases because NaPi cotransporters (both NaPi-IIa and NaPi-IIc) are rapidly (in 15 minutes) sequestered within subapical endocytic vesicles, after which they are delivered to lysosomes and undergo proteolysis.[62] cAMP and PKA mediate the rapid decrease in phosphate transport in response to PTH, though PLC activation by the PTH receptor is also required for prolonged suppression of phosphate transport by PTH.[63] This response to PTH is dependent upon Na^+/H^+ exchange regulatory factors (NHERFs), which physically interact with both the PTH/PTHrP receptor and the NaPi-II transporters and control the pattern of PTH receptor signaling.[64,65] Conversely, in hypoparathyroidism expression of NaPi protein and mRNA is strongly upregulated.

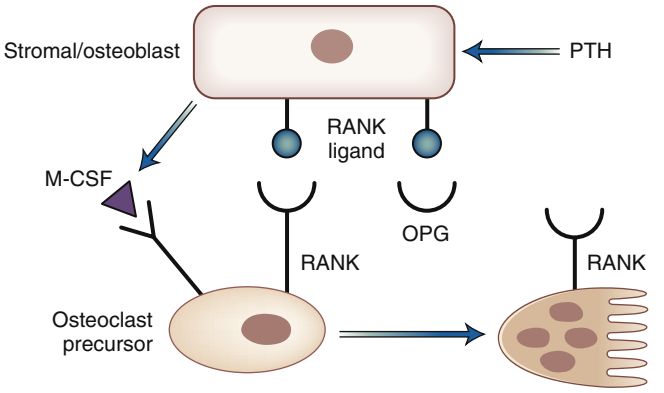
Dietary intake of phosphate also reciprocally regulates the expression and activity of NaPi cotransporters and thus the proximal tubular absorption of phosphate by a mechanism that is independent of PTH. Dietary deprivation of phosphate, for example, leads to a stimulation of phosphate reabsorption that can override the effects of PTH on the proximal tubule. It is likely that this dietary regulation of NaPi expression is mediated by FGF23[66] (see later discussion).

Other Renal Effects of Parathyroid Hormone

PTH stimulates the synthesis of $1,25(OH)_2D$ in the proximal tubule by rapidly inducing transcription of the 25-hydroxyvitamin D (25[OH]D) 1α-hydroxylase gene, an effect that can be overridden by hypercalcemia or by $1,25(OH)_2D$. The interactions of $1,25(OH)_2D$ and PTH in regulating the 25(OH)D 1α-hydroxylase gene involve both PKA-mediated phosphorylation of an activating transcription factor and protein kinase C–mediated demethylation of DNA upstream of the 25(OH)D 1α-hydroxylase gene.[67] PTH inhibits proximal tubular transcription of the 25(OH)D 24-hydroxylase gene and antagonizes the upregulation of 24-hydroxylase activity by $1,25(OH)_2D$. (See discussion under "Metabolism of Vitamin D.") PTH inhibits proximal tubular sodium, water, and bicarbonate reabsorption, mainly via inhibition of the apical Na^+/H^+ exchanger (NHE3) and the basolateral Na^+/K^+-ATPase. PTH also stimulates proximal tubular gluconeogenesis and acts directly on glomerular podocytes to decrease both single nephron and whole kidney GFR.

Actions of Parathyroid Hormone on Bone

The actions of PTH on bone are complicated because PTH acts on a number of cell types both directly and indirectly. For years, the release of calcium from bone through stimulation of bone resorption has been considered to be the major action of PTH on bone. This is only part of the story, however. In fact, PTH administration by any route increases both bone resorption by increasing osteoclast number and bone formation by increasing osteoblast number. Which action dominates depends on the dose of PTH and the route of administration. When PTH is administered continuously, the effect of PTH on bone resorption dominates, and the net result is release of calcium from bone and a decrease in bone mass. This action of PTH thus contributes to the increase in blood calcium seen in the disease, primary hyperparathyroidism. In similar fashion, administration of a soluble form of receptor activator for nuclear factor κB (RANK) ligand (RANKL), a major mediator of PTH's increase in osteoclastic bone resorption (Fig. 29.8), also increases osteoclast number. But RANKL



• **Fig. 29.8** Osteoblast lineage cell control of osteoclastogenesis and osteoclast activity. Parathyroid hormone *(PTH)* acts on PTH/PTH-related protein (PTHrP) receptors on precursors of osteoblasts to increase the production of macrophage colony-stimulating factor (M-CSF) and receptor activator for nuclear factor κB (RANK) ligand and to decrease the production of osteoprotegerin (OPG). M-CSF and RANK ligand stimulate the production of osteoclasts and increase the activity of mature osteoclasts by binding to the receptor RANK. OPG blocks the interaction of RANK ligand and RANK.

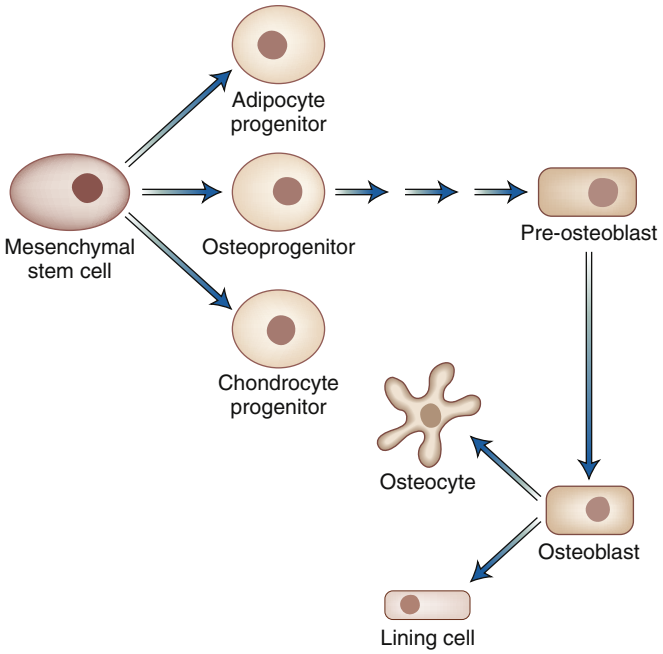
administration causes even lower bone mass than PTH because continuously administered PTH increases osteoblast number more vigorously than RANKL.[68] This finding suggests that one teleologic reason for PTH to increase bone formation is that this separate action of PTH might help preserve bone mass during prolonged requirements for PTH action.

PTH Increases Bone Formation

Administration of low doses of PTH or active amino-terminal fragments of PTH by once-daily subcutaneous injection leads to a net increase in bone mass, with only transient effects on blood calcium. Mechanisms for these divergent effects of PTH are incompletely understood but certainly reflect the variety of cell types in bone that respond directly to PTH, the varying time courses of these responses, and the indirect effects of PTH caused by autocrine and paracrine responses to PTH.[69]

Fig. 29.9 illustrates the cells of the osteoblast lineage (see also Chapter 30). Osteoblasts are probably derived from pluripotent mesenchymal stem cells that can differentiate into chondrocytes, adipocytes, osteoblasts, and other cell types.[70,71] Perivascular cells within human bone can reconstitute bone that supports hematopoiesis after subcutaneous transplantation in mice[72]; these cells may well represent one group of osteoblast stem cells in vivo. Within the osteoblast lineage, committed osteoprogenitor cells divide, become preosteoblastic stromal cells (which can divide further), and then become osteoblasts. Osteoblasts no longer divide and are cuboidal cells found on the bone surface actively laying down new bone. These cells can surround themselves with newly formed bone matrix and extend large numbers of dendritic processes, becoming osteocytes. Alternatively, osteoblasts can stop synthesizing matrix and remain on the bone surface as bone lining cells. Not all preosteoblasts and osteoblasts mature; a variable number die by apoptotic, programmed cell death.[73]

PTH administration can influence movement of cells through the osteoblast lineage.[69] PTH administration in vivo, whether administered continuously or intermittently, increases osteoblast surface and number and bone formation rate. PTH administration increases the number and rate of differentiation of early osteoblast precursors in a murine lineage-tracing model.[74] With



• **Fig. 29.9** Osteoblast lineage. All precursors of osteoblasts can proliferate; osteoblasts are transformed to osteocytes and lining cells without further proliferation. Lining cells can revert to osteoblast function after parathyroid hormone stimulation. At each stage in the lineage, apoptotic cell death is probably an alternative fate.

intermittent PTH administration to rats, the number of bone lining cells decreases as the number of active osteoblasts increases[75]: Subsequent studies using genetically marked mice showed that PTH converts bone lining cells to active osteoblasts.[76] Further, the decreased rate of osteoblast apoptosis after intermittent PTH administration leads to an increase in the number of osteoblasts.[73]

When PTH is administered continuously to rats, mimicking the findings in primary hyperparathyroidism, large numbers of proliferating, alkaline phosphatase–positive fibroblastic cells accumulate in the marrow, perhaps mimicking the findings of osteitis fibrosa in primary hyperparathyroidism. When the infusion of PTH was stopped, the fibroblastic cells disappeared and recently proliferated osteoblasts appeared, suggesting that many of the fibroblastic cells were osteoblast precursors.[77]

In addition to changing osteoblast numbers, PTH changes the activity of mature osteoblasts by a variety of mechanisms. When PTH is added to calvariae in vitro, the osteoblasts decrease their synthesis of collagen I and other matrix proteins. This action may reflect, in part, the action of PTH to steer the essential osteoblast transcription factor Runx2 toward proteosomal destruction.[78] In vivo, however, the most obvious effects of PTH are to increase bone formation by osteoblasts, probably by indirect actions of PTH on autocrine and paracrine pathways. PTH stimulation of osteoblastic cells leads to release of growth factors such as IGF1, FGF2, and amphiregulin from these cells.[79] PTH also decreases the synthesis of dickkopf-1[80] and sclerostin,[81] inhibitors of Wnt signaling[82]; these actions are expected to increase the anabolic actions of Wnt proteins on osteoblasts. Sclerostin is particularly synthesized by osteocytes, thus these cells respond to PTH to regulate the activity of nearby osteoblasts. Further, because bone matrix is a rich source of osteoblast growth factors, the release of these growth factors from this matrix following PTH-induced bone resorption may increase bone formation and bring osteoblastic cells to sites of bone formation.[83] Thus a variety of both direct and indirect actions of PTH can lead to the increased production of bone.

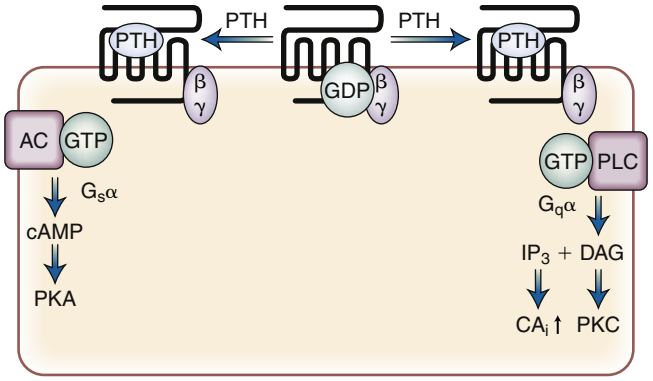
PTH Increases Bone Resorption

Surprisingly, osteoclasts, the bone-resorbing cells derived from hematopoietic precursors, have no PTH receptors on their surfaces. Instead, cells of the osteoblast lineage, including preosteoblasts, osteoblasts, and osteocytes, signal to osteoclast precursors to cause them to fuse and form mature osteoclasts. This signaling also serves to stimulate mature osteoclasts to resorb bone and to avoid apoptosis (see Fig. 29.8). Two cell surface proteins, macrophage colony-stimulating factor (M-CSF) and RANKL, are essential for stimulation of osteoclastogenesis,[84] and RANKL is essential for the activation of mature osteoclasts. The growth factor M-CSF (or CSF1) is expressed both as a secreted protein and as a cell surface protein; the production of both forms is stimulated by PTH.[85] RANKL—also named osteoprotegerin ligand (OPGL), osteoclast-differentiating factor (ODF), and TRANCE—is a membrane-bound member of the tumor necrosis factor (TNF) family; its synthesis is also increased by PTH. RANKL binds to its receptor, RANK, a member of the TNF receptor family. RANK is found both on osteoclast precursors and on mature osteoclasts. The binding of RANKL to RANK can be blocked by osteoprotegerin (OPG), another member of the TNF receptor family. OPG (also called OCIF and TR1) circulates and is also secreted by cells of the osteoblastic lineage. PTH decreases the synthesis and secretion of OPG from these cells. Thus PTH, by increasing RANK and decreasing OPG locally in bone, serves to increase bone resorption.

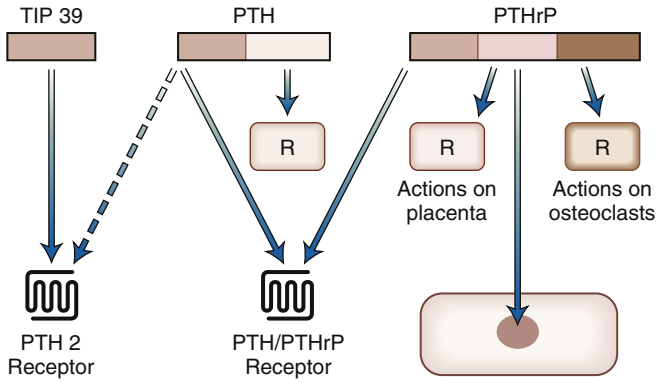
Activation of PTH receptors also causes release of calcium from bone by a less understood mechanism called osteocytic osteolysis. Osteocytes can directly release mineral from the matrix immediately surrounding them. These cells produce proteins associated with bone resorption by osteoclasts, including carbonic anhydrase 2, cathepsin K, and tartrate-resistant acid phosphatase.[86] For example, during lactation in mice, lacunae surrounding osteocytes release calcium; this release depends upon those osteocytes expressing PTH/PTHrP receptors.[87] Little is known about the quantitative importance of osteocytic osteolysis versus osteoclastic bone resorption in various settings.

Molecular Basis of Parathyroid Hormone Action

Ever since the discovery that PTH stimulates the secretion of cAMP into the urine,[88] PTH has been thought to act by triggering a cascade of intracellular second messengers. This guiding hypothesis, in its current form, postulates that all of the actions of PTH result from the binding of the hormone to a receptor on the plasma membrane of target tissues. This receptor is a member of a large family of G protein–linked receptors that span the plasma membrane seven times (Fig. 29.10). The binding of hormone on the outside of the membrane causes conformational changes in the disposition of the seven transmembrane helices that activate the receptor's ability to release guanosine diphosphate (GDP) from the α-subunit of a G protein bound to the receptor. The G protein then binds guanosine triphosphate (GTP) in place of GDP. The GTP-binding α-subunit of the G protein then separates from the βγ-subunits, and the separate subunits of the G protein then modulate the activity of enzymes and channels. The activity of these enzymes and channels then affects proteins farther downstream, eventually leading to the physiologic responses of bone and kidney cells.



• **Fig. 29.10** Parathyroid hormone (PTH)/PTH-related protein (PTHrP) receptors act as nucleotide exchangers. PTH binding to the receptor leads to exchange of guanosine triphosphate (GTP) for guanosine diphosphate *(GDP)* bound to G protein (G_s) α-subunits. G_s α-subunits bound to GTP are released from the receptor and from the βγ-subunits and then activate effectors. $G_s\alpha$ activates adenylate cyclase (AC), leading to the formation of cyclic adenosine monophosphate (cAMP), which then activates protein kinase A (PKA). $G_q\alpha$ and related α-subunits activate phospholipase C (PLC). PLC hydrolyzes phosphatidylinositol 1,4,5-trisphosphate to generate diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3). The DAG then activates protein kinase C (PKC), and the IP_3 activates a receptor on microsomal vesicles that directs the movement of calcium (CA_i) from microsomal vesicles into the cytosol.



• **Fig. 29.11** Network of parathyroid hormone (PTH) ligands and receptors (R). PTH and PTH-related protein (PTHrP) closely resemble each other at the amino-terminal region; TIP 39 (tubero-infundibular peptide of 39 residues) is more distantly related. Although only the PTH/PTHrP receptor and the PTH2 receptors have been cloned, biologic actions suggest that there are receptors specific for the carboxy-terminal portion of PTH, as well as distinct receptors for the midregion of PTHrP and for a more distal region of PTHrP. PTHrP is also found in nuclei and may act directly there.

Parathyroid Hormone and Parathyroid Hormone–Related Protein Receptors

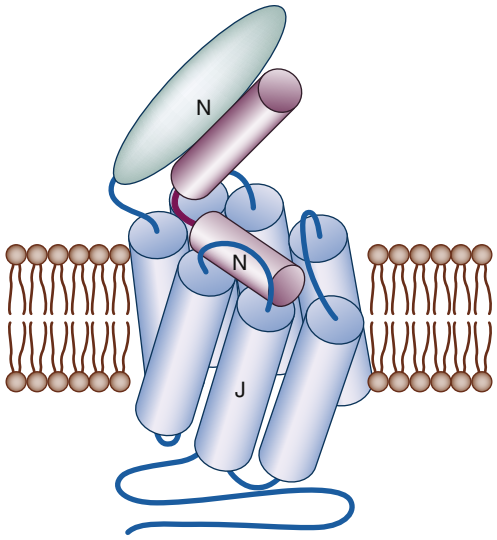
DNA encoding a PTH/PTHrP receptor has been isolated from tissues of many species, including rat, opossum, human, pig, *Xenopus* (toad), and zebrafish,[89] and even some insects.[90] The predicted amino acid sequence of the receptor and direct mapping of inserted epitopes suggest that the receptor spans the plasma membrane seven times, but the sequence does not closely resemble the sequences of most known G protein–linked receptors. Instead it is a member of a distinct subfamily of closely related receptors called family B. Most of these receptors bind peptides of 30 to 40 amino acids in length. Known members include receptors for the secretin family of peptides (secretin, vasoactive intestinal peptide [VIP], glucagon, glucagon-like peptide, growth hormone–releasing hormone [GHRH], pituitary adenylate cyclase–activating peptide, gastric inhibitory peptide), corticotropin-releasing hormone (CRH), calcitonin, and insect diuretic hormones related to CRH. The PTH/PTHrP receptor most closely resembles receptors of the secretin group. The gene encoding the PTH/PTHrP receptor has a complicated structure, with 13 introns interrupting the coding sequence.

The PTH/PTHrP receptor mediates many of the actions of both PTH and PTHrP. The cloned PTH/PTHrP receptor binds amino-terminal fragments of PTH and PTHrP with equal affinity. The receptor is expressed at high levels in kidney and in osteoblasts of bone but is also expressed in a wide variety of tissues, such as smooth muscle, brain, and a variety of fetal tissues, which are thought to be target tissues more for PTHrP than for PTH. When the PTH/PTHrP receptor is ablated in mice, the mutant mice show defects both in calcium homeostasis and in local actions of PTHrP on the growth plates of bone, for example.[91] Mutations in the receptor found in humans are also consistent with this idea (see upcoming discussion). Nevertheless, the scheme of PTH action illustrated in Fig. 29.10 should be considered a simplified outline. It is unlikely that all of the actions of PTH can be explained by interactions with the cloned PTH/PTHrP receptor: Fragments of PTH that seem not to bind the receptor may be biologically active.[92] Furthermore, the carboxy-terminal portion of PTH(1-84) binds a cell surface protein distinct from the PTH/PTHrP receptor.

A second PTH receptor, which can be activated by PTH but not by PTHrP, called the PTH2 receptor (PTH2R), has been cloned. This receptor is expressed in multiple tissues, including brain, vascular endothelium and smooth muscle, endocrine cells of the gastrointestinal tract, and sperm. Expression is not seen in osteoblasts or renal tubules, however. Although PTH activates the human PTH2R well, PTH only poorly activates the PTH2R in rats and other species. Furthermore, a novel ligand called TIP39 (tubero-infundibular peptide of 39 residues) has been characterized and shown to be a potent activator of PTH2R. TIP39 bears only a weak resemblance to PTH or PTHrP and is likely to be a physiologically relevant activator of the PTH2. The functional role of the PTH2R is unknown, but it appears to mediate many actions of TIP39 in the brain and testis; studies of knockout mice implicate TIP39 in regulation of responses to stress[93] and germ cell development.[94] The two cloned PTHRs, as well as distinct receptors for fragments of PTHrP (see later), probably are part of a complex network of ligands and receptors (Fig. 29.11).

Functional Implications of Parathyroid Hormone Structure

Two important advances have helped organize thinking about how PTH activates the PTH/PTHrP receptor. First, it is now clear that all G protein–coupled receptors have structural flexibility that allows them to interact with ligands through the use of multiple conformations.[95] These multiple conformations can bind closely related ligands differently and can lead to differing signaling consequences. Second, high-resolution structures of several family B receptors are now available, in the presence of agonists, antagonists, and G proteins. These structures are consistent with much prior functional work and serve to rationalize many results.[96] They all exhibit a large amino-terminal extracellular domain that binds the carboxy-terminal ends of their respective ligands. The crystal structure of this extracellular domain of the PTH/PTHrP receptor binds the carboxy-terminal portions of either PTH (1-34) or PTHrP (1-36) in similar fashion.[97,98]



• **Fig. 29.12** Binding of PTH(1-34) peptide of the parathyroid hormone (PTH) to the PTH/PTH-related protein (PTHrP) receptor. The amino-terminal *(N)* extracellular domain of the receptor (in *green*) binds rapidly to the carboxy-terminal portion of the ligand. The J domain of the receptor, containing the transmembrane domains and associated loops, binds to the amino-terminal domain of the ligand *(red cylinder marked N).* This binding is slower and may require conformational changes in both the ligand and receptor. These conformational changes then trigger G protein activation, receptor internalization, and other actions. (Courtesy Tom Gardella.)

The structures of the characterized family B receptors show how this binding of the carboxy-terminal portion of the ligands directs the amino-terminal portions of the ligands to interact with the region of the receptor that consists of seven transmembrane domains and associated extracellular loops (Fig. 29.12). The amino-terminal portion of the ligand changes the conformation of the sixth transmembrane domain to allow interaction of the receptor with G proteins to be activated. Amino-terminal fragments of PTH as short as PTH(1-34) have potency at least as great as that of the full-length PTH(1-84).[89] The first several residues of PTH are particularly important for triggering the conformational change in the receptor that results in activation of G_s and adenylate cyclase. Sequences responsible for transmembrane activation of G_s make up most of the first 13 residues of PTH; these are the residues that are highly conserved between PTH and PTHrP. At high concentrations, PTH(1-14) by itself can activate the PTH/PTHrP receptor. This activation domain interacts with the receptor's transmembrane domains and extracellular loops. When the first nine residues of PTH are covalently linked to the receptor's transmembrane domains and extracellular loops, they can activate the receptor. An analogue of PTH(1-14) can also trigger G_q activation, thus activating PLC.[99] These data, plus the observation that a PTH analogue modified at position 1 selectively loses its ability to activate PLC,[100] demonstrate that the amino-terminal portion of PTH is essential for activation of both G_s and G_q. More distal regions of PTH(1-34) can activate protein kinase C and can raise intracellular calcium levels by mechanisms that have not been fully clarified.

Activation of Second Messengers

Precisely how binding of PTH to the extracellular domains of the PTH/PTHrP receptor leads to activation of G proteins is not understood. The crystal structures of the transmembrane portions of other family B receptors resemble those of the more extensively studied rhodopsin family A receptors, but differ in that the potential pocket expected to bind the peptide ligands is larger, forming a V when seen from the side, with transmembrane domains (TMDs) 1, 6, and 7 forming one arm of the V and TMDs 2 to 5 forming the other. This proposed structure, with TMD 1 adjacent to TMDs 6 and 7, is consistent with the behavior of certain mutant PTH/PTHrP receptors.[101,102] Presumably, binding of PTH to several different regions of the receptor changes the relationships of the transmembrane domains[103] such that the receptor's three intracellular loops and carboxy-terminal tail interact with G proteins in an altered way.

Receptors with certain point mutations in the second, sixth, and seventh transmembrane domains can activate G_s even without stimulation by hormone. These mutant receptors were discovered by analyzing the PTH/PTHrP receptors in patients with Jansen metaphyseal chondrodystrophy.[104] Patients with this disorder have signs of parathyroid overactivity (hypercalcemia, hypophosphatemia, and high levels of $1,25[OH]_2D_3$ and urinary cAMP) but low PTH and PTHrP levels. These patients have growth abnormalities, presumably reflecting inappropriately vigorous PTHrP-like actions on growth cartilage. The mutations, all near the bottom of the predicted V-shaped structure of the transmembrane domains,[105] must change the conformation of the intracellular portion of the receptor in a way that resembles the effect of binding of PTH to the normal receptor. The observation that inappropriate activation of the PTH/PTHrP receptor in Jansen chondrodystrophy leads to all of the metabolic abnormalities found in primary hyperparathyroidism is one of the most persuasive pieces of evidence that the cloned PTH/PTHrP receptor does, in fact, mediate the actions of PTH in bone and kidney in humans in vivo.

PTH and PTHrP can both bind to and activate the PTH/PTHrP receptor on the surface of target cells. The fate of the ligand-receptor complexes differs dramatically subsequently, however.[106–108] PTH, but not PTHrP, is internalized in vesicles, along with the PTH/PTHrP receptor, β-arrestin, $G\alpha_s$, and adenylate cyclase. Remarkably, within these vesicles, PTH can signal for longer than PTHrP, which loses its signaling properties when it is internalized. Certain PTH analogs can signal for hours because of their intracellular stabilization and signaling. The tight and acid-resistant binding of PTH to its receptor probably explains the differing properties of PTH and PTHrP, but this distinction and its full functional significance are current topics of active investigation.

Second Messengers and Distal Effects of Parathyroid Hormone

The activation of multiple G proteins by PTH raises questions about the individual roles of each second messenger and their possible interactions. The importance of cAMP as a mediator of the physiologic actions of PTH has been demonstrated by studies in vivo[88] and in vitro.[109] Furthermore, patients with pseudohypoparathyroidism type I, who cannot increase urinary cAMP levels in response to PTH, show clear renal resistance to PTH (see later).

Activation of PLC, with concomitant activation of protein kinase C and synthesis of IP_3, may contribute to physiologic actions of PTH as well, such as inhibition of sodium-phosphate cotransport[110] and stimulation of the renal 25(OH)D 1α-hydroxylase.[111] Mice with mutant PTH/PTHrP receptors that cannot activate PLC have a mild delay in bone development[112]; growth plate abnormalities manifest when G_s is also defective in the growth plates,[113] and abnormalities of phosphate handling by the kidney

occur when challenged with a low-calcium diet.[114] When these mutant mice are challenged with infusions of PTH peptides, their phosphate response is normal at first, but a defect in phosphate handling occurs during prolonged infusion.[63] When these same mutant mice are infused with high levels of PTH, they also exhibit a defect in generation of the expected accumulation of stromal cells in the marrow (osteitis fibrosa) that normal mice exhibit after prolonged PTH infusion.[115] Thus the actions of PTH on bone and kidney that require PLC activation are most clearly seen with high levels of PTH sustained for some time.

The stimulation of one G protein or another by the PTH/PTHrP receptor can vary in different types of cells and even in differing regions of the same cell.[110] In some settings, this choice may be influenced by the interactions of the PTH/PTHrP receptor with intracellular scaffolding proteins, such as NHERF1 and NHERF2 (Na^+/H^+ exchanger regulatory factor). Binding of the PTH/PTHrP receptor to NHERFs is directed by the last four amino acids in the receptor sequence. This binding, particularly prominent at the apical surface of the proximal tubular cells of the kidney, for example, may change the G protein activated by the PTH/PTHrP receptor from predominantly G_s to predominantly G_i.[116]

Target Cell Responsiveness to Parathyroid Hormone

Physiologic responses to PTH depend not only on the concentration of PTH in blood but also on the responsiveness of target cells to PTH. This responsiveness can be modified by previous exposure to PTH or by exposure to a variety of other hormones and paracrine factors. Responsiveness can be changed by alterations at virtually every step in the cellular response to PTH.

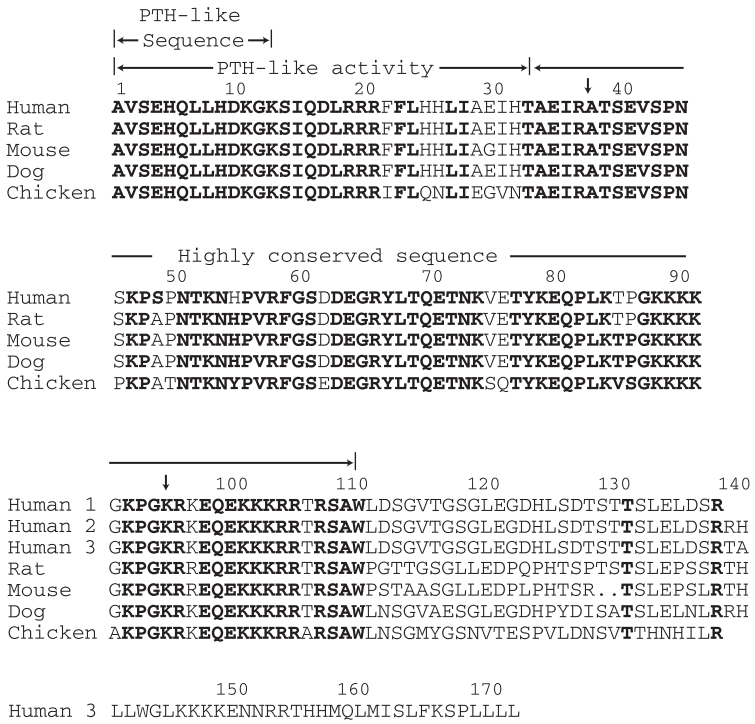
Major regulators of PTH/PTHrP receptor gene expression include, not surprisingly, PTH and $1,25(OH)_2D_3$, both of which can decrease PTH/PTHrP receptor mRNA in certain target cells. In some settings, PTH decreases the amount of immunoreactive and functional receptor on the cell surface without changing the levels of PTH/PTHrP mRNA. This decrease reflects ligand-induced internalization and degradation of receptors. Internalization of receptor is stimulated by PTH binding, which leads to phosphorylation of specific serines found in the receptor's cytoplasmic tail and subsequent internalization directed by binding of β-arrestin to the receptor.[117,118]

Parathyroid Hormone–Related Protein

PTHrP was discovered because the secretion of PTHrP by a wide variety of tumors contributes to the humoral hypercalcemia of malignancy. For this reason, the initial studies of PTHrP in humans and animals stressed the PTH-like structure and properties of the molecule. Subsequent studies soon showed, however, that PTHrP, unlike PTH, is made by a wide variety of tissues, in which it acts locally in ways that may have little relevance to the control of blood calcium.

Gene and Protein Structure

PTHrP sequences in several species, ranging from fish to humans, have been identified[119,120] (Fig. 29.13). In humans, alternative RNA splicing yields transcripts that encode three distinct proteins of 139, 141, and 173 residues that differ only after residue 139.



• **Fig. 29.13** Sequences of parathyroid hormone–related protein (PTHrP) from five species. Completely conserved residues are in *boldface*; note the high level of conservation through residue 111. *Arrows* indicate sites of internal cleavage after residues 37 and 95, which lead to generation of PTHrP(38-94) amide and PTHrP(38-95). Another site of cleavage, generating PTHrP(38-101) and, perhaps, PTHrP(107-139), is not shown.[120] The three human sequences represent proteins synthesized from alternatively spliced messenger RNAs and differ only after residue 139. Amino acids are indicated by the single-letter code (see Fig. 29.3).

Inspection of these sequences suggests that PTHrP has several functionally distinct domains. Eight or nine of the first 13 residues of PTHrP are identical to those in known mammalian PTH sequences. These sequences encompass the known "activation" domain of PTH that interacts with the receptor's transmembrane domain region (see earlier) and are instrumental in the ability of PTHrP to activate PTH/PTHrP receptors.

The sequences in PTHrP(14-34) are also highly conserved. Although these sequences little resemble the corresponding region of PTH, they can displace PTH from the PTH/PTHrP receptor and, in the crystal structure of the amino-terminal domain of the PTH/PTHrP receptor, bind to overlapping but distinct contact sites.[98]

The remaining portion of the PTHrP molecule bears no resemblance to corresponding sequences in PTH. Nevertheless, residues 35 to 111 of PTHrP are strikingly well conserved, with only nine residues differing between mammalian and chicken PTHrP sequences. This sequence conservation is considerably greater than that found in the carboxy-terminal portion of PTH, suggesting that this region of PTHrP has unique and important functions. This region also includes a nuclear localization signal that has been demonstrated to be functional in cultured cells.[121] After residue 111, the PTHrP sequences vary considerably from species to species.

Interspersed within the PTHrP sequences are multiple sites containing one or several basic residues that might serve as post-translational cleavage sites (see Fig. 29.13). Extensive analysis of PTHrP fragments in tumors, cell lines, and transfected cells has shown that several of these sites are, in fact, functional cleavage signals. PTHrP is cleaved after the arginine at residue 37; this cleavage, followed by carboxypeptidase cleavage, generates a PTH-like PTHrP(1-36) fragment as well as the fragments PTHrP(38-94) amide, PTHrP(38-95), and PTHrP(38-101).[122] More carboxy-terminal fragments of PTHrP have been detected in cells as well. Fragments such as PTHrP(107-139) and PTHrP(107-111) can trigger intracellular kinase cascades and affect bone mass in vivo,[123] though the physiologic roles of any of the carboxy-terminal fragments of PTHrP have not yet been established.

In the blood of patients with humoral hypercalcemia of malignancy, multiple immunoreactive species of PTHrP have been found that may well correspond to the fragments of PTHrP in cells and tissue culture media, although precise characterization of these various immunoreactive species is incomplete (see later). Full-length PTHrP may well not circulate, because an amino-terminal–specific immunoaffinity column was unable to extract carboxy-terminal immunoreactivity from the serum of patients with malignant hypercalcemia.[124]

Functions of Parathyroid Hormone–Related Protein

The first actions of PTHrP to be defined were the PTH-like actions associated with the humoral hypercalcemia of malignancy. In this pathologic entity, PTHrP acts as a hormone; it is secreted from the tumor into the bloodstream and then acts on bone and kidney to raise calcium level (see discussion under "Hypercalcemia of Malignancy" later).[125] Whether or not PTHrP circulates at high enough levels in normal adults to contribute to normal calcium homeostasis is an unanswered question. With metastases of breast cancer to bone, locally produced PTHrP can raise serum calcium without necessarily raising blood levels of PTHrP. PTHrP expression by tumors also contributes to the cachexia seen in cancer patients and stimulates the "browning" of adipocytes in tumor models.[126]

PTHrP acts as a calciotropic hormone during fetal life and in lactation. Fetal mice missing the PTHrP gene transport calcium-45 (^{45}Ca) across the placenta inefficiently. This action of PTHrP requires only the midregion of PTHrP and probably involves a receptor distinct from the PTH/PTHrP receptor. Amino-terminal portions of PTHrP and PTH may also be able to increase placental calcium transport, because PTH(1-84) can also increase placental calcium transport in mice missing the PTH gene.[127]

The second setting for humoral actions of PTHrP is lactation. In mice, secretion of PTHrP from the breast into the bloodstream leads to an increase in bone resorption.[128] Calcium then activates the CaSR in breast tissue, increases the movement of calcium into milk, and downregulates expression of PTHrP in the breast.[129] PTHrP therefore probably contributes to the dramatic but largely reversible bone loss during lactation in humans, which is only minimally affected by calcium supplementation.[130] The bone loss is caused both by an increase in osteoclastic bone resorption and by activities of osteocytes to resorb the matrix that surrounds them that require activation of the PTH/PTHrP receptor (osteocytic osteolysis).[87] An exaggeration of this lactational role of PTHrP may explain the rare presentation of hypercalcemia and high PTHrP levels in pregnant and lactating women.[131] Large amounts of PTHrP are also secreted into breast milk, although the role of PTHrP in milk is unknown.

Most of the actions of PTHrP are likely to be paracrine or autocrine.[132] PTHrP is synthesized at one time or another during fetal life in virtually every tissue. Its role in the development of fetal bone has been demonstrated through the striking abnormalities found in genetically engineered mice missing the PTHrP gene. These abnormalities suggest that PTHrP normally keeps chondrocytes proliferating in orderly columns, thereby delaying chondrocyte differentiation.[133] PTHrP blocks the actions of Mef2 and Runx2 transcription factors to activate chondrocyte differentiation by driving class IIa histone deacetylases into the nucleus.[134] The role of PTHrP in many other fetal tissues may analogously involve regulation of proliferation and differentiation. The widespread expression of the PTHrP in fetal life probably underlies the expression of PTHrP in a wide variety of malignancies. As is often the case in malignancy, the expression of PTHrP represents the reinitiation of a fetal pattern of gene expression.

PTHrP is synthesized by many adult tissues. In tissues such as skin, hair, and breast, it is likely that PTHrP regulates cell proliferation and differentiation. PTHrP is also synthesized in response to stretch in the smooth muscle of blood vessels and of the gastrointestinal tract, uterus, and bladder and acts in an autocrine fashion to relax the smooth muscle.[135] PTHrP is also widely expressed in neurons of the central nervous system. Its function in the brain is unknown, but it may protect neurons from excitotoxicity by decreasing flux through voltage-gated calcium channels. An analogous mechanism may explain the role of PTHrP in smooth muscle relaxation.

Many of the actions of PTHrP are mediated by the PTH/PTHrP receptor. Others, such as the activation of placental calcium transport, are probably mediated in part by a distinct receptor, and other actions on bone cells probably involve yet another receptor responsive to more distal portions of PTHrP. Increasing evidence suggests, furthermore, that some actions of PTHrP involve direct nuclear actions of PTHrP.[136] Thus both PTH and PTHrP are likely to use multiple mechanisms to stimulate cells (see Fig. 29.11).

• **Fig. 29.14** The amino acid sequences of calcitonin (CT), calcitonin gene–related peptide (CGRP), amylin, adrenomedullin (ADM), intermedin (IMD), and calcitonin receptor–stimulating proteins (CSRP) from selected species. The *bold Cs* represent the cysteine residues that form the disulfide linkages critical for the secondary structure of these peptides. The other conserved residues are indicated by a *dashed line* (see Fig. 29.3 for the single-letter amino acid codes).

Calcitonin

Calcitonin has an important role in regulating blood calcium in fish and a demonstrable role in rodents; however, the importance of calcitonin in human calcium homeostasis remains uncertain.

The existence of a second calcium-regulating hormone, in addition to PTH, was first demonstrated during perfusion studies of the thyroid/parathyroid glands of dogs.[137] High calcium perfusion resulted in a rapid decrease in plasma calcium, even more rapid than after parathyroidectomy. This suggested that calcium had stimulated the secretion of a hormone that lowered blood calcium. It was subsequently demonstrated that this missing hormone, named *calcitonin* for its role in regulating the "tone" or level of calcium, was elaborated by the thyroid gland, not the parathyroids. Calcitonin is found in the nonfollicular cells of the thyroid, called C cells, which originate from the neural crest.[138] In fish, the location of the C cells in discrete organs led to the rapid isolation of calcitonin from these ultimobranchial bodies in dogfish, salmon, and several other species. The identification of the glandular origin of calcitonin enabled the isolation of sufficient quantities of calcitonin for sequence analysis[139] and studies of its structure and biologic function.

Synthesis and Secretion

Calcitonin consists of a 32–amino acid polypeptide with an intrachain disulfide bond provided by the cysteines at positions 1 and 7 (Fig. 29.14). These two cysteine residues, along with the carboxy-terminal proline amide and six additional residues, are the only amino acids conserved among the calcitonins isolated from various species. The disulfide linkage and proline amide residues are important for the function of the molecule, although biologically active analogues lacking disulfide bonds have been developed. Interestingly, fish calcitonin is more potent in mammals than is the mammalian hormone. The mature peptide is derived from the middle of a 136–amino acid precursor. The human calcitonin gene, located on the short arm of chromosome 11, contains 6 exons, which are alternatively spliced in a tissue-specific manner to yield the mRNAs encoding calcitonin or calcitonin gene-related peptide (CGRP) (see Fig. 29.14). The mRNA encoding calcitonin is derived by splicing together the first four exons[140] and represents over 95% of mature transcripts in the thyroid C cells. The splicing of the first three exons to exons 5 and 6 results in an mRNA that encodes the 37–amino acid αCGRP peptide. The mRNA encoding αCGRP is expressed in multiple tissues and is the only mature transcript of the calcitonin gene detected in neural tissue. A second CGRP gene encodes the closely related βCGRP. In humans, the predicted sequence of the mature peptide differs from that of αCGRP by only three amino acids (see Fig. 29.14). The βCGRP gene is also found on chromosome 11; its tissue distribution is the same as that of αCGRP.

The synthesis and secretion of calcitonin are tightly regulated. Studies in a porcine model reveal a linear relationship between the secretion of calcitonin and ambient calcium levels.[141] Cell culture studies with calcium ionophores and calcium channel blockers demonstrate that the calcium ion concentration within the C cell determines this secretion rate.[142] The CaSR cloned from parathyroid cells is also expressed in C cells and contributes to the regulation of calcitonin secretion.[143] Other calcitonin secretagogues include glucocorticoids, CGRP, glucagon, enteroglucagon, gastrin, pentagastrin, pancreozymin, and β-adrenergic agents.[144] The physiologic role of the gastrointestinal hormones in regulating calcitonin remains unclear; however, they have been postulated to play a role in the regulation of postprandial hypercalcemia. The secretion of calcitonin is inhibited by somatostatin, which is also secreted by the thyroidal C cells. In vivo[145] and in vitro[146] studies have demonstrated that $1,25(OH)_2D_3$ decreases calcitonin mRNA levels by a transcriptional mechanism.

Calcitonin, when administered acutely, decreases tubular resorption of calcium[147] and impairs osteoclast-mediated bone resorption by a direct action on osteoclasts.[148] In rodents, calcitonin has been shown to play a role in the regulation of postprandial hypercalcemia[149] and the skeletal response to lactation.[150] Studies in calcitonin knockout mice reveal a doubling of bone formation rate in the absence of hormone, accompanied by resistance to ovariectomy-induced bone loss.[151] An increase in bone formation is also found in mice heterozygous[152] or homozygous for calcitonin receptor ablation.[153] This increase in bone formation is

thought to be due to absence of calcitonin-mediated inhibition osteoclast secretion of sphingosine-1-phosphate, which induces bone formation.[153]

The physiologic role of calcitonin in humans, however, remains elusive. The effect of calcitonin on bone density was examined in patients with long-term hypercalcitoninemia secondary to medullary carcinoma of the thyroid (MCT) and in patients with subtotal thyroidectomy resulting in lack of calcitonin secretory reserve.[154] The abnormal calcitonin levels had no influence on the bone density at the lumbar spine and distal radius. Furthermore, long-term, high-dose administration of exogenous calcitonin caused no physiologic abnormalities.[155]

Many of the effects of calcitonin are mediated by a G protein–coupled cell surface receptor in the PTH/secretin receptor family.[156,157] The mRNA encoding this receptor has been found in multiple tissues, including kidney, brain, and osteoclasts. The coupling of this receptor to different G proteins results in the activation of either adenylate cyclase or PLC; in some settings, this is cell cycle dependent.[158]

Calcitonin Family: Calcitonin Gene-Related Peptide, Amylin, Adrenomedullin, Calcitonin Receptor–Stimulating Peptides, and Intermedin

CGRP, amylin, adrenomedullin, calcitonin receptor–stimulating peptide 1 (CRSP1), and intermedin have all been shown to have high-affinity binding sites on cell membranes, and displacement studies suggest that several receptor subtypes for these related ligands are present. However, cloning of specific receptors for these ligands proved difficult, because the functional receptors consist of heterodimers between G protein–coupled receptors and single transmembrane proteins of the RAMP (receptor activity modifying proteins) family.[159,160] Interaction of the calcitonin receptor-like receptor, a relative of the calcitonin receptor, with RAMP1 results in a CGRP receptor, whereas RAMP2 and RAMP3 interactions with the same calcitonin receptor-like receptor generate adrenomedullin receptors. Interaction of RAMP1 with the calcitonin receptor generates an amylin receptor.[161] CGRP receptors have been shown to exhibit ligand-dependent and RAMP-dependent signaling bias among the $G\alpha_s$, $G\alpha_i$, and $G\alpha_{q/11}$ pathways.[162]

CGRP is thought to act as a neurotransmitter and vasodilator rather than as a hormone. In support of this hypothesis, inhibition of CGRP receptor signaling using monoclonal antibodies decreases the frequency of migraines in predisposed individuals,[163,164] and mice lacking αCGRP have been shown to have an increase in mean arterial pressure.[165] Immunohistochemical studies of CGRP in the brain and peripheral nervous system suggest that this neuropeptide also plays an important role in sensory and integrative motor functions.

Three structurally related peptides have been isolated from porcine brain (see Fig. 29.14). These calcitonin receptor-stimulating peptides (CRSPs) are also expressed in the thyroid gland. CRSP1, which is 60% homologous to αCGRP at the amino acid level, binds to the calcitonin receptor, dose-dependently stimulates cAMP production, and inhibits osteoclastogenesis.[166] Consistent with this observation, administration of CRSP1, like that of calcitonin, results in a decrease in serum calcium. The receptors for CRSP2 and CRSP3 have not been identified.[167]

Amylin is highly homologous to CGRP and calcitonin (see Fig. 29.14). Although amylin has been shown to have skeletal actions, the presence of amylin in the pancreas of patients with type 2 diabetes mellitus suggests an etiologic role for this peptide in this disorder.[168] Because amylin slows gastric emptying, promoting satiety and attenuating the postprandial rise in glucagon, analogues of this peptide are currently being used as therapeutic agents for type 2 diabetes and are being investigated for the treatment of obesity. Amylin administration inhibits bone loss associated with ovariectomy and streptozotocin-induced diabetes mellitus in rats.[169,170] Targeted ablation of amylin in mice results in low bone mass due to an increase in bone resorption.[152] Amylin has also been shown to decrease food intake and inhibit gastric acid secretion, protecting against ulcer development in numerous models.[171]

Adrenomedullin (see Fig. 29.14) has vasodilatory effects similar to those of CGRP. In addition to activating CGRP receptors, adrenomedullin binds to specific receptors in the vascular system.[172] Mice lacking adrenomedullin die in midgestation.[173] Haploinsufficiency of RAMP2, which regulates binding of adrenomedullin to the calcitonin receptor, results in hyperprolactinemia, delayed bone development, and decreased bone mineral density.[174] Unlike other family members, adrenomedullin does not inhibit osteoclast activity or formation.[166] The physiologic role of adrenomedullin in the skeleton remains to be clarified.

Intermedin (adrenomedullin-2), the newest member of this family (see Fig. 29.14), was identified by homology screening of expressed sequence tags. It is expressed primarily in the pituitary and the gastrointestinal tract. Intermedin is able to signal through CGRP receptors and competes with CGRP for receptor binding.[175] However, unlike CGRP and adrenomedullin, intermedin is a nonselective agonist for the RAMP coreceptors.

Calcitonin in Human Disease

Calcitonin is secreted by several endocrine malignancies and therefore can serve as a tumor marker. Basal and pentagastrin-stimulated calcitonin levels have been used to identify and follow those at risk for, or affected by, medullary carcinoma of the thyroid (see Chapter 42), although abnormal basal and stimulated levels may be observed in patients on chronic hemodialysis.[176] Calcitonin may also be ectopically secreted by other tumors, including insulinomas, VIPomas, and lung cancers. Severely ill patients, including those with burn inhalation injury,[177] toxic shock syndrome,[178] and pancreatitis,[179] may also have elevated calcitonin levels.

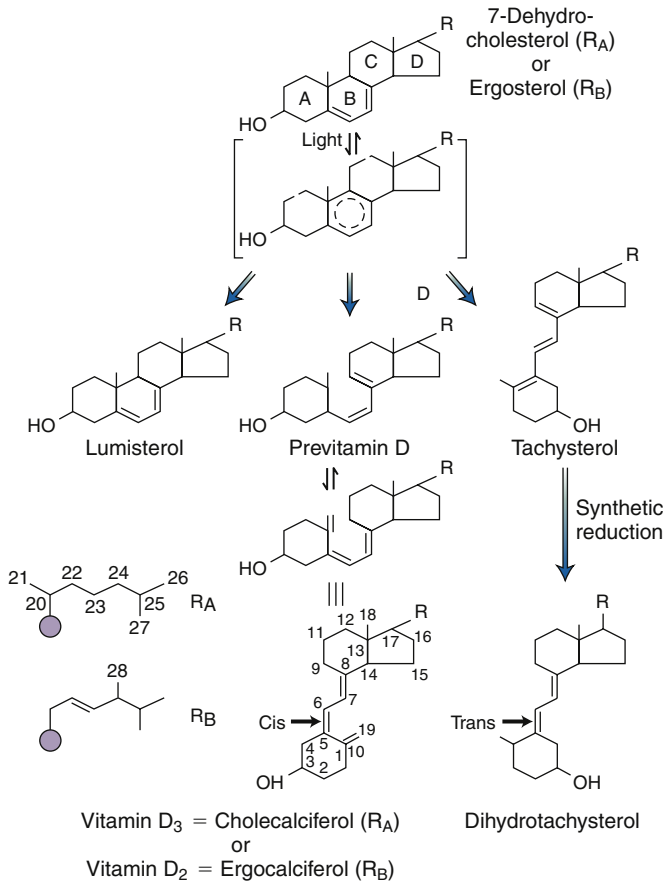
Therapeutic Uses

The observation that calcitonin inhibits osteoclastic bone resorption has led to its therapeutic use for the treatment of several disorders associated with excess bone resorption, including osteoporosis and Paget disease. Calcitonin has also been used for its analgesic effect, in the treatment of patients with vertebral crush fractures, osteolytic metastases, or phantom limb.[180,181] Based on the more beneficial effects of other agents and potential increased risk of malignancy in those being treated with salmon calcitonin, as well as the marginal efficacy of the drug, it is no longer recommended for treatment of osteoporosis.[182]

Vitamin D

Metabolism of Vitamin D

Vitamin D is not a true vitamin, because nutritional supplementation is not required in humans who have adequate sun exposure. When exposed to ultraviolet irradiation, the cutaneous precursor



• **Fig. 29.15** Vitamin D precursors and alternative reaction products. The numbering system for vitamin D carbons and the distinct structures of vitamin D_2 (ergocalciferol) and D_3 (cholecalciferol) are noted, as is the structure of dihydrotachysterol, a synthetic product not produced in vivo. Note that the 3-hydroxyl group of dihydrotachysterol is in a pseudo-1-hydroxyl configuration. This may explain the relatively high potency of dihydrotachysterol in conditions associated with low 1α-hydroxylase activity.

of vitamin D, 7-dehydrocholesterol, undergoes photochemical cleavage of the carbon bond between carbons 9 and 10 of the steroid ring (Fig. 29.15). The resultant product, previtamin D, is thermally labile and over a period of 48 hours undergoes a temperature-dependent molecular rearrangement that results in the production of vitamin D. Alternatively, this thermally labile product can isomerize to two biologically inert products, luminosterol and tachysterol. This alternative photoisomerization prevents production of excessive amounts of vitamin D with prolonged sun exposure. The degree of skin pigmentation, which increases in response to solar exposure, also regulates the conversion of 7-dehydrocholesterol to vitamin D by blocking the penetration of ultraviolet rays.

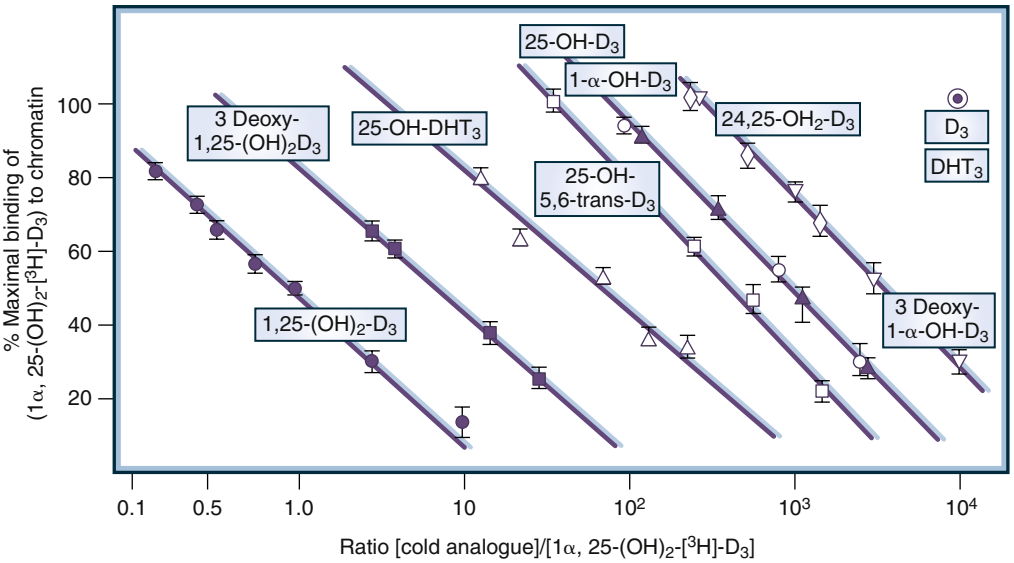
The alternative source of vitamin D is dietary. The elderly, the institutionalized, and those living in northern climates likely obtain most of their vitamin D from dietary sources. However, with increasing avoidance of sun exposure by the general population, ensuring adequate dietary intake of vitamin D has become important for the population at large. Vitamin D deficiency is prevalent and has been shown to contribute significantly to osteopenia and fracture risk. The major dietary sources of vitamin D are fortified dairy products, although the lack of monitoring of this supplementation results in marked variation in the amount of vitamin D provided.[183] Other dietary sources include egg yolks, fish oils, and fortified cereal products. Vitamin D provided by plant sources is in the form of vitamin D_2, whereas that provided by animal sources is in the form of vitamin D_3 (see Fig. 29.15). These two forms have equivalent biologic potencies and are activated equally efficiently by the hydroxylases in humans. While vitamin D_3 has been shown to be more effective at increasing 25-hydroxyvitamin D levels,[184] this effect is dependent upon vitamin D–binding protein (VDBP) genotype and concentration.[185]

Vitamin D is absorbed into the lymphatics and enters the circulation bound primarily to VDBP, although a fraction of vitamin D circulates bound to albumin. The human VDBP is a 52-KDa α-globulin synthesized in the liver. The protein has a high affinity for 25(OH)D but also binds vitamin D and $1,25(OH)_2D$. Approximately 88% of 25(OH)D circulates bound to the VDBP, 0.03% is free, and the rest circulates bound to albumin. In contrast, 85% of the circulating $1,25(OH)_2D_3$ binds to the VDBP, 0.4% is free, and the rest binds to albumin. Mice lacking VDBP have increased susceptibility to $1,25(OH)_2D_3$ toxicity as well as to dietary vitamin D deficiency.[186] Vitamin D–binding protein polymorphisms have been postulated to be the basis for difference in vitamin D levels in several groups, including African Americans and Finns.[187] Measurements of free 25(OH) vitamin D across multiple populations, however, suggest that the monoclonal antibody used in the former study can bring misleading results.[188]

Studies in megalin-deficient patients and megalin null mice demonstrate that VDBP is filtered by the glomerulus and reabsorbed by a megalin-dependent pathway in the proximal renal tubule. Further investigations will be required to determine the importance of this pathway in vitamin D metabolism and the tissues in which megalin-dependent endocytosis plays an important role.

In the liver, vitamin D undergoes 25-hydroxylation by a cytochrome P450–like enzyme present in the mitochondria and microsomes. The half-life of 25(OH)D is approximately 2 to 3 weeks. The 25-hydroxylation of vitamin D is not tightly regulated, therefore the blood levels of 25(OH)D reflect the amount of vitamin D entering the circulation. When levels of VDBP are low, such as in nephrotic syndrome, circulating levels of 25(OH)D are also reduced. The half-life of 25(OH)D is shortened by increases in levels of its active metabolite, $1,25(OH)_2D_3$.

The final step in the production of the active hormone is the renal 1α-hydroxylation of 25(OH)D to $1,25(OH)_2D_3$. The half-life of this hormone is approximately 6 to 8 hours. Like the 25-hydroxylase, the 1α-hydroxylase in the proximal convoluted tubule is a cytochrome P450–like mixed function oxidase, but unlike the 25-hydroxylase, the 1α-hydroxylase is tightly regulated. PTH and hypophosphatemia are the major inducers of this microsomal enzyme, whereas calcium, $1,25(OH)_2D$, and FGF23 repress it.[189,190] Analogous to mice lacking FGF23, mice with inactivating mutations of the FGF23 coreceptor, α-Klotho, a type I membrane protein with homology to β-glycosidases, develop hypercalcemia as a result of increased levels of $1,25(OH)_2D_3$. Like the FGF23 null mice, Klotho null mice have increased levels of the 1α-hydroxylase,[191] and their phenotype is ameliorated by impairment of $1,25(OH)_2D_3$ action. In animal models and in vitro studies, other hormones such as estrogen, calcitonin, growth hormone, and prolactin have been shown to increase 1α-hydroxylase activity; however, the clinical importance of these observations has not been established. Ketoconazole has been shown to decrease levels of $1,25(OH)_2D_3$ in a dose-dependent manner, presumably by interfering with 1α-hydroxylase activity.



• **Fig. 29.16** Relative potency of analogues of $1,25(OH)_2D_3$ (1,25-dihydroxyvitamin D_3) in competitive binding to vitamin D receptors of chick intestinal mucosa. Slopes are plotted for *(left to right)* $1,25\text{-}(OH)_2\text{-}D_3$ (1,25-dihydroxyvitamin D_3); 3 deoxy-$1,25(OH)_2D_3$ (3 deoxy-1,25-dihydroxyvitamin D_3); 25-OH-DHT_3 (25-hydroxydihydrotachysterol); 25-OH-5,6-trans-D_3 (25-hydroxy-5,6-transvitamin D_3); 25-OH-D_3 (25-hydroxyvitamin D_3); 1-α-OH-D_3 (1α-hydroxyvitamin D_3); 24,25-OH_2-D_3 (24,25-dihydroxyvitamin D_3); 3-deoxy-1-α-OH-D_3 (3-deoxy-1α-hydroxyvitamin D_3); D_3 (vitamin D_3); DHT_3 (dihydrotachysterol). (From Proscal DA, Okamura WH, Norman AW. Structural requirements for the interaction of 1α,25-(OH)2-vitamin D3 with its chick intestinal system. *J Biol Chem.* 1975;250:8382–8388.)

The 1α-hydroxylase enzyme is also expressed in keratinocytes, the trophoblastic layer of the placenta, and in granulomas, including sarcoid granulomas, among many other tissues. In granulomatous tissue, the 1α-hydroxylase gene that is expressed is identical to that expressed in the kidney but is not regulated by PTH, phosphate, calcium, or vitamin D metabolites in these cells. Activation of macrophages with interferon-γ[192] or with ligands that activate the heterodimer of toll-like receptors 1 and 2,[193] however, increases the expression of the 1α-hydroxylase in macrophages, whereas treatment of sarcoidosis-associated hypercalcemia with glucocorticoids, ketoconazole,[194] or chloroquine[195] has been shown to lower serum $1,25(OH)_2D_3$ levels. Activation of the VDR in human macrophages induces the antimicrobial peptide cathelicidin and increases killing of intracellular *Mycobacterium tuberculosis*.[193] Thus the pathologic excess of $1,25(OH)_2D_3$ in sarcoidosis may represent an exaggeration of a healthy paracrine response of tissue macrophages. This action can be viewed as a paradigm for many other actions of vitamin D that are mediated more by the local production of $1,25(OH)_2D_3$ than by circulating $1,25(OH)_2D_3$.

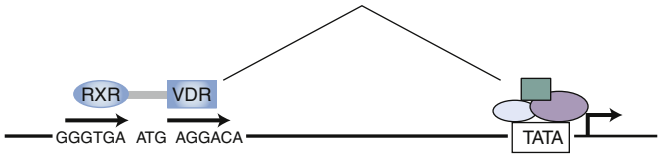
$25(OH)D$ and $1,25(OH)_2D_3$ can also be hydroxylated by vitamin D 24-hydroxylase, which is present in most tissues, including kidney, cartilage, and intestine. $1,25(OH)_2D_3$ increases the activity of the 24-hydroxylase, thereby inducing its own metabolism. The 24-hydroxylated vitamin D metabolites, $24,25(OH)_2D_3$ and $1,24,25(OH)_3D_3$, are not thought to play major biologic roles other than inactivation of $1,25(OH)_2D_3$. Mice and humans with nonfunctional 24-hydroxylase genes demonstrate hypercalcemia, hypercalciuria, and nephrocalcinosis due to vitamin D toxicity.[196,197]

$1,25(OH)_2D_3$ is also metabolized to several inactive products by 23-hydroxylation or 26-hydroxylation and side-chain oxidation and cleavage. This latter side-chain cleavage, resulting in the formation of calcitroic acid, occurs in the liver and intestine, whereas inactivation of $1,25(OH)_2D_3$ in a wide variety of target tissues occurs by 24-hydroxylation. In addition, polar metabolites of $1,25(OH)_2D_3$ are excreted in the bile. Some of these metabolites are deconjugated in the intestine and reabsorbed into the enterohepatic circulation.

Actions of Vitamin D

Vitamin D Receptors

$1,25(OH)_2D_3$ exerts its biologic functions by binding to a nuclear receptor, which then regulates transcription of DNA into RNA. Among the other nuclear receptors, the VDR most closely resembles the retinoic acid, triiodothyronine, and retinoid X receptors (RXRs). The affinity of the receptor for $1,25(OH)_2D_3$ is approximately three orders of magnitude higher than that for other vitamin D metabolites (Fig. 29.16). Although $25(OH)D_3$ is less potent on a molar basis, its concentration in the serum is approximately three orders of magnitude higher than that of $1,25(OH)_2D$. However, its free concentration is only two orders of magnitude greater than that of $1,25(OH)_2D_3$. Therefore, under normal circumstances, it is unlikely that $25(OH)D_3$ contributes importantly to calcium homeostasis. Because the affinity of the vitamin D–binding protein for $25(OH)D_3$ is greater than for $1,25(OH)_2D_3$, in states of vitamin D intoxication (with its associated high levels of $25[OH]D_3$), the free levels of $1,25(OH)_2D_3$ increase because $25(OH)D$ displaces it from the vitamin D–binding protein. $25(OH)D_3$ may therefore play a role in the clinical syndrome of vitamin D intoxication both by its direct biologic effects, when present at toxic levels, and by increasing free levels of $1,25(OH)_2D_3$. Under normal circumstances $25(OH)D$ is not thought to play a role in mineral ion homeostasis; however,



• **Fig. 29.17** Transcriptional activation by 1,25-dihydroxyvitamin D_3 ($1,25(OH)_2D_3$). A heterodimer of retinoid X receptor (RXR) and vitamin D receptor (VDR) binds to a pair of hexameric sequences separated by three intervening bases (ATG). *Arrows* indicate that the hexamers found in the upregulated rat osteocalcin gene are variants of a consensus sequence, repeated here with identical orientations (direct repeats). Upon binding to DNA, the RXR-VDR heterodimer facilitates formation of a transcription initiation complex, which binds to DNA at and near the TATA sequence.

local activation of this prohormone may contribute to host immune response and barrier function.

The vitamin D receptor acts by forming a heterodimer with the retinoid-X receptor, binding to DNA elements, and recruiting coactivators in a ligand-dependent fashion. These coactivators link the receptor complex to the basal transcription apparatus, thereby regulating transcription of target genes. In most cases, the upregulatory response elements for vitamin D contain hexameric repeats separated by three bases (Fig. 29.17).[198] The mechanism of transcriptional repression by vitamin D varies. For example, VDR-RXR heterodimers repress the 1α-hydroxylase and renin genes by blocking the function of other transcription factors,[199,200] and interaction of the VDR with the Ku antigen, acting as a transcription factor, is required for transcriptional repression of the hPTHrP gene.[201]

Glucocorticoids have been shown to decrease the expression of the VDR gene in osteosarcoma cell lines, whereas $1,25(OH)_2D_3$ increases its expression in many cell types. In the renal proximal convoluted tubule, however, $1,25(OH)_2D_3$ decreases the levels of vitamin D receptors. This decrease has been postulated to lead to decreased activation of the renal 24-hydroxylase by $1,25(OH)_2D_3$ and thereby protect the newly synthesized $1,25(OH)_2D$ from local inactivation.[202]

$1,25(OH)_2D_3$ also has some biologic effects that occur too rapidly for transcriptional mechanisms to be implicated. These so-called nongenomic actions, including a rapid increase in intracellular calcium, activation of phospholipase C, and opening of calcium channels, are observed in several cell types within minutes of exposure to $1,25(OH)_2D_3$. Additional data supporting the hypothesis that nongenomic actions are not dependent on the classic receptor include the identification of specific binding sites for $1,25(OH)_2D_3$ on the antiluminal surface of intestinal cells[203] and a disparity between the affinity of the various vitamin D analogues for the nuclear receptor and their potency in these nongenomic actions. However, both the rapid intracellular accumulation of cGMP in association with the vitamin D receptor and the rapid increase in intracellular calcium in response to $1,25(OH)_2D$ are dependent upon the presence of an intact nuclear receptor, because these effects are not observed in cells derived from patients and mice with VDR mutations.[204] However, 1,25-dihydroxyvitamin D binding to the cell surface receptor PDIA3/Erp57 causes a rapid increase in calcium uptake in enterocytes, which is abrogated by deletion of this receptor.[205] The physiologic importance of the nongenomic actions of vitamin D metabolites[206] has not yet been established.

The VDR is expressed in most tissues and has been shown to regulate cellular differentiation and function in many cell types. Nevertheless, the most dramatic physiologic effects of vitamin D, acting through the VDR, involve regulation of intestinal calcium transport. This is most clearly demonstrated by the phenotype of patients and mice with mutant VDRs (hereditary vitamin D–resistant rickets)[35,207]: Dramatic abnormalities in bone mineralization can be reversed by bypassing the defect in intestinal calcium absorption.[208–210]

Intestinal Calcium Absorption

Under normal dietary conditions, calcium intake is in the range of 700 to 900 mg daily. Approximately 30% to 35% of this calcium is absorbed; however, losses from intestinal secretion of calcium lead to a net daily uptake of approximately 200 mg. Though vitamin D is the major hormonal determinant of intestinal calcium absorption, the bioavailability of mineral ions in the intestinal lumen may be affected by a number of local factors and dietary constituents. Absorption of calcium and magnesium is impaired by bile salt deficiency, unabsorbed free fatty acids in steatorrheic states, and high dietary content of fiber or phytate. Gastric acid is needed to promote dissociation of calcium from anionic components of food or therapeutic preparations of calcium salts. Administration of calcium salts with meals, especially in achlorhydrics, and use of divided doses or more soluble salts such as calcium citrate are commonly used strategies to increase calcium bioavailability.

Calcium is thought to be absorbed by two pathways: a saturable transcellular pathway and a nonsaturable paracellular route. The transcellular pathway is dependent on $1,25(OH)_2D_3$. Although the necessity of vitamin D for paracellular calcium absorption remains controversial, substantial evidence exists that the hormone enhances this pathway as well.[211] Notably, $1,25(OH)_2D_3$ induces the expression of claudin-2 and claudin-12, which contribute to intestinal calcium absorption and are thought to form paracellular channels between neighboring cells.[212]

The most extensively studied mechanism of intestinal calcium absorption involves the transcellular route. This pathway is thought to involve three steps: entry of calcium into the enterocyte (which is the rate-limiting step), transport across the cell, and extrusion across the basolateral membrane.[213]

Entry Into the Enterocyte

$1,25(OH)_2D_3$ induces synthesis of a number of brush border proteins, including the intestinal membrane calcium-binding protein, brush border alkaline phosphatase, and low-affinity Ca^{2+}/Mg^{2+}-ATPase. The activity of these proteins correlates with active calcium transport; however, a causal relationship remains to be established. Two calcium channels, TRPV5 and TRPV6, members of the transient receptor potential vanilloid receptor subfamily containing six membrane-spanning domains, are expressed in the duodenum, the jejunum, and the kidney as well as in other tissues. TRPV6 is thought to play a critical role in intestinal calcium absorption, and $1,25(OH)_2D_3$ increases its expression, as well as that of TRP5.[214] Studies in mice lacking TRPV5 demonstrate that this channel is primarily responsible for renal calcium reabsorption, because mice lacking TRPV5 have enhanced, rather than impaired, intestinal calcium absorption due to their high circulating levels of $1,25(OH)_2D$.[215] Upon entering the enterocyte, calcium binds to components of the brush border complex subjacent to the plasma membrane. Calmodulin is redistributed to the brush border in response to $1,25(OH)_2D_3$ and may play a role in this process, as may the $1,25(OH)_2D_3$-inducible calcium-binding protein, calbindin-9K.

Transcellular Transport

The best studied effect of vitamin D on the enterocyte is the induction of synthesis of the intestinal calcium-binding protein, calbindin-9K. This protein has an EF hand structure that permits the binding of two calcium ions per molecule. The affinity of calbindin for calcium is approximately four times that of the brush border calcium-binding components, so calcium is preferentially transferred to calbindin. Calbindin serves to buffer the intracellular free calcium concentration during calcium absorption. It associates with microtubules and may play a role in the transport of calcium across the enterocyte. However, studies in mice lacking both TRPV6 and calbindin-D9k maintain 40% of normal $1,25(OH)_2D_3$-mediated calcium transport, demonstrating that other hormone-responsive genes may play a significant or compensatory role.[216] Organelles such as the mitochondria, Golgi apparatus, and endoplasmic reticulum also serve as repositories for intracellular calcium.

Exit From the Enterocyte

The transport of calcium across the antiluminal surface of the enterocyte, the final process involved in intestinal calcium absorption, is dependent on $1,25(OH)_2D_3$. The main mechanism of calcium extrusion is the $1,25(OH)_2D_3$-inducible ATP-dependent Ca^{2+} pump (PMCA1b). The affinity of the pump for calcium is approximately 2.5 times that of calbindin. With high calcium intake, a $1,25(OH)_2D_3$-independent Na^+/Ca^{2+} exchanger may play a role in the transfer of calcium across the basolateral membrane as well.

Actions on the Parathyroid Gland

$1,25(OH)_2D_3$ has been shown to regulate gene transcription and cell proliferation in the parathyroids. The hormone also inhibits the proliferation of dispersed parathyroid cells in culture, although the relative contribution of calcium and $1,25(OH)_2D_3$ in the regulation of parathyroid cell proliferation in vivo has not been established. Normocalcemic mice lacking functional vitamin D receptors have normal serum PTH levels and normal-size parathyroid glands, demonstrating that the genomic actions of $1,25(OH)_2D_3$ are not essential for parathyroid cellular homeostasis.[210] $1,25(OH)_2D_3$ has, however, been shown to decrease the transcription of the PTH gene both in vivo and in vitro. This action has been exploited in the use of $1,25(OH)_2D_3$ for the treatment of the secondary hyperparathyroidism associated with chronic renal failure (see discussions under "Parathyroid Hormone Biosynthesis" and "Vitamin D Deficiency").

Actions on Bone

The effects of $1,25(OH)_2D_3$ on bone are numerous. $1,25(OH)_2D_3$ is a major transcriptional regulator of the two most abundant bone matrix proteins: It represses the synthesis of type I collagen and induces the synthesis of osteocalcin. $1,25(OH)_2D_3$ promotes the differentiation of osteoclasts from monocyte-macrophage stem cell precursors in vitro and increases osteoclastic bone resorption in high doses in vivo by stimulating production of RANKL (also called osteoclast differentiating factor) by osteoblasts.[217] Notably, osteoblast-specific knockout of the vitamin D receptor leads to increased bone mass associated with impaired bone resorption due to decreased RANKL expression.[218] Consistent with this, and despite the multiple effects of $1,25(OH)_2D_3$ on the biology of bone in vitro, in vivo studies in $1,25(OH)_2D_3$-deficient rats and in mice lacking functional vitamin D receptors[35,208] suggest that the major osseous consequences of hormone and receptor deficiency can be reversed when mineral ion homeostasis is normalized. In addition, parenteral calcium infusions have been shown to heal the osteomalacic lesions in children with mutant VDRs.[209] These observations suggest that the major role of $1,25(OH)_2D_3$ in bone is to provide the proper microenvironment for bone mineralization through stimulation of the intestinal absorption of calcium and phosphate.

Other Actions of Vitamin D

The effects of $1,25(OH)_2D_3$ on phosphate transport are less well studied than those on calcium transport. $1,25(OH)_2D_3$ has been shown to promote the already efficient intestinal phosphate absorption and to induce the expression of the phosphaturic hormone FGF23.[66]

One of the striking clinical features of profound vitamin D deficiency that is poorly understood is the severe proximal myopathy. While some studies demonstrate VDR expression in skeletal myofibers,[219] both the expression and the role of this receptor in muscle remain controversial. Regardless, in vitro $1,25(OH)_2D_3$ treatment increases 25(OH)D[219] and amino acid uptake into muscle cells and alters phospholipid metabolism. Vitamin D administration has been shown to increase the concentration of troponin C, a calcium-binding protein in muscle that plays a role in excitation coupling and increases the rate of uptake of calcium by the sarcoplasmic reticulum. Vitamin D repletion of severely deficient adults has been shown to improve muscle strength, associated with an increase in mitochondrial function assessed by 31-phosphate nuclear magnetic resonance (NMR) spectroscopy.[220] Vitamin D receptor knockout mice demonstrate a delay in myoblast differentiation[221]; however, little is known regarding the direct role of vitamin D in normal muscle physiology. The myopathy that accompanies vitamin D deficiency is characterized by normal creatinine phosphokinase (CPK) levels, a myopathic electromyogram (EMG), and biopsy findings of loss of myofibrils, fatty infiltration, and interstitial fibrosis. The myopathy resolves within days to weeks of vitamin D replacement and is not related to normalization of mineral ion homeostasis; however, studies in vitamin D–deficient rats demonstrate that maintenance of normal mineral ion levels precludes the development of myopathy.[222] Vitamin D deficiency has also been implicated in statin-induced myopathy.[223] In contrast to these studies, which suggest a beneficial effect of vitamin D on muscle function, monthly administration of 60,000 IU vitamin D has been shown to be associated with an increased incidence of falls in those over the age of 70.[224]

While the vitamin D receptor is widely expressed, the clinical implications of these findings are not well understood. However, recent studies demonstrate that women with vitamin D levels above 30 ng/mL in early and late pregnancy have a lower risk of preeclampsia.[225] Prenatal vitamin D supplementation has also been shown to reduce the risk of early childhood asthma.[226]

Vitamin D Analogs

The recognition that $1,25(OH)_2D_3$ promotes cellular differentiation and inhibits cellular proliferation has led to efforts directed at producing new analogues that retain these effects but do not cause hypercalcemia. Several analogues have been shown to have antiproliferative effects on normal cells as well as on malignant cells in vitro and in xenografts in immunosuppressed mice.[227] In addition, analogues of vitamin D have been shown to synergize with cyclosporine in preventing rejection of transplanted islet cells in a murine model.[228] Nonhypercalcemic analogs have been shown to

suppress PTH synthesis and secretion in rats at doses that stimulate intestinal calcium absorption less than $1,25(OH)_2D_3$. Such analogs are currently used for the prevention and treatment of hyperparathyroidism associated with chronic kidney disease.[229] The antiproliferative effects of vitamin D have been exploited clinically in the treatment of psoriasis.[230] Although analogues with reduced calcemic activity are predominantly used, hypercalcemic crisis after excessive topical use of such compounds can occur.

The physiology underlying the differential biologic effects of these analogues is not completely understood. Altered affinity for the vitamin D–binding protein, metabolism by target tissues,[231] and effects on recruitment of coactivators by the vitamin D receptor may contribute to the unique properties of vitamin D analogs.[232]

Fibroblast Growth Factor-23

FGF23 in Human Disease

The search for the hormonal factor responsible for the hypophosphatemia in patients with tumor-induced osteomalacia (TIO, see Chapter 31) was brought to a close with the identification of the molecular basis for the human disorder, autosomal dominant hypophosphatemic rickets (ADHR).[233] Linkage analyses of affected kindreds identified mutation of the gene encoding FGF23 as the basis for ADHR. The mutation in affected individuals abolishes an RXXR protease recognition motif that is thought to be responsible for the cleavage and inactivation of FGF23.[234,235] The cDNA encoding FGF23 predicts a peptide of 251 amino acids, the first 24 of which comprise a signal peptide. Studies using recombinant FGF23 demonstrate that the full-length mature peptide is required for its biologic activity and that the cleavage site mutated in the ADHR patients is responsible for its inactivation. Cleavage of FGF23 is inhibited by furin inhibition, suggesting that the enzyme responsible is a subtilisin-like proprotein convertase.

Analyses of tumors isolated from patients with TIO reveal a dramatic increase in mRNA expression of FGF23.[236] A significant number of these tumors exhibit a fibronectin:FGFR1 or fibronectin:FGF1 fusion thought to underlie the increase in FGF23 production.[237] The elevated serum levels of FGF23 in patients with TIO have been shown to normalize after removal of the tumor, correlating with resolution of the hypophosphatemia that characterizes this disorder.[238,239] FGF23 is also responsible for the renal phosphate wasting observed in X-linked hypophosphatemia. Increased levels of FGF23 have been reported in disorders characterized by somatic moisaicism, including fibrous dysplasia and epidermal and large congenital melanocytic nevus syndrome. Exome sequencing in the latter individuals demonstrated somatic activating mutations in *HRAS* and *NRAS*, though how this leads to increased serum FGF23 levels is not clear.[240] Conversely, patients with the rare syndrome tumoral calcinosis present with hyperphosphatemia and soft tissue calcium-phosphate deposits. Some of these patients have point mutations in the FGF23 gene that cause abnormal processing of the protein, with low levels of the active hormone in the blood and high levels of inactive fragments.[241–243] Other affected individuals have been shown to have mutations in the FGF23 coreceptor α-Klotho or in GALNT 3, which normally O-glycosylates FGF23.[244,245] Thus human diseases of both increased and decreased FGF23 activity suggest that this factor is an important regulator of phosphate metabolism.

Actions of FGF23

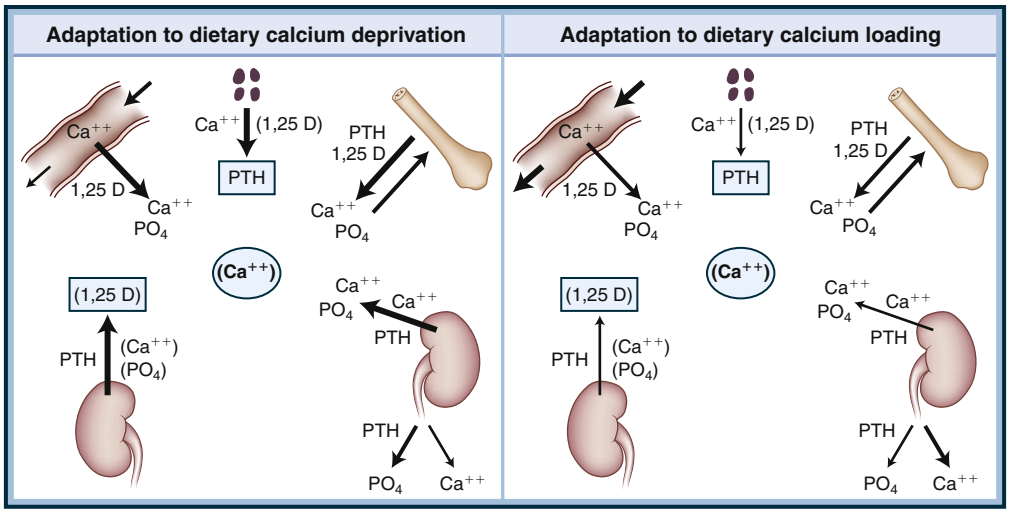
Evidence that FGF23 is a novel hormone that plays a key role in normal phosphate homeostasis has been obtained in murine models of overexpression and ablation. Overexpression of FGF23 or administration of FGF23 to animals results in the development of hypophosphatemia[235] and impaired 1α-hydroxylation of 25(OH)D,[190,246] thus recapitulating the findings observed in patients affected by TIO. Investigations in mice with targeted ablation of FGF23 have proven that endogenous production of this hormone is critical for normal phosphate homeostasis and the regulation of vitamin D metabolism.[247,248] Absence of FGF23 results in impaired renal phosphate excretion, leading to the development of hyperphosphatemia within the first 2 weeks of life. Affected mice also develop hypercalcemia due to high levels of 1,25-dihydroxyvitamin D, a result of the lack of the normal suppressive effect of FGF23 on the renal 25(OH)D 1α-hydroxylase.[190] Ablation of FGF23 results in premature death associated with ectopic mineralization of soft tissues, including the kidney. Impairing 1,25-dihydroxyvitamin D action in these animals prevents the development of hypercalcemia and improves survival, suggesting that the premature death is a direct consequence of impaired mineral ion homeostasis rather than a specific developmental or maturational effect of FGF23.[249]

FGF23 impairs Na-dependent phosphate transport in both intestinal and renal brush border membrane vesicles.[250] It has been shown to decrease the levels of the types IIa, IIb, and IIc Na-dependent phosphate transporters, thereby regulating both intestinal and renal phosphate transport.[251–253] FGF23 decreases circulating levels of 1,25-dihydroxyvitamin D, both by decreasing mRNA levels for the renal 25(OH)D 1α-hydroxylase as well as by increasing expression of the 24-hydroxylase, the key enzyme involved in inactivation of 1,25-dihydroxyvitamin D.[190] FGF23 activates FGF receptor 1 in the presence of α-Klotho, a single-pass transmembrane protein, which acts as a coreceptor.[254] Klotho knockout mice exhibit the same hyperphosphatemia and high $1,25(OH)_2D_3$ levels seen in the FGF23 knockout mice,[191] demonstrating that it plays a critical role in mediating the actions of FGF23.

In chronic kidney disease, FGF23 levels correlate with increased left ventricular mass. While FGF23 has been shown to have direct effects on cardiomyocytes,[255] it also enhances distal renal tubule sodium absorption contributing to hypertension.[256] High FGF23 levels in the setting of hypophosphatemia, such as is seen in humans[257] and mice with X-linked hypophosphatemia and in mice with mutations of the DMP1 gene,[257] do not lead to cardiac hypertrophy, suggesting that cooperative interactions between phosphate and FGF23 may be required.

Regulation of FGF23

Circulating FGF23 levels are increased by dietary phosphorus, serum phosphorus, and 1,25-dihydroxyvitamin D.[66,258,259] Parathyroid hormone induces FGF23 mRNA levels, but also increases furin cleavage, thus limiting target organ effects.[260] Iron deficiency has also been shown to increase expression of FGF23 in bone via an erythropoietin/hypoxia-inducible factor (HIF)-1α–dependent mechanism.[261,262] Interestingly, studies in mice with chondrocyte-specific ablation of the vitamin D receptor have increased circulating FGF23, suggesting that chondrocytes express a vitamin D–regulated repressor of FGF23 production.[263] In addition, studies in mice with mutations in the *PHEX* or *DMP1* genes



• **Fig. 29.18** Homeostatic responses to variations in dietary calcium content. Major homeostatic responses to dietary calcium deprivation or loading are depicted. *Arrow thickness* indicates relative activity of transport or secretory mechanisms, whereas amounts of hormones or transported ions are related to the size of their notations. *Parentheses* indicate an inhibitory regulation. Note that the extracellular calcium concentration is well maintained, although different underlying mechanisms are involved in the two circumstances (see text for details). *1,25 D,* 1,25-dihydroxyvitamin D_3; *PTH,* parathyroid hormone.

demonstrate that these genes suppress FGF23 expression.[248,264] It has been suggested that mutations in both *PHEX* and *DMP1* alter the set-point for extracellular phosphate induction of FGF23.[265] Circulating FGF23 levels are dramatically increased in acute renal injury[266] and in response to lipopolysaccharide (LPS)–induced inflammation. In the latter case, the spleen is a major source of circulating FGF23, demonstrating nonosseous contributions to circulating hormone levels.[266]

In patients with chronic renal failure, an increase in FGF23 levels has been shown to antedate the development of secondary hyperparathyroidism, and thus evaluation of FGF23 levels may be beneficial in predicting which individuals will develop this disorder.[267] Treatment of dialysis patients with sevelamer hydrochloride and calcium carbonate decreases phosphate and FGF23 levels in parallel, implicating increases in serum phosphate or intestinal absorption as the pathophysiologic basis for the increased FGF23 levels in this population.[268] Based on the increase in serum levels of FGF23 seen with iron deficiency and erythropoietin, careful attention to the iron stores of CKD patients and limited use of erythropoietin may also serve to attenuate increases in serum FGF23. Thus FGF23 has emerged as an essential regulator of normal phosphate and $1,25(OH)_2D_3$ homeostasis. Phosphate and $1,25(OH)_2D_3$ increase FGF23 levels; this FGF23 then acts on the renal proximal tubule to suppress synthesis of $1,25(OH)_2D_3$ and to decrease the reabsorption of phosphate.

Calcium and Phosphate Homeostasis

The cytosolic concentrations of intracellular calcium, phosphorus, and magnesium differ markedly, as reviewed previously, and their physiologic roles within cells are diverse and largely unrelated (see Fig. 29.1). In contrast, the concentrations of these mineral ions in extracellular fluid are quite comparable (i.e., 1–2 mmol/L), and it is here that they exert important interactions, both with cells and with one another, that are critical for bone mineralization, neuromuscular function, and normal mineral ion homeostasis. Extracellular calcium and phosphate, in particular, exist so close to the limits of their mutual solubility that stringent regulation of their concentrations is required to avoid diffuse precipitation of calcium phosphate crystals in tissues.

Serum concentrations and total body balances of the mineral ions are maintained within narrow limits by powerful, interactive homeostatic mechanisms. PTH, $1,25(OH)_2D$, and FGF23 regulate mineral ion levels; mineral ion levels, in turn, regulate PTH, $1,25(OH)_2D$, and FGF23 secretion; and these hormones may regulate the production of one another. Calcium sensors in the parathyroid glands control PTH secretion by monitoring the blood concentration of ionized calcium, and those in the kidney act to adjust tubular calcium reabsorption, independently of PTH or $1,25(OH)_2D$. In contrast, the mechanisms of the phosphate sensing needed for normal homeostasis are not understood. The operation of these homeostatic mechanisms can be appreciated by considering the following examples of how the organism adapts to changes in calcium loads (Fig. 29.18).

Dietary calcium restriction, for example, is followed by an increase in the efficiency of intestinal calcium absorption. This increased efficiency results from a sequence of homeostatic responses in which lowered blood ionized calcium activates secretion of PTH, PTH augments synthesis of $1,25(OH)_2D_3$ by the proximal tubules of the kidney, and $1,25(OH)_2D_3$ then acts directly upon enterocytes to increase active transcellular transport of calcium. Enhanced intestinal calcium absorption is quantitatively the most important response to calcium deprivation, but a series of other homeostatic events also occur that limit the impact of this stress. Renal tubular calcium reabsorption is increased by PTH, an effect that is enhanced by increased $1,25(OH)_2D_3$-stimulated expression of calbindin-D28K in the distal tubules. Calcium reabsorption is also enhanced directly by any tendency to hypocalcemia, which is detected by CaSRs in Henle loop (and possibly also in the distal nephron) that control transepithelial calcium movements independent of PTH or $1,25(OH)_2D_3$.

The impact of dietary calcium deprivation is reduced by approximately 15% through release of calcium from bone in response to PTH and $1,25(OH)_2D_3$. The concomitant increase

in net bone resorption causes release of phosphate as well as calcium into the extracellular fluid. Intestinal phosphate absorption also is increased by $1,25(OH)_2D_3$. These phosphate loads are problematic, in that phosphate directly lowers ionized calcium in extracellular fluid, suppresses renal synthesis of $1,25(OH)_2D_3$, and directly inhibits bone resorption. These potentially negative effects of phosphate are obviated by the powerful phosphaturic action of PTH and of FGF23, the secretion of which is promoted by phosphate, calcium, and $1,25(OH)_2D$.

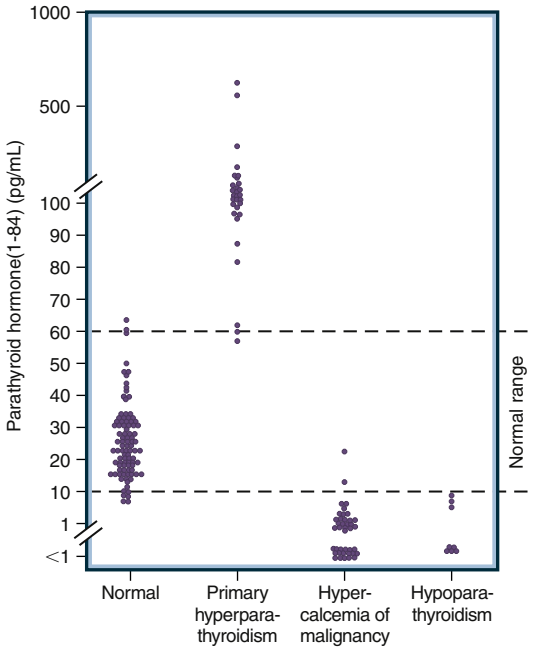
Finally, the possibility of unrestrained secretion of PTH, leading to excessive bone resorption and severe hypophosphatemia, is prevented by the effects of calcium on PTH secretion and by the direct suppressive effect of $1,25(OH)_2D_3$ on the synthesis of PTH and of PTH receptors. As a result of these homeostatic responses, calcium-deprived people maintain near-normal serum calcium and phosphate concentrations but display increased intestinal calcium absorption, increased bone resorption and progressive osteopenia, increased renal tubular calcium reabsorption, decreased renal tubular phosphate reabsorption, low urinary calcium excretion, elevated urinary phosphate excretion, and high serum concentrations of PTH and $1,25(OH)_2D_3$.

Calcium loads induce an opposite series of adaptations: parathyroid suppression, inhibition of renal $1,25(OH)_2D_3$ synthesis, decreased intestinal active transport of calcium, increased renal excretion of calcium and decreased renal excretion of phosphate (secondary to functional hypoparathyroidism), and a decrease in bone resorption sufficient to allow positive skeletal calcium balance. The decline in intestinal calcium absorption is the major safeguard against calcium overload, although this mechanism may be overridden with extraordinarily high intakes of calcium because of the persistence of the passive, non-vitamin D–dependent mode of calcium absorption. Moreover, nonenteral sources of calcium, such as intravenous calcium infusion or excessive net bone resorption (as from immobilization or malignancy), may readily overwhelm the limited homeostatic adaptations that remain once suppressed intestinal calcium absorption is bypassed. In such situations, the kidney rather than the intestine becomes the principal defense against hypercalcemia, and calcium homeostasis becomes critically dependent on adequate renal function. If renal function is impaired in these settings, as frequently occurs clinically, severe hypercalcemia and pathologic calcium deposition in extraskeletal sites may ensue.

Laboratory Assessment of Mineral Metabolism

Parathyroid Hormone

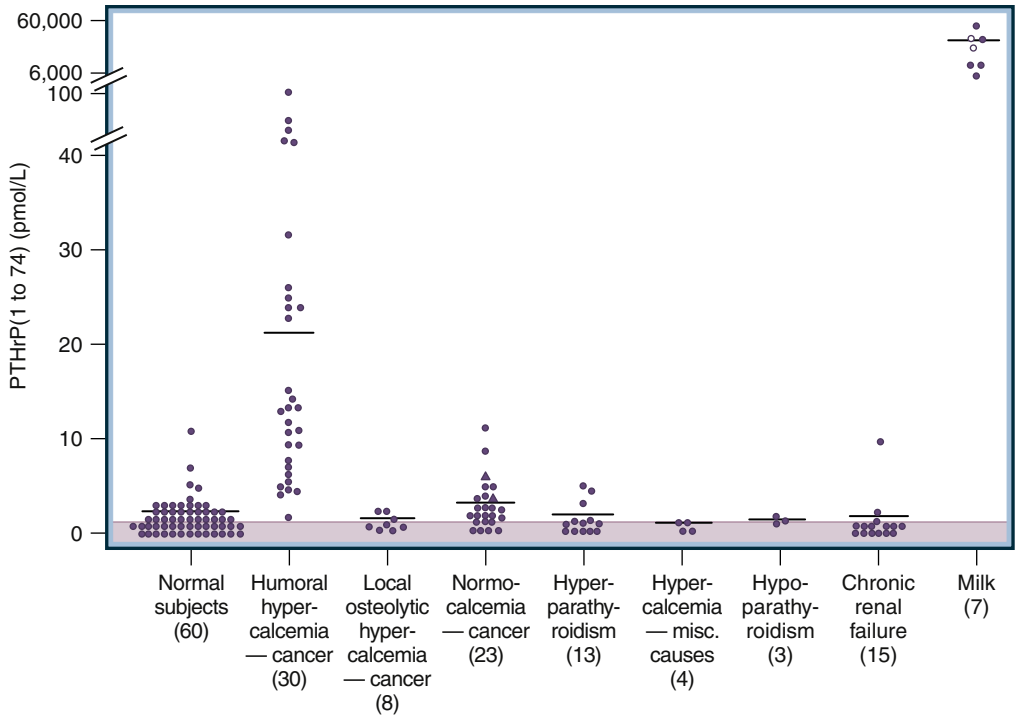
The major challenges in the measurement of blood PTH have been the low levels of circulating PTH and the presence of inactive PTH fragments in far greater abundance than for the intact, biologically active PTH molecule. The measurement of inactive fragments would not be a concern if the ratio of inactive to active PTH molecules remained constant. However, this ratio does change in response to changes in GFR and in parathyroid gland secretory activity (see earlier discussions under "Parathyroid Hormone Secretion" and "Metabolism of Parathyroid Hormone"). Consequently, radioimmunoassays of PTH have suffered from lack of sensitivity and from the inability to measure the biologically active hormone directly.



• **Fig. 29.19** Intact immunoreactive parathyroid hormone (PTH) determined using a two-site immunoradiometric assay in normal subjects and in three different patient groups. Note some overlap between normal people and patients with primary hyperparathyroidism, but no overlap between hypercalcemic patients with primary hyperparathyroidism and those with hypercalcemia of malignancy. (From Segre GV. Advances in techniques for measurement of parathyroid hormone: current applications in clinical medicine and directions for future research. *Trends Endocrinol Metab.* 1990;1:243–247.)

For these reasons, two-site assays that require the presence of amino-terminal and carboxy-terminal sequences of full-length PTH(1-84) on the same molecule have replaced older radioimmunoassays.[269] The assays are sensitive enough to detect PTH in all normal persons. The assays have demonstrated modest circadian variation in PTH levels and some pulsatility in PTH secretion, but these variations have not interfered with the diagnostic usefulness of randomly drawn PTH measurements. Some studies have reported modest increases of PTH levels with age, although others have not. Unlike older radioimmunoassays, the two-site assays demonstrate virtually no overlap in PTH levels between patients with primary hyperparathyroidism and those with nonparathyroid hypercalcemia (Fig. 29.19). Because this distinction represents the most important challenge in the clinical setting, the use of the two-site assay has dramatically facilitated the clinician's task.

This straightforward picture has been complicated by the realization that most two-site assays detect small amounts of PTH fragments that are large but do not extend to the hormone's amino-terminus.[270] These fragments accumulate in significant amounts in patients with renal failure. These observations have prompted the development of two-site PTH assays that use antibodies specific for the first four amino acids of PTH and thus do not detect large fragments of PTH. Although it seems plausible that such assays might prove particularly useful in some clinical situations, their role is presently unclear. They offer no advantage over older two-site assays, for example, in diagnosing primary hyperparathyroidism.[271] These assays do detect a minor peak of PTH immunoreactivity that is also recognized by antibodies directed to the carboxy-terminus of PTH and yet is not recognized by the usual



• **Fig. 29.20** Plasma PTHrP(1-74) determined by two-site immunoradiometric assay in selected patient groups and normal subjects. Also shown are concentrations of PTHrP in human milk *(filled circles)* and in bovine milk *(open circles)*. Two normocalcemic patients with cancer *(filled triangles)* subsequently became hypercalcemic. *Shaded area* denotes levels too low to detect with this assay. *PTHrP,* parathyroid hormone–related protein. (Adapted from Burtis WJ, Brady TG, Orloff JJ, et al. Immunochemical characterization of circulating parathyroid hormone–related protein in patients with humoral hypercalcemia of cancer. *N Engl J Med.* 1990;322:1106–1112.)

"intact" PTH assays, perhaps because of a post-translational modification of PTH in the PTH(15-20) region.[272] Perhaps because of detection of this unusual form of PTH, the PTH immunoreactivity recognized using the antibody to PTH(1-4) is particularly high in patients with parathyroid cancer when compared to patients with benign primary hyperparathyroidism.[273]

Parathyroid Hormone–Related Protein

The measurement of PTHrP in serum presents a series of challenges. The concentration of PTHrP in the bloodstream, even in some patients with PTHrP-mediated malignant hypercalcemia, is not high, and the molecular definition of circulating, biologically active fragments is incomplete. Despite these problems, several groups of investigators have developed assays for PTHrP that can be helpful in the evaluation of a subset of hypercalcemic patients. Radioimmunoassays for amino-terminal portions of PTHrP and two-site assays for amino-terminal and midregion PTHrP[124] separate healthy persons and patients with nonmalignant hypercalcemia from most patients with the humoral hypercalcemia of malignancy (Fig. 29.20). When measured with the most recently developed assays, PTHrP levels are elevated in almost all patients with malignant hypercalcemia without bone metastases and in most patients with hypercalcemia and bone metastases.

In occasional patients, the PTHrP assay has helped distinguish an occult malignancy from other causes of non–PTH-dependent hypercalcemia. Nevertheless, because the diagnosis of malignancy as the cause of hypercalcemia is usually clinically obvious, and the PTH assay can be used to diagnose primary hyperparathyroidism, the role of PTHrP assays in clinical practice is limited.[274]

Calcitonin

Several assays for measuring serum calcitonin are commercially available. The measurements are based on single or double antibody radioimmunoassays or enzyme immunoassays, several of which are sufficiently sensitive to detect calcitonin deficiency.[275] Interference with calcitonin assays has been reported in individuals with a heterophile antibody.[276] The calcitonin monomer is thought to be the biologically active molecule, therefore some investigators believe extraction of the multimeric forms prior to radioimmunoassay provides a more sensitive and specific measurement of serum calcitonin levels. However, the double antibody assays are thought to provide the same information with less sample manipulation. The only clinical use of the calcitonin assay is as a tumor marker, primarily in medullary carcinoma of the thyroid.

Vitamin D Metabolites

Several non-radioligand assays are available for determining the levels of vitamin D metabolites. These assays have shown considerable inter-assay variability, leading to misclassification of the vitamin D status of individuals.[277,278] Therefore mass spectrometry is being increasingly used for measuring 25(OH)D levels. Regardless of the method used, it has been recognized that a central repository for uniform standards is required for validation of these assays and of the laboratories performing them. The National Institute

of Standards and Technology in the United States has developed standard reference materials for this purpose.[279]

The levels of 25(OH)D correlate better with the clinical signs and symptoms of vitamin D deficiency than do the levels of $1,25(OH)_2D_3$. Because the 25-hydroxylation of vitamin D is not tightly regulated, measurements of 25(OH)D more accurately reflect body stores of vitamin D. Measurement of this metabolite should therefore be performed when vitamin D deficiency is suspected.

Measurements of $1,25(OH)_2D_3$ should be reserved for cases in which excessive or impaired 1α-hydroxylation is suspected. High $1,25(OH)_2D_3$ levels can be seen in sarcoidosis, lymphomas, Williams syndrome, and intoxication with 1α-hydroxylated metabolites (see "Parathyroid-Independent Hypercalcemia"). Impaired 1α-hydroxylation can contribute to the hypocalcemia of patients with renal dysfunction, oncogenic osteomalacia, and hereditary defects of vitamin D metabolism (see "Hypocalcemic Disorders").

Fibroblast Growth Factor-23

Currently two types of immunoassays are available for the measurement of serum FGF23 in humans. An assay using two polyclonal antibodies directed against C-terminal epitopes[280] detects most, if not all, circulating forms of FGF23 but does not discriminate between the intact active hormone and the cleaved fragment, which is not thought to have biologic activity. Assays for the intact hormone are classic sandwich assays with antibodies directed against both the N-terminus and C-terminus of the hormone.[235] These latter assays have been shown to be more useful for studying the effects of dietary phosphate on FGF23 levels in humans and thus are thought to provide a more precise determination of the biologically active levels of the hormone in the circulation.[281]

Hypercalcemic Disorders

Parathyroid-Dependent Hypercalcemia

It is useful to delineate two categories of hypercalcemia: (1) that associated with dysfunction of the parathyroid cell and (2) that in which hypercalcemia occurs despite appropriate parathyroid suppression. This distinction is particularly useful clinically because it emphasizes the centrality of the PTH assay in the diagnostic approach to the hypercalcemic patient. Abnormal parathyroid glands are associated with hypercalcemia in three settings: (1) primary hyperparathyroidism, (2) familial hypocalciuric hypercalcemia, and (3) lithium-induced hypercalcemia.

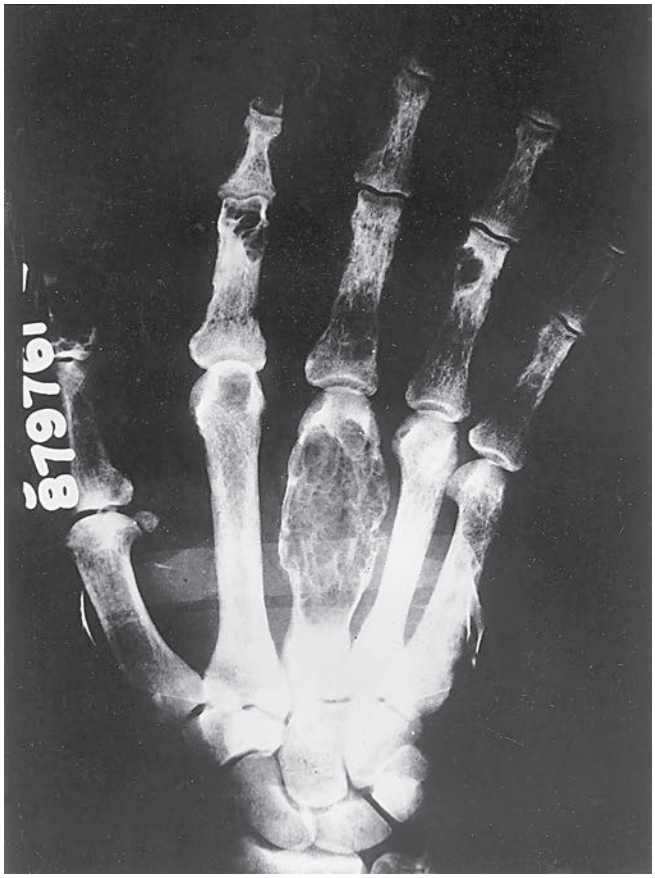
Primary Hyperparathyroidism

In primary hyperparathyroidism, a primary abnormality of parathyroid tissue leads to inappropriate secretion of PTH. In contrast, increased secretion of PTH that is an appropriate response to hypocalcemia is called secondary hyperparathyroidism. The inappropriately high serum concentration of PTH in primary hyperparathyroidism, in turn, sustains excessive renal calcium reabsorption, phosphaturia, and $1,25(OH)_2D$ synthesis, as well as increased bone resorption. These actions of PTH produce the characteristic biochemical phenotype of hypercalcemia and hypophosphatemia, loss of cortical bone, hypercalciuria, and the various clinical sequelae of chronic hypercalcemia. Primary hyperparathyroidism results most often (75–80%) from the occurrence of one or more adenomas in previously normal parathyroid glands, although in 20% of cases diffuse hyperplasia of all parathyroid glands may be present or, rarely, parathyroid carcinoma may be found (<1–2%).[282–285]

Classic Primary Hyperparathyroidism

The bone disease "osteitis fibrosa cystica" first was described by von Recklinghausen in 1891, but the etiologic link between this disease and parathyroid neoplasms was not established until 1925, when Mandl observed clinical improvement following removal of a parathyroid adenoma from a young male with severe bone disease. In early clinical descriptions of primary hyperparathyroidism, the disease emerged as a distinctly uncommon disorder with significant morbidity and mortality rates, in which nearly all affected patients manifested radiographically significant or symptomatic skeletal or renal involvement, or both.

The skeletal involvement in classic primary hyperparathyroidism reflects a striking and generalized increase in osteoclastic bone resorption, which is accompanied by fibrovascular marrow replacement and increased osteoblastic activity. The radiographic appearance (Fig. 29.21) features *generalized demineralization* of bone, with coarsening of the trabecular pattern (due to osteoclastic resorption of the smaller trabeculae); characteristic *subperiosteal resorption*, often most evident in the phalanges of the hands, which gives an irregular, serrated appearance to the outer, subperiosteal cortex and may progress to extensive cortical resorption; *bone cysts*, usually multiple, which contain a brownish serous or



• **Fig. 29.21** Radiograph of the hand of a patient with severe primary hyperparathyroidism. (Courtesy Fuller Albright Collection, Massachusetts General Hospital, Boston, MA.)

mucoid fluid, and tend to occur in the central medullary portions of the shafts of the metacarpals, ribs, or pelvis and may expand into and disrupt the overlying cortex; *osteoclastomas*, or *brown tumors*, composed of numerous multinucleated osteoclasts ("giant cells") admixed with stromal cells and matrix, which are found most often in trabecular portions of the jaw, long bones, and ribs; and pathologic *fractures*.

The skull may exhibit a finely mottled, "salt-and-pepper" radiographic appearance, with loss of definition of the inner and outer cortices. Dental radiographs typically show erosion or disappearance of the lamina dura due to subperiosteal resorption, often with extension into the adjacent mandibular bone. The erosion and demineralization of cortical bone may lead to radiographic disappearance of some bones, most notably the tufts of the distal phalanges of the hands, the inferolateral cortex of the distal third of the clavicles, the distal ulna, the inferior margin of the femoral neck and pubis, and the medial aspect of the proximal tibia. The clinical correlates of these changes may include aching bone pain and tenderness, "bowing" of the shoulders, kyphosis and loss of height, and collapse of lateral ribs and pelvis with "pigeon breast" and triradiate deformities, respectively.

The renal manifestations of classic severe primary hyperparathyroidism include recurrent calcium nephrolithiasis, nephrocalcinosis, and renal functional abnormalities that range from impaired concentrating ability to end-stage renal failure. Associated signs and symptoms include recurrent flank pain, polyuria, and polydipsia. No unique features of the stone disease in primary hyperparathyroidism serve to distinguish it from that associated with other, more common causes of calcium kidney stones. The stone disease more often may be recurrent and severe, and in some patients the stones may be composed entirely of calcium phosphate instead of the pure oxalate or mixtures of oxalate and phosphate more commonly encountered in other disorders. In patients diagnosed before 1965, the frequency with which nephrolithiasis complicated primary hyperparathyroidism was as high as 60% to 80% (the frequency is currently <25%), yet in studies of unselected patients conducted throughout the past 50 years, primary hyperparathyroidism has accounted for fewer than 5% of all calcium kidney stones.

Other clinical features that have been reported in association with classic severe primary hyperparathyroidism are conjunctival calcifications, band keratopathy, hypertension (50%), gastrointestinal signs and symptoms (anorexia, nausea, vomiting, constipation, or abdominal pain), peptic ulcer disease, and acute or chronic pancreatitis. The issue of whether primary hyperparathyroidism increases the risk for peptic ulcer disease and pancreatitis remains controversial. Although hyperparathyroidism is associated with a higher risk of hypertension, successful parathyroidectomy has not been shown to correct the hypertension.

Signs and symptoms in primary hyperparathyroidism may result from the involvement of bone (fracture, bone pain) or kidneys (renal colic, renal failure), peptic ulcer disease, pancreatitis, or hypercalcemia per se (weakness, apathy, depression, polyuria, constipation, coma). The presence and severity of neuropsychiatric symptoms, in particular, correlate poorly with the serum calcium concentration, although few patients with severe hypercalcemia are entirely asymptomatic. Elderly persons are most likely to exhibit such symptoms. A peculiar neuromuscular syndrome, first described in 1949 but rarely encountered now, includes symmetric proximal weakness and gait disturbance, with muscle atrophy, characteristic electromyographic abnormalities, generalized hyperreflexia, and tongue fasciculations.[286]

Contemporary Primary Hyperparathyroidism

The clinical spectrum of primary hyperparathyroidism was changed dramatically in the early 1970s by the introduction of routine multichannel serum chemistry screening, which unearthed a large population of patients with previously unsuspected, asymptomatic disease. In Rochester, Minnesota, for example, the annual incidence of the disease increased abruptly from 0.15 to 1.12 per 1000 persons between the prescreening era (1965–1974) and 1975, the year after routine screening was introduced.[287] The peak incidence occurs in the sixth decade of life, and the disease rarely is encountered in patients below age 15. It is two to three times more common in women, who are slightly older at diagnosis than are men. Subsequently, the incidence of primary hyperparathyroidism has fallen; this decreased incidence may not simply be a residual effect of "sweeping the population," because it remained low when serially checked in Rochester—most recently from 1992 to 2001, when the incidence was 0.21 per 1000.[288]

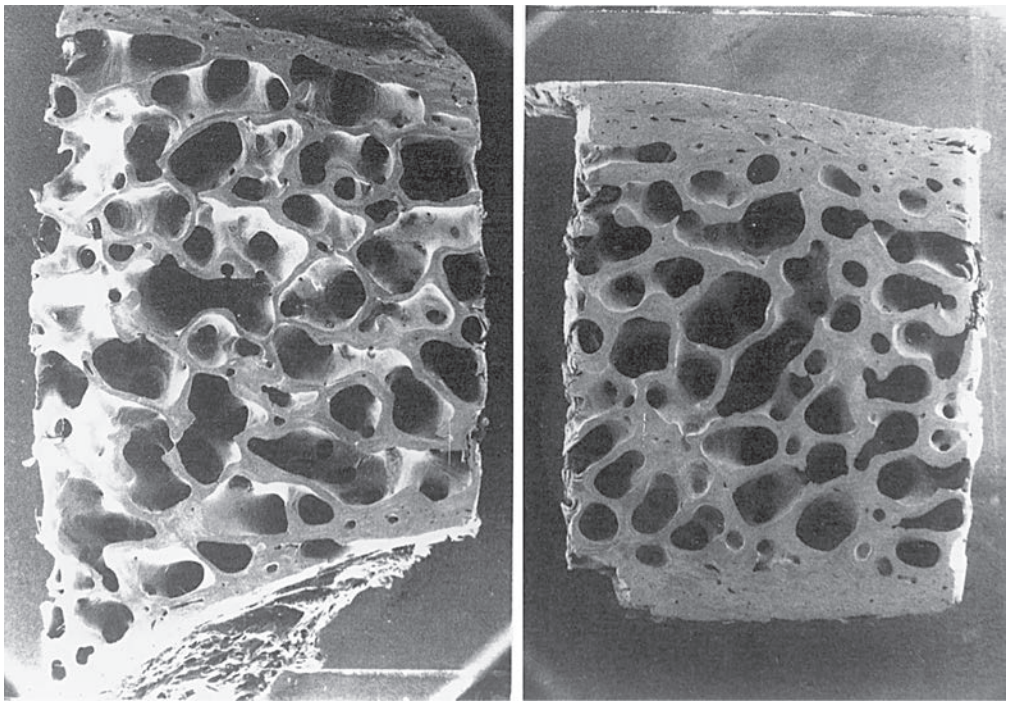
Ascertainment of mild or asymptomatic disease may decline even further in the future because of prevalent economic disincentives to routine serum chemistry screening in the primary care setting. On the other hand, insistence upon overt hypercalcemia as a diagnostic criterion may underestimate the true incidence of the disease. For example, when serum calcium and iPTH were measured in a large population of Swedish women undergoing routine mammographic screening, the prevalence of unsuspected primary hyperparathyroidism, defined by criteria that included the combination of high-normal serum calcium plus elevated or high-normal iPTH, was 2.1%.[289] Two-thirds of these women (72/109) were normocalcemic (10–10.4 mg/dL), yet bone density was reduced in the group as a whole, and the disease was confirmed histologically in 98% of the 61 who had surgery. Further, the widespread practice of evaluating PTH levels in patients with osteoporosis has led to the identification of patients with high PTH levels and normocalcemia.[290] Many of these patients become hypercalcemic during follow-up.

Not surprisingly, given that primary hyperparathyroidism now usually is diagnosed incidentally, few patients are found to have overt signs or symptoms of the classic disease and thus are considered to be asymptomatic. For example, only 2% of patients with primary hyperparathyroidism residing in Olmsted County, Minnesota, and only 17% of 121 patients studied at an academic referral center in New York City had classic disease symptoms.[287,291] In most of them, the relevant symptom was urolithiasis. Many clinicians argue, however, that most patients regarded as having asymptomatic primary hyperparathyroidism and only minimally elevated serum calcium actually suffer from various neuropsychiatric or other symptoms that may improve following curative surgery.[292] These symptoms, however, which include fatigability, weakness, forgetfulness, depression, somatization, polydipsia, polyuria, and bone and joint pain, are common in otherwise normal persons. In the small randomized studies of surgery for primary hyperparathyroidism (see later), the effects of surgery on measures of quality of life have been conflicting.[290,293–295] This remains a critical issue, as the advent of less invasive operative approaches and concerns regarding fracture, cancer, and mortality risk have lowered the threshold for consideration of surgery in many patients with the disease (see later). Throughout this chapter, *asymptomatic primary hyperparathyroidism* refers to patients who lack signs or symptoms of the classic disease, whether or not they experience any of the subtle symptoms mentioned earlier.

The natural history of untreated asymptomatic primary hyperparathyroidism, as currently detected, remains incompletely

understood. Few patients seem to experience progression of disease, as measured by extreme elevations of serum or urinary calcium, appearance of renal dysfunction or nephrocalcinosis, or worsening osteopenia, over many years of observation.[291] On the other hand, late cortical bone loss observed at the femoral neck and distal radius in a small number of patients followed without surgery for 15 years points to the potential importance of continued monitoring in such patients.[296] Also, an excess risk of mortality, mainly from cardiovascular disease, has been noted during extended follow-up of large cohorts of patients with chronic hypercalcemia (and presumed primary hyperparathyroidism) identified by population health screening in Sweden,[297] and similar observations have been made during extended follow-up of postsurgical patients with hyperparathyroidism.[292] Associations of hypertension, hyperuricemia, and glucose intolerance with primary hyperparathyroidism have been implicated, together with hypercalcemia per se, as contributors to this elevated risk.[291] Abnormal cardiac calcification and left ventricular hypertrophy (reversible by successful parathyroidectomy) have been reported in primary hyperparathyroidism as well.[298] Increased cardiovascular mortality risk may be a feature only of severe hyperparathyroidism, as it was restricted to those in the highest quartile of serum calcium in the Olmsted County study, which otherwise showed an overall decreased risk of death.[299] A 40% excess risk of malignancy also was reported among 4163 Swedish patients who had undergone surgery more than a year earlier for (presumably symptomatic) primary hyperparathyroidism.[300] It has been argued that these increased risks for mortality and malignancy, even if confirmed, may apply only to those with primary hyperparathyroidism that is more severe than the asymptomatic version typically encountered today.[291]

Abnormalities of bone in modern, mild primary hyperparathyroidism are far subtler than those associated with the classic disease. Histologically the rate at which new bone remodeling cycles are activated is increased. Because the phase of restorative bone formation at each remodeling site takes much more time than does the initial resorptive phase, such an increase in remodeling rate inevitably increases the ambient volume of the remodeling space and thus the porosity of bone. Depending upon the rate and extent of the accompanying increase in osteoblastic activity and the resulting local balance between net bone formation and resorption, mineralized bone volume may decrease further, remain stable, or even increase (despite an increased remodeling space). For reasons not yet understood, the balance achieved between increased resorption and formation of bone in primary hyperparathyroidism depends not only upon the severity of the hyperparathyroidism but also upon skeletal location. Thus net resorption of endosteal bone may predominate in cortical sites, whereas net apposition of mineral may occur in trabecular bone, when measured through biopsy of the iliac crest[301,302] (Fig. 29.22). Thus bone mineral density may be reduced, particularly at sites of predominantly cortical bone such as the midradius, by as much as 10% to 20%.[303] In contrast, studies using dual-energy x-ray absorptiometry (DXA) demonstrate relative preservation of vertebral bone mass in primary hyperparathyroidism.[304] Despite this evidence of preserved trabecular bone mass in primary hyperparathyroidism, the incidence of vertebral fracture is increased.[305,306] The explanation for this paradox appears to relate to abnormalities in trabecular (and cortical) microarchitecture that can be detected using high-resolution peripheral quantitative computed tomography (CT) or by evaluating the trabecular bone score during DXA measurements.[307,308] These abnormalities reflect shifts from



• **Fig. 29.22** Iliac crest biopsy specimens from a patient with primary hyperparathyroidism *(left)* and a normal control subject *(right)*, viewed by scanning electron microscopy. Note the thin cortices and contrasting maintenance of trabecular bone in the patient. (From Parisien M, Silverberg SJ, Shane E, et al. The histomorphometry of bone in primary hyperparathyroidism: preservation of cancellous bone structure. *J Clin Endocrinol Metab.* 1990;70:930–938.)

plate-like to rod-like microstructure that weaken the bone and presumably account for the elevated risk of vertebral fracture. These defects are improved following successful parathyroidectomy.[309]

Kidney stones now are reported in only 10% to 25% of patients with primary hyperparathyroidism, although some degree of renal dysfunction, either a significant reduction in creatinine clearance or impaired concentrating or acidifying ability, may be found in up to one-third of those with asymptomatic disease. These renal abnormalities are not progressive in the majority of affected patients.[291,310] No parameters of disease severity predict a lower estimated GFR.[311] The association of kidney stones with primary hyperparathyroidism generally is viewed as an indication for parathyroidectomy, however, because successful surgery usually prevents further symptomatic stone disease.[291,292] On the other hand, it is not possible at present to confidently predict, from biochemical measurements in blood or urine, which asymptomatic patients with hyperparathyroidism will go on to develop new stone disease. Stone-formers are more likely to be hypercalciuric than not, but less than one-third of hypercalciuric patients with hyperparathyroidism actually develop stones.

Etiology and Pathogenesis

Parathyroid adenomas are caused by mutations in the DNA of parathyroid cells; these mutations confer a proliferative or survival advantage for affected cells over their normal neighbors.[312,313] As a consequence of this advantage, the descendants of one particular parathyroid cell, a clone of cells, undergo clonal expansion to produce an adenoma.

Multiple chromosomal regions are missing in the parathyroid cells of individual parathyroid adenomas. These genetic deletions probably reflect the deletion of tumor suppressor genes. These chromosomal loci include portions of chromosome 1p–pter (in 40% of adenomas), 6q (in 32% of adenomas), 15q (in 30% of adenomas), and 11q (in 25–30% of adenomas). Many of the 11q deletions are associated, in the undeleted chromosome 11, with mutations in the gene encoding the transcription factor menin, the gene mutated in multiple endocrine neoplasia type 1 (MEN1). Thus this gene is also involved commonly in somatic mutations in patients with sporadic parathyroid adenomas. Somatic mutations have also been found in the mitochondrial genomes of a fraction of chief cell adenomas and have been found even more frequently in so-called oxyphil adenomas, known to exhibit mitochondria with abnormal morphologic appearance.[314] The widespread presence of somatic mutations in sporadic parathyroid adenomas, which are detectable only because large numbers of cells in any one tumor contain the same deletion, constitutes the strongest evidence that parathyroid adenomas are clonal expansions of mutant cells.

Cyclin D1, called initially PRAD1, was the first noted recurrent parathyroid proto-oncogene.[315] This gene was discovered at the breakpoint of an inversion on chromosome 11 in a parathyroid adenoma. This inversion led to the juxtaposition of the PTH gene's regulatory region and the DNA encoding cyclin D1. As a consequence, the cyclin D1 gene was overexpressed. Cyclin D1 is an important regulator of the transition from the G_1 phase of the cell cycle (which follows mitosis) to the S phase (associated with DNA synthesis) and is mutated or amplified in a wide variety of malignancies. Cyclin D1 is overexpressed in about 20% of parathyroid adenomas, though cyclin D1 gene rearrangements have been documented in only 5% of adenomas. Overexpression of cyclin D1 in the parathyroids of transgenic mice leads to formation of parathyroid adenomas and hypercalcemia over many months.[316] The phenotype of these mice demonstrates that cyclin D1 overexpression can cause primary hyperparathyroidism. Cyclin D1 enables the functions of cyclin-dependent protein kinases. More recently, inhibitors of cyclin-dependent protein kinases (encoding the proteins p21, p15, and p18) have been found mutated in the germline and somatically in sporadic parathyroid adenomas, in a pattern that suggests these genes act as tumor suppressors.[317] The gene mutated in multiple endocrine neoplasia, type 1 (encoding menin), is also mutated only in the tumors of a substantial fraction of sporadic parathyroid tumors (reviewed in Costa-Guda and Arnold[318]).

Improvements in DNA sequencing technology have allowed the sequencing of virtually all the exons in the human genome, and this sort of whole-exome sequencing has been performed by three groups.[319–321] The most striking finding of these studies (sequencing 43 tumors between them) was that these tumors averaged roughly 5 exome mutations per tumor (with the exception of one tumor with 110 mutations in association with a mutation in the protection of telomeres 1 gene *[POT1]* known to increase genetic instability). This number is considerably lower than the number of mutations typically found in cancers or even benign tumors that have been sequenced. In both studies 35% of the tumors harbored mutations in the *MEN1* gene, usually in association with deletion of the second *MEN1* gene. No other gene was mutated frequently in these series, though mutation in a known oncogene, an activating mutation in *EZH2,* was found a second time when a larger series of tumors was tested for that mutation.[319] A recent whole-exome sequencing study of 24 parathyroid cancers demonstrated that these tumors harbor a much higher frequency of mutations than do parathyroid adenomas; the genes mutated in parathyroid cancer, so far, appear distinct from the genes mutated in parathyroid adenomas.[322]

As expected for a disease caused by mutations in DNA, parathyroid adenomas occur more frequently in patients who underwent neck irradiation decades earlier, with greater radiation exposure leading to higher risk. Most patients have no definite history of exposure to specific mutagens, however. An intriguing clue that abnormalities of vitamin D physiology may predispose to primary hyperparathyroidism has come from the observation that patients with parathyroid adenomas are more likely than others to inherit a particular allele of the VDR gene.[323] These patients have tumors with particularly low levels of mRNA encoding the VDR. Nevertheless, no mutations in the coding regions of the gene encoding the VDR have been found in parathyroid adenomas.[324]

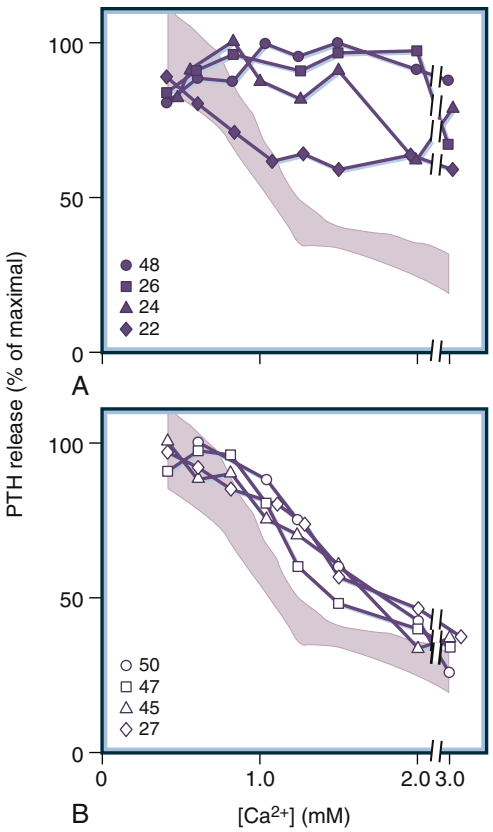
The cause of sporadic primary parathyroid hyperplasia is unknown. The known stimulus for parathyroid cell proliferation—low levels of blood calcium or $1,25(OH)_2D_3$—is not present in this disease. Presumably, some other stimulus outside the parathyroid glands or a genetic abnormality present in all four parathyroid glands leads to inappropriate cell proliferation. Such abnormalities have been found in several inherited forms of parathyroid hyperplasia (see later), but most cases of parathyroid hyperplasia are not found in familial clusters.

The theoretic distinction between adenoma as a clonal proliferation and hyperplasia as a polyclonal growth is clear cut. In some settings, however, clonal expansion can occur in the context of preexisting nonclonal proliferation. The clearest example of this complication has been found in the large glands associated with severe renal failure. In many such glands removed surgically because of hypercalcemia or severe parathyroid-dependent bone disease, evidence for clonal proliferation complicating secondary hyperplasia has been found. Interestingly, the pattern of chromosomal abnormalities in these clonal tumors differs from that

found in parathyroid adenomas in the absence of renal failure.[325] Analogous mechanisms may be operative in a number of settings associated with stimuli to parathyroid cell proliferation, such as X-linked hypophosphatemia and long-term lithium therapy. Furthermore, just as clonal tumors can arise in the setting of *secondary* parathyroid hyperplasia, they can also arise in the setting of sporadic *primary* parathyroid hyperplasia[326] and in MEN1.[327]

The distinction between adenoma and hyperplasia is clinically important, because removal of the one abnormal gland can be expected to cure a parathyroid adenoma, whereas removal of multiple glands is required to successfully treat parathyroid hyperplasia. Unfortunately, differentiating adenoma from hyperplasia from normal parathyroid tissue at pathologic examination is not straightforward. Pathologists distinguish normal from abnormal parathyroid glands by the increase in size and the paucity of fat in abnormal glands. Attempts have been made to distinguish an adenoma from an individual hyperplastic gland on the basis of morphologic features, but no criteria have proved completely reliable.[328] The formation of clonal neoplasms in originally hyperplastic tumors may explain some of the difficulty in pathologic diagnosis.

An increase in cell number is not the only abnormality in primary hyperparathyroidism. The ability of the normal parathyroid cell to suppress PTH secretion in response to hypercalcemia might be expected to protect the individual from sustained hypercalcemia, even if the number of parathyroid cells increased moderately. Unfortunately, parathyroid cells in parathyroid adenomas usually demonstrate abnormalities in their responsiveness to calcium, with a shift in set-point to the right (Fig. 29.23). This set-point shift, combined with the nonsuppressible component of PTH secretion, leads to a new steady state in which both the PTH level and the blood calcium level are higher than normal. The molecular underpinning of the abnormal parathyroid cell responsiveness is beginning to be understood. Parathyroid cells from adenomas respond to changes in extracellular calcium with smaller than normal increases in intracellular calcium, and the amount of CaSR protein on the cell surface is reduced.[329] Perhaps surprisingly, no mutations in the gene encoding the CaSR have been found in parathyroid adenomas. In the experimental model in which overexpression of cyclin D1 results in primary hyperparathyroidism,[316] reduced expression of the CaSR occurs only after cell proliferation has been increased for some time. Thus the decreased expression of the CaSR in parathyroid adenomas is likely to be a secondary response that occurs during tumor formation. One demonstrated regulator of expression of the *CASR* gene in parathyroid cells is the developmental regulator, *gcm2*.[330]



• **Fig. 29.23** Abnormal patterns of parathyroid hormone (PTH) secretion from cells prepared from adenomatous glands and stimulated with varying levels of calcium in tissue culture. The *shaded area* shows the pattern of PTH release (±1 SD) from normal human parathyroid cells. Panel (A) illustrates the pattern from four patients with little suppression of PTH secretion by calcium. Panel (B) illustrates the pattern from four patients with relatively intact mechanism of suppression of PTH secretion by calcium. Even in this group the set-point for calcium suppression is shifted to the right. (From Brown, EM. Calcium-regulated parathyroid hormone release in primary hyperparathyroidism: studies in vitro with dispersed parathyroid cells. *Am J Med*. 1979;66:923–931.)

Inherited Primary Hyperparathyroidism

Although uncommon, inherited forms of primary hyperparathyroidism are clinically important for several reasons. The management of the parathyroid tumors found in familial parathyroid syndromes often differs from that of sporadic primary hyperparathyroidism. Furthermore, extraparathyroidal manifestations of inherited syndromes may need treatment, and awareness of familial clustering should prompt systematic family screening.

Multiple Endocrine Neoplasia Type 1 (see also Chapter 42). MEN1 is caused by inactivating mutations in the tumor suppressor gene encoding menin.[331] Menin is a ubiquitously expressed transcription factor that is part of a complex that targets histone H_3 for methylation,[332] and thereby leads to expression of cell cycle inhibitors in pancreatic islets and other tissues.[333] Menin interacts with many nuclear proteins, and it is not known which interactions are central to the pathogenesis of MEN1.[334] Rarely, mutations in genes encoding cyclin-dependent kinase inhibitors, such as p27, are found in MEN1 patients without menin mutations[335]; some have termed this variant, which presents primarily with parathyroid and pituitary tumors, *MEN4*.[336] These patients can also harbor pancreatic neuroendocrine tumors, gonadal, adrenal, renal, and thyroid tumors.[337,338] Although MEN1 includes tumors of the parathyroid, anterior pituitary, and pancreatic islets, the parathyroid tumors are far more prevalent than the others; 95% of affected patients eventually develop hyperparathyroidism. Most of the parathyroid tumors harbor mutations in both copies of the menin gene; one mutation is inherited and the second occurs in the parathyroid cell whose progeny form the tumor.

The onset of hypercalcemia occurs in the second and third decades of life, though occasional patients present in the first decade. Hypercalcemia never presents at birth or in infancy. The disease involves all four parathyroid glands, although the involvement can be asymmetric and apparently asynchronous. Apart from the earlier age at diagnosis, the presenting clinical picture generally resembles that of sporadic primary hyperparathyroidism, perhaps with somewhat greater loss of bone density.[339] One common complicating feature is that hypercalcemia can

dramatically increase the gastrin levels and symptomatology of patients who also have gastrinomas. Treatment of the parathyroid disease in this setting can greatly simplify the management of the gastric hyperacidity. After parathyroid surgery, hypoparathyroidism and recurrent hyperparathyroidism are more common than in other forms of hyperparathyroidism.[340] The timing and type of surgery are therefore more complicated issues than in sporadic primary hyperparathyroidism. Most authorities agree that parathyroid disease recurs eventually, particularly if fewer than three glands are removed. Some surgeons prefer subtotal parathyroidectomy, whereas others prefer total parathyroidectomy with forearm implantation of a small amount of parathyroid tissue.

Multiple Endocrine Neoplasia Type 2a (see also Chapter 42). Parathyroid disease is a usually late and infrequent (5–20%) occurrence in MEN2a, a disease defined by the clustering of medullary carcinoma of the thyroid, pheochromocytoma, and hyperparathyroidism. The parathyroid disease is typically mild and can be asymptomatic.[338] In some families, hyperparathyroidism is more common; however, these families have the same mutations in the *RET* gene as are found in families without frequent hyperparathyroidism. Both parathyroid hyperplasia and adenoma have been noted at surgery. Because asymptomatic parathyroid hyperplasia has been noted at the time of thyroid surgery, a progression from hyperplasia to adenoma in MEN2a has been suggested. The approach to diagnosis and treatment of hyperparathyroidism is similar to that in sporadic primary hyperparathyroidism, but hyperplasia is more frequently the underlying disorder. The pathogenesis of the hyperparathyroidism is uncertain, but the *RET* gene, mutated in virtually all cases of MEN2a, is expressed in parathyroid cells,[341] so abnormal *RET* expression in parathyroid cells may directly cause parathyroid tumor formation. Hyperparathyroidism does not occur in MEN2b, the variant associated with mucosal neuromas.

Hyperparathyroidism–Jaw Tumor Syndrome. Patients with hereditary hyperparathyroidism–jaw tumor syndrome[342] present with parathyroid adenomas that can be multiple and that are usually cystic. These tumors are often but not invariably associated with fibrous jaw tumors that are unrelated to the hyperparathyroidism. Importantly, the parathyroid tumors are frequently malignant, in contrast to the findings in MEN1 and MEN2. Wilms tumor and polycystic renal disease also have occurred in affected families. The gene mutated in this syndrome, called *CDC73* or *HRPT2*, encodes the nuclear protein, parafibromin.[343] Parafibromin is part of the evolutionarily highly conserved PAF complex that binds RNA polymerase II, regulates chromatin structure, and regulates gene expression.[344–346] Parafibromin binds β-catenin and can mediate Wnt pathway signaling and notch signaling, though whether these properties of parafibromin are related to its tumor suppressor function is unknown.[347] Inactivating mutations in parafibromin are found in a high number of patients with apparently sporadic parathyroid cancer.[348] In a whole-exome sequencing study of sporadic parathyroid cancer, 8 of 17 patients harbored mutations in *CDC73*; half of the patients with *CDC73* mutations also manifest germline mutations, even though they presented as patients with apparently sporadic disease.[322] These findings suggest that all patients with parathyroid cancer should be screened for germline mutations in *CDC73*.

Management of Primary Hyperparathyroidism

The strategy for management of primary hyperparathyroidism has evolved in parallel with the changing presentation of the disease. The only opportunity for permanent cure is surgical removal of the abnormal gland(s), an approach that clearly was appropriate for virtually all patients in whom the classic, severe form of the disease was diagnosed many decades ago and which still is the treatment of choice for those patients who do present with recurrent kidney stones, nephrocalcinosis, clinically overt bone disease, or severe hypercalcemia.

In contrast, the choice of surgical versus medical management for patients with asymptomatic primary hyperparathyroidism remains an open and hotly debated question. Those who favor surgery point to the expected improvement in bone mineral density (at the hip and spine) and left ventricular hypertrophy following successful surgical intervention; evidence of increased risk for fracture, cardiovascular mortality, malignancy, and neuropsychiatric symptoms associated with primary hyperparathyroidism; and the recent successful development of effective minimally invasive surgical procedures (see later). Those who favor an observational approach emphasize the evidence for lack of disease progression in most asymptomatic patients; the small but finite risk of surgical failure and postoperative complications; the probability that excess mortality and cancer risks documented in patients with relatively severe disease may not apply to those with mild, asymptomatic primary hyperparathyroidism; the difficulty in assigning vague neuropsychiatric symptoms to the parathyroid disorder; the lack of evidence (or negative evidence) that hypertension and increased risk of cancer, fracture, or cardiovascular mortality, even if present, are improved by successful parathyroidectomy; and the availability of sensitive techniques for monitoring disease status in nonoperated patients.[291]

Unfortunately no large prospective studies powered to compare clinical outcomes in patients with asymptomatic primary hyperparathyroidism randomly assigned to surgery versus medical management have been conducted. Nevertheless, three valuable smaller, randomized controlled trials of surgery versus observation have been conducted that allow some conclusions about surrogate markers of disease.[293–295] All three trials demonstrated increases in bone density in the spine and hip in the surgical group; these increases were similar to those produced with bisphosphonate therapy in primary hyperparathyroidism (see later). Two of the three studies showed modest improvements in some quality-of-life measures, though the unblinded nature of the studies limits interpretation of these findings. All of the findings reported so far from these studies have been after 2 years or less. As useful as these studies have been, their limitations have forced the field to tap observational studies to draw tentative recommendations based on limited data.

Such provisional recommendations have emanated from a series of conferences: an NIH-sponsored Consensus Conference held in 1990, followed by more informal updates in 2002, 2008, and 2014.[349] The major conclusion of that group was that, although surgery is indicated for symptomatic hyperparathyroidism and always should be considered an appropriate option in asymptomatic hyperparathyroidism, many patients with asymptomatic disease can be safely monitored without surgery for many years. Those suitable for medical observation should have no evidence of significant compromise of skeletal integrity or renal function, should have no history of urolithiasis or gastrointestinal or neuropsychiatric symptoms, and should meet the criteria listed in Table 29.1.[350] Such patients account for at least 50% of those who currently present with primary hyperparathyroidism.

On the other hand, surgery could be preferable if the patient desired surgery even when asymptomatic, if the probability of consistent monitoring seemed low, if concomitant illness seemed

TABLE 29.1 Indications for Surgery in Primary Hyperparathyroidism

- Overt clinical manifestations of disease
  - Kidney stones or nephrocalcinosis
  - Fractures or classic radiographic findings of osteitis fibrosa
  - Classic neuromuscular disease
  - Symptomatic or life-threatening hypercalcemia
- Serum calcium >1 mg/dL above upper limit of normal
- Creatinine clearance <60 mL/min, presence of stone(s) by radiograph, CT, or ultrasound
- Urinary calcium >400 mg/day plus other urinary biochemical indices of stone risk
- Bone mineral density low (T score ≤–2.5) at any site[a]
- Presence of vertebral fracture by radiograph or by vertebral fracture analysis on DXA
- History of fragility fracture
- Young age (<50 years)
- Uncertain prospects for adequate medical monitoring

[a]Z-score ≤–2.5 in premenopausal women and in men <50 years old.

CT, Computed tomography; *DXA,* dual-energy x-ray absorptiometry.

Modified from Bilezikian JP, Khan AA, Potts Jr JT, Third International Workshop on the Management of Asymptomatic Primary Hyperthyroidism. Guidelines for the management of asymptomatic primary hyperparathyroidism: summary statement from the Third International Workshop. *J Clin Endocrinol Metab.* 2009;94:335–339. Based upon recommendations of the 2014 NIH-sponsored Workshop on the Management of Asymptomatic Primary Hyperparathyroidism.

likely to complicate management or obscure significant disease progression, or if the patient was relatively young (<50 years). The latter recommendation reflects the absence of reliable information about the natural history of the disease over many decades of follow-up; the cumulative cost of medical monitoring, which begins to exceed that of surgery by 5 to 10 years; and some data suggesting that young people are more likely than others to have progressive disease.[351] On the other hand, age alone was not viewed as a contraindication to parathyroidectomy, as the procedure has been accomplished with excellent results, with a perioperative mortality rate of 1% to 3%, in large numbers of appropriately selected patients over the age of 75 years. Because hypertension is not thought to be a feature of mild primary hyperparathyroidism, and because hypertension generally is not improved by parathyroidectomy, hypertension was not viewed as an indication for surgery.

Although the Consensus Conference recommendations and subsequent modifications provide a useful framework for decision making, supporting data from large clinical trials are lacking. In a series of 52 asymptomatic patients selected for nonoperative management mainly on the basis of the 1990 Consensus Conference criteria and whose course was followed for 10 years, approximately 25% developed one or more new indications for surgery.[291] Patients who do not meet the Consensus Conference criteria for surgery may nevertheless experience the same postsurgical increase in bone density as those who do.[352] Some have emphasized that evidence of baseline vertebral osteopenia, an unusual finding in primary hyperparathyroidism, should be considered among the criteria for surgery[353] and that surgery also should be considered for postmenopausal women who exhibit vertebral bone loss in the setting of primary hyperparathyroidism.[291]

A common dilemma is the inability to ascertain whether vague but troublesome symptoms such as fatigue, lethargy, weakness (without objective muscle weakness), and depression are due to hyperparathyroidism and thus qualify as "significant" in the context of considering the decision for surgery. Most clinicians do not routinely recommend parathyroidectomy on the basis of such symptoms alone, although dramatic responses to surgery are occasionally seen. With the availability of improved, minimally invasive surgical approaches, the threshold for considering surgery in patients who are significantly disabled by such symptoms clearly is lower now than in the past. Some have advocated, in selected cases, a limited trial of medical therapy to reduce serum calcium (i.e., calcimimetics—see later) and thereby attempt to predict the symptomatic response to surgical cure.

Medical Monitoring of Primary Hyperparathyroidism. The updated NIH Consensus Conference recommendations suggest that patients not treated surgically should be followed carefully, with annual measurement of serum calcium and calculated creatinine clearance and serial determination of bone mineral density at intervals of 1 to 2 years. The most appropriate bone densitometric site is considered to be one that reflects mainly changes in cortical bone (i.e., distal forearm), although the importance of following vertebral bone density as well has been emphasized,[291] and current criteria acknowledge the importance of significant bone loss at any site.[350]

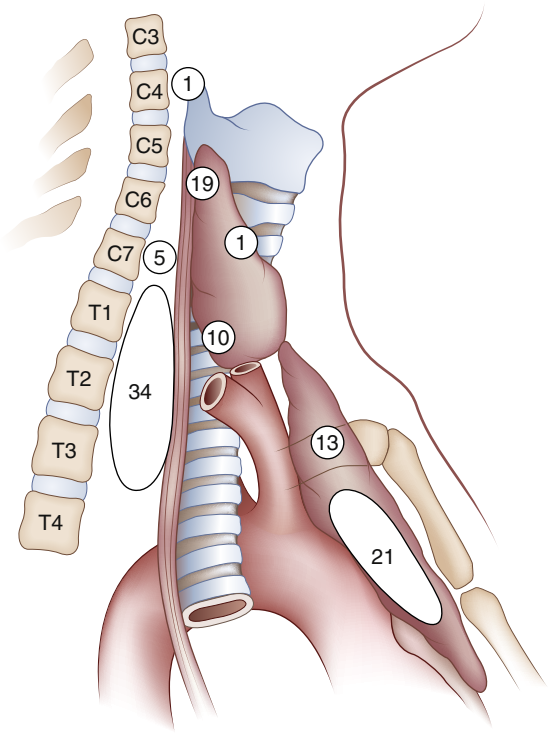
Patients undergoing nonoperative medical management must be cautioned to maintain adequate hydration, to avoid diuretics and prolonged immobilization, and to seek prompt medical attention in the event of illnesses accompanied by significant vomiting or diarrhea. Dietary calcium should not be restricted.

The goal of an effective pharmacologic therapy for primary hyperparathyroidism remains elusive, though studies of sex hormones and selective estrogen receptor modulators, bisphosphonates, and calcimimetics continue. Estrogens and progestins may reduce serum calcium and phosphorus, urinary calcium and hydroxyproline, and histologic evidence of active bone resorption in women with primary hyperparathyroidism, although safety concerns have limited these therapeutic options in postmenopausal women.

Intravenous bisphosphonates have been used successfully in the urgent therapy of hypercalcemia due to primary hyperparathyroidism, and several trials have shown that treatment with oral alendronate for 1 year or more improves bone density at the spine and hip, with only transient effects on serum calcium and PTH.[354,355] The calcimimetics represent a new class of agents that, by sensitizing the CaSR to extracellular calcium, can reduce PTH secretion. Cinacalcet, the first calcimimetic approved for control of secondary hyperparathyroidism in renal disease, was shown to lower serum calcium and PTH in primary hyperparathyroidism (and in some patients with parathyroid carcinoma), although improvement on bone density has not been documented in this population.[356]

Thus in patients for whom surgery for asymptomatic primary hyperparathyroidism is not an option, therapy with oral bisphosphonates can improve bone density without worsening other features of the disease, at least over 2 years of follow-up, and cinacalcet can control blood calcium. Whether these agents or any other medical therapy offers a beneficial long-term alternative to surgery is unknown.

Surgical Treatment of Primary Hyperparathyroidism. Parathyroidectomy is a safe and highly effective approach to definitive treatment of primary hyperparathyroidism. The most serious potential complications of parathyroid surgery—vocal cord paralysis and permanent hypoparathyroidism—occur after fewer than 1% and 4%, respectively, of procedures performed by highly skilled surgeons, although these rates can be much higher in less experienced



• **Fig. 29.24** Sites of ectopic location of 104 parathyroid glands found at reoperation for primary hyperparathyroidism. (From Wang C-A. A clinical and pathological study of 112 cases. *Ann Surg*. 1977;186:140–145.)

hands. Such complications occur most often in patients who require subtotal parathyroid resections for hyperplasia or resection of carcinoma. The surgical cure rate for primary hyperparathyroidism in the best hands is at least 95%.[357,358] Apart from operator inexperience, the usual cause of initial surgical failure ("persistent disease") is the presence of either unrecognized (often very asymmetric) parathyroid hyperplasia or ectopic parathyroid tissue (i.e., intrathyroidal, undescended, retroesophageal, or mediastinal glands)[359] (Fig. 29.24). Up to one in five parathyroid glands may be located ectopically, and this is especially true of supernumerary glands. Recurrent disease, defined as that occurring after an interval of at least 6 to 12 months of normocalcemia, varies in incidence from 2% to 16%. Recurrent hyperparathyroidism usually arises in unresected hyperplastic glands, but rarely it may be due to parathyroid carcinoma, to a second adenoma, or to a multicentric or miliary "parathyromatosis" engendered by inadvertent local seeding of parathyroid tissue (usually hyperplastic) into the neck during previous parathyroid surgery.[282,360]

In the past, there was broad agreement that the best approach is a bilateral neck exploration in which all four parathyroids are identified and all enlarged glands removed. With this procedure, preoperative parathyroid localization studies prior to initial cervical exploration are superfluous, as the positive predictive value of even the best technique (^{99m}Tc-sestamibi scanning) falls well short of the success rate of experienced surgeons unaided by prior imaging.[282,361]

With the advent of preoperative ^{99m}Tc-sestamibi scanning, which can accurately localize 80% to 90% of the single adenomas that account for 75% to 85% of cases, there has been renewed interest in performance of directed unilateral explorations, which reduce operative and recovery-room time, minimize the number of frozen sections required, are associated with significantly fewer postoperative complications, and can more readily be performed using minimally invasive techniques (including local anesthesia and intravenous sedation) that enable same-day discharge.[362] Sestamibi scanning also can identify the occasional mediastinal adenoma and thereby allow the avoidance of an unnecessary neck exploration. On the other hand, the sensitivity and positive predictive value of sestamibi scanning is poor (<50%) in the presence of multiglandular disease (hyperplasia or double adenomas), and thus the test may frequently miss the presence of bilateral disease.[358] To reduce this failure rate, which is unacceptably high in comparison to bilateral exploration, supplemental preoperative ultrasonic imaging or high-resolution CT with dynamic contrast administration (four-dimensional CT [4D-CT])[363] is often used (with or without needle biopsy), and rapid intraoperative PTH assays have been developed to verify successful excision.[364] Because the half-life of intact PTH in blood is very short (<2 minutes), a decline of 50% or more from baseline within 10 minutes or so can signal successful removal of all hyperfunctioning parathyroid tissue. This approach has functioned well in patients with single adenomas, but can be misleading in those with multiglandular disease unless more stringent criteria for cure are applied (i.e., >90% decline, or even normalization, of iPTH).[365]

At present, preoperative imaging enables consideration of a minimally invasive unilateral parathyroidectomy in approximately 70% of those patients thought preoperatively to have sporadic primary hyperparathyroidism due to a solitary adenoma. Surgical cure rates in appropriately selected patients are comparable to those after bilateral neck exploration (i.e., 95–97%),[358] although a recent study in which all patients selected for minimally invasive surgery were also subjected to immediate bilateral neck dissection demonstrated a failure to recognize multiglandular disease in 16% of these subjects.[366] Patients known or suspected to have multiglandular disease, such as those with MEN1 and those younger than 30 years of age, should undergo bilateral neck exploration.[367] Options for patients with hyperplasia include resection limited to visibly abnormal glands, subtotal parathyroidectomy with cryopreservation of tissue, and total parathyroidectomy with immediate autotransplantation (i.e., in the forearm) of some excised tissue. In patients with MEN1, considerations of recurrence rates (30–50% or higher with long-term follow-up) and the timing thereof versus the potential morbidity of surgical hypoparathyroidism tend to favor subtotal parathyroidectomy as the preferred approach at present.

The incidence of parathyroid carcinoma in primary hyperparathyroidism is less than 1%,[285] but this possibility should be strongly considered in patients with unusually severe hyperparathyroidism, a palpable neck mass, hoarseness, evidence of local invasion at surgery, or recurrent hypercalcemia.[368] Even so, parathyroid carcinoma rarely is suspected preoperatively and often eludes diagnosis at the time of initial surgery. When the disease is recognized, vigorous attempts should be made to remove the tumor en bloc. The incidence of local recurrence approaches 50%, however, and distant metastases, particularly to lung, may be heralded by recurrent, severe hyperparathyroidism.[369] Because apparently sporadic and isolated parathyroid cancer can occur in families with parafibromin mutations, a search for such mutations in all patients with parathyroid cancer can facilitate family counseling.[348]

The immediate postoperative management of parathyroidectomy focuses on establishing the success of the surgery and monitoring the patient closely for symptomatic hypocalcemia and for uncommon but potentially serious acute complications such as

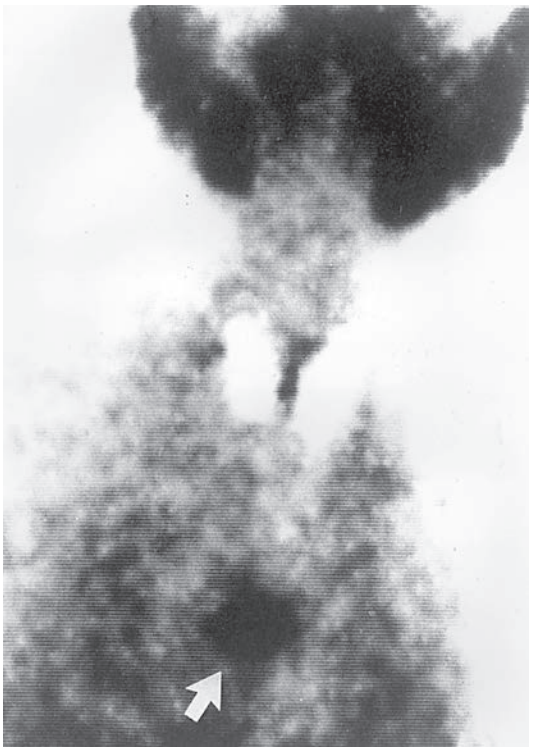
bleeding, vocal cord paralysis, or laryngospasm. After successful resection of a parathyroid adenoma, serum intact PTH levels decline rapidly, often to undetectable concentrations, with a disappearance half-time of about 2 minutes, whereas serum calcium typically reaches a nadir between 24 and 36 hours. Serum PTH returns to the normal range within 30 hours, although measurements of the parathyroid secretory response to hypocalcemia suggest that it does not fully normalize for at least several weeks.[370]

In the past, patients generally were maintained on a low-calcium diet until normalization of serum calcium was clearly documented, ampoules of injectable calcium and other seizure precautions were maintained at the bedside, serum calcium was measured at least every 12 hours until stable, and symptomatic hypocalcemia was promptly treated with calcium, either intravenously (90-mg bolus, 50–100 mg/hour) or orally (1.5–3 g/day). This approach is no longer appropriate for most patients, who are discharged within a few hours after limited surgery. Instead, oral calcium supplements routinely are provided as soon as oral intake is reestablished, and moderate doses of $1,25(OH)_2D$ (0.5–1 μg daily) are added for those with large adenomas and severe hyperparathyroidism or for those in whom alkaline phosphatase had been elevated properatively—that is, patients in whom an impressive calcium requirement can be anticipated, often for many weeks postoperatively, as they remineralize their skeletons. This "hungry bone" syndrome is associated with hypocalcemia, hypophosphatemia, and low urinary calcium excretion.

Serum calcium should be checked at intervals of several days initially to guide adjustment of calcium and vitamin D therapy as needed to achieve a stable result. In those in whom hypocalcemia persists for more than several days, serum PTH should be measured to exclude the possibility of postoperative hypoparathyroidism. Given evidence that bone mineral density continues to increase for at least 1 year after successful parathyroidectomy,[291] it is prudent to continue calcium supplementation for at least that long.

The approach to patients with persistent or recurrent hyperparathyroidism is informed by the recognition that parathyroid hyperplasia or carcinoma, ectopic or supernumerary parathyroid tissue, and postoperative hypoparathyroidism and other complications of further surgery all are more common in this population.[359,361] The first issue to address is whether surgery is indicated. When a presumed adenoma had not been identified initially, the original indications for surgery generally still exist, although some patients may not be suitable candidates for more extensive surgery, such as a median sternotomy, because of concurrent medical illness. Patients with parathyroid hyperplasia may have experienced significant clinical improvement, even after incomplete parathyroidectomy, although those with MEN1 are very likely to experience further progression of their disease.

Preoperative localization studies are recommended for patients with persistent or recurrent disease after a first operation. Scanning with ^{99m}Tc-sestamibi offers the highest sensitivity and accuracy, although other studies (ultrasonography, CT, magnetic resonance imaging [MRI]) may provide additional or confirmatory information.[371] Sestamibi does localize to thyroid nodules, which may accompany parathyroid disease in 20% to 40% of patients, although it tends to wash out of thyroid tissue much more rapidly than from parathyroids. ^{99m}Tc-sestamibi can be combined with ^{123}I scanning to improve distinction of parathyroids from thyroid nodules or with single-photon emission CT (SPECT) imaging to achieve accuracy in localization not possible with planar imaging (Fig. 29.25). On the other hand, sestamibi scanning may fail to reveal small glands (uptake is related to gland size and PTH levels[372]) or to demonstrate multiple abnormal glands in cases of parathyroid hyperplasia, the most common cause of persistent postoperative hyperparathyroidism.[358,373] Use of 4D-CT with synchronous contrast-enhanced multiplanar anatomic reconstruction has been shown to provide sensitivity superior to sestimibi scanning alone for localizing functioning parathyroid tissue in candidates for reoperation.[374]



• **Fig. 29.25** Technetium-99m (^{99m}Tc) sestamibi, iodine-123 (^{123}I) subtraction scanning of a patient with persistent hyperparathyroidism after two previous unsuccessful operations. *Arrow* points to parathyroid adenoma, shown as increased tracer uptake in the aortopulmonary window. (From Thule P, Thakore K, Vansant J, et al. Preoperative localization of parathyroid tissue with technetium-99m sestamibi123I subtraction scanning. *J Clin Endocrinol Metab*. 1994;78:77–82.)

More invasive techniques have been used as well, including angiography and selective venous sampling for measurement of PTH.[375,376] Ultrasound-guided or CT-guided fine-needle aspiration of suspected parathyroid tissue may be used to obtain cytologic or immunochemical confirmation prior to surgery, and intraoperative ultrasonography has been useful in some cases to locate cervical or intrathyroidal glands.[361] Success with video-assisted thoracoscopic resection of documented mediastinal lesions[348,377] offers a less invasive alternative to median sternotomy for this relatively common cause of persistent hyperparathyroidism.

The need for these procedures depends on the experience of the original surgeon and the confidence that the neck was adequately explored initially. For example, among reoperations at one center, over half of the "missed" hyperplastic parathyroid glands in those cases previously explored by a highly experienced parathyroid surgeon were found in the mediastinum or another ectopic location, whereas over 90% of those referred by less experienced surgeons were discovered in a normal anatomic location in the neck.[282]

Following successful surgery for primary hyperparathyroidism, bone mass generally improves by as much as 5% to 10% in the

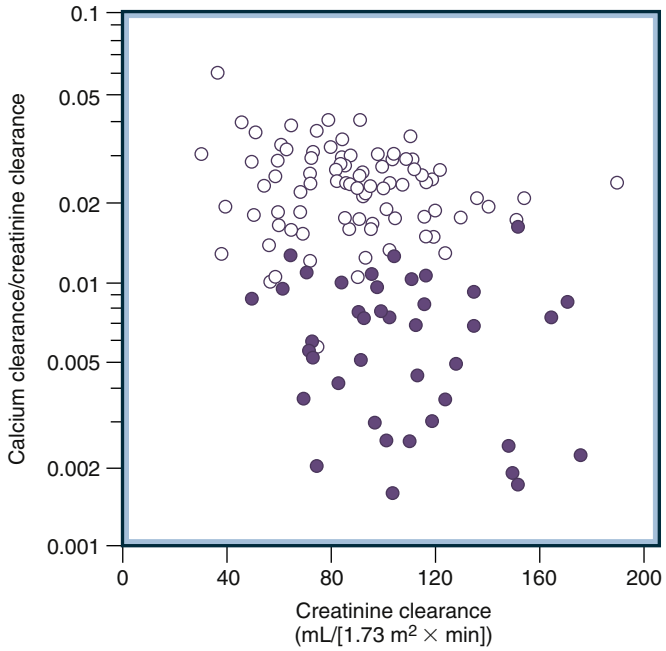
first year at sites rich in trabecular bone (spine, femoral neck), whereas improvement at cortical sites (distal radius) is less predictable.[378,379] Increases at trabecular sites may continue for several years, to as much as 12% to 15% after 10 years, although normal bone mineral density may not be achieved. This improvement, which is most apparent in those with the greatest preoperative reductions in bone mass, may be related in part to rapid remineralization of the previously enlarged bone remodeling volume,[352] but the continued improvement over years suggests a more sustained increase in net bone formation and total bone volume as well.[291]

Familial Hypocalciuric Hypercalcemia

FHH, also appropriately called *familial benign hypercalcemia*, is, in most families, a disorder of autosomal dominant inheritance caused most often by mutations of the *CASR* gene found in parathyroid glands, kidney, and other organs (see earlier discussion of calcium sensing). The mutations, which cause complete or partial loss of function of the CaSR, lead to a shift in the parathyroid cell's set-point for calcium.[380] As a consequence, higher than normal levels of blood calcium are needed to suppress PTH secretion. Furthermore, abnormal function of the CaSR in the renal thick ascending limb leads to increased PTH-independent calcium reabsorption and consequent hypocalciuria. In a minority of patients, mutations in two other genes in the signaling pathway activated by the CaSR have been found. One encodes the α-subunit of the G_{11} heterotrimeric G protein[381] known to participate in responding to the activation of the CaSR, and the other is in the *AP2S1* gene that encodes the α-subunit of adapter protein complex 2, a scaffolding protein needed for formation of clathrin-coated pits needed to internalize the CaSR.[382] Mutations in AP2S1 are considerably more common than mutations in $G\alpha_{11}$ in FHH[383,384]; patients with AP2S1 mutations have particularly severe hypercalcemia and can present with developmental delay and cognitive dysfunction.[383]

The presence of one normal calcium-sensing receptor gene with the abnormal one usually leads to a very mild clinical disorder, although the receptor functions as a dimer, and certain mutations can worsen the function of the normal allele. Rare patients who inherit mutant *CASR* genes from both parents present at birth with severe, life-threatening, primary hyperparathyroidism and almost always require immediate parathyroid surgery. In another genetic variation, a familial form of CaSR-dependent hypercalcemia has been described in association with other autoimmune disorders such as Hashimoto hypothyroidism and celiac sprue, in which autoantibodies directed against the sensor apparently antagonize calcium recognition by the parathyroids and renal tubules.[385,386]

FHH is manifested at birth by hypercalcemia. Although some controversy exists, most observers note that the condition associated with calcium-sensing receptor mutations is usually asymptomatic and that apparent symptoms represent ascertainment bias. Possible exceptions include the occurrence of chondrocalcinosis and perhaps pancreatitis. The blood calcium level is usually less than 12 mg/dL but can be higher. Phosphate measurements are low, as in primary hyperparathyroidism. Blood magnesium levels are high-normal or slightly elevated. PTH levels are inappropriately normal for the degree of hypercalcemia and are occasionally modestly elevated. Urine calcium is usually low, though one novel mutation in the receptor's intracellular tail has been associated with hypercalciuria, possibly because of only mild dysfunction in the kidney.[387]



• **Fig. 29.26** Index of urinary excretion rate for calcium as a function of creatinine clearance. Each point represents the mean of multiple determinations for a hypercalcemic patient with familial hypocalciuric hypercalcemia *(filled circles)* or with typical primary hyperparathyroidism *(open circles)*. The data are based on average 24-hour urinary excretion values and average fasting serum samples. (From Marx SJ, Attie MF, Levine M, et al. The hypocalciuric or benign variant of familial hypercalcemia: clinical and biochemical features in fifteen kindreds. *Medicine*. 1981;60:397–412.)

When patients present as adults, the distinction from mild primary hyperparathyroidism can be difficult. The distinction between FHH and primary hyperparathyroidism is a crucial one, however. Young patients with primary hyperparathyroidism are usually treated surgically and cured. In contrast, hypercalcemia always recurs after surgery for FHH, unless the patient is rendered hypoparathyroid by the removal of all parathyroid tissue. Therefore surgery is contraindicated as therapy for FHH, except in the very rare patient with severe, symptomatic hypercalcemia. No blood or urine measurements are completely reliable for distinguishing between the two conditions, though the ratio of calcium clearance to creatinine clearance distinguishes most patients with FHH from those with primary hyperparathyroidism.[388] Fig. 29.26 shows, however, that this ratio separates the two groups, with modest overlap between the groups. However, because primary hyperparathyroidism is much more common than FHH, most patients with values near the cutoff value of 0.01 for the ratio of calcium clearance to creatinine clearance will have primary hyperparathyroidism and not FHH.[389] Consequently, a case can be made[390] that many of such patients, particularly before parathyroid surgery, should undergo sequencing of their *CASR* gene, now available commercially. The most helpful diagnostic information is the presence of hypercalcemia in an infant relative; such early hypercalcemia does not occur in MEN1. Furthermore, a past history of clearly normal blood calcium, considerably lower than current measurements, makes FHH unlikely if no other reason, such as severe vitamin D deficiency, for a change in blood calcium exists. In the occasionally symptomatic patient, cinacalcet, a calcimimetic drug, can usually lower the blood level of calcium.[391]

Lithium Toxicity

Treatment of bipolar affective disorders with lithium commonly leads to mild, persistent increases in blood calcium.[392,393] Measurement of ionized calcium has shown that ionized calcium is a more sensitive index of lithium effect and was elevated in 24% of consecutive patients in a cross-sectional study.[394] After several years of therapy, clear elevations of PTH levels and modest increases in parathyroid gland size, detected by ultrasonography, often occur. Usually, when lithium therapy is stopped, the blood calcium and PTH normalize within several months. Uncommonly, substantial hypercalcemia and clear hyperparathyroidism ensue. At surgery, both single-gland and multigland disease are found, with a higher fraction of multigland disease than found in primary hyperparathyroidism not associated with lithium therapy.[395,396]

The management of patients with mild lithium-induced hypercalcemia is somewhat complicated. Like patients with mild primary hyperparathyroidism, patients taking lithium usually tolerate mild hypercalcemia without obvious symptoms. These patients can be monitored with protocols similar to those for patients with asymptomatic primary hyperparathyroidism. Close attention must be paid to urine-concentrating ability in these patients, however, because the nephrogenic diabetes insipidus associated with lithium therapy can lead to dehydration and sudden worsening of hypercalcemia. Substantial hypercalcemia should lead to withdrawal of lithium therapy, if possible, with substitution of newer psychopharmacologic agents. If hypercalcemia persists after withdrawal of lithium, decisions about surgery follow the same guidelines as those for patients with primary hyperparathyroidism.

Lithium increases the set-point for PTH secretion when it is added to isolated parathyroid cells in vitro. The set-point for PTH secretion in vivo is shifted to the right in patients who have received lithium for several years as well. A corresponding shift in the concentration of extracellular calcium needed to raise intracellular calcium levels[397] suggests that lithium interferes with the action of the parathyroid CaSR.

Parathyroid-Independent Hypercalcemia

In parathyroid-independent hypercalcemia, PTH secretion is appropriately suppressed. PTH levels, measured using two-site assays, are invariably lower than 25 pg/mL and are usually lower than normal or undetectable. Most affected patients have malignant hypercalcemia, although parathyroid-independent hypercalcemia occurs in a number of other settings as well.[398]

Hypercalcemia of Malignancy

The diagnosis of malignant hypercalcemia is seldom a subtle one.[125] Most malignancies produce hypercalcemia only when they are far advanced; the diagnosis becomes evident after routine studies, guided by the history and physical examination. Patients with malignant hypercalcemia usually die 1 to 2 months after hypercalcemia is discovered. Patients present with the classic signs and symptoms of hypercalcemia: confusion, polydipsia, polyuria, constipation, nausea, and vomiting. Perhaps because of the acuteness of the hypercalcemia and the elderly patient population involved, dramatic changes in mental status, culminating in coma, are relatively common. The diagnosis can be missed because the manifestations often overlap those of the underlying malignancy and because low blood albumin may lead to an apparently normal total blood calcium, despite an elevated blood ionized calcium. Even though the overall prognosis is grim, the diagnosis of malignant hypercalcemia is important to make.

Treatment is usually simple and effective in the short term; such treatment can importantly reverse the patient's symptoms for several weeks and even provide time for a fundamental attack on the underlying tumor, if it is treatable. Treatment consists of restoration of volume, followed by intravenous bisphosphonate or denosumab (see "Management of Severe Hypercalcemia"). Only effective treatment of the underlying neoplasm can significantly influence the long-term prognosis for patients with malignant hypercalcemia.

Although mechanisms in a given patient may be multiple, it is still useful to distinguish hypercalcemia associated with local involvement of bone from that caused by humoral mechanisms. In all cases, resorption of bone plays a pivotal role in the pathogenesis.

Local Osteolytic Hypercalcemia

Hypercalcemia resulting from tumors invading bone occurs most clearly in multiple myeloma and some patients with breast cancer. There is little evidence that the tumor cells themselves resorb bone. Instead, active osteoclasts found near the tumor cells are thought to be the proximate mediators of bone resorption.[399] Myeloma cells and marrow cells associated with myeloma cells secrete numerous cytokines and chemokines capable of stimulating bone resorption, including macrophage inflammatory protein 1 (MIP1), lymphotoxin (tumor necrosis factor-β), and interleukins 1β, 3, and 6. These factors lead to increased expression of RANKL (see Fig. 29.8) on the surface of marrow stromal cells and stimulation of osteoclast formation and activity. RANKL is also found on the surface of myeloma cells, and therefore these cells may directly stimulate the production and activity of osteoclasts. The increased bone resorption not only releases calcium into the circulation but also weakens the bone structurally. Bone is further weakened by the suppression of bone formation by the secretion of dickkopf-1, an inhibitor of Wnt signaling, by myeloma cells.[400–402] In patients with myeloma, treatment with intermittent intravenous bisphosphonates or denosumab inhibits bone resorption and reduces the incidence of bone pain, fracture, and hypercalcemia.[403]

The pathogenesis of hypercalcemia in breast cancer is not completely understood. Extensive metastases to bone are detected in most patients with hypercalcemia and breast cancer; this finding suggests that factors produced in bone by the metastatic tumor cells may be important. Breast cancer cells make a host of cytokines capable of stimulating bone resorption by osteoclasts.[404] The role of tumor-produced PTHrP may be particularly important.[401] A majority of breast cancer patients with hypercalcemia have elevated blood levels of PTHrP. This circulating PTHrP, as well as PTHrP produced in bone by metastatic tumor cells, may generate the hypercalcemia. Primary breast tumors that stain for PTHrP are more likely to result in bone metastases than are those that do not stain for PTHrP; this PTHrP may be instrumental in the establishment of lytic metastases. Animal models indicate that transforming growth factor-β (TGFβ), released from bone matrix by PTHrP-stimulated osteoclastic resorption, may further augment PTHrP secretion by the tumor cells. The latter may be further promoted by estrogen, which may explain the occasional occurrence of hypercalcemia following institution of estrogen or tamoxifen therapy in this disease.[405]

Humoral Hypercalcemia of Malignancy

Albright, in 1941, was the first to propose that a PTH-like humoral factor caused the hypercalcemia in patients with malignancy but few or no bone metastases.[406] Four decades later

biochemical analysis demonstrated that such patients have high blood calcium levels, low blood phosphate levels, and high urinary cAMP levels like those found in primary hyperparathyroidism, but no elevation in iPTH levels.[407] The stimulation of cAMP production was used as an assay to eventually purify PTHrP from human tumors associated with the humoral hypercalcemia of malignancy.[408]

The evidence that PTHrP mediates the humoral hypercalcemia of malignancy in most patients is substantial. As noted previously, PTHrP binds to the PTH/PTHrP receptor and mimics all of the actions of amino-terminal fragments of PTH. Blood levels of PTHrP are elevated in most patients with solid tumors and hypercalcemia. In animal models of the humoral hypercalcemia of malignancy, antibodies against PTHrP can reverse the hypercalcemia.[409]

The acute actions of PTHrP cannot explain all of the findings in patients with the hypercalcemia of malignancy, however. Acutely administered PTHrP increases blood levels of $1,25(OH)_2D_3$ by stimulating the renal 1α-hydroxylase, though the stimulation is less than that induced by PTH.[410] Nevertheless, patients with the humoral hypercalcemia of malignancy usually have low levels of $1,25(OH)_2D_3$.[407] This finding is particularly puzzling, because human tumors from patients with elevated calcium and PTHrP but with low $1,25(OH)_2D_3$ levels stimulate $1,25(OH)_2D_3$ synthesis after they are transplanted into nude mice.[411] Possible explanations for the low $1,25(OH)_2D_3$ levels in patients include the weak activation of the renal 1α-hydroxylase in humans by PTHrP, combined with the inhibition of the 1α-hydroxylase by hypercalcemia[412] or by tumor products.

A second disparity between the acute actions of PTHrP and the findings in patients with malignant hypercalcemia involves the rate of bone formation. Acutely, PTHrP infusions in rats, like PTH, leads to increased bone formation.[413] Nevertheless, in patients with malignant hypercalcemia, bone formation is markedly lower than normal. The explanation for this effect may well lie in the action of other cytokines, immobilization, or particular fragments of PTHrP with novel properties.

The tumors most commonly associated with humoral hypercalcemia include squamous cell cancers of the lung, head and neck, esophagus, cervix, vulva, and skin; breast cancer; renal cell cancer; and bladder cancer. Benign or malignant pheochromocytomas, islet cell tumors, and carcinoids can also overproduce PTHrP, causing hypercalcemia. The aggressive T-cell lymphoma associated with human T-cell lymphotropic virus type 1 (HTLV1) infection is the only hematologic malignancy commonly associated with PTHrP overproduction and hypercalcemia.

Cachexia often accompanies the hypercalcemia of malignancy. In experimental models, administration of a monoclonal antibody to PTHrP ameliorates the cachexia, not simply by lowering blood calcium but also by blocking the ability of PTHrP to convert white adipose tissue to brown, heat-generating adipose tissue.[126]

It is unlikely that PTHrP is the sole cause of the humoral hypercalcemia of malignancy. As noted previously, many cytokines produced by tumors can stimulate bone resorption. The actions of these cytokines have been shown to synergize with those of PTHrP in a number of experimental models. Furthermore, in hypercalcemic patients with non-Hodgkin lymphoma, blood levels of $1,25(OH)_2D_3$ were found to be higher than otherwise expected,[414] and such patients show abnormal sensitivity to 25-hydroxyvitamin D administration.[415] In these hypercalcemic patients, the relative importance of $1,25(OH)_2D_3$ cytokines, PTHrP, and immobilization needs to be clarified. Only a minority of patients with non-Hodgkin lymphoma have clear elevations of either PTHrP or $1,25(OH)_2D_3$.[416]

In a few reported cases, malignant tumors secrete PTH and not PTHrP.[125,417] Although this phenomenon has now been well documented, it should be stressed that in almost all patients with cancer and high PTH levels, concurrent primary hyperparathyroidism, not ectopic PTH production, is the cause of the hyperparathyroidism.

Vitamin D Intoxication

Because the synthesis of $1,25(OH)_2D_3$ is so tightly regulated, extremely large doses of vitamin D, on the order of 100,000 units per day, are required to cause hypercalcemia. Such doses are available in the United States only by prescription, therefore most cases of vitamin D intoxication are iatrogenic. Occasionally, inadvertent ingestion occurs. All over the world, including in the United States, particularly in the era of the internet and widespread enthusiasm about the potential properties of vitamin D, increasing reports of vitamin D intoxication caused by preparations of vitamin D containing much larger amounts of vitamin D than claimed have been published.[418] Patients present with nausea, vomiting, weakness, and altered level of consciousness. Hypercalcemia can be severe and prolonged, because of the storage of vitamin D in fat. As expected, PTH levels are suppressed, and levels of 25(OH)D, which are poorly regulated and reflect levels of ingested vitamin D, are dramatically elevated. In contrast, the levels of $1,25(OH)_2D_3$ are only modestly elevated or can be normal or even low. The modest changes in $1,25(OH)_2D_3$ levels result from the downregulation of the renal 1α-hydroxylase by low levels of PTH and high levels of phosphate, calcium, FGF23, and $1,25(OH)_2D_3$ itself. The cause of the hypercalcemia, when it occurs in the face of normal levels of $1,25(OH)_2D_3$, is uncertain but may reflect the direct action of 25(OH)D and possibly other vitamin D metabolites, which are capable of binding the $1,25(OH)_2D_3$ receptor weakly or which may be locally 1α-hydroxylated by nonrenal 1α-hydroxylases. Of note, vitamin D causes hypercalcemia in mice missing the 1α-hydroxylase gene,[419] arguing that 25(OH)D and other metabolites, when present in large amounts, are sufficient to cause hypercalcemia. Also, the weaker vitamin D metabolites may displace $1,25(OH)_2D_3$ from the circulating VDBP and increase the concentration of active, free $1,25(OH)_2D_3$.[420,421]

The hypercalcemia of vitamin D intoxication results both from increased intestinal absorption of calcium and from the direct effect of $1,25(OH)_2D_3$ to increase resorption of bone. Therefore in severe cases bisphosphonate therapy can be usefully added to the therapeutic regimen of hydration and omission of dietary calcium.

Sarcoidosis and Other Granulomatous Diseases

Sarcoidosis may be associated with hypercalcemia and, even more commonly, hypercalciuria.[422] Hypercalcemic patients have high levels of $1,25(OH)_2D_3$; the high level of $1,25(OH)_2D_3$ probably causes the hypercalcemia, although overproduction of bone-resorbing cytokines and PTHrP may contribute in some patients. As expected in $1,25(OH)_2D_3$-dependent hypercalcemia, intestinal absorption of calcium is increased and PTH levels are suppressed. Furthermore, the hypercalcemia and high levels of $1,25(OH)_2D_3$ fall upon treatment with glucocorticoids. The unregulated synthesis of $1,25(OH)_2D_3$, found even in an anephric patient, occurs not in the kidney but in the sarcoid granulomas. Removal of a large amount of granulomatous tissue can reverse hypercalcemia. Furthermore, isolated sarcoid macrophages can synthesize

$1,25(OH)_2D_3$ from 25(OH)D, as can normal macrophages stimulated with interferon-γ or after activation of toll-like receptors. Such macrophages express the gene encoding the identical 25(OH)D 1α-hydroxylase found in the kidney. The local synthesis of $1,25(OH)_2D_3$ by activated macrophages and activation of VDRs in those cells is a paracrine system that activates antibacterial mechanisms as part of the normal action of macrophages.[193]

The unusual increase in the numbers of activated macrophages in sarcoidosis leads, however, to elevations of blood calcium in these patients. These patients have unusual sensitivity to vitamin D and can become hypercalcemic in response to ultraviolet radiation or oral vitamin D intake. Abnormalities in calcium metabolism are usually found only in patients with active disease and large, clinically obvious total-body burdens of granulomas. Nevertheless, hypercalcemia can present in patients without obvious pulmonary disease. Furthermore, subtle abnormalities of vitamin D metabolism can be demonstrated even in patients with mildly active sarcoidosis.

Hypercalcemia is also associated with other granulomatous diseases, such as tuberculosis, fungal infections, and berylliosis and has been reported in Wegener granulomatosis, in acquired immunodeficiency syndrome (AIDS)–related *Pneumocystis jirovecii* infection, fat necrosis of the newborn,[423] and even in association with extensive granulomatous foreign-body reactions.[398] Patients with Crohn disease occasionally have hypercalcemia with elevations of $1,25(OH)_2D_3$ levels but often have elevated $1,25(OH)_2D_3$ levels with normal calcium levels and low bone mass, associated with increased production of $1,25(OH)_2D_3$ in intestinal macrophages.[424] In an analysis of 101 patients with hypercalcemia and high levels of $1,25(OH)_2D_3$ in Australia, half the patients had sarcoidosis and the others had hematologic malignancies, other infections, or other causes.[425]

CYP24A1 Loss of Function

Cyp24A1 encodes the vitamin D-24-hydroxylase, which is an important regulated inactivator of $1,25\text{-}(OH)_2D$. Homozygous loss of this gene leads to idiopathic infantile hypercalcemia, usually a severe disease presenting in early childhood. However, the spectrum of presentation is broad, and some patients present in late childhood and even adulthood, with hypercalciuria, kidney stones, and nephrocalcinosis.[426]

Hyperthyroidism

Mild hypercalcemia can result from thyrotoxicosis.[427] Blood calcium levels seldom exceed 11 mg/dL, but mild elevations are found in a quarter of patients. Patients have low PTH levels, low $1,25(OH)_2D_3$ levels, and hypercalciuria. The hypercalcemia is caused by a direct action of thyroid hormone to stimulate bone resorption.[428] β-Adrenergic blocking agents can reverse the hypercalcemia.[429]

Vitamin A Intoxication

Excess ingestion of vitamin A (retinol) results in a syndrome of dry skin, pruritus, headache from pseudotumor cerebri, bone pain, and occasional hypercalcemia. Hypercalcemia occurs only with the ingestion of 10 times the Recommended Dietary Allowance (RDA) (5000 IU/day). The identical syndrome can result from ingestion of the vitamin A derivatives isotretinoin (13-*cis*-retinoic acid [Accutane]) and tretinoin (all-*trans*-retinoic acid [Retin-A]), used to treat acne and acute promyelocytic leukemia.[430,431] Bones can show characteristic periosteal calcification on radiographs. The hypercalcemia is probably caused by the action of retinoids to stimulate bone resorption. The diagnosis is made by the association of a history of excess ingestion of retinoids with the characteristic syndrome and abnormal results of liver function tests; elevated vitamin A levels confirm the diagnosis. Treatment involves hydration and, if necessary, glucocorticoids or bisphosphonates.

Adrenal Insufficiency

Hypercalcemia occurs in the setting of adrenal insufficiency. Blood calcium is elevated partly as a result of hemoconcentration and increased albumin levels, but the level of ionized calcium can be increased as well.[432] PTH and $1,25(OH)_2D_3$ levels are low to low-normal.[433] The hypercalcemia in this study resulted from a combination of influx of calcium into the vascular space, probably from bone, combined with low renal clearance.

Thiazide Diuretics

Thiazide diuretics do not cause hypercalcemia by themselves, but they can exacerbate the hypercalcemia of primary hyperparathyroidism or any other cause of increased input of calcium into the bloodstream that is not suppressed by hypercalcemia. The mechanism of the hypercalcemia may involve the action of thiazide diuretics to increase proximal tubular calcium reabsorption as a secondary consequence of direct action of thiazides on the distal tubule.[434,435] Decreased renal clearance of calcium alone would be expected to raise blood calcium in the normal human only transiently because the transient hypercalcemia would be expected to suppress PTH secretion and lead to return of the blood calcium to normal. However, in the presence of primary hyperparathyroidism, sarcoidosis, excess calcium intake, or any other cause of high, fixed calcium load, thiazide administration will increase the level of calcium in blood.

As predicted by this model, thiazide administration leads to chronic hypercalcemia in patients with abnormal parathyroid physiology but not in normal subjects.[436] In primary hyperparathyroidism, thiazide administration exacerbates the hypercalcemia, and in hypoparathyroidism, thiazide administration facilitates the maintenance of normocalcemia when given in conjunction with $1,25(OH)_2D_3$ and calcium.

Milk-Alkali Syndrome

The triad of hypercalcemia, metabolic alkalosis, and renal failure can be the consequence of massive ingestion of calcium and absorbable alkali. This syndrome was first described when milk and sodium bicarbonate were used in large amounts to treat peptic ulcer disease. With the change in ulcer treatment to nonabsorbable antacids and suppression of acid secretion, milk-alkali syndrome became rare. In the last several years, however, the increased use of calcium carbonate to treat dyspepsia and osteoporosis has led to the reappearance of milk-alkali syndrome.[437,438] In most cases, a history of ingestion of several grams per day of calcium in the form of calcium carbonate can be elicited. Some reports suggest that less than 4 g of calcium daily can cause milk-alkali syndrome, fewer than previously estimated, perhaps because of greater ingestion of vitamin D than in the past.[439] The pathogenesis of the syndrome is not understood in detail but may well involve a vicious circle in which alkalosis decreases renal calcium clearance and hypercalcemia helps maintain alkalosis. Nephrocalcinosis, nephrogenic diabetes insipidus, decrease in GFR associated with hypercalcemia, and hypovolemia from vomiting all lead to renal failure, which can be severe. PTH levels, measured with currently available two-site assays, are invariably low in hypercalcemic patients, as are levels of $1,25(OH)_2D_3$. After clearance of the calcium by hydration

or dialysis, if necessary, renal function generally returns to normal, unless the disorder has been severe and longstanding.

Immobilization

Immobilization can lead to bone resorption sufficient to cause hypercalcemia. The immobilization is usually caused by spinal cord injury or extensive casting after fractures, though it can occur in settings such as Parkinson disease.[434] Hypercalcemia after trauma requiring immobilization is common, when studied prospectively, and is usually asymptomatic.[440] Hypercalcemia of immobilization occurs predominantly in the young or in patients with other reasons for a high rate of bone turnover, such as Paget disease or extensive fractures. Hypercalciuria and substantial bone loss are more common than hypercalcemia. After spinal cord injury, the hypercalciuria is maximal at 4 months and can persist for more than 1 year. PTH and $1,25(OH)_2D_3$ levels are suppressed; bone biopsies show increased resorption and decreased formation of bone. Bisphosphonates and denosumab have been used to reverse the hypercalcemia and hypercalciuria of immobilization.

Renal Failure

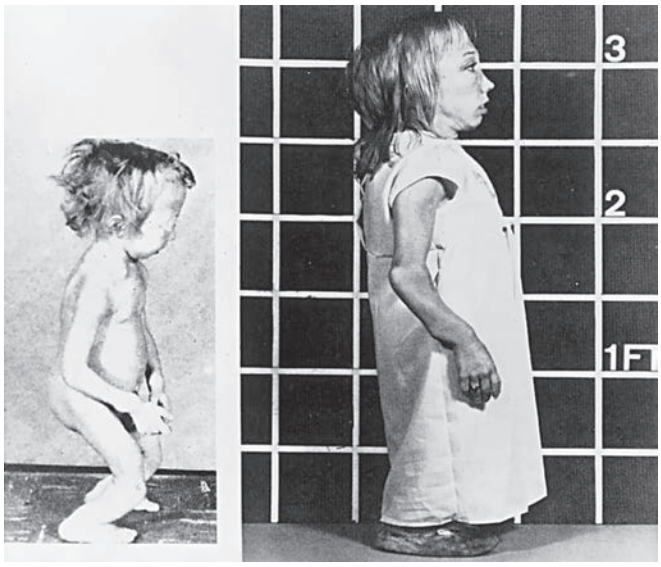
Following rhabdomyolysis, during the oliguric phase of acute renal failure, severe hypocalcemia can result from acute hyperphosphatemia and calcium deposition in muscle.[441] PTH levels are high, in response to the hypocalcemia. In the diuretic phase that follows, hypercalcemia can occur. The hypercalcemia results from the mobilization of the calcium deposits and, in a fraction of patients, from associated high $1,25(OH)_2D_3$ levels sometimes seen.[442]

In chronic renal failure, hypercalcemia can result from tertiary hyperparathyroidism or may appear during therapy of aplastic bone disease associated with low PTH levels and sometimes with aluminum toxicity.

Williams Syndrome

Williams syndrome is a developmental disorder in which supravalvular aortic stenosis is associated with elfin facies and mental retardation.[443] Hypercalcemia can occur transiently in the first 4 years of life, though, as a group, Williams patients have higher than normal calcium levels, usually at the top of the normal range.[444] Affected hypercalcemic infants have been found to have increased intestinal absorption of calcium and associated elevations of $1,25(OH)_2D_3$ that fall to normal as the blood calcium normalizes.[445] Levels of 25(OH)D are normal. The hypercalcemia can generally be controlled by dietary manipulation and, if needed, bisphosphonates.[446]

Molecular analysis has clarified the origin of the connective tissue component of Williams syndrome. Williams syndrome is a contiguous gene syndrome with deletions of one or several genes. Isolated supravalvular aortic stenosis is associated with deletion or translocation of the distal portion of the elastin gene. Williams syndrome, with more protean connective tissue abnormalities and mental retardation, is associated with large deletions that include the elastin gene and a gene encoding the protein kinase LIM-kinase 1. A gene within the Williams syndrome deletion region encodes a nuclear protein, Williams syndrome transcription factor, that is part of a large chromatin remodeling complex that can bind the VDR and influence the transcription of VDR-responsive genes.[447] For this reason, this gene is a strong candidate for the gene associated with transient hypercalcemia in this disorder. Genetic proof that this gene is responsible for the hypercalcemia and a connection between the gene and hypercalcemia, however, is lacking.



• **Fig. 29.27** A patient with Jansen metaphyseal chondrodysplasia at ages 5 years and 22 years. Note the short stature, characteristic facies, and misshapen metaphyseal region of long bones. (From Frame B, Poznanski AK. Conditions that may be confused with rickets. In DeLuca HF, Anastas CS, eds. *Pediatric Diseases Related to Calcium*. New York: Elsevier; 1980:269–289.)

Jansen Metaphyseal Chondrodysplasia

Jansen metaphyseal chondrodysplasia is a rare disease in which affected persons present in childhood with short stature and hypercalcemia (Fig. 29.27). Blood chemistry studies suggest hyperparathyroidism, with high calcium, low-normal phosphate, high $1,25(OH)_2D_3$, high alkaline phosphatase, and high urinary hydroxyproline levels, but PTH levels are suppressed.[448] A generalized defect in endochondral bone formation results from abnormally organized chondrocytes in growth plates. Metaphyses appear disordered and rachitic on radiographs. The bones may show signs of osteitis fibrosa cystica. Constitutive activation of the PTH/PTHrP receptor, caused by five different point mutations in three different amino acid residues in the transmembrane domains of the receptor, explains the findings in this disorder.[104,449,450] The abnormalities on serum chemistry studies result from PTH-like actions of the receptor in bone and kidney; one patient has been noted to have increased blood levels of FGF23.[451] The growth plate disorder results from PTHrP-like actions of the receptor on the growth plate.

Approach to the Hypercalcemic Patient

The diagnostic approach to the hypercalcemic patient is strongly influenced by the clinical setting and the knowledge that primary hyperparathyroidism is at least twice as common as all other causes combined (Table 29.2). These considerations are particularly significant in the patient who seems otherwise well and in whom the hypercalcemia is detected incidentally or is mild, stable, or known to be of long duration (i.e., years). Among outpatients referred to endocrinologists for evaluation of hypercalcemia, for example, more than 90% are found to have primary hyperparathyroidism. In ill or hospitalized patients, malignant disease is the cause in more than 50% of cases. The differential diagnosis is seldom complicated, however, because malignant hypercalcemia usually presents in the context of advanced, clinically obvious disease.

TABLE 29.2 Causes of Hypercalcemia

Parathyroid-Dependent Hypercalcemia

Primary hyperparathyroidism
Tertiary hyperparathyroidism
Familial hypocalciuric hypercalcemia
Lithium-associated hypercalcemia
Antagonistic autoantibodies to the calcium-sensing receptor

Parathyroid-Independent Hypercalcemia

Neoplasms
- PTHrP dependent
- Other humoral syndromes
- Local osteolytic disease (including metastases)

PTHrP excess (nonneoplastic)
Excess vitamin D action
- Ingestion of excess vitamin D or vitamin D analogues
- Topical vitamin D analogues
- Granulomatous disease
- Williams syndrome

Thyrotoxicosis
Adrenal insufficiency
Renal failure
- Acute renal failure
- Chronic renal failure with aplastic bone disease

Immobilization
Jansen disease
Drugs
- Vitamin A intoxication
- Milk-alkali syndrome
- Thiazide diuretics
- Theophylline

PTHrP, Parathyroid hormone–related protein.

Because hypercalcemia usually is first detected as an elevation of total serum calcium, it is important to distinguish hemoconcentration or rare instances of calcium-binding paraproteinemia or thrombocythemia-associated hypercalcemia (due to release of intracellular calcium in vitro) from a true increase in serum ionized calcium (Fig. 29.28). The presence of hypercalcemia should be confirmed by direct measurement of ionized calcium, and total calcium should be repeated, together with albumin, globulin electrolytes, blood urea nitrogen, creatinine, and phosphate. Especially when hypercalcemia is mild, it is prudent to repeat the serum total or ionized calcium measurement at least twice, preferably fasting and without venous occlusion, before proceeding with more costly studies directed at its cause.

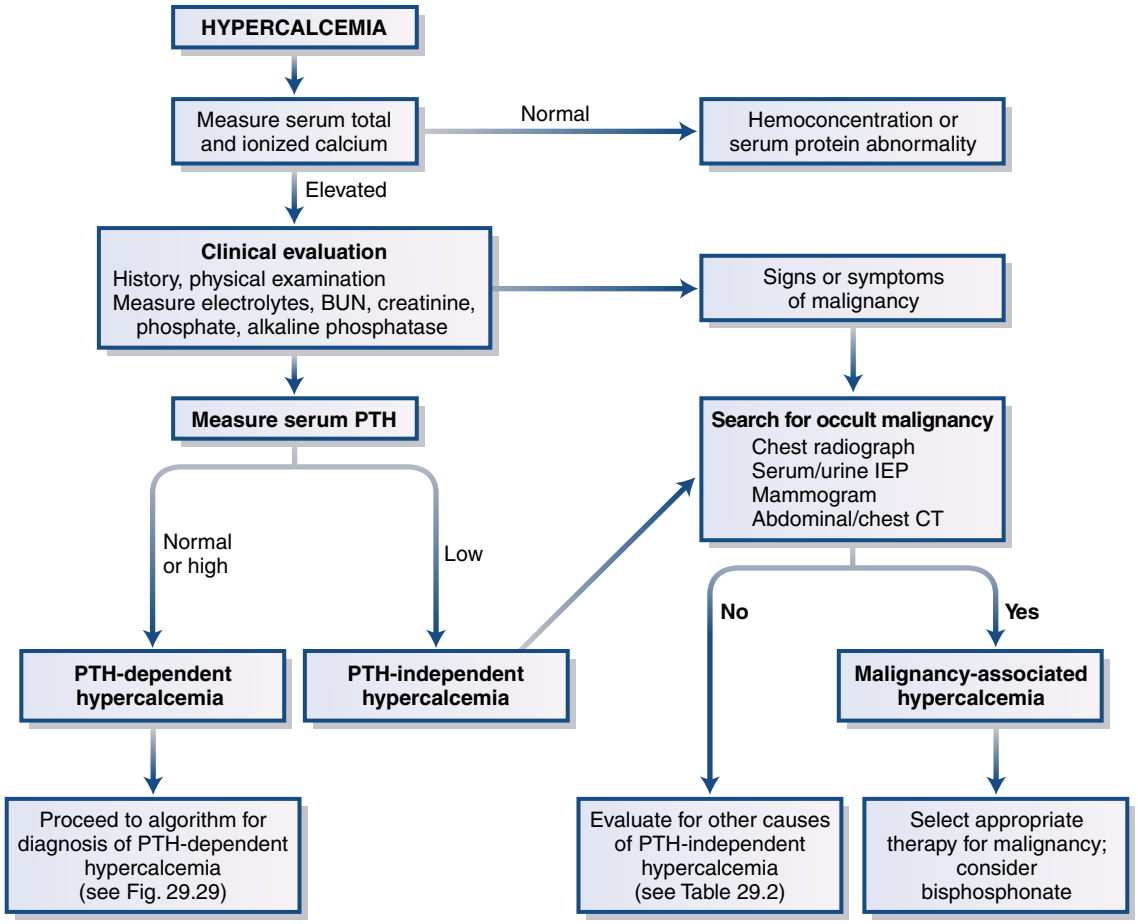
A careful history and physical examination, combined with efforts to assess chronicity by seeking prior results of routine multichannel serum chemistry determinations, most often will point to the likely diagnosis. Serum phosphate often is low in hyperparathyroidism, but as this often is true also of PTHrP-secreting malignancies, the presence of hypophosphatemia is not helpful in distinguishing these possibilities. When serum phosphate is normal or high despite correction of dehydration, the possibility of PTH-independent or PTHrP-independent hypercalcemia should be considered more strongly, however. Elevations in serum chloride and alkaline phosphatase, often observed in primary hyperparathyroidism, cannot be reliably used in the differential diagnosis of hypercalcemia. Important elements of the medical history of hypercalcemic patients include inquiries about kidney stones or fractures; weight loss; back or bone pain; fatigue or weakness; cough or dyspnea; ulcer disease or pancreatitis; ingestion of vitamins, calcium preparations, lithium, or thiazides; dates of most recent mammograms and chest radiographs; and a family history of hypercalcemia, kidney stones, ulcer disease, endocrinopathy, or tumors of the head or neck. Because malignancy is a common cause of hypercalcemia and may occur concomitantly with primary hyperparathyroidism, clinical findings strongly suggestive of malignancy should be acted upon by proceeding directly to a search for an underlying tumor, regardless of serum PTH.

The single most important test in the differential diagnosis of hypercalcemia is the measurement of serum PTH, preferably in a two-site assay specific for the intact, biologically active molecule (see Fig. 29.19). New PTH assays have been introduced that ignore long circulating fragments of the hormone, which lack the amino-terminal residues required for activity at the PTH/PTHrP receptor, but whether these new assays will be more useful than standard "intact PTH" assays remains to be established.[452,453] A consistently elevated serum PTH in the presence of true hypercalcemia always is abnormal and almost always indicates the presence of primary hyperparathyroidism. The exceptions that also can be associated with elevated PTH levels are FHH, autonomous parathyroid secretion complicating secondary hyperparathyroidism (tertiary hyperparathyroidism), lithium-associated hyperparathyroidism, and, very rarely, ectopic PTH secretion by a malignant neoplasm or antagonizing autoantibodies directed against the CaSR in patients with other autoimmune disease(s)—an acquired condition that mimics FHH.[385,386]

Diagnosis of primary hyperparathyroidism is complicated, however, by the fact that some patients fail to exhibit both hypercalcemia and elevated iPTH. In up to 10% of patients with hypercalcemia and primary hyperparathyroidism, PTH levels may fall within the normal range (high normal) with current PTH assays. Such PTH levels are inappropriate in the face of hypercalcemia, however, and support the diagnosis of PTH-dependent hypercalcemia. In fact, many such patients will manifest frankly elevated serum PTH if retested, especially if dietary calcium is restricted beforehand. As noted earlier, some patients may present with serum calcium in the high-normal range (>10 mg/dL) together with an elevated or high-normal PTH. This may be discovered incidentally in an otherwise asymptomatic subject or in the course of evaluating recurrent urolithiasis or osteopenia. Those with persistently high-normal serum calcium and high-normal iPTH should be retested at intervals and, meanwhile, given a provisional diagnosis of hyperparathyroidism and evaluated accordingly.

In patients with PTH-dependent hypercalcemia (Fig. 29.29), calcium and creatinine should be measured in a 24-hour urine collection and simultaneous serum sample to measure total urinary calcium output (mg/day) and the clearance ratio of calcium (Ca)/creatinine (Creat) in urine (U) and serum (S): $U_{Ca}/S_{Ca} \times S_{Creat}/U_{Creat}$). A daily calcium excretion of less than 100 mg per day, or a clearance ratio less than 0.01, should prompt consideration of FHH, especially in patients younger than 40 years, or those with a family history of FHH, or patients whose serum iPTH levels are within the normal range. A urinary calcium excretion greater than 4 mg/kg per day or clearance ratio greater than 0.02 effectively excludes FHH. In FHH, serum phosphate is normal or slightly low, serum magnesium may be slightly high, and serum $1,25(OH)_2D_3$ is normal or low (unlike in primary hyperparathyroidism).

A definite diagnosis of FHH, as in the MEN syndromes, may be provided by confirming the presence of mutations in the relevant genes, although such studies are not invariably informative



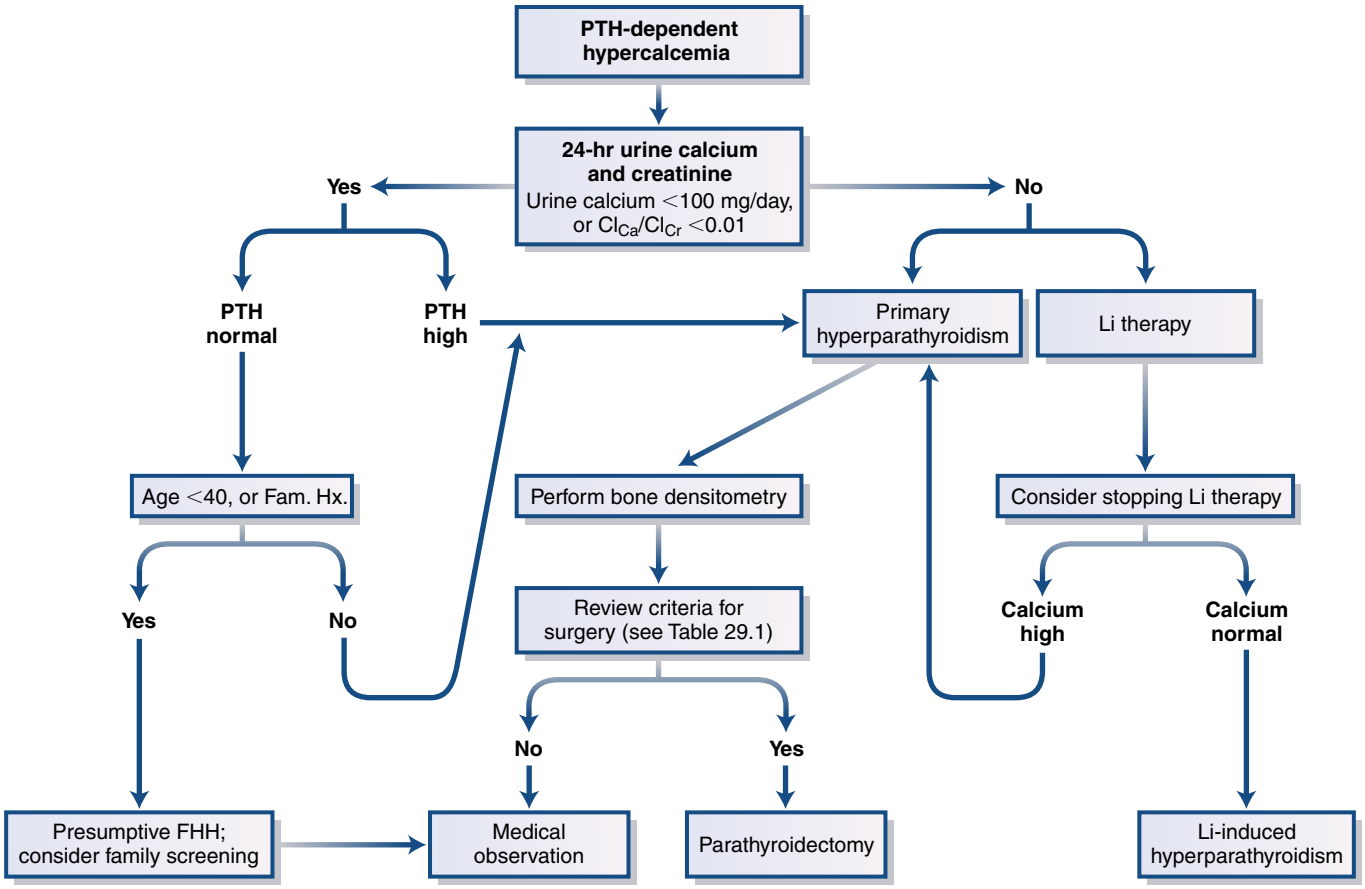
• **Fig. 29.28** Approach to the management of the hypercalcemic patient. *BUN,* blood urea nitrogen; *CT,* computed tomography; *IEP,* immunoelectrophoresis; *PTH,* parathyroid hormone.

(presumably because of mutations in introns and other unchecked regions) and usually are unnecessary. The identification of *RET* gene mutations is now an essential part of the management of families with MEN2 because this information most effectively guides the decision for preventive thyroidectomy to prevent medullary cancer of the thyroid. In contrast, the identification of *MENIN* gene mutations has not yet led to any effective preventive strategies, thus genetic analysis may be useful only for genetic counseling in families with MEN1. Even for this purpose, the incomplete ascertainment of mutations limits the effectiveness of such analysis.

In patients with suspected lithium-induced hyperparathyroidism, a trial off lithium, if feasible clinically, may confirm the diagnosis or indicate the presence of persistent primary hyperparathyroidism. Patients with primary hyperparathyroidism should undergo bone densitometry, preferably at sites rich in cortical and trabecular bone (i.e., forearm or hip and lumbar spine, respectively) to assist in the decision about surgery. Those younger than 40 years of age or having a family history of hypercalcemia (or other MEN manifestations) should be evaluated for these syndromes as well. Patients not meeting criteria for parathyroidectomy should be followed medically, as should those with FHH. In rare patients with CaSR-blocking autoantibodies, hypercalcemia may respond to glucocorticoids.[386]

A low or undetectable serum PTH level signifies the presence of nonparathyroid hypercalcemia and should prompt a detailed evaluation for malignancy or other causes of PTH-independent hypercalcemia (see Table 29.2). Breast and lung cancers alone account for over 50% of all malignancy-associated hypercalcemias. Mammography, chest radiography with or without CT, abdominal CT, and serum and urinary immunoelectrophoresis are among the more useful tests for detecting the cause of nonparathyroid hypercalcemia. Although humoral mechanisms, especially secretion of PTHrP, are implicated in the pathogenesis of most cancer-associated hypercalcemias, bone metastases are common, particularly in breast cancer. Technetium-99m bone scanning therefore generally is useful for detecting this syndrome and identifying bones vulnerable to fracture. The utility of serum PTHrP measurements probably is limited to the unusual situation in which serum PTH is suppressed but an underlying malignancy cannot readily be demonstrated. PTHrP-associated hypercalcemia can occur rarely during pregnancy and lactation, via secretion from benign neoplasms, or in association with lymphoid hyperplasia in lupus erythematosus or human immunodeficiency virus (HIV).[398]

In the absence of evident malignancy, unusual causes of hypercalcemia should be sought.[398] Vitamin D and vitamin A intoxication can be excluded by measurement of serum 25(OH)D and retinoids, respectively. Elevated $1,25(OH)_2D_3$ and hypercalcemia may occur in several settings, including sarcoidosis and other granulomatous diseases, B-cell and T-cell lymphomas (including AIDS-associated lymphomas), and uncommonly, in Crohn disease, in neonatal subcutaneous fat necrosis syndrome, or in epithelial neoplasms such as lung cancer. Very rarely, patients



• **Fig. 29.29** Approach to the management of the hypercalcemic patient with parathyroid hormone–dependent hypercalcemia. *Cl,* clearance; *Fam. Hx.,* family history; *FHH,* familial hypocalciuric hypercalcemia; *Li,* lithium; *PTH,* parathyroid hormone.

with severe idiopathic hypercalciuria and excessive absorption of dietary calcium may manifest mild, dietary-dependent hypercalcemia. Overtreatment of hypoparathyroidism or other conditions with oral $1,25(OH)_2D_3$ or topical use of analogues of the active metabolite in psoriasis should be obvious from the history. Because hypercalcemia and hypercalciuria are observed in up to 10% and 30%, respectively, of patients with thyrotoxicosis, measurement of serum thyroid-stimulating hormone (TSH) may be helpful, especially in older patients who may be less overtly symptomatic. Adrenal insufficiency and pheochromocytoma usually are accompanied by characteristic clinical features, but a definite diagnosis may be sought with appropriate studies. Granulomatous diseases are among the more common disorders that underlie initially unexplained hypercalcemia.

Causes of Severe Hypercalcemia

The need for urgent therapy of acute, severe hypercalcemia, usually defined as a serum calcium concentration greater than 14 mg/dL (>3.5 mmol/L), is unusual. This is because most patients with hypercalcemia have primary hyperparathyroidism, in which hypercalcemia is typically chronic and mild. Episodes of acute, severe hypercalcemia may occur occasionally in primary hyperparathyroidism (parathyroid crisis), usually in patients with large parathyroid adenomas and very high PTH levels. The severe hypercalcemia in this setting may be triggered by dehydration due to diarrheal illness, protracted vomiting or diuretic therapy, recovery from major surgery, immobilization, ingestion of large amounts of oral calcium salts, hemorrhage or rupture of a cystic parathyroid neoplasm, or parathyroid carcinoma.

Most often, acute, severe hypercalcemia is encountered in patients with underlying malignancy, in whom accelerated bone resorption dramatically increases the filtered load of calcium. The ensuing profound hypercalciuria impairs renal tubular sodium reabsorption, which induces progressive extracellular volume depletion, reduces GFR, impairs renal calcium clearance, and further aggravates the hypercalcemia. In many such patients, elevated circulating levels of PTHrP compound the problem by mimicking the action of PTH to enhance distal tubular calcium reabsorption.

Clinical Features of Severe Hypercalcemia

The indications for urgent therapy of hypercalcemia usually relate more to the presence of clinical symptoms of hypercalcemia than to the absolute level of serum calcium, although few clinicians would hesitate to treat patients in whom total serum calcium exceeded 14 mg/dL (>3.5 mmol/L). Many patients with previously mild hypercalcemia become symptomatic when serum calcium concentrations exceed 12 mg/dL (>3 mmol/L). It is important to remember that hypoalbuminemia may mask significant elevations of ionized calcium. The most common symptoms of severe hypercalcemia are referable to disturbances of nervous system and gastrointestinal function—fatigue, weakness, lethargy, confusion, coma (rarely), anorexia, nausea, abdominal pain (rarely

TABLE 29.3 Treatment of Severe Hypercalcemia

Type of Therapy	Usual Dose	Frequency
Rehydration	2–4 L/day of 0.9% NaCl IV	qd × 1–5 days
Furosemide	20–40 mg IV (after rehydration)	q12–24 hr
Pamidronate	60–90 mg IV over 2–4 hr	Once
Zoledronate	4 mg IV over 15–30 min	Once
Denosumab	60 mg SC	Weekly
Calcitonin	4–8 IU/kg SC	q12–24 hr
Gallium nitrate	200 mg/m^2 IV over 24 hr	qd × 5 days
Glucocorticoids	200–300 mg hydrocortisone IV 40–60 mg prednisone PO	qd × 3–5 days qd × 3–5 days
Dialysis		

IV, Intravenous; *PO,* orally; *q,* every; *qd,* every day; *SC,* subcutaneous.

due to pancreatitis), and constipation. Polyuria, nocturia, and polydipsia commonly are present also.

Bone pain is often present but is usually due to underlying metastatic disease. Cardiac arrhythmias may occur, particularly bradyarrhythmias or heart block; digitalis toxicity may be potentiated; and ST-segment elevation responsive to treatment of the hypercalcemia may be seen. Patients who suffer a fatal outcome from acute severe hypercalcemia may manifest coma, hypotension, acute pancreatitis, acute renal failure, widespread soft tissue calcification, heart failure, or venous thrombosis, particularly of the renal veins.

Management of Severe Hypercalcemia

The first decision to be made in the management of acute, severe hypercalcemia is whether or not to treat the problem at all. This may become an issue for the patient with an untreatable, widely disseminated malignancy, when all other approaches to controlling the neoplasm have been exhausted, and the patient has chosen not to have complications treated. Otherwise, as noted earlier, patients who are symptomatic or have serum calcium levels above 14 mg/dL ordinarily should be treated aggressively. Treatment most often entails rehydration and administration of a bisphosphonate intravenously (Table 29.3). Calcitonin can be useful as a temporary measure early in therapy, and glucocorticoids or dialysis may be indicated in some patients.[125]

Volume Repletion

When treatment is indicated, the first priority is to correct the extracellular volume depletion that almost invariably is present, usually by infusing isotonic saline at a rate of 2 to 4 L/day. The aggressiveness with which the individual patient is rehydrated must be considered in relation to both the patient's volume status and the risk of precipitating or aggravating congestive heart failure or ascites. Diuretics, particularly thiazides, should be discontinued. The use of furosemide or other potent "loop" diuretics to promote calciuresis may exacerbate extracellular volume depletion if used too early in the course of treatment. In light of the availability of highly effective alternatives for the therapy of hypercalcemia, such drugs probably are best avoided, except in circumstances in which vigorous rehydration fails to improve severe hypercalcemia or might precipitate congestive heart failure. In any case, prolonged use of saline-induced calciuresis without the early introduction of an effective antiresorptive agent is ill advised and ultimately futile.

Bisphosphonates

Intravenous bisphosphonates rapidly inhibit bone resorption and currently are the agents of first choice in managing severe hypercalcemia that is known or suspected to be driven mainly by osteoclastic bone resorption.[125] Bisphosphonates should not be used in patients with milk-alkali syndrome, for example, in whom they are likely to induce posttreatment hypocalcemia.[454] Pamidronate and zoledronate are approved by the Food and Drug Administration (FDA) for treatment of hypercalcemia of malignancy and are the most widely used agents in the United States, although ibandronate and clodronate have been successfully used elsewhere. These drugs generally are well tolerated, although local pain or swelling at the infusion site, low-grade fever 1 to 2 days after the infusion, transient lymphopenia, and mild hypophosphatemia or hypomagnesemia may occur. Serum calcium usually declines within 24 hours and reaches a nadir within 1 week following a single infusion, at which point calcium levels may be normal in 70% to 90% of treated patients. Intravenous bisphosphonates may be nephrotoxic, but clinical data to guide their use in patients with renal insufficiency are not yet available. Most clinicians will use the standard dose (see Table 29.3)—perhaps at half or less of the usual rate of administration—in patients with moderate renal insufficiency (GFR >30 mL/minute), which is common in the setting of severe hypercalcemia. In patients with more severe renal insufficiency, bisphosphonates probably are best avoided and dialysis may be a more appropriate alternative (see later). The duration of the response to intravenous bisphosphonate treatment is quite variable, ranging from 1 or 2 weeks to several months. Depending on clinical circumstances, repeated courses of therapy may be indicated and effective.

Denosumab

Denosumab, a monoclonal antibody directed against RANKL, has been shown to be effective in managing malignancy-associated hypercalcemia, including patients refractory to bisphosphonates.[455] Denosumab offers an alternative to intravenous bisphosphonates in patients with renal failure, but like bisphosphonates, denosumab carries a small risk of osteonecrosis of the jaw. Typical dosage is 60 mg given subcutaneously every week for a month, followed by 60 mg per month.

Calcitonin

Calcitonin, which directly inhibits osteoclast function, may be used with other antiresorptive agents to achieve more rapid control of severe hypercalcemia. Calcitonin rarely produces a decline in serum calcium of more than 1 to 2 mg/dL, and its efficacy typically is limited to a few days at most, possibly because of receptor downregulation in target cells of bone and kidney. Its major advantages are a more rapid onset of action than bisphosphonates (several hours) and its potential to augment renal calcium excretion directly. Calcitonin generally is well tolerated, although transient nausea, vomiting, abdominal cramps, flushing, and local skin reactions may occur.

Other Approaches to Treatment of Severe Hypercalcemia

Because of their potential toxicity, other antiresorptives such as gallium nitrate, plicamycin (mithramycin), and intravenous

phosphate (in patients with severe hypophosphatemia) have largely been abandoned in the treatment of severe hypercalcemia, although a randomized trial demonstrated that gallium nitrate may be more effective than bisphosphonate in controlling hypercalcemia of malignancy.[456] Oral or enteral phosphate repletion is appropriate for patients with significant hypophosphatemia (<2.5 mg/dL), provided that serum phosphate and renal function are closely monitored. Intravenous or oral glucocorticoids should be considered early in patients with suspected vitamin D–dependent hypercalcemia, including those with lymphoma or granulomatous disease. The response to glucocorticoids may be more delayed than that to bisphosphonates. Successful treatment of hypercalcemia in Crohn disease with infliximab has been reported.[457]

In patients with severe renal insufficiency, with or without complicating heart disease, in whom saline rehydration and associated calciuresis may not be feasible and bisphosphonates probably are best avoided, dialytic therapy against a low-calcium or zero-calcium dialysate may be the most appropriate tactic. In patients with known primary hyperparathyroidism and intercurrent severe hypercalcemia (parathyroid storm), urgent parathyroidectomy (following initial medical stabilization) should be considered.

Novel approaches to the treatment of severe hypercalcemia currently are in development. One available therapy for parathyroid carcinoma is the calcimimetic cinacalcet, which may be effective in some patients,[458] and monoclonal antibodies directed against PTHrP could prove useful in controlling PTHrP-dependent hypercalcemia.[459]

Hypocalcemic Disorders

Clinical Presentation

The predominant clinical symptoms and signs of hypocalcemia are those of neuromuscular irritability, including perioral paresthesias, tingling of the fingers and toes, and spontaneous or latent tetany. Tetany can be elicited by percussion of the facial nerve below the zygoma, resulting in ipsilateral contractions of the facial muscle (Chvostek sign) or by 3 minutes of occlusive pressure with a blood pressure cuff resulting in carpal spasm, which, on occasion, can be very painful (Trousseau sign) (Fig. 29.30). The usefulness of these signs in diagnosing hypocalcemia and in following therapeutic responses cannot be overemphasized.

Electrocardiographic abnormalities also result from hypocalcemia, including prolonged QT intervals and marked QRS complex and ST-segment changes that may mimic acute myocardial infarction or conduction abnormalities. Ventricular arrhythmias are a rare complication of hypocalcemia, although congestive heart failure, corrected by normalization of serum calcium, has been reported. In profound hypocalcemia or during acute falls in serum calcium, grand mal seizures or laryngospasm also may be observed. Chronic hypocalcemia is associated with milder symptoms and signs of neuromuscular irritability and may even be asymptomatic. Longstanding hypocalcemia associated with hyperphosphatemia (observed with PTH deficiency or resistance) may lead to calcification of the basal ganglia[460–463] and occasionally, extrapyramidal disorders. In addition, mineral ion deposits in the lens may lead to cataract formation. Chronic hypocalcemia, when associated with hypophosphatemia, as in vitamin D deficiency, is associated with growth plate abnormalities in children (rickets) and defects in the mineralization of new bone (osteomalacia) (see Chapter 31). These findings are not seen in the hypocalcemia of hypoparathyroidism. Severe symptomatic hypocalcemia is an emergency that requires immediate attention to prevent seizures and death from laryngospasm or cardiac causes.

• **Fig. 29.30** Trousseau sign. (From Burnside JW, McGlynn TJ. *Physical Diagnosis*. 17th ed. Baltimore: Williams & Wilkins; 1987:63.)

Total calcium in serum includes both the free (biologically active) and protein-bound components; the major binding protein is albumin (discussed earlier). Therefore measurements of total calcium cannot be interpreted without concurrent measurement of albumin. Studies of hypoalbuminemic patients with cirrhosis have led to a formula for correction of total calcium based on concurrent albumin levels (a decrease in calcium of 0.8 mg/dL for every 1-g/dL decrease in albumin). No formula has proved to be accurate, however, for assessment of calcium in acutely ill patients. This probably relates to the variety of factors that may increase protein binding and decrease the fraction of total calcium present as the free ion, including alkalosis, elevated circulating free fatty acids, and lipid infusions. Consequently, ionized calcium should be measured when the diagnosis of hypocalcemia is considered in the setting of acute illness and severe hypoalbuminemia.

Chronic hypocalcemia is most often due to deficiency of PTH or $1,25(OH)_2D_3$ or to resistance to the biologic effects of these calcium-regulating hormones (Table 29.4).

Parathyroid-Related Disorders

Hypocalcemia associated with parathyroid dysfunction can be differentiated from other causes of hypocalcemia by routine laboratory tests. Serum calcium is low owing to lack of PTH-mediated bone resorption and urinary calcium reabsorption. Serum phosphate is increased owing to impaired renal clearance. Serum $1,25(OH)_2D_3$ is low because PTH and hypophosphatemia stimulate the renal 25(OH)D 1α-hydroxylase. Consequently, $1,25(OH)_2D_3$-mediated intestinal calcium absorption is markedly decreased, further exacerbating the hypocalcemia. PTH levels measured using sensitive two-site PTH assays (see Fig. 29.20) are usually low or undetectable but may be inappropriately normal if some degree of PTH production is preserved. Elevated levels of PTH are found in syndromes associated with resistance to the biologic effects of PTH.

Congenital or Inherited Parathyroid Disorders

Several rare syndromes associated with congenital or inherited hypoparathyroidism appear sporadically or in a variety of

TABLE 29.4 Causes of Hypocalcemia

Parathyroid-Related Disorders

Absence of the Parathyroid Glands or of PTH

Congenital
- DiGeorge syndrome
- X-linked or autosomally inherited hypoparathyroidism
- Autoimmune polyglandular syndrome type I
- PTH gene mutations

Postsurgical hypoparathyroidism
Infiltrative disorders
- Hemochromatosis
- Wilson disease
- Metastases

Hypoparathyroidism post radioactive iodine thyroid ablation

Impaired Secretion of PTH

Hypomagnesemia
Respiratory alkalosis
Activating mutations of the calcium sensor or *GNA11*

Target Organ Resistance

Hypomagnesemia
Pseudohypoparathyroidism
- Type I
- Type II

Vitamin D-Related Disorders

Vitamin D deficiency
- Dietary absence
- Malabsorption

Accelerated loss
- Impaired enterohepatic recirculation
- Anticonvulsant medications
- CYP3A4 mutation

Impaired 25 hydroxylation
- Liver disease
- Isoniazid
- *CYP2R1* mutation

Impaired 1α-hydroxylation
- Renal failure

Vitamin D–dependent rickets, type I
Oncogenic osteomalacia
Target organ resistance
- Vitamin D–dependent rickets, type II
- Phenytoin

Other Causes

Excessive deposition into the skeleton
- Osteoblastic malignancies
- Hungry bone syndrome

Impaired bone resorption
- Vitamin D deficiency
- Bisphosphonates
- RANKL inhibition

Chelation
- Foscarnet
- Phosphate infusion
- Infusion of citrated blood products
- Infusion of EDTA containing contrast reagents
- Fluoride

Neonatal hypocalcemia
- Prematurity
- Asphyxia
- Diabetic mother
- Hyperparathyroid mother
- Vitamin D–deficient mother
- Infantile malignant osteopetrosis

HIV
- Drug therapy
- Vitamin D deficiency
- Hypomagnesemia
- Impaired PTH responsiveness

Critical illness
- Pancreatitis
- Toxic shock syndrome
- Intensive care unit patients

inheritance patterns, suggesting multiple causes. Mutation of a parathyroid-specific transcription factor, glial cells missing homolog B (GCMB) (chromosome 6p23), which is expressed in the PTH-secreting cells of the developing parathyroids, has been shown to be a cause of familial hypoparathyroidism in humans and mice.[44] The genetic abnormality responsible for X-linked, recessive hypoparathyroidism has been identified as a deletion/insertion of DNA near the *SOX3* gene at Xq26-Xq27.[47] Analyses of a second kindred implicated mutations in the *FHL1* (four and a half LIM domains 1) gene as the molecular basis for the phenotype.[464]

In a number of diseases, hypoparathyroidism is associated with multiple abnormalities in embryonic development in the neck/chest region. DiGeorge syndrome occurs sporadically and is associated with an embryologic defect in the formation of the third, fourth, and fifth branchial pouches, resulting in the absence of parathyroid glands. DiGeorge syndrome may in fact be a neurocrestopathy, since ablation of the premigratory cephalic neural crest in chick embryos produces the same phenotype.[465] The contribution of homeobox genes to parathyroid development and their potential relationship to DiGeorge syndrome also has been demonstrated by the absence of thymic and parathyroid tissue, accompanied by cardiac and craniofacial abnormalities, in mice lacking the homeobox gene *hoxa3*.[466] DiGeorge syndrome is often associated with other congenital abnormalities in a syndrome referred to by the acronym CATCH 22 (*c*ardiac defect, *a*bnormal facies, *t*hymic hypoplasia, *c*left palate, *h*ypocalcemia, and *22*q11 deletions).[467] Microdeletion of 22q11.21–q11.23 and a t(2;22)(q14;q11) balanced translocation suggest that a gene at chromosome 22q11 may be pathogenetic in this syndrome. Recent studies identified the *TBX1* gene as being the locus affected since point mutations in this gene result in DiGeorge syndrome.[463] A number of cases of DiGeorge and velocardiofacial syndromes have been shown to have no detectable abnormality at 22q11, but rather terminal 10p deletions or interstitial 10p13/10p14 deletions, suggesting that two loci may be critical for development of branchial pouch structures. Terminal deletions of 10p accompanied by hypoparathyroidism can be further subdivided into DiGeorge critical region II (10p13-14) and a more telomeric region (10p14-10pter), wherein mutation of the transcription factor GATA3 causes the syndrome of hypoparathyroidism, sensorineural deafness, and renal anomaly (HDR).[468] Studies in murine models have demonstrated that GATA3 regulates the expression of GCM2 (the murine homolog of GCMB) and is essential for the

development of parathyroid glands.[469] The genetic basis for Kenny-Caffey syndrome type 1, characterized by hypoparathyroidism, extreme short stature, mental retardation, and dysmorphism, is mutations in the chaperone protein, TBCE, which is required for the proper folding of α tubulin and the formation of α-β tubulin heterodimers.[470] In contrast, autosomal dominant Kenny-Caffey syndrome type 2, characterized by short stature, hypoparathyroidism, and osteocraniostenosis, is caused by mutations in *FAM111A,* a gene of unknown function with protease motifs.[461]

Familial hypoparathyroidism is seen in conjunction with mucocutaneous candidiasis, Addison disease, and other immune disorders in autosomal recessive autoimmune polyglandular syndrome, type I, caused by mutations in the autoimmune regulatory gene (*AIRE*)[471,472] (see Chapter 43). NALP5 has been identified as a parathyroid-specific antigen in affected patients.[473] Hypoparathyroidism may also be observed in association with mitochondrial myopathies such as mitochondrial trifunctional protein deficiency[474] and the Kearns-Sayre syndrome.[475] Other inherited forms of hypoparathyroidism may be observed as an isolated defect or may present with other features such as lymphedema, dysmorphism, and renal and cardiac abnormalities.

Abnormalities in the PTH Gene

Specific defects have been found in the PTH gene in a small number of kindreds affected by congenital hypoparathyroidism. These include point mutations in the signal peptide[4,5] and in an intron border, leading to aberrant splicing[476] as well as a homozygous mutation in exon 2 of the PTH gene, leading to premature termination of the transcript.[477] A homozygous mutation in amino acid 25 of PTH(1-84) has also been described in familial hypoparathyroidism.[478]

Destruction of the Parathyroid Glands

The most common cause of chronic hypocalcemia is postsurgical hypoparathyroidism. This may occur after removal of all parathyroid tissue during thyroidectomy and radical neck dissection for malignancies or after inadvertent interruption of the blood supply to the parathyroid glands during head and neck surgery. Transient hypoparathyroidism, attributed to reversible damage to the remaining normal glands, is common after parathyroidectomy; permanent hypoparathyroidism may occur after vascular or surgical injury or inadvertent removal of all parathyroid tissue. Rarely, transient hypoparathyroidism may follow spontaneous infarction of autonomous tissue in primary hyperparathyroidism.[479] Hypoparathyroidism is a rare complication of radioactive iodine ablation of the thyroid gland for Graves disease.[480]

Hypoparathyroidism also can occur as a result of infiltrative diseases of the parathyroids. This is seen in diseases of iron overload such as hemochromatosis and in patients with thalassemia major who have been heavily transfused.[481] Copper deposition in Wilson disease[482] may also cause parathyroid dysfunction. Metastatic disease to the parathyroids can cause hypoparathyroidism, but rarely, presumably because of the need for four-gland involvement before significant hypoparathyroidism is observed.

Impaired PTH Secretion

Impaired secretion of PTH from the parathyroid glands can lead to functional hypoparathyroidism. This is commonly seen in profound hypomagnesemia,[483] in which target organ resistance to PTH can also occur. Both of these abnormalities are reversible upon magnesium repletion[484,485] (see "Disorders of Magnesium Metabolism").

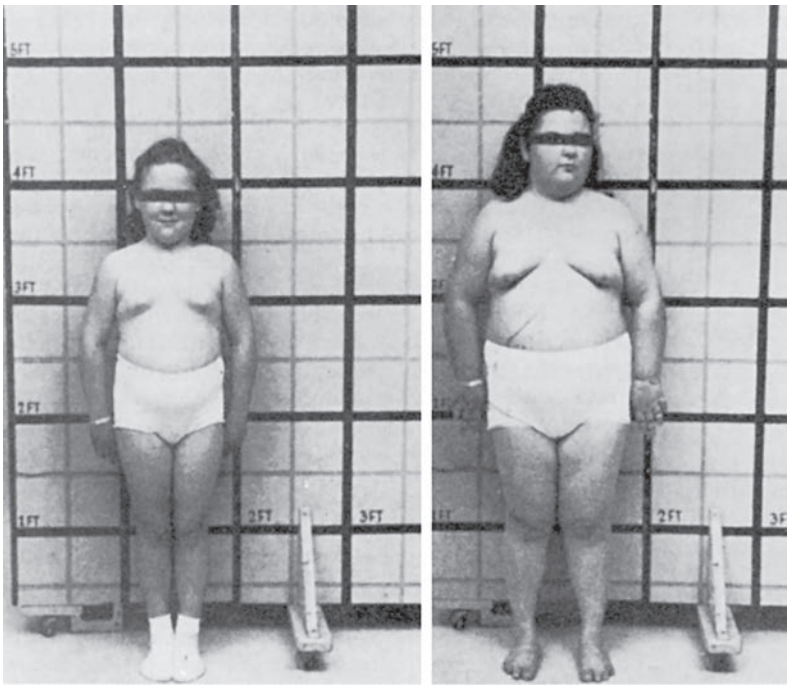
Chronic respiratory alkalosis leads to hyperphosphatemia and decreased ionized calcium levels accompanied by impaired renal calcium resorption and inappropriately normal PTH levels.[486] This biochemical phenotype suggests both an abnormality of PTH secretion and renal resistance to PTH. Acute alkalosis in dogs also suppresses PTH secretion.[487]

Activating mutations in the CaSR cause autosomal dominant hypocalcemia type 1 (ADH1) associated with inappropriately normal PTH levels. This syndrome can also be seen in patients with activating antibodies directed against this receptor.[488] ADH2 has been shown to be caused by gain-of-function mutations of the G protein subunit α11 (*GNA11*).[381] The clinical syndrome is variable; patients present with hypocalcemia and seizures, whereas their affected relatives may be only subsequently diagnosed with asymptomatic hypocalcemia.[14] Unlike patients with inactivating mutations of the calcium sensor, homozygously affected individuals with ADH1 do not appear to have a more severe phenotype. The presence of hypercalciuria in these patients makes medical management uniquely challenging. Treatment with vitamin D metabolites often results in a marked increase in renal calcium excretion, associated with renal calcification and resultant renal impairment. Based on these observations, it has been suggested that asymptomatic individuals be left untreated and that the goal of therapy in individuals with symptomatic hypocalcemia be solely to relieve symptoms, not to achieve normocalcemia. Treatment with calcium and vitamin D metabolites should be accompanied by the use of thiazide diuretics to decrease urinary calcium excretion as well as ensuring adequate urinary volume to decrease urinary calcium concentration.

Pseudohypoparathyroidism

The idiopathic and inherited forms of PTH resistance are referred to as pseudohypoparathyroidism (PHP). There are two main types of PHP: type I, which is characterized by impaired cAMP and phosphaturic responses to PTH, and type II, where the cAMP response is preserved but the phosphaturic response is not. The first cases of documented PTH resistance were described by Albright in 1942. The patients were hypocalcemic, hyperphosphatemic, and exhibited a number of features now called Albright hereditary osteodystrophy (AHO). These features include short stature, rounded face, foreshortened fourth and other metacarpals, obesity, and subcutaneous ossifications (Figs. 29.31 and 29.32). PTH administration to these patients failed to provoke a phosphate diuresis or an increase in serum calcium. It was subsequently demonstrated that hypocalcemic patients with features of AHO had elevated PTH levels and that PTH infusions failed to stimulate renal production of cAMP. Failure of stimulation of cAMP production suggested a defect in the PTH receptor or in its cAMP-mediated signal transduction. The measurement of cAMP in the urine following an infusion of synthetic PTH(1-34) can be used to establish the diagnosis of PTH resistance.[489]

The variable presence of AHO and renal resistance to PTH has led to the subclassification of pseudohypoparathyroidism (Table 29.5). Type IA is characterized by AHO and diminished $G\alpha_s$ activity (~50% of normal). The diminished $G\alpha_s$ activity has been demonstrated in several tissues, including kidney, fibroblasts, transformed lymphocytes, platelets, and erythrocytes. Decreased amounts of $G\alpha_s$ mRNA (50%) are present in fibroblasts of many patients with PHP1A, and inactivating mutations involving exons 1 to 13 of *GNAS*, the gene encoding $G\alpha_s$, have been identified in numerous kindreds and individual patients. Epigenetic changes like those seen in PHP1B (to come) play an etiologic role in a subset of patients with PHP1A.[490] Mutations in *PRKAR1A, PDE3A,* and *PDE4D* have also been found in subjects with acrodysostosis and clinical findings similar to those in patients with AHO without GNAS abnormalities; however, most of these patients have no or only mild PTH resistance.[491]



• **Fig. 29.31** Daughter *(left)* and mother *(right)* with pseudohypoparathyroidism and Albright hereditary osteodystrophy.

Impaired cognition is seen in approximately half of the patients with PHP1A and appears to be related to the $G\alpha_s$ deficiency rather than to chronic hypocalcemia, since patients with other forms of hypocalcemia do not have cognitive impairment. The $G\alpha_s$ deficiency in PHP1A may be associated not only with PTH resistance but also with resistance to other hormones such as TSH, glucagon, and gonadotropins, resulting in thyroidal and gonadal dysfunction. Paradoxically, two unrelated males with both PHP1A and gonadotropin-independent precocious puberty have been described. The $G\alpha_s$ point mutation found in these individuals is thought to lead to a protein that is unstable at 37°C and therefore confers renal resistance to PTH. At the lower temperature of the testes, however, the protein is not degraded. In this setting, the stable but mutated protein is constitutively active and stimulates the Leydig cell in a manner similar to the skeletal effects of the G_s mutations in McCune-Albright syndrome (see Chapter 26).[492]

Individuals with PHP1A also exhibit a decrease in resting energy expenditure[493] and a decrease in insulin sensitivity,[494] which may contribute to the development of diabetes.

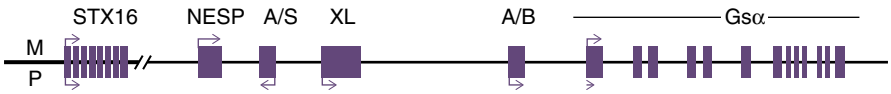
Pseudo-pseudohypoparathyroidism (pseudo-PHP) is a term used to refer to individuals with the phenotype of AHO but with normal biochemical parameters. Patients with pseudo-PHP often are found in the same kindreds as those with PHP1A, but never in the same sibship, and they invariably inherit the same *GNAS* mutations involving the $G\alpha_s$-encoding exons found in their PTH-resistant relatives.[495] When patients inherit the *GNAS* mutation from their father, they exhibit pseudo-pseudohypoparathyroidism; when they inherit the mutant allele from their mother, they exhibit PHP1A.[496,497] This pattern, in which the phenotype depends on the parent of origin, is termed *genetic imprinting*; mice with targeted ablation of *Gnas* also display such imprinting.[498] In addition to the AHO phenotype, inheritance of paternal mutations involving *GNAS* exons 1 to 13 leads to severe intrauterine growth retardation suggesting a role for an mRNA transcribed from the paternal GNAS locus in fetal growth and development.[499]

• **Fig. 29.32** Radiograph of the hand from a patient with pseudohypoparathyroidism and Albright hereditary osteodystrophy. Note the shortened fourth metacarpal.

TABLE 29.5 Types of Pseudohypoparathyroidism

Disorder	Urinary cAMP Response to PTH	Urinary PO_4 Response to PTH	Other Hormonal Resistance	AHO	Pathophysiology
Pseudohypoparathyroidism IA	Decreased	Decreased	Yes	Yes	$G\alpha_s$ mutation or imprinting abnormality
Pseudo-pseudohypoparathyroidism	Normal	Normal	No	Yes	$G\alpha_s$ mutation
Pseudohypoparathyroidism IB	Decreased	Decreased	Rare	No	GNAS1 locus imprinting abnormality
Pseudohypoparathyroidism IC	Decreased	Decreased	Yes	Yes	$G\alpha_s$ function normal, imprinting abnormality
Pseudohypoparathyroidism II	Normal	Decreased	No	Rare	Vitamin D deficiency or myotonic dystrophy

AHO, Albright hereditary osteodystrophy; *cAMP*, cyclic adenosine monophosphate; *GαS*, G protein alpha subunit S; *GNAS1*, guanine nucleotide-binding protein, alpha-stimulating activity polypeptide 1; *PO_4*, phosphate; *PTH*, parathyroid hormone.



• **Fig. 29.33** The GNAS locus. A schematic representation of the GNAS locus is shown, with the *black boxes* indicating exons for STX16, NESP55 *(NESP),* the antisense *(A/S)* NESP55 transcript, $XL\alpha_s$ *(XL),* A/B and $G\alpha_s$ *(Gsα).* The start site of and direction (sense vs antisense) of transcription is indicated by the *arrows*. Genes that are maternally transcribed (M) are indicated by *arrows* above the relevant genes, whereas those that are paternally transcribed (P) are indicated below. The expression of $XL\alpha_s$, A/B, and A/S is from the paternal allele, whereas the maternal NESP55 transcript is expressed. Deletions from exon 4 to 6 or, less commonly, from exon 2 to 4, along with associated introns, in the region containing the STX16 gene are associated with imprinting abnormalities in GNAS. The *arrowhead* below the Gsα locus indicates that only the maternal allele is expressed in the renal tubules.

The observation of a phenotype in a heterozygous loss of function mutation affecting $G\alpha_s$ is in contrast to the findings in mice with targeted deletions of the other Gα genes ($G\alpha_{i2}$, $G\alpha_o$, $G\alpha_q$, $G\alpha_{11}$, $G\alpha_{13}$), in which a phenotype is observed only in the homozygous state.[500] The fact that the *GNAS* gene is imprinted in certain tissues has partly resolved the dilemma of this dominant phenotype. Notably, mice with targeted ablation of one *GNAS* exon 1 fail to express $G\alpha_s$ mRNA in the renal cortex when the mutant gene is inherited from the mother but have normal expression in the cortex when the mutant gene is inherited from the father. No such imprinting pattern is seen in the inner medulla; this correlates with the mice (and patients) exhibiting PTH, but not vasopressin, resistance.[498]

Pseudohypoparathyroidism type IB (PHP1B) presents with hypocalcemia, high PTH levels, and failure of PTH infusions to increase urinary cAMP production. However, in most patients it is neither accompanied by any of the clinical features of AHO nor associated with abnormal $G\alpha_s$ levels in fibroblasts. Although mild TSH resistance is frequent,[501–503] renal resistance to PTH is the most prominent feature of PHP1B; therefore several investigators had postulated that this syndrome was due to an isolated abnormality of the PTH receptor. However, a search for mutations in the coding exons of the receptor gene failed to reveal a functional receptor abnormality in those affected.[449] Subsequently, a family with a homozygous mutation in the PTH receptor coding sequence was identified, with some manifestations of PTH resistance and cognitive difficulties, but without functional testing of the mutant receptor.[504] Further studies are needed to clarify the role of the receptor mutation in this family's presentation. The target organ manifestations of PHP1B are variable, with some affected individuals having manifestations of PTH overactivity in bone and PTH resistance in the proximal tubule of the kidney. Cultured osteoblast-like cells from a patient with this disorder demonstrated normal cAMP responsiveness to PTH, despite the lack of renal responsiveness.[505]

The locus responsible for the familial, autosomal dominant forms of PHP1B resides on chromosome 20q13.3,[506] the same region that contains the *GNAS* gene encoding $G\alpha_s$. The methylation defect found most consistently in these PHP1B patients is a loss of methylation at exon A/B, which leads to decreased $G\alpha_s$ expression in the proximal renal tubule leading to the hormone resistance observed.[507] While the familial forms (15–20%) exhibit autosomal dominant inheritance,[508,509] the disease is otherwise inherited with the imprinting characteristic of PHP1A. Autosomal dominant PHP1B is caused in most cases by heterozygous maternal deletions within STX16 or GNAS, which are associated with loss-of-methylation (LOM) at exon A/B either alone or loss of methylation at three maternal GNAS promoters, respectively. The disease-causing mutations for the sporadic form of PHP1B remains unknown (except for a few cases with paternal uniparental disomy of 20q[501]), but it is the most frequent form of the disease and is also characterized by imprinting abnormalities of the *GNAS* locus.[502,507,510] The *GNAS* locus gives rise to multiple transcripts (Fig. 29.33), including $G\alpha_s$, which is biallelically expressed in most tissues, but only the maternal transcript is expressed in the renal proximal tubules, thyroid, gonads, pituitary, and possibly a few other tissues. In contrast, the XLαs, A/B, and antisense (A/S) transcripts are paternally expressed, whereas the NESP55 transcript is maternally expressed. Linkage analyses in multiple kindreds had pointed to deletion of a 3-kb region, approximately

220 kb centromeric of *GNAS*, in most families, in addition to an overlapping deletion in another family.[511,512] These deletions remove several *STX16* exons, which encode syntaxin-16, a protein that plays a role in intracellular trafficking, as well as associated introns. Although the development of PHP1B correlates with maternal inheritance of this gene defect and loss of methylation at the distant *GNAS* exon A/B, *STX16* itself is not imprinted.[512] Other deletions in this region, including that of DNA encoding NESP55, a chromogranin-like neurosecretory peptide, and of two noncoding *GNAS* antisense exons have also been found in autosomal dominant PHP1B.[512–514] Maternal inheritance of these deletions causes abnormal imprinting in this locus.

While most sporadic cases of PHP1B are not associated with *STX16* or NESP55/AS deletions, they are uniformly associated with impaired methylation of *GNAS* exon A/B. In addition to the methylation defects in the A/B region, gain of methylation at NESP55 and loss of methylation of XL and of the promoter of the A/S transcript are found. Some sporadic PHP1B cases share the same maternal *GNAS* haplotype with an unaffected sibling and an unaffected daughter, thus excluding the *GNAS* region as the disease-causing locus.[515] It is likely that an additional genetic locus underlies the methylation abnormalities in both sporadic and some familial PHP1B cases. Whether a common locus will be identified as the genetic basis for the majority of these PHP1B cases remains to be determined.

Several patients with AHO and PTH resistance have been found to have normal $G\alpha_s$ activity; this subgroup has been designated *PHP1C*. However, these patients have mutations involving the carboxy-terminal region of $G\alpha_s$ that lead to normal levels of $G\alpha_s$ activity when assayed in erythrocytes but defective activation by receptors.[516] Additional analyses of methylation patterns of A/B, XL, A/S, and NESP55 in 26 patients with normal $G\alpha_s$ activity demonstrated abnormal methylation patterns in at least one of these differentially methylated *GNAS* regions in six individuals, raising the possibility that these individuals represent sporadic PHP1B cases.[517]

In PHP2, PTH infusions increase urinary cAMP normally; however, PTH does not elicit a phosphaturic response.[518] This syndrome, like PHP1B, lacks signs of AHO, and no familial cases have been described. The age of onset of patients with this disorder is variable, ranging from infancy to senescence, suggesting that it is an acquired defect or that the biochemical phenotype may be unmasked by intercurrent abnormalities. A subset of patients with myotonic dystrophy display the biochemical features of PHP2, the degree of PTH resistance correlating with the degree of expansion of the pathogenic CTG repeats in the myotonin protein kinase gene. A similar biochemical phenotype can also be observed in vitamin D deficiency.[519] Minagawa and colleagues reported cases of three neonates with no signs of rickets and with normal levels of vitamin D who presented with transient PHP2 that resolved at about 6 months of age.[520] They postulated that PTH responsiveness is subject to maturation during fetal and neonatal development. Several unrelated patients with acrodysostosis, displaying a skeletal phenotype similar to AHO and a biochemical phenotype consistent with PHP2, were found to have heterozygous mutations in *PRKAR1A,* the gene encoding the regulatory subunit of PKA. Mutation in this gene impairs the protein kinase A response to cAMP stimulation, consistent with the normal urinary cAMP response to PTH observed in PHP2.[521] PHP2 therefore seems to reflect a heterogeneous clinical disorder associated with defects in PTH responsiveness distal to cAMP or involving a separate signal transduction pathway.[522]

Unlike the proximal tubules, which show resistance to PTH in PHP1A and PHP1B, bone-forming osteoblasts isolated from patients with PHP1A and PHP1B[505] show a normal cAMP response to PTH. This suggests that the hypocalcemia in PHP is not secondary to skeletal resistance but is a consequence of the renal resistance to PTH and the associated low levels of $1,25(OH)_2D$. Thus hypocalcemia occurs in the face of relatively normal bone and renal distal (hypocalciuric) tubular responses to PTH.[523] The lack of activation of vitamin D results in diminished intestinal calcium absorption and osteomalacia, both of which further exacerbate the hypocalcemia. Deficiency of $1,25(OH)_2D$ and the resultant hypocalcemia can, in turn, impair the phosphaturic but not the urinary cAMP responses to PTH[524]; therefore it is imperative that studies to confirm the diagnosis of PHP2 be performed in normocalcemic patients who have normal vitamin D status. Recent investigations have demonstrated that, despite the presence of secondary hyperparathyroidism, region-specific bone density is not reduced in PHP1A, and total body bone mineral density is greater than normal.[525] Patients with PHP1B have been reported to have skeletal changes consistent with hyperparathyroid bone disease that resolve with treatment.[526,527] Additionally, two brothers with PHP1B due a *STX16* deletion were found to have osteosclerosis with lumbar Z-scores of +5.4 and +4.9 associated with increased cortical width, and bone formation rate on trabecular and endocortical surfaces on iliac crest biopsy.[528]

Vitamin D–Related Disorders

Hypocalcemia secondary to vitamin D deficiency or resistance to the biologic effects of $1,25(OH)_2D_3$ is easily differentiated from the hypocalcemia of hypoparathyroidism by routine clinical and laboratory evaluation. The primary cause of hypocalcemia in vitamin D deficiency is decreased intestinal absorption of calcium. In the setting of normal renal function, the hypocalcemia of vitamin D deficiency, unlike that of hypoparathyroidism, is accompanied by hypophosphatemia and increased renal phosphate clearance. This increase in phosphate clearance is a direct result of compensatory (secondary) hyperparathyroidism. The hyperparathyroidism is a consequence of the hypocalcemic stimulus to PTH secretion, as well as the stimulation of PTH gene expression and parathyroid cell proliferation caused by hypocalcemia (see "Parathyroid Hormone Biosynthesis"). Therefore measurement of serum phosphate and PTH are very useful in distinguishing these disorders from hypoparathyroidism. The secondary hyperparathyroidism results in increased calcium mobilization from the skeleton, increased renal reabsorption of calcium, and increased renal 1α-hydroxylation of 25(OH)D. In severe vitamin D deficiency, the increased levels of PTH no longer lead to increased bone resorption, perhaps because osteoclasts do not resorb unmineralized osteoid.

In profound vitamin D deficiency the level of $1,25(OH)_2D_3$ is usually low, but in moderate vitamin D deficiency the stimulation of the renal 1α-hydroxylase by PTH can result in a normal or even elevated $1,25(OH)_2D_3$ level. These high levels of $1,25(OH)_2D_3$ reflect the action of PTH on the renal 1α-hydroxylase. The ineffectiveness of the high levels of total $1,25(OH)_2D_3$ to normalize serum calcium may be explained by increased binding of this metabolite to vitamin D binding protein when the levels of 25(OH)D are very low or may be a consequence of impaired local activation of 25(OH)D.

Vitamin D Deficiency

Because the two sources of vitamin D are the diet and cutaneous synthesis after ultraviolet (UV) irradiation, lack of solar irradiation

and decreased intake or impaired absorption of vitamin D can lead to vitamin D deficiency. As the population has become increasingly educated about the risks of skin cancer from solar irradiation, the avoidance of long periods of intense sun exposure and the use of high solar protective factor (SPF) sunblocks have resulted in increased reliance on dietary sources of vitamin D. Based on the Institute of Medicine (USA) 2010 report, the recommended daily allowance for vitamin D is 600 IU from 1 to 70 years of age and 800 IU for those over 70. However, increased supplementation may be required to maintain vitamin D sufficiency during pregnancy,[529] in those with underlying medical conditions, as well as the elderly and the obese.[530,531] Genetic variants in vitamin D metabolizing enzymes, including CYP2R1 and CYP24A1, in the VDR and in vitamin D–binding protein also impact the vitamin D intake required to achieve normal levels.[532,533] Vitamin D is present in many food sources, both vegetable and animal. In addition, many prepared foods, especially cereal products, are fortified with vitamin D. Although dairy products have been fortified with vitamin D as well, the actual amount of vitamin D provided does not correlate well with the purported content.[183] The vitamin D derived from vegetable sources is vitamin D_2 and that from animal sources is vitamin D_3. These two forms of vitamin D are metabolized identically and are used to fortify foods.

The Institute of Medicine has defined vitamin D "sufficiency" as a level greater than 50 nmol/L (>20 ng/mL); however, higher levels may be required to optimize intestinal calcium absorption in those with disorders such as intestinal disease, short bowel syndrome, intestinal bypass, and obesity as well as in the elderly. Although elderly, homebound individuals are at high risk, several studies have demonstrated that vitamin D deficiency is prevalent in the general population (as reviewed in Thomas and Demay[534]). The clinical relevance of this vitamin D deficiency has been confirmed by a study demonstrating that vitamin D administration (800 IU/day) to an ambulatory elderly population decreases serum PTH levels as well as the incidence of hip fracture.[535] Similarly, a meta-analysis of randomized clinical trials performed between 2011 and 2015 supports the use of calcium and vitamin D for the prevention of fractures.[536] Malabsorption also remains an important cause of vitamin D deficiency in all age groups. Because vitamin D is a fat-soluble vitamin, its absorption is dependent upon emulsification by bile acids. Any cause of fat malabsorption or short bowel syndrome (including bypass surgery for morbid obesity) can result in vitamin D deficiency, therefore malabsorption should be ruled out in patients with low 25(OH)D levels.

Accelerated Loss or Inactivation of Vitamin D

25(OH)D and $1,25(OH)_2D_3$ are secreted with bile salts and undergo enterohepatic circulation, therefore intestinal disease may also result in vitamin D deficiency due to excessive losses. Increased metabolism of vitamin D, leading to low blood levels of 25(OH)D, is seen in individuals given anticonvulsant medications and antituberculous therapy. Phenobarbital, primidone, phenytoin,[537] rifampin, and glutethimide[538] have all been reported to accelerate the hepatic inactivation of vitamin D.

Two unrelated subjects with early-onset rickets and impaired responsiveness to vitamin D metabolites were found to have a mutation in CYP3A4. This mutation dramatically increased the ability of CYP3A4 to inactivate vitamin D metabolites.[539]

Impaired 25-Hydroxylation of Vitamin D

The vitamin D that is absorbed undergoes 25-hydroxylation in the liver, therefore severe hepatic parenchymal damage can result in 25(OH)D deficiency. Clinically, severe vitamin D deficiency as a consequence of liver disease is rare, since the degree of hepatic destruction necessary to impair 25-hydroxylation is incompatible with long-term survival. However, isoniazid has been shown to decrease the 25-hydroxylation of vitamin D.[540]

Studies in individuals with mutations in CYP2R1 have identified this gene as the principal 25-hydroxylase in humans. The clinical and biochemical presentations and therapeutic responses support an inherited 25-hydroxylation defect.

Impaired 1α-Hydroxylation of 25-Hydroxyvitamin D

The final step in the activation of vitamin D is the hydroxylation of 25(OH)D by the renal 1α-hydroxylase to yield $1,25(OH)_2D_3$. Renal parenchymal damage therefore can result in deficiency of the active metabolite of vitamin D. Impaired 1α-hydroxylation is observed once creatinine clearance decreases to approximately 30 to 40 mL per minute. Unlike with liver failure, with renal failure, dialysis permits long-term survival, therefore deficiency of $1,25(OH)_2D_3$ as a result of impaired renal 1α-hydroxylation is a common and important clinical entity. The metabolic consequences of chronic renal failure on the parathyroid glands and the skeleton are complex. Impaired renal 1α-hydroxylation leads to decreased intestinal absorption of calcium, resulting in hypocalcemia. The diminished phosphate clearance associated with renal failure leads to elevated levels of blood phosphate and consequently increases in circulating FGF23; this, in turn, further lowers levels of $1,25(OH)_2D_3$ and calcium. The resultant secondary hyperparathyroidism increases release of calcium and phosphate from bone; however, because of the renal insufficiency, PTH does not have a phosphaturic effect. As a result, serum phosphate rises further. Oral phosphate binders are used to lower blood phosphate, including calcium-containing antacids and the phosphate-binding exchange resin, sevelamer. Calcium administration also attenuates the hypocalcemic stimulus to parathyroid secretion. $1,25(OH)_2D_3$ therapy is critical for the absorption of this calcium and should be administered early in the course of renal failure (when the creatinine clearance falls below 30–40 mL/minute) to avoid the development of secondary hyperparathyroidism, with careful monitoring to avoid hypercalcemia. Once secondary hyperparathyroidism has developed, pharmacologic doses of $1,25(OH)_2D_3$, delivered intravenously or orally, or calcimimetics[541] may be required to suppress PTH gene transcription and parathyroid cellular proliferation.

Decreased levels of $1,25(OH)_2D_3$ may also be observed in patients taking ketoconazole and in ADHR, X-linked hypophosphatemia, and TIO, diseases associated with high FGF23 levels (see Chapter 31).[190]

A rare heritable defect of vitamin D activation has been described in several kindreds. Biochemically, pseudo-vitamin D deficiency rickets (PDDR) is characterized by hypocalcemia and secondary hyperparathyroidism. The only metabolic abnormalities that differentiate it from dietary vitamin D deficiency are the presence of normal or elevated levels of vitamin D and 25(OH)D accompanied by low levels of $1,25(OH)_2D_3$.[542,543] The disease is inherited in an autosomal recessive fashion and presents in infancy with rickets, osteomalacia, and seizures.[544] Cloning of the 1α-hydroxylase gene confirmed that mutation of this gene is the molecular basis for the disorder and, as expected, physiologic replacement doses of 1α-hydroxylated metabolites of vitamin D result in clinical remission.[545]

Target Organ Resistance to 1,25(OH)$_2$D$_3$

A second rare inherited disorder, characterized by resistance to the biologic actions of 1,25(OH)$_2$D$_3$, has been described in several kindreds. This disorder, referred to as hereditary vitamin D–resistant rickets (HVDRR) is also characterized by autosomal recessive inheritance. Its biochemical presentation, with hypocalcemia, hypophosphatemia, and secondary hyperparathyroidism, resembles that of vitamin D deficiency, but it is accompanied by elevated levels of 1,25(OH)$_2$D$_3$. The molecular basis for this disease is mutation of the vitamin D receptor gene, resulting in impaired target organ responsiveness. Most of the mutations that have been described involve the DNA-binding domain of the receptor. These mutations result in a decreased affinity of the receptor for its response elements on target genes leading to impaired regulation of these genes. Mutations in the hormone-binding and nuclear receptor coactivator–binding domains of the receptor have also been described in kindreds with HVDRR.[546]

The clinical presentation of HVDRR is variable; however, most patients present in infancy with rickets, hypophosphatemia, and seizures, although presentation in late adolescence has also been described. Alopecia totalis, developing in the first 2 years of life, is present in some kindreds. The finding of alopecia in mice with VDR mutations[35] confirms that alopecia is due to disruption of the VDR gene.

Because of target organ resistance to the active metabolite of vitamin D, there is no ideal treatment for HVDRR. Pharmacologic doses of vitamin D—25(OH)D, 24,25(OH)D, and 1,25(OH)$_2$D$_3$—have been administered in an attempt to overcome this target organ resistance[547] with variable effects. In those patients in whom the hypocalcemia and osteomalacia are resistant to such therapeutic interventions, parenteral calcium infusions have been used to heal osteomalacic lesions.[209] Studies in VDR-ablated mice have demonstrated that maintenance of normal mineral ion homeostasis prevents all the complications of VDR ablation except alopecia.[208,210] Based on these observations, patients with VDR mutations should be treated early and aggressively to prevent skeletal abnormalities and parathyroid hyperplasia. Lifelong therapy is usually required, although spontaneous remissions off therapy have been described. The pathophysiology of the spontaneous remissions is not well understood since the underlying genetic defect still exists. It is likely that these so-called remissions reflect compensated calcium homeostasis once the needs of the growing skeleton are met. In support of this hypothesis is a report of a relapse in a pregnant woman, followed by a remission postpartum.[548]

Phenytoin causes target organ resistance to the biologic effects of 1,25(OH)$_2$D$_3$, in addition to its acceleration of the hepatic catabolism of vitamin D metabolites. Phenytoin has been shown to impair intestinal calcium absorption in vivo in rats[549] and impair PTH and 1,25(OH)$_2$D$_3$-mediated bone resorption in vitro. Combination chemotherapy with 5-fluorouracil and low-dose leucovorin has been reported to cause hypocalcemia in 65% of patients, associated with an acute decrease in plasma 1,25(OH)$_2$D$_3$ levels.[550]

Other Causes of Hypocalcemia

Excessive Deposition Into the Skeleton

Excessive deposition of calcium into the skeleton can occur in association with osteoblastic metastases, with chondrosarcomas,[551] or in the hungry bone syndrome. This syndrome presents as prolonged hypocalcemia, hypocalciuria, and hypophosphatemia post parathyroidectomy for primary hyperparathyroidism (see "Primary Hyperparathyroidism"). The hypocalcemia is a consequence of remineralization of a skeleton that has been subjected to the bone resorbing effects of PTH over a prolonged period. Hungry bone syndrome can also be observed after treatment of other diseases that are associated with excessive bone resorption. It has been described following radioactive iodine treatment of a patient with Graves disease.[552]

Impaired Resorption

Hypocalcemia can be observed as a consequence of administration of drugs that impair osteoclast-mediated bone resorption, including bisphosphonates and denosumab. Vitamin D deficiency is thought to be a significant risk factor for hypocalcemia associated with antiresorptive therapy.

Chelation

Decreases in ionized calcium have been reported with foscarnet, a pyrophosphate analog that is used as an antiviral agent,[553] perhaps because of complex formation between ionized calcium and the drug.

Hyperphosphatemia, due to phosphate administration or rapid destruction of soft tissue (i.e., rhabdomyolysis, chemotherapy of hematologic malignancies), may produce profound hypocalcemia by directly complexing and precipitating calcium in bone or soft tissues, by inhibiting bone resorption, and by blocking renal synthesis of 1,25(OH)$_2$D$_3$ (see "Hyperphosphatemia").

Massive infusions of citrated blood products may cause hypocalcemia, presumably because citrate complexes calcium in the recipient's plasma.[554] Large doses of ethylenediaminetetraacetic acid (EDTA)–containing radiographic contrast dyes have also been reported to cause hypocalcemia. Hypocalcemia, due to complexes of calcium and fluoride, has been reported with hydrofluoric acid burns[555] or ingestion.[556]

Neonatal Hypocalcemia

Neonatal hypocalcemia is seen in infants of hyperparathyroid mothers, infants of diabetic mothers, in premature infants, and in infants with birth asphyxia. The cause of hypocalcemia in infants of diabetic mothers is likely multifactorial. Prematurity per se does not account for the higher incidence.[557] The response of premature infants and infants of diabetic mothers to exogenous PTH suggests that functional hypoparathyroidism may, in part, account for the increased hypocalcemia in these two populations.[557,558] The hypocalcemia in infants of hyperparathyroid mothers is presumably secondary to the maternal hypercalcemia that, in turn, suppresses fetal parathyroid function.[559] Neonatal hypocalcemia is also seen in offspring of vitamin D–deficient mothers and in infantile malignant osteopetrosis.[560,561]

HIV

Hypocalcemia is sixfold more prevalent in HIV-infected patients than in the general population.[562] Although hypocalcemia is often a consequence of antiretroviral and antibiotic/antimycotic therapy, vitamin D deficiency and hypomagnesemia are also common in patients with AIDS. Impaired parathyroid responsiveness to hypocalcemia has also been documented (see Chapter 44).

Critical Illness

Hypocalcemia is commonly seen in critically ill patients and is thought to be a reflection of parathyroid gland suppression, failure

to activate vitamin D, calcium chelation or sequestration, and/or hypomagnesemia. However, an increased basal level and secretory response of PTH to lowering of serum calcium has been observed in some septic and nonseptic intensive care unit (ICU) patients, emphasizing the multifactorial origin of the hypocalcemia.[563] There was a correlation between cytokine levels and hypocalcemia in this and other studies, suggesting that these inflammatory agents may play a role in redistribution of calcium to the intracellular or other pools. Interleukin 1 (IL1) has been shown to increase the expression of the calcium-sensing receptor on parathyroid cells and lower PTH secretion and blood calcium in rats injected with the cytokine.[564] Severe acute pancreatitis is often associated with hypocalcemia and is a negative prognostic indicator. The hypocalcemia occurs shortly after the onset of pancreatitis and is associated with an increase in PTH levels, suggesting that parathyroid function is normal. It has long been thought that this hypocalcemia is secondary to deposition of "calcium soaps" consisting of calcium and fatty acids. Supporting this hypothesis, studies in a patient with a pancreatic fistula have demonstrated hypocalcemia (4.3 mg/dL) in the setting of high levels of calcium (26 mg/dL) and fatty acids in ascitic fluid.[565] Subsequent studies in a rat model have supported this finding and demonstrated that oleate has a high binding capacity for calcium.[566] However, other investigations in a porcine model of experimental pancreatitis have demonstrated that hypocalcemia does not occur if the animals are subjected to thyroidectomy prior to the induction of pancreatitis.[567] This finding suggests a role for calcitonin in the development of hypocalcemia with acute pancreatitis, although several clinical studies have documented normal calcitonin levels in hypocalcemic individuals with pancreatitis.[568] Severe hypocalcemia with hypercalcitoninemia and hypophosphatemia has been reported in the toxic shock syndrome sepsis and in critically ill patients.[569] As in acute pancreatitis, this hypocalcemia is usually accompanied by increases in serum levels of PTH, and the degree of hypocalcemia is a negative prognostic indicator. The mechanism of hypocalcemia in these patients is likely to be heterogeneous and has not been clearly defined.

Treatment of Hypocalcemia

Acute hypocalcemia is an emergency that requires prompt attention. If symptoms of neuromuscular irritability are present and carpopedal spasm is elicited on physical examination, or if electrocardiogram (EKG) changes are present, treatment with intravenous calcium is indicated until the signs and symptoms of hypocalcemia subside. Approximately 100 mg of elemental calcium should be infused over a period of 10 to 20 minutes (Table 29.6). If this is not sufficient to alleviate the clinical findings of hypocalcemia, an infusion of 100 mg per hour can be given to adults for several hours with close monitoring of calcium levels. In hypocalcemia associated with hypomagnesemia, magnesium replacement also is required. Magnesium should be given intravenously, 100 mEq over 24 hours in the acute setting. Because most of the parenteral magnesium is excreted in the urine, oral magnesium oxide should be instituted as soon as possible to replete body stores. Special caution and reduced doses are necessary when administering magnesium to patients in renal failure (see "Magnesium Disorders").

The treatment of hypocalcemia should be directed at the underlying disorder. In all cases, replacement with exogenous calcium (1–3 g elemental calcium daily, from food sources or oral supplements) should be instituted. Calcium carbonate is the least expensive formulation, but it requires acidification for efficient absorption. This becomes important in patients with achlorhydria and those in whom gastric acid production is being suppressed with pharmacologic agents. Notable in this respect is the acid buffering capacity of calcium carbonate. Because of this, it is recommended that patients take their calcium carbonate supplements in divided doses of 1 g or less. In these cases, the calcium should be taken with food or citrus drinks to promote maximal absorption.

In cases of vitamin D deficiency or resistance, the metabolite of vitamin D chosen depends on the underlying disorder. If impaired renal 1α-hydroxylation is present, such as in renal failure, hypoparathyroidism (or PTH resistance), or the vitamin D–dependent rickets syndromes, metabolites that do not require this modification should be administered (calcitriol 0.25–1 μg/day or doxercalciferol 2.5–5 mg/day). If decreased intake or increased losses are the problem, vitamin D should be administered and the treatment directed at the underlying disorder. Initial repletion of stores can be undertaken with 50,000 IU of vitamin D daily for 1 to 3 weeks, followed by a daily maintenance dose that significantly exceeds the RDA. In patients with resistance to vitamin D, such as those on phenytoin, 5000 IU daily or more may be required as maintenance therapy. The use of sublingual vitamin D has been shown to effectively replete levels in a patient with malabsorption due to Crohn disease.[570] In those without chronic conditions, once treatment of the underlying disorder and repletion of body stores have been addressed, 800 to 1200 IU should provide sufficient maintenance therapy.

Patients should be monitored closely to assess both response to therapy and to prevent therapeutic complications. Serum calcium should be monitored frequently (daily in profound hypocalcemia, weekly in moderate hypocalcemia) for the first week to month of therapy. Concomitant with resolution of hypocalcemia, one should observe a decline in the serum PTH level as secondary hyperparathyroidism resolves. Measurement of serum PTH and assessment of 24-hour urinary calcium excretion should be performed within 2 to 4 weeks of institution of therapy. The urinary calcium measurement reflects the effect of therapy on the patient's ability to absorb calcium and the net uptake of calcium by bone. A low urine calcium indicates poor adherence to a regimen, poor absorption of calcium, or increased uptake by bone. In addition, the urine calcium provides important information on which to base therapeutic modifications to avoid nephrolithiasis. Once normalization of serum and urinary calcium and a decrease in PTH levels are observed, a transition from aggressive replacement therapy to maintenance therapy should be undertaken to prevent hypercalcemia and nephrolithiasis. These same parameters should be monitored 1 and 3 months after a dose change to assess the effect of the therapeutic intervention. Monitoring of the alkaline phosphatase can also be performed at this time. Alkaline phosphatase levels may actually increase soon after starting treatment because of healing of the osteomalacic lesions; however, by 3 to 4 months after institution of therapy, a clear downward trend should be observed. Alkaline phosphatase and PTH values may remain elevated for 6 to 12 months after institution of therapy; they should not be a cause for alarm provided they are declining and the other parameters suggest therapy is effective.

The treatment of hypoparathyroidism is similar to that of vitamin D deficiency with the exception that these patients have impaired renal 1α-hydroxylation of 25(OH)D and therefore require treatment with 1α-hydroxylated metabolites. PTH(1-84) has also been approved for therapy. This therapy controls hypocalcemia with lower urine calcium excretion than with calcium

[a]Molecular weights (MW) shown are for the usual chemical form, including water molecules (e.g., $MgSO_4 \bullet 7\ H_2O$).

[b]Other formulations exist. Those shown are among those approved in the United States.

[c]Phosphate preparations contain buffered mixtures of monobasic ($H_2PO_4^-$) and dibasic (HPO_4^-) ions; the phosphorus content therefore is specified in millimoles. Oral phosphates contain 7 mEq sodium and potassium per capsule (Na/K form) or 14 mEq potassium per capsule (K form). Parenteral solutions typically contain 4 mEq of sodium or potassium per milliliter.

and calcitriol therapy, but it is expensive and requires parenteral administration. Oral calcium and 1α-hydroxylated vitamin D metabolites therefore remain the mainstay of therapy. Monitoring of serum and urinary calcium should be performed as in the treatment of vitamin D deficiency. Therapy in these patients is lifelong, therefore careful monitoring is required to avoid renal or hypercalcemic complications. The aim of therapy should be to maintain serum calcium in the low-normal range without causing frank hypercalciuria. Because PTH plays an important role in renal calcium reabsorption, difficulties are often encountered attaining these therapeutic goals. In such cases, renal calcium losses can be minimized by the addition of a thiazide diuretic to the treatment regime. Replacement therapy with PTH(1-34) has also been shown to be effective in treatment of hypoparathyroidism.[571]

One of the frustrations often encountered in treating patients with hypoparathyroidism is the fluctuating response to a seemingly stable therapeutic regimen. Episodes of hypercalcemia are occasionally observed without any discernible cause. Because of this, serum calcium should be monitored every 3 months to permit temporary withdrawal of $1,25(OH)_2D_3$, should a hypercalcemic trend be observed. Fortunately the half-life of this metabolite is short, so that discontinuation for a few days to a week with resumption of a lower dose is usually efficacious.

All patients receiving vitamin D metabolites and calcium need to be aware of potential therapeutic complications. Importantly, the mild symptoms of hypercalcemia should be emphasized to the patient. It is essential that these patients be aware that their calcium should be monitored more frequently during intercurrent illnesses that may affect the absorption of calcium or their hydration status, to prevent the development of hypocalcemia or severe hypercalcemia.

Disorders of Phosphate Metabolism

Hyperphosphatemia

Serum phosphate levels are controlled primarily by the rate of proximal renal tubular phosphate reabsorption, which is due, in turn, to the integrated activity of the major sodium-dependent cotransporters (NaPi-IIa and NaPi-IIc). The latter are strongly downregulated by parathyroid hormone and FGF23, both of which are stimulated by phosphate. Thus absent extraordinary filtered loads of phosphate, the capacity of normal kidneys to excrete phosphate is not easily exceeded. Consequently, the occurrence of hyperphosphatemia usually signifies impaired renal functon, hypoparathyroidism, defective FGF23 action, a huge flux of phosphate into the extracellular fluid, or some combination of these factors (Table 29.7).

The most common cause of hyperphosphatemia is acute or chronic renal failure in which GFR is so reduced that the usual daily load of phosphate cannot be excreted at a normal level of serum phosphate, despite maximal inhibition of phosphate reabsorption in the remaining functional nephrons. In hypoparathyroidism (or PHP), serum phosphate may rise to levels as high as 6 to 8 mg/dL because of loss of the tonic inhibitory effect of PTH on phosphate reabsorption, although elevated FGF23 levels may prevent even further increases in serum phosphate.[572] The hyperphosphatemia of hypoparathyroidism is only partly due to the absence of PTH per se. Hypocalcemia may further impair phosphate clearance in this setting, and correction of hypocalcemia by treatment with vitamin D metabolites and oral calcium may reduce serum phosphate, for example, even though PTH levels remain low.[573]

Other circumstances in which renal tubular phosphate excretion is decreased, in the absence of renal failure, include acromegaly,[574] chronic therapy with heparin, and familial tumoral calcinosis.[575] Familial tumoral calcinosis can result from inactivating mutations in either FGF23 or the *O*-linked glycosyl transferase GalNAc-T3, which glycosylates FGF23 at its cleavage site targeted by furin-like proteases, thereby suppressing this cleavage.[576] In the absence of GalNAc-T3, FGF23 is cleaved at an accelerated rate.[577–579] The choice of FGF23 assay is important therefore for diagnosing tumoral calcinosis. The responsible FGF23 and GalNac-T3 mutations may render the molecule more susceptible to proteolyic degradation, such that the blood levels of (inactive) carboxyl fragments may be quite high in contrast to low levels of (bioactive) intact FGF23.[578] Affected patients may display focal hyperostosis; large, lobulated periarticular ectopic calcifications, especially around shoulders or hips; hyperphosphatemia due to increased renal tubular reabsorption of phosphate; increased serum $1,25(OH)_2D$ despite normal or low serum PTH; and increased intestinal calcium absorption, consistent with the elevated serum $1,25(OH)_2D$ concentration. The disorder may present in childhood or adulthood, is more common in African Americans, and is lifelong, with a tendency for the tumoral calcifications to progress at affected sites. In contrast to the elevated serum $1,25(OH)_2D$, hyperphosphatemia is not a constant feature of tumoral calcinosis, although it tends to be most severe in those with prominent calcifications. Despite their chronic hyperphosphatemia, secondary hyperparathyroidism does not develop in these patients, presumably because of the high $1,25(OH)_2D$ levels and intestinal hyperabsorption of calcium. Treatment is problematic, although some success has been reported with phosphate-binding antacids, calcium deprivation, calcitonin, and acetazolamide therapy.[580]

Hyperphosphatemia may result from overly rapid administration of therapeutic phosphate preparations or phosphate-rich drugs (fosphenytoin, liposomal amphotericin B), especially if renal function is compromised[581] or from rapid shifts of phosphate out of cells, most often provoked by mechanical injury or metabolic insult. Most cases of hyperphosphatemia associated with intestinal phosphate loads have involved children who received phosphate-containing laxatives or enemas or older adults with impaired renal function receiving phosphate-based cathartics in preparation for colonoscopy.[582] Hyperphosphatemia due to cytolytic release of intracellular phosphate can be quite dramatic, with serum phosphate concentrations up to or exceeding 20 mg/dL. This disorder was described initially as a complication of rapid induction chemotherapy for certain hematologic malignancies (tumor lysis syndrome), although it also may occur from cellular injury associated with trauma, hyperthermia, overwhelming infection, hemolysis, rhabdomyolysis, or metabolic acidosis.[583] Rarely, apparent hyperphosphatemia may reflect measurement artifact caused by paraproteins in myeloma.[584]

Most often, hyperphosphatemia is mild and asymptomatic, although chronic hyperphosphatemia is an important factor in the development of secondary hyperparathyroidism in progressive renal failure. The clinical manifestations of acute, severe hyperphosphatemia are related mainly to those of the accompanying hypocalcemia, caused by formation of insoluble calcium phosphate precipitates. Thus tetany, muscle cramps, paresthesias, and seizures may occur, and they may be compounded by other metabolic disturbances (hyperkalemia, acidosis, hyperuricemia) that frequently coexist. Generalized precipitation of calcium phosphate into soft tissues may produce organ dysfunction, notably renal failure.[582]

Therapeutic options for hyperphosphatemia are limited. Volume expansion may be helpful to improve GFR in acute syndromes. Identification and removal of any exogenous sources of phosphate are important, and phosphate-binding aluminum hydroxide antacids may be useful in limiting intestinal phosphate absorption and chelating phosphate secreted into the intestine. Hemodialysis is the most effective approach and should be considered early in severe hyperphosphatemia, especially in the tumor lysis syndrome and particularly if symptomatic hypocalcemia cannot be adequately treated for fear of inducing widespread soft tissue calcification.

Hypophosphatemia

Etiology

Hypophosphatemia may result from one or more of three general mechanisms (Table 29.8): increased urinary losses due to decreased net renal tubular phosphate reabsorption; rapid shifts of phosphate from extracellular fluid into the intracellular space or the mineral phase of bone; or rarely, severe and selective deprivation of dietary phosphate, as may occur with chronic ingestion of large amounts of nonabsorbable aluminum-containing antacids. Fasting or starvation does not lead directly to hypophosphatemia, apparently because phosphate is mobilized from catabolized bone and soft tissue in amounts sufficient to maintain serum phosphate, even during prolonged caloric deprivation.[585] Starvation does induce phosphate deficiency and therefore predisposes to subsequent hypophosphatemia upon refeeding.[586]

Chronic hypophosphatemia usually can be traced to ongoing renal phosphate wasting. Elevation of serum PTH for any reason (other than renal failure), as in primary hyperparathyroidism or secondary hyperparathyroidism due to vitamin D or calcium deficiency, results in inhibition of tubular phosphate reabsorption and fasting hypophosphatemia. Phosphate clearance also is increased in PTHrP-associated hypercalcemia of malignancy, although when such patients develop severe hypercalcemia, hypophosphatemia may be masked initially by underlying volume depletion and compromised GFR. Therapy with the tyrosine kinase inhibitors imatinib and nilotinib appears to cause hypophosphatemia, at least in part by inhibiting both osteoblast and osteoclast formation, lowering serum calcium, and stimulating secondary hyperparathyroidism.[587–589] When PTH secretion is compromised by severe hypomagnesemia, rapid intravenous administration of magnesium alone, without concurrent attention to coexisting hypocalcemia, can provoke massive phosphaturia and hypophosphatemia in patients with underlying phosphate depletion.

The discovery that gain-of-function mutations in FGF23 cause autosomal dominant hypophosphatemic rickets inaugurated a new era in understanding of phosphate homeostasis.[590–592] Elevated FGF23 also occurs in autosomal recessive hypophosphatemia (ARHP), which is caused by mutations in the genes encoding dentin matrix protein-1 (DMP1) and FAM20C. DMP1 is expressed in osteocytes and presumably regulates local production of FGF23.[593] FAM20C is a secreted kinase that phosphorylates FGF23 near the furin cleavage site; this phosphorylation is required for inactivating cleavage by a furin-like protease. Immunoassays for FGF23[594] have pointed to elevated circulating FGF23 as at least one "phosphatonin" responsible for reduction of phosphate reabsorption and serum $1,25(OH)_2D$ levels in the more common disorder, X-linked hypophosphatemic rickets (XLH), in the rare but distinctive TIO and epidermal nevus syndromes, and in the approximately 50% of patients with McCune-Albright syndrome (fibrous dysplasia of bone) who manifest hypophosphatemia.[590–592,595–597] These disorders share a common biochemical phenotype, which may include a more generalized proximal tubular dysfunction, with modest proteinuria and aminoaciduria. Serum calcium usually is normal or low-normal, urinary calcium often is low, PTH is normal or only slightly elevated, and $1,25(OH)_2D$ is inappropriately normal. The clinical picture is dominated by weakness, bone pain, and other features attributable to the associated rickets or osteomalacia (see Chapter 31). Increased FGF23 also may play a role in impaired phosphate reabsorption seen in the 20% or so of patients with calcium kidney stones and idiopathic hypercalciuria who exhibit fasting hypophosphatemia,[598] although a few such patients may harbor mutations in the NaPi-IIa sodium phosphate cotransporter.[599]

Renal phosphate clearance may be impaired in the context of a more generalized renal tubular disorder such as Fanconi syndrome(s) or others associated with systemic diseases such as amyloidosis, Wilson disease, or cystinosis (see Table 29.8). In addition to NaPi-IIa mutations, inactivating mutations in the NaPi-IIc cotransporter, also expressed in the proximal tubule and known to be regulated by both PTH and FGF23, have been shown to account for the rare disorder known as *hereditary hypophosphatemic rickets with hypercalciuria*, in which primary

renal tubular phosphate wasting causes appropriate elevation of serum $1,25(OH)_2D$ and resulting hypercalciuria.[600,601] Other causes of impaired renal tubular phosphate reabsorption include the osmotic diuresis associated with poorly controlled diabetes, alcoholism, hyperaldosteronism, and exposure to any of a wide variety of drugs or toxins (see Table 29.8). The pathogenesis of phosphate wasting that often follows partial hepatectomy or renal transplantation remains unclear, but humoral mechanisms seem to be involved.[602,603]

Rapid egress of extracellular phosphate into cells is the cause of hypophosphatemia that develops acutely during administration of intravenous glucose, insulin therapy for hyperglycemia, administration of catecholamines (pressors or bronchodilators), thyrotoxic periodic paralysis, profound respiratory alkalosis, refeeding syndrome in the wake of severe acidosis or starvation, recovery from acute hepatic failure (in which hypophosphatemia is a recognized favorable prognostic factor[604]), or other circumstances involving rapid cellular proliferation such as leukemic blast crisis or responsiveness to hematopoietic growth factors. Hypophosphatemia in these situations is most pronounced when there is underlying phosphate depletion, as in hyperparathyroidism or vitamin D deficiency, or following prolonged malnutrition, alcoholism, or glycosuria. Accelerated uptake of phosphate into cells is particularly common in postsurgical, burn, or trauma patients, in whom it may be promoted by high levels of circulating catecholamines and exacerbated by concurrent respiratory alkalosis, fever, volume expansion, sepsis, and hypokalemia. Situations of greatly accelerated net bone formation, such as hungry bone syndrome occurring immediately following parathyroidectomy for primary or tertiary hyperparathyroidism, during initial treatment of severe vitamin D deficiency or Paget disease, or in occasional patients with extensive osteoblastic bone metastases, may manifest hypophosphatemia as well as hypocalcemia.

Clinical Features

The clinical significance of hypophosphatemia depends on the presence and severity of underlying phosphate depletion. Unfortunately the status of the total-body phosphorus pool, and more particularly the critical intracellular pool, is reflected only indirectly by the concentration of phosphate in the extracellular fluid, which contains less than 0.5% of body phosphorus. Thus, although serum phosphate concentrations generally are used to characterize hypophosphatemia as severe (<1–1.5 mg/dL, <0.3–0.5 mmol/L), moderate (1.5–2.2 mg/dL, 0.5–0.7 mmol/L), or mild (2.2–3 mg/dL, 0.75–1 mmol/L), serum phosphate may be normal or even high (depending on renal function) in the presence of profound intracellular phosphate deficiency. Conversely, it may be low when intracellular phosphate is relatively normal, such as following a sudden movement of extracellular phosphate into cells.

The prevalence of severe hypophosphatemia among hospitalized patients overall is less than 1%, whereas mild or moderate hypophosphatemia may be detected in 2% to 5%.[605] Hypophosphatemia is recognized most often in critically ill patients, alcoholics or other malnourished individuals, decompensated diabetics, and those with acute infectious or pulmonary disorders.[605]

The clinical manifestations of severe hypophosphatemia are protean. Among the most common are various neuromuscular symptoms, ranging from progressive lethargy, muscle weakness, and paresthesias to paralysis, coma, and even death, depending on the severity of the phosphate depletion. Confusion, profound weakness, paralysis, seizures, and other major sequelae generally are limited to those with serum phosphate concentrations below 0.8 to 1 mg/dL.[606] Biochemical evidence of muscle injury is observed within 1 to 2 days in over one-third of patients whose serum phosphate concentrations fall to less than 2 mg/dL.[607] Overt rhabdomyolysis also may occur, especially in the setting of chronic alcoholism with underlying malnutrition and phosphate depletion.[608,609] However, by the time this is recognized the serum phosphate often has been raised by the large amounts of cellular phosphate released from damaged muscle. Reversible respiratory failure due to respiratory muscle weakness may preclude successful weaning from ventilatory support.[610,611] Left ventricular dysfunction, heart failure, and ventricular arrhythmias may result from profound hypophosphatemia but may not be significant if serum phosphate is greater than 1.5 mg/dL.[612] Correction of moderate hypophosphatemia (<2 mg/dL) in patients with septic shock led to a significant increase in blood pressure as well as left ventricular function and arterial pH.[612] Hematologic sequelae of severe hypophosphatemia include hemolysis, platelet dysfunction with bleeding, and impaired leukocyte function (phagocytosis and killing).[613] Erythrocytes demonstrate increased fragility; altered membrane composition, rigidity, and microspherocytosis; and reduced levels of ATP and 2,3-diphosphoglycerate (2,3-DPG).[613] The reduction in erythrocyte 2,3-DPG impairs oxyhemoglobin

dissociation and thereby may reduce oxygen delivery to tissues. This problem, together with accelerated hemolysis, may provoke a substantial increase in cardiac output. The blockade in cellular glycolysis becomes demonstrable at levels of serum phosphate between 1 and 2 mg/dL.[614] Glucose intolerance and insulin resistance also have been demonstrable in these patients.[615]

Treatment

Hypophosphatemia appears most often in acutely or critically ill individuals. Accordingly, it often is difficult to discern whether hypophosphatemia is responsible for features of the multiple organ dysfunction commonly encountered in this population. For example, although depression of intracellular high-energy organophosphates has been demonstrated during treatment of diabetic ketoacidosis and phosphate repletion leads to more rapid recovery of erythrocyte 2,3-DPG concentrations, opinion is divided as to whether phosphate therapy in this setting hastens recovery, prevents complications, or reduces mortality rate.[616,617] Nevertheless, because severe hypophosphatemia has been associated, in a variety of clinical settings, with serious neuromuscular, cardiovascular, and hematologic dysfunction that is at least partially reversible with phosphate repletion, most now agree that one should adopt a relatively low threshold for treatment.[612]

The decision to correct hypophosphatemia urgently should be guided by the estimated severity of the cellular phosphate deficit, the presence of signs or symptoms suggestive of phosphate depletion, and the overall clinical status of the patient. The presence of renal insufficiency (a risk for iatrogenic hyperphosphatemia), concomitant administration of intravenous glucose (alone or as a component of hyperalimentation solutions), and the potential for aggravating coexistent hypocalcemia also should be considered.

Limited data are available from clinical trials to predict the appropriate dose and rate of phosphate administration. In patients without severe renal insufficiency or hypocalcemia, administration of intravenous phosphate at rates of 2 to 8 mmol/hour of elemental phosphorus over 4 to 8 hours frequently corrects hypophosphatemia without provoking hyperphosphatemia or hypocalcemia.[605,618–620] Suggested guidelines based on serum phosphate are shown in Table 29.9. It is essential that serum calcium and phosphate be monitored every 6 to 12 hours during and after phosphate therapy, both to detect untoward consequences and because many patients require additional infusions for recurrent hypophosphatemia within 24 to 48 hours of apparently successful repletion.[619] Less acute or severe hypophosphatemia should be managed with oral (or enteral) phosphate supplements if possible, generally given as a total of 1 to 2 g a day (as elemental phosphate) of neutral sodium or potassium phosphate in divided doses three to four times a day (see Table 29.6). In many patients, however, oral phosphate therapy is limited by gastrointestinal symptoms such as nausea or diarrhea.

TABLE 29.9 Urgent Therapy of Hypophosphatemia[a]

Factors to Consider

Severity of hypophosphatemia
Likelihood of underlying phosphate depletion
Clinical condition of the patient
Renal function
Serum calcium
Concurrent parenteral therapy (glucose, hyperalimentation)

GUIDELINES			
Serum PO_4 (mg/dL)	Rate of Infusion (mmol/hr)	Duration (hr)	Total PO_4 (mmol)
<2.5	2	6	12
<1.5	4	6	24
<1	8	6	48

[a]Rates shown are normalized for a 70-kg person. Most formulations available in the United States provide 3 mmol/mL of sodium or potassium phosphate.

Disorders of Magnesium Metabolism

The fourth most abundant extracellular cation, magnesium, like calcium, plays a critical physiologic role, particularly in neuromuscular function but also as a component of the mineral phase of bone. Intracellular magnesium is crucial for normal energy metabolism, as a cofactor for ATP and numerous enzymes and transporters, which is reflected in the rather global clinical effects that accompany disorders of magnesium homeostasis. Hypomagnesemia and hypermagnesemia are among the most common electrolyte disturbances; one or the other of these abnormalities is observed in as many as 20% of hospitalized patients and even more frequently (i.e., 30–40%) among those admitted to ICUs.[621]

Hypermagnesemia

Magnesium homeostasis is achieved mainly through highly efficient regulation of tubular magnesium reabsorption in the loop of Henle.[1] Because normal kidneys can readily excrete even large amounts of magnesium (i.e., 500 mEq/day), high filtered loads of magnesium rarely cause hypermagnesemia except in patients with significant renal insufficiency.[622] Increased magnesium loads in such cases may arise from ingestion of large amounts of oral magnesium salts, typically given as cathartics or antacids, or from extensive soft tissue ischemia or necrosis in patients with trauma, sepsis, cardiopulmonary arrest, burns, or shock[622] (Table 29.10). Hypermagnesemia may result from parenteral administration of magnesium salts, such as when magnesium is used to treat preeclampsia or as a tocolytic.[623] The infants of such hypermagnesemic mothers may manifest transient hypermagnesemia as well, along with parathyroid suppression and neurobehavioral symptoms.[624,625] The use of oral magnesium preparations as laxatives may lead to hypermagnesemia if absorption is increased by intestinal ileus, obstruction, or perforation.[626]

The most prominent clinical manifestations of hypermagnesemia are vasodilatation and neuromuscular blockade, which may involve both presynaptic and postsynaptic inhibition of neuromuscular transmission.[627] Signs and symptoms generally do not appear unless the serum magnesium exceeds 4 mEq/L.[622] Hypotension, often refractory to pressors and volume expansion, may be one of the earliest signs of progressive hypermagnesemia.[627,628] Lethargy, nausea, and weakness, accompanied by reduction or loss of deep tendon reflexes, may progress to stupor or coma with respiratory insufficiency or quadriparesis at serum concentrations in excess of 8 to 10 mEq/L. Gastrointestinal hypomotility or ileus is common. Facial flushing and pupillary dilatation may be observed. Hypotension may be complicated by a paradoxic relative bradycardia, and other cardiac effects may be evident, including

prolongation of the PR, QRS, and QTc intervals, appearance of heart block, and ultimately asystole as serum concentrations approach 20 mEq/L.

Hypermagnesemia activates CaSRs in the parathyroids, thereby suppressing PTH secretion,[629] and in the renal distal tubules, thereby reducing tubular calcium and magnesium reabsorption. Severe hypocalcemia opposes the effect of hypermagnesemia on PTH secretion so that serum PTH may remain within the normal range but still inappropriate for the level of serum calcium.[630]

Successful treatment of hypermagnesemia requires identification and interruption of the source of magnesium, together with measures to increase clearance of magnesium from the extracellular fluid. Use of magnesium-free cathartics or enemas to accelerate clearance of ingested magnesium from the gastrointestinal tract, together with vigorous intravenous hydration, generally have been successful in reversing hypermagnesemia. Refractory cases, especially those with advanced renal insufficiency, may require hemodialysis. Intravenous calcium (100–200 mg) infusions have been advocated as an effective antidote to hypermagnesemia, and there are examples in which this approach has apparently been successful, at least temporarily.[622,627,631]

Hypomagnesemia

Hypomagnesemia may occur because of impaired intestinal magnesium absorption or, more commonly, because of excessive gastrointestinal losses due to diarrhea, preprocedural bowel preparation, or prolonged drainage. Most often, hypomagnesemia reflects defective renal tubular reabsorption of magnesium, although rapid shifts into cells, other extrarenal losses, or incorporation into new bone may occur (Table 29.11). Because only 1% of the body's magnesium content is present in extracellular fluid, measurements of serum total or ionized magnesium concentration may not adequately reflect total-body magnesium or the magnesium status of the intracellular compartment in critical tissues such as muscle.[632] Thus patients with deficiency of tissue magnesium may fail to manifest overt hypomagnesemia[633] but may exhibit abnormal retention (i.e., >50% in 24 hours) of infused magnesium, a maneuver that may be used to assess magnesium status.[634]

Etiology

Intestinal Causes of Hypomagnesemia

Selective dietary magnesium deficiency does not occur, and it is remarkably difficult, in fact, to induce magnesium depletion experimentally by feeding magnesium-deficient diets, probably because renal magnesium conservation is so efficient. Large amounts of magnesium may be lost in chronic diarrheal states (this fluid may contain >10 mEq/L magnesium) or via intestinal fistulas or prolonged gastrointestinal drainage.[635] More commonly, magnesium becomes trapped within fatty acid soaps in disorders associated with chronic malabsorption.[636] Investigation of a rare autosomal recessive disorder, hypomagnesemia with secondary hypocalcemia (HSH), led to the identification of the transient receptor potential channel protein TRPM6 in the form of a hetero-oligomer, with the closely related channel protein TRPM7 as a key molecular mediator of intestinal (and renal tubular) transepithelial magnesium transport.[637]

Renal Causes of Hypomagnesemia

Roughly 60% of renal magnesium reabsorption occurs in the thick ascending limb of Henle loop, and another 5% to 10% is reabsorbed in the distal tubules.[1] Investigation of the pathogenesis of several genetic disorders associated with renal magnesium wasting has identified key pathways of magnesium reabsorption at these sites (see Table 29.11). Thus in familial hypomagnesemia with hypercalciuria and nephrocalcinosis, loss-of-function mutations in the claudin 16 gene encoding the paracellin-1 protein (or in the related gene, claudin 19), a component of the tight junctions between adjacent epithelial cells, selectively impair paracellular magnesium (and calcium) reabsorption in response to the (lumen-positive) transepithelial voltage gradient.[57,638]

In Bartter syndrome(s), inactivating mutations in any of several transporters involved in sodium chloride reabsorption in the ascending limb cause salt wasting, compromise the voltage gradient, and similarly impair paracellular magnesium and calcium reabsorption.[639–641] In autosomal dominant hypocalcemia, mutations causing increased sensitivity of CaSRs to cationic agonists cause hypomagnesemia, as well as hypocalcemia, through inappropriate CaSR-dependent suppression of PTH secretion and of renal tubular cation reabsorption.[642]

In Gitelman syndrome, inactivating mutations in the luminal thiazide-sensitive NaCl cotransporter (NCC) expressed in the distal convoluted tubules lead to sodium chloride and magnesium wasting, in this case with hypocalciuria.[639–641,643] The manner whereby impaired NCC activity compromises (transcellular) magnesium reabsorption in this segment is unclear, although NCC-knockout mice (or normal mice treated with thiazides) display reduced distal tubular expression of the TRPM6 channel protein required for normal magnesium transport across the apical membrane.[434]

Mutations in the FXYD2 γ-subunit of the distal tubular basolateral Na^+/K^+-ATPase similarly impair salt and magnesium reabsorption at that site and account for some, but not all, cases of isolated renal magnesium wasting.[644,645] An autosomal recessive form of renal hypomagnesemia is caused by inactivating mutations in the EGF gene, which likely also explains why hypomagnesemia may complicate use of cetuximab, a monoclonal antibody directed against the EGF receptor.[646] Another genetic syndrome featuring renal magnesium wasting and hypocalciuria (as in Gitelman syndrome), and thus presumably involving a defect in distal tubular function as well, in association with hypertension and hypercholesterolemia, is linked to a mutation in mitochondrial tRNA DNA.[647] Other rare genetic causes of distal tubular

magnesium wasting involve mutations in K channels (Kv1.1 or Kir4.1) that disrupt voltage gradients needed for efficient magnesium reabsorption.[648]

Most often, renal magnesium wasting is attributable to an acquired abnormality in tubular magnesium reabsorption. In normal subjects, magnesium reabsorption is virtually complete within several days of instituting experimental dietary magnesium deficiency, even before serum magnesium has declined substantially.[649] Thus the finding of more than 1 mEq per day of urinary magnesium in a frankly hypomagnesemic patient indicates a defect in renal tubular magnesium reabsorption. The causes of acquired primary tubular magnesium wasting include various tubulointerstitial disorders, recovery from acute tubular necrosis or obstruction, renal transplantation, various endocrinopathies, alcoholism, and exposure to certain drugs (see Table 29.11).

Hypomagnesemia or magnesium depletion due to subnormal renal reabsorption may complicate a variety of endocrinopathies, including hyperaldosteronism, hyperthyroidism, and disorders associated with hypercalcemia, hypercalciuria, or phosphate depletion.[634] In primary hyperparathyroidism, PTH stimulates increased tubular magnesium reabsorption, but this action is opposed by a direct tubular effect of hypercalcemia. As a result, serum magnesium in primary hyperparathyroidism generally is normal or only slightly reduced.[650] In hypoparathyroidism, serum and urinary magnesium are low. The magnesium depletion in hypoparathyroidism is consistent with loss of both the magnesium-retaining renal action of PTH and the stimulatory effect of $1,25(OH)_2D$ on intestinal magnesium absorption.[651]

Diabetes is among the most common disorders associated with hypomagnesemia.[652,653] The severity of the hypomagnesemia in diabetics correlates with indices of glycosuria and poor glycemic control,[654] suggesting that urinary losses of magnesium on the basis of glycosuria may partly explain the magnesium depletion. Rapid correction of hyperglycemia with insulin therapy causes magnesium to enter cells and may further lower the extracellular magnesium concentration during treatment.

Alcoholism is another very common clinical setting in which hypomagnesemia occurs. Magnesium depletion in alcoholism may result in part from nutritional deficiency of magnesium, overall caloric starvation and ketosis, and gastrointestinal losses due to vomiting or diarrhea, but an acute magnesuric effect of alcohol ingestion likely plays the major role.[655] This effect of alcohol is most evident during the rising limb of the blood ethanol curve and may be related to transient suppression of PTH secretion.[655] Other factors that may contribute to hypomagnesemia in alcoholism include pancreatitis, malabsorption, secondary hyperaldosteronism, respiratory alkalosis, and elevated plasma catecholamines, which increase intracellular sequestration of magnesium.[634]

A number of drugs have been identified as causes of defective renal tubular magnesium reabsorption and hypomagnesemia.[634] These drugs include diuretics (especially loop diuretics), digoxin, cisplatin, cetuximab, pentamidine, cyclosporine, tacrolimus, interleukin 2, aminoglycosides, foscarnet, and amphotericin B. Most often, drug-induced hypomagnesemia is mild and reversible, particularly when it is associated with diuretic therapy. In over half of patients treated with cisplatin, hypomagnesemia occurs within days or weeks, and roughly half of those who develop it exhibit persistent hypomagnesemia many months or even years later. The median duration of hypomagnesemia in cisplatin-treated patients is about 2 months, but recovery has been observed for up to 2 years after treatment.[656] Cisplatin may induce a more global nephropathy and azotemic renal failure, but the magnesium wasting appears to be an isolated functional abnormality.

Other Causes of Hypomagnesemia

Magnesium, like phosphate, is a major intracellular ion, and significant shifts of magnesium from the extracellular compartment therefore may occur during recovery from chronic respiratory acidosis or acute ketoacidosis, after refeeding, following administration of hyperalimentation solutions, and in response to elevations of circulating catecholamines.[634] Other rapid losses of extracellular magnesium may occur during periods of greatly accelerated net bone formation (after parathyroidectomy, during recovery from vitamin D deficiency, with osteoblastic metastases) or with large losses due to pancreatitis, cardiopulmonary bypass surgery,[657] massive transfusion,[658] extensive burns, excessive sweating, pregnancy, or lactation.

Consequences of Hypomagnesemia

Most of the signs and symptoms of hypomagnesemia reflect alterations in neuromuscular function: tetany, hyperreflexia, positive Chvostek and Trousseau signs, tremors, fasciculations, seizures, ataxia, nystagmus, vertigo, choreoathetosis, muscle weakness, apathy, depression, irritability, delirium, and psychosis.[634] Patients usually are not symptomatic unless serum magnesium falls below 1 mEq/L, although occurrence of symptoms, such as intracellular magnesium, may not correlate well with serum magnesium. Atrial or ventricular arrhythmias may occur, as may various electrocardiographic abnormalities—prolonged PR or QT intervals, T-wave flattening or inversion, or ST-segment straightening.[634] Hypomagnesemia also increases myocardial sensitivity to digitalis intoxication.[659]

Hypomagnesemia evokes important alterations in mineral ion and potassium homeostasis that frequently aggravate the clinical syndrome. Magnesium-deprived humans or animals develop hypocalcemia, hypocalciuria, hypokalemia (due to impaired tubular reabsorption of potassium), and positive calcium and sodium balance.[649,660] Sustained correction of hypocalcemia or hypokalemia cannot be achieved by administration of calcium or potassium alone, respectively, whereas both abnormalities respond to administration of magnesium.[636,661]

The mechanism of hypocalcemia in this setting may be multifactorial. Inappropriately normal or low serum PTH, despite hypocalcemia, is common and indicates a defect in PTH secretion,[662] which is due to augmented signaling by CaSR-associated G proteins, normally inhibited by magnesium, within the parathyroid cell.[663] Other evidence indicates that hypomagnesemia also may impair PTH action on target cells in bone and kidney, although some have observed normal responsiveness; the issue remains controversial.[483,484,661,662,664]

Vitamin D resistance also is a feature of hypomagnesemic states.[665,666] This disorder appears to be due mainly to impaired renal 1α-hydroxylation of 25(OH)D, although tissue resistance to $1,25(OH)_2D$ also may play a role.[651,667] The serum $1,25(OH)_2D$ concentration usually is low during hypomagnesemia, which may result from magnesium depletion per se, parathyroid insufficiency, or coexistent vitamin D deficiency.[668–670] Deficiency of $1,25(OH)_2D$ probably is not the main cause of hypocalcemia in these patients, however, because hypocalcemia can be rapidly corrected (within hours to days) by magnesium therapy alone, well in advance of any increase in the serum $1,25(OH)_2D$ concentration.[668,669]

Therapy of Hypomagnesemia

Patients with mild, asymptomatic hypomagnesemia may be treated with oral magnesium salts (i.e., $MgCl_2$, MgO, $Mg[OH]_2$), usually given in divided doses totaling 40 to 60 mEq (480–720 mg) per day (see Table 29.6). Diarrhea sometimes occurs with larger doses but generally is not a problem. The gluconate form (54 mg magnesium per gram) is said to cause less diarrhea.[634] Patients with malabsorption or ongoing urinary magnesium losses may require chronic oral therapy to avoid recurrent magnesium depletion. Although intestinal magnesium absorption is severely impaired in renal failure,[671] oral magnesium must be administered with great caution in this setting, especially in patients receiving concomitant therapy with $1,25(OH)_2D$.

Symptomatic or severe (<1 mEq/L) hypomagnesemia, especially if complicated by hypocalcemia, usually signifies magnesium deficits of at least 1 to 2 mEq/kg and is best treated promptly with parenteral magnesium salts. The use of intramuscular $MgSO_4$ is to be discouraged, as the injections are painful and provide relatively little magnesium (2 mL of 50% $MgSO_4$ supplies only 8 mEq of magnesium, compared with typical magnesium deficits in excess of 100 mEq). Moreover, because unretained sulfate ions also may increase urinary calcium excretion, intravenous magnesium chloride or gluconate probably is the most logical approach to initial parenteral therapy for patients who also may be hypocalcemic. In adult hypomagnesemic patients with normal renal function, rates of infusion of 2 to 4 mEq per hour (i.e., 50–100 mEq/day) generally are needed to maintain serum magnesium in the range of 2 to 3 mEq/L.[630,662,666] Up to 100 mEq per day for 2 days can be safely administered without elevating serum magnesium above 4 mEq/L, whereas doses of 200 mEq per day may increase serum magnesium to 4.5 to 5.5 mEq/L and thus are excessive.[672] In patients with active seizures or other urgent indications, the infusion may be preceded by a slowly administered bolus of 10 to 20 mEq, followed by a higher rate of infusion (i.e., 10–15 mEq/hour) for the first 1 to 2 hours only. Patients with normal renal function can readily excrete over 400 mEq per day of magnesium in the urine without becoming hypermagnesemic, but even mild renal failure may greatly limit magnesium excretion. Therefore doses of magnesium supplements should be reduced twofold to threefold, and careful serial monitoring of serum magnesium should be performed in patients with compromised renal function.

It is important to appreciate that a large fraction of parenterally administered magnesium may be excreted in the urine, even in patients with profound magnesium deficiency. Many such patients will excrete as much as 50% to 75% of infused magnesium, whereas in normal subjects this approaches 100%.[636] Moreover, because equilibration of the intracellular and extracellular magnesium pools is relatively slow, it is generally necessary to continue magnesium therapy for 3 to 5 days to achieve adequate

repletion of the typical deficit of 1 to 2 mEq/kg. Because serum magnesium may become normal well before tissue stores are repleted, monitoring of urinary magnesium excretion is a more reliable measure of the approach to full repletion, especially after patients are switched to oral therapy.

The need for calcium, potassium, and phosphate supplementation should be considered in the usual clinical setting of hypomagnesemia. Vitamin D deficiency also frequently coexists and should be treated with oral or parenteral vitamin D or 25(OH) D. Use of $1,25(OH)_2D$ is not necessary, does not hasten recovery, and may actually worsen hypomagnesemia by suppressing PTH secretion and thereby promoting renal magnesium excretion.[673]

Initial parenteral magnesium therapy in hypocalcemic patients may produce dramatic hypophosphatemia via the rapid stimulation of PTH secretion. This is most likely to be problematic in those with underlying phosphate depletion (malabsorption, alcoholism, diabetes), in whom it may provoke acute neuromuscular dysfunction, and it may be avoided by concomitant intravenous calcium therapy.

Osteoporosis: Basic and Clinical Aspects

FRANCISCO J.A. DE PAULA, DENNIS M. BLACK, AND CLIFFORD J. ROSEN

CHAPTER OUTLINE

KEY POINTS

- The functional significance of bone has been reassessed in light of recent discoveries. In addition to the well-known mechanical support and storage of mineral, mineralized mesenchymal tissue also exports peptides critical for regulation of circulating phosphate and whole-body energy metabolism. We now have a more complete picture of the skeleton and its role in maintaining mineral and metabolic homeostasis.
- Osteoporosis has a great impact on quality of life and mortality because of its negative impact on bone strength. In the past three decades, risk factors for fractures have been exhaustively scrutinized. Online algorithms are available to help predict long-term fracture risk and are a readily available and important tool for evaluating patients. In parallel, biochemical markers of bone remodeling and imaging techniques to evaluate bone metabolism and structure, respectively, are employed for early recognition of fracture susceptibility.
- Advances in our knowledge of mechanisms driving bone loss have accelerated development of cost-effective drugs for the prevention of fractures. Moreover, ongoing studies point to additional and more effective drugs for osteoporosis. Curiously, clinical awareness for diagnosing and treating osteoporosis remains underdeveloped; unfortunately, few individuals benefit from the level of knowledge and technology available to diagnose and manage the disorder.
- Unlike available therapeutic options for other chronic disorders, osteoporosis therapy is unique in that weekly, monthly, biannual, or even annual dosing may be sufficient to accomplish successful treatment.

Historical Context

Osteoporosis is a disorder characterized by reduced bone mass, impaired bone quality, and a propensity to fracture in both men and women. Previously, this disease was considered within the context of a syndrome identified by back pain, vertebral fractures, and reduced mineralization on plain radiographs. In the past, the approach to patients with these features focused on identifying secondary causes of low bone mass and treating fractures with orthopedic intervention and pain management.[1] However, with the advent of bone density measurements, the development of new treatment options, and greater public awareness, osteoporosis emerged as a primary disease manifested in multiple ways and suitable to be managed by aggressive prevention and intervention. During this period, significant progress was also made in understanding the complex pathogenesis of the disease.[2,3] Furthermore, there have been tremendous advances in delineating the role of bone remodeling in normal physiology, particularly in defining the process of peak bone acquisition.[4] Recently, the skeleton was also found to be an endocrine organ regulating metabolic homeostasis through the release of bone-specific peptides that modulate glucose transport, phosphate balance, and muscle function.

In addition to these developments, a consensus began to emerge concerning the strength of the association between low bone mineral density (BMD) and fracture risk and about the importance of qualitative aspects of the skeleton as additional risk determinants for fractures.[5,6] Newer imaging technology has provided a window into the microstructural world of bone, and these advances now allow investigators to better understand the many diseases and drugs associated with skeletal fragility.[7,8] Great strides have also been accomplished in understanding the epidemiology of this disease and the socioeconomic impact of fractures on both patients and society. The picture that has emerged is that osteoporosis is a disease with a significant degree of morbidity and mortality risks.[9,10] Advances in the field have led to the development of drugs capable of increasing bone mass and improving bone quality that have proven to be effective in reducing the incidence of fractures. Since 1995, when US Food and Drug Administration (FDA) approval for new antiosteoporotic drugs first began, there has been a significant decline in the rate of fracture in the US population.

Unfortunately, in the past few years, this auspicious trend has reversed, attracting great interest in what has been coined the "crisis in osteoporosis treatment."[11] Although the incidence of adverse events are rare, their significance has served to understate the vast fracture prevention benefits enjoyed by the majority of patients, leading to physician underprescription and patient reluctance to use the medication. Thus, a systematic approach to understanding and treating this disease lies in appreciating the physiology of skeletal remodeling and the processes by which the basic skeletal unit becomes disordered, as well as on the appropriate use of the tools available for diagnosis and management.

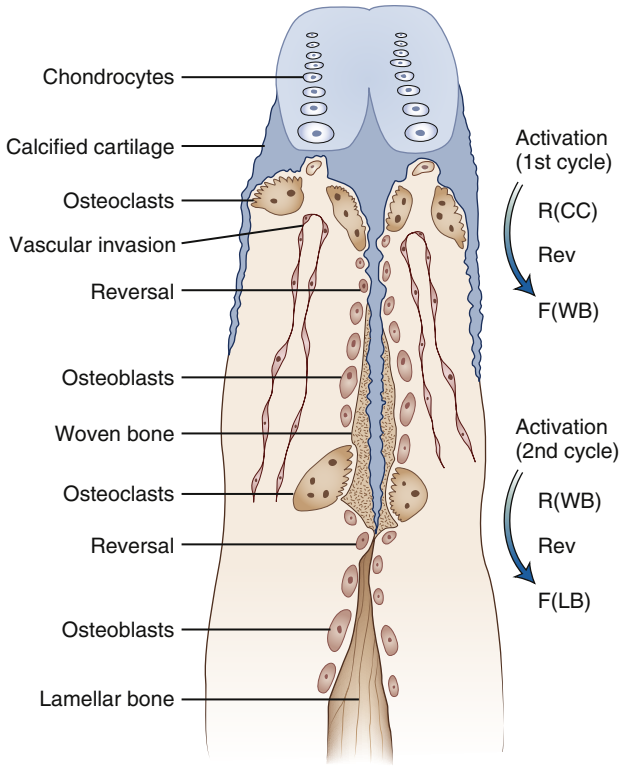
Skeletal Biology

Structure and Function of the Skeleton

The skeleton is one of the largest organ systems in the body, consisting of a mineralized matrix and a highly active cellular remodeling unit, composed of osteoblasts, osteoclasts, osteocytes, adipocytes, and lining cells. The most apparent function of the skeleton is to provide structural integrity for the organism that allows for a range of locomotor activity while concomitantly keeping additional body weight to a minimum. In addition to its structural function, the skeleton also serves as a mineral depot ensuring the maintenance of serum calcium and phosphate levels through normal remodeling processes and by secretion of bone-specific factors, such as fibroblast growth factor 23 (FGF23). Just as important, the skeleton is the home for hematopoiesis, maintaining a niche within trabecular bone elements that consists of osteoblasts, adipocytes, reticuloendothelial cells, sinusoids, and mesenchymal stromal and stem cells in a hypoxic environment. That niche provides progenitors that can respond to injuries at any site in the body for critical repair processes. Remarkably, the adult skeleton also harbors a huge adipose depot, composing 10% to 15% of all fat tissues in the body. Thus, it is clear that alterations in either the structural or metabolic functions of the skeleton have tremendous implications for the overall health of the organism.[12]

Embryology and Anatomy

Skeletal development begins early in embryonic life. The process starts with the condensation of mesenchymal cells that differentiate into a cartilaginous structure. Bone formation can then take place through one of two mechanisms: endochondral (i.e., through use of a cartilage framework and involving osteoblasts laying down true bone matrix on top of the cartilaginous matrix, followed by osteoclast-driven turnover of matrix and cells) or intramembranous bone formation, in which the mesenchymal precursors differentiate into bone-forming osteoblasts and lay down bone matrix without a cartilage template.[13] The growth of long bones and vertebrae involves endochondral bone formation. The cartilage cells in the growth plate proliferate and undergo hypertrophy; the hypertrophic chondrocytes then direct the mineralization of their matrix and, along with the action of osteoclasts, partly degrade their matrix. The cartilage is invaded by vessels, and the spicules of mineralized cartilage are covered by osteoblasts to form a cancellous or trabecular bone often called the *primary spongiosa.* These structures are resorbed and replaced by trabecular plates made up entirely of bone, called *secondary spongiosa* (Fig. 30.1). This process occurs at the ends of the long bones and in the bodies of the vertebrae.

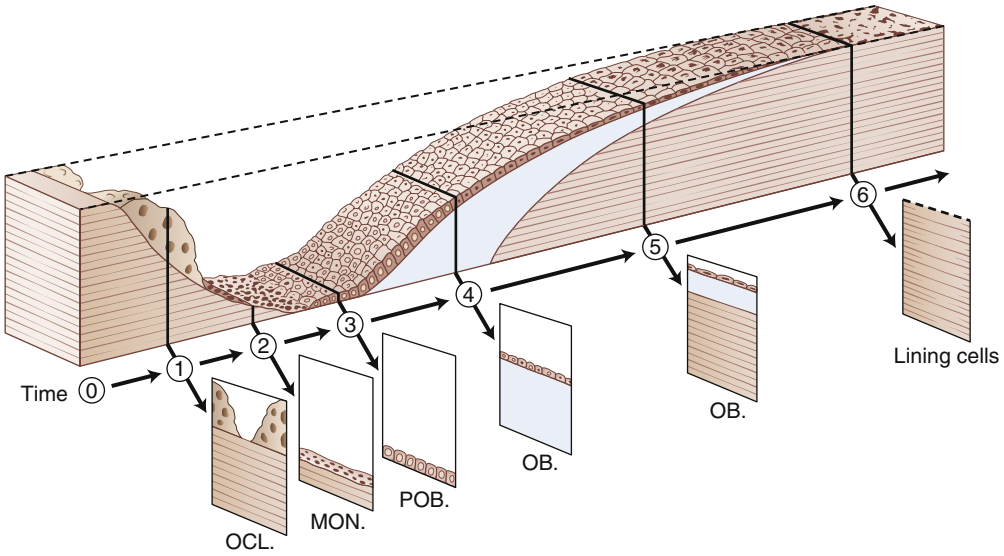


• **Fig. 30.1** Steps in endochondral bone formation. *CC,* calcified cartilage; *F,* formation; *LB,* lamellar bone; *R,* resorption; *Rev,* reversal; *WB,* woven bone. (Redrawn from Baron R. Anatomy and ultrastructure of bone. In: Favus MJ, ed. *Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism.* 2nd ed. New York, NY: Lippincott-Raven; 1993:3–9. Copyright 1993, American Society for Bone and Mineral Research.)

Intramembranous bone formation occurs next to the cartilage template in flat bones, such as the skull, scapula, and ileum, and on the outer surfaces of long bones, leading to periosteal apposition and expansion. Woven bone, with disordered fibrils of collagen I and a disorganized osteocyte network, is formed during the early stages of intramembranous acquisition but then becomes more organized as lamellar bone is produced by oriented layers of osteoblasts. As noted previously, the main difference between endochondral and intramembranous bone formation is that the latter does not use calcified cartilage as a direct template for osteoblasts.

Cortical bone is dense bone found in the shafts of long bones. It makes up 80% of the mass of the skeleton, determines its shape, and provides much of its strength. During longitudinal skeletal growth, endochondral and periosteal appositional bone formation determine the length and width of the bones.[4] New cortical bone is shaped by a process called *modeling*, in which osteoblast activity occurs uncoupled to osteoclastic bone resorption. Modeling leads to skeletal shape changes, which are critical for defining the strength of bone. Importantly, modeling is influenced by mechanical forces and is increased during the adolescent growth spurt.[4] As bones elongate, the wide cortex formed just below the growth plate must be sculpted by the modeling/resorption process to allow these bones to elongate while maintaining and extending the narrow tubular structure of the diaphysis.

Bone remodeling is an essential element of skeletal activity that provides skeletal stability and elasticity. It is the process that defines adult bone mass and maintenance (Fig. 30.2).



• **Fig. 30.2** Three-dimensional reconstruction of the remodeling sequence in human trabecular bone. *1*, Early bone resorption with osteoclasts (OCL). *2*, Late bone resorption with mononuclear cells (MON). *3*, Reversal phase with pre-osteoblasts (POB). *4*, Early matrix formation by osteoblasts (OB). *5*, Late bone formation with mineralization. *6*, Completed remodeling cycle with reversion to lining cells. (From Eriksen EF. Normal and pathological remodeling of human trabecular bone: three dimensional reconstruction of the remodeling sequence in normals and in metabolic bone disease. *Endocr Rev*. 1986;7:379–408. Copyright 1986 by The Endocrine Society.)

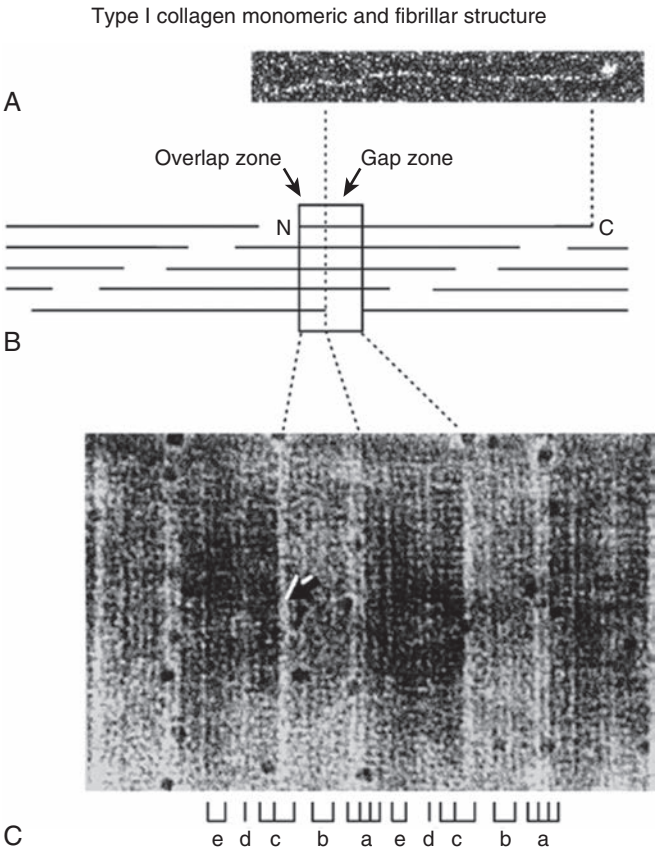
Remodeling is temporally orchestrated to maintain a balance between the amount of bone formed and the amount resorbed. Basic multicellular units (BMUs) carry out bone remodeling and consist of osteoblasts, osteoclasts, bone lining cells, and osteocytes. Remodeling is more active in cancellous or trabecular bone than in cortical bone.[14] In smaller animals, such as rodents, cortical bone can remain lamellar. In large animals and humans, lamellar cortical bone is gradually replaced through haversian remodeling to form cylindrical osteons. The initiation of bone remodeling is directed by endocrine, paracrine, and autocrine factors. The osteocyte, communicating by release of factors through tiny canaliculi, is thought to initiate the remodeling process, providing signals to both the lining cell and the osteoblast.[15] These cells can then signal to attract the osteoclast to the remodeling site where bone resorption occurs. This is followed by the release of matrix proteins that, in combination with osteoclast-derived factors, direct osteoblast differentiation, collagen synthesis, and ultimately matrix mineralization.

Bone Matrix and Mineral

The bone matrix consists of fibers of type I collagen laid down in layers that have various orientations, a portion of which in the mammalian skeleton may be disordered but still adds to the strength of the matrix (Figs. 30.3 and 30.4). The matrix contains several additional proteins, including other collagen types that may be important in the interaction of type I collagen with noncollagen proteins within the matrix. The noncollagen proteins, such as osteocalcin and several proteoglycans, represent about 10% of the total protein in bone and may direct the formation of fibers, mineralize bone, regulate the attachment of bone cells to its matrix, and play a role in the function of bone-forming and resorbing cells.

Protein composition of the matrix may vary, particularly between woven and lamellar bone.[16] The proteins range from the large cell-attachment proteins (e.g., thrombospondin, fibronectin), which have molecular masses higher than 400 kDa, to the small, vitamin K–dependent γ-carboxylated proteins (e.g., matrix Gla protein and osteocalcin), which are 6-kDa calcium-binding proteins. Osteocalcin can be incompletely or totally carboxylated depending on the number of glutamic acid sites within the molecule that are changed to γ-carboxylated glutamic acid by vitamin K–dependent enzymes; incomplete γ-carboxylation may represent the action of inhibitors such as warfarin or the action of decarboxylating processes. Undercarboxylated osteocalcin (GLU13-OCN) is released from the skeletal matrix during bone resorption (see later discussion). Some noncollagen proteins (e.g., biglycan, decorin, bone sialoprotein, osteopontin, osteoadherin) are highly acidic and play an important role in signaling and in the matrix of the hematopoietic niche. In addition to cell-attachment sequences, these proteins contain various amounts of carbohydrate and are called *glycoproteins* or *proteoglycans*. Noncollagen proteins of bone are often highly phosphorylated, which enables them to bind calcium, and thus may regulate mineralization. Genetic manipulations in experimental mouse models have provided important information on the function of noncollagenous proteins. For example, null mutations of the osteonectin gene lead to osteopenia in some studies, indicating that this matrix protein may be important for the maintenance of a normal bone structure.[17] However, deletion of the osteocalcin gene has been shown to increase bone mass.[18]

Osteocalcin null mice also have a striking body composition and insulin sensitivity phenotype.[19] Studies principally from the Karsenty laboratory, but now validated by other groups, have shown that GLU13-OCN is released from the skeletal matrix and can bind to a G protein–coupled receptor on the surface of beta cells and adipocytes.[20] This results in enhanced insulin production and greater glucose transport in adipocytes. Moreover, insulin itself can stimulate release of matrix GLU13-OCN. This activity requires the co-participation of osteoclasts, integrating bone remodeling in the regulation of insulin sensitivity. Insulin



• **Fig. 30.3** Type I collagen monomeric and fibrillar structure. (A) By rotary shadowing electron microscopy, procollagen (≅300 nm long) appears as a rope-like triple helix to which globular carboxy (C)-terminal (to the right) and amino (N)-terminal domains are attached. (B) Chapman's model of the collagen fibril. Diagram showing the arrangement of tropocollagen monomers within the collagen fibril, relative to the location of the overlap and gap zone fibril staining pattern. Tropocollagen molecules are shown as horizontal rods, and the polarity of all monomers in the fibril is indicated by *N* (NH2 terminus) and *C* (COOH terminus) markings on one monomer. (C) Electron micrograph of glutaraldehyde-fixed, heparin-gold type I collagen fibril complexes, in fibrils visualized by uranyl acetate staining. Letters below the micrograph show positions of positively stained fibril bands, following the accepted notation. Dotted lines between the molecular model in (B) and the electron micrograph show corresponding overlap and gap zones. The location of heparin-gold particles relative to the molecular structure of the fibril can be measured within each 67-nm period, beginning at the center of the left border of the overlap zone (origin, *arrow*), and extending to the center of the right border of the gap zone. Heparin-gold particles appear as circular dark objects present mainly in the "a" bands region of the fibrils. (From San Antonio JD, Lander AD, Karnovsky MJ, Slayter HS. Mapping the heparin-binding sites on type I collagen monomers and fibrils. *J Cell Biol*. 1994;125:1179–1188 by copyright permission of The Rockefeller University Press.)

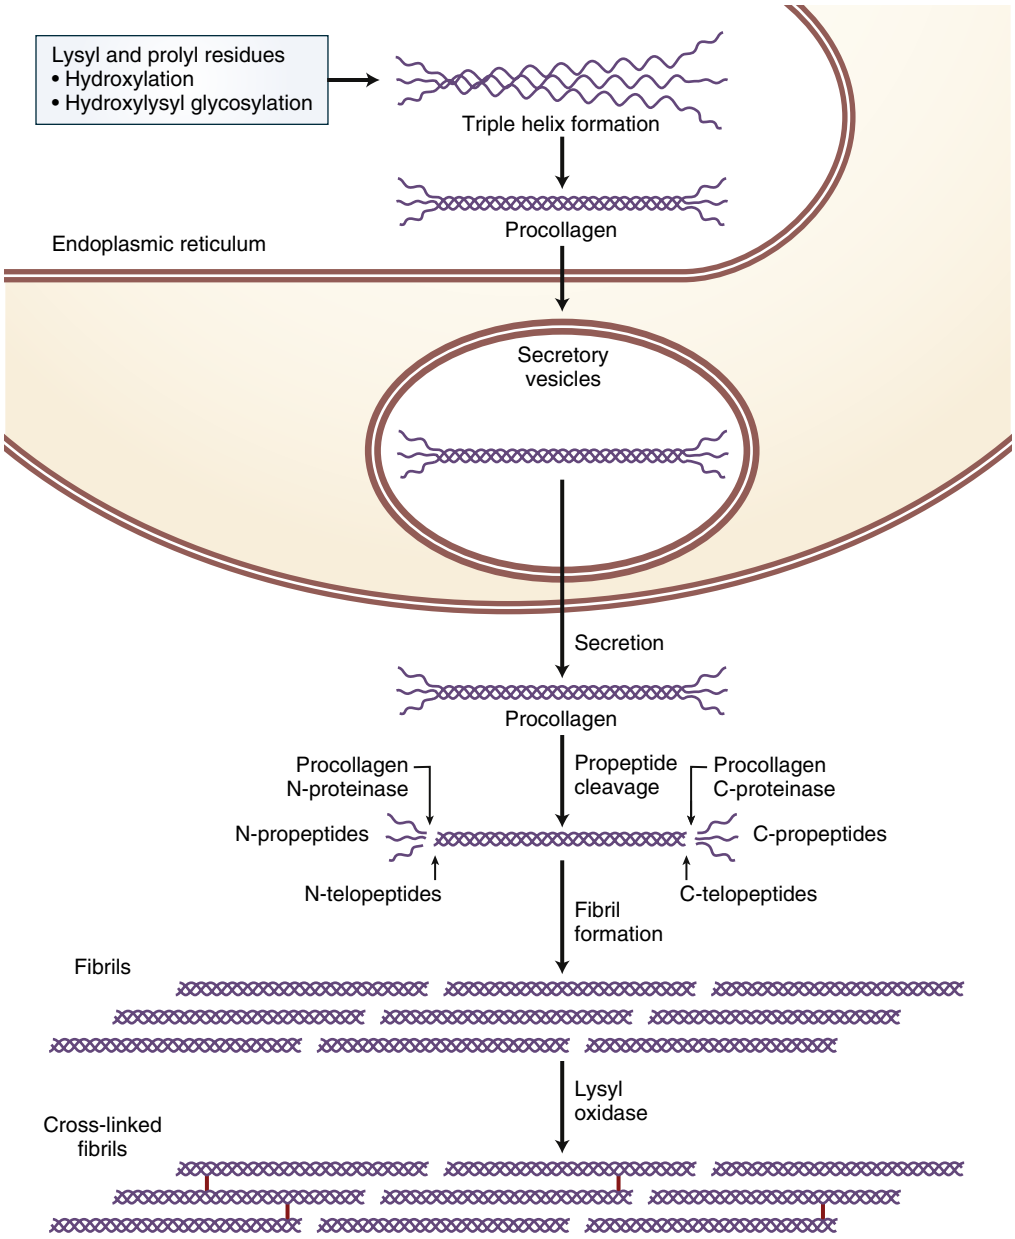
signaling in osteoblasts downregulates osteoprotegerin (OPG) via the forkhead box protein O1 (FOXO1), thereby enhancing osteoclastogenesis and ultimately greater bone resorption. The resultant increased osteoclastic activity creates the conditions necessary for acid-mediated decarboxylation of γ-carboxyglutamate residues[21,22] (Fig. 30.5). This was the first of several remarkable studies demonstrating the endocrine nature of the skeleton, in this case due to release of matrix proteins. Importantly, this finding led to even greater insights into the role of the skeleton in modulating energy metabolism.

Collagen Synthesis

Type I collagen is the most abundant protein of the bone matrix. It is a rigid, rod-like, insoluble molecule composed of two α1 chains and one α2 chain[23,24] (see Fig. 30.4). Collagen chains consist of repeating triplets of amino acids, with glycine in every third position and a high content of proline and lysine. The two α1 and the α2 collagen chains form a triple helix that is stabilized by the hydroxylation of proline and lysine residues and requires ascorbic acid. Collagen is synthesized as a soluble proprotein with large nonhelical extensions at the carboxy (C)- and amino (N)-terminal ends. Procollagen also contains C-terminal interchain disulfide bonds that help to initiate formation of the triple helical structure. Procollagen is released into the cisternae of the rough endoplasmic reticulum, packaged in the Golgi vesicles, and secreted extracellularly. The procollagen peptide ends are then removed by specific peptidases to produce mature insoluble collagen molecules, which are further stabilized by intramolecular and intermolecular cross-links. The major collagen cross-links are formed by lysine and hydroxylysine residues that ultimately form pyridinium ring structures (Fig. 30.6). In addition, nonenzymatic cross-links are formed as a result of reactions that create advanced glycation end products (AGEs), such as pentosidine. With advancing age, and particularly in the presence of diabetes mellitus, this process is more pronounced, compromising the structure and functional role of type I collagen in bone.[25]

Mineralization

Bone mineral is formed by small, imperfect hydroxyapatite crystals, which contain carbonate, magnesium, sodium, and potassium in addition to calcium and phosphate. Mineralization occurs by two distinct mechanisms, one outside the cell and catalyzed by alkaline phosphatase, and one in matrix vesicles that is accelerated by the enzyme phospho1.[26] Both enzymes are critical for adequate mineralization, the former acting to enhance the breakdown of pyrophosphate, an inhibitor of calcium-phosphate precipitation, and the latter to accelerate phosphate availability within the matrix by acting on phosphocholine and phosphoethanolamine. The initial mineralization of calcified cartilage and woven bone probably occurs by means of matrix vesicles.[26] These membrane-bound bodies are released from chondrocytes and osteoblasts, contain alkaline phosphatase, and can form a nidus for crystallization in the presence of adequate phosphate. In contrast, in lamellar bone, the collagen fibers are tightly packed, and matrix vesicles are rarely seen. Mineralization does not occur immediately after collagen deposition, and there is a layer of 10 to 100 μm of unmineralized osteoid between the mineralization front and the osteoblast. Changes in the packing of the fibrils and in the composition of the noncollagen proteins may be required for mineralization. A group of proteins, named SIBLINGs (small, integrin-binding ligand, N-linked glycoprotein), synthesized in osteocytes (i.e., osteopontin, dentin matrix protein 1 [DMP1], bone sialoprotein, and matrix extracellular phosphoglycoprotein [MEPE]), have a crucial role in the deposition of calcium into bone matrix. SIBLINGs combined with several endopeptidases, including phosphate-regulating endopeptidase homolog, X-linked (PHEX) modulate phosphate metabolism through the regulation of FGF23 synthesis, but also affect osteoclastogenesis and energy metabolism.[27,28] Mineralization of collagen fibrils begins in the *hole zones* of the calcium fibrils, where there is more room for inorganic ions to accumulate (see Fig. 30.3). Mineralization requires calcium, phosphate, and alkaline

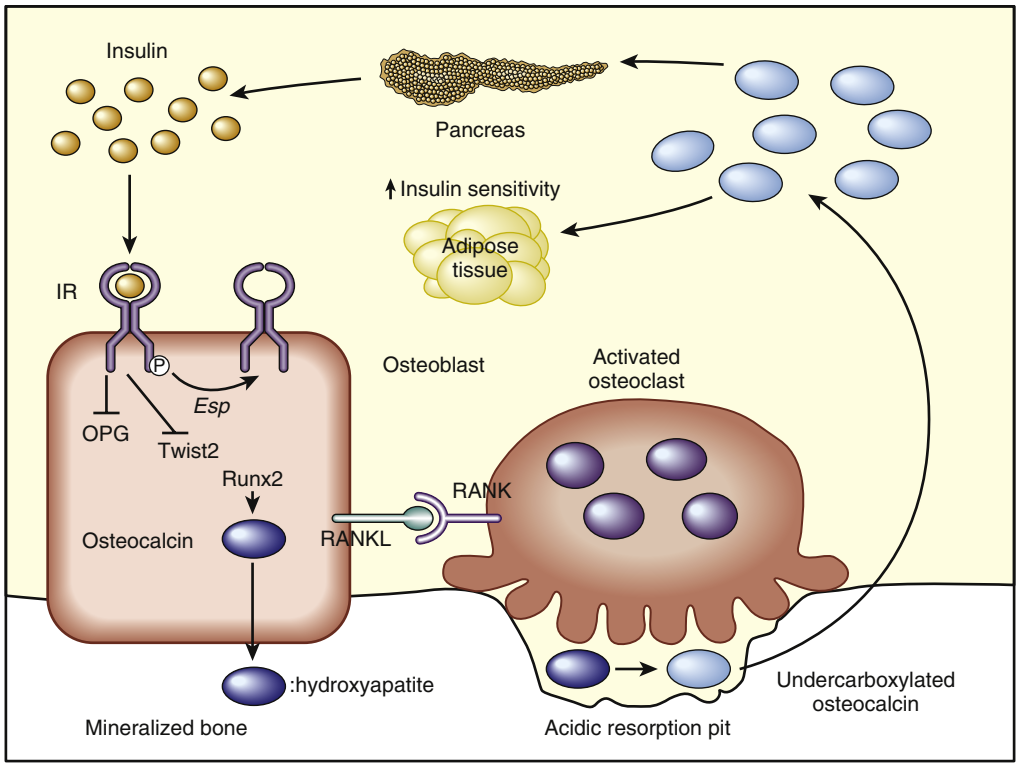


• **Fig. 30.4** Schematic diagram showing the different post-translational modifications and assembly of type I collagen into fibrils. (Modified from Myllyharju J, Kivirikko KI. Collagens, modifying enzymes and their mutations in humans, flies and worms. *Trends Genet.* 2004;20:33–43 and Viguet-Carrin S, Garnero P, Delmas PD. The role of collagen in bone strength. *Osteoporos Int.* 2006;17:319–336, with permission.)

phosphatase. This process is impaired in circumstances of vitamin D deficiency, very low calcium intake, hypophosphatemia, mutation in the gene encoding alkaline phosphatase, and importantly by the mineralization inhibitor pyrophosphate.[29] The characteristic feature of undermineralization on bone biopsy is greater osteoid (i.e., newly synthesized, nonmineralized collagen at the bone surface), and the most dramatic undermineralization occurs in the syndrome of hypophosphatasia, which is due to an absence of total nonspecific alkaline phosphatase. Recent work using a recombinant form of alkaline phosphatase has shown promising results by promoting complete mineralization of the skeleton and improvement in quality of life of patients with hypophosphatasia.[30]

Collagen Degradation by Osteoblasts and Osteocytes

As part of the bone remodeling process, collagen is cleaved and degraded by a group of proteases called *collagenases*. They are matrix metalloproteases (MMPs) that can initiate cleavage of collagen fibrils at neutral pH, and they are central to the process of collagen degradation, matrix breakdown, and bone remodeling. Three collagenases in bone have been described: collagenase 1 (MMP1), 2 (MMP8), and 3 (MMP13).[31] Human osteoblasts express the collagenase 1 and 3 genes (*MMP1* and *MMP13*). Resting osteoblasts secrete limited amounts of collagenase, and changes in the synthesis of collagenase correlate with changes in bone resorption. Collagenase plays a critical function in bone remodeling. Mice with deletions of the collagenase 3 gene or mutations of the



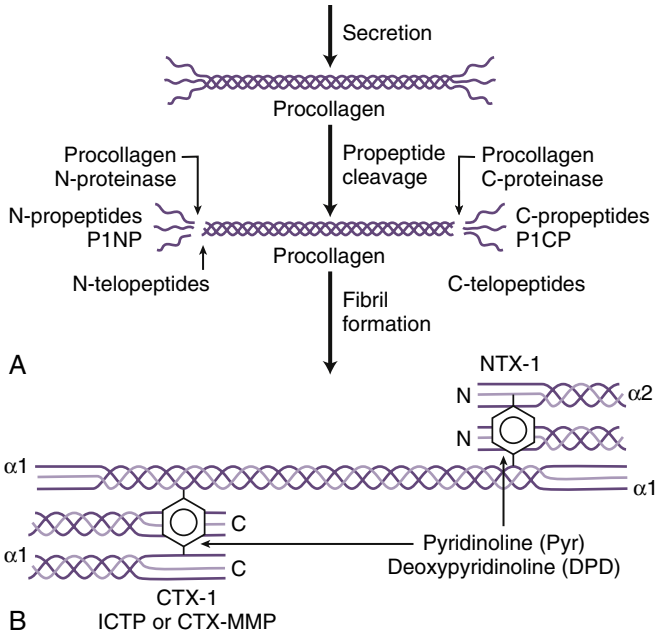
• **Fig. 30.5** Energy regulation and bone turnover by the insulin/osteocalcin Axis. A putative feed-forward regulatory loop ties bone turnover to energy regulation as proposed by Ferron and associates[22] and Fulzele and colleagues.[21] Insulin activates skeletal remodeling (i.e., increases bone formation by osteoblasts and resorption by osteoclasts), which in turn releases uncarboxylated osteocalcin from the skeletal matrix into the circulation. This enhances insulin secretion and increases the insulin sensitivity of adipocytes. A tyrosine phosphatase OST-PTP, which is encoded by the *Esp* gene, binds the insulin receptor (IR) and suppresses its activation through dephosphorylation. The transcription factor Twist2 is a critical downstream suppressor of osteoblast differentiation. Osteoprotegerin (OPG) is an osteoblast-specific inhibitor of receptor activator for nuclear factor κB ligand (RANKL), acting as a decoy receptor to block bone resorption. Hydroxyapatite is the mineral component of bone. (From Rosen CJ, Motyl KJ. No bones about it: insulin modulates skeletal remodeling. *Cell*. 2010;142[2]:198–200.)

α1[32] type I collagen gene have resistance to collagenase 3 cleavage and fail to resorb bone after exposure to parathyroid hormone (PTH).[33] The synthesis of collagenase by osteoblasts is regulated by hormones and by cytokines in the bone microenvironment that act by transcriptional and post-transcriptional mechanisms.[34] It should be noted that although cleavage by collagenase is an early and obligatory event, most degradation of collagen during remodeling is accomplished by osteoclasts that secrete protons and enzymes (e.g., cathepsin K) that solubilize mineral and degrade the matrix. Cleavage of collagen fragments leads to their excretion in the urine, in which sensitive assays can detect the N-terminal or C-terminal fragments (see later discussion).

Recent evidence points to the participation of osteocytes in aspects of remodeling. Osteocytes are terminally differentiated osteoblasts that are buried within the matrix of the skeleton but possess receptors for PTH and have metabolic activity. These cells are arranged in a functional unit termed the *osteon* that includes an elaborate dendritic network that communicates with the bone surface and probably participates in mechanical sensing. Osteocytes also are a rich source of receptor activator for nuclear factor κB ligand (RANKL), which enhances osteoclast differentiation, particularly during states of increased calcium demand, such as lactation, or immediately following estrogen deficiency. Moreover, osteocytes can secrete enzymes that directly degrade bone matrix in a process called *osteocytic osteolysis*, likely through elaboration of acid phosphatase and collagenases. Whether osteocytes also secrete alkaline phosphatase and participate in normal skeletal remodeling per se is still open to debate.

Bone Lining Cells, Osteoblasts, and Osteocytes

Bone is formed by *osteoblasts*, which are terminally differentiated cells that do not undergo mitosis and have many unique features (Fig. 30.7). Osteoblasts are derived from mesenchymal cells in the skeletal microenvironment.[35] Some osteogenic precursors may appear in the circulation, particularly during growth or following injury; they originate from skeletal tissue, and their contribution to bone formation is not certain. Osteoprogenitor cells, or preosteoblasts, replicate and differentiate into active osteoblasts that exhibit various phenotypic characteristics.[36] For example, osteoblasts in early development and during repair produce woven bone, whereas more mature osteoblasts produce lamellar bone. Osteoblast activity varies during bone formation. Some cells are tall and closely packed and produce a large amount of matrix in a small area; others are flatter and produce matrix at a slower rate over a larger area. Nevertheless, all differentiated osteoblasts share certain features. They are connected by gap junctions and contain a dense network of rough endoplasmic reticulum and a large Golgi complex, and they secrete collagen and noncollagen



• **Fig. 30.6** (A) During bone formation, the type I collagen molecule is synthesized as procollagen, and then amino (N)-terminal and carboxy (C)-terminal propeptides (P1NP and P1CP, respectively) are cleaved. The central part of the molecule, triple helix of collagen, is incorporated into bone matrix. (B) During bone resorption, different products of the breakdown of type I collagen are produced: cross-linked molecules (pyridinoline [Pyr], deoxypyridinoline [DPD]), C-terminal and N-terminal cross-linked telopeptides generated by cathepsin K (CTX-I and NTX-I, respectively), and C-terminal telopeptide generated by metalloproteinases (ICTP or CTX-MMP). (Redrawn from Szulc P, Kaufman JM, Delmas PD. Biochemical assessment of bone turnover and bone fragility in men. *Osteoporos Int.* 2007;18:1451–1461.)

proteins in an oriented fashion. Some products, such as osteocalcin, are synthesized almost uniquely by osteoblasts and osteocytes. A large proportion of the osteocalcin originating from osteoblasts is deposited in the matrix and subsequently released during bone remodeling. Hence, changes in serum levels of osteocalcin reflect bone turnover rather than bone formation per se. As noted previously, GLU13-OCN may serve as an endocrine hormone prompting insulin secretion and enhancing insulin sensitivity in peripheral tissues.

Mature osteoblasts have a finite capacity to produce matrix, and bone formation is sustained by the arrival of new populations of cells at the bone surface. The number and function of osteoblasts are determined by hormones, local growth factors, and cytokines. Some act as classic cell mitogens and increase the population of pre-osteoblastic cells, some determine their differentiation into mature osteoblasts, and others modify the function of mature cells or enhance osteocytic formation.[37] The ultimate fate of mature osteoblasts varies. They may die by apoptosis; they may become embedded in the matrix and become osteocytes; or they may be converted to flattened lining cells, which synthesize little protein and cover a large percentage of the surface of bone with a thin cytoplasmic layer (i.e., the bone lining cell) (see Fig. 30.7).

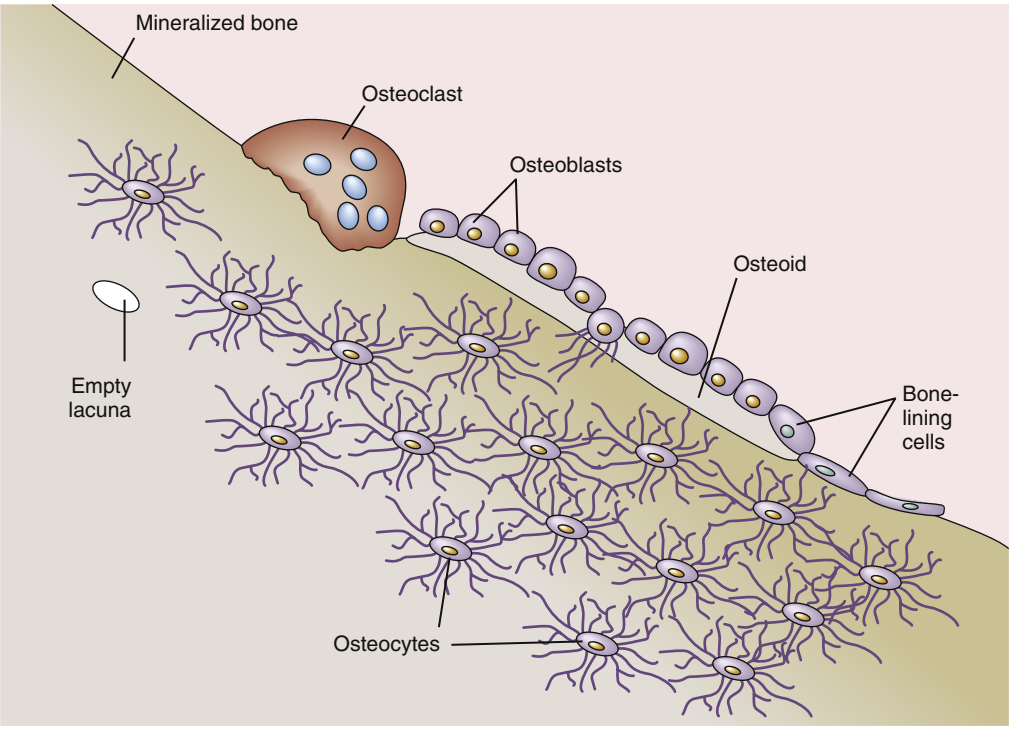
The bone lining cells are flattened and have a fibroblastic-like appearance. Recent work has begun to clarify the role of these lining cells as more active participants in the remodeling unit, in a manner similar to the osteocyte rather than purely quiescent cells. For example, bone lining cells express *osterix* (Sp7), which is a major transcription factor for osteoblast differentiation. In addition, these cells are in communication through small canaliculi with osteocytes buried within the matrix and express similar markers of differentiation. In response to PTH, which is a bone remodeling stimulant, bone lining cells differentiate into osteoblasts and thus become a pool of reserve cells necessary during accelerated turnover within the remodeling unit.[38] Bone lining cells also express stem-like genes that potentially indicate that there could be dedifferentiation of osteoblasts or that these cells are another reservoir for skeletal or even adipogenic progenitors (see later discussion).

Bone marrow stroma contain pluripotent cells that can differentiate into diverse cells of mesenchymal lineage, including osteoblasts, chondrocytes, and adipocytes[35] (Fig. 30.8). The ultimate cellular phenotype depends on factors present in the cellular microenvironment, the degree of hypoxia, the biochemical and metabolic signature of these cells, and their effects on intracellular signals and gene expression. The types and numbers of transcription factors are nuclear proteins that bind to DNA to regulate gene transcription. Some can determine the fate of undifferentiated cells, although the process is complex and includes metabolic determinants such as sufficient mitochondrial and glycolytic machinery.[39]

CCAAT/enhancer-binding proteins β and δ and peroxisome proliferator-activated receptor γ (PPARγ) play an essential role in the differentiation of cells toward adipocytes, whereas runt-related transcription factor 2 (RUNX2) plays a central role in the differentiation of cells toward osteoblasts.[40,41] Targeted disruption of the *RUNX2* gene results in disorganized chondrocyte maturation and a complete lack of bone formation due to an arrest of osteoblast development.[42]

Osterix (Sp7) is another transcription factor that is required for endochondral and intramembranous bone formation. It is regulated by RUNX2 and thought to be the next stage in osteoblast differentiation. *Sp7* null mice fail to develop a mineralized skeleton because of an arrest of late stages of osteoblast differentiation. Interactions between nuclear factors are common steps in the regulation of transcription and differentiation.[43] Osterix associates and acts cooperatively with a nuclear factor of activated T cells (NFAT), a transcription factor that regulates osteoblastogenesis and osteoclastogenesis.[44] CCAAT/enhancer-binding proteins can interact with RUNX2 and with the activating transcription factor (ATF)/cyclic adenosine monophosphate response element–binding protein family of proteins. ATF4 plays a central role in osteoblastic function, and its activity is regulated by a nuclear matrix attachment region binding protein, SATB2, which interacts with ATF4 and RUNX2 to regulate osteoblast differentiation.[45]

The conversion of osteoblasts to osteocytes involves a change in metabolic activity and the development of an extensive network of dendrite-like processes that communicate with those on adjacent osteocytes and cells of the bone surface (Fig. 30.9). Both osteoblasts and bone lining cells contain cell processes that are connected to underlying osteocytes through small canaliculi. After mineralization is complete and the osteocyte is encased in mineralized bone, these processes maintain connections among osteocytes and allow for at least two important features that are essential for the multicellular unit. First, the extended syncytium with its extensive canalicular network that allows rapid diffusion of small molecules from the marrow space, along with cell-cell junctions that allow transport from the cytoplasm of one osteocyte directly to that of another, is important for supporting the viability of the osteocytes. Second, it allows a constant exchange of information



• **Fig. 30.7** Microstructure of an actively remodeling trabecular bone surface. The osteoclast initiates the remodeling cycle by resorbing an area of bone matrix, immediately followed by osteoblast differentiation and osteoid (unmineralized bone matrix) production to replace the resorbed bone. During this process, a small fraction of osteoblasts differentiate further to become osteocytes, encasing themselves within the mineralizing bone matrix and joining the osteocyte network. Mature bone surfaces are populated with bone lining cells, whose origin and function remain unclear. (From DiGirolamo DJ, Clemens TL, Kousteni S. The skeleton as an endocrine organ. *Nat Rev Rheumatol.* 2012;8[11]:674–683.)

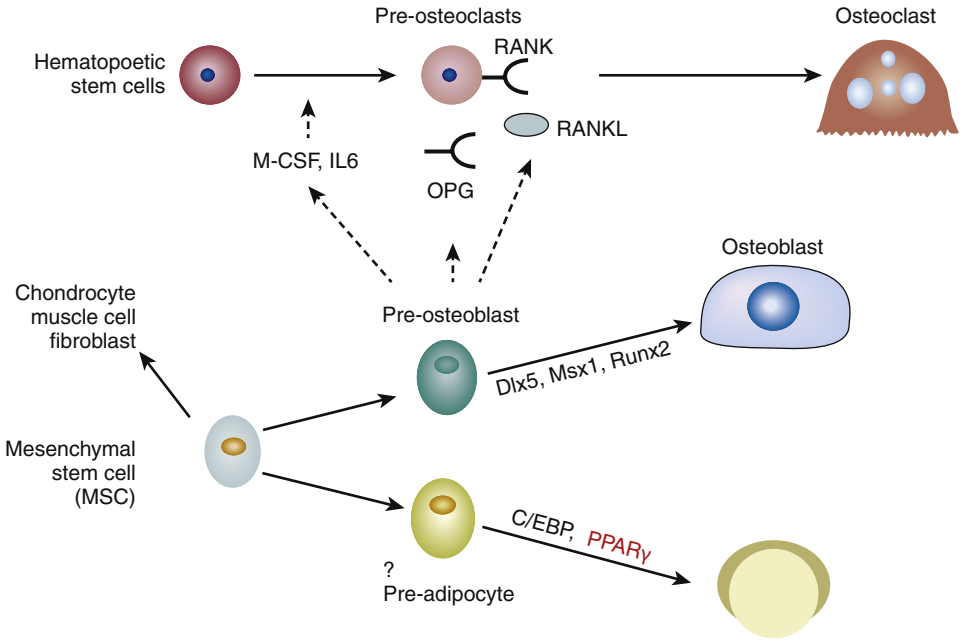
in the form of secreted factors between the endocortical surface and the matrix to regulate remodeling, as well as potential recruitment of precursors, such as the bone lining cells (Fig. 30.10; see Fig. 30.9).

Initially, osteocytes may continue to synthesize collagen and play a role in mineralization. Later, the major role of the osteocyte-osteoblast syncytium may be to sense mechanical forces.[46] Osteocytes probably sense bone deformation, as well as fluid shifts, and provide signals for the adaptive remodeling of bone size and shape.[46] One hypothesis is that small strains produce fluid shear stress in the canaliculi between osteocytes. This effect may result in intracellular signaling through changes in ion channels or in the production of biologically active molecules. Regions of bone microdamage contain apoptotic osteocytes, which may provide signals for the initiation of bone remodeling by osteoclasts and the consequent removal of damaged bone.[23]

Cells of the osteoblastic lineage are important for forming bone and for initiating bone resorption. Both mature osteoblasts and osteocytes may play a role in activating resorption. Most of the hormonal factors that stimulate bone resorption act on cells of the osteoblastic lineage. They stimulate the synthesis and perhaps release of RANKL and colony-stimulating factor 1 (CSF1), which are essential for osteoclastogenesis.[46,47] Osteoblasts also produce additional factors that regulate bone resorption, including cytokines, prostaglandins, and local growth factors. In cell culture, contact between osteoblastic cells and hematopoietic cells appears to be necessary for osteoclast formation (Fig. 30.11). Osteoblasts, as noted earlier, may also play a role in initiating bone resorption by releasing collagenases, other metalloproteinases, and plasminogen activator. These enzymes may remove the surface proteins of bone, which prevent the access of osteoclasts to the mineralized matrix. Osteoblasts also influence the development and maintenance of the marrow through their production of growth factors, cytokines, and chemokines that regulate the growth and development of hematopoietic cells.

Osteoclast Differentiation and Function

Osteoclasts are derived from hematopoietic progenitors and are myeloid in origin. Hematopoietic stem cells under the direction of cytokines and possibly cell-cell interactions express transcription factors that define their commitment to the osteoclast lineage (Fig. 30.12). CSF1 (i.e., macrophage CSF [M-CSF]) is the major cytokine regulating the replication and development in bone marrow of progenitor cells that are capable of differentiating into osteoclasts. Expression of the transcription factor SPI1 (formerly called *PU.1*) is also necessary for the osteoclast precursor cell to develop.[48] In bone marrow, the osteoclast precursor cell is multipotent and can differentiate into monocyte-macrophages, dendritic cells, or pre-osteoclasts.[49] The latter fuse to form highly differentiated, multinucleated osteoclasts that resorb bone. Osteoclasts also exhibit other remarkable characteristics, including a high number of mitochondria, the capacity to function in both oxygenated and hypoxic environments, and susceptibility to apoptosis.[50] Progression through the osteoclast pathway is influenced by multiple local and systemic hormones that may include 1,25-dihydroxyvitamin D [1,25$(OH)_2$D], prostaglandins, and the cytokines interleukin 1 (IL1), IL6, and tumor necrosis factor (TNF). Osteomacs are macrophages in the bone remodeling unit and may be important for



• **Fig. 30.8** For a mesenchymal stem cell to become an osteoblast, activation of several key factors, such as Runx2, BMP 2, TGFβ, and transcription factor Sp7 (osterix), are necessary, although the precise sequence of events in this cascade has not been fully clarified. In contrast, to achieve full adipocytic differentiation, there are two groups of critical factors already present in mesenchymal stem cells that need to be activated: C/EPBs α, β, and δ, and PPARs α, γ2, and δ. PPARγ2 activation by endogenous (e.g., prostaglandin J_2, long-chain and oxidized fatty acids) or exogenous (e.g., rosiglitazone) ligands dramatically shifts allocation of mesenchymal stem cells toward the adipocytic pathway and away from the osteoblast lineage. In vitro, this shift is characterized as an *either/or* allocation: *either* the cell becomes a fat cell *or* it becomes a bone cell, but not both. Inflammatory cytokines can be released from adipocytes, and circulating hormones such as leptin, adipsin, adiponectin, and resistin are also produced by fat cells. The *solid arrows* represent confirmed networks for regulation, and the *dashed arrows* represent potential regulatory pathways. development of a canopy over the remodeling unit and clearance of degraded proteins, as well as antigen presentation. Additionally, osteomacs may participate in the removal of "old" osteoblasts.

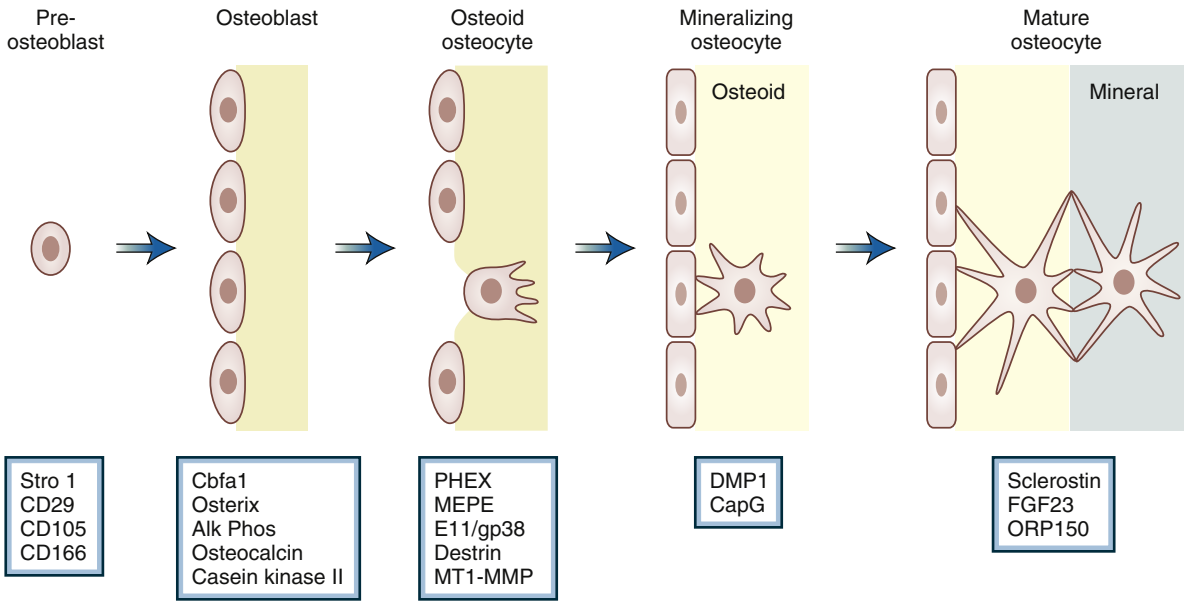
The nature of the osteoblast-lineage cell products, which directly regulate osteoclast formation and function, has been clarified.[47] The principal stimulator of osteoclast formation is RANKL, a member of the TNF protein superfamily. This protein was originally identified as a product of activated T lymphocytes, but it is also recognized as a critical stimulator of osteoclastogenesis from mesenchymal stromal cells, pre-osteoblasts, osteocytes, and hypertrophic chondrocytes. Production of RANKL in osteoblast-lineage cells is stimulated by essentially all agents that enhance osteoclast formation, including PTH, $1,25(OH)_2D$, prostaglandins, and many cytokines. Mice that are deficient in RANKL do not form osteoclasts and have osteopetrosis. In contrast, injection of RANKL into mice stimulates osteoclast formation and bone resorption but may also be associated with increases in marrow adiposity. RANKL is produced as a membrane protein; in activated T lymphocytes, RANKL is cleaved from the cell membrane and is released as a soluble factor.[51] It is unclear whether similar events occur in osteoblast-lineage cells, although there is some evidence that cleavage and release of soluble RANKL occurs in malignant cells that metastasize to bone.

OPG is a native inhibitor of osteoclastogenesis; it is a soluble receptor for RANKL that binds this ligand and prevents interaction of RANKL with its cognate receptor, RANK. OPG is produced widely. In bone marrow cultures, a number of stimulators of resorption, including PTH, $1,25(OH)_2D$, and prostaglandin E_2 (PGE_2), inhibit OPG production. For these factors, there is a reciprocal relationship between RANKL stimulation and OPG inhibition that causes activation of osteoclastogenesis and enhanced resorption. Mice that are deficient in OPG have osteoporosis, whereas mice that overexpress OPG have increased bone mass. These results, together with those for RANKL-deficient mice and mice injected with RANKL, demonstrate that osteoclast-mediated bone resorption is tightly regulated by the combined actions of RANKL and OPG.

The active receptor for RANKL is RANK, a member of the TNF receptor superfamily. Osteoclasts and their immediate precursor cells express RANK, and this expression is induced



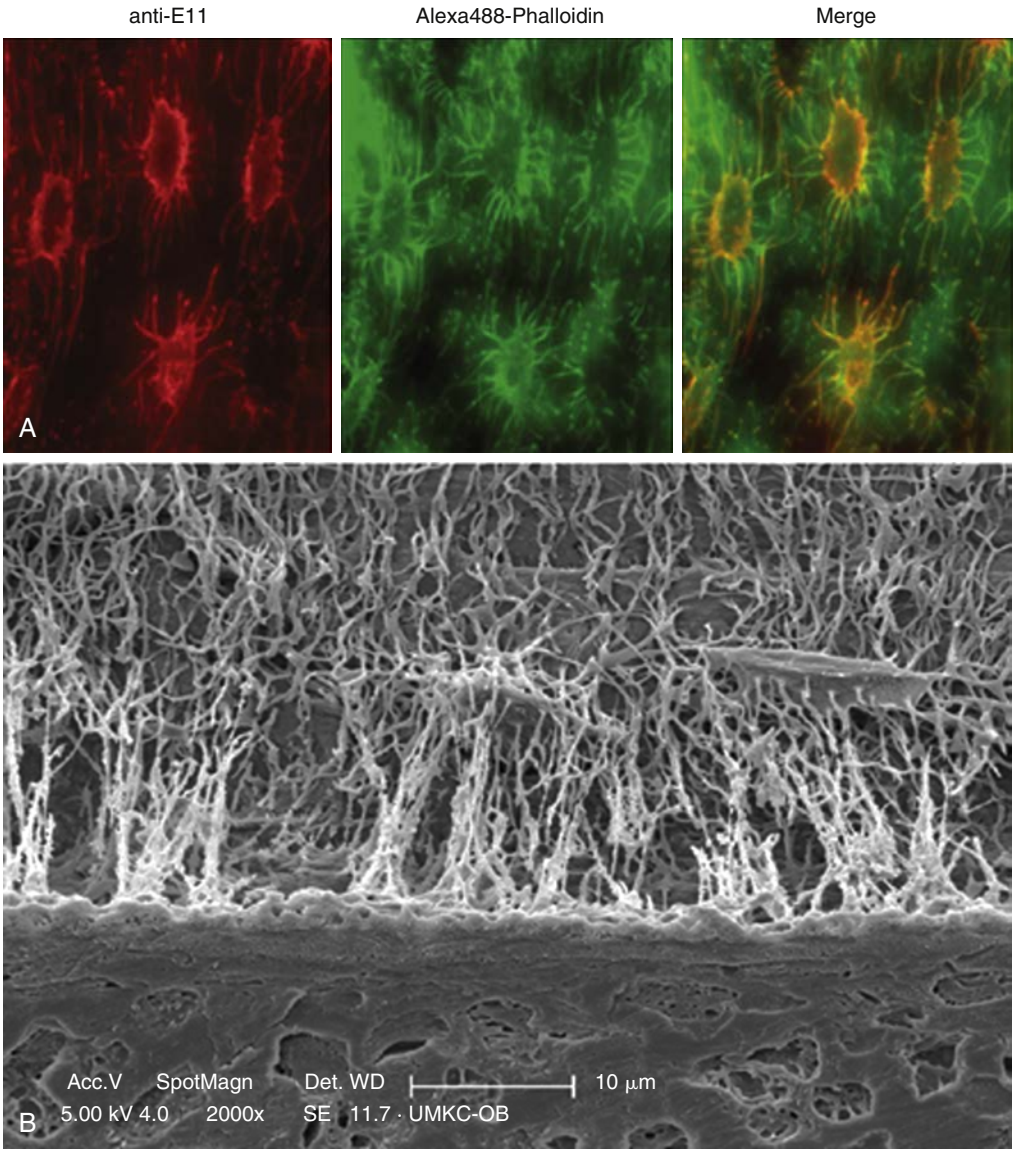
• **Fig. 30.9** Expression of markers during osteoblast-to-osteocyte ontogeny. The osteocyte appears to be the descendant of the matrix-producing osteoblast, which is a descendant of the mesenchymal stem cell known to express markers such as Stro1, CD29, CD105, and CD166. Matrix-producing osteoblasts express Cbfa1 and osterix, necessary for osteoblast differentiation, followed by alkaline phosphatase and collagen, necessary for the production of osteoid. Osteocalcin is produced by the late osteoblast and continues to be expressed by the osteocyte. By some unknown mechanism, some designated cells begin to embed in osteoid and begin to extend dendritic projections, keeping connections with already embedded cells and cells on the bone surface. Molecules such as E11/gp38 and MT1-MMP appear to play a role in dendrite/canaliculi formation, whereas molecules such as destrin and CapG regulate the cytoskeleton. Phosphate-regulating endopeptidase homolog, X-linked (PHEX), matrix extracellular phosphoglycoprotein (MEPE), and dentin matrix protein 1 (DMP1) regulate biomineralization and mineral metabolism, and fibroblast growth factor 23 (FGF23) regulates renal phosphate excretion. FGF23 is elevated not only in osteocytes from hypophosphatemic animals but also in those of normal rats. Sclerostin is a marker of the mature osteocyte and is a negative regulator of bone formation. ORP150 may preserve viability of this cell in a hypoxic environment. (Redrawn from Bonewald LF. The amazing osteocyte. *J Bone Miner Res.* 2011;26[2]:229–238.)

by M-CSF.[52] Binding of RANKL to RANK activates a series of intracellular pathways that activate NF-κB and mitogen-activated protein kinases, as well as NFAT and the activator protein 1 (AP1) family of transcription factors. The TNF receptor-associated factors (TRAFs), and particularly TRAF6, are ubiquitin E3 ligases that bind RANK intracellularly and are involved in RANK responses. Mice deficient in TRAF6, like those deficient in RANK, develop osteopetrosis. In addition to its effects on bone, the RANKL/RANK system is involved in lymphocyte function, barrier functions in the skin, and breast and lymph node development. Mature osteoclasts express RANK, and treatment of these cells with RANKL inhibits apoptosis and stimulates resorptive activity.[53]

In addition to RANKL, M-CSF is essential for osteoclast formation. Mice that are deficient in M-CSF have osteopetrosis and few osteoclasts.[54] In cultures of isolated osteoclast precursor cells, both M-CSF and RANKL must be present to form mature osteoclasts. M-CSF enhances RANK production in osteoclast precursors and inhibits apoptosis of osteoclast precursors and mature osteoclasts. The receptor for M-CSF, CSF1 receptor (CSF1R) (formerly designated C-FMS), is present on osteoclast precursors and mature osteoclasts.[52] Binding of CSF1R by M-CSF activates tyrosine kinase activity in the receptor, which initiates a series of intracellular downstream events.

A series of coactivator molecules is critical for osteoclast development. These molecules include members of the cytoplasmic immunoreceptor tyrosine-based activation motif (ITAM) family, namely Fc-receptor γ-subunit (FcRγ) and DNAX activation protein 12 (DAP12). ITAM proteins interact with receptor proteins in the cell membrane of osteoclast precursor cells. The search for receptors associated with these ITAM adaptors in myeloid cells has identified at least two candidates that associate with FcRγ (osteoclast-associated receptor [OSCAR] and paired immunoglobulin-like receptor [PIR] and two that associate with DAP12 (the triggering receptor expressed by myeloid cells 2 [TREM2] and the signal regulatory protein β1 [SIRPB1]). Mice that are deficient in FcRγ and DAP12 have osteopetrosis and deficient osteoclast formation despite their ability to express RANKL, RANK, M-CSF, and CSF1R.[44,55] This signaling pathway responds to ligands that have not yet been established genetically; together with RANK, it stimulates the accumulation of intracellular calcium, which is required for dephosphorylation of NFAT; this allows the transport of NFAT into the nucleus, where it acts as a transcription factor.

The formation of multinucleated osteoclast-like cells in vitro requires hematopoietic precursors and cells of the mesenchymal/osteoblast lineage present within the niche.[56] In vivo and in cultures with devitalized bone, mononuclear pre-osteoclasts attach to the bone surface and form multinucleated osteoclasts by fusion.[57] The accumulation of additional nuclei into osteoclasts by fusion probably continues while the cell is actively resorbing. The life span of the osteoclast is limited. As osteoclasts become inactive, they die by apoptosis. Hormones that enhance bone resorption may delay

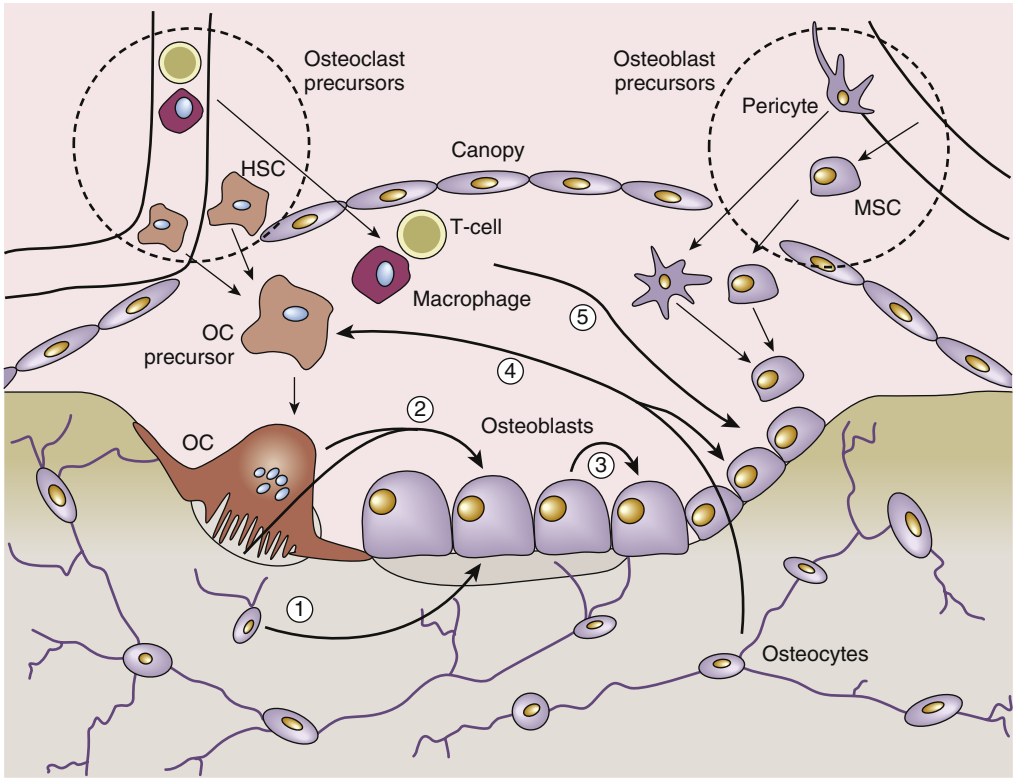


• **Fig. 30.10** (A) Visualization of early, embedding osteocytes. Using anti-E11 immunostaining and visualization of the actin cytoskeleton by alexa488 staining for phalloidin, one can visualize the embedding osteocyte and the early osteocyte in 12-day murine calvaria. The merged image shows that the majority of the E11 is on the cell surface and along the dendritic processes. In addition, if one looks closely, the dendrites that end on the cell surface have a bulbous tip of unknown function. This structure must interface with the cells on the bone surface. (B) An acid-etched resin-embedded murine sample showing an osteocyte lacuna sending canaliculi to the bone surface. Note the rough surfaces of canaliculi toward the bone surface and the smooth surface of canaliculi that project away from the bone surface, suggesting a difference between forming and formed canaliculi. Both sets of images demonstrate the complexity of this network and the interface of osteocytes with the bone surface. (The images in A are provided by Dr. Sarah Dallas, University of Missouri at Kansas City, MO; B, from Bonewald LF. The amazing osteocyte. *J Bone Miner Res.* 2011;26[2]:229–238.)

apoptosis, and inhibitors of resorption probably accelerate it. The mechanisms that limit the extent of osteoclastic resorption are incompletely understood and may involve inhibition by calcium ions, which accumulate under the osteoclast resorbing surface, or by local inhibitory factors, such as transforming growth factor β (TGFβ), which are released and activated during resorption.

The mature osteoclast is a unique and highly specialized cell (Fig. 30.13). It usually contains 10 to 20 nuclei, but giant osteoclasts with up to 100 nuclei can be seen in Paget disease and in giant cell tumors of bone. The large size of osteoclasts is probably essential for their resorptive function. The best evidence for this comes from studies of dendritic cell–specific transmembrane protein (DC-STAMP), because inhibition of this protein or its complete deficiency in mouse models results in the generation of only mononuclear osteoclasts that have impaired resorptive activity.[58]

The capacity of osteoclasts to resorb bone depends on their ability to isolate a region of the bone surface from the extracellular fluid and produce a local environment that can dissolve bone mineral and degrade matrix. The osteoclast must polarize and produce a basolateral membrane opposite the resorption space, which



• **Fig. 30.11** Intercellular communication pathways within the basic multicellular unit that comprise all steps of the bone remodeling process. *1*, Stimulatory and inhibitory signals from osteocytes to osteoblasts (e.g., Oncostatin M [OSM], parathyroid hormone–related peptide, and sclerostin). *2*, Stimulatory and inhibitory signals from osteoclasts to osteoblasts (e.g., matrix-derived transforming growth factor β and insulin-like growth factor 1, secreted CT-1, Sema4D, and S1P). *3*, Signaling within the osteoblast lineage (e.g., ephrinB2 and EphB4, Sema3a, parathyroid hormone–related peptide, OSM). *4*, Stimulatory and inhibitory signals between the osteoblast and osteoclast lineages (e.g., receptor activator for nuclear factor κB ligand, Sema3B, Wnt5a, and osteoprotegerin). *5*, Marrow cell signals to osteoblasts (e.g., macrophage-derived OSM, T cell–derived interleukins, and receptor activator for nuclear factor κB ligand). *HSC,* hematopoietic stem cell; *MSC,* mesenchymal stem cell; *OC,* osteoclast. (From Sims NA, Martin TJ. Coupling the activities of bone formation and resorption: a multitude of signals within the basic multicellular unit. *Bonekey Rep.* 2014;3:481.)

facilitates the excretion of resorption products (see Fig. 30.13). The resorbing apparatus consists of a central ruffled border area, which secretes hydrogen ions and proteolytic enzymes, surrounded by a clear or sealing zone in a structure called the *podosome*. The podosome contains filamentous actin linked to $\alpha_v\beta_3$ integrin, and it anchors the cell to the bone surface. The osteoclast attaches to bone through the interaction of integrins in the podosome with noncollagenous proteins such as vitronectin and osteopontin in the matrix.

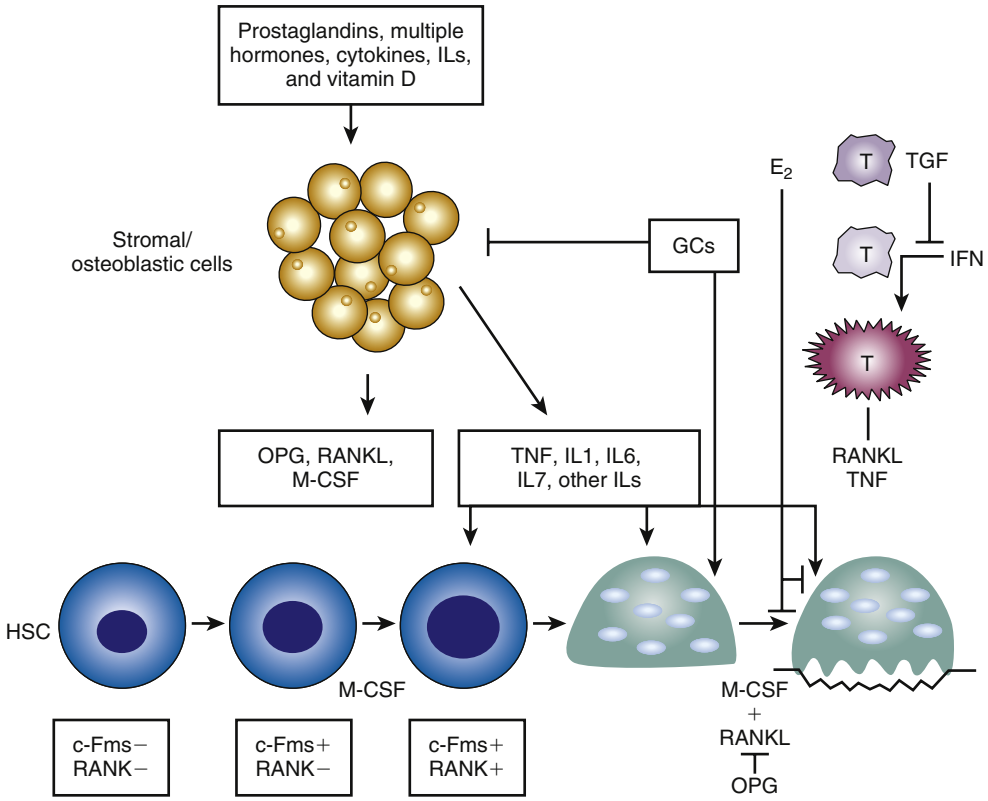
Acidification of the resorption space adjacent to the ruffled border membrane requires that osteoclasts have a vacuolar proton pump (H^+-ATPase [adenosine triphosphatase]) and a chloride channel that is charge coupled to H^+ secretion across the ruffled membrane to preserve electron neutrality.[59,60] These osteoclast H^+-ATPase pumps are similar to the vacuolar proton pumps that acidify intracellular organelles, but in the osteoclast they are exteriorized to increase the extracellular hydrogen ion concentration in the resorption space (see Fig. 30.13). The hydrogen ions dissociate from carbonic acid, which is synthesized by carbonic anhydrase II; the bicarbonate generated by this dissociation is removed from the cell by chloride-bicarbonate exchange at the basolateral membrane of the osteoclast. Ion pumps can transport the dissolved calcium from the bone surface through the cell to the extracellular fluid.

However, calcium can also reach the extracellular fluid directly if the sealing zone is disrupted. The proteolytic enzymes produced by the osteoclast include lysosomal enzymes and metalloproteinases.[61] Lysosomal proteases can degrade collagen at the low pH present in the ruffled border area. Cathepsin K is probably the most important of these.[62] Metalloproteinases, which are active at neutral pH, have also been detected at the resorption site.[63] The products of resorption are transported across the ruffled border membrane and excreted through the basolateral membrane of the osteoclast by a process called *transcytosis*.[64] In trabecular bone, osteoclasts characteristically resorb to a limited depth and then move laterally to produce irregular, plate-like resorption areas called *Howship lacunae*. In cortical remodeling, the path of directed resorption is longer, possibly because of renewal of osteoclasts from hematopoietic cells brought to the site through the haversian canal.

Bone Remodeling and Its Regulation

Overview of Remodeling

Adult bone mass is determined by two processes: acquisition of peak bone mass during adolescence and the subsequent bone loss

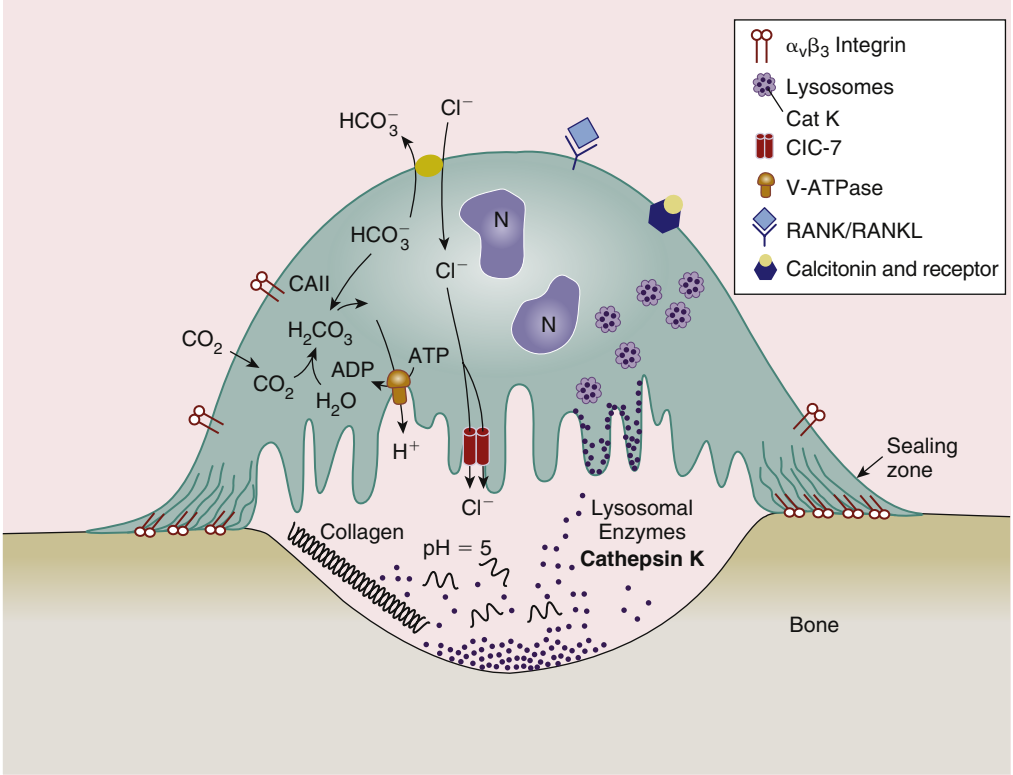


• **Fig. 30.12** Role of cytokines, hormones, steroids, and prostaglandins in osteoclast formation. Under the influence of other cytokines (data not shown), hematopoietic stem cells (HSCs) commit to the myeloid lineage, express c-Fms and receptor activator for nuclear factor κB (RANK), the receptors for macrophage colony-stimulating factor (M-CSF) and RANK ligand (RANKL), respectively, and differentiate into osteoclasts. Mesenchymal cells in the marrow respond to a range of stimuli, secreting a mixture of pro- and antiosteoclastogenic proteins, the latter primarily osteoprotegerin (OPG). Glucocorticoids (GCs) suppress bone resorption indirectly but possibly also target osteoclasts and their precursors. Estrogen (E_2), by a complex mechanism, inhibits activation of T cells, decreasing their secretion of RANKL and tumor necrosis factor α (TNFα); the sex steroid also inhibits osteoblast and osteoclast differentiation and life span. A key factor regulating bone resorption is the RANKL/OPG ratio. *IFN,* interferon; ILs, interleukins; *M-CSF,* macrophage colony-stimulating factor; *TGF,* transforming growth factor. (From Rosen CJ, ed. *Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism.* 8th ed. Ames, IA: Wiley-Blackwell; 2013:2–33, Copyright 2013, American Society for Bone and Mineral Research.)

after maturity. Changes in bone mass result from physiologic and pathophysiologic processes in the bone remodeling cycle, and ultimately this can lead to skeletal fragility.[65] The most vulnerable periods in women are during accelerated linear growth in adolescence (ages 10–16 years) and later in life, usually immediately after menopause (ages 45–60 years). Male bone loss is much more gradual but is also determined by peak acquisition and age-related loss.

The bone remodeling cycle is a tightly coupled process whereby bone is resorbed at approximately the same rate as new bone is formed. BMUs comprise the remodeling unit of bone and, as noted previously, include osteoclasts, osteoblasts, osteocytes, and bone lining cells.[66] The bone marrow niche includes these cells plus hematopoietic elements, adipocytes, reticuloendothelial cells lining the sinusoids, and mesenchymal stromal cells (see Fig. 30.11). Activation of the remodeling cycle serves two functions in the adult skeleton: (1) to supply calcium acutely, as well as chronically, to the extracellular space, and (2) to provide elasticity and strength to the skeleton. When the remodeling process is uncoupled so that resorption exceeds formation, bone is lost. However, during peak bone acquisition, formation exceeds resorption, resulting in a net gain of bone. Remodeling is more pronounced in the trabecular skeleton (e.g., spine, calcaneus, and proximal femur), the most metabolically active compartment of bone. The trabecular elements are likely surrounded by a canopy that encloses the BMU and contains a capillary network for nutrient supply, as well as cells that can be identified as osteomacs. Although trabecular bone remodels more frequently than cortical bone, it is also extremely vulnerable to perturbations by local or systemic factors that can cause significant imbalances in bone turnover.

The bone remodeling cycle begins with activation of resting osteoblasts on the surface of bone, as well as the bone lining cells (see Fig. 30.11). The initial signal for remodeling has been actively debated, as has been the source of that signal (i.e., systemic or local). Microdamage or force changes sensed by the osteocyte may initiate the remodeling signal, although it is likely that local factors secreted by osteoblasts, osteoclasts, or lining cells could also begin the process. That initiating signal is followed by a series of secretory products originating from activated osteoblasts to osteoclasts and their precursors. These intercellular signals recruit and differentiate multinucleated cells from hematopoietic stem cells.[67] After osteoclast-induced bone resorption, matrix components



• **Fig. 30.13** Schematic representation of a resorbing osteoclast. The osteoclast acidifies the resorption lacunae by secreting H^+ and Cl^- ions for demineralization, and lysosomal cathepsin K for degradation of type I collagen. *ADP,* adenosine diphosphate; *ATP,* adenosine triphosphate; *ATPase,* adenosine triphosphatase; *CLC-7,* chloride channel 7; *RANK,* receptor activator of nuclear transcription factor κB; *RANKL,* RANK ligand. such as TGFβ and insulin-like growth factor 1 (IGF1), as well as collagen, osteocalcin, calcium, and other protein and mineral components, are released into the microenvironment. Growth factors released by resorption contribute to the recruitment of new osteoblasts to the bone surface, which begin the process of collagen synthesis and biomineralization. In addition, cytokines released by activated osteoclasts such as bone morphogenetic protein (BMP) 7, Wnt 10b, and sphingosine 1-phosphate can stimulate osteoblastogenesis in reverse sequence.[68] Ephrins serving as both ligands and receptors also contribute to this bidirectional signaling mechanism[69] (Fig. 30.14). In healthy adults, as many as 2 million remodeling sites may be active at any given time, and it is estimated that nearly one fourth of all trabecular bone is remodeled each year. In general, resorption takes only 10 to 13 days, whereas formation is much more deliberate and can take upward of 3 months (see Fig. 30.2). Under ideal circumstances, by the end of the cycle, the amount of bone resorbed equals the amount reformed.

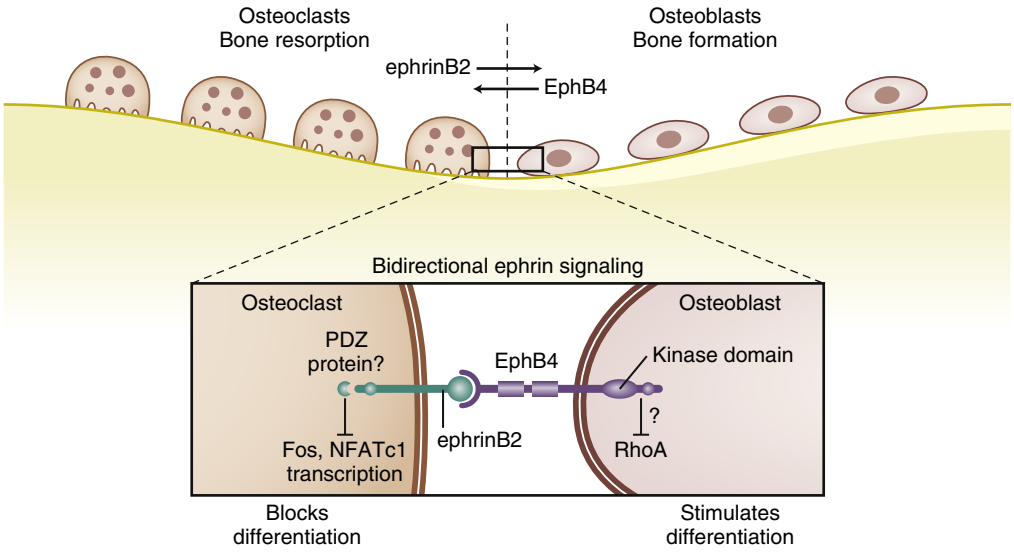
Although 80% of skeletal mass is cortical bone, the surface area of cortical bone is only about one fifth that of cancellous bone. Moreover, more osteoclast precursor cells are available in cancellous bone and on the endosteal surfaces of cortical bone. Consequently, turnover is greater on these surfaces than on periosteal bone, which normally undergoes little remodeling. However, subperiosteal resorption can be activated in hyperparathyroidism, and the periosteal surface contains pre-osteoblasts that may become active late in life and cause an age-related increase in the periosteal diameter of long bones.[70] This periosteal expansion may maintain bone strength and compensate for losses at the endosteal surfaces and in cancellous bone.[71]

Several key components of the remodeling cycle are susceptible to systemic and local alterations, which can lead to deleterious changes in bone mass. In particular, activation of remodeling via the osteoblast and recruitment of osteoclasts represent the two most vulnerable sites in the cycle. Often, with systemic changes in circulating hormones, such as estrogen deficiency, chronic PTH excess, or hyperthyroidism, the remodeling cycle is stressed such that coupling of the two processes cannot be maintained. This failure is due to the difference in timing between resorption, which generally occurs within a BMU over about 2 weeks, and formation, which can take upward of 12 weeks to fully mineralize newly synthesized matrix. Not surprisingly, a third cell altered in disease states is the osteocyte. Remodeling of the skeleton implies coupling of resorption to formation, and therefore no net change in bone mass. Because the osteocyte responds to mechanical loading or stress by communicating with bone lining cells and osteoblasts, these cells could also become damaged[72] (see Fig. 30.11). Indeed, osteocyte apoptosis may contribute to age-related osteoporosis either directly or through the elaboration of systemic peptides. Interestingly, remodeling may end with the osteocyte as well because it produces the protein *sclerostin*, which inhibits osteoblast activity by antagonizing the Wnt/lipoprotein receptor–related protein (LRP) 5 and BMP pathways.[15] Monoclonal antibodies



• **Fig. 30.14** Ephrin-Eph signaling and bone homeostasis. Osteoclasts are responsible for the resorption of a localized packet of bone, and when they cease their activity, a team of osteoblasts is attracted to the resorption site, where they proliferate, differentiate, and then re-form the packet of bone. **Inset,** Ephrin-Eph forward signaling from osteoclasts to osteoblasts may be responsible for driving the formation of the new bone packet, and ephrin-Eph reverse signaling may be responsible for the cessation of continued bone resorption by osteoclasts. (Redrawn from Mundy GR, Elefteriou F. Boning up on ephrin signaling. *Cell*. 2006;126[3]:441–443.)

that bind to sclerostin have been developed, and at least one is currently in phase III trials as a means of reducing the inhibitory effect of this protein on osteoblast differentiation, thereby increasing bone mass.[73,74]

As noted, uncoupled remodeling occurs during menopause because of estrogen deprivation or in response to endogenous PTH fluxes, cytokine stimulation, growth hormone surges, glucocorticoid excess, or changes in serum calcium. For the most part, estrogen deprivation remains one of the most common and critical elements in shifting resorption rates to a higher set-point. Although bone formation initially can "catch up," the length of time for each component of the remodeling cycle clearly favors resorption over formation, as the process of laying down new bone requires the interaction of several processes[72] (see Fig. 30.2). However, it is still unclear why falling estrogen levels, which is a universal event during the menopausal years, causes rapid bone loss in a relatively small percentage of women, although insidious bone loss has been clearly demonstrated for most, if not all, women who enter menopause.[75] Other factors such as peripheral conversion of testosterone to estradiol, which occurs to a greater degree in individuals who are obese, higher adrenal androgen production, and/or genetic determinants, as well as other local signals, may be important. Although the genetic causes of rapid bone loss have not been identified in humans, mice have strong heritable determinants that affect the rate of age-related and estrogen-deficient bone loss.[76,77] With advancing age, regardless of gender, a negative balance in bone remodeling is a natural occurrence when the number of senescent cells within bone increases. Remarkable changes are found in the chromatin and secretome profile of senescent cells. Their presence within the tissue microenvironment can be recognized by detecting increased expression of the biomarker p16Ink4a. Proinflammatory molecules are part of the repertory of paracrine and endocrine peptides secreted by senescent cells, producing a negative environment both locally and systemically. Osteocytes, the most abundant cells within bone tissue, can acquire the senescent phenotype. In experimental studies, these cells were removed by using the INK-ATTAC "suicide" transgene encoding an inducible caspase 8 expressed specifically in senescent cells. The investigators observed improvements in bone mass and microstructure, as well as in the biomechanical properties of bone. These results were reinforced by pharmacologic elimination of senescent cells, using a "senolytic compound," which also reversed bone deterioration in aged mice. Moreover, these results are in line with previous data suggesting that the removal of senescent cells potentially has beneficial effects on the cardiovascular system, insulin sensitivity, and frailty, opening the door for the development of new opportunities for preventing age-associated degenerative diseases.[78]

The nature of osteocyte-osteoblast-osteoclast interaction has been one of the most active areas of investigation (see Fig. 30.11). External signals (e.g., PTH, growth hormone, IL1, estrogen deprivation) to resting osteoblasts and stromal cells cause these cells to release cytokines (i.e., interleukins [e.g., IL1, IL6, and IL11], as well as M-CSF, TNF, and TGFβ) that enhance the recruitment and differentiated function of multinucleated giant cells destined to become bone-resorbing cells.[79] However, one of the most critical pathways in the osteoblast-osteoclast interaction scheme is the RANKL-OPG relationship.[47]

The OPG, RANKL, and RANK system, which affects osteoclast differentiation, in addition to the effects of M-CSF on osteoclast proliferation, provides the critical link between osteoclasts

and osteoblasts. It has also led to the synthesis of RANKL antibodies that, after successful human trials, have become therapeutic agents to inhibit bone resorption. Denosumab (Prolia) is the first monoclonal antibody against RANKL and was approved by the FDA, European regulatory agencies, and the Endocrinologic and Metabolic Drugs Advisory Committee for the treatment of postmenopausal osteoporosis, as well as for metastatic bone diseases, owing to its strong efficacy in reducing spine and hip fractures.[80] It is administered once every 6 months and suppresses bone resorption by 80% to 90%. Long-term follow-up of the original phase III trials reveals significant improvement in bone mass at both the spine and hip out to 10 years, with maintenance of antifracture efficacy and few, if any, adverse events.[81] After 10 years of treatment, the gain in bone mass was 21.7% in the lumbar spine, 9.2% in the total hip, and 9.0% in the femoral neck, with a continuous increase in BMD throughout therapy.[81] However, therapy withdrawal leads to a rapid inflexion in the BMD curve, implicating significant bone loss. The magnitude of reduction in BMD after a 17-month therapy gap was 8.1% and 8.4%, respectively, in the lumbar spine and the total hip, which corresponds to 35.5% of the total gain in the spine and 103.3% in the total hip.[82] Denosumab has also been approved for the treatment of women with breast cancer and skeletal metastases and is the only agent shown to reduce fractures in men undergoing androgen deprivation therapy for prostate cancer.[83,84]

The osteoblast functions not only to signal osteoclasts during remodeling but also to lay down collagen and orchestrate mineralization of previously resorbed lacunae in the skeletal matrix. These complex functions are tied to differentiation of mesenchymal stromal cells and bone lining cells, which become osteoblasts and rest on the surface of the remodeling space.[85] Recruitment of stromal cells into osteoblasts, rather than adipocytes, is a critical step in bone formation and requires a series of factors that enhance differentiation (see Fig. 30.8). One of the most important drivers of this process is RUNX2, a transcription factor that is essential for the early differentiative pathway of stromal cells toward bone and away from adipogenesis.[86,87] Regulation of RUNX2 and its downstream effects has become a major focus of work as investigators have begun to consider novel ways to enhance bone formation and reduce marrow adipogenesis. However, within that context, it is clear that pre-adipocytes or pre-osteoblasts may have significant plasticity such that the older paradigm illustrated in Fig. 30.8 may not truly represent the status of mesenchymal cells within the marrow niche.

During activation of resting osteoblasts, the mature cells synthesize collagen I; several minor collagens; the noncollagenous matrix proteins; and a series of growth factors, such as IGF1, IGF2, and TGFβ. These, in turn, are necessary for further recruitment of bone-forming cells.[88] In addition, osteoblasts deposit growth factors in the skeletal matrix, where they are stored in latent forms (e.g., TGFβ, IGF1, IGF2) and released during subsequent remodeling cycles. Osteoblast fate is determined within the remodeling sequence by several different systemic and local factors. Osteoblasts can further differentiate into osteocytes, become quiescent lining cells on the bone surface, or die through apoptosis.[85] As noted earlier, osteocytes may participate in bone resorption of the cortex by secreting RANKL to stimulate osteoclastogenesis and can also participate in osteocytic osteolysis, which may occur during lactation and other states of high calcium demand.[89]

The Wnt/β-catenin signaling pathway has emerged as a major regulator of bone formation and a potential mediator of the mechanostat. Wnts belong to a large family of proteins that bind to frizzled receptors and activate multiple pathways within the cell. When Wnts also bind to several coreceptors LRP5, LRP6, and probably LRP4, a so-called canonical signaling pathway is triggered.[90] Activation of this pathway occurs through a complex intracellular signaling pathway mediated by β-catenin, which translocates to the nucleus and stimulates the transcription of genes through cooperative interactions with TCF/Lef transcription factors. Sclerostin (the product of the *SOST* gene), the osteocyte-specific protein that inhibits bone formation and another important Wnt inhibitor, dickkopf 1 (Dkk1), work by binding to LRP5 and LRP6, thereby blocking Wnt signaling.[91]

Local Regulators of Remodeling

Characterization of local regulators produced within the bone itself represents a major advance in bone biology.[92,93] These local factors can be synthesized by bone cells or by adjacent hematopoietic cells and can interact with each other and with systemic hormones. They are critical in the repair of skeletal damage and in the response to mechanical forces.

Cytokines

The proinflammatory cytokines IL1α, IL1β, TNFα, and TNFβ are potent stimulators of bone resorption and inhibitors of bone formation; thus, they may play a role in the bone loss after estrogen withdrawal.[79] IL6 increases osteoclastogenesis in cell cultures and may mediate some of the resorbing activity of PTH. IL6 is synthesized by osteoblasts and immune cells, and its production is stimulated by PTH,[94] PGE_2, and other factors that increase bone resorption. There is also evidence suggesting that IL6 may modulate osteocyte communication toward osteoclasts.[95]

IL11, another member of the IL6 cytokine family, also stimulates resorption. LIF, also a member of the IL6 family, increases proliferation of osteoblast precursors but then slows their subsequent differentiation into mineralizing osteoblasts.[96] Inflammatory cytokines such as IL7, IL15, and IL17 stimulate bone resorption, whereas IL4, IL10, IL13, and IL18 inhibit bone resorption.[51,97–99] Interferon-β and interferon-γ inhibit resorption by blocking RANK signaling pathways.[100] IL10 is an inhibitor of osteoclastogenesis and bone resorption.[101] IL15 and IL17 stimulate resorption, whereas IL18 is inhibitory through its ability to increase production of granulocyte-macrophage CSF (GM-CSF).[102] Interferon-β and interferon-γ inhibit resorption by blocking RANK signaling pathways.[100] In addition to direct effects, responses to cytokines can be blocked by inhibitors such as the IL1 receptor antagonist and the soluble TNF receptor, or they can be enhanced by activators such as the soluble IL6 receptor.

TGFα and Epidermal Growth Factor

These peptides stimulate bone resorption through the same receptor and act by prostaglandin-dependent and -independent pathways. TGFα and epidermal growth factor (EGF) are potent mitogens in bone that probably act on mesenchymal and hematopoietic precursors.[103,104] The EGF family of peptides regulates cell migration and adhesion, playing an important role in the early recruitment of osteoblast progenitors to the remodeling site. Signaling in pre-osteoblasts by the EGFs is via the Cdc42/Rac network.[105] Studies in vitro, using immortalized and primary bone marrow stromal cells, reported that EGF receptor signaling enhances mechanotransduction, suggesting that the EGF system may act as a mechanosensitizer in bone marrow stromal cells.[106] TGFα is produced by neoplasms and may play a role in the increased bone resorption that occurs in certain malignancies.

Prostaglandins

Prostaglandins are potent regulators of bone cell metabolism and are synthesized by many cell types in the skeleton.[107] Prostaglandin production in bone is regulated by effects of local and systemic hormones and mechanical forces on the inducible cyclooxygenase 2. Increased prostaglandin production may contribute to the increase in bone resorption that occurs with immobilization, the enhanced bone formation seen with impact loading, and the bone loss after estrogen withdrawal. Many of the hormones, cytokines, and growth factors that stimulate bone resorption also increase prostaglandin production. Prostaglandins have biphasic effects on bone formation. Stimulation of bone formation is seen in vivo, and inhibition of collagen synthesis occurs in osteoblast cultures. Bone cells produce PGE_2, $PGF_{2\alpha}$, prostacyclin, and lipoxygenase products (e.g., leukotriene B_4), which may also stimulate bone resorption.

Peptide Growth Factors

Skeletal cells synthesize a variety of growth factors that regulate the replication, differentiation, and function of bone cells. These growth factors are not synthesized only by skeletal cells, and some are present in the systemic circulation and can act as local and systemic regulators of bone remodeling. Skeletal cells also synthesize growth factor binding proteins, which regulate the activity and storage of specific factors and their interactions with other proteins in the extracellular matrix.[92]

Fibroblast Growth Factors

FGFs form a large family of polypeptides characterized by their affinity to glycosaminoglycan heparin-binding sites.[108] FGF1 and FGF2, which have been studied extensively, have mitogenic properties for cells of the osteoblastic lineage, although eventual differentiation into mature osteoblasts does not occur in the presence of the FGF family of peptides.[109] In fact, FGF2 inhibits Wnt signaling and the synthesis of IGF1, which results in a decrease in osteoblastogenesis and in osteoblastic function.[110,111] In vivo experiments have confirmed this action of FGF, and mice overexpressing FGF2 are osteopenic.[112] However, studies in *Fgf2* null mice indicate that FGF is necessary for osteoblast formation, possibly because of its early effects on cell replication.[113] FGF can stimulate bone resorption by prostaglandin-dependent and -independent pathways.[114] The FGFs bind to a series of four FGF receptors that have intrinsic tyrosine kinase activity. In vertebrates, the 22 members of the FGF family range in molecular mass from 17 to 34 kDa and share 13% to 71% amino acid identity. Among vertebrate species, FGFs are highly conserved in both gene structure and amino acid sequence. FGFs have a high affinity for heparan sulfate proteoglycans and require heparan sulfate to activate one of four cell-surface FGF receptors. During embryonic development, FGFs have diverse roles in regulating cell proliferation, migration, and differentiation. In the adult organism, FGFs are homeostatic factors and function in tissue repair and response to injury. When inappropriately expressed, some FGFs can contribute to the pathogenesis of cancer.

FGF19, FGF21, and FGF23 are unique in that they bind to FGF receptors that heterodimerize with α- or β-Klotho. FGF23 is secreted by osteocytes and has been shown to regulate phosphate homeostasis by inhibiting vitamin D 1α-hydroxylase activity in the kidney, thereby suppressing the production of $1,25(OH)_2D$. In addition, FGF23 promotes phosphate loss in the renal tubule, acting as an endocrine hormone produced by bone cells. Disorders in FGF23, including excess production or impaired degradation, result in several syndromes that are characterized by hypophosphatemia and rickets/osteomalacia. FGF21 is produced in the liver and in adipocytes. It is an important counterregulatory hormone that stimulates PPARα and oxidation of fatty acids.[115] FGF21 is high during calorie restriction, malnutrition, and lactation. It can potentially cause browning of white adipocytes, but in mice it has been shown to stimulate bone resorption. Recently, FGF21 has been shown to induce significant bone resorption, and the FGF21 null mice have very high bone mass.[116] Increased production of IGFBP1 may mediate bone resorption, at least in part, by increasing the production of FGF21.[117,118]

Platelet-Derived Growth Factors, Vascular Endothelial Growth Factors, Hypoxia-Inducible Factors, and Reactive Oxygen Species

Platelet-derived growth factor (PDGF) was originally isolated from human platelets, and four members of the *PDGF* gene family have been identified: *PDGFA*, *PDGFB*, *PDGFC*, and *PDGFD*.[119] These peptides signal through the PDGFR family of receptors. Vascular endothelial growth factor (VEGF) shares a high degree of sequence homology with PDGF, and these factors are often referred to as members of the PDGF/VEGF family.[120]

PDGFs must form homodimers or heterodimers to exhibit activity. PDGF-AA, -AB, and -BB are the isoforms studied more extensively in skeletal cells, and they exert similar biologic actions. The primary function of PDGF in bone is the stimulation of cell replication, and PDGF impairs osteoblast differentiation and function.[121] PDGF also stimulates bone resorption. In mice, null mutations of *Pdfga* or *Pdfgb* and their receptors cause embryonic lethality or perinatal death, not allowing the study of the function of PDGF in the postnatal skeleton.[122] Although skeletal cells express products of the *Pdfga*, *Pdfgb*, and *Pdfgc* genes, the major source of PDGF is the systemic circulation, and skeletal cells become exposed to PDGF after platelet aggregation. PDGF receptor 1a (PDGFR1a) is expressed on numerous progenitor cells in the hematopoietic niche, including early osteoblasts and adipocytes.

VEGFA is essential for angiogenesis, and *VEGFA* and VEGF receptor genes are expressed by chondrocytes and osteoblasts.[123] VEGFA is essential for blood vessel formation and vessel invasion into cartilage during the process of endochondral bone formation and for chondrocyte survival during skeletal development.[124] Importantly, VEGFA is also required for intramembranous bone formation and osteoblastic maturation.[125] Osteoblast expression of PDGF and VEGF is regulated by other locally derived growth factors.

Hypoxia-inducible factors (HIFs) are produced locally in response to low oxygen tension in the hematopoietic niche and are transcription factors that mediate pathways that lead to angiogenesis, including production of VEGF. HIFs also induce genes essential for glycolysis, an essential biochemical pathway for ATP generation in the niche. During fracture repair, it has been demonstrated that more bone is produced in a mouse model with constitutively active HIF1α in osteoblasts. Conversely, mice deficient in HIF1α in osteoblasts had defective bone healing.[126]

Reactive oxygen species (ROS), which are free radicals that include peroxides, are products of cell metabolism, particularly oxidative phosphorylation. These products are inactivated by several enzymes that serve to prevent mitochondrial and cell damage. In several mouse models of aging, changes that occur in bone turnover and cell metabolism were associated with increases in ROS in bone cells.[127] Suppressing ROS through antioxidant therapy can

reverse some of the effects on bone from the loss of sex steroids.[128] However, ROS generation may be important to maintain a certain level of metabolic activity, and differences in ROS production may be critical to determining the fate switch between osteoblasts and adipocytes.

Insulin-Like Growth Factors

IGFs are mitogens that also can increase the differentiated function of the osteoblast, supporting mineralization and bone formation.[129] Animal models have demonstrated that both systemic and locally synthesized IGF1 contribute to bone formation.[130,131] Transgenic mice overexpressing IGF1 have increased bone mass, whereas *Igf1* null mice exhibit decreased bone formation, reduced mineralization, and decreased cortical bone.[132] IGF1 stimulates bone turnover by increasing osteoclastogenesis and bone remodeling.[133] Both IGF1 and IGF2 are synthesized by bone cells and are stored in the bone matrix, but IGF1 is a more potent stimulator of osteoblastic function.[129] Six IGF-binding proteins have been identified in bone and in the circulation (e.g., IGFBP1 through IGFBP6). IGFBPs can inhibit or enhance IGF responses, depending on their local concentration relative to IGFs and the presence of proteases that can cleave the IGFBPs. IGFBP2 has been shown to be synergistic in its actions on osteoblasts with IGF1 via signaling through the pleiotropic receptor that phosphorylates PTEN (phosphatase and tensin homolog).[134] PTH and PGE_2 are major inducers of skeletal IGF1 and IGFBP2 synthesis, and glucocorticoids suppress IGF1 transcription.[129] Thus, IGFs can mediate selected effects of these hormones on bone formation.

Transforming Growth Factor β

TGFβ belongs to a family of closely related polypeptides with various degrees of structural homology and important effects on cell function that are only expressed in mammals.[135] Skeletal cells express TGFβ1, TGFβ2, and TGFβ3. TGFβ has complex and somewhat contradictory actions in bone cells. TGFβ can stimulate osteoblastic cell replication and bone formation, but it does not favor osteoblastic differentiation.[136,137] The effects of TGFβ depend on the target cell and experimental conditions. The actions of TGFβ on bone resorption have been a source of controversy. TGFβ has a biphasic effect on osteoclastogenesis, but it decreases bone resorption.[138] Targeted disruption of the mouse *Tgfb1* gene is lethal but does not result in abnormal skeletal development.[139] TGFβ is secreted as a latent high-molecular-weight complex consisting of the C-terminal remnant of the TGFβ precursor and a TGFβ-binding protein.[140] The biologically active levels of TGFβ depend on changes in its synthesis and in its activation from its latent form.

BMPs and Wnt Proteins

BMPs are members of the TGFβ superfamily of polypeptides, and they were originally identified because of their ability to induce endochondral bone formation. BMPs are expressed by osteoblasts and play an autocrine role in osteoblastic differentiation and function.[92] The fundamental function of BMPs is the induction of osteoblastic cell differentiation, endochondral ossification, and chondrogenesis.[92,141] The genesis and differentiation of osteoblasts and osteoclasts are coordinated events, and BMPs also induce osteoclastogenesis and osteoclast survival.[142]

BMP activity is regulated by a large group of secreted polypeptides that bind and limit BMP action. These extracellular BMP antagonists prevent BMP signaling. Extracellular BMP antagonists include noggin, follistatin, myostatin, twisted gastrulation, the chordin family, and the Dan/Cerberus family of proteins.[92] These molecules can also bind to one or two activin receptors, ACVR2A and ACVR2B. Myostatin, a TGFβ superfamily member, is a negative regulator of muscle growth acting through ACVR2B. Inhibitors of these signaling peptides and their receptors may result in enhanced muscle mass and in some cases increased bone mass.[143]

The Wnt family of secreted cysteine-rich glycoproteins, like BMPs, plays a critical role in directing osteoblastogenesis. In skeletal cells, many Wnt family members use the canonical Wnt/β-catenin signaling pathway.[144] In the absence of Wnt, the proteins axin, adenomatous polyposis coli (APC), and β-catenin form a complex that facilitates the phosphorylation and degradation of β-catenin. Binding of Wnt family proteins to specific frizzled membrane receptors and their coreceptors (LRP5 and LRP6) leads to the stabilization of β-catenin. This allows β-catenin to be translocated to the nucleus, where it can regulate the transcription of target genes. The Wnt/β-catenin signaling pathway is central to osteoblastogenesis and bone formation, and Wnt and BMPs act in concert to regulate cell differentiation. Deletions of Wnt or β-catenin genes result in the absence of osteogenesis and of skeletal tissue, and inactivating mutations of Wnt coreceptors result in osteopenia.[145] For instance, either the loss-of-function or gain-of-function mutation in LRP5 results in skeletal diseases respectively characterized by either low bone mass (osteoporosis pseudoglioma)[146] or high bone mass.[147] Wnt/β-catenin signaling induces OPG, and through this mechanism, Wnts are negative regulators of osteoclastogenesis.[148,149] Wnt activity, like that of BMPs, is controlled by extracellular antagonists and intracellular signaling proteins.[93] Extracellular antagonists such as sclerostin and Dkk1 prevent interactions between Wnt family members and coreceptors, although others, like soluble frizzled-related proteins, bind Wnts directly and block their actions. These antagonists limit Wnt signaling, which decreases osteoblast function and bone mass.[144,150] Conversely, deletion of sclerostin in mice produces a high bone mass phenotype.[151] Sclerostin, made predominantly by osteocytes, is regulated by systemic factors such as PTH and by mechanical forces on bone. Precisely how circulating versus local sclerostin regulates bone formation and resorption is an important unanswered question, particularly because circulating sclerostin levels have been shown to have a negative or positive relationship to bone mass and fractures in normal individuals and patients with type 2 diabetes mellitus (T2DM).[152,153]

Systemic Hormones and Bone Remodeling

Remodeling is activated by both systemic and local factors. Changes in mechanical force can activate remodeling to improve skeletal strength, and remodeling removes and repairs bone that has undergone microdamage. This occurs particularly in cortical bone and may explain the fact that remodeling is sustained in the aging skeleton.[154] However, loss of osteocytes with age may impair this response.[155] Systemic hormones influence bone remodeling to regulate the movement of mineral from bone to the extracellular fluid to maintain serum calcium levels and to sustain linear growth. During pubertal growth, bone modeling and remodeling intensify and correlate with serum levels of IGF1, supporting the role of growth hormone as a major mediator of skeletal formation.[156] In addition to the growth hormone/IGF1 axis, it is now apparent that testosterone and estradiol must be present during peak acquisition to attain the highest possible BMD. Mineralization of newly formed bone is assured by activation of vitamin D 1α-hydroxylase in the kidney leading to greater calcium

absorption and higher $1,25(OH)_2D$ levels. Hence, modeling and epiphyseal closure are both modulated by systemic hormones that are both calcium regulating and growth centric.

Calcium-Regulating Hormones

Parathyroid Hormone

PTH acts on bone to stimulate resorption but does not act on osteoclasts in the absence of cells of the osteoblastic lineage. PTH receptors are abundant on osteoblasts, bone lining cells, and osteocytes, but not on osteoclasts.[157] PTH acts on osteoblasts to cause cell contraction; to induce immediate-early response genes, including c-Fos and the inducible form of prostaglandin G/H synthase (i.e., cyclooxygenase), and to increase the synthesis of local mediators, IGF1 and IL6.[157,158] High concentrations of PTH in vitro inhibit the expression of type I collagen, but intermittent administration of PTH in vivo or in vitro can stimulate bone formation.[159] PTH induces the production of RANKL and inhibits the production of OPG by cells of the osteoblast lineage, thereby increasing osteoclastogenesis and thus bone resorption. In some circumstances, PTH increases proliferation of cells of the osteoblast lineage and decreases their death by apoptosis.[157] PTH also induces 1α-hydroxylase activity in the kidney, thereby enhancing the active form of vitamin D (see later discussion). In osteocytes, PTH not only stimulates production of RANKL but also inhibits production of sclerostin and increases synthesis of FGF23. In this way, PTH uses osteocytes to regulate bone remodeling and systemic calcium/phosphate homeostasis. Genetic deletion of the PTH/PTHrP receptor (PTH1R) gene in mesenchymal stem cells of mice has a great impact on bone phenotypes (i.e., low bone formation, increased bone resorption, and high bone marrow adipose tissue [MAT]).[160] In addition, the same study showed that intermittent PTH administration to control group mice reduced bone MAT significantly.[160] These results suggest that PTH also drives progenitor cells differentiation into osteoblasts.

Vitamin D

The hormonal form of vitamin D, $1,25(OH)_2D_3$, is necessary for intestinal calcium and phosphorus absorption and therefore for mineralization. This form of vitamin D also has effects on the skeleton, but its physiologic role in bone remodeling is not clear.[161] By increasing RANKL production on osteoblasts or osteoblast progenitor cells, vitamin D is a potent stimulator of osteoclast formation in cell culture. High concentrations increase osteocalcin synthesis by osteoblasts and inhibit collagen synthesis and mineralization in vitro.[162] Lower concentrations may increase bone formation, although not to the extent seen with intermittent administration of PTH. Recent studies using conditional deletions of the vitamin D receptor (VDR) in bone and intestine provide further insight into the physiologic role of vitamin D on the bone remodeling unit. Intestinal deletion of the VDR mimics a low-calcium diet and is associated with bone loss related to increased bone resorption and decreased bone formation. However, serum calcium is preserved.[162] But in the osteocyte and mature osteoblast-specific *Vdr* null mice, there is no alteration in circulatory levels of calcium, phosphorus, PTH, and $1,25(OH)_2D$, as well as no bone phenotype. Moreover, mice missing the VDR only in the intestine have a delay in mineralization through the actions of high levels of $1,25(OH)_2D_3$ on osteoblastic cells.[162] These data provide a strong mechanistic rationale for active vitamin D action on remodeling: high $1,25(OH)_2D$ levels due to increased $1,25(OH)_2D$ bind to the VDR on osteoblasts and stimulate RANKL production leading to increased bone resorption as a way to protect the body against low serum calcium. It further slows entry of calcium into the skeleton by suppressing mineralization in vitro and in vivo, thereby preserving essential functions of the mammal.

Calcitonin

Calcitonin inhibits bone resorption by acting directly on the osteoclast, but it appears to play a smaller role in the regulation of bone turnover in adults.[163] Bone mass is not greatly altered in patients with medullary thyroid carcinoma, who have an excess of calcitonin production, or in athyreotic patients receiving adequate thyroid hormone replacement, who have low calcitonin levels.[164,165] Bone turnover is increased in patients with medullary thyroid carcinoma.[166] Mice with a deletion of the gene for calcitonin/calcitonin-related polypeptide α (*CALCA*), which is responsible for the production of calcitonin and its alternate transcript calcitonin gene–related peptide, have increased bone mass and enhanced rates of bone formation.[167] In contrast, mice with a deletion of only the calcitonin gene–related peptide have decreased bone mass.[168] These results imply that calcitonin influences both bone formation and bone resorption. However, the mechanisms by which calcitonin affects bone formation remain unknown.[169]

Other Systemic Hormones That Influence Remodeling

Growth Hormone

Deficiency and excess of growth hormone have marked effects on skeletal growth, as noted previously.[170,171] Growth hormone increases circulating and local levels of IGF1, which mediates many of the skeletal effects of growth hormone. Exogenous growth hormone and IGF1 increase bone remodeling presumably by directly acting on osteoblasts, although IGF1 is also present on osteoclasts, and recombinant IGF1 stimulates bone resorption. Osteocytes also possess IGF1,[172] and one can speculate that it might play an important role in regulating phosphate homeostasis via FGF23 during critical growth phases. Growth hormone stimulates cartilage growth, probably through an increase in local and systemic IGF1 production and possibly by direct stimulation of cartilage cell proliferation because low levels of growth hormone receptors are present in chondrocytes.

Glucocorticoids

Glucocorticoids exert profound effects on bone remodeling.[173] Glucocorticoids decrease the intestinal absorption of calcium and have the potential to induce osteoclastogenesis and bone resorption because they increase the expression of RANKL and CSF1 in osteoblasts.[174] However, the most significant effect of glucocorticoids is their ability to suppress bone remodeling through depletion of the osteoblastic cell population.[175,176] Glucocorticoids inhibit the replication of osteoblast precursors and their differentiation into mature osteoblasts. This effect occurs in part because they suppress Wnt signaling and factors necessary for osteoblastic differentiation.[177] In a recent study, it was observed in humans that glucocorticoids have diverse effects in the serum levels of two Wnt signaling antagonists: a progressive decrease in Dkk1 with a significant increase in circulatory levels of sclerostin.[178] Glucocorticoids induce the apoptosis of osteoblasts and osteocytes, contributing to the decrease in bone-forming cells.[179] Glucocorticoids inhibit the differentiated function of the osteoblast and bone formation. This results from direct effects of glucocorticoids on the osteoblast and suppression of IGF1 transcription.[180]

Thyroid Hormones

Thyroid hormone signaling is mediated by thyroid hormone receptor (TR), a ligand-dependent transcription regulator molecule. TR is encoded by the thyroid hormone receptor α (*THRA* or c-erbAα) and β (*THRB* or c-erbAβ) genes, which have different isoforms for which distribution is tissue- and age dependent.[181,182] The TRβ1 and TRα1 isoforms are expressed in bone, but previous studies suggested that TRα1 is the major mediator of thyroid hormone effects in the skeleton.[183] However, the net effect of thyroid hormone is complex and depends on the circumstances.[184,185] In children, hyperthyroidism is associated with increased bone mineralization and epiphyseal maturation, and hypothyroidism results in decreased growth.[186] But in adults, hyperthyroidism is associated with bone loss. Thyroid hormones are crucial for cartilage growth and differentiation and enhance the response to growth hormone. Thyroid hormones increase bone resorption and turnover, although their effects on bone formation are less clear.[187] Coupled with their effects on bone resorption, thyroid hormones increase the transcription of collagenase and gelatinase by osteoblasts.[188] As thyroid hormones increase bone remodeling, thyroxine (T_4) may also increase bone formation. Thyroid hormones also have indirect effects on skeletal metabolism by suppressing the synthesis of thyroid-stimulating hormone (or thyrotropin), which can inhibit osteoclast formation and survival and as a consequence suppressed bone resorption.[187,189,190] However, it is still debated whether thyroid-stimulating hormone (or thyrotropin) has direct effects on osteoblasts and osteoclasts.

Insulin

Normal skeletal growth depends on an adequate amount of insulin.[191] Excess insulin production by the fetuses of mothers with uncontrolled diabetes results in excessive growth of the skeleton and other tissues, possibly through its actions on IGF1. Poorly controlled diabetes mellitus leads to impaired skeletal growth and mineralization. Children and adolescents with type 1 diabetes mellitus (T1DM) are at increased risk for decreased bone mineral acquisition and accumulation of AGEs.[192] T2DM is associated with normal bone mass but increased skeletal fragility in part due to enhanced cortical porosity and increased AGEs in the matrix. In vitro, insulin at physiologic concentrations selectively stimulates osteoblastic collagen synthesis by a pretranslational mechanism. Insulin can mimic the effects of IGF1, although only at supraphysiologic levels.[109] Mice deficient in insulin receptor substrate 1, a major substrate of insulin and IGF1 receptor tyrosine kinases, exhibit impaired differentiative osteoblast function, low-turnover osteopenia, and an impaired response to PTH, documenting the central role of insulin and IGF1 signaling in the maintenance of bone remodeling.[193] More recently, insulin has been shown to stimulate osteoblastic function and bone resorption leading to greater release of GLU13-OCN (see Fig. 30.5), which in turn causes greater insulin sensitivity and enhanced insulin synthesis in the islet cells. The effect of insulin on glucose transport in osteoblasts is still controversial, although deletion of the insulin receptor in osteoblasts, using the osteocalcin Cre promoter, results in low bone mass, obesity, and insulin resistance. In humans, the ultimate effect of insulin resistance on bone still is to be elucidated, but there is much clinical evidence suggesting that it does not have detrimental effects on bone mass. Both pandemic (i.e., obesity) and rare (i.e., generalized congenital lipodystrophy) conditions linked to insulin resistance are associated with high bone mass.[194,195] In addition, there is no consensus in the literature about the association between visceral adipose tissue and bone mass.[196] In commonality, insulin deficiency and insulin resistance are associated with excessive formation of AGEs, which are involved in the development of classic diabetic micro- and macroangiopathy. AGEs may also impact bone microarchitecture through effects on collagen cross-linking, major post-translational modifications of collagen that influence bone strength. Collagen cross-links can be formed by lysyl hydroxylase and lysyl oxidase–mediated enzymatic immature divalent cross-links and mature trivalent pyridinoline and pyrrole cross-links, and cross-links can also be produced by glycation- or oxidation-induced nonenzymatic cross-links (AGEs), such as glucosepane and pentosidine. The last may impair mineralization and the capacity of bone to repair itself from microdamage. This mechanism can be a common link to bone fragility, which is common in both T1DM and T2DM patients.[197,198]

Gonadal Hormones

Estrogens and androgens are critical for skeletal development and maintenance. Bone cells contain estrogen and androgen receptors, but it has been difficult to demonstrate direct effects of gonadal steroids on bone formation or resorption in cell and organ culture. Gonadal hormones are crucial for the pubertal growth spurt, and estrogen is necessary for epiphyseal closure.[199] In addition, gonadal steroids contribute to skeletal gender differences. Men exhibit larger bones due to androgen stimulation of periosteal formation, whereas estrogen has an inhibitory effect.[200] Skeletal gender dimorphism impacts on bone biomechanical properties and, at least in part, explains the higher incidence of osteoporotic fracture in women.[201] Deficiency of estrogen or androgen increases bone resorption in vivo, partly by increasing the local synthesis or sensitivity to cytokines, such as IL1 and IL6 or TNFα; to prostaglandins; and through direct actions on estrogen receptors in osteoclasts. Androgens can increase bone formation in vivo.[202] The effect of estrogens on bone formation is less clear, depending on the animal model and the dose of estrogen. The absolute rate of bone formation is increased in estrogen deficiency states because of an increase in bone remodeling. However, estrogen deficiency causes bone loss, implying a relative deficiency in bone formation. In other words, in the condition of hypoestrogenism, the increase in bone formation is not of the same magnitude as the enhancement in bone resorption.

Epidemiology of Osteoporosis and Fractures

Over the past 25 years, our understanding of fractures and their causes has significantly evolved and along with it, the definition of the disease osteoporosis. The current definition of *osteoporosis* was developed by an international consensus development committee in 1993 as "a disease characterized by low bone mass and microarchitectural deterioration of bone tissue, leading to enhanced bone fragility and a consequent increase in fracture risk."[203] This definition reflects our understanding of the link between low bone quantity, compromised bone quality, and increased fracture risk. Although hip, vertebral, and wrist fractures are most commonly associated with osteoporosis, risk of other fractures is also increased.

Fractures

Hip Fractures

Proximal femur fractures are a major cause of morbidity and fatality and occur much more frequently in older people, increasing

the costs of osteoporosis. Most commonly, these fractures occur in the femoral neck or intertrochanteric regions and require surgical repair. Increased risk of falls together with decreases in bone strength account for the increased risk with increasing age. Morbidity and mortality rates associated with hip fractures are substantial. The mortality rate within 1 year of the fracture is between 5% and 20%.[204] They are a major source of disability and loss of independence. For example, it is estimated that of those living independently before a hip fracture, only 50% are able to do so 1 year after the hip fracture.[205] After a hip fracture, there is also a substantial risk of other fractures, including a second hip fracture, and it is therefore important that further assessment and possible treatment be considered in patients with fractures at the hip (and other sites).[206,207]

Vertebral Fractures

Vertebral fractures are the most common manifestation of osteoporosis.[208] These fractures occur in a range of severities. Mild fractures, only some of which may be symptomatic, may only be apparent via radiographic or other types of imaging but are still, in aggregate, associated with clinical symptoms.[209,210] However, severe vertebral fractures can be accompanied by significant acute back pain that may persist for many weeks or indefinitely. Long-term consequences of vertebral fractures, particularly accumulation of multiple vertebral fractures, are substantial, leading to height loss, kyphosis, increased disability, decreased pulmonary function, substantial chronic back pain, and diminished overall quality of life.[211] There is also increased fatality associated with vertebral fractures.[212] Severity of these consequences increases with increasing severity and number of these fractures. Although they can be caused by trauma, they are often associated with little or no trauma.

Vertebral fractures have often been referred to as the hallmarks of osteoporosis and tend to occur at younger ages than other fractures. Vertebral fractures increase the future risk of additional vertebral fractures by 5 to 10 times and are associated with a much higher risk of nonvertebral fractures, including hip fractures.[213,214] Therefore, like hip fractures, they should lead to further assessment (e.g., dual-energy x-ray absorptiometry [DXA]) and consideration of osteoporosis prevention and treatment. This is particularly true of incidental findings noted on chest and lumbar radiographs for other reasons. Often, vertebral fractures reported on radiographs are asymptomatic, and a history of trauma cannot be ascertained. This does not diminish the importance of the fracture with respect to future risk or associated morbidity.

Wrist Fractures

Fractures of the distal radius are common in postmenopausal women and are associated with osteoporosis. However, in general, they have less morbidity and fewer costs than hip or spine fractures. Their incidence rises in women at menopausal age but then rises no further with increasing age. This pattern may be explained by different reactions to falling with age. Men have a much lower incidence of wrist fracture.

Other Types of Fractures

In addition to hip, spine, and wrist fractures, a large number of other fracture sites, such as the arm, lower leg, humerus, and ribs, are common and have been shown to have significant morbidity and mortality risks.[215] Furthermore, there is increasing evidence that the risk of most, if not all, of these fracture types are increased in those with low BMD or osteoporosis[216] and can be reduced by osteoporosis treatment.[207,217–219] A recently published study evaluated the relationship of mortality within a group of individuals with nonhip, nonvertebral fractures with or without comorbidities.[9] The mortality rate attributable to any fracture without comorbidity was 9.2% in women and 5.3% in men. Moreover, comorbidity independently worsened the mortality rate; for instance, a woman showing both humeral fracture and one comorbidity had a similarly reduced 5-year survival to that of a woman with a hip fracture and no comorbidities.[9]

TABLE 30.1 Diagnostic Categories for Osteoporosis Based on Measurements of BMD and Bone Mineral Content

Category	Definition
Normal	BMD ±1 SD of the young adult reference mean
Low bone mass (osteopenia)	BMD >1 SD and <2.5 SD lower than the young adult mean
Osteoporosis	BMD >2.5 SD lower than the young adult mean
Severe osteoporosis (established osteoporosis)	BMD >2.5 SD lower than the young adult mean in the presence of one or more fragility fractures

BMD, Bone mineral density; *SD*, standard deviation.

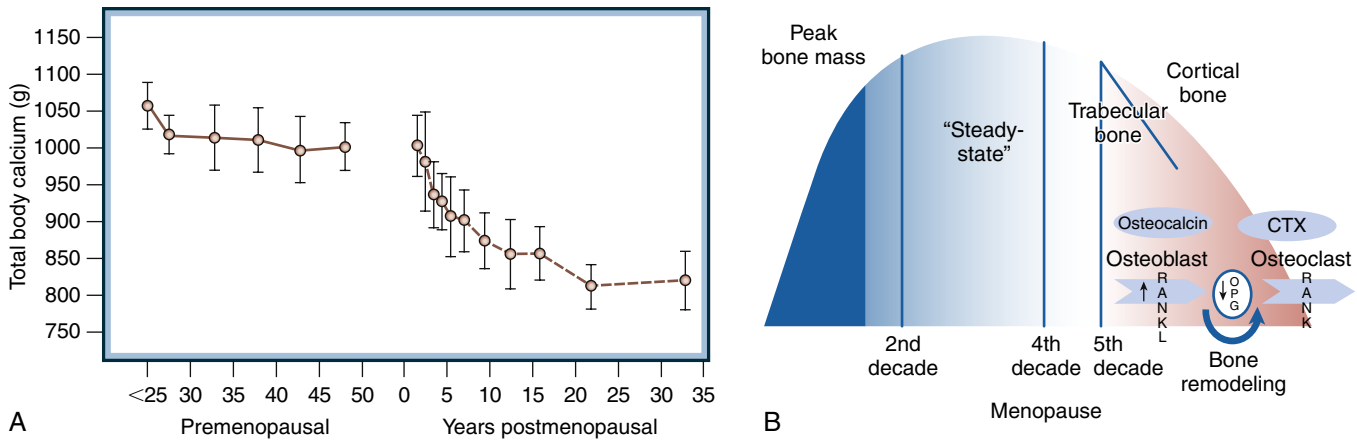
Clinical Assessments of Osteoporosis

Dual-Energy X-Ray Absorptiometry

DXA is the standard method for assessing the presence and extent of osteoporosis. DXA is most often performed at the spine and hip, although other sites (whole body, distal radius) can also be assessed. Although not a true density, it provides an areal density of mass per area in units of grams per square centimeter. The International Osteoporosis Foundation and other organizations have developed a classification system for DXA values called *T-scores* that classify the measurement (Table 30.1). T-scores are calculated by comparing a specific value with a normative reference range for patients of the same gender and ethnicity. The T-score is the number of standard deviations (SD) below young normal values. A value below −2.5 SD is usually considered osteoporotic. Clinically, usually three regions are used for diagnosis: BMD at the total hip, the femoral neck, and the lumbar spine.

DXA values at the hip generally peak at about age 30 to 40 years and then begin to decline (Fig. 30.15). The decline is somewhat accelerated at menopause for a few years and then becomes accelerated again after about age 65 or 70 years in women.[220] Spine BMD measurements can be useful; however, in older women and especially men, they can be confounded by osteophytes, aortic calcification, degenerative disease, and other conditions that increase the apparent spinal BMD and therefore are less reliable in those older than 65 to 70 years.

A large number of studies (many of them prospective) have consistently shown that DXA BMD is strongly predictive of future risk of fracture. Hip BMD is predictive of various types of both nonvertebral and vertebral fracture but is particularly strongly predictive of hip fractures. Although the risk of fracture increases significantly with decreasing BMD, several studies have verified that



• **Fig. 30.15** (A) Bone mass development, maintenance, and loss: trabecular bone loss starts earlier and is more intense than in cortical bone. (B) The decline of total body calcium with years since menopause. *CTX,* cross-linked telopeptide of type I collagen; *OPG,* osteoprotegerin; *RANK,* receptor activator of nuclear transcription factor κB. (Redrawn from Tella SH, Gallagher JC. Prevention and treatment of postmenopausal osteoporosis. *J Steroid Biochem Mol Biol.* 2014;142:155–170.)

osteoporotic fractures occur across a wide spectrum of BMDs. Most likely, these events are related to bone quality, a component not captured by DXA measurements. The World Health Organization definition is a guideline for interpreting DXA results, not a definitive way of diagnosing osteoporosis. Therefore, DXA is the primary imaging tool used in diagnosing and treating osteoporosis. It can be used in conjunction with other risk assessment tools that combine other risk factors with DXA (see later discussion). DXA measurements have been somewhat standardized across different types of scanners, although follow-up measures to assess change should be performed on the same scanner if at all possible.

Trabecular Bone Score

Approved by the FDA in 2012, the trabecular bone score (TBS) is now incorporated into clinical practice for the estimation of fracture risk. The TBS is an optional tool added to the menu of DXA equipment, which provides gray-scale textural analysis of spine DXA images, utilizing variograms of two-dimensional projection images. The TBS is a surrogate measurement of trabecular microarchitecture, and there is evidence showing correlation between the several parameters of quantitative computed tomography (QCT) and TBS values. The strongest association is observed at lumbar spine trabecular volumetric BMD, whereas in other sites the relationship between TBS with bone microarchitectural parameters has more variation. Several studies show convergent results that the TBS is an independent predictor of fracture in osteoporotic postmenopausal women, as well as in men. A large prospective study performed in Manitoba, Canada, which included more than 29,000 postmenopausal women followed for almost 5 years, reported the accuracy of the TBS in predicting fracture. Moreover, it demonstrated that the combination of BMD with TBS assessment provides a better estimate of fracture risk than either evaluation by itself.[221] Similar results were obtained in smaller samples in the United States (Osteoporotic Fractures in Men Study [MrOs]) and in Japanese populations who were followed for 10 years.[222] The TBS has also been shown to enhance the power of fracture prediction obtained by the use of the algorithm FRAX, which was designed to estimate a 10-year probability of fracture.[223]

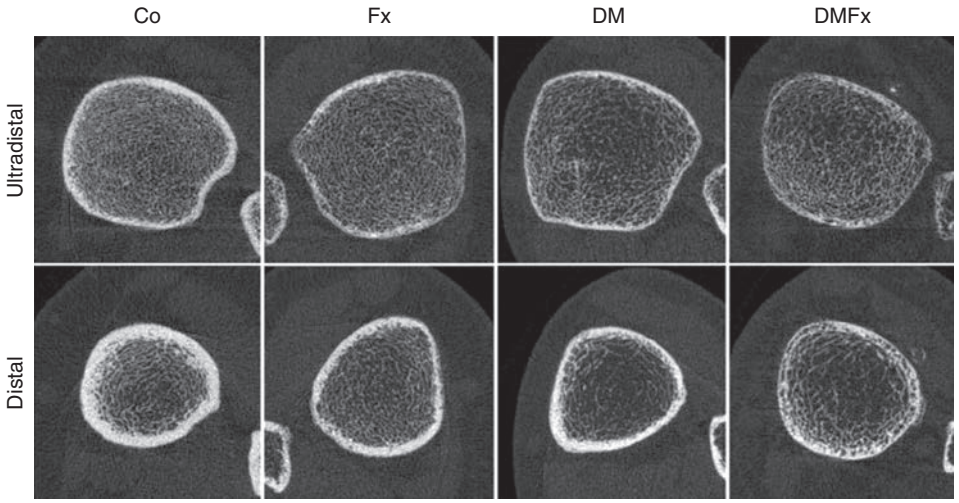
Quantitative Computed Tomography

Other imaging modalities have been studied and may be used for osteoporosis assessment, although DXA remains the preferred method, when available. QCT can be performed at the hip and spine, and studies have shown that it can predict fracture risk.[219,224,225] Several versions of software[226,227] are commercially available for analysis of QCT scans. One advantage of QCT is that it can provide specific measurements of trabecular and cortical BMD. However, QCT has the disadvantages (compared with DXA) of higher radiation exposure, less standardization across computed tomography scanners, and higher cost. Peripheral QCT (pQCT) and high-resolution pQCT have been developed and can currently measure bone density and bone microarchitecture (in the case of high-resolution pQCT) in the radius and tibia. Although these measurements can be helpful in the research context to help understand the impact of diseases such as diabetes and medications such as bisphosphonates on bone microarchitecture and quality, there is little evidence that they have advantages in clinical practice for predicting fracture risk compared with DXA (examples of such measurements are shown in Fig. 30.16).

Other measurement tools to assess risk include ultrasound of the fingers, calcaneus, and distal extremities and magnetic resonance imaging of the radius. Ultrasound has predictive value for fracture risk, but longitudinal assessments have not proved helpful clinically.[228] Magnetic resonance imaging provides significant insight into trabecular and cortical microstructure but is basically a research tool because of expense and time on the machines.

Bone Turnover Markers

The balance between bone resorption and formation is an important contributor to bone loss and osteoporosis. Bone turnover markers (BTMs) can provide an assessment of resorption and formation and might therefore be useful in understanding these imbalances within individual patients, prediction of fracture risk, and the effect of treatment. Bone formation can be assessed by several biochemical markers, including bone-specific alkaline phosphatase (BSAP), total procollagen type 1 N-terminal propeptide (P1NP), and osteocalcin. Bone resorption has traditionally been



• **Fig. 30.16** Representative high-resolution peripheral quantitative computed tomography images of the ultradistal (*above*) and distal (*below*) tibia: shown are the mid-stack tomograms for the Co (*left*), Fx (*left-center*), DM (*right-center*), and DMFx (*right*) groups. Major cortical porosity can be seen in DMFx (*right*). *Co,* controls; *Fx,* nondiabetic fracture patients; *DM,* diabetic patients without fractures; *DMFx,* diabetic patients with fractures. (From Patsch JM, Burghardt AJ, Yap SP, et al. Increased cortical porosity in type 2 diabetic postmenopausal women with fragility fractures. *J Bone Miner Res.* 2013;28[2]:313–324.)

assessed with urinary N-terminal cross-linked telopeptide (NTX) but is now more commonly assessed by serum C-terminal cross-linked telopeptide (CTX), both being collagen cross-linked peptides assessed with antibodies (Table 30.2).

There are several potential clinical applications of BTMs. However, all of them must take into account the high analytic variability (both within individual and between assays and laboratories) for these markers.[229] Important sources of variation within individuals include circadian variation, food intake, exercise, seasonal variation, diseases such as renal impairment, and recent fractures.[230] For predicting fracture risk, there is controversy about whether BTMs predict fracture independently of BMD and other risk factors, with some studies showing a positive relationship; however, others have not shown that BTMs independently predict fracture.[231–233] Because BTMs change dramatically and quickly with both antiresorptive and anabolic treatment, it has been suggested that they may be of some use in monitoring therapy. Although the value of this application is controversial, they could have some value for a clinician with patients whose self-reported compliance may be unreliable.[234–236] They are more commonly used in specialty practices where they can be helpful in defining secondary causes of osteoporosis. BTMs are particularly useful when measured in groups of patients during the development of new medications. In the research setting, these measurements can provide early assessments of potency of drugs, their effects over time, and assist in determining optimal doses.[237,238]

Bone Biopsy

Bone biopsy is used clinically to assess dynamic and static indices related to bone remodeling. It is rarely used clinically to diagnose osteoporosis but can be useful to assess the degree of mineralization (e.g., to exclude osteomalacia), rates of bone formation or resorption, and the overall status of remodeling (e.g., to exclude adynamic renal bone disease). Universal criteria can then be applied to the indices obtained after labeling bone by timed tetracycline administration.[239] Transiliac biopsies can be performed by physicians who specialize in osteoporosis medicine or by orthopedic surgeons and requires local anesthetic for a core biopsy, which generally requires a 7.5-mm trephine core for bone histologic diagnosis and histomorphometry. Mineral apposition rate, mineralizing surface, bone formation rate, eroded surfaces, number of osteoblasts and osteoclasts, and osteoid volume/bone volume all can be determined from a single biopsy, but only after serial tetracycline labeling, which is required to measure the distance between two mineralization fronts. Labeling intervals vary somewhat but generally are for 3 days at the beginning (days 1–3) and for 3 days 21 days later, using 200 mg of demeclocycline three times per day. Several commercial laboratories provide analysis of biopsies, although turnaround time can vary from 1 to several months. Not infrequently, however, bone biopsies in age-related or postmenopausal osteoporosis are normal, and hence the diagnostic specificity is low.

Fracture Epidemiology

Some of the central features of the epidemiology of fractures for the three primary osteoporotic fractures are illustrated in Fig. 30.17. These data show very clearly the exponential increase in women in hip and spine fractures. For example, an average Caucasian woman at age 50 years has about a 15% to 20% annual risk of hip fracture that increases still further beyond age 80 years. Wrist fractures show a different pattern in women with an increase at the time of menopause but then no further increase with time. In men, the exponential increase in hip and spine fractures with age is parallel to that for women. However, importantly, the age-specific risk of hip and spine fractures in men is much lower than that in women (approximately 50%), highlighting the key role of gender in the epidemiology of osteoporotic fractures. Wrist fracture incidence in men is much lower than in women at all ages.

TABLE 30.2 Markers of Bone Turnover

Marker	Tissue of Origin	Specimen	Analytic Method	Remarks
Bone Formation				
Bone-specific alkaline phosphatase (BAP)	Bone	Serum	Electrophoresis, precipitation, IRMA, EIA, ECMA	Specific product of osteoblasts; some assays show up to 20% cross-reactivity with the liver isoenzyme (LAP)
Osteocalcin (OC)	Bone, platelets	Serum	RIA, IRMA, EIA	Specific product of osteoblasts; many immunoreactive forms in blood; some may be derived from bone resorption
C-terminal propeptide of type I procollagen (PICP)	Bone, soft tissue, skin	Serum	RIA, EIA	Specific product of proliferating osteoblasts and fibroblasts
N-terminal propeptide of type I procollagen (PINP)	Bone, soft tissue, skin	Serum	RIA, EIA	Specific product of proliferating osteoblast and fibroblasts; partly incorporated into bone extracellular matrix
Markers of Bone Resorption				
Collagen-Related Markers				
Hydroxyproline, total and dialyzable (Hyp)	Bone, cartilage, soft tissue, skin	Urine	Colorimetry HPLC	Present in all fibrillar collagens and partly in collagenous proteins, including C1q and elastin Present in newly synthesized and mature collagen (i.e., both collagen synthesis and tissue breakdown contribute to urinary hydroxyproline)
Hydroxylysine-glycosides	Bone, soft tissue, skin, serum complement	Urine, serum	HPLC, EIA	Hydroxylysine in collagen is glycosylated to varying degrees, depending on tissue type Glucosylgalactosyl-OH-Lys in high proportion in collagens of soft tissues, and C1q Galactosyl-OH-Lys in high proportion in skeletal collagens
Pyridinoline (PYD)	Bone, tendon, cartilage, blood vessels	Urine, serum	HPLC, EIA	Collagens, with highest concentrations in cartilage and bone; absent from skin; present in mature collagen only
Deoxypyridinoline (DPD)	Bone, dentin	Urine, serum	HPLC, EIA	Collagens, with highest concentration in bone; absent from cartilage or skin; present in mature collagen only
C-terminal cross-linked telopeptide of type I collagen (ICTP, CTX-MMP)	Bone, skin	Serum	RIA, EIA	Collagen type I, with highest contribution probably from bone; may be derived from newly synthesized collagen
C-terminal cross-linked telopeptide of type I collagen (CTX-I)	All tissues containing type I collagen	Urine (α/β), serum (β only)	EIA, RIA	Collagen type I, with highest contribution probably from bone; isomerization of aspartyl to β-aspartyl occurs with aging of collagen molecule
N-terminal cross-linked telopeptide of type I collagen (NTX-I)	All tissues containing type I collagen	Urine, serum	EIA, RIA, CLIA	Collagen type I, with highest contribution from bone
Collagen I alpha 1 helicoidal peptide (HELP)	All tissues containing type I collagen	Urine	EIA	Degradation fragment derived from the helical part of type I collagen, $\alpha 1$ chain, AA (620-633); correlates highly with other markers of collagen degradation, no specific advantage or difference in regard to clinical outcomes
Noncollagenous Proteins				
Bone sialoprotein (BSP)	Bone, dentin, hypertrophic cartilage	Serum	RIA, EIA	Acidic, phosphorylated glycoprotein, synthesized by osteoblasts and osteoclast-like cells, laid down in bone extracellular matrix; appears to be associated with osteoclast function
OC fragments (uf-OC, U-Mid-OC, U-Long-OC)	Bone	Urine	EIA	Certain age-modified fragments are released during osteoclastic bone resorption and may be considered an index of bone resorption

Continued

TABLE 30.2 Markers of Bone Turnover—cont'd

Marker	Tissue of Origin	Specimen	Analytic Method	Remarks
Osteoclast Enzymes				
Tartrate-resistant acid phosphatase (TRAcP)	Bone	Blood plasma	Serum colorimetry, RIA, ELISA	Six isoenzymes found in human tissues (osteoclasts, platelets, erythrocytes); band 5b predominant in bone (osteoclasts)
Cathepsins (e.g., K, L)	K: Primarily in osteoclasts; L: macrophage, osteoclasts	Plasma, serum	ELISA	Cathepsin K, a cysteine protease, plays an essential role in osteoclast-mediated bone matrix degradation by cleaving helical and telopeptide regions of collagen type I; cathepsin K and L cleave the loop domain of tartrate-resistant acid phosphatase and activate the latent enzyme; cathepsin L has a similar function in macrophages; tests for measurement of cathepsins in blood are presently under evaluation

BAP, Serum bone alkaline phosphatase; *BMD,* bone mineral density; *β-CTX-I,* epitope of C-terminal cross-linked telopeptide of collagen type I; *CLIA,* chemiluminescent immunoassay; *C-terminal,* carboxy-terminal; *CTX-MMP,* C-terminal cross-linking telopeptide of type I collagen generated by matrix metalloproteinases; *DPD,* deoxypyridinoline; *ECMA,* electrometric immunoassay; *EIA,* enzyme immunoassay; *HPLC,* high-performance liquid chromatography; *ICTP,* carboxyterminal type I collagen telopeptide; *IRMA,* immunoradiometric assay; *N-terminal,* amino-terminal; *PICP,* C-terminal propeptide of procollagen type I; *PINP,* N-terminal propeptide of procollagen type I; *PTH,* parathyroid hormone; *PTHrP,* parathyroid hormone–related peptide; *PYD,* pyridinoline; *RIA,* radioimmunoassay; *TAP,* serum total alkaline phosphatase; *ufOC,* urinary fragments of osteocalcin; *U-Long-OC,* long N-terminal fragment; *U-Mid-OC,* midmolecule epitope of the OC.

Ethnicity and culture also play a key role in the epidemiology of osteoporosis (Fig. 30.18). For hip fractures, those of Caucasian ethnicity are at higher risk, Hispanics and Asians are at medium risk, and African Americans are at lowest risk. However, these general relationships can often be more subtle. For example, in Asians, there is evidence that rates are very low in areas with traditional lifestyles and that they increase substantially with increasing urbanization and adoption of Western lifestyles.[240] Rates of spine fractures are more challenging to assess, but many studies suggest that these rates vary less geographically than do rates of hip fracture.

Another key epidemiologic factor that interacts with age, gender, and ethnicity is weight or body mass index (BMI). There are studies showing that low lean mass is an independent predictor of incident fractures in a cohort of 65-year-old community dwellers.[241] In addition to the obvious mechanical connection between muscles and bones, other factors are important determinants of this association, including molecular, genetic, and endocrine interaction.[242] In general, higher BMI individuals are at lower risk of hip and spine fractures, owing to several factors, including a larger number of fat cells that produce greater amounts of estrogen, which is protective, and the higher amount of padding in higher BMI patients, which produces a larger distribution of the forces in the event of a fall. Although some data suggest that individuals who are obese have a higher risk of fractures, most studies support the tenet that a higher BMI is protective for most types of fractures, the exception possibly being lower limb fractures. Very importantly, those at low BMI are at particularly high risk of hip fracture for several reasons, one of which may be that low BMI, particularly in the elderly, may be a sign of frailty.[243,244]

Clinical Risk Factors and Their Combination With BMD

Several other clinical risk factors (in addition to BMD, age, gender, and race) have been consistently associated with fracture risk (Table 30.3; Fig. 30.19). Most important of these is a history of fracture since age 50 years or a mother's (or father's) history of hip fracture.[245] Other risk factors, including cigarette smoking, excessive alcohol consumption (more than two drinks per day), rheumatoid arthritis, and glucocorticoid use, also have some association with risk.[244,246] Compromised neurologic or muscular function is a strong risk factor, probably through an increased likelihood of falls. There is also a growing awareness that diabetics, despite a generally high BMI, are at higher risk of fracture and that this risk at the same BMD is higher than that for nondiabetics.[247] Surprisingly, some recent studies have suggested that obesity may be a risk factor for fracture in some settings: in the MrOS study, it was suggested that at the same BMD, elderly men who were obese were at higher risk than those who were not obese.[248]

There is a growing appreciation that fracture risk, like heart disease risk, is multifactorial and that these risk factors work in combination to increase risk.[244,246] More recently, risk assessment tools predicting 5- or 10-year risk of fracture from combinations of BMD and risk factors together have been developed. The most widely used and available is the FRAX fracture risk

• **Fig. 30.18** Age-standardized hip fracture incidence rates in women and men according to country. TABLE 30.3 Different Combinations of Relevant Fracture Risk Factors Used to Calculate an Individual's Probability of Fracture in 10 Years

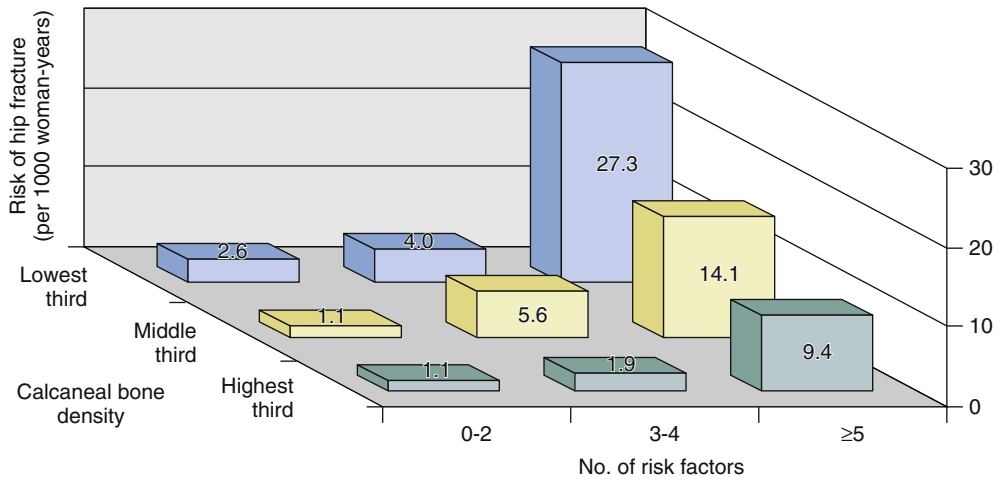
FRAX	Q-Fracture Score	Garvan
Age	Age	Age
Sex	Sex	Sex
Weight	Weight	
Personal history of fracture (vertebral inclusive)		Personal history of fracture
Parental history of hip fracture	Parental history of hip fracture	
Current smoking	Current smoking (graded)	
Glucocorticoid (prednisolone equivalent 5 mg for ≥3 months)	At least two prescriptions for systemic corticosteroids in the 6 months before baseline	
Rheumatoid arthritis	Rheumatoid arthritis	
Secondary osteoporosis, type 1 diabetes mellitus, osteogenesis imperfecta in adults, hyperthyroidism, hypogonadism, chronic malnutrition, and liver disease	Secondary osteoporosis, cardiovascular disease, type 2 diabetes mellitus, asthma, chronic liver disease, gastrointestinal conditions likely to result in malabsorption (e.g., Crohn disease, ulcerative colitis, celiac disease, steatorrhea, blind loop syndrome), thyrotoxicosis, primary or secondary hyperparathyroidism, Cushing syndrome	
Alcohol ingestion (>3 units/day)	Alcohol ingestion (>3 units/day) At least two prescriptions for tricyclic antidepressants in the 6 months before baseline At least two prescriptions for hormone replacement therapy (in women) in the 6 months before baseline	
	History of falls before baseline	History of falls
Bone mineral density (optional)		Bone mineral density

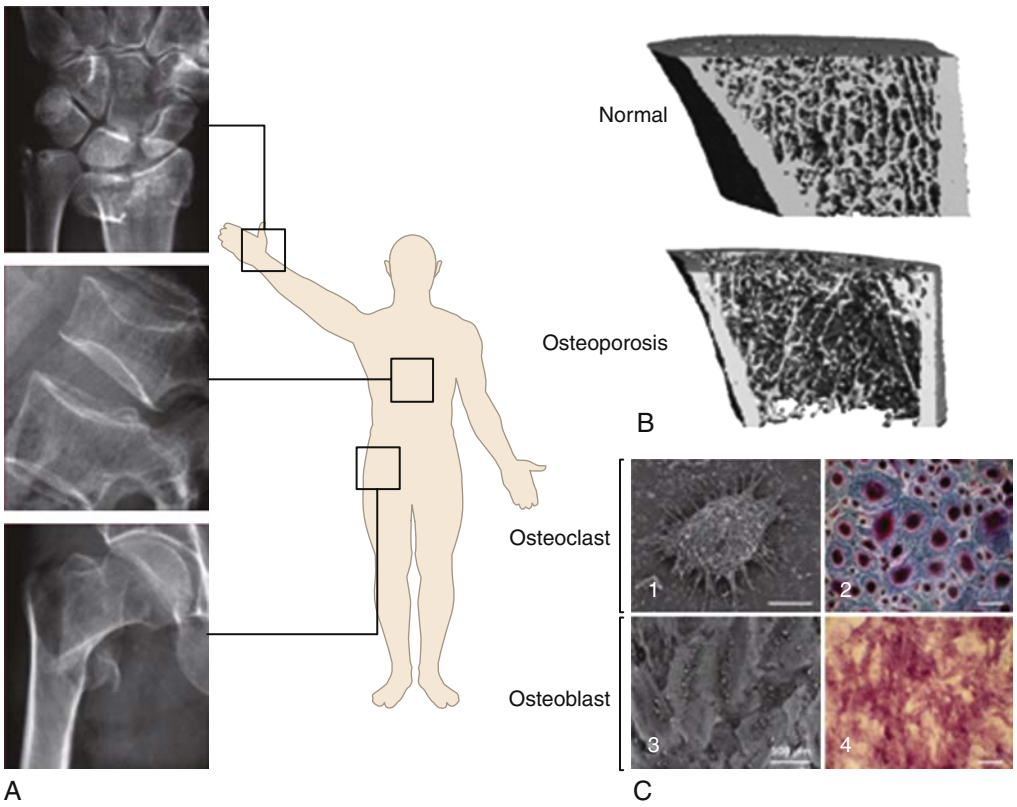


• **Fig. 30.19** Annual risk of hip fracture according to the number of risk factors and the age-specific calcaneal bone density. (Redrawn from Cummings SR, Nevitt MC, Browner WS, et al. Risk factors for hip fracture in white women. Study of Osteoporotic Fractures Research Group. *N Engl J Med*. 1995;332:767–773. Copyright © 1995 Massachusetts Medical Society. Reprinted with permission.)

assessment tool, which includes the risk factors in Table 30.3 and has been implemented with country-specific versions[249] for predicting risk of hip and major osteoporotic fractures. Other risk assessment tools have also been proposed and include different or fewer risk factors.[250] Clinical guidelines for treatment have been developed incorporating these tools (discussed later; see Table 30.3).

Prevalence of Osteoporosis and Incidence of Fractures in the Population

Estimates of the prevalence of osteoporosis have depended on the working definition of this disease and the appropriate diagnostic criteria, and they have been based on either the prevalence of low BMD or fracture incidence.[251–253] Basing a definition solely on BMD became increasingly possible after the development and



• **Fig. 30.20** Osteoporosis at a glance. Osteoporosis is a systemic skeletal disease in which bone resorption exceeds bone formation and results in microarchitectural changes. (A) Fragility fractures typically involve the wrist, vertebrae, and hip. (B) Microcomputed tomography shows marked trabecular thinning of osteoporotic bone compared with normal bone. (C) Microscopic views of bone-resorbing osteoclasts and bone-forming osteoblasts: *1*, osteoclast with its distinctive morphologic appearance; *2*, tartrate-resistant acidic phosphatase staining of multinucleated osteoclasts; *3*, multiple osteoblasts on mineralized matrix; *4*, alkaline phosphatase staining of osteoblasts. clinical availability of DXA. In 1992, the World Health Organization set a cutoff point of 2.5 SD below a young normal mean value for BMD as a tool for estimating osteoporosis prevalence and comparing across populations[254] (see Table 30.1). The use of DXA in larger epidemiologic studies in women (e.g., the Study of Osteoporotic Fractures) and men (the MrOs study), and particularly in population-based samples (e.g., the National Health and Nutrition Examination Study), has provided estimates of the proportion of people with osteoporosis by BMD.[255–257] Estimates of overall prevalence of osteoporosis vary greatly but place the number close to 40 million Americans.[251,258]

Based on fracture incidence, currently most estimates suggest that there are approximately 0.3 million hip fractures per annum in the United States and 0.6 million hip fractures in Europe.[252,253] Best estimates are that more than a million American postmenopausal women will suffer a spine fracture in the course of a single year.[251,258] Considering the importance of fracture from an individual's point of view, a 50-year-old Caucasian woman has approximately a 15% to 20% lifetime risk of hip fracture, a similar lifetime risk of wrist fracture, about a 16% lifetime risk of clinical spine fracture, and approximately a 50% risk of at least one osteoporotic fracture.[259–261] Men have about one third the lifetime risk of hip and spine fractures as women but a much lower risk of wrist fracture. Combining osteoporosis prevalence based on either the presence of osteoporotic fractures (i.e., vertebral compressions, wrist fractures, hip fractures, or humerus/tibial fractures) or low BMD, it is estimated that more than 40 million Americans are afflicted with osteoporosis.[262] Worldwide, there are approximately 9 million fractures per year.[263]

Although numbers of fractures are likely to increase in the United States and Europe, this increase will be much more striking in the developing world, particularly in Asia and Latin America, because of an intersection of several trends including increasing population size, increasing life span (into the high-fracture-risk ages), and adoption of a more Western lifestyle (particularly decreasing activity in daily living).[264,265] This increase will result in a consequent increase in need for health care resources. Interestingly, although hip fractures are the most costly individual fractures, the overall costs of other types of fractures together may be greater than that for hip fractures.[266]

Pathogenesis of Osteoporosis

Osteoporosis is a complex disease with a multifactorial origin (Fig. 30.20). The cardinal feature of this disease is fractures usually accompanied by enhanced skeletal fragility. Although the primary focus of this chapter is on the endocrine and metabolic aspects of this disease, it should be noted that falls cause fractures and that one of the primary causes of osteoporotic fractures is falling. Falls are also multifactorial, particularly in older individuals, because

primary muscle weakness, neurologic disorders, drugs, vitamin D deficiency, balance problems, and cardiovascular events such as syncope all can cause falls. Hence, primary prevention of osteoporosis also mandates specific steps to reduce the chance of any fall for whatever reason. Noted in this section are causes of imbalance in the bone remodeling unit that lead to secondary bone loss and subsequent reduction in BMD, enhancing skeletal fragility.

Gonadal Deficiency

Estrogen

Altered bone remodeling is at the heart of the osteoporosis syndrome and can take many forms. Historically, the importance of estrogen in maintaining calcium homeostasis via coupled remodeling in the postmenopausal woman was first established by Fuller Albright in 1947.[267] Since that time, much evidence has accumulated from randomized intervention trials demonstrating that gonadal steroid replacement (estrogen with or without progesterone) reduces bone turnover and increases bone mass, thus protecting the skeleton from fractures.[202,268] However, these data provide only indirect evidence that estrogen levels are important as pathogenic components of the osteoporosis syndrome. More recent studies provide stronger evidence of the association between low estradiol concentrations and low bone mass. Several investigators have demonstrated that the lowest estradiol levels in postmenopausal women (i.e., <5 pg/mL) are associated with the lowest BMD and the greatest likelihood of fracture.[269] In addition, several studies have shown that males with osteoporosis have lower serum levels of estradiol than do age-matched men who do not have low bone mass.[270] Moreover, there are now several case reports describing mutations in genes encoding either aromatase or the estrogen receptor, producing a phenotype of severe osteoporosis in men.[271,272] In the former case, estrogen replacement therapy in those men resulted in a marked increase in spine and hip BMD. In both situations, the lack of functional estrogen, despite normal to high levels of testosterone, resulted in severely low BMD.[199]

Although declining estradiol levels contribute to the osteoporosis syndrome, the precise molecular events or sequences that result from changes in ambient hormonal concentrations are not clear. In some animal models, estrogen deprivation is associated with a marked increase in IL6 synthesis from stromal and osteoblastic cells. This is consistent with experimental findings demonstrating that estrogen regulates the transcriptional activity of the IL6 promoter.[273] However, results in other studies are conflicting. In other experimental paradigms, changes in TNF, IL11, and IL1 can be associated with increased bone resorption.[274–276] RANKL has been identified as a major regulator of osteoclast differentiation, and increases (both locally and systemically) likely contribute to the rapid increase in osteoclastogenesis after estrogen withdrawal. Thus, it seems likely that several cytokines, working in concert with RANKL, are active during estrogen deprivation, and each can accelerate the process of bone resorption. Osteoclasts express estrogen receptors, and some evidence suggests that direct actions of estrogen on osteoclasts are important as well. Enhanced bone resorption eventually leads to bone loss from estrogen deprivation because bone formation rates cannot keep up with the high rates of bone resorption[277] (see Fig. 30.15).

Androgens

In contrast to the plethora of studies on uncoupled bone remodeling and bone loss with low estradiol levels, there are fewer studies relating androgen deprivation to bone loss in both men and women. Androgen receptors are present on osteoblasts, and testosterone and dihydroxytestosterone both stimulate osteoblast differentiation.[278] Testosterone may also increase skeletal and circulating IGF1. However, both in vitro and in vivo studies in men have yielded conflicting results with respect to bone resorption. Like estrogen, androgens can regulate the IL6 promoter, and in experimental animals, orchiectomy has been associated with increased IL6 production and bone loss.[279] Men who undergo androgen deprivation therapy after prostate cancer lose bone rapidly as a result of increased bone resorption. Similarly, hypogonadal men, either due to primary or secondary insufficiency, have lower bone density values than control men. Because, unlike estradiol, testosterone can stimulate bone formation, this may be an additional factor that contributes to bone loss when absent in men.[280]

Low testosterone levels that are found in postmenopausal women have not been causally associated with rapid bone loss, but women with greater body weight have greater capacity to enzymatically convert testosterone to estradiol, which may contribute to the protective effect of obesity on bone mass, at least in women. Notwithstanding, because in men with chronically low androgen levels have been associated with low bone mass, testosterone replacement can be used to both enhance BMD and increase lean body mass.[280] However, as noted, estradiol levels in men may be a more important risk factor for fracture than androgen levels. In sum, the combination of both estrogen and androgens probably determines peak bone mass and maintenance of BMD in both men and women. In elderly men, estradiol levels may be essential for maintaining trabecular bone mass. To underline that tenet, in one randomized trial using a gonadotropin-releasing hormone analogue (to suppress gonadotropins) with and without an aromatase inhibitor in men, changing estrogen levels were associated with protection of the trabecular skeleton from bone resorption, whereas circulating androgen levels were more related to markers of bone formation than those of resorption.[202] In another study, Almeida and colleagues[281] found that in rodents, protection of cortical bone mass by estrogens is mediated via estrogen receptor α. In contrast, the androgen receptor of mature osteoblasts was indispensable for the maintenance of trabecular bone mass in male mammals but was not required for the anabolic effects of androgens on cortical bone.[278,282]

In men, conditions other than hypogonadism can contribute to bone loss and fractures. These states include chronic alcoholism, glucocorticoid excess, smoking, and idiopathic hypercalciuria. In the first two cases, low testosterone levels probably contribute to the pathogenic features of osteoporosis syndrome, whereas hypercalciuria due to renal loss probably causes bone loss through secondary hyperparathyroidism. Less frequent but still important secondary causes of osteoporosis in men must also be considered independent of androgen levels, and these include gluten enteropathy, primary hyperparathyroidism, thyrotoxicosis, multiple myeloma, lymphomas, or granulomatous diseases, all of which can present with multiple fractures and low bone mass[283] (see Table 30.3).

Age-Related Bone Loss

In women, bone loss is accelerated immediately after menopause. However, recent studies demonstrate that markers of bone resorption are also very high later in life. In particular, women in their 80s and 90s have been noted to lose bone at a rate of greater than 1% per year from the spine and hip[220] (see Fig. 30.15). Contrary to earlier studies, it is now evident that the older woman who is not

as physically active, and is not taking estrogen, is at extremely high risk of bone loss and subsequent fractures. The pathogenesis of this process is multifactorial, although dietary calcium deficiency, leading to secondary hyperparathyroidism, certainly plays some role. The average calcium intake of women in their eighth and ninth decades of life is now estimated to be between 800 and 1000 mg/day. If vitamin D intake is also suboptimal and serum levels of 25-hydroxyvitamin D are less than 20 ng/mL, or 50 nmol/L, secondary hyperparathyroidism may occur, although there are other causes in the elderly for increases in PTH, including a low glomerular filtration rate and low calcium intake.[284] PTH stimulates osteoblasts and provokes the remodeling sequence including the elaboration of several cytokines that accelerate bone resorption. Unfortunately, in most elders, bone formation is not enhanced, although the reasons for this are not entirely clear. Overall, the secondary hyperparathyroidism coupled with high $1,25(OH)_2D$ (see later discussion in the Vitamin D section) leads to further uncoupling in the bone remodeling cycle and significant bone loss. Furthermore, among elders with poor calcium intake who live in northern latitudes, seasonal changes in vitamin D levels, lowering levels below 20 ng/mL, might aggravate bone loss.[284,285] Whether increased bone loss is an independent risk factor for future fractures in the elderly remains somewhat controversial, necessitating further studies to define such a risk.

Many older individuals already have established osteoporosis, so coincidental vitamin D deficiency due to poor intake, absent sunlight exposure, or impaired conversion of vitamin D to its active metabolite can result in osteomalacia and aggravate preexisting osteoporosis.[286] Osteomalacia can lead to dramatic changes in skeletal microarchitecture, as was recently demonstrated in a cohort from Germany.[287] Trabecular and cortical changes seen in that study led to microcracks and greater skeletal fragility. Priemel and associates[287] reported that more than 50% of elders who presented with a hip fracture were vitamin D deficient. Combining vitamin D deficiency with inadequate calcium intake enhances the likelihood of rapid bone loss in a very susceptible population. Despite these findings, elevated PTH levels in older women have been associated with bone loss in some studies but not in other studies. In elderly individuals, it has been reported that PTH levels are closely correlated with increased synthesis of IGFBP4, which suppresses IGF action on bone cells and may increase sclerostin secretion.[288,289] Because IGF1 is an important growth factor for osteoblasts, it is conceivable that PTH downregulates IGF activity during states of relative calcium or vitamin D deficiency. This would shift the remodeling balance toward preserving intravascular calcium concentrations while inhibiting new calcium incorporation into the skeletal matrix. This response makes teleologic sense, although further studies are needed to assess whether serum IGFBP4 is a reliable marker of calcium deficiency in older individuals.[289] In sum, there is little doubt that calcium and vitamin D insufficiency can cause accelerated bone loss in the elderly, although the threshold for low vitamin D and poor calcium intake is still actively debated. Other concomitants of aging, such as accumulation of ROS (seen in aged mice) and other causes of damage to bone cells, appear likely to contribute to age-associated osteoporosis as well.[290]

Secondary Osteoporosis

The division of osteoporosis into primary and secondary forms is somewhat arbitrary. For example, patients with diseases that lead to hypogonadism early in life are considered to have *secondary osteoporosis*, whereas osteoporosis in women with natural menopause and older men with low sex hormone levels is called *primary osteoporosis*. Moreover, patients may have a combination of primary and secondary forms. Although most postmenopausal women and older men do not have a definable secondary cause, those who do can be treated more effectively. This possibility should be considered for every patient. There are many causes of secondary osteoporosis (Table 30.4), only a few of which are discussed here.

Glucocorticoid-Induced Bone Loss

The most common cause of secondary osteoporosis is glucocorticoid-induced bone loss, which is often a result of pharmacologic doses of steroids used to treat inflammatory or autoimmune disorders. Generally, it is considered that glucocorticoids have a dose-dependent effect on the skeleton such that longer duration and higher doses of steroids are most likely to cause bone loss and fractures. However, there clearly are subsets of individuals who are more or less sensitive to the skeletal effects of high doses of glucocorticoids. As a clinical rule, those individuals with a cushingoid appearance and fat redistribution phenotypes almost always have low bone mass and fractures. Notwithstanding, BMD measurements are indicated in patients on long-term glucocorticoids for both preventive approaches and treatment decisions.[291,292]

As noted previously, high circulating levels of glucocorticoids have a significant impact on bone acquisition and maintenance. In 1932, Harvey Cushing recognized the syndrome of endogenous steroid excess, which included marked osteopenia and fractures.[293,294] Long-term exposure to pharmacologic doses of glucocorticoids results in significant bone loss and enhanced marrow adipogenesis as marrow stromal cells differentiate down the fat lineage. In addition to having direct effects on the osteoclast and osteoblast, glucocorticoids also induce secondary hypogonadism and hyperparathyroidism, impaired vitamin D metabolism, muscle atrophy, and hypercalciuria. All of these factors contribute to a rapid and sustained loss of bone during the first few months of steroid therapy.[295,296] The addition of other immunosuppressants, such as cyclosporine, has been shown to aggravate bone loss by further increasing bone resorption. Because the number of organ transplants has increased exponentially over the past decade, the prevalence of post-transplantation osteoporosis has risen substantially. Steroid-induced osteoporosis is now considered the second most common cause of low bone mass in the general population and one of the most common causes of osteoporotic fractures.[297]

The effects of glucocorticoids on the skeleton are multifaceted and are particularly devastating because these agents cause uncoupling in the remodeling unit. Besides the indirect suppressive effects of glucocorticoids on the hypothalamic-gonadal axis, and inhibition of calcium absorption in the gut due to impaired $1,25(OH)_2D$ production, high doses of steroids can stimulate osteoclastogenesis, increase RANKL production, and decrease OPG. This situation results in higher rates of bone resorption. Additionally, glucocorticoids also have a strong negative effect on bone formation by suppressing expression of IGF1 in bone cells and by shifting marrow stromal cells into the fat lineage rather than down the osteoblast differentiation pathway.[292] It is presumed that just as fat redistribution is a clinical hallmark of Cushing syndrome in the supraclavicular and mediastinal area, enhanced adiposity in the bone marrow is a characteristic feature of steroid-induced bone disease, almost certainly as a function of increased stromal cell differentiation into adipocytes.[295] Bone strength is markedly compromised by dramatic uncoupling in remodeling, and bone loss can be rapid over a short period,

TABLE 30.4 Causes of Secondary Osteoporosis

Endocrine Disorders
Diabetes mellitus
Hyperparathyroidism
Hyperthyroidism
Cushing syndrome
Hypogonadism
Menstrual irregularity (even athletes)
Premature menopause
Low testosterone and estradiol levels in men
Hyperprolactinemia
Pregnancy and lactation

Autoimmune Disorders
Rheumatoid arthritis
Inflammatory bowel disease
Lupus erythematosus
Multiple sclerosis
Ankylosing spondylitis

Digestive and Gastrointestinal Disorders
Celiac disease
Inflammatory bowel disease
Weight loss surgery
Gastrectomy

Hematologic/Blood Disorders
Leukemia and lymphoma
Multiple myeloma
Sickle cell disease
Blood and bone marrow disorders
- Plasma cell dyscrasias: multiple myeloma and macroglobulinemia
- Myeloproliferative disorders: polycythemia

Thalassemia

Neurologic/Nervous System Disorders
Stroke, Parkinson disease, and multiple sclerosis
Spinal cord injuries

Mental Illness
Depression
Eating disorders

Cancer
Breast
Prostate

Connective Tissue Disorders
Osteogenesis imperfecta
Ehlers-Danlos syndrome
Marfan syndrome
Menkes syndrome

Drug-Induced Disorders
Glucocorticoids
Heparin
Anticonvulsants
Methotrexate, cyclosporine
Luteinizing hormone–releasing hormone agonist or antagonist therapy
Proton pump inhibitors
Aluminum-containing antacids

Other Diseases and Conditions
AIDS/HIV
Chronic obstructive pulmonary disease
Female athlete triad
Kidney disease
Liver disease
Organ transplant
Poliomyelitis and post-polio syndrome
Poor diet, including malnutrition
Weight loss
Lipidoses: Gaucher disease
Scurvy

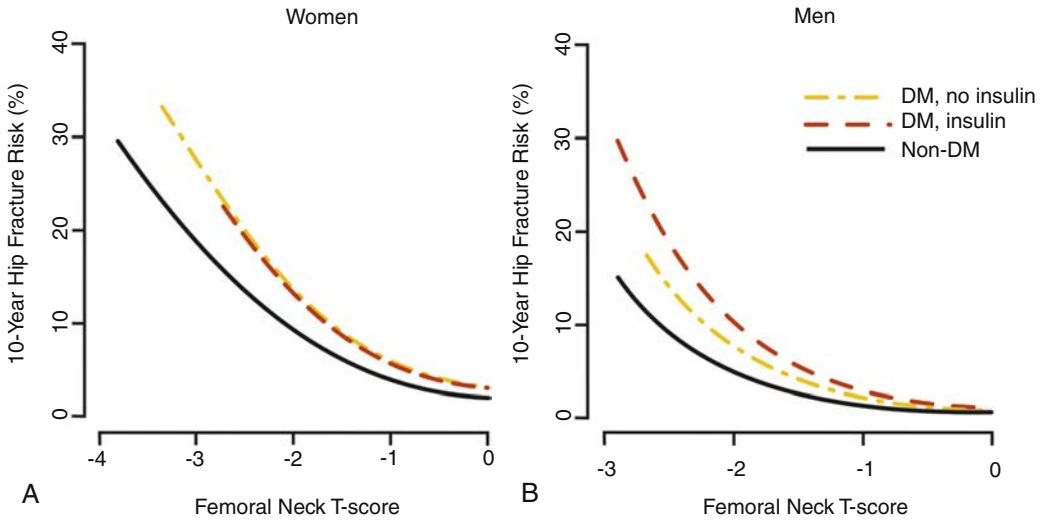
AIDS, Acquired immunodeficiency syndrome; *HIV*, human immunodeficiency virus.

particularly with high doses of glucocorticoids. Although there is no true dose-dependent effect on bone resorption, it is thought that prednisone doses as low as 5 mg/day may increase fracture risk.[298] Indeed, in this syndrome, baseline BMD is not predictive of fractures and can often be normal even in the presence of ongoing resorption and recurrent fractures.[299] Trabecular bone suffers the most in this syndrome, and spine DXA is the most sensitive indicator of bone loss. Markers of bone turnover are not helpful in the management of these patients.

Therapy for steroid-induced bone loss centers on treating the underlying disease and reducing the dose of glucocorticoids to the lowest possible regimen. Barring that, several interventions have been shown to retard bone loss and prevent fractures. Adequate calcium and vitamin D intake is critical for every patient receiving glucocorticoids. However, these measures alone are not sufficient. Regulatory approval for the prevention and treatment of glucocorticoid-induced osteoporosis has been consistent for the group of bisphosphonates, including alendronate, risedronate, and zoledronic acid.[300–303] These drugs are administered either weekly or cyclically to prevent bone loss and reduce the risk of fractures. Some anecdotal data support the use of gonadal steroids in this condition, but clearly bisphosphonates are superior. In a randomized trial, PTH (20 μg of teriparatide subcutaneously daily for 18 months) significantly increased hip and spine bone mass density and reduced the number of new vertebral fractures (7.2% to 3.4%) but not other fractures compared with alendronate.[304] More studies are needed to establish its long-term efficacy in this disease, particularly because secondary hyperparathyroidism is a frequent accompaniment of steroid-induced osteoporosis.

Osteoporosis Associated With Diabetes Mellitus

Diabetes mellitus includes a group of heterogeneous metabolic disorders that in common show hyperglycemia. The association between diabetes mellitus and osteoporosis underpins several relevant aspects. First, energy metabolism integrates the whole body; as such, severe disorders affecting energy metabolism do not spare any single system or tissue. Second, the endocrine regulation of bone and energy metabolism is not restricted to classical glands and neural regulation. Au contraire, there is an intricate mutual regulation between energy metabolism and mesenchymal tissues, including bone.[305] Last, bone fragility in diabetes mellitus represents another aspect of the heterogeneity of diabetes mellitus;



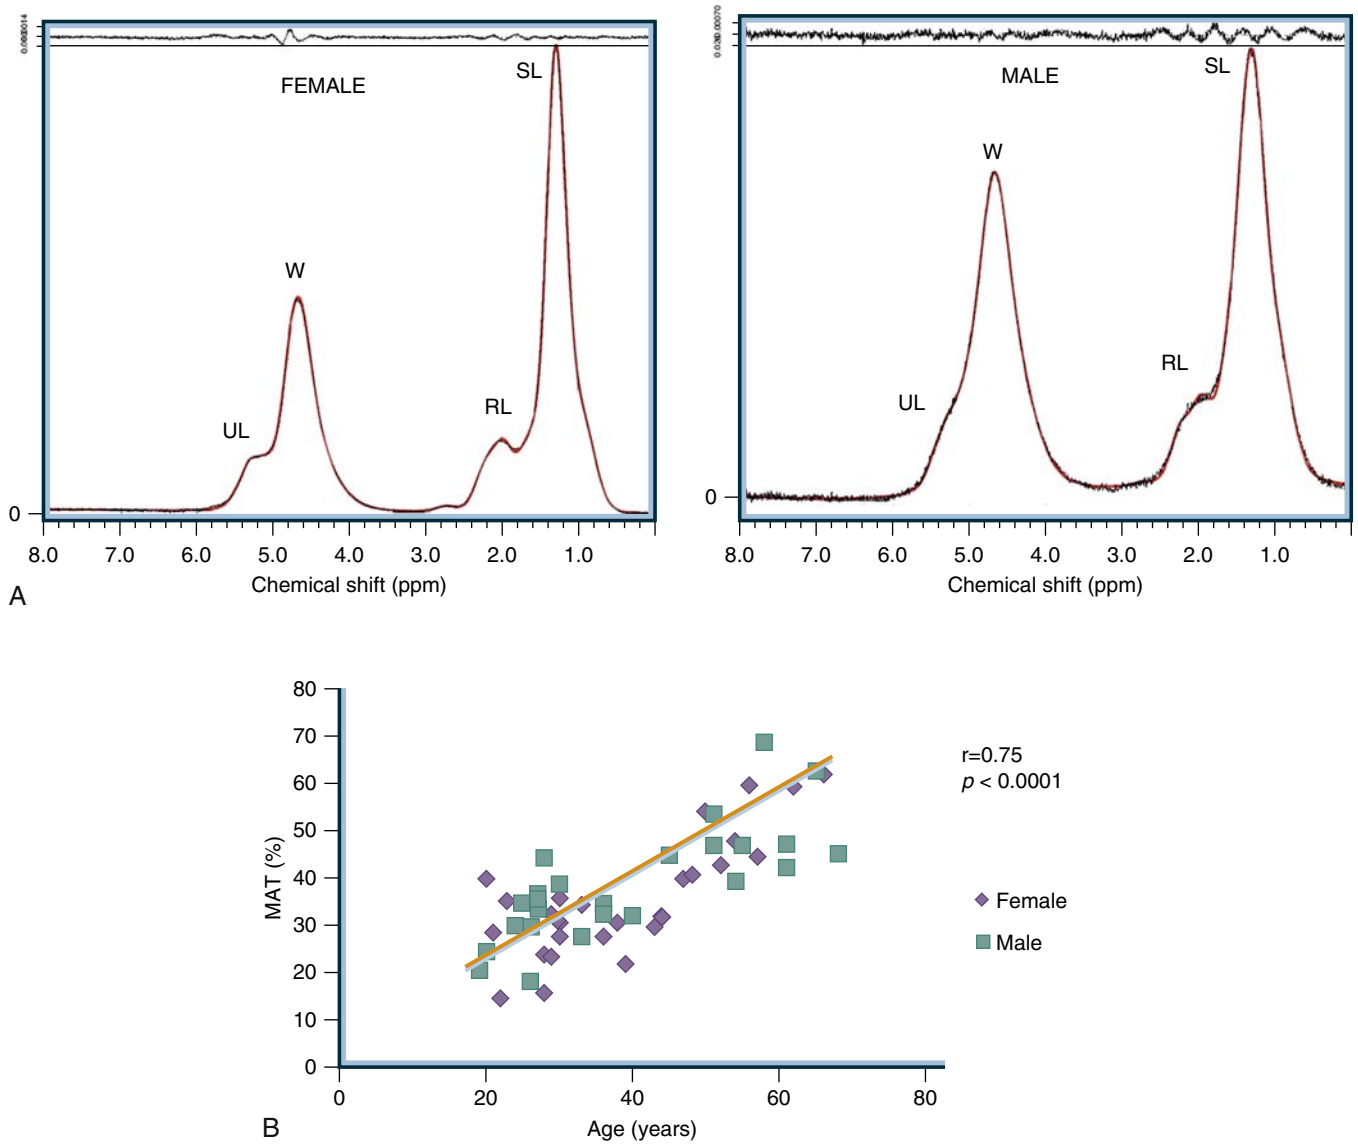
• **Fig. 30.21** Femoral neck bone mineral density T-score and 10-year fracture risk at age 75 years by diabetes status and insulin use. Estimated 10-year cumulative fracture risk at age 75 years in women (A) and men (B), calculated using the Cox proportional hazards regression model baseline survival function raised to the power of the relative hazard for each combination of diabetes group and T-score. *DM,* diabetes mellitus. (From Schwartz AV, Vittinghoff E, Bauer DC, et al. Association of BMD and FRAX score with risk of fracture in older adults with type 2 diabetes. *JAMA.* 2011;305[21]:2184–2192.)

striking differences exist between bone disorders in T1DM and T2DM. T1DM is associated with bone loss and was rapidly recognized as a risk factor for osteoporosis and bone fractures. However, bone mass is preserved or increased in T2DM, meaning that bone quality instead of quantity is the primordial mechanism affecting bone strength in this disorder.

Findings from epidemiologic studies in recent decades indicating dramatic increases in the prevalence of T2DM worldwide mirror the evolving numbers of US residents diagnosed with this metabolic disorder. The "Diabesity" (obesity and T2DM) epidemic has been referred to as the biggest epidemic in human history.[306] T2DM accounts for approximately 90% of all cases of diabetes. Globally, the number of people with diabetes is estimated to be 415 million, affecting more than one third of the US population. Therefore, the magnitude of the importance of osteoporosis in diabetes mellitus has only recently been fully recognized when it was demonstrated that the risk of fracture is increased not only in T1DM but also in T2DM. The delayed inclusion of T2DM among the risk factors of fracture was certainly influenced by consistent documentation that T2DM does not affect bone mass. Although there are studies suggesting that the rate of bone loss is increased in T2DM, in all probability bone quality, rather than quantity, is primarily affected by this disorder. At the same level of BMD, individuals with T2DM have increased fracture risk when compared with normoglycemic individuals[247] (Fig. 30.21).

Several findings support the increased bone mass observed in T2DM. First of all, obesity, which is the central determinant for the emergence of insulin resistance and hyperglycemia, has a positive effect on bone mass.[307] Bone remodeling is typically reduced in diabetes mellitus.[308] Moreover, a clinical study described a negative association between bone mass and the serum levels of osteocalcin in T2DM. Most likely, these results mean that bone turnover is not only reduced, but it also exerts a protective effect on bone mass in T2DM.[194] Hyperinsulinemia is another element involved in the protection of bone mass in T2DM. The striking difference in the secretion of growth factors and adipokines between T1DM and T2DM certainly is another point to be taken into consideration. T1DM is usually associated with low serum levels of IGF1, whereas this is not part of the hormonal alterations in T2DM. However, T2DM predominantly exhibits an inflammatory profile in adipokine secretion by the white adipose tissue that is represented by increased levels of leptin, chemerin, resistin, TNF, and interleukins, whereas adiponectin is reduced. Leptin and adiponectin have complex effects on bone, and there are still no conclusive results about their ultimate effects on bone.[305]

The paradoxical increase in fracture risk in T2DM has respectively challenged researchers and clinicians to unveil mechanisms determining bone fragility and expedite the identification of individuals at risk, as well as the best therapeutic options to prevent fracture in this population. Using an animal model mimicking T2DM, structural alterations in collagen and deterioration in bone strength were found coincidently with the onset of hyperglycemia.[309] The analysis showed an increase in AGEs, whereas a decrease in immature enzymatic collagen cross-links occurred in diabetic animals.[309] Under clinical investigation, it was observed that the urinary excretion of pentosidine, an AGE, was associated with vertebral and hip fracture in postmenopausal women.[310] Advances in imaging techniques allowed the detection of alterations not previously captured by conventional methods. Long bone cortical porosity was described in individuals diagnosed with T2DM.[311,312] Although this finding was not confirmed in other studies, cortical porosity remains a potential alteration determining fracture susceptibility in individuals with T2DM.[313,314] Magnetic resonance has been successfully used to quantify MAT and the composition of lipids within marrow adipocytes[305] (Fig. 30.22A). In several conditions, such as anorexia nervosa, glucocorticoid therapy, and aging, there is an inverse relationship between bone mass and MAT (see Fig. 30.22B). The amount of MAT was similar in normal weight/normoglycemic, obese/normoglycemic and obese/diabetic individuals.[194] However, another study found that both fractures and T2DM are associated with alterations in the composition of lipids in MAT, namely increased saturated and decreased unsaturated lipids.[315] In accordance, individuals with diabetes who are diagnosed with fractures exhibit remarkable



• **Fig. 30.22** (A) 1H magnetic resonance spectroscopy allows the estimation of lipids composition in MAT. Recent studies called attention for the clinical relevance of this parameter, such as the association of saturated lipids with fracture in diabetic individuals. The top figure exhibits differences in unsaturated fat between male and female (female > male). (B) Age-related increase in marrow adipose tissue in a group of healthy controls: 53 individuals, 28 females and 25 males; age, female: 38.8 ± 13.2 years and male: 39.7 ± 15.6 years; weight, female: 60.4 ± 6.4 kg and male: 66.0 ± 8.0 kg; height, female: 1.65 ± 0.08 m and male: 1.71 ± 0.06 m; and body mass index, female: 22.1 ± 1.8 kg/m^2 and male: 22.3 ± 1.9 kg/m^2). *H,* hydrogen; *MAT,* marrow adipose tissue; *RL,* residual lipids; *SL,* saturated lipids; *UL,* unsaturated lipids, *W,* water. (Redrawn from de Paula FJ and Rosen CJ. Structure and function of bone marrow adipocytes. *Compr Physiol*. 2017;8[1]:315–349.)

accentuation of saturated lipids within MAT.[315] More recently, a clinical investigation, using an in vivo microindentation device, observed an alteration in a bone material property, namely the bone material strength index (BMSi). The studies also highlighted a negative association between BMSi and long-standing poor metabolic control, indicating a connection between bone disease and chronic diabetes complications.[313] Reinforcing these results, there was also an inverse association between BMSi and AGEs, as determined by skin autofluorescence.[313]

Altogether, BMD underestimates fracture risk in individuals with T2DM (see Fig. 30.21). Objectively, for a similar hip fracture risk, it was estimated that T2DM women and men have higher T-scores of 0.59 (95% confidence interval, 0.31–0.87) and 0.38 (95% confidence interval, 0.09–0.66), respectively, than normoglycemic individuals.[247] Awareness regarding the implication of osteoporotic fractures in individuals with diabetes has to be highlighted due to their increased morbidity and mortality rate, as well as the worse fracture outcomes in this population.

The intricate relationship between bone and energy metabolism aggregates issues concerning the potential repercussions of osteoporosis therapy on glucose metabolism, on one side, and the effects of diabetes management on bone mass and fracture occurrence, on the other. Osteoblasts express insulin receptor, and the experimental silencing of insulin receptor specifically in osteoblasts results in both decreased bone mass and impairment in glucose tolerance. Two research groups independently collected evidence

that uncarboxylated osteocalcin is an endocrine molecule originating in osteoblasts that modulates insulin secretion and sensitivity.[21,22] Initially produced in a carboxylated form, osteocalcin is the most abundant noncollagenous protein in the bone matrix and has a role in the mineralization process. The acidic environment created by osteoclasts to elicit bone resorption promotes osteocalcin decarboxylation. GPRC6A, a G-protein coupled receptor, has been identified as the pancreatic effector of uncarboxylated osteocalcin promoting beta-cell hyperplasia and insulin secretion, as verified in several experimental models.[316] Moreover, uncarboxylated osteocalcin seems to increase insulin sensitivity by stimulating adiponectin secretion in white adipose tissue.[317] However, inconclusive findings have been reported in clinical investigations related to the association between osteocalcin and insulin sensitivity, as well as glucose tolerance. For instance, individuals showing decreased circulatory levels of osteocalcin due to bisphosphonate and denosumab therapy do not exhibit increased incidence of diabetes.[318,319] Moreover, patients diagnosed with primary hyperparathyroidism exhibit insulin resistance despite an increased rate of bone remodeling and increased serum levels of osteocalcin.[320]

Antidiabetic drugs have diverse effects on bone, from beneficial to neutral or even detrimental effects[321] (Table 30.5). Thus, implementation of an appropriate strategy is necessary to preclude undesirable increase in fracture risk in these individuals. Thiazolidinediones are a group of drugs associated with adverse effects on bone mass and increased risk of fracture. Thiazolidinediones are exogenous agonists of PPARs that drive bone marrow mesenchymal stromal cells to differentiate into adipocytes, inhibiting osteoblastogenesis via decreasing Runx2 transcription factor, as well as IGF1 and Wnt signaling pathways. Insulin positively affects bone mass; notwithstanding, insulin therapy is associated with bone fracture. The mechanism determining bone fragility and whether it is mediated through hypoglycemia and increased risk of falls are still to be clarified. Metformin and sulfonylureas, however, seem to have neutral or beneficial effects on bone. Among the sodium-dependent glucose transporter 2 inhibitors, issues have been raised regarding the bone safety of canagliflozin.[322] There are several potential determinants of detrimental effect of sodium-dependent glucose transporter 2 inhibitors on bone, including hyponatremia-induced bone resorption.[323] In addition elevation in the serum levels of phosphate can stimulate the secretion of PTH and possibly FGF23, thereby leading to bone loss.[324] Experimental evidence indicates that incretins-based therapy (DDP4 inhibitors) and GLP1 receptor agonists (GLP1RA) have positive effects on bone. Osteopenia, increased osteoclast activity/numbers, and reduced bone strength are components of the bone phenotype in GLP1 receptor (GLP1R) knockout mice. Moreover, administration of GLP1RA reversed the bone loss in rats subjected to an experimental model of disuse osteoporosis.[325] Notwithstanding, there is limited clinical data about the bone effects of DPP4 inhibitors and GLP1RA; additional studies are needed to clarify the effects of the incretins-based therapy on fracture risk.

Factors That Impair Peak Bone Acquisition

Peak bone mass is acquired between the ages of 10 to 16 years. It is the zenith of bone acquisition and represents the sum of several processes including a marked increase in bone formation.[326] Boys tend to peak 2 years later than girls, and their BMD is higher than women at all skeletal sites. In part, this difference relates to a greater cross-sectional bone area in males than females.[326] Peak bone mass results from linear growth and consolidation of cortical and trabecular components. Acquisition is most rapid during the latter stages of puberty and coincides with maximum growth hormone secretion, high serum IGF1 levels, and rising levels of estradiol and testosterone. In addition, calcium absorption is maximum and skeletal accretion is optimal owing to higher levels of $1,25(OH)_2D$. These processes coalesce over a relatively short period to produce a bone mass that subsequently plateaus and then falls during later life. It is estimated that more than 60% of adult bone mass can be related to peak acquisition.[327] Hence, understanding the mechanisms responsible for low bone mass must include perturbations in peak bone acquisition.

There are several hormonal, environmental, and heritable determinants of peak bone mass, including estrogen/testosterone, growth hormone/IGF1, calcium/vitamin D, and unknown genetic factors. If any is perturbed, dramatic alterations in peak bone mass may occur, setting the stage for low bone density throughout life. Not surprisingly, gonadal steroids are essential not only to bone maintenance but also to acquisition. During puberty, estrogen and testosterone levels rise and contribute to consolidation of bone mass. Estrogen is also necessary for epiphyseal closure. Studies of males with an estrogen receptor mutation and men with an aromatase deficiency have established that estradiol is critical for

bone acquisition.[199,271,272] These young men share several phenotypic characteristics, including tall stature, unfused epiphysis, and very low bone mass. Hence, there must be a threshold effect for estradiol in men, and this effect must be time dependent. Similar conclusions can be drawn from studies in women. Acquired deficiencies in estrogen, such as occur with anorexia nervosa or chemotherapy-induced ovarian dysfunction, result in low peak bone mass and lead to subsequent risk for osteoporosis.[328,329] Similar findings have been noted in patients with untreated Turner syndrome and in men with Klinefelter syndrome.[330,331]

The timing of gonadal steroid surges is critical for bone acquisition because there is a relatively short window of time in which bone formation is favored and matrix synthesis is markedly enhanced.[332] That time window is likely to be less than 3 years and earlier in girls than boys. Probably the best study that addressed this issue comes from a retrospective analysis of men in their 30s who underwent late onset of puberty (i.e., at the age of 17 or 18 years) but were otherwise normal by full endocrine testing.[333] These men had significantly lower BMD than age-matched men who went through puberty at the normal time. These data suggest that both timing and quantity of gonadal steroids are critical for bone acquisition.

Pubertal surges of estrogen and androgens are also important for priming the growth hormone/IGF1 axis. Rising levels of both contribute to growth hormone surges that lead to increases in circulating and tissue expression of IGF1, an essential growth factor for chondrocyte hypertrophy and expansion. IGF1 may also be critical in defining the cross-sectional size of bone, a potentially important determinant of bone strength.[334] Once again, studies in individuals who are growth hormone deficient or resistant have established that low levels of circulating IGF1, especially during puberty, are associated with reduced bone mass.[170,335] In addition, recombinant human growth hormone replacement has been shown to restore linear growth and improve peak bone mass acquisition. Several studies in experimental animals, including inbred strains of mice, have established that IGF1 is important for bone acquisition and that the timing of IGF1 peaks coincides with maximal rates of bone formation.[336] Impairment in production of IGF1 due to acquired disorders (e.g., anorexia nervosa), malnutrition, delayed puberty, or diabetes mellitus can also impede peak bone acquisition.[337]

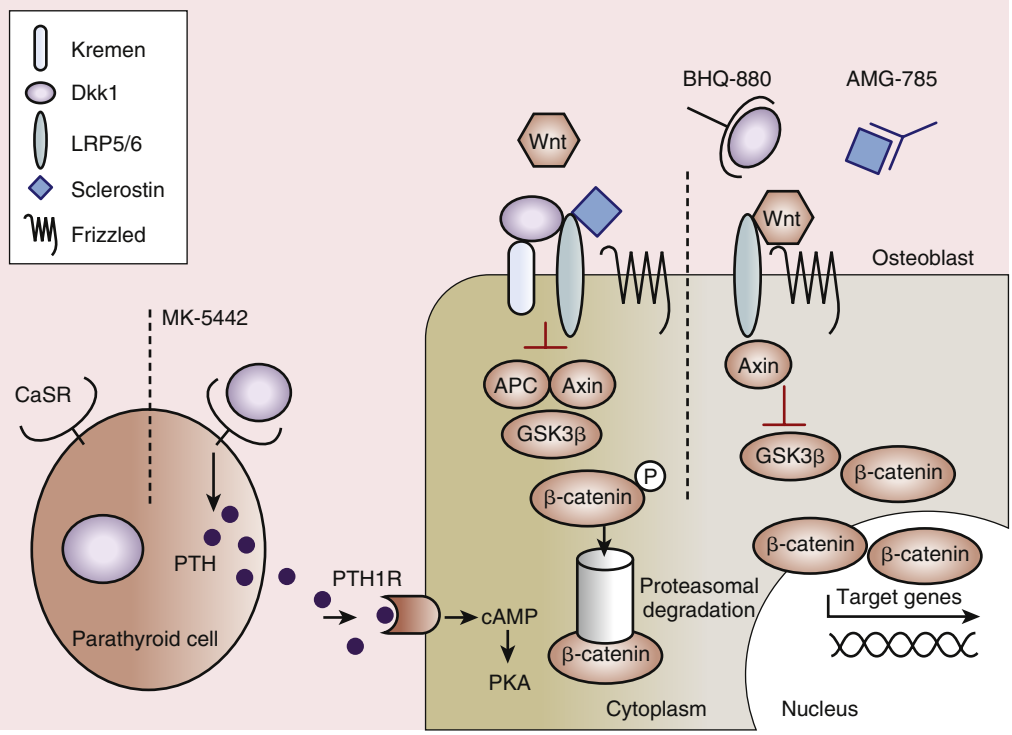
Hormonal abnormalities not only enhance bone resorption in older individuals but also may blunt the capacity of bone cells to maximize bone formation during adolescence. Clearly, hypogonadal boys and girls have impaired peak bone mass, resulting in low adult BMD.[330,331] One form of contraception, medroxyprogesterone, may reduce estrogen concentrations enough in the teenage girl to reduce her capacity to acquire peak bone mass.[338] Similarly, it seems likely, although not yet proved, that smoking during the teen years could impair osteoblast activity and flatten projected trajectories for peak bone acquisition.

To mineralize newly synthesized bone, calcium must become bioavailable to the skeletal matrix. In experimental studies in rodents and humans, it is clear that the several pools of available calcium are markedly enhanced during puberty. These sources include calcium efflux from the gastrointestinal tract and the calcium pool available for incorporation in the matrix. It is no coincidence that growth hormone surges not only increase IGF1 (thereby enhancing skeletal growth and matrix biosynthesis) but also result in increases in $1,25(OH)_2D$ (possibly via IGF1 induction of 1α-hydroxylase activity), the active metabolite of vitamin D, which markedly enhances calcium absorption from the gut.[339–341] Although there are no longitudinal studies in pubertal individuals with prolonged calcium deficiency, several randomized, placebo-controlled trials (RPCTs) in pubertal and prepubertal girls and boys have established that supplemental calcium can enhance BMD.[342,343] In a twin study in which one twin received calcium supplementation and one received placebo, radial BMD increased by as much as 5% after 3 years in the twins given calcium when compared with those given placebo.[343] This study suggests that there is significant gene-environmental interaction, and that even in those individuals with heritable determinants of low peak bone mass, calcium supplementation may provide an important and relatively simple means of protecting individuals from future osteoporotic fractures.

Genetic Factors That Determine Peak Bone Mass

Probably the most important determinant of peak bone mass, albeit one that has lacked clear definition, is the genetic contribution. As noted earlier, low peak bone mass may be the most important pathogenic factor in the osteoporosis syndrome of later life. Further, it appears that at least 50% of peak bone mass is determined by genetic factors.[344–346] Efforts to define heritable determinants of peak bone mass have been plagued by several issues that are also common to other complex diseases. They include the following: (1) a quantifiable phenotype, (2) heterogeneity within a given population under study, and (3) the polygenic nature of the disorder. In the postgenomic era, it has become clear that complex diseases, such as osteoporosis, cannot be settled by single nucleotide polymorphisms (SNPs). Instead, they are originated by a confluence of multiple genetic variations. Naturally, the interest has been driven to assess epistasis to unveil the complex network involved within multiple SNP interactions, as well as the influence of environmental factor into gene expression. Notwithstanding these barriers, it is now clear that BMD is an acceptable phenotype for defining heritable determinants. In addition, BMD is fully quantifiable and therefore is amenable to complex trait analysis. Moreover, BMD in the population is distributed in a gaussian manner, thereby allowing analyses at the extremes (<–2.0 SD or >2.0 SD) of the density distribution. Large homogeneous and heterogeneous populations are now being studied to ascertain genetic determinants of bone density in humans. Candidate genes identified by whole genome studies include RANKL, OPG, the VDR, collagen IA1, the estrogen receptor IL1, IGF1, and others. Depending on the cohort, the phenotype, and the number of individuals studied, there are likely to be hundreds of genes that contribute to individual variation in bone mass.[347] Indeed, in most large genome-wide association studies using validation cohorts to confirm candidate genes, the effect size of most noncoding SNPs is at best 1%. Notwithstanding, there has been a major effort to consolidate studies from around the world to increase power and detect rare variants that might provide even greater insight into genetic determinants, and importantly shed greater light on the biology of low bone mass. Twin studies examining discordant or concordant phenotypes are also helpful, as are sibling-pair studies, although the results have been disappointing.[76,347,348]

Originally, Johnson and colleagues[349] identified an extended family with very high bone density and fine mapped the locus to a region in chromosome 11. After several years of intense high-throughput analysis, the high-bone-density gene that was mutated in this family was identified as *LRP5*.[350] This member of the lipoprotein receptor family is important for binding Wnts, ligands critical for cell differentiation in several organisms. One year earlier, Gong and colleagues[351] identified mutations in the *LRP5* gene in several children with osteoporosis-pseudoglioma syndrome. The potential pathways that direct osteoblast function and



• **Fig. 30.23** Osteoblast physiology and potential therapeutic targets. The calcium-sensing receptor is antagonized by MK-5442 and triggers short bursts of PTH secretion. Binding of PTH to its receptor enhances osteoblast functions and bone formation. Presence of Wnt antagonists Dkk1 and sclerostin inhibits Wnt signaling. Dkk1 needs to form a complex with Kremen to bind LRP5/6, whereas sclerostin binds LRP5/6 directly. BHQ-880 and AMG-785 are antibodies for Dkk1 and sclerostin, respectively. After neutralizing Dkk1 and sclerostin, Wnt can bind to LRP5/6, which results in degradation GSK3β. As a consequence, β-catenin is stabilized, accumulates, and translocates into the nucleus, where it regulates transcription of osteoblastic genes. *APC,* adenomatosis polyposis coli; *cAMP,* cyclic adenosine monophosphate; *CaSR,* calcium-sensing receptor; *Dkk1,* dickkopf 1; *GSK,* glycogen synthase kinase 3; *LRP,* lipoprotein receptor–related protein; *PKA,* protein kinase A; *PTH,* parathyroid hormone; *PTH1R,* PTH 1 receptor. (From Rachner TD, Khosla S, Hofbauer LC. Osteoporosis: now and the future. *Lancet.* 2011;377[9773]:1276–1287.)

mineralization through LRP5, a coreceptor for the Wnt receptor, frizzled, have opened up new areas of investigation (Fig. 30.23). Moreover, natural antagonists to the Wnt/LRP5 signaling system, including sclerostin and Dkk1, have been studied using genetic engineering in mice. In the past 5 years, LRP5 has been studied extensively both in its function and its allelic effects through genome-wide association studies, as well as in translational bench work. Importantly, LRP5 polymorphisms have been strongly associated with BMD and fractures in large cohort studies, consistent with the central role of LRP5 in human skeletal biology. Hence, this pathway must be important in defining peak bone mass. However, it is also clear that because BMD is a polygenic trait, other genes are soon to be discovered.

In addition to the search for osteoporosis genes, intervention studies in adolescents have provided insight into the environmental impact on genetic determinants.[347] In another twin study from the Indiana group, the investigators found that as long as calcium supplementation continued during puberty, young boys could enhance their peak bone mass.[352] In a Swiss study, younger prepubertal girls supplemented with a protein product had a significant increase in spine bone density, as did a cohort of pubertal girls receiving a milk powder in England.[353] Remarkably, in the latter cohort, serum IGF1 levels also rose dramatically, providing further indirect evidence of a link between pubertal status, bone mass, and the growth hormone/IGF1 axis.[353]

Approach to Management of Osteoporosis

A comprehensive management plan for osteoporosis includes diagnosing those at highest risk, excluding secondary causes of low BMD, and selecting appropriate treatment. Screening by DXA to assess BMD at the hip and spine has been commonly recommended in most women older than 65 years and men older than 70 years,[354,355] and many, but not all, have this assessment. In addition, there is a growing appreciation that occurrence of a fracture, particularly one due to minimal trauma, should be a signal for more comprehensive risk assessment including BMD and has led to the explosion in development of fracture liaison services over the past 5 years and the emphasis on their importance by many groups.[263,354,356]

With increasing recognition of the importance of risk factors in addition to BMD, an assessment of risk should include both BMD and risk factors. These factors can be easily combined in the FRAX algorithm to attain an overall risk of fracture, which may be helpful, in addition to BMD alone, in making clinical decisions. FRAX scores are available online and have now been implemented within the software for most DXA scanners so that primary care physicians can easily obtain relevant diagnostic information in one report.

One commonly used algorithm in the United States is within the guidelines developed by the National Osteoporosis Foundation[354] (see Table 30.3), which strongly emphasize that patients

with a BMD T-score below –2.5 or a history of hip or spine fracture be considered for treatment. In these guidelines, FRAX is used for patients with BMD that is low but not in the osteoporotic range. In other countries, treatment decisions are based solely on risk, but consideration of treatment of those with BMD T-scores below –2.5, regardless of other risk, is well justified by many clinical trial results.[357–359]

Clinical decision making regarding pharmacologic therapy should consider several caveats. First, osteoporosis therapy can reduce fracture risk by as much as 50%, but this means that some people will continue to have fractures despite treatment. Second, lifestyle and pharmacologic interventions may be long-term commitments, and therefore cost, compliance, and safety must be factored into therapeutic decisions. Studies suggest that with weekly or monthly oral bisphosphonate therapy, more than 40% of individuals treated will not continue therapy beyond 1 year. Third, it is not uncommon for women with T-scores higher than –2.5 to have fragility fractures and therefore have osteoporosis by the consensus conference definition mentioned earlier.[198] In fact, in the National Osteoporosis Risk Assessment cohort of more than 140,000 postmenopausal women in the United States, almost one third of the women who had fractures also had BMD scores in the low BMD (T-score between –1 and –2.5) range.

General Measures

Diet

Calcium

Calcium supplementation should be an adjunct to drug treatments for women with established osteoporosis and must be part of any prevention strategy to ameliorate bone loss. Increased calcium intake reduces the secondary hyperparathyroidism often seen with advancing age and can enhance mineralization of newly formed bone. Evidence that calcium and vitamin D together or individually reduce fracture risk in the osteoporotic individual remains somewhat controversial. However, a recent meta-analysis of calcium and vitamin D intervention trials demonstrated a consistent, albeit small, increase in BMD and a reduction in nonvertebral fractures when 1200 mg of calcium is combined with more than 800 units of vitamin D.[360] Calcium supplementation alone has not been shown to reduce the incidence of nonvertebral fractures in high-risk women. Recently, a very large calcium intervention trial from the Women's Health Initiative (WHI) did not demonstrate hip fracture reduction with daily calcium supplements and 400 IU of vitamin D for all postmenopausal women, but for those older than 60 years, the risk reduction was statistically significant.[361] Interestingly, calcium supplementation in this cohort was associated with a 17% greater risk of kidney stones. Currently, an average total calcium intake of 1200 mg/day is still recommended by the Institute of Medicine (IOM) for all postmenopausal women. With intakes greater than 2000 mg/day, the risk of nephrocalcinosis certainly increases.

Vitamin D

Vitamin D is essential for skeletal maintenance and for enhancement of calcium absorption. Insufficiency of this vitamin is a growing problem; as many as two thirds of all patients who have hip fractures are classified as vitamin D deficient. Elderly people in chronic care living situations are particularly vulnerable. One large RPCT demonstrated a 43% reduction in hip fractures for nursing home residents, 84 years of age, who received calcium and vitamin D compared with those receiving placebo.[362] However, those subjects had significantly suppressed 25(OH)D levels and hence were likely to also have osteomalacia. In a large population-based study with calcium and vitamin D, supplementation had no effect on nonvertebral fractures,[361] although compliance and assessment of vitamin D levels were not sufficiently well documented to exclude an effect. At least one meta-analysis suggests that 800 IU/day of vitamin D plus 1200 mg of calcium per day is needed to reduce hip fractures by about 10%.[360] The IOM recommends an average intake of 600 IU/day, except for men and women older than 70 years, for which the IOM recommends 800 IU of vitamin D per day. The tolerable upper limit of vitamin D supplementation noted by the IOM was 4000 IU/day.

It should be noted that the US Preventive Services Task Force meta-analysis failed to show an effect of calcium and vitamin D on fracture risk.[363] And three systematic reviews showed that vitamin D alone did not affect BMD.[364–366] Thus, if there is an effect of vitamin D on bone mass and fracture, it probably is limited to older individuals who are at high risk and have low calcium intake. Besides the potentially positive effects of vitamin D supplementation on the skeleton, particularly in older women, vitamin D may reduce the risk of falling, although there continues to be significant controversy over the effect size, as noted in a recent meta-analysis. Moreover, it is uncertain whether the VDR expression level in adult muscle tissue is sufficient to mediate any direct effects. Therefore, for most individuals with osteoporosis, 800 IU/day of vitamin D is sufficient to maintain adequate levels of 25-hydroxyvitamin D. However, in those patients with low bone mass and insufficient or deficient 25-hydroxyvitamin D levels (i.e., <20 ng/mL), administration of 50,000 IU of ergocalciferol (vitamin D_2) or cholecalciferol (vitamin D_3) given once weekly is a safe and effective way to restore vitamin D levels to the normal range. Moreover, high-dose bolus vitamin D supplementation to prevent fractures, falls, and or/cardiovascular disease should be avoided due to inefficacy (100,000 IU of cholecalciferol monthly),[367,368] or even an increased risk of falls and fractures (annual dose of 500,000 IU of cholecalciferol administered orally).[369] Upper levels of vitamin D are currently being reviewed to determine if there is toxicity at higher doses. The current upper limit of tolerability is set at 4000 IU per day. The US Preventive Services Task Force did not recommend screening of normal individuals for adequacy of vitamin D levels; however, among osteoporotic patients, measurement of at least one serum 25(OH)D level is considered to be standard of care, particularly for those individuals starting bisphosphonate therapy.

Vitamin D analogues have been used in the treatment of osteoporosis since the early 1980s. However, this remains a controversial area. High doses of $1,25(OH)_2D$ increase bone mass, but many patients develop hypercalciuria or hypercalcemia. At doses of 0.5 μg/day, $1,25(OH)_2D$ reduced the rate of both vertebral and nonvertebral fractures and increased bone density, but this finding was made in a very small randomized trial. Other studies have found little benefit with a narrow therapeutic window, particularly in relation to renal function and hypercalcemia. Currently, vitamin D analogues are not recommended for the routine treatment of osteoporosis. A subset of patients with renal insufficiency (chronic kidney disease ≥3 and high PTH levels) may benefit from supplementation with calcitriol, with very careful monitoring of serum PTH.

Physical Activity

Bed rest or immobility, particularly in elderly persons, can result in rapid bone loss. Moreover, the number of falls increases with age, and the number of falls that result in fractures also rises. A meta-analysis by the Cochrane Review Group demonstrated that

muscle strengthening, balance retraining, home hazard assessment, withdrawal of psychotropic medications, and use of a multidisciplinary risk factor assessment program are beneficial in protecting against falls.[370] An alternative approach is to reduce loads applied to the hip during a fall by padding. Hip protectors have been shown to reduce the risk of hip fractures in at least one population, although compliance is generally poor. A more recent study failed to demonstrate the efficacy of these devices in older women in an assisted living facility.[371] Regular physical activity, including aerobic, weight-bearing, and resistant exercises, is effective in increasing spine BMD and in strengthening muscle mass in postmenopausal women, but no large-scale studies have established whether these interventions reduce fracture risk.

Lifestyle

Other interventions, such as smoking cessation and reduction of alcohol intake, should be considered within the framework of an individual's preventive health strategy. However, studies to date have been inconclusive with respect to understanding how changes in these lifestyles affect overall fracture risk. Notwithstanding, some promising data support the use of Tai Chi to enhance balance and reduce falls and fractures.[370] The data on cigarette smoking and fractures are somewhat conflicted, although most investigators support the notion that smoking may impair peak bone acquisition in adolescence and could contribute to postmenopausal bone loss directly or via the development of chronic obstructive lung disease with hypoxia and hypercarbia.[372] Lifestyle also includes tools to manage activities of daily life with a particular focus on avoiding falls and eliminating barriers to ambulation.

Pharmacologic Approaches to the Treatment of Osteoporosis

Abundant evidence indicates that an aggressive intervention program can be successful in reducing fracture risk and in improving quality of life among postmenopausal women with preexisting osteoporosis. Several pharmacologic options are available, and they can be classified by their mechanism of action. The two major classes of osteoporosis drugs are (1) *antiresorptives* (i.e., agents that block bone resorption by inhibiting osteoclasts) and (2) *anabolics* (i.e., drugs that stimulate bone formation by primarily acting on osteoblasts).

Antiresorptive Agents

Antiresorptives inhibit bone resorption by suppressing osteoclast activity. Slowing the remodeling cycle allows bone formation to catch up to resorption, thereby enhancing matrix mineralization and stabilizing trabecular microarchitecture. The antiresorptives increase BMD and reduce fracture risk, but their efficacy varies.

Estrogen

Estrogen replacement therapy was long considered the cornerstone of therapy for postmenopausal women with osteoporosis. Studies in vitro and in vivo have supported the hypothesis that this hormone works by slowing bone resorption through inhibition of cytokine signaling from the osteoblast to the osteoclast, thereby increasing BMD. However, there is also compelling evidence from at least two groups that osteoclasts have estrogen receptors and that estrogen blocks apoptosis of osteoclasts.[373,374]

Estrogen treatment inhibits both cortical and trabecular bone loss, and BMD generally increases by 3% to 5% after 3 years.[375] There does not appear to be an additive effect from progesterone on bone mass in women also receiving estrogen. Conversely, progesterone is a necessary part of hormone replacement therapy in women with a uterus because it prevents the development of endometrial hyperplasia and carcinoma. In the WHI, estrogen and progesterone lowered hip fracture risk by one third.[268] Low-dose conjugated estrogens (0.3 or 0.45 mg/day) and ultralow-dose estradiol increase BMD and have been approved for the prevention of bone loss, but antifracture efficacy for these preparations has not been established. Discontinuation of estrogen results in measurable bone loss (3–5% in the first year), although controversy exists as to whether that translates into a greater fracture risk.

Significant concern has been noted about the nonskeletal risks associated with long-term estrogen and estrogen in combination with progesterone. Particularly troublesome is the increased risk of breast cancer with the long-term use of estrogen and progesterone. In the WHI, there was a 26% increase in risk of invasive breast cancer over a 5.2-year period of follow-up.[268] Hence, estrogen replacement is contraindicated in any woman with a history of breast cancer; yearly mammograms are indicated in all women receiving hormone replacement therapy. Previous case-control and retrospective studies suggested that estrogen could reduce the risk of coronary artery disease; however, in the WHI, the risk of myocardial infarction or death from coronary artery disease was 29% higher in women receiving combination therapy.[268] Thromboembolic disease is also increased more than threefold by hormone replacement therapy.[268] Hence, the use of estrogen or estrogen in combination with progestins for the prevention and treatment of osteoporosis has fallen dramatically. Moreover, the availability of newer and effective antiresorptive drugs for the treatment of osteoporosis has lessened enthusiasm for primary hormonal therapy in osteoporotic women.

Selective Estrogen Receptor Modulators

Selective estrogen receptor modulators, such as tamoxifen and raloxifene, also inhibit bone resorption by the same mechanisms used by estradiol. Both have been shown to reduce bone loss in postmenopausal women with breast cancer, but only raloxifene is approved by the FDA for the prevention and treatment of osteoporosis.

Both of these agents block the actions of estrogen on the breast but act like an estrogen agonist in bone; tamoxifen, but not raloxifene, has estrogen agonistic properties on the uterus and is associated with a greater risk of endometrial carcinoma with long-term use.[376] Both agents have been associated with a reduction in new cases of breast cancer when they are administered as prophylaxis for high-risk patients.[377] Low-density lipoprotein cholesterol levels are also reduced in patients receiving these selective estrogen receptor modulators. Raloxifene increases spine BMD slightly (as does tamoxifen) and lowers the risk of vertebral fracture by 40%, although it has no effect on nonvertebral fracture risk.[378] Hot flashes, leg cramps, and a greater risk of deep venous thrombosis can occur with raloxifene therapy. The recommended dose of raloxifene is 60 mg once daily.

Tissue selectivity with these selective estrogen receptor modulators and others being investigated is a subject of great scientific interest. Raloxifene and estradiol both bind to the same region of the estrogen receptor, but they induce different conformational changes in that receptor. Differing coactivating and corepressing proteins are recruited to these receptor-ligand complexes, and it is thought that these coactivators and corepressors ultimately determine the activity of the nuclear complexes. Because recruitment also depends on cell type, it is highly likely that significant tissue selectivity exists for these partners. Newer agents have been designed to facilitate particular complexes and rearrangements within the nucleus; they are being studied at both preclinical and clinical levels.

Bisphosphonates

Bisphosphonates are the most widely prescribed antiresorptives and are often considered first-line therapy for the treatment of severe postmenopausal osteoporosis. These drugs are carbon-substituted analogues of pyrophosphate that bind tightly to hydroxyapatite crystals. It is thought that these agents directly suppress resorption by inhibiting osteoclast attachment and enhancing programmed cell death. The first-generation bisphosphonates include etidronate and clodronate. Neither is approved for the treatment of osteoporosis in the United States, although etidronate is used off label and in Europe. The dose of etidronate is 400 mg/day for 2 weeks every 3 months. The drug has few gastrointestinal side effects, and vertebral fracture risk reduction is significant with this agent. Alendronate and risedronate, two second-generation nitrogen-containing bisphosphonates, are effective in suppressing bone resorption and increasing BMD. In RPCTs of postmenopausal women with established osteoporosis, alendronate and risedronate reduced vertebral, hip, and nonvertebral fractures by nearly 50%, particularly during the first year of treatment.[219,379] As with other antiresorptive drugs, increases in BMD with alendronate or risedronate account for a small fraction of their antifracture efficacy. Hence, follow-up DXA measurements may significantly underestimate fracture risk reduction. Recent clinical trials have shown that these drugs can be safely administered for at least 5 years without adversely affecting bone strength. Moreover, discontinuation of alendronate after 5 years results in minimal bone loss over the ensuing 5 years without a significant increase in fracture risk.[380] Both drugs have excellent safety profiles, although erosive esophagitis is a serious complication of all oral nitrogen-containing bisphosphonates. Once-weekly administration of alendronate has been shown to reduce the prevalence of drug-induced esophagitis, and currently both alendronate and risedronate are marketed as once-weekly treatments.

Two other bisphosphonates have been approved by the FDA and have reached the market since 2007: ibandronate and zoledronate. The former is given orally in a single monthly dose (150 mg) or intravenously every 3 months (3 mg).[381,382] Ibandronate suppresses bone resorption and reduces the rate of spine fractures by nearly 50%,[358,383] but its efficacy in nonspine fractures is somewhat less than that of alendronate or risedronate. Compliance with the once-monthly regimen is higher than with the weekly dosing, although long-term data are not encouraging that this effect persists. First-dose hypersensitivity can occur with ibandronate, and because it is a nitrogen-containing bisphosphonate, it is also associated with esophageal reflux. Zoledronate is also approved for the prevention and treatment of osteoporosis. It is administered as a single intravenous infusion over 15 minutes (5 mg) once yearly. Large randomized controlled trials have unequivocally established antifracture efficacy for hip, spine, and other nonspine fractures.[384] Recently, the FDA approved the use of zoledronate for prevention of osteoporosis by administration of the drug once every 2 years. Both newer bisphosphonates can cause side effects with the first dose, including joint pain, stiffness, and low-grade fevers. Generally, these do not persist with recurrent administration of the drug. However, the FDA has cautioned that zoledronic acid should be administered over an hour rather than over 15 minutes to lessen any risk, albeit small, of renal damage. In addition, it should not be used in patients with a reduced glomerular filtration rate (<30 mL/minute) and should be used with caution in the elderly. Intravenous zoledronate has been approved for the treatment of malignant hypercalcemia, multiple myeloma, and skeletal metastases.

Other bisphosphonates are available for off-label use or are being studied for the treatment of osteoporosis. Intravenous pamidronate has been available since the mid-1990s for the treatment of Paget disease and malignant hypercalcemia. It is currently also used to treat osteoporotic women who cannot tolerate oral bisphosphonates, although it has not been formally approved by the FDA, and its antifracture efficacy has not been established. The dose ranges from 30 to 90 mg given every 3 to 9 months. Acute and delayed-type hypersensitivity reactions can occur with this drug, and its use is contraindicated in patients who are vitamin D deficient because it can precipitously drop serum calcium—a concern that also applies to use of zoledronic acid and denosumab.

With widespread use of bisphosphonates for both prevention and treatment, two uncommon but serious adverse events have been associated with administration of this class of agents: subtrochanteric, or atypical, femur fracture and osteonecrosis of the jaw (ONJ).[385,386] With respect to the former, atypical femur fractures were found in some but not all studies to be associated with duration of bisphosphonate use and generally were noted in younger individuals relative to those affected by other types of hip fractures. Prodromal symptoms of hip or thigh pain and associated cortical thickening or beaking in the shaft of the proximal femur are risk indicators of these fractures, which with minimal trauma can have devastating consequences in terms of quality of life and mobility. Some guidelines recommend prophylactic rod placement to prevent fractures in high-risk individuals in the ipsilateral and contralateral femora. Currently, the prevalence of this fracture is not well established, although meta-analyses suggest that there is a causal association with bisphosphonate use.

The prevalence of ONJ is very low when bisphosphonates are used in the doses used to treat osteoporosis. When much higher doses are used to prevent the skeletal complications of cancer, ONJ is a substantial concern. However, in osteoporosis patients, the prevalence is estimated to be less than 1 in 100,000 patients exposed to oral or intravenous bisphosphonates who are otherwise healthy. ONJ has devastating effects on the mandible and can require prolonged antibiotic treatment and local oral care. Patients with dental procedures that invade bone, such as tooth implantation and tooth extraction, are at increased risk. Concomitant treatment with glucocorticoids likely enhances the risk, and infection often accompanies the necrosis.

Calcitonin

Calcitonin is a 32–amino acid peptide normally produced by the thyroid C cells. Osteoclasts have calcitonin receptors, and calcitonin can rapidly inhibit bone resorption. Salmon calcitonin is more potent than human and is the preferred treatment choice. Nasal and subcutaneous calcitonin are both approved for the treatment of postmenopausal osteoporosis. However, the evidence favoring a strong effect from this hormone on either bone loss or fracture efficacy is lacking. In an RPCT of women with postmenopausal osteoporosis, 200 IU/day of nasal calcitonin reduced vertebral fracture incidence by one third.[387] However, methodologic flaws in that trial have limited enthusiasm for this agent as a primary treatment for osteoporosis. In at least one placebo-controlled study, nasal calcitonin reduced the pain associated with new spine fractures. The recommended dose of nasal calcitonin is 200 IU/day, and that of subcutaneous calcitonin is 100 IU/day. Side effects are uncommon with intranasal calcitonin and include nasal stuffiness and flushing. With subcutaneous administration, nausea is not infrequent.

Strontium Ranelate

Strontium ranelate is orally administered and stimulates calcium uptake in bone while it inhibits bone resorption. It is thought to have some anabolic activity, although the precise mechanism

of action in the skeleton, where it is incorporated, is not known. In an RPCT of postmenopausal women with established disease, daily strontium reduced the risk of vertebral fractures by 40%.[388] However, a statistically significant effect on nonvertebral fractures was limited to a small subset of women in a post hoc analysis.[389] Recent data raised the safety issue of an increase in cardiovascular events among strontium users.[390] This drug was originally approved by European regulatory agencies but not by the FDA.

Strontium ranelate has been associated with increased risk of severe allergic skin reactions, venous thromboembolism, stroke, and heart ischemia. The European Medicine Agency has decided to restrict the use of strontium ranelate only to patients with severe osteoporosis who cannot be treated with other drugs approved for osteoporosis. The agency has also warned about the necessity of regular medical care and advised the discontinuation of therapy in those patients who develop heart or circulatory problems, including high blood pressure or angina. As expected, it has maintained the recommendation against using strontium ranelate in individuals with antecedent of cardiovascular disorders.

Denosumab

Denosumab is a fully human monoclonal antibody to the RANKL, the essential osteoclast-differentiating factor. The antibody inhibits osteoclast formation, decreases bone resorption, increases BMD, and reduces the risk of fracture. As noted previously, RANKL is a member of the TNF superfamily of ligands that is essential for the function of bone-resorbing osteoclasts. RANKL interacts with its receptor (RANK) on both osteoclast precursors and mature osteoclasts, and the RANKL-RANK interaction results in activation, migration, differentiation, and fusion of hematopoietic cells of the osteoclast lineage to begin the process of bone resorption. Denosumab blocks that activation by binding directly to RANKL. Unlike bisphosphonates, denosumab does not persist in the skeleton and hence needs to be administered once every 6 months to maintain its efficacy. In fact, discontinuation of denosumab can lead to a rebound increase in bone resorption but no increase in fractures.[391]

Clinical trials with denosumab, 60 mg once every 6 months, included the very large (>7000 postmenopausal women with low bone mass and fractures) FREEDOM (Fracture Reduction Evaluation of Denosumab in Osteoporosis Every 6 Months) trial. This trial, which was used for registration of the agent with the FDA, demonstrated that after 3 years, denosumab improved BMD of the spine and hip compared with placebo (9.2% vs. 0% and 4.0% vs. −2.0%, respectively).[80] In addition, biochemical markers of bone turnover were significantly reduced in patients taking denosumab. Importantly, fractures of spine were reduced by 70%, and nonvertebral fractures, including hip fractures, were also significantly reduced. The long-term extension of the FREEDOM trial revealed that at 6 years, BMD continued to improve and fracture risk remained low.[392] In males undergoing androgen deprivation therapy, denosumab reduced bone loss and prevented fractures. Denosumab was the first biologic approved by the FDA for the treatment of osteoporosis in both men and women. Surprisingly, long-term studies (in 2015, out to 8 years in the extension trial) have failed to show significant adverse events for this agent, although atypical femoral fractures occur.

Cathepsin K Inhibitors

Cathepsin K is a proteinase that is secreted by osteoclasts and results in bone degradation, primarily of type I collagen (see Fig. 30.4). In addition, it is also produced by cancer cells that metastasize to bone. Odanacatib, one cathepsin K inhibitor, has been tested in postmenopausal women with osteoporosis and is shown to be an effective suppressor of bone resorption. In addition, women receiving this agent in a large phase III registration trial showed significant increases in BMD of the spine and hip, as well as a reduction in spine and nonvertebral fractures, prompting premature discontinuation of the trial due to enhanced efficacy.[393] However, the safety profile for odanacatib is still not clearly defined, and the FDA has not yet approved this agent for use. Interestingly, women treated with odanacatib have suppressed bone resorption but no change or a slight increase in bone formation. This may be due to the finding that this agent blocks the breakdown of collagen but does not kill osteoclasts; hence, signals from osteoclasts to osteoblasts may be maintained, thereby preserving bone formation. If correct, this is one of the first drugs for osteoporosis that can uncouple remodeling in a positive manner. A correlative study examining the effect of odanacatib in the setting of bony metastases from breast cancer demonstrated that it suppressed a biochemical marker of bone resorption, N-terminal telopeptide, in much the way that zoledronic acid did.[394] In 2015, Merck released promising bone results from the LOFT (Long-Term Odanacatib Fracture Trial) study.[395] In comparison to individuals receiving placebo, patients treated with odanacatib showed the following reductions in relative risk rates: (1) 54% of new and worsening morphometric vertebral fractures, (2) 47% of clinical hip fractures, (3) 23% of clinical nonvertebral fractures, and (4) 72% of clinical vertebral fractures (all $p < 0.001$). In addition, the company recognized that adjudicated events of morphea-like skin lesions and atypical femoral fractures were a more frequent occurrence in the odanacatib group than in the placebo group.[396] Moreover, the number of adjudicated stroke events was more common in the odanacatib than in the control group. The sponsor, Merck, decided to remove odanacatib from consideration by the FDA.

Anabolic Agents

A new class of antiosteoporosis drugs was introduced in 2002. These so-called anabolic agents stimulate bone formation more than bone resorption. As such, these agents can enhance bone remodeling and contrast sharply with the antiresorptives, which slow bone turnover. PTH(1-34) (teriparatide) was the first of this class of drugs to be approved by the FDA. Previously, the prototypical anabolic drug was sodium fluoride, which saw widespread use in the 1970s and 1980s because of its ability to stimulate new bone formation. However, an RPCT in 1990 established that although there were dramatic increases in BMD, nonvertebral fracture risk actually increased.

Parathyroid Hormone

It has been known for several decades that PTH, when given intermittently, increases bone formation and bone mass in mammals.[397] The increase in bone turnover begins with a dramatic increase in bone formation that is followed later by a marked rise in bone resorption, maintaining the coupling in the multicellular unit. However, chronically high levels of PTH cause bone loss in the cortical compartment as noted for primary and secondary hyperparathyroidism.[398] The development of PTH as an anabolic agent centered on defining the intermittent nature of administration, which for teriparatide (human PTH[1-34]) was by daily subcutaneous injections. Teriparatide has been approved in virtually every country for the treatment of postmenopausal osteoporosis because it not only increases bone mass but also reduces fractures. In the largest RPCT using teriparatide in postmenopausal women

with severe osteoporosis, 20 μg/day of PTH, administered subcutaneously, reduced spinal and nonvertebral fractures by more than 50% while it substantially increased (i.e., 8%/year) lumbar BMD.[399] Similar findings were noted in men with osteoporosis who were treated for 11 months.[400] Unfortunately, the PTH trial in postmenopausal women was stopped after 20 months because of concerns related to the development of osteosarcoma in rats treated with high doses of PTH(1-34). However, retrospective studies have found no association between osteosarcoma and primary or secondary hyperparathyroidism, and only one case of osteosarcoma in PTH-treated patients has been reported from more than a million users. More recently, recombinant human PTH(1-84) has shown similar benefits and is approved for the treatment of hypoparathyroidism in the United States.[401] In Europe and Asia, but not in the United States, PTH(1-84) is approved for the treatment of postmenopausal osteoporosis. Currently, it is recommended that PTH therapy be limited to those individuals with moderate to severe osteoporosis and then given for only 2 years, based on a long-term toxicity study in rats demonstrating an increased risk of osteosarcoma.

Despite the appeal of using an anabolic with an antiresorptive, most evidence indicates that combinations of classes of drugs are not additive or synergistic. PTH plus bisphosphonates initiated together do not raise BMD more than PTH alone in either men or women.[402,403] However, PTH plus denosumab has been shown to increase BMD in the spine to 13% after just 1 year, a greater increase than that seen with other drugs.[404] That difference is maintained even after 2 years of combination therapy. Unlike with discontinuation of bisphosphonates, discontinuation of PTH can result in bone loss of 3% to 4% in the first year after PTH cessation. This posttreatment effect is prevented by adding an antiresorptive agent once PTH is stopped. In general, PTH is well tolerated, although nausea, flushing, hypotension, and mild but asymptomatic hypercalcemia (i.e., serum calcium <11 mg/dL) can occur. Cost and compliance have been limiting factors.

PTH-Related Protein

Since the approval of teriparatide in 2002, it took 15 years for the launching of a new bone anabolic drug in the US market. PTH-related protein (PTHrP) has been shown to work via the PTH receptor on osteoblasts to stimulate new bone formation in a manner analogous to PTH. PTHrP acts primarily as a paracrine growth/differentiation factor but also functions as a hormone during normal lactation and in the hypercalcemia of malignancy. However, when administered intermittently, PTHrP(1-36), an analogue of native PTHrP, increases BMD without significant hypercalcemia, similar to PTH.[405] Phase III trials with PTHrP(1-36) have been completed in Europe and show a significant reduction in both vertebral and nonvertebral fractures (including hip fractures). In April 2017, the N-terminal fragment of PTH-related peptide analogue (abaloparatide) received approval from the FDA for subcutaneous application in postmenopausal women with osteoporosis at high risk for fracture. Abaloparatide is appropriately indicated for those postmenopausal women with history of osteoporotic fracture, those harboring multiple risk factors for fracture, or patients showing failure or intolerance to other therapy options. The ACTIVE (Abaloparatide Comparator Trial in Vertebral Endpoints) study was a phase III, double-blind, randomized controlled trial developed in 10 countries. In comparison to placebo, after 18 months of therapy, abaloparatide significantly increased BMD in the lumbar spine (11.20% vs. 0.63%), femoral neck (3.60% vs. −0.43%), and total hip (4.18% vs. −0.10%). More importantly, the number of new morphometric vertebral fractures was significantly lower in the abaloparatide group (0.58% [n = 4] vs. 4.22% [n = 30] in the placebo group). In addition, the ACTIVE study reported a similar 80% reduction in vertebral fracture rate with abaloparatide compared with teriparatide. However, abaloparatide was associated with a significant reduction in nonvertebral fractures when compared with placebo—an effect not observed in teriparatide therapy. The occurrence of hypercalcemia was lower in women using abaloparatide (3.4%) than teriparatide (6.1%).[406]

Future Anabolic Agents

There is a significant appeal for the use of anabolic agents for the treatment of low bone mass and fractures in severely affected individuals (see Fig. 30.22). Bone remodeling is a highly regulated activity encompassing bone resorption and formation that dictates bone mass maintenance. Skeletal anabolic drugs stimulate bone formation, enhancing the number and function of bone-forming cells. Advances in knowledge of bone biology have allowed the recognition of paracrine peptides that represent local modulators of the differentiation of progenitor cells into osteoblasts. Wnt signaling is a positive driver of osteoblast differentiation, which is cautiously regulated by both intra- and extracellular mechanisms. In parallel, Wnt signaling inhibits osteoclastogenesis. Osteocytes, the terminally differentiated osteoblasts, have an important role in maintaining a constitutive inhibition of the Wnt/β-catenin canonical signaling pathway by secreting sclerostin. Mechanical loading on bone and PTH therapy stimulates bone formation by downregulating sclerostin. Osteopetrosis (i.e., sclerosteosis and van Buchem disease) can emerge due to a loss of function mutation in the *SOST* gene, leading to high bone mass. Those studies encouraged the development of monoclonal humanized antibody to sclerostin.

Monoclonal Antibodies to Sclerostin

As noted previously, sclerostin is produced by osteocytes and inhibits bone formation by blocking canonical Wnt signaling. *Sost* null mice have increased bone formation and high bone mass. It follows, therefore, that inhibition of sclerostin should enhance osteoblast function and improve bone mass. In animal models and in a phase I trial in healthy adults, administration of a sclerostin monoclonal antibody does increase bone mass. Similarly, in a phase II trial in postmenopausal women, all doses of a monoclonal antisclerostin antibody (romosozumab) increased bone density at the lumbar spine, total hip, and femoral neck.[73] In this 1-year trial, 419 postmenopausal women with low bone mass (T-score between −2.0 and −3.5 at the lumbar spine, total hip, or femoral neck) were randomly assigned to subcutaneous romosozumab (variable dosing once monthly or once every 3 months), an active comparator, versus alendronate (70 mg weekly), or subcutaneous teriparatide (20 μg daily), or placebo injections. The greatest increase in BMD was seen in the group receiving romosozumab (210 mg monthly; 11.3% compared with 4.1% and 7.1% in the alendronate and teriparatide groups, respectively).[73] Interestingly, there was a transient increase in bone formation markers and a more sustained decrease in bone resorption markers, a pattern that has not been seen among available osteoporosis therapies, again suggesting that it is possible to uncouple remodeling toward a more favorable balance. The suppression in bone resorption is most likely a function of reduced RANKL production due to inhibition of the Wnt/LRP5/6 signaling pathway. QCT examinations detailed that the positive effects of romosozumab occurred in

trabecular bone of the vertebrae and total hip, as well as in the cortical compartment of the vertebrae.[407] In accordance to the previous results, finite element analysis showed improved vertebrae and total hip strength in postmenopausal women treated with romosozumab.[408] The reported data suggested that romosozumab has beneficial effects in both trabecular and cortical compartments of bone. The head-to-head comparison between romosozumab and other agents showed that romosozumab has better performance in several aspects. Romosozumab therapy induced greater increase in BMD than alendronate (70 mg weekly) and teriparatide (20 μg daily). The improvement in bone strength, as assessed by infinite element analysis, was higher in osteoporotic women receiving romosozumab than teriparatide. Moreover, romosozumab potentially seems to have greater capability to enhance bone mass and volume in patients previously receiving a bisphosphonate.[409]

Romosozumab entered in a phase III trial but is not yet approved by the FDA.[348] Actually, the efficacy of romosozumab to alleviate fracture occurrences has been tested in two clinical trials. In the first, romosozumab (210 mg subcutaneously monthly) was compared with placebo for 1 year, then both arms changed to open-label denosumab for a year (60 mg biannually). In the whole period of 24 months, in 75% of patients, romosozumab/denosumab reduced the incidence of new vertebral fractures and had a statistically insignificant reduction in nonvertebral fractures.[410] In the second clinical trial, the authors defined the following design: monthly subcutaneous romosozumab (210 mg) or weekly oral alendronate (70 mg) administered in a blinded fashion for 12 months, followed by open-label alendronate in both groups. The romosozumab/alendronate group showed a 48% and 19% reduction, respectively, in incident vertebral and nonvertebral fractures compared with the alendronate-only group.[411] Necrosis of the jaw and atypical fractures have rarely been reported with romosozumab. In addition, there are concerns about serious cardiovascular events. During year 1, positively adjudicated serious cardiovascular adverse events were observed more often with romosozumab than with alendronate (50 of 2040 patients [2.5%] vs. 38 of 2014 patients [1.9%]). Safety studies and completion of the phase III trial will determine the place of this agent in treating osteoporosis.

Rickets and Osteomalacia

ARTI BHAN, AJAY D. RAO, SANJAY K. BHADADA, AND SUDHAKER D. RAO

CHAPTER OUTLINE

KEY POINTS

- Rickets is a specific bone disorder of growing children and adolescents and is associated with characteristic skeletal deformities.
- Osteomalacia is a generalized softening of the bones regardless of age or cause and thus occurs both in children and adults.
- Worldwide nutritional vitamin D deficiency is the most common cause of rickets and osteomalacia. However, in countries where routine fortification of dairy and food products is implemented, genetic and acquired forms of rickets and osteomalacia are relatively more common.
- Calcium-deficiency rickets is a specific type of rickets that is mostly confined to certain geographic regions of the world. Calcium-deficiency osteomalacia in adults has not been reported.
- There are several types of genetic rickets and osteomalacia resulting in excess renal loss of phosphate due to inhibition of renal tubular reabsorption of phosphate.
- Several acquired forms of rickets and osteomalacia occur due to ectopic production of fibroblast growth factor 23, mostly by benign mesenchymal or skeletal tumors—the removal of which cures the bone disease.
- Several drugs, such as etidronate, sodium fluoride, and aluminum-containing antacids, as well as iron overload, directly inhibit the bone mineralization process, producing unusual types of histologic osteomalacia.
- The antiviral drugs tenofovir and adefovir, which are now widely used for the treatment of human immunodeficiency virus and hepatitis, cause renal tubular damage resulting in acquired forms of hypophosphatemic rickets and osteomalacia.
- Many rare bone disorders resemble either rickets on x-rays or osteomalacia on bone biopsy but do not respond to conventional doses of vitamin D therapy.

Introduction

Rickets is a specific bone disorder of the growing skeleton, thus occurring only in children and adolescents before the epiphyseal fusion has occurred, and is associated with characteristic skeletal deformities,[1] whereas osteomalacia is a generalized softening of the bones regardless of age or cause and therefore occurs in both children and adults.[2] Rickets is due to defective mineralization of both preosseous cartilaginous and mature osseous matrix resulting in subnormal linear growth, a consequence of the involvement of growth plates. In contrast, osteomalacia is due to defective mineralization of the mature lamellar bone. Of the four major metabolic bone diseases, osteoporosis is by far the most common (see Chapter 30), whereas rickets and osteomalacia combined are a distant second, followed by osteitis deformans (also known as Paget disease of bone; see Chapter 30). Osteitis fibrosa cystica, the typical bone disease of severe primary, secondary, or tertiary hyperparathyroidism, is the least common, and is rarely seen in the United States but still prevalent in other parts of the world where vitamin D deficiency is endemic[3,4] (see Chapter 29). The key contrasting features of these four common metabolic bone diseases are summarized in Table 31.1.

Soon after the discovery of vitamin D, rickets and osteomalacia became synonymous with any condition that could be cured by vitamin D therapy. However, with the recent discovery of fibroblast growth factor 23 (FGF23), and the understanding of its critical role in phosphate homeostasis and vitamin D metabolism[5,6] (see Chapter 29), several types of both genetic and acquired forms of rickets and osteomalacia are now better characterized with specific genotypic and phenotypic features[5–9] (see the specific sections that follow). These unusual FGF23-mediated rickets and osteomalacia do

TABLE 31.1 Contrasting Features of Four Major Metabolic Bone Diseases

Variable	Rickets and Osteomalacia	Osteoporosis	Osteitis Fibrosa	Osteitis Deformans
Basic abnormality	Defective mineralization of cartilage and bone	Insufficient replacement of normal lamellar bone	Replacement by woven bone and fibrous tissue	Abnormal woven bone
Prevalence	Second most common	Most common	Uncommon	Not uncommon
Serum calcium	Normal/Low	Normal	High/Very high	Normal
Serum phosphate	Normal/Low/Very low	Normal	Frequently low	Normal
Alkaline phosphatase	High	Normal/High	High/Very high	High
Parathyroid hormone	High	Normal/High	High/Very high	Normal
25-Hydroxyvitamin D	Low/Normal	Normal/Low	Frequently low	Normal/Low
Cortical thinning	Yes, except in X-linked hypophosphatemia	Sometimes	Yes	No
Vertebral deformities	Biconcave or cod fish like	Wedged/Compressed	Variable	Enlarged size
Long bone deformities	Bowing and pseudofractures	None, except fragility fractures	Brown tumors	Bowing and stress fractures

not respond to the conventional doses of vitamin D that cure nutritional vitamin D deficiency rickets and osteomalacia, and indeed many are resistant to even 10- to 100-fold the therapeutic doses of vitamin D used to treat vitamin D–deficiency rickets and osteomalacia. Furthermore, a variety of rare genetic bone disorders either resemble rickets on x-rays[10] or osteomalacia on bone biopsy,[11–14] but their pathogenesis is distinct from that of vitamin D–related or hypophosphatemic rickets and osteomalacia with variable or inconsistent response to therapy with vitamin D or its analogues.[12,13,15–17] In addition, a few rare acquired forms of osteomalacia are the result of adverse effects of a variety of drugs that either impair bone mineralization or inhibit renal tubular reabsorption phosphate and respond to the withdrawal of the offending drugs.

The following sections begin with a historical perspective of rickets and osteomalacia that is both instructive and informative, followed by epidemiology and demographics, process of normal and abnormal bone mineralization, pathogenesis, and clinical manifestations. The treatment strategies will be discussed in detail for nutritional-deficiency rickets and osteomalacia, but specific aspects as they relate to different types and forms of rickets and osteomalacia will be dealt within the specific sections. Where appropriate, reference will be made as it applies to management in children and adults.

Historical Perspective

Rickets

The earliest reports of rickets date back to the 17th century, with the first detailed contemporaneous descriptions by William Glisson and Daniel Whistler in 1645.[18] Glisson was also the first to recognize rickets as a separate entity from infantile scurvy, which often coexisted with rickets during that time. Even more interesting is that Glisson believed that rickets was neither congenital nor inherited,[18] although it is now clear that both types of rickets forms can occur. As early as in the middle of the 17th century, rickets was attributed to the industrial revolution and growing urbanization (presumably less sunlight exposure),[19] as well as to breastfeeding (breast milk has poor vitamin D content).[20] The temporal relationship between rickets and sunshine was not appreciated until the 19th century,[21] and the "proof of concept" that sunshine can cure rickets did not occur until the beginning of the 20th century.[18,19] Early 20th-century reports on rickets were exclusively from the regions of the world where vitamin D deficiency was endemic, numerically the most common, and almost all cases were due to nutritional vitamin D deficiency.[22–33] With the current policies of routine fortification of milk and other food products with vitamin D, nutritional vitamin D–deficiency rickets and osteomalacia all but disappeared from developed countries.[34–36] Consequently, genetic[37–40] and acquired[8,9,41–49] forms of rickets and osteomalacia are more prevalent in nonendemic regions of the world.[8,9,11,12,41–46,50]

Osteomalacia

The term *osteomalacia* originally referred to the generalized softening of the bones resulting in crippling deformities, and the most comprehensive report on its etiology and treatment dates back to 1896.[51] In earlier publications, various descriptive terms, such as *mollities ossium*,[52] *rheumatic*, *syphilitic*, *senile*, and even *neurotic osteomalacia*, were used to describe osteomalacia, implying that the bone disease was due to either infection or inflammation.[53] Because of the grotesque deformities involving long bones, even more descriptive terms, such as *boomerang bones* or *osteomalacia sclerotica*, were used to describe a peculiar disease seen rather exclusively in Australian Aborigines and in Sudanese populations.[54] Since osteoporosis was such a frequent accompaniment of osteomalacia, the term *osteoporomalacia* was often used in the 20th century.[55,56] The distinction between rickets that specifically involved metaphyses, and to a lesser extent epiphyses, and osteomalacia, which affected all of the bones, was recognized early in the 18th century,[51–53] and was reemphasized by Fuller Albright in his classic monograph.[57]

The histologic differentiation of osteomalacia from both osteoporosis and osteitis fibrosa was first made by Pommer in the late 19th century by examining cadaveric bones[58] and later confirmed

in humans by Fuller Albright with his elegant balance studies.[57] The first detailed tetracycline-based bone histomorphometric measurements were made by Harold Frost in 1966.[59] Although the original descriptions defined *rickets* and *osteomalacia* as distinct entities, the two terms are often used (and probably can be used, except that rickets occurs only in children) interchangeably. However, and perhaps more confusing, is that the descriptive terms have been extended to include various other conditions that resembled radiologic or bone histologic phenotypes of vitamin D–related disorders.[12–14,60] This is both unfortunate and unwarranted, as it may erroneously be misconstrued that conditions resembling rickets and osteomalacia will respond to vitamin D therapy; a recent review on the subject underscores this cautionary approach.[61]

Epidemiology and Demographics

Worldwide, nutritional deficiency of vitamin D and calcium is still the most common cause and type of rickets and osteomalacia.[15,34,40,62–73] Unlike the known prevalence, incidence, epidemiology, and demographics of osteoporosis (see Chapter 30), osteitis fibrosa (see Chapter 29), and osteitis deformans (see Chapter 30), precise estimates for the prevalence of rickets and osteomalacia are lacking. Recent reports suggest a rising trend in the prevalence of nutritional rickets worldwide, including the regions where routine fortification of dairy and other food products with vitamin D is practiced.[34,64–68,74–76] The most recent estimates of vitamin D–deficiency rickets ranged from 2.2 in 100,000 people in 1980 to 24 in 100,000 people in 2000.[64] Similarly, the prevalence of osteomalacia in adults due to vitamin D depletion may be rising because of the increasing rates of bariatric surgery for morbid obesity, which results in malabsorption of both vitamin D and calcium.[4,62,77] Although precise estimates on the prevalence or incidence of osteomalacia following bariatric surgery are lacking, it was the most common cause of osteomalacia at our institution in Detroit, Michigan.[4,77] A similar trend was observed following earlier, but now abandoned, intestinal bypass surgeries for obesity[4,77–79] and after gastrectomy (partial or total) for peptic ulcer disease, which is now performed rarely.[80–83] Rarity of vitamin D deficiency rickets and osteomalacia in developed countries[84–87] explains the relatively higher prevalence of genetic and acquired forms of rickets and osteomalacia in the Western world.[6–8,88,89] It is estimated that the most common genetic form of rickets and osteomalacia occurs 1 in 20,000 live births.[90] In the past decade, there has been a growing number of reports of osteomalacia related to the expanding use of the antiretroviral drugs tenofovir[9] and adefovir.[91] Although rickets in children due to antiviral drug therapy has not yet been reported, it is most likely because of the low prevalence of their use in the pediatric population. In addition, the incidence of rickets and osteomalacia due to anticonvulsants, antacids, and aluminum toxicity remains very low. Thus, rickets and osteomalacia not related to *nutrition* and *drugs* are most prevalent in the developed countries, whereas rickets and osteomalacia related to *vitamin D and calcium deficiency* are most common in developing countries.

Certain individuals and ethnic groups are particularly susceptible to the development of nutritional rickets and osteomalacia. Both secular and nonsecular tendencies of the populations, geographic locations, prevailing sunlight, and local dietary habits all contribute to the development of rickets and osteomalacia related to deficiency of vitamin D and calcium. Immigrants, particularly those with darkly pigmented skin or specific dietary habits (vegetarians, high phytate intake) moving to temperate zones with limited or reduced sunlight exposure are at risk of developing rickets and osteomalacia—so-called immigrant osteomalacia.[15] Because of the rarity of rickets and osteomalacia due to vitamin D deficiency in developed countries,[64,67,68,74,75] the diagnosis is often missed or delayed.[4,77]

Bone Remodeling and Mineralization

Bone remodeling is a necessary mechanism by which old bone is replaced by new bone throughout the life span of an individual and is sufficient to maintain integrity of the skeleton, both as an organ to serve its metabolic functions and as a structure for locomotion (see Chapters 29 and 30). In the course of normal bone remodeling, a moiety of old bone is removed and replaced by the same amount of normal lamellar bone in young adults, but in aging and disease, the replacement mechanism is not as efficient as it is in the young. A lesser amount of normal lamellar bone is replaced in osteoporosis (see Chapter 30), by a mixture of woven bone and fibrous tissue in osteitis fibrosa due to hyperparathyroidism (see Chapter 29), by an abnormal local production of woven bone in osteitis deformans, and by an unmineralized bone matrix (or osteoid tissue) in osteomalacia.[92] This fundamental difference in the nature of the replaced bone distinguishes osteomalacia from the most common metabolic bone diseases (see Table 31.1), as well as from rare bone disorders such as hypophosphatasia, fibrogenesis imperfecta ossium, and axial osteomalacia that resemble classical osteomalacia in one respect or another (see the Conditions That Resemble Rickets and Osteomalacia section).

Despite significant advances in our understanding of bone biology, very little is known about mechanisms that control or regulate the process of mineralization in bone. Why does biologic mineralization normally occur only in certain types of connective tissues but not in others, and how is the temporal and spatial regulation of matrix production and mineralization process accomplished? For proper and optimal mineralization of bone, at a minimum, two principal requirements must be met: synthesis of mature lamellar bone matrix by osteoblasts (see Chapter 30) and exposure of this newly synthesized lamellar bone matrix to optimal calcium × phosphate product provided by the mineral homeostatic system regulated by parathyroid hormone (PTH) and vitamin D (see Chapter 29). Any abnormality in either component will result in defective mineralization. In classical osteomalacia, deficiency of minerals, however produced, results in the accumulation of unmineralized bone matrix or osteoid. In contrast, in all other bone disorders that resemble osteomalacia (or "osteomalacia like"), the osteoid accumulation is a consequence of abnormalities outside of these two principal components. In hypophosphatasia, it is the enzyme deficiency, whereas in Paget disease of bone, fibrous dysplasia, fibrogenesis imperfecta ossium, and possibly osteogenesis imperfecta, it is the abnormal bone matrix, and in certain drug-induced osteomalacia (etidronate, fluoride, aluminum, and iron), it is the toxic effects of the drugs inhibiting matrix mineralization. Understanding the differences in the mechanism of osteoid accumulation in different diseases is critical for clinical management because disorders that resemble osteomalacia do not respond to vitamin D therapy as the term *osteomalacia* might imply.

Normal mineralization of bone matrix occurs in two stages. In the rapid phase, termed *primary mineralization*, 75% to 80% of the maximal mineral content is deposited within a few days to weeks. In the second and much slower phase, termed *secondary mineralization*, the mineral content of the bone increases further

to reach about 90% to 95% over a period of months. The remaining 5% to 10% represents the bone matrix that is newly formed but not yet mineralized. Accordingly, an osteoid surface greater than 15% of the bone surfaces, sometimes referred to as hyperosteoidosis, can be seen in conditions with high rates of bone turnover, such as immediately after estrogen depletion in postmenopausal women, hyperparathyroidism (primary or secondary), hyperthyroidism, and osteitis deformans. However, strictly speaking, the bone histologic features and osteoid indices in these high bone turnover diseases do not conform to the classical definition of osteomalacia (see the next section).

Definition and Histologic Evolution of Osteomalacia

Classical vitamin D deficiency osteomalacia, irrespective of its cause, evolves in three stages. The first stage is characterized by an increased bone remodeling due to secondary hyperparathyroidism (2°HPT), associated with increased osteoid surface and osteoid volume, *but not the thickness of osteoid*, and normal mineralization of bone. This represents the earliest bone histologic phenotype of vitamin D deficiency, designated as hypovitaminosis D osteopathy stage I (HVO I) or preosteomalacia[87] (Fig. 31.1). Similar bone histologic features can also be seen in patients with calcium malabsorption, but without vitamin D deficiency, designated as 2°HPT. However, the osteoid indices are much lower than in HVO I with some overlap (see Fig. 31.1). In both HVO I and 2°HPT, there is evidence of mainly cortical bone loss due to excess PTH secretion,[93] and the patients are usually asymptomatic at this stage but may present with fragility fractures. Serum levels of calcium and phosphate are normal, and the serum level of alkaline phosphatase is usually, but not always, elevated.[62,77] The serum 25-hydroxyvitamin D level is low (<10 ng/mL), and serum levels of PTH and 1,25-dihydroxyvitamin D are elevated. The increases in serum levels of alkaline phosphatase and 1,25-dihydroxyvitamin D respectively are related to increased bone turnover and increased 1α-hydroxylase activity in the kidney (see Chapter 29) as a consequence of 2°HPT. In addition, an irreversible PTH-mediated cortical bone loss may have already occurred.[93]

In the second stage, designated as HVO II, there is further accumulation of osteoid with increases in osteoid surface, osteoid volume, and *osteoid thickness* but with preservation of some mineralization as assessed by tetracycline uptake at the mineralization front.[87] Both serum PTH and alkaline phosphatase levels increase further, but serum 1,25-dihydroxyvitamin D levels may return to normal or low depending on the degree of vitamin D deficiency (as assessed by its substrate, 25-hydroxyvitamin D) and PTH elevation. The serum calcium level usually declines at this stage with low normal or frank hypocalcemia, and serum phosphate levels are usually low. Patients may be symptomatic with bone pain, muscle weakness, and fragility or pseudofractures.

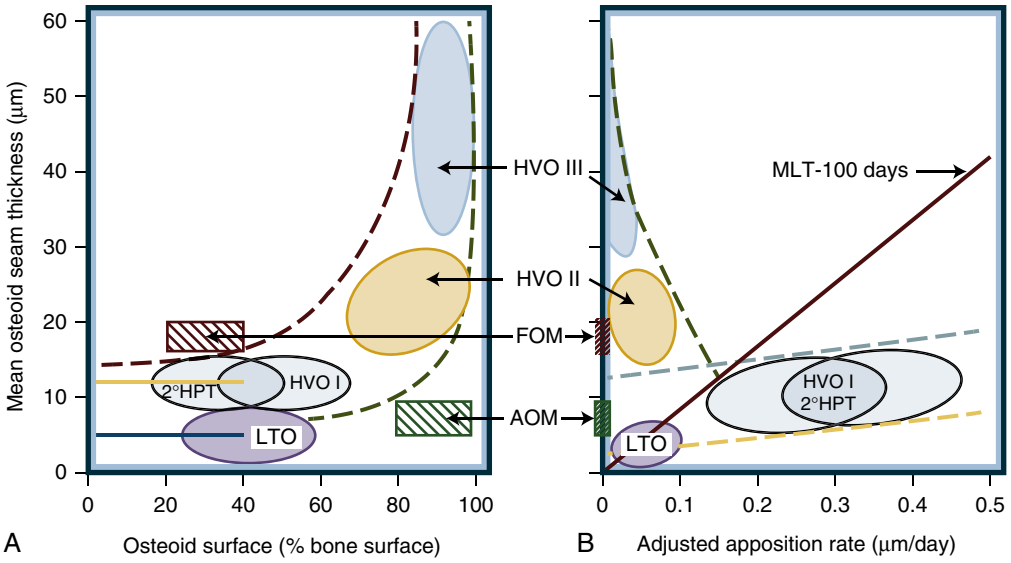
In the third stage, designated as HVO III, the mineralization of bone matrix ceases and osteoid accumulation continues to cover more than 90% of the bone surfaces. It is at this stage that hypocalcemia is invariable, as the osteoid covered bone is resistant to osteoclastic bone resorption, which is a necessary mechanism to maintain normal serum calcium levels. The extensive coverage of the bone surfaces with osteoid is perhaps a "protective mechanism" to prevent complete dissolution of bone. However, peritrabecular and bone marrow fibrosis, a feature of more severe hyperparathyroidism, occurs only in HVO III and can be demonstrated on bone biopsy.[4] Patients are almost always symptomatic at this stage, with diffuse bone pain, muscle weakness, and pseudofractures (Fig. 31.2), although an occasional patient may present primarily with muscle weakness without bone pain.[94] Osteomalacia defined by an osteoid thickness greater than 12.5 μm and a mineralization lag time of more than 100 days (see Fig. 31.1) conforms to the conventional clinical and radiologic descriptions of osteomalacia. Regrettably, no such data exist on the evolution of hereditary or acquired forms of hypophosphatemic osteomalacia, as most of those patients present clinically late in the course of their disease, corresponding to the third stage (HVO III) of vitamin D–deficiency osteomalacia.[87,92]

Pathogenesis of Rickets and Osteomalacia

The three principal mechanisms by which rickets and osteomalacia develop are vitamin D depletion or deficiency, phosphate depletion or deficiency, and calcium deficiency—in that order of frequency.[62,95,96] Hypophosphatemia due to nutritional phosphate deficiency is a very rare cause of rickets or osteomalacia, although occasional cases have been reported in patients on prolonged total parenteral nutrition. Vitamin D deficiency or depletion, however produced (Table 31.2), if prolonged or left untreated, ultimately leads to rickets and osteomalacia.[97] Phosphate depletion, however caused (genetic, tumor induced, or acquired), is the second most common cause of rickets and osteomalacia, and the most prevalent type in parts of the world where vitamin D deficiency is not endemic. The two most common causes of hypophosphatemic rickets and osteomalacia are hereditary hypophosphatemic syndromes[5,7] and FGF23-secreting tumors.[8] Other less frequent causes of hypophosphatemic rickets and osteomalacia include prolonged use of phosphate-binding antacids,[41,98] as well as various genetic and acquired renal tubular defects[99] (Table 31.3). Even more uncommon, but histologically distinct from the vitamin D–deficiency and hypophosphatemic rickets and osteomalacia syndromes, are the atypical and focal osteomalacia caused by the toxic effects of drugs such as sodium fluoride,[100,101] etidronate,[102] aluminum, and iron, which directly inhibit bone mineralization[49,103] (Table 31.4; see Fig. 31.1).

Vitamin D deficiency can be extrinsic or intrinsic. Extrinsic vitamin D deficiency is due to deficient endogenous cutaneous production of vitamin D_3 or poor dietary intake (see Table 31.2). Inadequate exposure or avoidance of sunlight,[21,104] use of sun-protective lotions or sunscreens,[105,106] darkly pigmented skin,[107] excessive covering of the body with clothing for cultural reasons,[108,109] and aging[104] all contribute to the decreased production of vitamin D_3 or cholecalciferol from its precursor 7-dehydrocholesterol (see Chapter 29). Although inadequate intake of vitamin D as a cause of rickets and osteomalacia is rare in the United States, occasional cases or case series have been reported.[64,84,86]

Rickets and osteomalacia due to intrinsic vitamin D depletion (the descriptive term *depletion* for all intrinsic causes of vitamin D deficiency is probably more appropriate) is most commonly caused by impaired gastrointestinal absorption of vitamin D (and calcium)[110,111] as a result of intestinal disease, resection, or gastric bypass surgery (see Table 31.2). Vitamin D deficiency can also result from genetic or acquired causes of impaired or defective *vitamin D 25-hydroxylase* in the liver or impaired or deficient *25-hydroxyvitamin D 1α-hydroxylase* in the kidney and other target tissues, the necessary enzymes to convert the parent compound vitamin D to its biologically active metabolites,[112–118] or increased catabolism of vitamin D and its active metabolites to inert compounds.[119,120] Strictly speaking, rickets and osteomalacia due to



• **Fig. 31.1** Topographic depiction of stages of hypovitaminosis D osteopathy (HVO I, II, and III), atypical osteomalacia (AOM), and focal osteomalacia (FOM). For comparison, secondary hyperparathyroidism (2°HPT) without mineralization defect and low turnover osteoporosis (LTO) are shown. In (A), the location of the seven types of bone lesions is based on the relationship between osteoid thickness (y-axis) and the extent of bone surface covered by osteoid (x-axis). In (B), the location is based on the relationship between osteoid thickness (y-axis) and adjusted appositional rate (x-axis) as determined by tetracycline uptake (x-axis). In normal subjects, and in patients with 2°HPT, HVO I, and LTO, there is no relationship between osteoid thickness and osteoid surface until the osteoid surface exceeds greater than 50% to 60% of the bone surface (*straight solid horizontal lines*), after which the relationship becomes hyperbolic (*interrupted curvilinear lines*). By contrast, there is a positive relationship between osteoid thickness and the adjusted mineral apposition rate (*straight interrupted lines*) in normal subjects and in patients with 2°HPT, HVO I, and LTO (B). The *oblique interrupted line* indicates the reversal of this relationship in patients with more severe osteomalacia (HVO II and III), the cardinal feature of osteomalacia unlike all other conditions (2°HPT, LTO, AOM, and FOM). The *solid straight line* represents a mineralization lag time of 100 days (MLT, the time delay between matrix deposition osteoblasts and subsequent mineralization) that separates patients with and without osteomalacia. Locations are shown for clarity and simplicity. Note a significant overlap of 2°HPT, HVO I, and LTO. (Modified from Bhan A, Qiu S, Rao SD. Bone histomorphometry in the evaluation of osteomalacia. *Bone Rep*. 2018;8:125–134.)

TABLE 31.2 Causes of Vitamin D–Deficiency Rickets or Osteomalacia, or Both

Extrinsic

Inadequate dietary intake of vitamin D
Decreased exposure or avoidance of sunlight
Use of sunscreens (especially a solar protective factor >8)
Excess clothing (veil/hijab)
?Increased or dark skin pigmentation

Intrinsic

Advancing age with decreased cutaneous production of vitamin D
Malabsorption due to various gastrointestinal disorders
- Gastrectomy (partial, total, or bypass procedure)
- Small intestinal disease, resection, or bypass
- Gluten enteropathy (Celiac sprue)
- Biliary cirrhosis (uncommon)
- Pancreatic insufficiency including cystic fibrosis (uncommon)
- Impaired or genetically defective vitamin D 25-hydroxylase enzyme
- ?Immaturity
- ?Neonatal hepatitis
- ?Cirrhosis of the liver
- Genetic defect (vitamin D–dependent rickets type 1B)
- Impaired or genetically defective 25-hydroxyvitamin D 1α-hydroxylase enzyme
- Genetic defect (vitamin D–dependent rickets type 1A)
- Chronic renal failure
- "Acquired" vitamin D deficiency
- Increased catabolism due to microsomal enzyme induction
- Anticonvulsants
- Calcium deficiency with secondary hyperparathyroidism

TABLE 31.3 Causes of Hypophosphatemic Rickets or Osteomalacia, or Both

Genetic

Autosomal dominant rickets
Autosomal recessive rickets
X-linked dominant rickets (X-linked hypophosphatemia)
X-linked recessive
Hypophosphatemic hypercalciuric hereditary rickets (or Dent disease)
Neurofibromatosis
Fibrous dysplasia
Genetic Fanconi syndrome (may have renal failure)

Acquired

Tumor-induced osteomalacia (most common acquired cause)
Renal tubular damage or nonfamilial Fanconi syndrome
- Paraproteinemia
- Wilson disease
- Galactosemia
- Tyrosinemia
- Glycogenosis
- Drug induced
  - Tenofovir and adefovir (second most common acquired cause)
  - Phosphate-binding antacids
  - Cadmium poisoning
  - ?Use of outdated tetracycline
  - ?Amphotericin

target organ resistance to vitamin D action[37,38,121–123] are neither a vitamin D deficient state nor a genetic defect in the vitamin D activation pathway (see Tables 31.2 and 31.3). Although excessive intestinal loss of 25-hydroxyvitamin D via enterohepatic circulation or renal loss of vitamin D and its metabolites due to heavy proteinuria (as in nephrotic syndrome) as a cause of vitamin D depletion has been proposed, the magnitude and scope of these mechanisms contributing to vitamin D depletion are not well characterized.[124–126]

Of all the intrinsic causes of vitamin D depletion, malabsorption of vitamin D is by far the most common cause of osteomalacia.[110] Both gluten enteropathy and Crohn disease have been associated with osteomalacia due to vitamin D depletion.[62,127–131] Although decreased bone mineral density (BMD), increased fracture risk, and growth retardation (possibly related to rickets) have been associated with inflammatory bowel disease,[132–134] osteomalacia due solely to inflammatory bowel disease has not been reported. Severe calcium malabsorption, malnutrition, or both, as seen in patients with inflammatory bowel disease, may lead to 2°HPT with the consequent cortical bone loss and increased risk of fragility fractures (see Chapter 30) but without vitamin D depletion severe enough to cause osteomalacia.[78,93,135] Total and partial gastrectomy, vagotomy and pyloroplasty,[80,81,136–139] intestinal resection,[125,140] and gastric or intestinal bypass surgery for morbid obesity[62,80,128,138,141,142] have all been associated with vitamin D depletion and osteomalacia (see Table 31.2). Because of the malabsorption of multiple nutrients, including calcium and vitamin D, the bone phenotype varies from simple osteopenia detected by BMD testing to osteoporosis with increased fracture risk, to frank osteomalacia on bone histomorphometry. The relative frequency of osteomalacia in patients with various gastrointestinal disorders or surgeries is not clearly established but may be as high as 50%.[4,77,128,135,143,144] Prolonged 2°HPT can occasionally lead to bone marrow fibrosis and hypercalcemic 2°HPT (or tertiary hyperparathyroidism; see Chapter 29).[4,130,145–147]

By contrast, hepatobiliary and pancreatic disorders are relatively less common causes of rickets and osteomalacia, although osteoporosis is very common in both kinds of disorders (see Chapter 30). Because of the large functional reserve, by inference adequate availability of vitamin D 25-hydroxylase enzyme activity, vitamin D depletion sufficient to cause rickets and osteomalacia is unlikely in patients with the usual types of parenchymal liver diseases.[148–152] Most often, additional factors, such as poor dietary vitamin D intake, antiviral drug therapy for hepatitis[153–156] (see the Drug-Induced Osteomalacia section), and coexistent primary biliary cirrhosis,[124,152,157–159] contribute to severe vitamin D depletion and osteomalacia. Immaturity and neonatal hepatitis are also rare causes of rickets in children[2,114] and osteomalacia in adults,[160] most likely related to defective or insufficient vitamin D 25-hydroxylase enzyme, although not conclusively documented. Despite a significant fat malabsorption and steatorrhea in patients with exocrine pancreatic insufficiency, rickets and osteomalacia are uncommon, but both rickets and osteomalacia have been reported in patients with cystic fibrosis.[161–165] Drugs that interfere with the 25-hydroxylation step in the vitamin D activation pathway are discussed in the section on drug-induced rickets and osteomalacia (see Table 31.6).

Calcium-Deficiency Rickets

Unlike nutritional vitamin D and phosphate deficiency, which cause both rickets and osteomalacia, only rickets has been convincingly documented as resulting from nutritional calcium deficiency without associated vitamin D deficiency as assessed by normal or low normal serum 25-hydroxyvitamin D levels.[1,96] Although much has been learned on the role of calcium nutrition in the pathogenesis of

TABLE 31.4 Relevant Abnormalities in Various Types of Vitamin D–Related Rickets and Osteomalacia

Variable	Vitamin D Deficiency	Vitamin D Dependency Type 1B	Vitamin D Dependency Type 1A	Vitamin D Dependency Type 2	Hypophosphatemic Vitamin D Resistant[a]
Basic defect	Nutritional/ malabsorption	25-Hydroxylase defect	1α-Hydroxylase defect	VDR defect	Excess FGF23
Gene locus	Not applicable	Chromosome 11p15.2	Chromosome 12q13.1	Chromosome 12q12-q14	Xp22.11
Enzyme defect	Not applicable	CYP2R1	CYP27B1	Receptor defect	*PHEX* gene defect
Serum calcium	Low/normal	Low	Low	Low	Normal/High
Serum phosphate	Normal/low	Normal/Low	Normal/Low	Normal/Low	Very low
Alkaline phosphatase	High	High	High	High	High
Parathyroid hormone	High	High	High	High	Normal/high
25-Hydroxyvitamin D	Low	Low/very low	Normal	Normal	Normal
1,25-Dihydroxyvitamin D	Variable	Low/low normal	Low	High	Low
Urine calcium	Low	Low	Low	Low	Normal/high
Vitamin D dose required to heal/ cure rickets[b]	1000–2000 IU daily Few weeks to months	10,000 IU daily Lifelong	10,000 IU daily Lifelong	100,000 units daily Lifelong	100,000 units daily Lifelong
Calcitriol dose required to heal/ cure rickets	0.04 μg/kg per day Few weeks to months	0.04 μg/kg per day Lifelong	0.04 μg/kg per day Lifelong	1–2 μg/day Lifelong	1–2 μg/day and oral phosphate Lifelong

[a]Previously referred to as vitamin D–resistant rickets because of the large doses of vitamin D required to heal rickets; the current name is X-linked hypophosphatemic rickets and osteomalacia.

[b]Shown only to illustrate comparative effective doses. Both calcitriol and alphacalcidol are now widely available and used to treat all vitamin D–dependent rickets and osteomalacia

osteoporosis (see Chapter 30), no case of osteomalacia in an adult due to calcium deficiency alone has been reported; the reasons for this discordant effect of calcium nutrition on the skeleton in children and adults is perplexing. A more severe 2°HPT over a relatively short period due to severe calcium malnutrition in a growing child may produce radiologic features similar to rickets—the so-called short-latency disease.[166] However, a milder 2°HPT over a longer period of time caused cortical bone loss, osteoporosis, and increased fracture risk—the so-called long-latency disease.[166] Further studies are needed to clarify this apparent paradox: why two different nutrient (calcium and vitamin D) deficiencies independently produce the same disease in children (rickets) but different diseases in adults (osteoporosis and osteomalacia).

Calcium malnutrition as a cause of rickets was first suggested in a child from San Francisco, California, who responded to calcium infusion, but the child also had aminoaciduria, and vitamin D deficiency was not conclusively excluded.[167] A similar case of rickets in an Italian child from Toronto, Canada, in whom both vitamin D deficiency and resistance were excluded with appropriate biochemical testing, probably represents the first unambiguous human case of true calcium-deficiency rickets.[168] A more comprehensive study on calcium-deficiency rickets in children from rural South Africa further characterized the condition as a separate entity,[169] with additional reports from Nigeria,[96,170] India,[171] Mongolia,[172] and Europe,[173] confirming the concept, but many children also had some degree of vitamin D insufficiency. A daily calcium intake of greater than 200 mg appears to be the lowest threshold for the risk of developing calcium-deficiency rickets independent of vitamin D nutritional status[1]; "wet-nursing" and prolonged breastfeeding, practices that are prevalent in some cultures, are other risk factors for calcium-deficiency rickets.[174,175] Rickets due to calcium deficiency tends to occur later in life than that due to vitamin D deficiency, with an average age at presentation of 4 years in Nigeria, but ranging from 4 to 16 years in other series.[1] Interestingly, calcium-deficiency rickets appears to be particularly prevalent in parts of the world with abundant sunshine.[96,170,171,176] Clinically, calcium-deficiency rickets differs from other forms of rickets, especially in adolescents who may have significant genu valgum without many end-plate deformities.[177] The rarity of calcium-deficiency rickets in developed countries may be related to a much higher dietary calcium intake and less prolonged breastfeeding.[176,178] Nevertheless, when a child is encountered with rickets and if the serum level of 25-hydroxyvitamin D is normal, think of calcium-deficiency rickets, particularly if serum calcium is low and PTH is elevated.

Phosphate-Deficiency/Depletion Rickets and Osteomalacia

Nutritional phosphate deficiency is a very rare cause of rickets and osteomalacia, as there is abundant phosphate in foods, fruits, vegetables, and dairy products. Since intestinal absorption of phosphate is mostly passive and quite efficient, it is very difficult to produce true nutritional phosphate deficiency in an otherwise healthy individual. The serum phosphate level is maintained within a narrow range by the kidney under the control of PTH and FGF23.[179,180] Hypophosphatemia, however, is not uncommon in hospitalized patients,[181] in patients with iron deficiency,[182] and in those receiving phosphate binders and antacids known to deplete phosphorus in the body.[41,43,45,98] Such hypophosphatemic states usually do not last long enough to produce rickets and osteomalacia. Consequently, almost all hypophosphatemic rickets and osteomalacia are either genetic or acquired (see later discussion).

Clinical Manifestations of Classical Rickets and Osteomalacia

The symptoms and signs of rickets and osteomalacia are primarily related to the musculoskeletal system. With few exceptions (discussed later in detail in the relevant sections), the clinical manifestations are similar regardless of their pathogenesis—nutrient deficiencies, genetic or acquired causes, tumor induced, or drug induced. Because rickets involves the growth plates affecting linear growth, short stature is common. When nutritional deficiencies begin in childhood, and if left untreated for prolonged periods, as usually occurs in vitamin D and calcium-deficient endemic regions, deformities of the skeleton are common. In long bones, rickets affects diaphysis (bowing), metaphysis (widening, fraying, and cupping), and epiphysis (irregular margins), whereas osteomalacia involves only the diaphysis of the long bones. If osteomalacia develops later in life without a history of rickets during infancy and childhood, as is common in clinical practice in developed countries, the clinical manifestations are subtle and resemble those of age-related osteoporosis (see Chapter 30). In general, the later the onset of osteomalacia, the more easily its clinical clues are missed and the more likely the symptoms are dismissed as aches and pains of aging. The most common presenting clinical symptoms are bone pain, muscle weakness and difficulty in walking, skeletal deformities, and fractures. Carpal and pedal spasms, muscle cramps, and seizures due to hypocalcemia are uncommon but mostly seen in children with rickets than in adults with osteomalacia. Triradiate pelvis, a rare complication of osteomalacia due to softening of the pelvic bones (see Fig. 31.2), may cause difficult or obstructed labor in childbearing women; however, it is far less common today, and its presence suggests severe disease.

Bone Pain

Bone pain in osteomalacia is diffuse, nondescript, dull aching, deep seated, and poorly localized, and at times can be debilitating.[85,183–185] It is felt more in the bones than in the joints and often is bilaterally symmetric. Because of its vague nature, bone pain is often misdiagnosed as tension headache (so-called osteomalacic cephalalgia), "angina" (chest pain due to pseudofractures in the ribs), rheumatism, and fibromyalgia.[186–188] The pain is persistent and gnawing, is aggravated by weight bearing or muscle contractions during attempted walking, and is rarely relieved by rest. The pain usually begins in the lower back and spreads to the pelvis, hips, thighs, upper back, and ribs but is nonradiating and is rarely felt below the knees unless fragility or pseudofractures are present in tibiae and fibulae. Bone tenderness can be elicited by pressure or percussion over the shin bones, squeezing of the forearm with a fist, lateral compression of the pelvis and rib cage, and posterior compression of the sternum. The propensity of pain to localize to the axial skeleton is probably related to an earlier and a greater accumulation of osteoid in the cancellous bone, whereas the appendicular skeleton, rich in cortical bone, is more subject to fragility fractures. The mechanism for bone pain is believed to be related to the stretching of the periosteum by the overhydrated unmineralized bone matrix. Bone pain almost never occurs in patients with osteoporosis in the absence of a fracture, but in osteomalacia, bone pain occurs with or without a fracture. A significant minority of the patients can be completely asymptomatic.[94]

Muscle Weakness

Proximal muscle weakness, especially in the lower extremities, is the most common muscular manifestation in osteomalacia, although weakness in the upper arms can also be demonstrated by physical examination. The severity of muscle weakness varies from subtle abnormalities detectable only on careful examination to severe debilitating disabilities mimicking more serious muscle disorders and rarely can cause total paralysis. In mild cases, the muscle weakness must be distinguished from the patient's reluctance to stand or walk for fear of aggravating the bone pain. Difficulty in rising from a sitting position or going up and down stairs without using the arms is quite specific. In advanced cases, classical waddling gait (walking like a duck), the result of a combination of muscle weakness and bone pain, is observed. With prolonged vitamin D depletion of increasing severity, as seen in endemic regions that are vitamin D and calcium deficient, a patient may become completely immobilized and bed bound because of profound weakness and excruciating bone pain, sometimes masquerading as a terminal illness.

Despite profound muscle weakness, muscle atrophy is uncommon, although mild muscle wasting with atrophy of the type II fibers has been reported occasionally. Hypotonia can be present, but fasciculation and clonus are absent. Deep tendon reflexes are normal or increased—all helpful clinical signs to distinguish the muscle weakness of rickets and osteomalacia from other types of muscle diseases and myopathies. Rarely, dilated cardiomyopathy that responds to vitamin D repletion has been reported in severe rickets.[189] Other muscular symptoms such as muscle cramps and spasms, tingling and numbness, and seizures (usually in children) occur when the serum calcium level falls below 6.0 mg/dL. Both the muscle weakness and atrophy are commonly attributed to hypocalcemia and 2°HPT, but both muscle abnormalities are also seen in patients with primary and tertiary hyperparathyroidism in whom the serum calcium level is elevated (see Chapter 29). Since muscle weakness is also a manifestation of hypophosphatemic osteomalacia in the absence of hyperparathyroidism or hypocalcemia, the relative contributions of hypocalcemia, hypophosphatemia, and hyperparathyroidism to muscular manifestations of rickets and osteomalacia is not entirely clear. In general, muscle weakness is more prominent in hypophosphatemic rickets and osteomalacia, whereas bone pain is more common in vitamin D–deficiency osteomalacia. Interestingly, despite a significant muscle weakness in patients with X-linked hypophosphatemia (XLH), bone mass, bone size, and estimated bone strength are normal or increased.[190,191]

Skeletal Deformities and Fractures

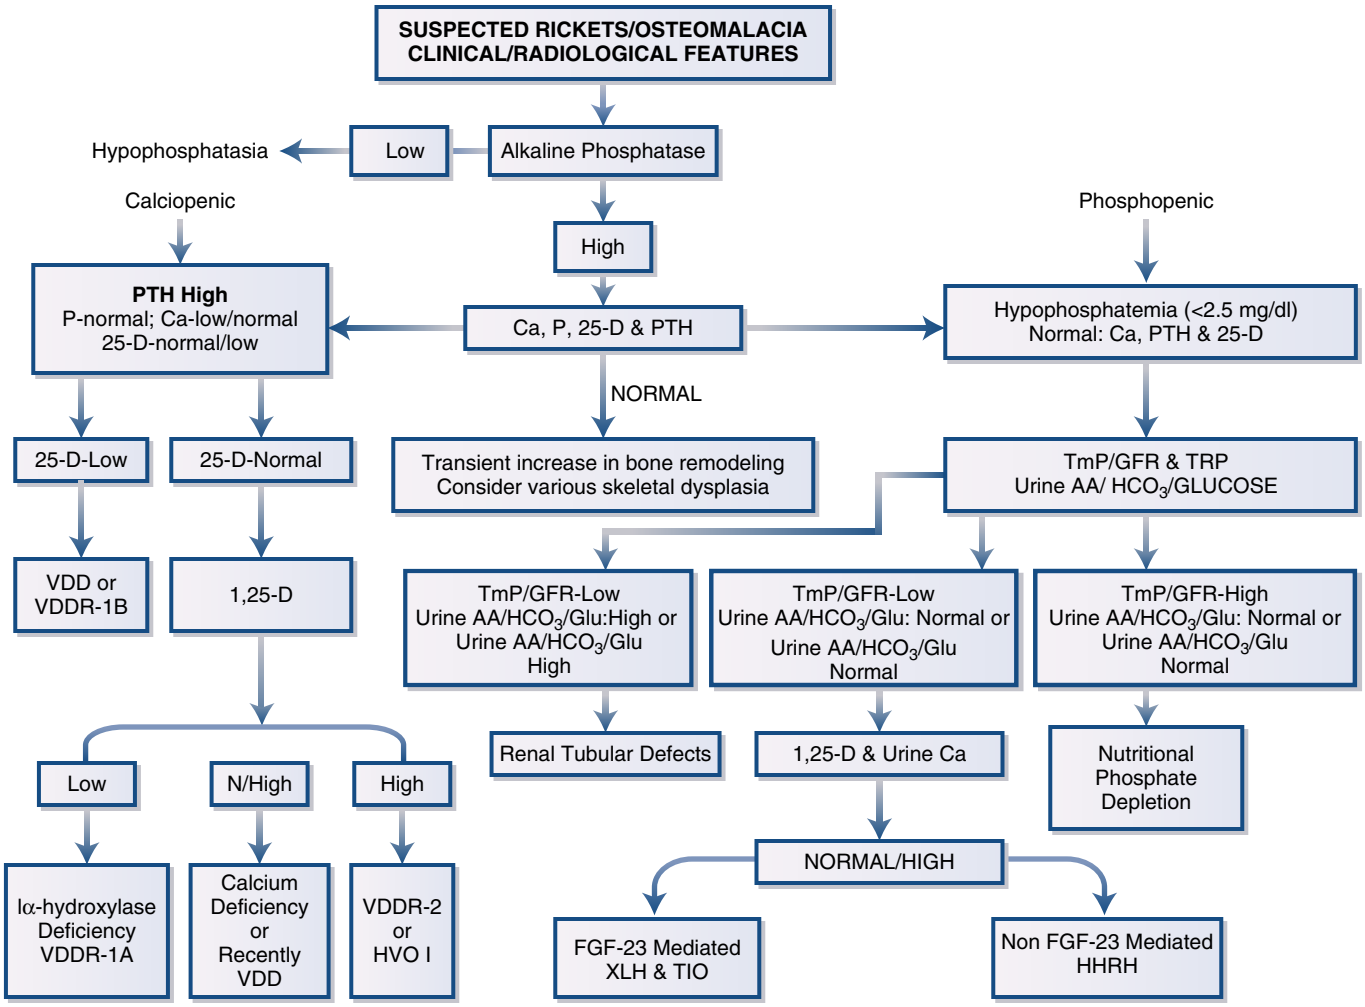
Skeletal deformities are common in children with rickets, vary with the age of presentation, and may remain permanent, whereas bone deformities are uncommon in adult-onset osteomalacia unless fractures have occurred. Infants present with open fontanelles, dolichocephaly, frontal bossing, rachitic rosary (due to consecutive pseudofractures of multiple ribs often bilaterally symmetric), Harrison sulcus (a visible horizontal line of depression at the level of the diaphragm due to weakness of the chest muscles), swollen wrist and ankle joints (due to widened metaphysis), and double malleoli. Once the child starts walking, bowing of the long bones, genu valgum, genu varum, and windswept deformity are seen. The skeletal deformities are usually more severe in genetic hypophosphatemic rickets and osteomalacia, and they predominantly involve lower limbs, resulting in a disproportionate short stature.[191] Fragility fractures are not uncommon, but Looser zones or pseudofractures, the diagnostic radiologic abnormalities (see Fig. 31.2), are more common in patients with rickets and osteomalacia. Pseudofractures are linear radiolucent bands perpendicular to the long axis of the bones, and are stress fractures that can extend to a complete fracture with separation or displacement with the pseudofractures that can progress to a complete fracture, usually in the subtrochanteric region of the femur or metatarsals—the greatest load-bearing bones. Rib fractures also commonly occur. The osteomalacic bones in children with rickets are soft rather than brittle, so fractures are less common. Conversely, when osteomalacia begins later in adult life, the usual types of fractures are more common.

Biochemical Changes

Relevant biochemical abnormalities at presentation of various forms of rickets and osteomalacia are summarized in Tables 31.4 and 31.5. Several excellent reviews have been published,[62,87] and only the salient abnormalities within each type and contrasting features between the types are briefly discussed in the following. In all types of rickets and osteomalacia, elevated serum alkaline phosphatase is the most frequent (~80–90%) and the earliest biochemical abnormality,[77] although an occasional patient may have normal alkaline phosphatase with histologically confirmed osteomalacia.[94] In general, hypocalcemia is a late biochemical manifestation, but it occurs earlier in the course of development of rickets in children than during the evolution of osteomalacia in adults. Mild to moderate hypocalcemia (serum calcium level of 7.0–8.5 mg/dL) is often asymptomatic unless it falls below the threshold for symptoms (usually <6.0 mg/dL). Like other types of biochemical abnormalities in clinical practice, it is the rate of change rather than the absolute value that determines the development of relevant symptoms. Most importantly, serum calcium is always normal in all forms of hypophosphatemic rickets and osteomalacia, except in certain types of renal tubular defects. The serum phosphate level is quite variable, lacks specificity, and is subject to diurnal variation, meal ingestion (and hence should be measured in the fasting state in the morning), renal function, and degree of serum PTH elevation—a known regulator of the serum phosphate level[179]; thus, serum phosphate in nutritional rickets and osteomalacia can be normal, low, and occasionally high, particularly in patients with more severe hypocalcemia.[94] By definition, the serum phosphate level is less than 2.5 mg/dL in all forms of hypophosphatemic rickets and osteomalacia. Although all patients with nutritional rickets and osteomalacia, by definition, have low 25-hydroxyvitamin D levels (usually <10 ng/mL), not all patients with low 25-hydroxyvitamin D levels necessarily develop rickets or osteomalacia.[62,87] This distinction is important in planning therapy, underscores the need not to equate low serum 25-hydroxyvitamin D level to osteomalacia, and avoids the often misused phrase "biochemical osteomalacia." In calcium-deficiency rickets, serum 25-hydroxyvitamin D is either normal or slightly reduced, although not to the same extent as in vitamin D–deficiency rickets and osteomalacia. An accelerated catabolism of 25-hydroxyvitamin D to its more polar and biologically active 1,25-dihydroxy vitamin D or to its inert metabolites contributes to the lower levels of serum 25-hydroxyvitamin D, sometimes referred to as conditional or obligatory vitamin D insufficiency. Serum levels of 1,25-dihydroxyvitamin depend on the stage in the evolution of nutritional rickets and osteomalacia, the availability of its precursor (25-hydroxyvitamin D), and the degree of PTH elevation; thus, the serum levels of 1,25-dihydroxyvitamin D can be high, normal, or low.[62,77,87,143] By contrast, serum 1,25-dihydroxyvitamin D levels are low, although not invariably, in hypophosphatemic rickets and osteomalacia.[8,88,89] Serum levels of PTH are always elevated in nutritional-deficiency (both vitamin D and calcium) rickets and osteomalacia, and the levels are normal in hypophosphatemic disorders regardless of the pathogenesis, unless vitamin D deficiency also exists. However, serum PTH levels rise progressively over time in patients with hypophosphatemic rickets and osteomalacia treated with long-term oral phosphate supplements and in some patients may even progress to hypercalcemic hyperparathyroidism that requires surgery.[192] A suggested clinical algorithm based on biochemical abnormalities in the evaluation of patients suspected of having rickets and osteomalacia is presented in Fig. 31.3.

Radiologic Imaging Features

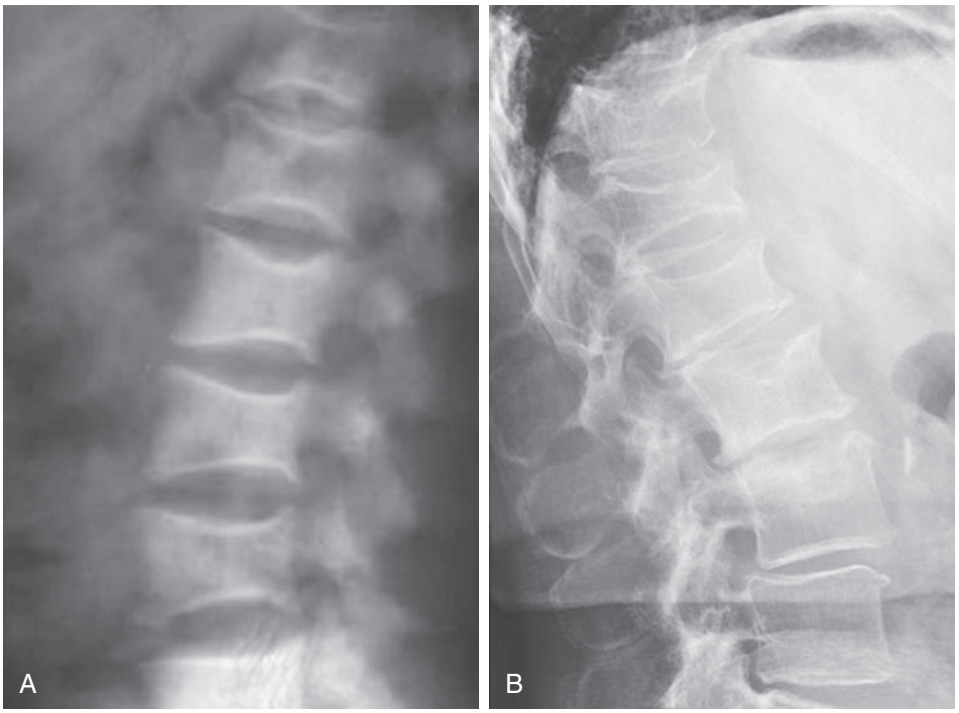
The major radiologic manifestations of nutritional rickets and osteomalacia are bone structural changes discernible on routine x-rays (now better defined on digital images), generalized decrease in apparent bone density on x-rays, vertebral deformities (Fig. 31.4), and pseudofractures (or Looser zones; see Fig. 31.2). Generalized thinning of cortices in the long bones is probably the earliest radiologic manifestation due to PTH-mediated endocortical bone resorption. Subperiosteal bone resorption (best seen on the radial aspect of the middle phalanges, metacarpals, and metatarsals) and brown tumors (osteitis fibrosa cystica; see Fig. 31.2) are seen in more advanced cases with severe hyperparathyroidism[193,194] (see Chapter 29). Although these latter bone abnormalities may resolve following vitamin D therapy, cortical thinning remains permanent and increases the fracture risk for the remainder of the patient's life.[93,195] Symmetrical biconcavity of vertebrae, referred to as cod fish vertebrae because they resemble vertebrae in cod fish, involves almost all vertebrae. "Fish-mouth" appearance of the intervertebral space, another structural change in the vertebral column, is the result of yielding of the soft vertebral bone to the pressure of the intervertebral discs (see Fig. 31.4A). This characteristic appearance of the vertebral column in osteomalacia is in stark contrast to the random anteriorly wedged or compressed asymmetrical vertebral deformities seen in patients with osteoporosis (see Fig. 31.4B; also see Chapter 30); when present, the cod fish vertebrae–like appearance of the spine is virtually diagnostic of osteomalacia (see Fig. 31.4A). The generalized apparent decrease in density of the bones on radiographs is manifested as decreased BMD by dual energy x-ray absorptiometry. Looser zones or pseudofractures are lucent



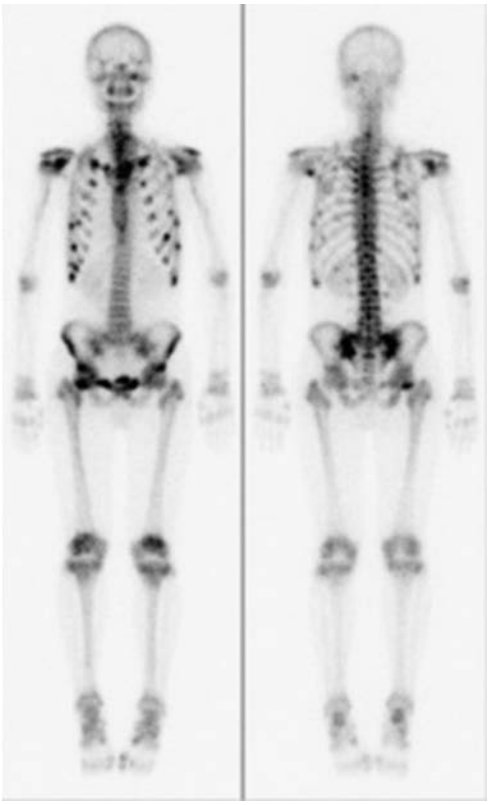
• **Fig. 31.3** Suggested clinical algorithm based on biochemical abnormalities in evaluating patients suspected of having rickets, osteomalacia, or both. Analytes: *Ca,* serum calcium; *P,* serum phosphate; *25-D,* serum 25-hydroxyvitamin D; *1,25-D,* 1,25-dihydroxyvitamin D; *PTH,* serum parathyroid hormone; *TmP/GFR,* tubular maximum for phosphate reabsorption/glomerular filtration rate; *HVO I,* hypovitaminosis D osteopathy stage I; *TRP,* tubular reabsorption of phosphate; *AA,* urine amino acid analysis; HCO_3, urine bicarbonate excretion; *Glu,* urine glucose. Conditions: *VDD,* vitamin D deficiency; *VDDR,* vitamin D–dependent rickets; *XLH,* X-linked hypophosphatemic rickets and osteomalacia; *TIO,* tumor-induced osteomalacia; *HHRH,* hereditary hypophosphatemic rickets with hypercalciuria.

bands (2–5 mm in width) perpendicular to the long axis of the bone or periosteum, often bilaterally symmetrical with sclerotic borders (Milkman syndrome); they occur more commonly in the ribs, pubic rami, and outer border of the scapulae (see Fig. 31.2), and less commonly at the inferomedial region of the proximal femurs and medial aspect of the shafts of the long bones. However, insufficiency fractures, sometimes inappropriately referred to as pseudofracture, can be seen in Paget disease of bone, hypophosphatasia, fibrous dysplasia, and atypical femur fractures due to long-term bisphosphonate therapy but usually occur (or begin) on the lateral cortex of long bones. Both insufficiency fractures and pseudofractures can progress across the shaft of the bone to a complete fracture. Looser zones or pseudofractures are caused by erosion of bone by nutrient arterial pulsation, which explains their specific medial cortical location, and represent the unhealed insufficiency type of stress fracture.

The generalized increase in radionuclide uptake throughout the skeleton, referred to as super scan, is specific for conditions associated with increased bone turnover but is more common in osteomalacia. Typically, there are no discrete focal abnormalities in the absence of pseudofractures, and the radionuclide uptake in the kidneys, in the absence of renal dysfunction, is either faint or absent, as most of the isotope is retained in the skeleton and very little is available for renal excretion (Fig. 31.5). When present, Looser zones are seen as "hot spots" on nuclear imaging (see Fig. 31.5). With a few exceptions, most radiologic features are similar among the various type of rickets and osteomalacia. Cortical thinning in long bones is not seen in XLH, and in fact, thick cortices are the rule rather than the exception. Similarly, enthesopathy is seen exclusively in XLH, but the underlying mechanisms for its development is not known. In most acquired forms of hypophosphatemic osteomalacia (tumor- and drug-induced or renal tubular defects), cortical thinning and decreased BMD may be seen, most likely the result of age-related bone loss considering that 2°HPT is not a feature of the genetic or acquired forms of hypophosphatemic disorders. Horizontal bands of endplate sclerosis of the vertebrae with relative lucency in the middle portion of the vertebral bodies (Rugger-Jersey spine, so named as the appearance resembles jerseys of rugby players) are sometimes observed in osteomalacia due to renal tubular acidosis but is a more characteristic feature of renal osteodystrophy (see Chapter 29).



• **Fig. 31.4** (A) Typical symmetrical biconcave deformities of all the vertebrae, sometimes referred to as cod fish vertebrae because they resemble the vertebrae of the fish. When present, it is diagnostic of osteomalacia of all types. (B) Typical random osteoporotic wedge and compression deformities in a postmenopausal woman with osteoporosis.



• **Fig. 31.5** Characteristic bone scan in a patient with osteomalacia. Note increased nuclide uptake throughout the skeleton with very little or no uptake in the kidneys as the radionuclide is all retained in the high remodeling skeleton. Also see multiple bilateral symmetrical uptake in the ribs (*left*) due to pseudofractures, often confused with metastatic disease.

Bone Mineral Density

BMD as assessed by dual energy x-ray absorptiometry is reduced at all of the relevant sites (lumbar spine, proximal hip, and forearm), usually with a greater deficit at the site of rich cortical bones in the forearms. By contrast, BMD is either normal or even increased at the lumbar spine in adults with XLH osteomalacia (see later discussion). A lower BMD in tumor-induced osteomalacia (TIO) is more likely age related. Although the patterns of BMD deficits are different in different types of osteomalacia, the findings are neither sensitive nor specific to differentiate osteomalacia from osteoporosis. Accordingly, in vivo tetracycline-labeled bone histomorphometry is the gold standard method to conclusively establish the diagnosis of osteomalacia in suspected cases.[87]

Treatment of Nutritional Rickets and Osteomalacia

Treatment of rickets and osteomalacia must be based on their pathogenesis. Since therapeutic approaches to treat and manage various types of rickets and osteomalacia (nutritional, genetic, and acquired) differ, the treatments that substantially differ will be discussed in the relevant sections in this chapter. In general, there is no "fixed-dose" or "one-size-fits-all" regimen to treat all varieties of rickets and osteomalacia. Several points deserve emphasis in the management of rickets and osteomalacia. First, most recommendations are largely based on personal preferences, clinical experience, and availability of suitable vitamin D preparations. Second, moderate to severe rickets and osteomalacia related to vitamin D and calcium deficiency, but not the hypophosphatemic variety, are frequently associated with hypocalcemia and thus require much higher doses of vitamin D and calcium supplements initially.

Third, it must be kept in mind that patient symptom relief is much faster (a few weeks to a few months) than the biochemical, radiologic, or histologic improvements, which may take a few months to years. Fourth, even after apparent "cure" of clinical, biochemical, radiologic, and bone histologic abnormalities, many patients remain at risk for fractures because of irreversible cortical bone loss. In some patients with long-standing vitamin D–deficiency rickets and osteomalacia, 2°HPT may persist[196] with continued bone loss for years and may even progress to hypercalcemic 2°HPT (or tertiary hyperparathyroidism) requiring parathyroidectomy.[146,197,198] This is analogous to the development of tertiary hyperparathyroidism after long-term oral phosphate therapy in patients with hypophosphatemic (genetic or acquired) osteomalacia,[192] and in patients on chronic maintenance dialysis[199] or after kidney transplantation.[200] Accordingly, the goals of therapy are not only to simply relieve symptoms but also to restore bone strength by mineralizing the excess osteoid and prevent bone loss by correcting 2°HPT.

Several dose regimens have been suggested, each with some merit,[201] but there is no perfect method. Whichever method is chosen, it must achieve the therapeutic goals, and which method to choose depends heavily on the urgency with which vitamin D repletion is needed, local standard of practice, availability of appropriate vitamin D preparations, cost, and potential for lapses in patient adherence. In symptomatic patients with moderate to severe rickets and osteomalacia, we recommend 50,000 IU of either ergocalciferol (vitamin D_2) or cholecalciferol (vitamin D_3) weekly for 8 to 12 weeks followed by a maintenance dose of 1000 to 2000 units daily. Despite the contradictory claims,[202,203] there is not much difference between vitamin D_2 and vitamin D_3 in replenishing depleted vitamin D stores,[203] and both vitamin D preparations are equally effective in treating rickets and osteomalacia. During follow-up, adjustments to the vitamin D dose should be made based on serum and urine levels of calcium, alkaline phosphatase, PTH, and achieved serum 25-hydroxyvitamin D levels, with target levels of 25-hydroxyvitamin D greater than 30 ng/mL and PTH in the reference range. Once achieved, a maintenance dose of 1000 to 2000 IU/day is recommended. Several vitamin D formulations (oral, sublingual, and injectable) are available, and most have comparable therapeutic efficacy, although no formal studies have been conducted. In addition, certain vitamin D metabolites (calcidiol, calcitriol, and alphacalcidol) are available in other countries, but only calcitriol is available in the United States. Perhaps calcidiol (25-hydroxyvitamin D_3), if available, is preferred because it has a shorter half-life (~2 weeks), which is an advantage should hypercalcemia develop during therapy, it can be measured directly to monitor treatment, and the dose can be adjusted based on serum levels. The other active metabolites (calcitriol and alphacalcidol) are not preferred in treating vitamin D–deficiency rickets and osteomalacia but have been used. The active vitamin D metabolites are a bit more expensive and do not provide any major advantage except for more rapid and effective suppression of PTH. Therefore, the use of calcitriol along with vitamin D is suggested in patients with more severe 2°HPT (PTH levels >500 pg/mL), in some patients with significant malabsorption of calcium due to celiac sprue or gastric bypass surgery, in patients with documented bone marrow fibrosis,[4] or in those with compromised kidney function. However, calcitriol should not be either the first-line or sole therapy for vitamin D–deficiency rickets and osteomalacia. Although the therapeutic efficacy of all formulations is comparable, the frequency with which they are administered differs.

In malabsorptive states, particularly in patients with small intestinal resection or gastric bypass surgery, higher doses of vitamin D (10,000–50,000 IU/day) may be required to replete vitamin D stores. Variable strengths of injectable preparations of cholecalciferol (300,000–600,000 units) are available in some countries but not widely in the United States and may be preferable in specific situations, such as in patients with significant malabsorption or poor compliance or intolerance to oral preparations. Compared with parenteral administration, the rise in serum 25-hydroxyvitamin D levels is rapid with oral preparations. Careful close follow-up is essential during the first few months (1–3 months) of treatment to monitor treatment-related adverse events, such as hypercalcemia, hypercalciuria, and renal dysfunction. Occasionally, high-dose vitamin D supplementation may unmask underlying primary hyperparathyroidism (see Chapter 29).

Vitamin D deficiency of sufficient severity to produce osteomalacia is invariably associated with decreased intestinal calcium absorption and negative calcium balance. Accordingly, oral calcium supplements in the form of calcium carbonate (or citrate) 1000 to 1500 mg/day in divided doses must be prescribed with vitamin D administration to accomplish not only clinical and biochemical but also radiologic and bone histologic responses. With effective therapy, symptoms of osteomalacia start improving within a few weeks, but complete disappearance of symptoms usually takes a few months and sometimes years.

Although nutritional rickets is mostly curable, osteomalacia is only treatable but not curable and requires long-term maintenance therapy largely dictated by the clinical and biochemical responses. Complete healing of osteomalacia and resolution of 2°HPT must be ensured before commencing antifracture therapy for the associated osteoporosis (see Chapter 30). Almost all patients with vitamin D deficiency due to gastrointestinal disorders, resection, or bypass require lifelong vitamin D supplements/therapy and regular follow-up to prevent recurrence of osteomalacia due to lapses in therapy. Nonadherence to long-term therapy is not uncommon because both the patient and sometimes the treating physician might assume that the condition is "cured" based on clinical symptoms, and therefore there is no need for continued therapy.

Rickets Due to Genetic Disorders of Vitamin D Metabolism

Vitamin D–Dependent Rickets Types 1A, 1B, and 2

There are three unique forms of rickets due to genetic disorders, resulting in the loss of function of the enzymes required for vitamin D biologic activation.[204] A unique case of osteomalacia resistant to high-dose vitamin D therapy was reported in 1979, perhaps the first documented case of osteomalacia due to possible defective vitamin D 25-hydroxylase,[160] although evidence presented was less than convincing, and no additional similar cases of osteomalacia in adults have been reported since. Severe rickets despite adequate vitamin D intake that responded only to high doses of vitamin D_2 in two siblings was probably the first example of rickets due to a possible genetic defect in the 25-hydroxylase enzyme.[114] Recent genetic studies suggest that mutations in the *CYP2R1* gene,[112,113] the principal 25-hydroxylase in humans, are responsible for the severe atypical form of vitamin D deficiency and rickets, although no mutations were found in another child with a similar phenotype.[118]

The genetic transmission appears to be both autosomal dominant and recessive, and this rare atypical form rickets is now designated as vitamin D–dependent rickets type 1B (VDDR1B).[205] The other two types—vitamin D–dependent rickets type 1A (VDDR1A) and vitamin D–dependent rickets type 2 (VDDR2)—are due either to a defective 25-hydroxyvitamin D 1α-hydroxylase, the critical enzyme required in the final step of vitamin D biologic activation,[204] or to an end-organ resistance to vitamin D action due to loss of vitamin D receptors,[206] respectively. Impairment of 1α-hydroxylase enzyme activity can also be acquired, as in chronic kidney disease, various renal tubular disorders,[99] or excess or ectopic production of FGF23, known to inhibit 1α-hydroxylase enzyme activity.[207] Genetic defect in the 25-hydroxyvitamin D 1α-hydroxylase enzyme, VDDR1A, or pseudo–vitamin D deficiency, is a rare autosomal recessive disorder due to mutations in the cytochrome P450 (*CYP27B1*) gene for the 1α-hydroxylase enzyme located on the chromosome 12q13.3, resulting in decreased serum levels of 1,25-dihydroxyvitamin D.[208,209] Rickets develops during the first year of life, and clinical features include growth failure, hypotonia, weakness, convulsions, tetany, open fontanels, and pathologic fractures, as well as oral and dental manifestations.[209] As can be predicted, the condition responds to the physiologic doses (0.04 μg/kg per day) of active vitamin D metabolite, 1,25-dihydroxyvitamin D or calcitriol, but requires much higher doses of the parent compound vitamin D (~10,000 units/day) to heal rickets—hence the name vitamin D–dependent rickets. Similar to VDDR1A, but even more resistant to vitamin D therapy, is due to defects in the vitamin D receptor, designated as VDDR2.[206] Children with VDDR2 have alopecia, a very unique feature that distinguishes VDDR2 from both VDDR1A and VDDR1B. However, the prevalence of alopecia is variable as is its extent of involvement ranging from alopecia of the head to alopecia of the entire body—"alopecia universalis." Interestingly, although the biochemical and radiologic abnormalities in VDDR2 respond to high-dose vitamin D or calcitriol and phosphate therapy, alopecia does not. Vitamin D receptors are lacking in fibroblasts of the skin.[210]

Biochemical and radiologic features of vitamin D–dependent rickets are similar to those seen in nutritional rickets, except serum 25-hydroxyvitamin D levels are normal in VDDR1A and VDDR2, and low or very low in VDDR1B (see Table 31.4). Because of the low or very low serum 25-hydroxyvitamin D levels, the biochemical findings in VDDR1B resemble those of nutritional vitamin D–deficiency rickets (see Table 31.4) and thus may be misdiagnosed as nutritional rickets. Family history, adequate vitamin D intake, lack of clinical and biochemical response to standard-dose vitamin D therapy, and lack of rise in serum 25-hydroxyvitamin D levels with vitamin D therapy should raise suspicion for the possibility of this very rare inborn error of vitamin D metabolism due to mutations in the *CYP27B1* gene.[205,211]

Both VDDR1A (due to 25-hydroxyvitamin D 1α-hydroxylase deficiency) and VDDR1B (due to vitamin D 25-hydroxylase deficiency) respond to physiologic replacement doses of calcitriol (0.04 μg/kg per day), just as nutritional rickets.[208] However, patients with VDDR2 require much higher doses of vitamin D or calcitriol because of end-organ resistance as a result of vitamin D receptor defects.[206] All children with vitamin D–dependent rickets regardless of the type require adequate calcium and phosphate supplements during therapy with calcitriol to achieve healing of the rickets and suppress 2°HPT. Hypercalciuria and hypercalcemia are potential complications during long-term therapy. All patients must be monitored closely, regularly, and throughout their lifetime.

Hereditary Hypophosphatemic Rickets and Osteomalacia

There are several types of hereditary rickets that in the past were collectively referred to as vitamin D–resistant rickets because of the very high doses of vitamin D required to cure rickets.[50,95,190,212] These rare types of rickets can be distinguished from the other types of rickets by the pattern of their inheritance, underlying genetic defects, and hypophosphatemia with normal serum calcium level, and if they are FGF23 dependent or independent.[6,7,95] The most common type of rickets and osteomalacia among them and clinically most relevant is XLH rickets and osteomalacia.

Autosomal Dominant and Recessive Rickets

Autosomal dominant hypophosphatemic rickets (ADHR) is caused by mutations in the *FGF23* gene,[212] whereas inactivating mutations in the dentin matrix protein (DMP1) and the ectonucleotide pyrophosphatase/phosphodiesterase 1 (*ENPP1*) genes are responsible for autosomal recessive hypophosphatemic rickets (ARHR) type 1 and type 2, respectively.[212,213] In patients with ADHR, there are mutations in several amino acids (Arg^{176} or Arg^{179}) resulting in resistance to proteolytic processing. In addition, the degree of hypophosphatemia correlates with the intact FGF23 levels.[95] In patients with FGF23-dependent hypophosphatemia due to mutations in the *DMP1* gene, there are deformities of the legs and short stature in childhood, similar to the clinical phenotype of nutritional rickets.[7,95] ARHR typically manifests during childhood with characteristic clinical features of rickets[7]; however, in adulthood, ARHR patients may manifest with bone pain, fatigue, muscle weakness, and repeated bone fractures.

X-Linked Recessive Hypophosphatemic Rickets

X-linked recessive hypophosphatemic rickets—a rare genetic form of hypophosphatemic rickets also known as the Dent disease complex—comprises of a group of heterogeneous inherited disorders characterized by a proximal renal tubular reabsorptive disorder of the Fanconi type.[50] It is caused by missense, nonsense, frameshift, and splicing mutations in genes located on the chromosome Xp11.22 and X25.[50,214,215] Two subtypes are known to exist: type 1 (~50–60% of cases), caused by an inactivating mutations in the chloride channel 5 (*CLCN5*) gene that codes for a chloride-proton exchanger, and type 2 (~15% of cases), by inactivating mutations in the oculocerebrorenal syndrome (*OCRL*) gene located on an X chromosome that codes for inositol polyphosphate 5-phosphatase OCRL-1.[50] Similar to other types of genetic or acquired forms of Fanconi syndrome,[9,156,216] Dent disease is associated with hypercalciuria with variable other proximal renal tubular dysfunction, nephrocalcinosis or nephrolithiasis, low-molecular-weight proteinuria, and progressive renal insufficiency, but only a minority of patients manifest rickets.[214] In addition to hypercalciuria and proteinuria, the disease may be associated with defective renal tubular reabsorption of one or more of the following solutes: glucose, phosphate, uric acid, potassium, bicarbonate, and amino acids. However, unlike all other forms of hereditary rickets, Dent disease is the only type of genetic rickets associated with nephrocalcinosis and nephrolithiasis, and it is the least common of all types of rickets.

X-Linked Hypophosphatemic Rickets and Osteomalacia

XLH (OMIM #307800) is an X-linked dominantly inherited disorder with an estimated prevalence of about 1 in 20,000 live births.[7] It is the most common form of hereditary

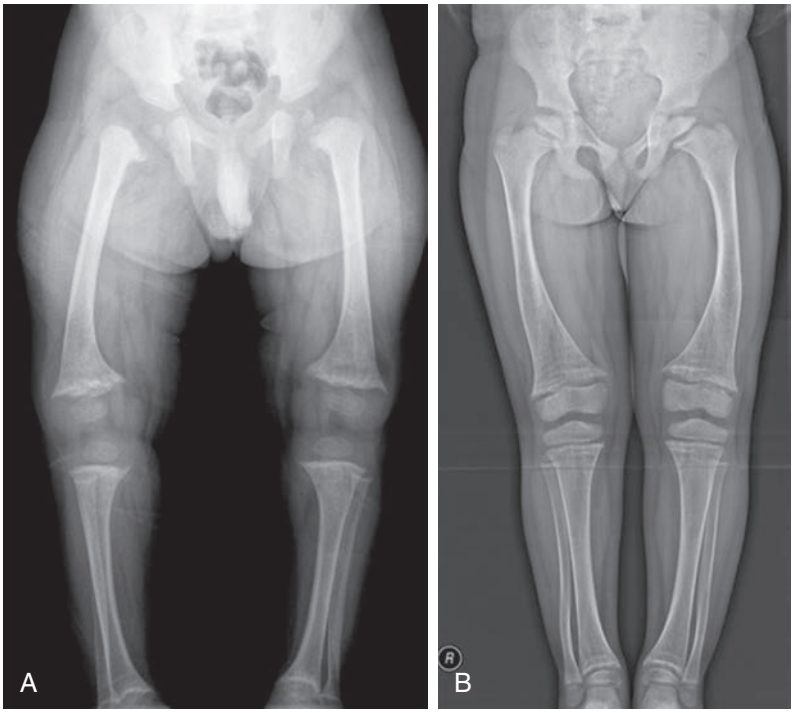
hypophosphatemic rickets, caused by an inactivating mutation in the phosphate-regulating gene with homologies to endopeptidases on the X chromosome (PHEX).[6,7,95,212] PHEX is expressed on the cell surface of bones and teeth. It is the most common form of FGF23-mediated hypophosphatemic rickets, but the substrate for PHEX remains largely unknown.[217] More than 300 types of mutations in the *PHEX* gene have been reported in patients with XLH, and the mutations may be de novo in some patients. The prevailing hypothesis is that the mutations found in the *PHEX* gene in patients with XLH are likely to enhance the production of FGF23 in bones, but the pathogenic implications to the clinical expression of the disorder are unclear.[7,95,212,217] Nevertheless, the unifying hypothesis proposed by Jan de Beur and Levine is most convincing and probably the most clinically relevant.[5] It is worthwhile to restate the concept: Although TIO, XLH, and ADHR all have overlapping phenotypical features, all three types of rickets share a common biochemical phenotype—*hypophosphatemia* as a result of defective renal tubular reabsorption of phosphate. Current evidence supports the notion that under normal physiologic conditions, the concentration of FGF23 in serum (and possibly other tissues) is regulated by PHEX-dependent proteolysis. However, conditions with excess circulating FGF23 concentrations or activity are associated with a marked depression in the proximal renal tubular reabsorption of phosphate and hypophosphatemia. When PHEX is inactive, as in patients with XLH, FGF23 is not degraded and accumulates in the circulation. In ADHR, missense mutations replace the key amino acids in FGF23 and render the protein resistant to proteolysis, thereby leading to increased circulating FGF23 concentrations or action. Similarly, ectopic overproduction of FGF23 by tumors causing TIO (see the following) may saturate the capacity of endogenous proteolytic enzymes, such as PHEX, to degrade FGF23. It is clear that FGF23 plays a central role in the pathogenesis of these disorders; however, the role of FGF23 in normal physiology and the mechanism(s) by which it regulates renal phosphate handling or calcitriol synthesis is not fully understood.

The clinical features of XLH are variable, with most patients presenting with rickets during childhood (Fig. 31.6). In childhood-onset XLH, skeletal deformities such as bowed legs and short stature are common. In adults, XLH may be discovered during a routine biochemical work-up revealing hypophosphatemia. Symptoms in adults resemble those seen in osteomalacia, such as bone pain, insufficiency fractures, muscle weakness that is often disabling, neurologic complications related to enthesopathy, and ectopic calcifications. In addition, dental disease, such as root abscesses, often develop due to a defect in dentin and enamel microdefects.[218]

Radiologic and Biochemical Findings

The radiologic features of all hereditary rickets are similar to those seen in nutritional rickets, except metaphyseal involvement is slightly asymmetrical and bowing is slightly more common (see Fig. 31.6). As adults, most patients are obese and manifest a disproportionate short stature with greater shortening of the lower extremities. However, none of these findings is specific enough to distinguish the type of rickets, but enthesopathy occurs almost exclusively in XLH and is almost never seen in other types of rickets and osteomalacia.

The most common and consistent biochemical findings are hypophosphatemia, renal phosphate wasting as assessed by tubular reabsorption of phosphate or tubular maximum for phosphate



• **Fig. 31.6** Nutritional vitamin D–deficiency (A) and X-linked hypophosphatemic (B) rickets in 5-year-old black and 5-year-old white children. Typical metaphyseal widening, fraying, and cupping at the ends of all of the long bones can be seen. Note the similarities, but a few subtle differences can be appreciated. Bowing is more pronounced and cortices are thicker in X-linked hypophosphatemic rickets (B) than in nutritional rickets (A).

reabsorption adjusted for glomerular filtration rate (GFR; TmP/dlGFR), and elevated serum alkaline phosphatase levels. Serum calcium, 25-hydroxyvitamin D, and PTH levels are characteristically normal in the untreated state. Serum FGF23 levels are inappropriately elevated in the context of chronic hypophosphatemia.

Although the constellation of clinical and biochemical findings is unmistakably diagnostic, the differential diagnosis of XLH includes nutritional rickets, metaphyseal dysplasia, physiologic bowing, and other forms of renal phosphate wasting disorders. In a patient with rickets with chronic hypophosphatemia and inappropriately elevated serum FGF23 levels, a diagnosis of FGF23-related hypophosphatemia is highly likely. Considering the possibility of de novo mutations in the *PHEX* gene, an absence of family history of rickets does not necessarily exclude XLH. Genetic testing is not a prerequisite for a clinical diagnosis of XLH.

Treatment of Hereditary Hypophosphatemic Rickets and Osteomalacia

Standard Treatments

The standard of practice for the treatment of XLH in children includes a combination of active vitamin D metabolites (calcitriol or alphacalcidol) and oral phosphate supplementation.[7] Skeletal deformities and growth retardation may improve with treatment but do not completely resolve. In adults, these same medications are used for symptom management and to improve impaired bone mineralization. In one observational study, treatment of adult patients with XLH reduced pain symptoms and improved fracture healing following orthopedic surgery but did not prevent or reverse enthesopathy.[219] In one prospective study, 6 years of treatment showed increases in bone resorption markers albeit without changes in spine and hip areal BMD.[220]

Novel Treatments

Recently, the use of burosumab, a recombinant human immunoglobulin G1 monoclonal antibody that binds to the FGF23 receptor and inhibits its activity, was evaluated in a phase 1 double-blind, placebo-controlled randomized clinical trial.[221,222] With a single dose, burosumab increased the TmP/GFR, and serum levels of phosphate and 1,25-dihydroxyvitamin D.[221,222] The peak serum phosphate concentration achieved was between 8 and 15 days and returned to the baseline within 50 days after the initial subcutaneous injection. In a subsequent phase 1/2 open-label, dose-escalation study, monthly burosumab resulted in a sustained improvement in TmP/GFR, and in serum phosphate and 1,25-dihydroxyvitamin D levels, with a favorable safety profile.[221,222] However, at present, it is not clear if these early clinical trials will have long-lasting effects on clinical and radiologic resolution of rickets and osteomalacia. Several clinical trials with burosumab in patients with both XLH and TIO are currently under way.

Long-Term Management

Treatment with active vitamin D metabolite, calcitriol, and oral phosphate supplements has the potential for adverse effects over the long term. Hypercalciuria with or without hypercalcemia may develop and may lead to nephrolithiasis, nephrocalcinosis, and impaired renal function. Use of oral phosphate supplements causes diarrhea and abdominal pain, which in turn leads to poor medication adherence. An unintended consequence of long-term (usually years) oral phosphate therapy is the development of 2°HPT, which may evolve into hypercalcemic 2°HPT (also referred to as tertiary hyperparathyroidism).[223–225] Several treatment strategies for tertiary hyperparathyroidism have been suggested depending on the degree of hypercalcemia, severity of hyperparathyroidism, and clinical status.[192,224] Cinacalcet, which produces a relative hypoparathyroidism, radiofrequency ablation of the tumor to reduce ectopic production of FGF23, and deliberate total parathyroidectomy have all been tried with variable success.[192]

Tumor-Induced Osteomalacia

TIO was first reported by Robert McCance in 1947,[226] but the first "proof of concept" was provided by Andrea Prader in 1959, who postulated the production of a "rachitogenic substance" by a "giant cell reparative granuloma of bone," the removal of which cured the young patient's rickets.[227] Interestingly, the discovery of FGF23 and characterization of its function as a major phosphate-regulating hormone did not occur until a few decades later.[228] The condition is conventionally referred to as osteomalacia, as most cases are detected in adults, but rickets in children has been reported.[226,227] Nearly 500 cases of TIO have been reported in the literature; the majority are adults with a mean age of 45 years at the time of diagnosis and a wide age range, and there does not appear to be any gender predilection.[8]

TIO is a rare paraneoplastic syndrome that clinically manifests with diffuse nonspecific bone pain, profound muscle weakness, and fractures.[8,88,89,229] The pathogenesis is related to the ectopic production of FGF23—a phosphatidic hormone secreted by small mesenchymal tumors.[228] The biochemical hallmark of TIO is the triad of hypophosphatemia due to renal phosphate wasting, inappropriately low or normal serum 1,25-dihydroxyvitamin D level, and elevated or inappropriately normal serum FGF23 level.[8,207]

FGF23, produced exclusively by osteocytes and osteoblasts,[6,230] exerts its effects on the kidney and parathyroid glands to maintain normal phosphate homeostasis and regulate 1,25-dihydroxyvitamin D synthesis and metabolism.[6,95,207] The kidney is the principal target for FGF23, where it regulates renal tubular reabsorption of phosphate and production of 1,25-dihydroxyvitamin D.[6,95,179,207] FGF23 inhibits both sodium-dependent phosphate reabsorption and 1α-hydroxylase activity in the proximal tubule, leading to hypophosphatemia and aberrant production and inappropriately low levels of 1,25-dihydroxyvitamin D. The combination of hypophosphatemia and "low" 1,25-dihydroxyvitamin D causes muscle weakness and mineralization defect, respectively.

TIO is usually caused by tumors of mesenchymal origin, referred to as phosphaturic mesenchymal tumor of mixed connective tissue variant, and rarely by other types of tumors, such as osteosarcoma, giant cell tumor, glomus tumor, small cell carcinoma of the lung, and adenocarcinoma of the colon.[8,88,89] These tumors tend to be small (often escaping clinical detection), slow growing,[231] and difficult to localize; about half of the tumors are located in the skeleton, and the remaining are located in soft tissues. Histology of the tumors reveals neoplastic spindled and stellate-shape cells with low nuclear and mitotic activity that stain for FGF23.[229] Although FGF23 is the predominant secretory product of the tumors and the most common phosphatonin, other phosphatonins such as frizzled-related protein 4, FGF7, and matrix extracellular phosphoglycoprotein have been described.

Patients with TIO usually present with long-standing and progressive debilitating symptoms that go undiagnosed for years, but an occasional patient may cruise along without necessarily suffering, except for the progressive slow growth of the tumor over

TABLE 31.5 Key Abnormalities in Various Types of Rickets and Osteomalacia

Variable	Vitamin D Deficiency	Vitamin D–Resistant Hypophosphatemic	Tumor-Induced Osteomalacia	Drug-Induced Osteomalacia
Basic defect	Nutritional/malabsorption	*PHEX* gene defect Defective catabolism of FGF23	Ectopic production of FGF23	Renal tubular damage Direct effect on bone mineralization
FGF23 levels	Not applicable	Usually high	Almost always high	High/variable
Serum calcium	Low/normal	Normal/high	Normal	Variable
Serum phosphate	Normal/low	Very low	Low/very low	Variable
Alkaline phosphatase	High	High	High	Variable
Parathyroid hormone	High	Normal/high	Normal	Variable
25-Hydroxyvitamin D	Low	Normal	Normal	Low/normal
1,25-Dihydroxyvitamin D	Variable	Low	Low	Low/variable
Bone mineral density	Low	Normal/high	Often low	Often low
Therapeutic strategy	Vitamin D + Calcium	Calcitriol and phosphate Burosumab	Resection of the tumor Other therapies (see text)	Discontinuation of offending drug

FGF23, Fibroblast growth factor 23; *PHEX*, phosphate-regulating endopeptidase homolog, X-linked.

decades causing minimal disability.[231] Symptoms can be nonspecific, and the most common complaints are bone pain, fatigue, muscle weakness, and multiple fractures. Many patients with TIO receive various erroneous diagnoses (rheumatologic, malignant, and even psychiatric) and, consequently, inappropriate treatments for years before the tumor causing osteomalacia is found.[88]

Laboratory evaluation of a patient suspected of having TIO should begin with measurement of serum phosphate, preferably in the fasting state. Since hypophosphatemia is uncommon in the ambulatory nonhospitalized patient, a serum phosphate level less than 2.5 mg/dL should raise suspicion in the right clinical setting. Elevated serum alkaline phosphatase supports the clinical suspicion. Other relevant biochemical abnormalities are summarized in Table 31.5. Once hypophosphatemia is detected and confirmed, further assessment of the renal tubular handling of phosphate (tubular reabsorption of phosphate and TmP/GFR: tubular maximum for phosphate reabsorption per unit of GFR; also see Chapter 29) should be performed, and a low value for either measurement clinches the diagnosis of a phosphate-wasting condition.

As in genetic hypophosphatemic disorders, serum levels of calcium, 25-hydroxyvitamin D, and PTH are normal in TIO, but similar to genetic disorders, 1,25-dihydroxyvitamin D levels are either inappropriately "normal" or low (see Table 31.5). Interestingly, serum levels of alkaline phosphatase are elevated in all varieties of hypophosphatemic rickets and osteomalacia despite low or absent bone remodeling, and the reason for this biochemical abnormality is not well understood.

Serum FGF23 levels are elevated in the majority of, but not all, patients with TIO and depend on the type of assay used (intact vs. C-terminal fragment).[232] Although an elevated level of FGF23 supports diagnostic suspicion, a normal serum FGF23 level does not exclude the diagnosis. A positive family history of rickets or osteomalacia, or presence of metabolic acidosis, makes TIO unlikely. In addition, serum FGF23 levels do not distinguish different types of hypophosphatemic rickets and osteomalacia. Similarly, tumors with demonstrable FGF23 expression by immunohistochemistry may not necessarily cause osteomalacia and are referred to as nonphosphaturic variants. Whether they represent a separate entity or simply the preclinical stage of the disease is unknown, because preoperative serum phosphate and FGF23 levels have not been reported in any of the so-called nonphosphaturic tumors.[229]

Radiologic and radionuclide manifestations of TIO are similar to those seen in other types of rickets and osteomalacia (see the following) with some exceptions: unlike genetic hypophosphatemic but similar to nutritional deficiency disorders, BMD is low, most likely the result of some combination of age-related bone loss and impaired bone mineralization due to hypophosphatemia. In addition, unlike XLH but similar to nutritional rickets and osteomalacia, enthesopathy is not seen in TIO, but fractures are common. Except for higher osteoid volume, which may remain high even after clinical "cure," bone histologic features are similar to other types of osteomalacia.[62,84,87]

Localization of the tumor can be quite challenging because most are small tumors, often found in obscure locations. A detailed physical examination followed by imaging is necessary. Since somatostatin receptors are expressed in many phosphaturic mesenchymal tumors of mixed connective tissue variant, an octreotide scan can help with tumor localization in about 50% of cases, especially when the extremities and skull are involved. 18F-fluorodeoxyglucose positron emission tomography is quite sensitive in localizing tumors but can lead to false-positive results. Gallium-DOTATATE positron emission tomography is an emerging imaging modality for tumors producing TIO, is now more widely available, and may be the imaging method of choice. Functional imaging can be supported by selective venous sampling with measurement of FGF23 to confirm the location of the tumor in cases in which the imaging studies suggest multiple lesions or the location of the single lesion poses a significant surgical risk.[8,89]

The treatment of choice for TIO is resection of the tumor, which results in clinical, biochemical, radiologic, and bone

histologic improvements. Wide surgical resection is essential to avoid tumor recurrence. Levels of serum phosphate and FGF23, which has a half-life of ~45 minutes, return to normal rapidly, often within 24 hours, after tumor resection, but healing of osteomalacia may take several months. Rarely, recurrences with metastasis can occur. If the tumors are not readily identifiable, or not amenable to surgical removal, lifelong medical therapy with oral phosphate and calcitriol is required. Oral phosphate in three to four divided doses with meals and calcitriol 0.5 to 1.0 μg/day in divided doses to maintain serum phosphates level at the lower end of the age-appropriate reference range is recommended. However, long-term oral phosphate therapy may lead to secondary and occasionally hypercalcemic 2°HPT (tertiary hyperparathyroidism) that requires surgical intervention.[192,225,233,234] Other potential treatment options in situations where the tumor cannot be surgically removed or localized, use of calcium-sensing receptor agonists, radiofrequency ablation of the tumor, or deliberate total parathyroidectomy can be considered.[192,235–237]

Drug-Induced Osteomalacia

Several drugs have been implicated in the pathogenesis of rickets and osteomalacia, and the most relevant drugs are listed in Table 31.6, along with the proposed mechanisms by which various drugs cause mineralization defects. Among them, nucleoside reverse transcriptase inhibitors (NRTIs), tenofovir and adefovir, are currently the most common causes of drug-induced rickets and osteomalacia.[9,156] Other drugs that cause rickets or osteomalacia, although less common, include anticonvulsants, aluminum-containing antacids, non-nitrogen containing bisphosphonates, and sodium fluoride.

Tenofovir and adefovir, adenosine analogue NRTIs, are now widely used in the treatment of human immunodeficiency virus and viral hepatitis infections. Sporadic Fanconi syndrome, renal failure, and osteomalacia have been reported in patients treated with this class of drugs.[9,156] Fanconi syndrome is a generalized transport defect in the proximal tubules, resulting in losses of glucose, phosphate, calcium, uric acid, amino acids, bicarbonate, and other organic compounds leading to hypophosphatemia, metabolic acidosis, and glycosuria.[216] Phosphate depletion due to renal phosphate wasting results in hypophosphatemic rickets and osteomalacia similar to the genetic and tumor-induced hypophosphatemic disorders (see later discussion). However, unlike other hypophosphatemic syndromes, serum FGF23 levels are characteristically normal in NRTI-related hypophosphatemia.[238] Studies have shown that a time interval between initiation of NRTI treatment and the development of Fanconi syndrome varies from 1 to 26 months, and the prevalence of osteomalacia is about 0.5% in patients receiving the drugs.[9,156] Concomitant use of ritonavir-boosted protease inhibitor increases NTRI toxicity because protease inhibitors increase intracellular concentrations of the drugs.[9,156,216] The exact mechanism of tenofovir-induced nephrotoxicity is not well understood, but it appears to be due to mitochondrial damage and alterations in human organic anion transporter 1.[216] Proximal renal tubular mitochondrial injury due to the inhibition of mitochondrial DNA polymerase results in decreased mitochondrial DNA replication and impairs molecular transport, vitamin D activation, and urinary acidification.[216] There is a modest decline in renal function that can become relevant in patients with preexisting renal dysfunction.[216] Discontinuation of the causative drug promptly corrects hypophosphatemia and renal dysfunction if detected early, but additional therapy with oral phosphate and vitamin D or its metabolites is required for patients with osteomalacia.[9,156]

TABLE 31.6 Causes of Drug-Induced Rickets and Osteomalacia

1. Drugs that cause renal tubular defects (Fanconi syndrome)
   - Nucleotide reverse transcriptase inhibitors
     - Tenofovir
     - Adefovir
     - Cidofovir
     - Protease inhibitor
     - Ritonavir
2. Drugs that produce "conditional vitamin D deficiency"
   - Cytochrome P450 enzyme inducers
   - (Increased catabolism of 25-hydroxyvitamin D)
   - Phenytoin
   - Phenobarbital
   - Primidone
   - Carbamazepine
     - Inhibits enzyme activity
   - Sodium valproate
3. Inhibition of 25-hydroxyvitamin D 1α-hydroxylase
   - Ketoconazole
4. Inhibition of osteoid mineralization
   - Aluminum
   - Fluoride
   - Iron
   - Etidronate

Anticonvulsants, phenytoin, primidone, phenobarbital, and rifampin induce the hepatic cytochrome P450 oxidase enzyme system, which increases the conversion of vitamin D to polar inactive metabolites in the liver, reducing the bioavailable 25-hydroxyvitamin D.[239,240] The resulting conditional vitamin D deficiency, if prolonged and severe, ultimately leads to rickets and osteomalacia.[46,239,241,242] The clinical manifestations, biochemical changes, and radiologic and bone histologic features are similar to those seen in patients with nutritional vitamin D deficiency and defective genetic 25-hydroxylase or VDDR1B (see later discussion). Treatment with vitamin D and calcium in the recommended doses for nutritional vitamin D deficiency is usually effective (see later discussion). Unlike in the case of NRTIs, there is no need to discontinue the drugs that caused the problem in the first place, but lifelong monitoring for vitamin D deficiency is required. Although both isoniazid and ketoconazole inhibit 1α-hydroxylase enzyme in the kidney, resulting in conditional vitamin D deficiency, cases of rickets and osteomalacia have not been reported.

In earlier times, a unique form of "vitamin D–resistant" osteomalacia related to the use of tap water in dialysate solution and aluminum-containing phosphate binders was seen exclusively in patients on maintenance hemodialysis.[243–245] Aluminum is preferentially deposited at the interface of mineralized and unmineralized (osteoid) bone, and uncouples matrix synthesis and its subsequent mineralization, resulting in excess osteoid accumulation.[246] With the use of deionized water, reverse osmosis, and abandonment of aluminum-containing phosphate binders, aluminum-induced osteomalacia has all but disappeared.[243,244,246] A similar form of osteomalacia has been reported with the use of sucralfate, another aluminum-containing antacid, particularly if used in conjunction with aluminum-containing phosphate binders or antidiarrheal preparations.[42]

Osteomalacia due to iron deposition is more complex.[247,248] Interestingly, both aluminum and iron co-localize in bone at the mineralized bone–osteoid interface, and some patients receiving

iron infusions develop FGF23-mediated hypophosphatemic osteomalacia.[247,248]

Drug-induced osteomalacia has rarely been reported with the use of etidronate and sodium fluoride, usually in high doses and over long periods, but no currently approved second-generation nitrogen-containing bisphosphonates have been reported to cause osteomalacia.[87] Neither etidronate nor sodium fluoride is approved for the prevention or treatment of osteoporosis (see Chapter 30) in the United States, but both drugs are approved for management of osteoporosis in other countries, including Canada. In addition, etidronate is used in high doses (up to 20 mg/kg per day) to treat rare bone and mineral disorders such as fibrous dysplasia, heterotopic ossification, and myositis ossificans with some success. Since the etidronate dose used in these conditions is much higher than the recommended dose (5 mg/kg per day) for osteoporosis and Paget disease of bone, the risk of osteomalacia exists; the exact scope of this complication is currently unknown.

Bone histologic features of drug-induced mineralization defects due to aluminum, iron, etidronate, and sodium fluoride differ substantially from the osteomalacia as defined earlier due to vitamin D and phosphate deficiency (see the earlier Definition and Histologic Evolution of Osteomalacia section). Defective bone mineralization due to aluminum overload, the osteoid accumulation is generalized, as in vitamin D deficiency and hypophosphatemic osteomalacia, but osteoid thickness is not increased and may even be thinner. This type of bone histologic abnormality is designated as atypical osteomalacia[87] (see Fig. 31.2). Bone turnover is extremely low, staining for aluminum is positive at the osteoid-mineralized bone interface establishing the diagnosis, and the bone lesion does not respond to vitamin D therapy. Osteoid accumulation in etidronate- and sodium fluoride–related osteomalacia is patchy with very thick osteoid seams randomly distributed throughout bone (both on bone surfaces and within the interstitial bone), which is designated as focal osteomalacia (see Fig. 31.2). A full exposition on the evolution of such bone lesions has recently been reviewed.[87]

Conditions That Resemble Rickets and Osteomalacia

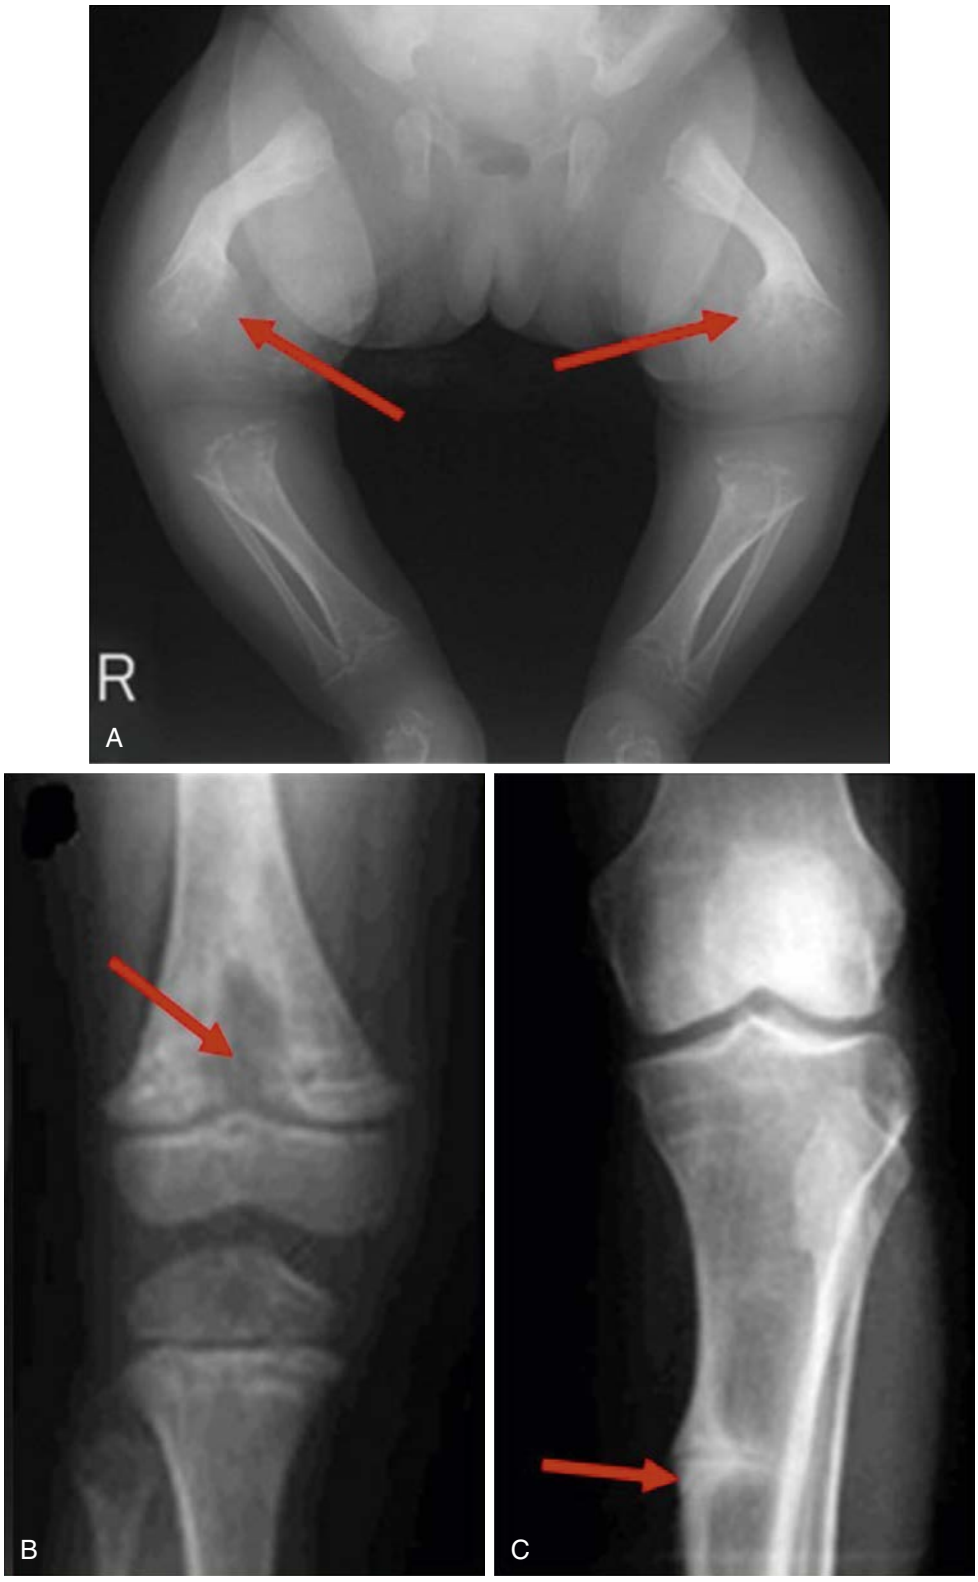
Several other bone diseases, some rather poorly characterized, resemble rickets and osteomalacia in one respect or another, but all have unique distinguishing features that separate them from classical rickets on x-rays or osteomalacia on bone histology. Much of the confusion has arisen because of the extension of the terms *rickets* and *osteomalacia* to include these other disorders without regard to the mechanisms by which the abnormalities occur. By not conforming to the strict definitions for *rickets* and *osteomalacia*, the terms lose their clinical relevance and might give a false impression that the conditions might respond to vitamin D administration. In fact, many of these conditions were once treated with large doses of vitamin D without much improvement in clinical, radiologic, or bone histologic features.

Pathogenesis of many of these rare bone disorders is currently poorly understood. The mechanism for the development of radiologic abnormalities and mineralization defect is different from that of classical rickets and osteomalacia. In most, but not all, conditions listed in Table 31.6, the abnormalities are either due to the effects of PTH excess on bone or to the defects in bone collagen matrix structure that does not mineralize normally.

In children with primary hyperparathyroidism, metaphyseal abnormalities resemble rickets or a child might have rickets due to both vitamin D deficiency and masked primary hyperparathyroidism. The radiologic abnormalities respond to parathyroidectomy. Similarly, in severe 2°HPT in children with end-stage renal disease, both "rickets" and "osteomalacia" have been noted. Any condition that increases bone remodeling inevitably increases the extent of osteoid surface (usually <50% of the bone surface) and by extension osteoid volume (usually >3–5% of bone volume), but osteoid thickness, the hallmark of mineralization defect in traditional osteomalacia, is always normal (<12 μm). Some have used the term *hyperosteoidosis* to describe this type of histologic abnormality, which is seen in conditions associated with increased bone remodeling, such as renal osteodystrophy, hyperthyroidism, primary hyperparathyroidism, and osteitis deformans (Paget disease of bone). However, the use of such a descriptive term as *hyperosteoidosis* does not serve any useful purpose and potentially confuses our understanding of these various disorders.

In certain very rare disorders, such as fibrogenesis imperfecta ossium and axial osteomalacia, various degrees of defective mineralization are seen, but they are due to abnormal collagen structure. Bone histomorphometric measurements in these disorders differ substantially from those of classical osteomalacia as defined earlier.

One rare bone disorder deserves special mention in the context of rickets and osteomalacia. Hypophosphatasia is now reasonably well characterized, and enzyme replacement therapy with asfotase alfa was recently approved for childhood onset of the disease. It is due to "loss of function" mutations in the gene that codes for the tissue nonspecific alkaline phosphatase. It is an autosomally inherited disorder with more than 300 different gene defects reported so far. Although radiologic and bone histologic findings may resemble rickets and osteomalacia, the condition is easily distinguished by the low serum alkaline phosphatase levels (<40 IU/L). Age-appropriate references ranges must be used for children and adolescents, and many laboratories now provide a lower limit for serum alkaline phosphatase ranges. As noted previously, the serum alkaline phosphatase is almost always elevated in vitamin D– and phosphate-deficiency rickets and osteomalacia. Bowing of long bones with insufficiency fractures resemble radiologic features of osteomalacia in adults, and metaphyseal and epiphyseal changes resemble those of rickets in children (Fig. 31.7A and B). The tongue-like lucent in the metaphyses of the long bones, especially in the distal femur, is characteristic of childhood hypophosphatasia (see Fig. 31.7B). However, cortical thinning, a feature of vitamin D–deficiency osteomalacia, is not seen in hypophosphatasia. In addition, pseudofractures are usually located on the lateral cortex of long bones, unlike the medial location in osteomalacia related to vitamin D and phosphate deficiency, but this feature lacks diagnostic specificity because it can sometimes be seen on the medial cortex (see Fig. 31.7C). Many adult patients with a milder form of the disease may present as having age-related osteoporosis, and the prevalence of hypophosphatasia in unselected patients with osteopenia and osteoporosis is unknown. Some have speculated that the pathogenesis of atypical femur fractures after long-term bisphosphonate therapy may be related to unrecognized hypophosphatasia, but convincing evidence is lacking. Nevertheless, it is clear that patients with hypophosphatasia should not receive bisphosphonate therapy for their "osteoporosis." The diagnosis is supported by high serum levels of vitamin B_6, pyridoxal phosphate, and inorganic pyrophosphate. Genetic testing for mutations is not mandatory, but any gene abnormalities should be interpreted with caution because not all carriers



• **Fig. 31.7** (A) Radiologic features of lower extremities in a child with hypophosphatasia. Note abnormalities in the distal ends (*arrows*) resembling nutritional and X-linked hypophosphatemia rickets (see Fig. 31.4). (B) Tongue-like lucent area (*arrow*) in the metaphysis of the distal femur, characteristic radiologic sign of hypophosphatasia. In addition, note abnormal metaphyseal regions resembling mild rickets (see Fig. 31.4). (C) Pseudofracture (*arrow*) in the tibia. Note the similarity of pseudofractures seen in vitamin D–deficiency osteomalacia (see Fig. 31.2).

manifest the disease. Enzyme replacement therapy with asfotase alfa is now available for childhood-onset hypophosphatasia. It is unclear how many patients with adult-onset hypophosphatasia are missed or misdiagnosed as "usual age-related" osteoporosis because the relevant reference ranges for the alkaline phosphatase have not yet been widely adopted by all clinical chemistry laboratories. One clinically relevant aspect of unrecognized adult hypophosphatasia is that it may contribute to the development of atypical femur fractures after long-term bisphosphonate therapy, although proof of this speculation is still lacking. Nevertheless, attention should be paid to lower alkaline phosphatase levels (<40 IU/L) in women with postmenopausal osteoporosis in whom antifracture therapy with a bisphosphonate or denosumab is considered (see Chapter 30).

Concluding Remarks

Rickets and osteomalacia are a group of disorders due to varied pathogenic mechanisms, but they all respond to administration of vitamin D or its metabolites, calcium, or phosphate supplements as appropriate, removal of a tumor producing ectopic FGF23, or administration of an antibody to FGF23. The resolution of clinical, biochemical, radiologic, and bone histologic abnormalities is usually complete in most cases, but lifelong therapy is needed in some forms of rickets and osteomalacia. In nutritional rickets and osteomalacia, 2°HPT may persist for months or years despite clinical improvement and confers an increased fracture risk due to irreversible cortical bone loss that has already occurred by the time of diagnosis. In a few patients, particularly those with hypophosphatemic rickets and osteomalacia, long-term oral phosphate therapy leads to hypercalcemic 2°HPT (or tertiary hyperparathyroidism) requiring parathyroidectomy. In most patients, the clinical response is excellent and gratifying, both to the patients and caring physicians. However, one must not lose sight of the fact that genetic rickets and osteomalacia, as well as TIOs, require lifelong follow-up for the development of therapy-related complications or malignant transformation of the tumors causing TIO.

Acknowledgments

The authors thank Ms. Stephanie Stebens, MLIS, Sladen Library, for literature search and citation help; Sarah Whitehouse, senior medical writer, for editing and proofreading; and Wendy Gill for the preparation of all illustrations. The chapter is dedicated to the memory of the late A. Michael Parfitt, who taught me (DSR), one on one, everything I know about bone and mineral disorders from 1974 to 2015, and to the late Harold Frost, who first described the detailed tetracycline-based bone histomorphometry in osteomalacia from the Henry Ford Hospital, Detroit, Michigan. The senior author (SDR) still continues work in the same laboratory created by Dr. Frost in 1954. One of Dr. Parfitt's last desires was to report in more detail on the histologic evolution of osteomalacia and its response to vitamin D, calcidiol, and calcitriol, but this never materialized.

This work was partly supported by National Institutes of Health grant AR062103; Fund for Henry Ford Hospital, Fred Whitehouse Chair in Endocrinology, Diabetes, and Bone & Mineral Disorders; and the Indian Society of Bone and Mineral Research.

Kidney Stones

DAVID A. BUSHINSKY

CHAPTER OUTLINE

KEY POINTS

- Numerous factors, including sex, age, race, and the patient's geographic location, determine the prevalence of kidney stones.
- Kidney stones form when urine becomes supersaturated with respect to the specific components of the stone's constituents.
- A multitude of monogenic hereditary disorders that result in changes of either calcium handling at the level of kidney, bone, and gut, or calcium sensing at the calcium-sensing receptor on the parathyroid glands and renal tubular cells, can lead to hypercalciuria and stone formation.
- All patients, even those with a single stone, should undergo at least a basic evaluation to rule out a systemic etiology of stone formation.
- Increasing fluid intake is a simple measure that has considerable impact on reducing stone growth and new stone formation.

Nephrolithiasis is a common disorder with an incidence greater than one case per 1000 patients per year. In the year 2000, this resulted in nearly 2 million physician office visits with an estimated annual cost between $2.0 and $5.5 billion in the United States alone.[1–3] The prevalence in industrialized nations is approximately 7% in women and 11% in men and appears to be rising over time.[4,5] The incidence of nephrolithiasis peaks when patients are in their 30s and 40s, and the prevalence increases with age until about the seventh decade of life.[5,6] The prevalence of nephrolithiasis in the United States increased from nearly 3% in the late 1970s to nearly 5% in the 1990s, which is far faster than can be accounted for by alterations in our genome indicating that changes in our diet and/or environment are responsible, at least in part, for the increasing prevalence.[6]

Stones may be composed of calcium oxalate, calcium phosphate, uric acid, magnesium ammonium phosphate (struvite), or cystine, alone or in combination. A variety of pathogenic mechanisms determine the type of stone formed. Symptomatic stones tend to localize in the renal tubules and collecting system but are also commonly found within the ureters and bladder.[7,8] The recurrence rate of calcium oxalate stones is about 10% to 30% at 5 years and 50% at 10 years and higher for cystine, uric acid, and struvite stones.[9–11]

Kidney stones result in substantial morbidity. The severe pain of renal colic can lead to frequent hospitalization, shock wave lithotripsy, or invasive surgical procedures. Although rarely a cause of end-stage renal disease (ESRD), nephrolithiasis has been associated with chronic kidney disease (CKD) in various populations.[12–16] Patients with kidney stones have an increase in aortic calcification, and even mild CKD is associated with significant adverse cardiovascular events,[17–20] especially in men, and an increase in stroke, especially in women.[21] There is a significant decrease in bone mineral density leading to fracture in patients with nephrolithiasis.[22]

Insight into the mechanisms involved in stone formation can help direct appropriate therapy, which is known to significantly decrease the incidence of stone formation and its associated morbidity.

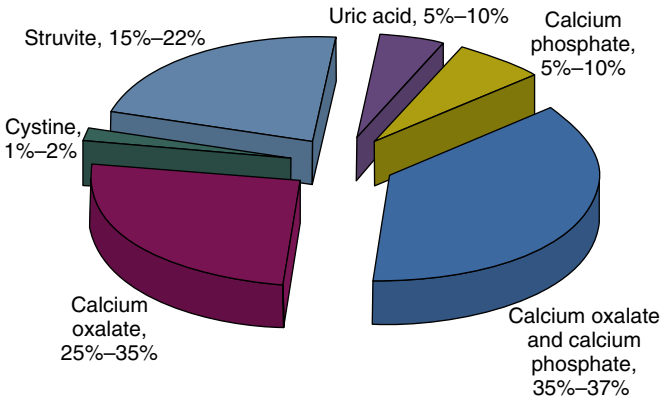
Epidemiology of Stone Formation

Numerous factors determine the prevalence of stones, including sex, age, race, obesity, and geographic distribution. Men are more likely to get nephrolithiasis than women.[5,6,23] In the United States, blacks, Hispanics, and Asian Americans are much less likely to have stones than whites.[5] Obesity is correlated with the risk for kidney stone formation.[24–26] Those weighing more than 220 pounds or having a body mass index (BMI) greater than 30 are more likely to form stones than those weighing less than 150 pounds or having a BMI between 21.0 and 22.9.[27] Geography also appears to influence stone formation in the United States, with a decreasing prevalence from south to north and, to some degree, from east to west.[23] The greater exposure to sunlight in the southeastern United States may be responsible for the increased rates of nephrolithiasis in that area. Sun exposure can lead to more concentrated urine by increasing insensible fluid losses due to sweating.[28,29] Although increased sun exposure should increase levels of serum 25-hydroxyvitamin D

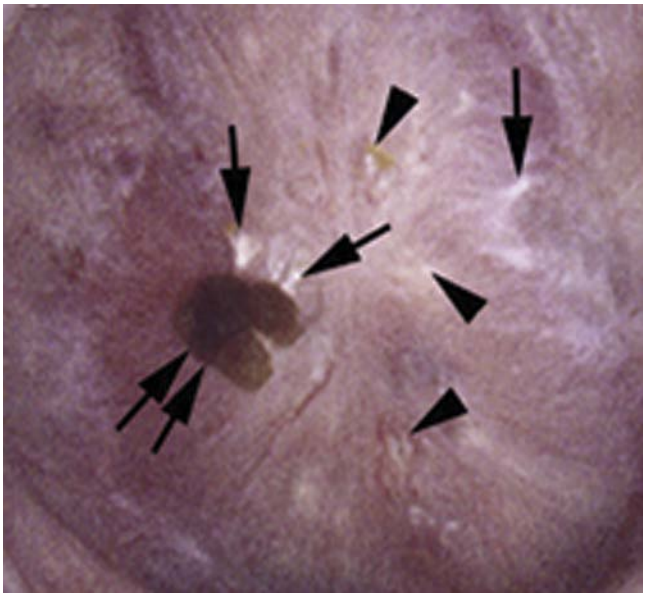
[25(OH)D], there is no evidence for a subsequent increase in the level of 1,25-dihydroxyvitamin D [1,25$(OH)_2$D], nor is there any evidence that hypercalciuria will worsen.

Along with geography, genetic predisposition can influence the type of stone formed.[28,30] For example, uric acid stones are seen in up to 75% of all cases in Mediterranean and Middle Eastern countries but constitute fewer than 10% of cases in the United States. By contrast, more than 70% of stones formed in the United States are calcium based.[31] Less common are magnesium ammonium phosphate (struvite or infection) stones, which account for about 10% to 25% of stones formed, and cystine stones, which are due to an autosomal recessive disorder and constitute only about 2% of all stones formed[6,30,32] (Fig. 32.1).

Diet and pharmacologic agents can also significantly impact stone formation. In a dramatic example, an outbreak of nephrolithiasis in Chinese infants was attributed to ingestion of melamine in infant formulas and milk powder. Melamine, intentionally added to raise the apparent protein content of the concentrates, led to formation of large particles in the kidney and resulted in many cases of nephrolithiasis and renal failure due to obstructive uropathy.[33–35] A variety of other dietary factors can have a significant impact on both formation and prevention of kidney stones (see the following discussion).



• **Fig. 32.1** Frequency of different types of kidney stones.



• **Fig. 32.2** An attached stone (*paired arrows*) is seen resting on a region of white plaque (*single arrows*) and intermixed with small areas of white (*single arrow*) and yellow plaques (*arrowheads*). (From Evan AP, Lingeman JE, Worcester EM, et al. Renal histopathology and crystal deposits in patients with small bowel resection and calcium oxalate stone disease. *Kidney Int*. 2010;78:310–317.)

Pathogenesis of Stone Formation

Physiology

Kidney stones form when urine becomes supersaturated with respect to the specific components of the stone.[7,8] Saturation is dependent on chemical free ion activities of the stone constituents. Factors that affect chemical free ion activity include urinary ion concentration, pH, and the combination of the constituent with other substances. For example, an increase in the urinary calcium concentration or a decrease in urine volume increases the free ion activity of calcium ions in the urine. Urinary pH can also modify chemical free ion activity. A low urinary pH increases the free ion activity of uric acid ions but decreases the activity of calcium and phosphate ions. Citrate combines with calcium ions to form soluble complexes and will decrease the free ion activity of unbound citrate and calcium. When the chemical free ion activities are increased, the urine becomes supersaturated (also termed *oversaturated*). In this setting, new stones may form and established stones may grow. In the event of decreased free ion activity, urine becomes undersaturated, and stones do not grow and can even dissolve. The equilibrium solubility product is the chemical free ion activity of stone components in a solution at which the stone neither grows nor dissolves.

Stones form through the processes of homogeneous or heterogeneous nucleation. In homogeneous nucleation, progressive supersaturation eventually results in formation of small clusters secondary to the aggregation of identical molecules. These clusters grow to form a permanent solid phase, or crystals. Heterogeneous nucleation refers to crystal formation on the surface of a different crystal type or on other dissimilar substances, such as cells. In vivo, this type of nucleation is more common than homogeneous nucleation because crystals form at a lower level of supersaturation in the presence of a solid phase.

The small crystals may then aggregate into larger clinically significant stones. Crystals generally anchor to renal tubular epithelium; this allows more time for growth. This anchoring of crystals occurs at the renal papillae, over areas of interstitial calcium phosphate present in the form of apatite termed *Randall plaques*[36–40] (Fig. 32.2). The apatite crystals appear to originate at the basement membrane of tubular cells in the thin loop of Henle and extend into the interstitium without damaging the cells themselves or filling the tubular lumens. A combination of apatite crystal and organic material extends from the loop of Henle tubular basement membrane to the papillary uroepithelial surface, where calcium oxalate crystals or other crystals can adhere and form stones. If the stone breaks this anchor to the urothelial surface, it will then be carried by the urine through the ureter and into the bladder. If the stone is small (generally <5 mm in diameter), it may pass with minor discomfort; however, if it has grown sufficiently, this migration may be extremely painful and, if the stone is of sufficient size, it may even completely obstruct the ureter leading to nonfunction of the unilateral kidney.

An important factor in the development of kidney stones may be the absence of adequate levels or activity of crystallization inhibitors in the urine.[8] Uropontin, pyrophosphate, citrate, and nephrocalcin are endogenously produced substances that have been shown to inhibit calcium crystallization. Differences in the

amount or activity of inhibitors are thought to account for the variability in stone formation among people with similar degrees of urinary supersaturation.[32]

Clinically, most physicians evaluate the lithogenic potential of the urine from stone formers by measuring the rate of excretion of the principal stone-forming elements in mass per unit time (e.g., milligrams or millimoles per 24 hours). It is clear, however, that the lithogenic potential of urine is better determined by the degree of supersaturation. Computer programs that calculate saturation from concentrations of various elements in the urine and the urinary pH are now available (e.g., Quest Diagnostics, Mayo Clinic, and Litholink are laboratories that measure urine ion excretion and calculate supersaturation) and more accurately determine the risk of stone formation. Any calculation of mean saturation underestimates the maximum supersaturation that may drive stone formation because of hourly variations in water and solute excretion throughout the day.

Diet

Dietary factors have a great influence on the concentration of excreted ions. Simply instructing patients to increase fluid intake appears to have a considerable impact on reducing stone growth and formation.[41–44] Renal calcium excretion is augmented by increased sodium excretion,[45–47] and hypercalciuric patients tend to have a greater calciuric response to a sodium load than control subjects.[48] Dietary sodium restriction with the consequent decrease in urinary sodium excretion reduces calcium excretion and lowers supersaturation with respect to calcium-containing kidney stones. Patients are counseled to limit their daily sodium intake to a maximum of 3000 mg (~130 mEq) to reduce hypercalciuria.[6,7,49]

A moderate reduction in animal protein (~1.0 mg/kg per day) is known to be beneficial in patients with nephrolithiasis. Animal protein contributes to stone formation via multiple mechanisms.[49,50] A mild metabolic acidosis develops when animal proteins are metabolized. To buffer the excess hydrogen ions, calcium is resorbed from bone, which leads to an increased filtered load of calcium.[51] Metabolic acidosis also directly decreases renal tubular calcium reabsorption, which further enhances hypercalciuria.[51] In addition, metabolism of amino acids contained in animal protein generates sulfate ions, which couple with calcium ions to form insoluble complexes.[51,52] Citrate, a base, acts as a urinary inhibitor of stone formation. Citrate forms soluble complexes with calcium and lowers calcium oxalate and calcium phosphate supersaturation. During metabolic acidosis, citrate is reabsorbed proximally, reducing the amount excreted in the urine.[52,53] Hypokalemia can also lead to reduced citrate excretion. An animal protein–induced reduction in urinary citrate can promote formation of both calcium oxalate and uric acid stones.[48,54] Indeed, the Dietary Approaches to Stop Hypertension (DASH) diet appears to reduce the risk of forming a kidney stone.[55–57]

Fructose has become a ubiquitous sweetener in American processed foods. In large food questionnaire studies, this sugar has been associated with a significant risk of developing nephrolithiasis. Although the mechanism is not known, fructose is the only carbohydrate that can increase uric acid production, and fructose metabolism may increase stone formation.[58]

Several studies have demonstrated the benefits of a diet containing an age- and gender- appropriate amount of calcium in patients with kidney stones.[42,49,50,59] Ingested calcium binds intestinal oxalate, reducing its absorption and consequent renal excretion.[42] In a long-term prospective trial, Borghi and colleagues[49] randomized hypercalciuric male stone formers to either a low-calcium diet or to a diet with a normal amount of calcium but low in sodium and animal protein. Both groups of men were instructed to restrict oxalate intake and drink 2 to 3 L of water daily. The group of men on a normal-calcium, low-sodium, and low–animal protein diet had a significantly lower recurrence of nephrolithiasis and a greater reduction in oxalate excretion and calcium oxalate supersaturation compared with the men on the low-calcium diet.[49]

Thus, patients should be maintained on an age- and gender-appropriate intake of calcium.[50] Dietary calcium restriction should be strongly discouraged because it not only increases risk of stone formation but also engenders a significant risk of bone demineralization and development of osteoporosis.[22,60,61] Note that although *dietary* calcium intake has been associated with a reduced incidence of kidney stones, calcium intake in the form of *supplements* can exacerbate stone formation in older women. The recommended dietary intake for men and women is 1000 mg of elemental calcium from ages 19 through 50 years and 1200 mg of calcium thereafter.[62] Teenagers should consume 1300 mg of calcium per day. Excess calcium should be avoided, because the combination of calcium and vitamin D supplementation has been shown to significantly increase the risk of kidney stones in postmenopausal women.[63]

Pathogenesis of Idiopathic Hypercalciuria

Idiopathic hypercalciuria (IH) is defined as excessive urinary calcium excretion in the setting of normocalcemia and the absence of secondary causes of hypercalciuria. IH is the most common cause of calcium-containing kidney stones. The disorder is familial; it was initially thought to exhibit an autosomal dominant pattern of inheritance but is almost certainly polygenic.[64–67]

The mechanism by which IH leads to hypercalciuria is not known. It has been postulated that IH comprises three distinct disorders: excessive intestinal calcium absorption, decreased renal tubular calcium reabsorption, and enhanced bone demineralization. In a genetic strain of hypercalciuric stone-forming rats, hypercalciuria appears to be due to an excessive number of enteric vitamin D receptors leading to a generalized disorder of calcium transport at all sites of calcium transport including the kidney, intestine, and bone.[67,68] In humans, recent observations also suggest that IH may be a systemic disorder of calcium homeostasis with dysregulation of calcium transport. An understanding of calcium homeostasis helps elucidate the potential mechanisms involved in IH.

Calcium Homeostasis

Urinary calcium homeostasis is regulated in the gastrointestinal (GI) tract, kidneys, and bone by the hormones parathyroid hormone (PTH) and $1,25(OH)_2D$ (also see Chapter 29 for additional discussion on calcium homeostasis). Approximately 99% of the calcium in the body is contained within the bone mineral. Daily bone resorption and bone formation, which in healthy, nonpregnant, nonosteoporotic adults should be equal, allow less than 1% of bone calcium to be exchanged with that in the extracellular fluid.

Both PTH and $1,25(OH)_2D$ at high concentrations stimulate release of calcium from the bone mineral through osteoclast-mediated bone resorption. Net calcium influx into the extracellular fluid is achieved by absorption from the GI tract, which occurs through $1,25(OH)_2D$-dependent and -independent mechanisms. Although PTH appears to have no direct effect on GI calcium

absorption, increased levels of the hormone stimulate production of $1,25(OH)_2D$, which in turn leads to enhanced absorption. Increased serum levels of calcium and $1,25(OH)_2D$ provide negative feedback to the parathyroid glands, resulting in reduced PTH secretion.

The roughly 60% of calcium in the extracellular fluid is not protein bound and is freely filtered by the renal glomeruli. Approximately 80% to 85% of this amount is passively reabsorbed in the proximal tubule. Most of the remaining calcium is reabsorbed in the thick ascending limb (TAL) of Henle and distal cortical tubules under PTH stimulation. Ultimately, these reabsorptive mechanisms result in a urinary calcium excretion that is less than 2% of the daily filtered load of calcium.[69] Except during pregnancy and lactation, in healthy, nonosteoporotic adults, urinary calcium excretion (and any calcium lost in sweat) precisely equals net intestinal calcium absorption.

Potential Mechanisms for the Development of IH

Dysregulation of calcium transport in the intestine, kidney, or bone can lead to hypercalciuria. For example, excessive calcium absorption by the GI tract leads to a transient increase in the serum calcium. This increase in serum calcium suppresses secretion of PTH that, along with the increased filtered load of calcium to the kidneys, results in hypercalciuria. Excessive $1,25(OH)_2D$ has a similar effect of increasing intestinal calcium absorption but also results in an influx of calcium into the extracellular fluid because of enhanced bone resorption. The result is hypercalciuria even in the setting of a low-calcium diet or an overnight fast. The excess $1,25(OH)_2D$ also suppresses PTH secretion, thereby further reducing renal tubular reabsorption of calcium.

If a primary defect in renal calcium reabsorption leads to hypercalciuria, there is a fall in the serum calcium concentration that stimulates synthesis of PTH and $1,25(OH)_2D$. Increased $1,25(OH)_2D$ results in enhanced intestinal calcium absorption and bone resorption. The renal loss of calcium persists even with a low-calcium diet or an overnight fast.

Hypercalciuria can also develop as a result of a defect in renal phosphate reabsorption. The resultant hypophosphatemia leads to enhanced $1,25(OH)_2D$ production, which stimulates intestinal absorption of phosphorus and calcium. The increased serum calcium and $1,25(OH)_2D$ suppresses PTH synthesis and release. The increased filtered load of calcium in the setting of suppressed PTH leads to hypercalciuria. Enhanced bone resorption due to excessive $1,25(OH)_2D$ increases the serum calcium concentration, which in turn suppresses PTH production further. The increase in the filtered load of calcium in this setting results in hypercalciuria.

Thus, there are several potential mechanisms for hypercalciuria. Do human or animal data support one mechanism above all others? From a clinical therapeutic standpoint, is it worth differentiating among the various potential mechanisms in each patient with suspected IH?

Human Data

Lemann[70] compiled the results of numerous calcium balance studies on patients with IH and normocalciuric control subjects and normalized the results for calcium intake. He found that intestinal calcium absorption was significantly higher in the subjects with IH.

Bushinsky and associates[8] and Coe and colleagues[71] also collected data from published metabolic balance studies, and compared net intestinal calcium absorption and urinary calcium excretion in hypercalciuric and normocalciuric adults. They also noted an increase in intestinal calcium absorption in subjects with IH but found that urinary excretion of calcium was increased to an even greater degree, thus placing many of these patients in net negative calcium balance. Although these data confirm that enhanced intestinal absorption of calcium probably plays a role in the pathogenesis of IH, the investigators could not clarify whether this is the primary defect or if it is secondary to another lesion, such as a primary dysregulation of renal tubular calcium reabsorption. Others suggested that the increase in intestinal calcium absorption, in combination with a decrease in renal calcium reabsorption, indicated a more generalized defect in calcium homeostasis. Nonetheless, the finding of enhanced calcium absorption makes enhanced bone resorption an unlikely primary mechanism of IH, because the increase in serum calcium concentration resulting from bone resorption would suppress $1,25(OH)_2D$-mediated intestinal calcium absorption.

In most published studies, patients with IH have higher serum levels of $1,25(OH)_2D$ than normocalciuric control subjects.[72–74] Kaplan and associates[74] determined that $1,25(OH)_2D$ levels were higher than control values in approximately one third of patients with IH and that intestinal calcium absorption was inappropriately high for the level of $1,25(OH)_2D$. These studies support either $1,25(OH)_2D$-mediated intestinal calcium absorption or a primary defect in renal tubular calcium reabsorption as a primary mechanism of hypercalciuria in IH.

PTH levels in patients with IH have been reported as normal or slightly lower than those in controls.[54,60] This finding argues against a reduction in renal tubular calcium reabsorption as the primary defect in IH, because with this mechanism, the hypercalciuria would lead to low serum calcium levels and stimulation of PTH secretion. This finding also does not support the hypothesis that elevated levels of PTH are the stimulus for the increased levels of serum $1,25(OH)_2D$ observed in many studies. It is, however, consistent with the other potential mechanisms for IH.

Bone mass in patients with IH has been assessed by several methods, including radiologic densitometry, quantitative computed tomography (CT), dual-energy x-ray absorptiometry, and single-photon absorptiometry, among others. Studies of patients with IH have generally shown a reduction of bone mineral density compared with values in controls.[22,54,60,75] The studies were unable to reveal a unifying mechanism for the mild reduction in bone mineral density. Altered $1,25(OH)_2D$ regulation would be consistent with this finding because the effects of $1,25(OH)_2D$ on bone resorption would be mitigated by the increased intestinal calcium absorption stimulated by the hormone.

Previously, it was considered important to determine whether a patient with IH tended to have excessive GI calcium absorption (absorptive hypercalciuria) or excessive renal excretion (renal leak).[76,77] Patients with excessive renal calcium excretion were prescribed thiazide diuretics, and those thought to have a predominantly absorptive defect were prescribed a low-calcium diet. Coe and associates[60] undermined the validity of this approach in a study in which 24 patients with IH and nine control subjects were given a low-calcium diet (2 mg/kg per day) for more than 1 week. Urine and blood tests revealed normal serum calcium levels, a mild decrease in PTH levels in the patients with IH, and no difference in $1,25(OH)_2D$ levels. The striking finding was that whereas all of the normocalciuric subjects excreted less calcium than they ingested on the low-calcium diet, 16 of the 24 subjects with IH had urinary calcium excretion that exceeded their intake. Thus, most of the patients with IH receiving a low-calcium diet were in net negative calcium balance. There was no clear demarcation

between the patients who excreted excessive amounts of calcium and those who did not. Instead, there was a smooth continuum of urinary calcium excretion among patients with and without IH that appeared not to be influenced by calcemic hormones. From a therapeutic standpoint, these findings have rendered obsolete both the need to clinically distinguish IH mechanisms in humans and also the prescription of a low-calcium diet in any of these patients. This approach to diet is important because a low-calcium diet can result in a dangerous reduction in bone mineral density, especially in women.[22,61,75,78] As mentioned earlier (see the Pathogenesis of Stone Formation section), a low-calcium diet also appears to increase recurrent stone formation.[42,49,59] Thus, there is no benefit, and additionally, there are several well-documented risks to advising a low-calcium diet to prevent recurrent stone formation in patients with IH.

Genetic Hypercalciuric Stone-Forming Rats

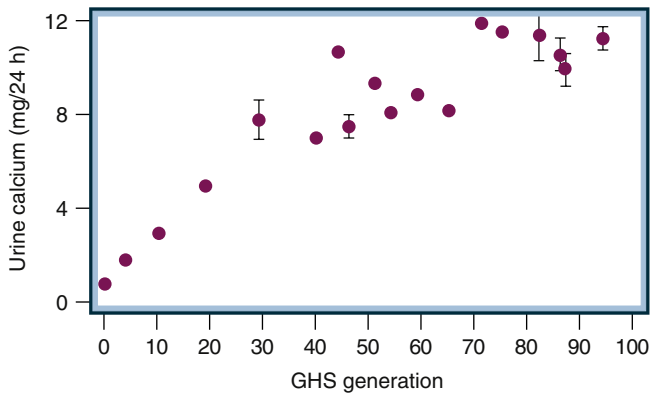
To more fully explain the mechanism of IH in humans, we have developed an animal model of this disorder.[67,79–85] Through more than 100 generations of successive inbreeding of the most hypercalciuric progeny of hypercalciuric Sprague-Dawley rats, we have established a strain of rats that excrete more than 10 times as much urinary calcium as control Sprague-Dawley rats (Fig. 32.3).

Compared with control Sprague-Dawley rats, the genetic hypercalciuric rats absorb far more calcium at lower dietary levels of $1,25(OH)_2D$.[86,87] When these hypercalciuric rats were fed a diet very low in calcium, their urinary calcium excretion remained elevated compared with that of similarly treated control rats, indicating a defect in renal calcium reabsorption or an increase in bone resorption, or both,[88] again similar to observations in humans.[60,89] Bone from these hypercalciuric rats released more calcium than the bone of control rats when exposed to increasing amounts of $1,25(OH)_2D$,[90] and their bone mineral densities were lower than control rats.[91] The administration of a bisphosphonate to the genetic hypercalciuric rats fed a low-calcium diet significantly reduced urinary calcium excretion.[92] In addition, a primary defect in renal calcium reabsorption was observed during clearance studies.[93] We have shown that besides the intestine, both the bone and kidney of the hypercalciuric rats have an increased number of vitamin D receptors and calcium receptors.[90,94,95]

Studies suggest the hypothesis that an increased number of vitamin D and/or calcium receptors may be the underlying mechanism for hypercalciuria in the rats.[96] Since the hypercalciuric rats have normal levels of serum $1,25(OH)_2D$, the higher levels of vitamin D receptors suggest that these receptors are undersaturated with $1,25(OH)_2D$. We tested the hypothesis that $1,25(OH)_2D$ would induce a greater increase in urine calcium in the hypercalciuric rats.[82] After injecting $1,25(OH)_2D$, urine calcium in both the controls and hypercalciuric rats increased; however, the increased urine calcium with $1,25(OH)_2D$ in the hypercalciuric rats exceeded that of controls, indicating that the increased number of vitamin D receptors in the hypercalciuric rats induces a greater biologic response. This increase in urine calcium must come from the intestine and/or bone. To determine whether the excess urine calcium was derived primarily from diet or from increased bone resorption, we asked whether $1,25(OH)_2D$ would increase urine calcium in genetic hypercalciuric stone-forming (GHS) rats fed a low-calcium diet.[83] On this low-calcium diet with $1,25(OH)_2D$, urine calcium in controls increased; however, urine calcium again increased significantly more in the hypercalciuric rats. In the hypercalciuric rats on the low-calcium diet with or without $1,25(OH)_2D$, urine calcium far exceeded daily calcium intake, implying a loss of bone mineral. To determine the role of bone resorption in the increased urine calcium in these hypercalciuric rats, we tested the hypothesis that a low-calcium diet, coupled with inhibition of bone resorption by the bisphosphonate alendronate, would eliminate the enhanced $1,25(OH)_2D$-induced hypercalciuria in GHS rats.[81] Alendronate eliminated the $1,25(OH)_2D$-induced increase in urine calcium in controls. However, in the hypercalciuric rats, alendronate decreased, but did not eliminate, the $1,25(OH)_2D$-induced hypercalciuria, suggesting that maximal alendronate cannot completely prevent the 1,25D-induced bone resorption in the GHS rats. These results confirm the role of increased bone resorption in the hypercalciuria of GHS rats. To study the effect of the increased number of vitamin D receptors on the osseous response to $1,25(OH)_2D$, we fed hypercalciuric and control rats ample calcium and injected $1,25(OH)_2D$ or vehicle daily.[80] With $1,25(OH)_2D$, there was a mineralization defect and a loss of bone mineral density in the hypercalciuric rats that exceeded changes in controls and contributed to increased hypercalciuria, suggesting that these bones would be more prone to fracture. The enhanced effect of $1,25(OH)_2D$ in the hypercalciuric rats indicates that the increased number of vitamin D receptors are biologically active and supports our hypothesis that in these hypercalciuric rats at baseline, their increased number of vitamin D receptors remain available for stimulation by exogenous $1,25(OH)_2D$.

These studies suggest that an increased number of vitamin D receptors in the hypercalciuric rats may be the underlying mechanism for their hypercalciuria, and perhaps this occurs in humans as well.[68,97,98] Circulating monocytes from humans with IH have been shown to have an increased number of vitamin D receptors.[99]

Thus, hypercalciuric rats appear to have a systemic abnormality in calcium homeostasis. They absorb more intestinal calcium, resorb more bone, and do not adequately reabsorb filtered calcium. Because every one of the hypercalciuric rats forms renal stones, we have described them as GHS rats.[68,97]



All data from published studies.

• **Fig. 32.3** Hypercalciuria in subsequent generations of genetic hypercalciuric stone-forming (GHS) rats. All data are from published studies.

Genetics of IH in Humans

The difficulty in ascertaining the genetics of IH arises, in part, from the numerous other factors that influence stone formation, such as diet, environment, and gender. Because half of patients with IH report a family history of stones and male patients often have fathers or sons with the disorder, inheritance is not believed to be recessive or X-linked.[100] A multitude of monogenic hereditary

disorders (see later discussion) can lead to hypercalciuria because they are caused by a variety of mutations resulting in changes in calcium handling at the level of kidney, bone, gut, and the calcium-sensing receptor in the kidneys and parathyroid glands. Given the evidence that IH is a complex trait with multiple pathways for developing the hypercalciuria phenotype, it is most likely a polygenic disorder, with heterogeneity of loci and possibly polygenic modifiers.[65,101] Lieske and associates[66] found that genetic factors appear to explain 20% to 36% of the interindividual variation in excretion of the ions critical to stone formation. Although attempts to diagnose the exact cause of IH in a particular patient might not be critical from a therapeutic standpoint, determining the etiology of IH in a particular family is essential for researchers attempting to clarify the genetics of IH.[8,65,66,85,102] Genome-wide association studies have found that genes associated with phosphate carrier NPT2a and NPT2c, claudin 14, aquaporin I, and others are associated with calcium nephrolithiasis.[65]

Other Genetic Causes of Stones and Nephrocalcinosis

Numerous monogenic disorders cause hypercalciuria leading to nephrolithiasis or nephrocalcinosis.[8,65,66,85,102] Disorders that lead to hypercalciuria by augmenting bone resorption include osteogenesis imperfecta type 1, multiple endocrine neoplasia type 1 syndrome with hyperparathyroidism, McCune-Albright syndrome, and infantile hypophosphatemia. Disorders that result in hypercalciuria because of excessive intestinal absorption of calcium include hypophosphatemia, Down syndrome, and congenital lactate deficiency. Others include autosomal dominant hypocalcemia (which is caused by an activating mutation of the calcium-sensing receptor), Lowe oculocerebrorenal syndrome, and Wilson disease. Next, we describe in more detail several disorders that result in hypercalciuria via their effect on genes expressed in the kidney.

X-Linked Hypercalciuric Nephrolithiasis (Dent Disease and Others)

Several families around the world have an X-linked disorder of proximal renal tubular dysfunction that is manifested by a variable combination of disorders including hypercalciuria, low-molecular-weight proteinuria, nephrocalcinosis or stones, hypophosphatemic rickets, and renal failure.[103–107] Some affected persons demonstrate evidence of defects in proximal tubular reabsorption of amino acids, glucose, or phosphate. PTH tends to be quite low and $1,25(OH)_2D$ high in the majority of patients. The abnormalities completely resolve in the patients who receive renal transplants, a finding that suggests a renal tubular disorder rather than a systemic process. In all families, the pattern of inheritance is consistent with an X-linked recessive disorder, with male patients affected to a greater extent than female patients. The latter are often minimally affected but transmit the disorder to half of their male offspring. Over time, the various disorders—X-linked recessive nephrolithiasis in the United States, Dent disease in the United Kingdom, X-linked recessive hypophosphatemic rickets in Italy, and low-molecular-weight proteinuria with hypercalciuria and nephrocalcinosis in Japan—have all been linked to mutations affecting the genes encoding the Cl^-/H^+ exchanger ClCN5 in the majority of patients and/or inositol polyphosphate 5-phosphatase (OCRL1), both on the X chromosome.[103–105] How defects in these genes lead to the array of these proximal tubular disorders is not yet understood.

Bartter Syndrome

Bartter syndrome is caused by at least five genetic mutations, predominantly autosomal recessive, that lead to sodium chloride wasting at the TAL of the loop of Henle.[37,38,64,83,105] Bartter syndrome is an autosomal disease caused by mutations of bumetanide-sensitive NKCC2 (the Na-K-2Cl cotransporter), ROMK (the renal outer medullary potassium channel), CaSR (the calcium-sensing receptor), and CLC-Kb (the voltage-gated chloride channel) or the CLC-Kb beta subunit barttin. These genes, all expressed in the TAL, cause a defect in sodium transport that leads to a reduction in the transtubular potential difference, resulting in a decrease in paracellular calcium reabsorption in the TAL. The ensuing reduction in intravascular volume also induces an aldosterone-mediated metabolic alkalosis. Bartter syndrome therefore resembles high-dose furosemide administration (that targets NKCC2) and differs from Gitelman syndrome in that hypercalciuria, nephrocalcinosis, and nephrolithiasis are seen with Bartter but not with Gitelman. An autosomal dominant form of Bartter results from a gain-of-function mutation in the calcium sensing receptor in renal tubular cells. This mutation leads to reduced calcium reabsorption and also hypocalcemia caused by low PTH levels. Therapy with vitamin D and calcium supplementation can exacerbate stone disease in this disorder.

Familial Hypomagnesemia With Hypercalciuria and Nephrocalcinosis

Familial hypomagnesemia with hypercalciuria and nephrocalcinosis is an autosomal recessive disorder that results in hypomagnesemia, hypercalciuria, nephrolithiasis, and distal renal tubular acidosis (dRTA). Polyuria and severe nephrocalcinosis also ensue, and progressive kidney failure is common by late childhood.[37,108–110] The genetic disorder results in defective production of either of the tight junction proteins, claudin-16 and claudin-19, that bind together to facilitate paracellular calcium and magnesium transport in the TAL, as well as renal sodium reabsorption. Currently, there is no effective treatment for the hypercalciuria or progression to kidney failure.

Distal Renal Tubular Acidosis

dRTA is caused by dysfunctional α-intercalated cells, resulting in defective acid excretion.[37,38,111–115] This inability to adequately acidify the urine results in metabolic acidosis, hypocitraturia, hypokalemia, hypercalciuria, nephrocalcinosis, and stones. The metabolic acidosis leads to resorption of both calcium and phosphate from bone. The increased filtered load of calcium and phosphate, along with the elevated urine pH and hypocitraturia, results in favorable conditions for calcium phosphate stone formation. Although there are secondary causes of dRTA, such as Sjögren syndrome and use of carbonic anhydrase inhibitors (e.g., acetazolamide), there are also several hereditary causes of dRTA.[116,117] Some are autosomal recessive and can also result in hearing loss; others are autosomal dominant. One form of dRTA that targets carbonic anhydrase II results in osteopetrosis and brain calcifications.[117] Patients with dRTA fail to lower their urine pH below 5.5 following ingestion of an acid load. Their urine citrate is extremely low despite mildly reduced or even normal serum bicarbonate levels.

Hereditary Hypophosphatemic Rickets With Hypercalciuria

Hereditary hypophosphatemic rickets with hypercalciuria is an autosomal form of hypophosphatemic rickets that is manifested clinically by hypophosphatemia secondary to renal phosphate wasting.[118–121] This disease is caused by mutations in solute carrier family 34, member 3 (SLC34A3), which is the gene that encodes

the sodium Na^+-dependent phosphate cotransporter 2c (NPT2c). These patients have hypophosphatemia-induced increase in levels of $1,25(OH)_2D$, which leads to increased intestinal calcium absorption and results in hypercalciuria. The bone pain, muscle weakness, limb deformities, and rickets resolve with administration of oral phosphate.

Primary Hyperoxaluria and Cystinuria

Primary hyperoxaluria and cystinuria are each discussed in the Therapy section.

Clinical Presentation and Evaluation

Kidney stones vary in clinical presentation, from those discovered asymptomatically on routine imaging to their painful passage through the ureters to large and obstructing staghorn calculi that can significantly impair renal function and even lead to ESRD.[6,7] The severity of stone disease depends on the pathogenic factors contributing to the rate of stone formation, as well as the stone type, size, and location.

In its most classic form, nephrolithiasis manifests as renal colic. This discomfort of abrupt onset intensifies over time into an excruciating, severe flank pain that resolves only with stone passage or removal. The pain often migrates anteriorly along the abdomen and inferiorly to the groin, testicles, or labia majora as the stone moves toward the ureterovesical junction. Gross hematuria, urinary urgency and frequency, nausea, and vomiting may be present. Nephrolithiasis can also result in a dull, poorly localizing abdominal pain. The probability of passing a kidney stone without intervention depends on its size and varies from about 70% for kidney stones 5 mm or less in size, whereas stones between 5 and 7 mm have a 60% chance, stones between 7 and 9 mm have a 48% chance, and stones 9 mm or larger have a 25% chance of passing spontaneously.[122]

Several studies, including a large meta-analysis, demonstrate that nephrolithiasis is associated with an increase in CKD that is independent of other risk factors, such as diabetes and hypertension found in stone formers; however, at least one other study did not find an increased risk of CKD.[123–127] A French study estimated the incidence rate of ESRD because of nephrolithiasis to be about 3.1 cases per million population per year,[128] whereas a Canadian study demonstrated that although only 0.8% of patients with ESRD had nephrolithiasis, any stone episode previously was associated with an increased risk of ESRD (hazard ratio 2.16).[129] The common reasons for loss of a single kidney in stone formers were staghorn calculi, high stone burden, infection, and ureteral obstruction.[130] However, no association between nephrolithiasis and incident CKD could be found in a recent study of more than 10,000 patients.[123]

The development of CKD from stone disease is thought to be from ureteral obstruction leading to parenchymal damage.[125] Most data are derived from animal models and suggest that unilateral ureteral obstruction causes intense renal vasoconstriction that reduces renal blood flow and glomerular filtration rate (GFR).[131] Brushite ($CaHPO_4$) stone formers have an increased risk of cortical fibrosis,[132] and the formation of Randall plaques in such patients was associated with duct plugging, collecting duct cell death, and inflammation.[133] Renal biopsy specimens in patients with staghorn calculi demonstrate extensive inflammation and macrophage infiltration.[134] Other stone-forming diseases like primary hyperoxaluria, cystinuria, and Dent disease have all been associated with crystal formation in the renal parenchyma that presumably triggers subsequent inflammation and CKD.[133]

Certain disorders can lead to diffuse renal parenchymal calcifications termed *nephrocalcinosis*.[6,38,115,135] The calcifications, usually calcium phosphate or calcium oxalate, may be present in the cortex or medulla. Among the most common causes of stone-related nephrocalcinosis are primary hyperoxaluria and medullary sponge kidney.

Metabolic Evaluation of Stone Formers

Although it is uniformly accepted that patients with multiple stones merit a thorough investigation into the cause of nephrolithiasis, the need for evaluation of the patient with a single stone is controversial. This is probably due to the difficulty in determining the cost-to-benefit ratio of stone evaluations and wide differences in reported rates of stone recurrence.

The National Institutes of Health has convened several consensus conferences to resolve such issues related to the prevention and treatment of kidney stones.[136] These panels determined that all patients, even those with a single stone, should undergo at least a basic evaluation to rule out a systemic etiologic mechanism. Patients with an increase in number or size of stones (metabolically active stones), all children, all non–calcium oxalate stone formers, and those in demographic groups not typically susceptible to stone formation warrant a more complete metabolic evaluation.[136]

The Basic Evaluation

Elements of the basic evaluation are listed in Table 32.1.[6,7]

History

In addition to the medical history typically obtained from new patients, the evaluation of the stone former includes a stone history and a thorough review of diet, fluid intake, and lifestyle. Specific laboratory studies and radiographic tests are also required.

Stone History

The stone history begins with a chronology of stone events: age of incidence of first stone, size and number of stones formed, frequency of passage, stone type (if known), and whether the stones occur equally in both kidneys or unilaterally. Also helpful is a report of the patient's symptoms with each episode, as well as the need for and response to surgical intervention.

This information is useful to judge not only the severity of the stone disease but also clues to the origin of the patient's nephrolithiasis. For example, nephrolithiasis that begins at a young age may be attributable to an inherited metabolic disorder such as primary hyperoxaluria or cystinuria. Large staghorn calculi that are difficult to eradicate and tend to recur despite frequent surgical intervention are more likely to be composed of struvite ($NH_4MgPO_4.6H_2O$) instead of calcium oxalate. Cystine stones are not disintegrated thoroughly with the use of lithotripsy, and alternative surgical modalities are generally required for stone removal. In patients who tend to form stones in only one kidney, the possibility of congenital abnormalities of that kidney, such as megacalyx or medullary sponge kidney, should be explored.

Medical History

Systemic disorders that can contribute to nephrolithiasis are sought in the medical history. For example, any disorder that can result in hypercalcemia, such as sarcoidosis or certain malignancies, may also lead to hypercalciuria. A variety of GI disorders associated with malabsorption (e.g., sprue, Crohn disease) can

cause calcium oxalate nephrolithiasis on the basis of enteric hyperoxaluria. Patients with gout or insulin resistance are more likely to have uric acid stones[30,137] (Tables 32.2 and 32.3).

Family History

As noted earlier, several stone disorders are inherited, making the family history an important component of the basic evaluation. IH appears to be a familial disorder. Although the exact chromosomes and genes have not yet been identified, the pattern of inheritance is almost certainly polygenic.

Stones arising in childhood or young adulthood can be related to autosomal recessive disorders such as cystinuria and primary oxaluria. These genetic disorders are reviewed in the later sections on treatment of cystine and primary hyperoxaluria.

The high prevalence of uric acid stones in certain areas of the world is suggestive of both genetic and environmental risk factors. Genes that cause either excessively acidic urine or hyperuricosuria have been implicated.[30,37,65,66,78,135,138,139]

Medications

Medications can contribute to stone formation in several ways. Calcium-containing supplements, for example, can increase the amount of calcium absorbed and subsequently excreted.[63] Loop diuretics can directly promote renal tubular excretion of calcium and are associated with nephrocalcinosis in neonates who have received the drug.[140,141] Acetazolamide, a weak diuretic, induces a mild metabolic acidosis and alkaline urine, which are favorable conditions for the development of calcium phosphate stones. Other uricosuric medications, such as salicylates and probenecid, have been implicated in uric acid lithiasis.[142]

Certain crystals or stones can consist completely of precipitated medication. Such medications include intravenously administered acyclovir, triamterene, indinavir, and various sulfonamides, such as sulfadiazine. Oxalate is a metabolic end product of vitamin C, and large doses increase oxalate excretion and may predispose to stone formation[143,144] (Table 32.4).

Lifestyle and Diet

Occupation and lifestyle are aspects of the social history that can be relevant to stone formation. Surgeons and traveling salespeople, for example, tend to minimize fluid intake to avoid frequent micturition throughout the day. Insensible losses of fluid can also exacerbate nephrolithiasis and may be related to employment (e.g., construction work) or hobbies (running, gardening).

The evaluation proceeds with a thorough review of the patient's diet and fluid intake. Patients are asked to review what they eat at all meals and snacks. Particular attention is paid to ingestion of foods high in sodium (fast foods, canned foods, added salt or soy sauce) and the quantity of animal protein consumed (see later discussion). Patients are also asked to list four or five favorite foods or snacks to assess whether they may be consuming foods high in oxalate or purine as well. Many patients are erroneously counseled by physicians to avoid calcium-containing foods. As noted earlier, doing so is associated with increased risk of stone formation

TABLE 32.4 Medications Associated With Renal Lithiasis and Nephrocalcinosis

Medications That Promote Calcium Stone Formation

Acetazolamide
Amphotericin B
Antacids (calcium and noncalcium antacids)
Calcium supplements
Glucocorticoids
Loop diuretics
Theophylline
Vitamin C
Vitamin D

Medications That Promote Uric Acid Lithiasis

Allopurinol (associated with xanthene stones)
Probenecid
Salicylates

Medications That Can Precipitate Into Stones or Crystals

Acyclovir (when infused rapidly intravenously)
Indinavir
Nelfinavir
Sulfonamides
Triamterene

Data from Monk RD, Bushinsky DA. Nephrolithiasis and nephrocalcinosis. In: Johnson RJ, Frehally J, Floege J, eds. *Comprehensive Clinical Nephrology*, 5th ed. Philadelphia, PA: Elsevier; 2015:688–702.

and may also result in bone demineralization, a grave concern in women with stones.[42,49,59]

Physical Examination

For most patients with nephrolithiasis, physical findings are normal. In some patients, however, the findings may reveal a systemic disorder related to the stone disease. An enterocutaneous fistula, for example, may be associated with Crohn disease, a common cause of enteric hyperoxaluria. A paraplegic patient with an indwelling catheter may be susceptible to frequent urinary tract infections with urease-producing organisms and consequent struvite stone formation. Hyperuricosuria and uric acid stone formation may be seen in patients with tophi related to gout.[6,7,73]

Laboratory Tests

Although valuable information is gleaned from the history and physical examination, it is often difficult to determine the metabolic cause of a patient's nephrolithiasis without laboratory data. The urinalysis is an easy and inexpensive test that provides a great deal of information. Often, the presence of different kinds of crystals can suggest the type of underlying stone (Fig. 32.4). Uric acid and calcium oxalate stones, for example, grow more favorably at an acidic pH, and a consistently high urinary pH may suggest calcium phosphate or struvite nephrolithiasis. The specific gravity, if high, can confirm suspicions of inadequate fluid intake.

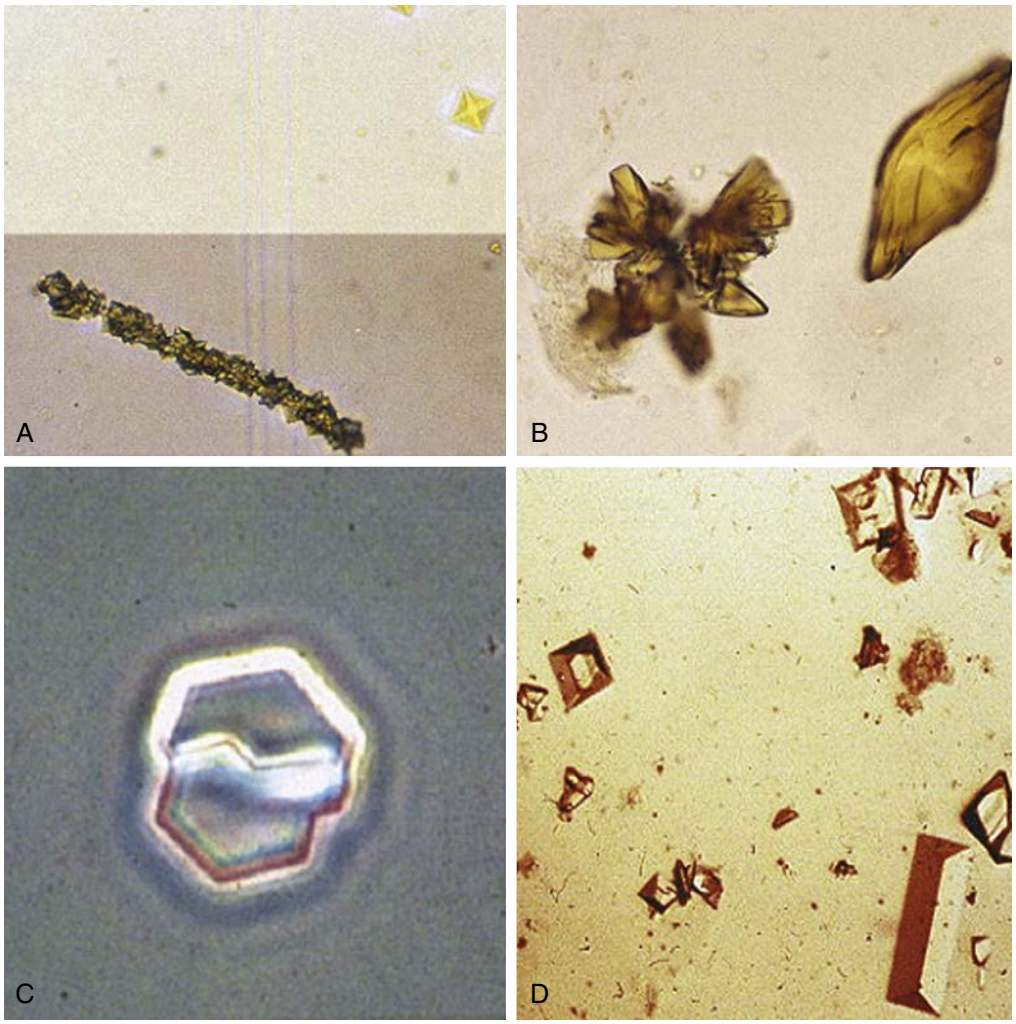
Hematuria is often present in active stone disease. Microscopic examination of the urine in this case might reveal characteristic crystals. Bacteria and pyuria noted in conjunction with a high urinary pH (~6.5) are characteristic of struvite stone disease. Urine specimens for culture should be obtained in this setting. Because enough urease may be produced to form struvite stones even when colony counts are low (~50,000 colony-forming units), the microbiology laboratory should be instructed specifically to identify the organism and check for urease-producing bacteria despite low colony counts.[145]

Qualitative cystine screening should be performed on a urine specimen. Urine turns purple-red when sodium nitroprusside is added to a specimen containing cystine at a concentration greater than 75 mg/L.[138]

Recommended blood tests in the basic evaluation include electrolytes (sodium, potassium, chloride, bicarbonate) uric acid, calcium, phosphorus, and serum creatinine to determine renal function.[73,78,111] If the serum calcium level is elevated or at the upper limit of normal, or if the serum phosphorus level is reduced or at the lower limit of normal, a serum intact PTH level is also determined to rule out primary hyperparathyroidism. Low serum bicarbonate levels suggest a hypocitraturic disorder such as renal tubular acidosis (RTA) or acetazolamide ingestion.

Stone Analysis

Stone analysis should be performed, whenever possible, in patients with a new history of nephrolithiasis or in patients with



• **Fig. 32.4** Crystals seen in urine of stone formers. (A) Calcium oxalate. (B) Urate. (C) Cystine. (D) Struvite.

long-standing stone disease who note a difference in clinical presentation or in the color, shape, or texture of any stone passed. Knowing the constituents of a stone can help the physician target certain elements of the medical history and specific urine studies. In most cases, the stone must be sent to an outside laboratory for examination. X-ray diffraction crystallography and infrared spectroscopy are currently the most accurate methods available for stone analysis.[32]

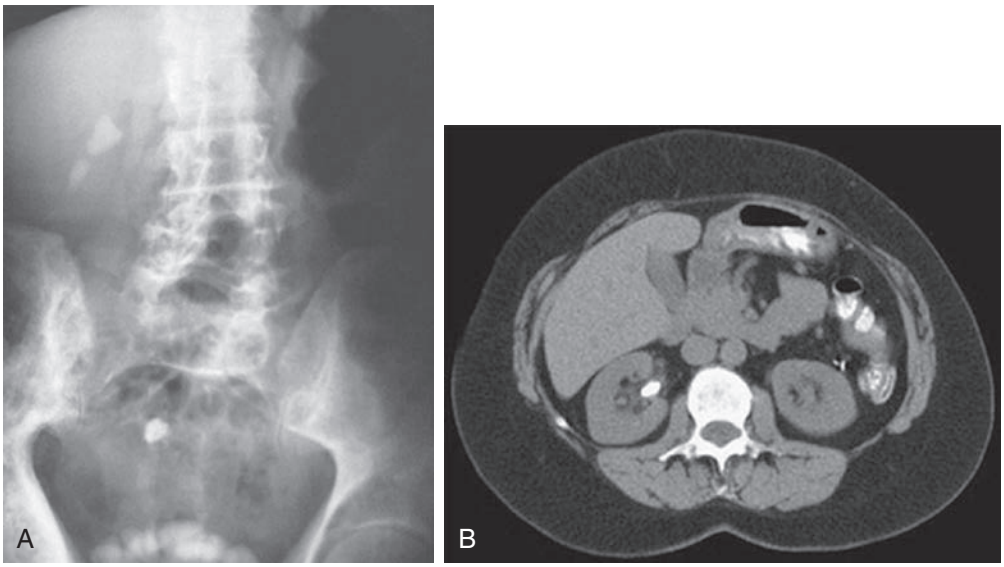
Radiologic Evaluation

Various radiologic tests can help determine the location and extent of the stone burden and might elucidate genitourinary abnormalities contributing to stone formation (Fig. 32.5). For acute renal colic, spiral (or helical) CT without contrast (unenhanced) has replaced intravenous pyelogram (IVP) as the optimal test for detection and localization of kidney stones. Helical CT has proved to be more sensitive (95%) and specific (98%) than IVP in detecting stones of all types in both the kidneys and ureters.[146] In addition, it can more accurately reveal causes of flank pain and hematuria not related to stones, and it circumvents the use of intravenous contrast material. Radiation exposure is a disadvantage of both CT and IVP, and the exposure to patients undergoing helical CT may be triple that of IVP. As such, it should be used judiciously, especially in young patients with frequent episodes of renal colic. Helical CT takes less time to perform, which is a potential advantage in an emergency department setting, but it is more expensive.[147–150] Some institutions are exploring the use of low-dose CT, which has about one third of the radiation exposure of conventional CT with a similar sensitivity and specificity.[146]

CT should be followed by a plain film (radiograph) of the abdomen that includes the kidneys, ureter, and bladder (KUB). Plain films can assist in determining stone composition. Stones composed of calcium, cystine, and struvite are radiopaque and visible on KUB, whereas radiolucent stones, such as those composed of uric acid and xanthine, are not.

Renal ultrasound is a useful test for patients who must avoid exposure to radiation or contrast, such as pregnant women and children. It is almost as sensitive (84%) but not as specific (53%) as spiral CT for detecting kidney stones.[151] Ureteral stones are very difficult to visualize on ultrasound. Emergency department patients with suspected nephrolithiasis who initially have ultrasonography have been shown to have a lower total radiation exposure than those initially evaluated with CT without any difference in serious adverse events, missed important diagnoses, pain scores, or subsequent emergency department visits or hospitalizations.[152,153]

IVPs are useful in detecting certain genitourinary abnormalities that can predispose to nephrolithiasis, such as medullary sponge kidney and caliceal abnormalities. Another advantage of IVP is that the osmotic diuresis generated by the administered contrast agent may aid in excretion of the offending stone during an episode of acute



• **Fig. 32.5** Renal stones on an abdominal radiograph and a computed tomography scan. (A) Radiolucent kidney stone can be seen on the kidneys, ureter, and bladder radiograph at the ureterovesical junction. (B) A large stone is seen in the renal pelvis of the right kidney.

renal colic. A major disadvantage of IVP is exposure to radiographic contrast material. Administration of contrast should be avoided in patients who are at high risk for developing nephrotoxicity from the contrast, such as the elderly; those with diabetes mellitus, proteinuria, or preexisting kidney disease; and patients with significant intravascular volume depletion. With the numerous advantages of CT and ultrasound, IVPs are rarely indicated.

Once a patient is known to have a certain type of stone, specific tests may be used in follow-up. For example, a patient known to have asymptomatic calcium stones can have a KUB test 6 to 12 months later to assess for any increase in stone size or number.[6,7,78] However, because of the radiation exposure, reimaging should be limited to patients in whom the results of the test will alter treatment. Little is gained in asymptomatic patients by checking for stone growth or movement if maximal dietary and pharmacologic therapy is already being prescribed.

The Complete Evaluation

The complete evaluation comprises the entire basic examination as well as a 24-hour urine collection to determine volume and levels of calcium, oxalate, citrate, sodium, urate, phosphorus, creatinine, and the urinary supersaturation with respect to the common solid phase components[6,7,111] (Table 32.5). Creatinine is used to assess the adequacy of the collection: men should excrete approximately 15 to 20 mg/kg of creatinine per day, whereas women should excrete 10 to 15 mg/kg of creatinine per day. Cystine should also be measured in patients known to have cystine stones or in whom prior urine studies have not determined if there is excessive excretion of this amino acid.

Patients should be instructed to collect their urine on a day when they perform usual activities and have their typical fluid and dietary intake. The first morning's urine specimen is discarded; following this, all urine for the next 24 hours (including the next morning's specimen) is collected in the container. The ideal 24-hour urine collection includes measurement and reporting of the daily excretion of the constituents listed in Table 32.5 and also reports supersaturation of calcium oxalate, calcium phosphate, and uric acid. Patients should be instructed to discontinue multivitamins approximately 5 days before the collection to prevent any antioxidant effect of the vitamins on the urine sample. In most cases, an acid or antibiotic is included in the collection container or added with the first urine sample as a preservative. Certain laboratories require various preservatives for the different factors measured. Physicians should ask their laboratory how many 24-hour urine

TABLE 32.5 Optimal 24-Hour Urine Values in Patients With Nephrolithiasis

Parameter	Value
Volume	>2.0–2.5 L
pH	>5.5, <7.0 (24-hour specimen not required)
Calcium	<300 mg or <3.5–4.0 mg/kg in men <250 mg or <3.5–4.0 mg/kg in women
Oxalate	<40 mg
Sodium	<3000 mg or <130 mEq
Uric acid	<800 mg in men <750 mg in women
Phosphorus	<1100 mg
Citrate	>320 mg
Creatinine	~15 mg/kg in men ~10 mg/kg in women to ensure adequacy of collection
Supersaturation of calcium oxalate	<5
Supersaturation of calcium phosphate	0.5–2.0[a] (ideally <1.0)
Supersaturation of uric acid	0–1[a]

[a]Ideal values can vary among laboratories that perform supersaturation analysis.

collections and which preservatives are required for the complete evaluation. Simplifying this process to a single urine collection in which all of the measurements are performed and resultant supersaturation calculated is available from several national laboratories and almost certainly improves adherence and perhaps accuracy of the calculation of supersaturation.[78,154]

Patients who require the complete evaluation are as follows: all children, nonwhite patients (demographic groups not typically prone to nephrolithiasis in the United States), non–calcium stone formers, and patients with metabolically active stone disease (metabolically active stones are those that grow in size or number within 1 year).[6,7]

Therapy

Surgical Treatment

Treatment of an acute episode of renal colic often involves surgical management for large stones that do not pass spontaneously. Stones less than 5 mm in size have a 68% chance of passing spontaneously, whereas those greater than 5 mm but less than 10 mm have a spontaneous stone passage rate less than 50%.[155] Most stones greater than 10 mm, and many greater than 5 mm in size, require surgical intervention for relief of renal colic, ureteral obstruction, or other symptoms of clinically active stone disease. With the advent of newer, less invasive urologic therapies, open surgical stone extraction is rarely performed. Current urologic therapy includes percutaneous nephrolithotomy (PNL), extracorporeal shock wave lithotripsy (ESWL), and ureteroscopic removal of stones (URS). The exact procedure used varies according to stone location in the kidney or ureter, size, composition, various patient factors, and surgical expertise.[155–158]

PNL involves placement of a large needle through the flank into the renal collecting system. The tract is dilated, and instruments are used to rupture and remove the stone. Although more invasive than URS and ESWL, PNL is more effective in removing large (>2 cm) or staghorn calculi, as well as stones that do not fragment well with lithotripsy. Large, infected stones, such as struvite stones, in which complete removal is desired, are best treated with PNL.[157,158] ESWL involves focusing sound waves from a lithotripter outside the body onto the kidney stone. The impulses fragment the stone into smaller stones, or "gravel," that can more easily be passed spontaneously. Newer-generation lithotripters do not require a water bath and often require less analgesia.[159] Kidney stones less than approximately 15 mm, proximal ureteral stones, upper and middle pole kidney stones, and those not composed of cystine or calcium oxalate monohydrate respond best to ESWL.[155,157–159] Because fluoroscopy is typically used to visualize radiopaque stones during the procedure, ESWL may be more complicated in patients with uric acid lithiasis. ESWL is relatively contraindicated in patients with coagulopathy and in pregnant women. It may be less successful in patients with a higher BMI, as a low skin to stone distance is necessary to achieve optimal success.[158,159]

Recent meta-analyses found that PNL is superior to ESWL for most ureteral stones because it results in longer stone-free rates and decreases the need for retreatment. However, it is associated with more, although generally minor, complications and longer hospitalizations.[160,161]

Ureteroscopy, the passage of a semirigid or flexible scope through the bladder and into the ureter, is a mainstay of surgical stone extraction for many ureteral stones, especially distal ureteral stones, and larger proximal stones. Endocorporeal lithotripsy can be added to URS to directly fragment visualized stones. One of the more commonly used devices is the holmium:YAG (yttrium-aluminum-garnet) laser lithotripter, which combines both pneumatic and ultrasound lithotripsy to fragment stones. This results in high stone-free rates following the procedure.[156,162] Complications of ESWL and URS include urinary tract infection; sepsis; ureteral stricture; ureteral injury; and steinstrasse, or "stone street," the linear accumulation of small stones blocking a ureter following fragmentation of a larger stone.

Medical Expulsive Therapy

Another form of therapy that has been shown to reduce the time to stone passage is medical expulsive therapy. Medical expulsive therapy may be utilized with ureteral stones that are less than 10 mm in diameter for up to 6 weeks if kidney function is normal, there is no evidence of infection or significant obstruction, and pain can be controlled. Several medications have shown benefit in reducing the time to stone passage and in assisting with passage of larger stones.[163] A recent trial found that tamsulosin (0.4 mg/day) and nifedipine (30 mg/day) were not effective at decreasing the need for further treatment to achieve stone clearance in 4 weeks.[164] However, meta-analyses have demonstrated a benefit for α-adrenergic blockers such as tamsulosin, terazosin (2–5 mg/day), or doxazosin (4 mg/day).[165,166] These agents act by reducing spasm of the ureteral smooth muscle and allowing ureteral peristalsis to more effectively move the stone through. The addition of corticosteroids may also assist with stone passage by reducing ureteral inflammation and swelling in the ureter where the stone is lodged. In a controlled study, these therapies were compared with control groups involving placebo[167] or standard therapy, such as antispasmodic therapy, nonsteroidal anti-inflammatory agents, or analgesics. In studies comparing α-adrenergic receptor blockers to calcium channel blockers, the α-adrenergic blocker tamsulosin was found in a few studies to result in higher stone passage rates and more rapid stone expulsion than nifedipine.[163,168,169] Both agents were generally well tolerated, although perhaps with less hypotension in the tamsulosin groups. The selective α-1A receptor blocker silodosin (8 mg/day) provided a significantly higher expulsion rate than tamsulosin for distal ureteral stones.[170] Frequent follow-up and occasional imaging with ultrasound is recommended to ensure that the patient remains free of complications while awaiting stone passage.

Medical Preventative Therapy

Medical preventative therapy is the mainstay of medical management, and the remainder of the chapter will focus on prevention of stone recurrence.

Nonspecific Therapy

Most patients, irrespective of stone type, are given general advice about fluid and dietary modification to prevent further stone formation.[6,7,111] These nonpharmacologic interventions, which include an increase in fluid intake, as well as restriction of dietary sodium and animal protein, can reduce the incidence of stone formation—a result termed the *stone clinic effect*.[42,171–173] In one study, such interventions resulted in a 40% decrease in stone recurrence over 5 years.[41]

The mainstay of nonspecific therapy involves dietary measures (see the Diet discussion in the Pathogenesis of Stone Formation section): increased fluid intake to raise urine volume to approximately 2 to 2.5 L, a reduction in sodium intake to less than 3000 mg/day (130 mEq), moderate reduction in animal protein ingestion to approximately 1.0 mg/kg per day, and perhaps eating certain fruits or juices high in citrate.[42,45,78,171,172,174,175]

Dietary calcium restriction is no longer recommended, because it not only can lead to a reduction in bone mineral content but also increases the rate of stone recurrence presumably by decreasing intestinal calcium oxalate absorption and increasing urinary oxalate excretion.[42] In retrospective studies of dietary intake, both women and men have been found to have reduced stone formation with increased dietary calcium ingestion. Calcium supplements, however, were associated with an increased risk of stones in women. Patients should therefore be advised to maintain an age- and gender-appropriate intake of dietary calcium, preferably without supplements.[42,49,59,63,176]

Specific Therapy Matched to Specific Pathogenesis

The optimal therapy for a patient with metabolically active stone disease is directed at the patient's particular metabolic abnormality.[8,177] Before medications for nephrolithiasis are prescribed, all patients should be treated with the nonspecific measures noted earlier. Prior to any therapeutic intervention, some clinicians assess the patient's existing stone burden with a radiologic examination (KUB, spiral CT, IVP, or ultrasonography). If stones are present, any subsequent passage of stones would not necessarily indicate therapeutic failure, because the patient may simply be passing the stones formed prior to therapy. However, this approach must be weighed against the expense and the radiation exposure associated with the radiologic examination. Our personal opinion is to not obtain baseline or follow-up radiographs in asymptomatic patients unless the results will alter subsequent therapy. The basic and complete evaluations help direct the clinician to the specific treatments discussed here.

Calcium Stones

Most kidney stones (~70%) contain calcium (see Fig. 32.1). More than one third of these are composed of calcium oxalate alone, and another 7% are composed of calcium phosphate alone. The rest are composed of a combination of calcium oxalate with either urate or calcium phosphate. The stones tend to be gray, brown, or tan and rarely grow larger than 1 to 2 cm.[78,178,179]

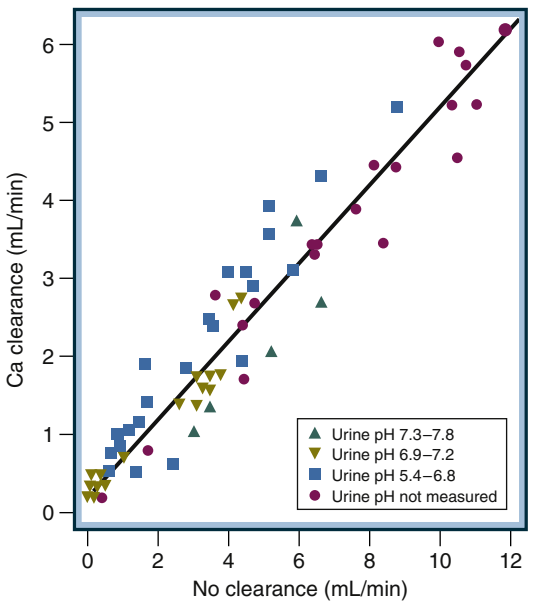
The main causes of calcium stone formation are hypercalciuria (excessive urinary calcium excretion), hyperoxaluria (excessive oxalate excretion), hyperuricosuria (excessive uric acid excretion), hypocitraturia (insufficient citrate excretion), RTA, congenital abnormalities of the genitourinary tract, and certain medications (see Tables 32.2 and 32.3).

Hypercalciuria. Patients with persistent hypercalciuria often benefit from a thiazide diuretic. This class of drugs is inexpensive and extremely effective at reducing urinary calcium excretion and stone formation.[44,78,180] To maximize the efficacy of thiazides, patients must consume a sodium-restricted diet. Urinary calcium excretion parallels sodium excretion (Fig. 32.6), and reducing sodium consumption is essential to reducing hypercalciuria. Whereas hydrochlorothiazide is commonly used for hypertension, chlorthalidone is favored for treating hypercalciuria because it has a longer half-life and requires only once-daily dosing. The starting dose is 25 mg and can be increased to 50 mg. In petite patients or those with low blood pressure, therapy can be initiated with 12.5 mg.

Side effects of thiazides include an increase in serum lipid levels and hyperglycemia. For patients in whom this is a concern, such as those with hypercholesterolemia, other cardiac risk factors, or elevated blood glucose levels, indapamide (1.25–2.5 mg) is an effective alternative.[181] This agent has less of an effect on serum lipids and blood sugar than thiazides.

Hypokalemia is another common side effect of thiazide therapy. Patients should be advised to increase their dietary intake of potassium-rich foods, and the potassium level should be checked 7 to 10 days after starting the medication. Hypokalemia can result not only in cardiac and neuromuscular problems but also in hypocitraturia—another risk factor for stone formation. The supplement of choice is potassium with a base, such as citrate or bicarbonate, as the accompanying anion. Potassium citrate is available as a liquid or as a wax-matrix tablet. The wax-matrix form is preferable because many patients find the liquid unpalatable. Patients with malabsorption disorders, however, may absorb potassium citrate better in the liquid form. Potassium citrate in the wax-matrix formulation is available as 5- and 10-mEq tablets; 20 to 40 mEq/day in single or divided doses is usually adequate supplementation. Determination of follow-up potassium and bicarbonate levels may be required for further dose adjustment. Because citrate is a base, metabolic alkalosis can result with this medication, especially when given with a thiazide diuretic. In such a situation, an alternative potassium supplement (e.g., potassium chloride) may be necessary. If hypokalemia persists or if large doses of supplemental medication are required, the patient might benefit from the addition of a potassium-sparing diuretic. Triamterene is generally avoided because it can precipitate into stones. Amiloride may be initiated at a starting dose of 5 mg or in a combination tablet with thiazide.

After 4 weeks of therapy with the new medication, the 24-hour urine collection should be repeated to assess the efficacy of therapy in reducing calcium levels. The 24-hour urinary sodium and citrate levels should also be measured. The thiazide dose may need to be increased to decrease calcium excretion to less than 3 to 4 mg/kg per day. If sodium excretion remains high in conjunction with elevated urinary calcium excretion, further dietary counseling aimed at reducing dietary sodium may be required. Additional



• **Fig. 32.6** Relationship between urinary calcium and sodium excretion. This study shows how urinary calcium excretion parallels urinary sodium excretion. There is almost a linear relationship between the urinary excretion of calcium and sodium, making sodium restriction in the diet imperative in the treatment of hypercalciuria. (From Walser M. Calcium clearance as a function of sodium clearance in the dog. *Am J Physiol*. 1961;200:1099–1104.)

potassium citrate may be required if urinary citrate or serum potassium levels remain low.[78,182]

Hyperoxaluria. Oxalate is produced predominantly by endogenous metabolism of glyoxylate and, to a lesser extent, by ascorbic acid. Some urinary oxalate is derived from dietary sources, such as rhubarb, cocoa, nuts, tea, and certain leafy green vegetables. Absorbed oxalate is excreted unchanged in the urine and raises urinary supersaturation with respect to calcium oxalate.[72,134,183,184] Hyperoxaluria, as the sole metabolic abnormality, accounts for the formation of only approximately 5% of all calcium-based stones, even though it is often present with other urinary abnormalities that lead to an increase in supersaturation.[37,185,186]

The three main causes of hyperoxaluria are excessive oxalate ingestion (dietary oxaluria), malabsorptive GI disorders (enteric oxaluria), and excessive endogenous production of oxalate related to a hepatic enzyme deficiency (primary hyperoxaluria).

Because ethylene glycol (used as antifreeze in automobiles) is metabolized to oxalate, nephrolithiasis, in conjunction with severe metabolic acidosis and renal failure, is often observed in patients after ingestion of ethylene glycol.[8]

Dietary Oxaluria. Dietary oxaluria results in urinary oxalate levels that are mildly elevated (40–60 mg/day). Many high-oxalate foods are fruits, vegetables, and nuts that are generally considered beneficial in most diets. In a retrospective analysis, patients consuming diets similar to the DASH diet have fewer stones than those who consume diets that are markedly different despite the DASH diet being high in oxalate.[187] The diet is also high in potassium and calcium and low in sodium, which are factors that may be more preventive in stone formation than oxalate is detrimental. Patients with dietary hyperoxaluria should be provided with a detailed list of high-oxalate foods to review (Table 32.6). How restrictive patients need to be with regard to the list is guided by urinary supersaturation and common sense, especially because many patients with stones may also have hypertension and diabetes mellitus and benefit from a diet high in fruits and vegetables.

TABLE 32.6 Foods High in Oxalate

Beans (green and dried)
Beer (draft, stout, lager, pilsner)
Beets
Berries (blackberries, blueberries, raspberries, strawberries, juice made from berries)
Black tea
Black pepper
Celery
Chocolate, cocoa
Eggplant
Figs, dried
Greens (collard greens, dandelion greens, endive, escarole, kale, leeks, mustard greens, parsley, sorrel, spinach, Swiss chard, watercress)
Green peppers
Lemon, lime, and orange peel
Nuts
Pecans, peanuts, peanut butter
Okra
Rhubarb
Sweet potato
Tofu

Data from Monk RD, Bushinsky DA. Nephrolithiasis and nephrocalcinosis. In: Johnson RJ, Frehally J, Floege J, eds. *Comprehensive Clinical Nephrology*, 5th ed. Philadelphia, PA: Elsevier; 2015:688–702.

Patients should be instructed to ingest calcium-containing foods, such as a glass of milk, when eating foods high in oxalate. The calcium in milk binds the dietary oxalate and may prevent its absorption.[37,42] In patients who have severe dietary hyperoxaluria with active stone disease, two or three calcium carbonate tablets (500–650 mg/tablet) may be prescribed with high-oxalate meals. However, this should be done cautiously given the association between calcium supplements and kidney stones in women in the general population (see the earlier Nonspecific Therapy section).

Enteric Oxaluria. Enteric oxaluria results in higher urinary oxalate levels (60–100 mg/day) than dietary hyperoxaluria. GI malabsorptive conditions associated with normal colonic function, such as Crohn disease, celiac sprue, jejunoileal bypass, chronic pancreatitis, and biliary obstruction, can lead to enteric oxaluria. In these disorders, malabsorbed fatty acids bind calcium in the intestinal lumen, making more "free" oxalate available for absorption in the colon. In addition, the colonic mucosa becomes more permeable to oxalate as a result of exposure to malabsorbed bile salts.[188–190]

The mainstay of treatment, whenever possible, is therapy for the underlying disorder. A gluten-free diet, for example, can significantly reduce hyperoxaluria associated with sprue. For other conditions (e.g., surgical short bowel syndrome), no specific therapy is feasible. In such cases, reduction of malabsorption and oxalate absorption may be achieved by instituting general therapy for steatorrhea, such as a low-fat diet, cholestyramine, and medium-chain triglycerides. As in patients with dietary oxaluria, an oxalate-restricted diet and calcium carbonate with meals should be prescribed.[42,191] Because of chronic diarrhea, these patients are at substantial risk for low urine volumes, hypocitraturia, hypokalemia, and hypomagnesuria. The acidic, concentrated urine also predisposes to development of uric acid stones.[192,193] Additional fluid intake must be stressed, and potassium citrate (the liquid form is generally better absorbed but poorly tolerated in these patients) and magnesium supplementation are often prescribed. Magnesium appears to be an inhibitor of stone formation and is supplied as magnesium oxide at 400 mg by mouth two times a day or magnesium gluconate at 0.5 to 1.0 g by mouth three times a day.[194]

Primary Hyperoxaluria. Primary hyperoxaluria (PHO) leads to nephrolithiasis because of hepatic enzyme deficiencies that lead to massive endogenous oxalate production and excretion in these patients.[135,195–198] PHO results not only in severe hyperoxaluria (80–300 mg/day) but also in widespread deposition of oxalate in numerous organs and tissues such as the heart, bone marrow, muscle, and renal parenchyma at a young age. Cardiomyopathy, bone marrow suppression, and renal failure can ensue. In type 1 PHO (80% of cases), the deficient hepatic enzyme is alanine glyoxylate aminotransferase (AGT), and deficiency is caused by one of several mutations found in the AGT gene, *AGXT*. In some patients with type 1 PHO, pyridoxine (vitamin B_6) can increase enzyme activity, thereby reducing oxalate production. In type 2 PHO (10% of cases) patients lack D-glycerate reductase and glyoxylate reductase due to mutations in the *GRHPR* gene. PHO type 3 is due to a defect in the *HOGA1* gene that encodes for mitochondrial 4-hydroxy-2-oxoglutarate aldolase and makes up the remaining cases of PHO.[199]

All patients with PHO should be treated with measures that reduce calcium oxalate supersaturation, such as ample fluid supplementation, potassium citrate, magnesium, and orthophosphate.[197] Orthophosphate is an effective inhibitor of calcium oxalate crystallization but should be avoided in patients with a GFR less than 50 mL/minute. The combination of pyridoxine and orthophosphate improved renal survival at 20 years from 20%

to 74% in patients with PHO I and II.[200,201] *Oxalobacter formingenes* is an enteric bacteria that relies on oxalate for its metabolism.[144,202] In small studies, probiotic supplementation of these bacteria to patients with PHO type 1 resulted in a slight reduction in urinary oxalate excretion.[203,204] Provision of these bacteria, if they become commercially available, may provide additional therapy in the treatment of PHO. PHO patients with renal failure might benefit from renal transplantation because dialysis is not as effective as a functioning kidney in oxalate removal. The general measures to treat PHO should be continued after renal transplantation to prevent rapid loss of the allograft caused by calcium oxalate deposition. Ultimately, for patients with type 1 PHO, liver transplantation can supply the missing AGT and is curative, especially if it is performed before the development of end-stage renal failure. Some patients require combined liver and kidney transplantation.[135,195,205]

Hyperuricosuria. Up to 15% of patients with hyperuricosuria have calcium stones. In contrast to patients with pure calcium oxalate stones, these patients typically have elevated urinary uric acid levels but normal urinary calcium and oxalate levels.[206–208] They also differ from patients with pure uric acid stones in that they tend to have a higher urinary pH.

The mechanism by which uric acid promotes calcium stone formation is unclear. The terms *heterogeneous nucleation* or *epitaxy* are used to describe the preferential formation of calcium oxalate crystals around a lattice of uric acid crystals present in the urine.[72,209,210] More recently, this mechanism has come into question. Grover and associates[211,212] have shown that the addition of sodium urate to urine or similar solutions increases calcium oxalate crystallization, with denser, more aggregated deposits, without the presence of urate crystals, and with no increase in calcium oxalate supersaturation. They attribute this to "salting out"—a process in which the solubility of electrolytes (or salts) in a solution is reduced (or the ion activity increased) by the addition of different electrolytes/salts. As such, the activity coefficient of calcium and oxalate would be increased not only by the concentrations of calcium and oxalate in the urine but also the urate concentration. This theory would explain why allopurinol is often an effective therapy for recalcitrant calcium oxalate nephrolithiasis, even in the absence of hyperuricosuria.[213,214] Another potential mechanism (but not borne out by studies) is that urate may reduce the concentration or the activity of urinary stone inhibitors.[215–217]

Whatever the mechanism, uric acid in the form of sodium urate is important in calcium oxalate crystal formation. Therapy has generally consisted of dietary purine restriction and increased fluid intake. If urinary uric acid levels remain uncontrolled with these measures, allopurinol, 100 to 300 mg/day, may be added.[206,207]

Hypocitraturia. Citrate, by combining with calcium to form a soluble complex, reduces calcium oxalate and calcium phosphate precipitation, thus acting as the most important inhibitor of calcium crystallization in urine.[8,72,177] In some patients, hypocitraturia is the principal metabolic abnormality found in the 24-hour urine collection. Risk factors for hypocitraturia include high protein intake, hypokalemia, metabolic acidosis, exercise, infection, starvation, and therapy with androgens or acetazolamide. Men tend to have lower urinary citrate concentrations than women, which may be responsible for the higher incidence of stone formation in men. Furthermore, women with nephrolithiasis have lower urinary citrate concentrations than non–stone-forming women.[218] Although citrate excretion below 320 mg/L per day of urine is defined as hypocitraturia, the risk of nephrolithiasis is a continuous function of urinary citrate concentration.[219]

Along with therapy for the underlying condition, such as moderating dietary protein intake, potassium citrate or potassium-magnesium citrate is prescribed, and both formulations are effective in preventing calcium stones, even in patients who are not hypocitraturic.[220] The potassium salt is preferable to sodium citrate because sodium excretion promotes calcium excretion in parallel and leads to hypercalciuria. Again, potassium citrate in the wax-matrix formulation is preferred to the liquid preparation because of increased palatability. Large amounts may be required (30–75 mEq/day) in divided doses to raise the urinary citrate concentration to more than 320 mg/day. Potassium and bicarbonate levels should be closely monitored, especially in patients with CKD. If metabolic alkalosis or hyperkalemia ensues, reduction of the dose may be necessary.[221,222]

Renal Tubular Acidosis. dRTA (type 1) is a disorder in which distal tubular hydrogen ion excretion is impaired, resulting in a non–anion gap metabolic acidosis and a persistently alkaline urine.[223,224] The acidosis leads to calcium and phosphate release from bone, as well as enhanced proximal tubular reabsorption of citrate and diminished tubular reabsorption of calcium.[8] The net result is an increased filtered load and excretion of calcium and phosphate, severe hypocitraturia, and an elevated urinary pH, all of which promote calcium phosphate precipitation. Nephrocalcinosis, or renal parenchymal calcification, is frequently seen in this setting.[6]

The 24-hour urinary citrate levels are commonly lower than 100 mg in patients with dRTA. Therapy consists of potassium citrate or potassium bicarbonate supplementation to treat both the metabolic acidosis and hypocitraturia. Large doses of these medications are often required: 1 to 3 mEq/kg per day in two or three divided doses.[178,195,206]

Nephrocalcinosis. Nephrocalcinosis is a process in which calcium is deposited in the renal parenchyma.[6] There are two forms: dystrophic calcification and metastatic calcification.

In dystrophic calcification, calcium deposition arises from tissue necrosis secondary to neoplasm, infarction, or infection. It may be seen in the setting of renal transplant rejection, renal cortical necrosis, chronic glomerulonephritis, ethylene glycol toxicity, acquired immunodeficiency syndrome–related infections, and Alport syndrome. In general, in dystrophic calcification, serum calcium and phosphorus levels are normal, and calcium phosphate deposition predominantly occurs in the renal cortex.

In metastatic calcification, patients often have elevated serum calcium and phosphate levels or an elevated urinary pH. Calcification in this setting occurs more commonly in the renal medulla. Common causes include RTA; primary hyperparathyroidism (or any disorder resulting in elevated serum calcium levels); medullary sponge kidney; papillary necrosis; PHO; hereditary hypophosphatemic rickets; and administration of acetazolamide, amphotericin B, oral sodium phosphate bowel preparations, and triamterene. PHO can result in both medullary and cortical calcifications.

Both medullary and cortical parenchymal calcifications are easily noted with ultrasonography and CT scanning, even before they can be detected on plain radiographs. Therapy consists of treating the underlying disorder whenever possible. Otherwise, measures aimed at reducing hypercalcemia, oxalosis, and hyperphosphatemia should be attempted.[38,114,225]

Uric Acid Stones

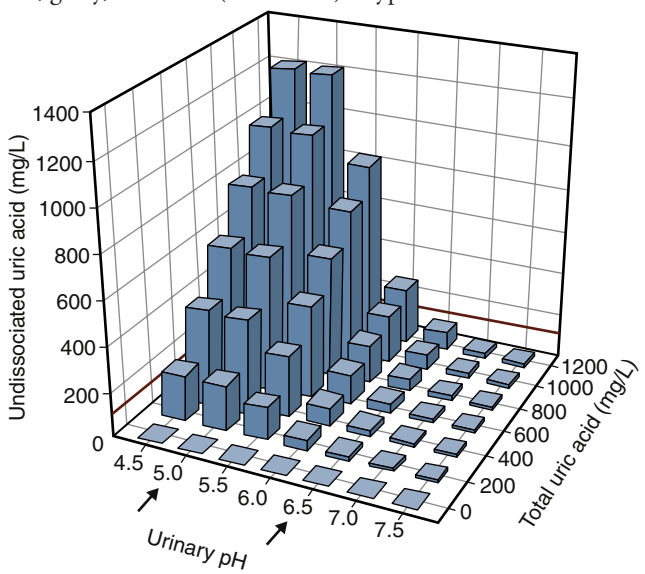
Uric acid lithiasis is far more common in Mediterranean countries than in the United States. However, the incidence of uric acid stones in the United States appears to be rising in parallel

with the epidemic of obesity. Obesity and the metabolic syndrome are associated with insulin resistance, which results in a very low urine pH.[30,226–228] Uric acid stones tend to be round, smooth, and yellow-orange. Because they are radiolucent, they are not visible on plain films but can be detected by ultrasonography or CT or as filling defects on IVP. Uric acid is a purine metabolite and is also found in large quantities within cells. Most patients with uric acid stones have a reduced urinary pH, whereas other less common causes are low urine volume or elevated urinary uric acid levels. Factors associated with uric acid stones are listed in Table 32.3.

A low urine pH is the major cause of uric acid nephropathy. The solubility of uric acid increases sixfold with an increase in urine pH from 5.3 to 6.5[207,226] (Fig. 32.7). Thus, conditions that lower urine pH tend to predispose patients to uric acid lithiasis. Loss of bicarbonate during chronic diarrheal diseases and the higher acid load of diets rich in animal protein lead to acidemia and contribute to an acidic urinary pH. In four studies, every patient with uric acid stones had a urine pH less than 6.0.[229–232] A low urinary pH leads to the formation of poorly soluble uric acid as opposed to the more soluble urate anion, thus predisposing to uric acid lithiasis, even when the total amount of uric acid being excreted is not above normal.[233]

Uric acid stone formers often have greater body weight and a higher incidence of insulin resistance and type 2 diabetes mellitus. Most of these patients have significantly lower urinary pH compared with non–uric acid stone formers. It is thought that insulin resistance leads to impaired ammoniagenesis and ammonium excretion, resulting in excretion of more urinary hydrogen ions with anions other than ammonia and at a lower urinary pH.[29,30,226,230]

Hyperuricosuria may be evident in patients who ingest large quantities of dietary purine or animal protein. Foods high in purine include organ meats, shellfish, certain fish, meat extracts, yeast, gravy, and stock (Table 32.7). Hyperuricemic disorders such as gout, myeloproliferative disorders, tumor lysis syndrome, and certain inborn errors of metabolism (e.g., glucose-6-phosphatase deficiency, Lesch-Nyhan syndrome) can also contribute to an increased urinary filtered load of uric acid. Certain medications such as salicylates and probenecid are hyperuricosuric as well and can predispose patients to uric acid lithiasis.[6,7,30,143,225]



• **Fig. 32.7** The pH and solubility of uric acid. The relationship between undissociated uric acid, total uric acid, and urinary pH is presented. The limit of solubility of undissociated uric acid is depicted by the *colored line* (~100 mg/L). Two hypothetical urine pHs are considered (*two arrows*). At low urinary pH (e.g., 5.0), even a modest amount of total urinary uric acid will exceed its solubility. At high urine pH (e.g., 6.5), even massive hyperuricosuria is well tolerated. (From Maalouf NM, Cameron MA, Moe OW, Sakhaee K. Novel insights into the pathogenesis of uric acid nephrolithiasis. *Curr Opin Nephrol Hypertens*. 2004;13:181–189.)

Therapy for patients with uric acid stones begins with nonspecific measures such as increasing fluid intake to maintain urine volume at about 3 L/day. A lowered animal protein diet is generally beneficial because the decreased endogenous acid production raises urinary pH.[51] Ideally, the urinary pH should be elevated to approximately 6.5 to 7.0, a level that can dissolve existing crystals and stones. However, care should be taken to prevent the urine pH from rising above 7.0 to minimize the risk of calcium phosphate lithiasis. A low-fructose diet may also be beneficial in reducing uric acid levels and hyperuricosuria (see the discussion in the Nonspecific Therapy section).[58]

Potassium citrate at doses of 30 mEq by mouth two times a day or more may be required to raise the urinary pH sufficiently to decrease supersaturation with respect to uric acid (see "Hypercalciuria" and "Hypocitraturia" on available potassium citrate preparations). If the urinary pH cannot be raised adequately despite high doses of potassium citrate or if the dose prescribed results in hyperkalemia, the carbonic anhydrase inhibitor acetazolamide may be initiated. Use of this medication results in an alkaline urine and mild systemic metabolic acidosis, a pattern similar to that in type 1 RTA. The urinary pH should be maintained at less than 7.0 to avoid calcium phosphate precipitation.[206] Prescription of nitrazine paper allows patients to monitor the urinary pH at various times of day and adjust their potassium citrate intake accordingly.

Patients with hyperuricemia are prescribed a low-purine diet to decrease uric acid production. Despite dietary intervention, hyperuricemia often persists, especially in patients with disorders of cellular metabolism. In this setting, allopurinol should be prescribed at a starting dose of 100 mg/day, increasing to 300 mg/day as needed.[72,234] Although sodium bicarbonate can effectively alkalinize the urine, it should be avoided because the additional sodium excretion encourages sodium urate formation, which may result in further crystal formation (see the earlier Hyperuricosuria section).

Struvite Stones

Struvite stones are also called *triple phosphate stones*, *magnesium ammonium phosphate stones*, and *infection stones*.[8] Although they make up only about 10% to 15% of all stones formed, most staghorn calculi (large stones that extend beyond a single renal calyx) are composed of struvite. The propensity of these stones to grow rapidly to a large size, to recur despite therapy, and to result in significant

TABLE 32.7 Foods High in Purine

Organ meats: brain, heart, kidney, liver, sweetbreads
Meat extracts: bouillon, consommé, stock, gravy
Meat: beef, chicken, goose, lamb, pork
Shellfish: clams, mussels, scallops, shrimp, oysters
Fish: anchovies, fish roe, herring, mackerel, sardines, and others
Certain vegetables: asparagus, cauliflower, kidney beans, lentils, lima beans, mushrooms, peas, spinach

Data from Monk RD, Bushinsky DA. Nephrolithiasis and nephrocalcinosis. In: Johnson RJ, Frehally J, Floege J, eds. *Comprehensive Clinical Nephrology*, 5th ed. Philadelphia, PA: Elsevier; 2015:688–702.

morbidity (and potential mortality) has also led to the appellation "stone cancer." Infection with urease-producing bacteria must be present for these stones to form, and therefore severe renal infections, as well as sepsis and loss of renal function, can develop. Factors associated with struvite stones are listed in Table 32.3.

In contrast to other stone types, struvite stones occur with a higher incidence in women than in men, largely because of the increased susceptibility of women to urinary tract infections.[235] Other groups at risk for development of struvite stones because of urinary stasis or infection include elderly people and patients with neurogenic bladders, indwelling urinary catheters, spinal cord lesions, or genitourinary abnormalities. Even without a stone analysis, struvite stones should be suspected in patients with large stones, an alkaline urinary pH (~7.0), and the presence of urease-producing urinary bacteria. Early detection and therapy are essential to prevent great potential morbidity.[145]

Urease-Producing Bacteria. The formation of struvite stones depends on the presence of both ammonium ions and an alkaline urinary pH—conditions met clinically only through the actions of urease-producing bacteria. Ammonium, magnesium, and carbonate apatite [$Ca_{10}(PO_4)_6CO_3$] in the urine combine with phosphate, which is present in its trivalent form in this setting.[8]

Numerous bacteria, both gram negative and gram positive, as well as *Mycoplasma* and yeast species, have been implicated in urease production. Bacteria species in which urease is frequently isolated include *Proteus*, *Haemophilus*, *Corynebacterium*, and *Ureaplasma*. *Escherichia coli*, despite its frequent role as a urinary tract pathogen, has not been shown to produce urease and thus is not implicated in the genesis of struvite stones. Urease production adequate to stimulate stone formation may be present despite low bacterial colony counts. For this reason, the microbiology laboratory should be asked specifically to perform identification of bacteria and determine sensitivities even if colony counts are lower than 100,000 colony-forming units. If no bacteria are isolated but a urease producer is suspected, special cultures should be ordered for *Ureaplasma urealyticum*, which is a mycobacterium that tends to be a fastidious grower on regular culture media.[236]

Therapy for Struvite Stones. To eradicate struvite stones, early and aggressive medical and urologic management is required.[237] Appropriate antibiotic therapy is essential but must be combined with long-term bacterial suppression and complete surgical or medical stone removal. ESWL is often adequate for fragmentation of stones smaller than 2 cm, but percutaneous nephrostolithotomy, or a combination of the two procedures, is usually required for larger stones.[238] Antibiotics should be continued on the basis of cultures of any stone fragments retrieved. After approximately 2 weeks of antibiotic therapy, when the urine culture is sterile, the dose of antibiotic should be halved. Suppressive antibiotics should continue at this dose until monthly surveillance cultures remain sterile for 3 consecutive months. At this point, antibiotics may be discontinued as long as surveillance urine cultures are obtained monthly for 1 year.[236,239]

In addition to antimicrobial therapy, medical treatment may involve urease inhibition and chemolysis. In chemolysis, the kidney is irrigated with an acidic solution through a nephrostomy tube or ureteral catheter. Although rarely used today with the advent of less invasive surgical techniques, this procedure may be useful in the dissolution of residual stone fragments. Ten percent hemiacidrin, the solution most commonly used, is composed of carbonic acid, citric acid, D-gluconic acid, and magnesium at a pH of 3.9. The use of chemolysis has been controversial because high mortality rates have been reported in the past.[240,241] The morbidity and mortality were mainly due to sepsis from instrumentation, local bacterial or fungal infections, and uroepithelial irritation rather than toxicity from the agents. When used as an adjuvant to surgical removal, chemolysis leads to lowered stone and infection recurrence rates.[240,242,243] The safety of the procedure remains in question due to the variety of techniques, stone burden, and comorbidities reported in older literature, but with close monitoring of serum magnesium levels, intrapelvic pressures, infection, and obstruction to flow, it may have a supporting role in the treatment of large struvite stones.[236,240,244]

Urease inhibition has been shown to retard stone growth and prevent new stone formation.[245,246] It does not decrease bacterial counts and cannot eradicate existing stones. Combined with antimicrobial therapy, it serves primarily as palliative care for patients who cannot undergo definitive surgical management. The agent most commonly used is acetohydroxamic acid (AHA). These medications require adequate renal clearance for therapeutic efficacy and are contraindicated in patients with a GFR less than 60. CKD increases the incidence of side effects of these medications, which are numerous and limit their use. Side effects that result in discontinuation of the drug include neurologic symptoms, GI upset, hair loss, hemolytic anemia, and rash. Fortunately, the side effects all resolve with discontinuation of the drug. AHA is also teratogenic. The starting dose of AHA is 250 mg by mouth two times a day. If it is well tolerated for about 1 month, the dose is increased to 250 mg by mouth three times a day.[236]

Cystine Stones

Cystinuria, which is not to be confused with the more serious and debilitating disorder cystinosis that results in extensive intracellular cystine accumulation, is an autosomal disorder that may be recessive or dominant with incomplete penetrance.[247] The disorder is due to mutations of the *SL3A1* gene on chromosome 2 or to mutations of the *SCLC7A9* gene on chromosome 19, both resulting in decreased renal tubular reabsorption and excessive urinary excretion of the dibasic amino acids cystine, ornithine, lysine, and arginine.[248] The genetic defect would probably go unnoticed were it not for the low solubility of cystine of approximately 300 mg/L. Factors associated with cystine stones are listed in Table 32.3.

People with no tubular defect in cystine transport excrete approximately 30 to 50 mg of cystine per day that dissolves in the normal daily urine volume. Patients heterozygous for this condition excrete about 400 mg/day, whereas homozygotes often excrete more than 600 mg/day.[138] Even though the solubility of cystine increases significantly when urine pH is greater than 6.5, the excessive amounts produced in this condition leads to cystine crystals precipitating and aggregating as cystine stones.

Stones usually develop in patients within the second or third decade of life. The stones can grow to a large size and can appear as staghorn calculi or multiple stones. They are radiopaque because of the sulfur content of cystine. The disease should be suspected in any patient with stone onset in childhood, frequent recurrence of nephrolithiasis, and a strong family history of the disease. The presence of the classic hexagonal cystine crystals in the urine can verify the diagnosis. Because these crystals might not be evident in dilute or alkaline urine, qualitative screening with the sodium nitroprusside test better confirms the presence of cystinuria at a concentration greater than 75 mg/L. Quantitative cystine measures with a 24-hour urine sample should follow to determine the risk of stone formation and to guide therapy.

Therapy for Cystine Stones. The aim of treatment is to lower the urinary cystine concentration below the limits of solubility

(~300 mg/L). Patients are advised to drink large quantities of fluids. A patient with a cystine excretion of 750 mg/day, for example, should ideally drink enough fluid to increase urine output to more than 3 L/day. Large quantities of milk should be avoided because dairy products and foods high in protein contain large amounts of methionine, an essential amino acid that is a precursor of cystine.[249] Because cystine is more soluble at a higher pH, juices are encouraged because they tend to alkalinize the urine. Potassium citrate (see the Hypercalciuria and Hypocitraturia sections for details) is also prescribed to maintain the urinary pH between 6.5 and 7.0.[250]

Approximately 50% of cystine stones are mixed stones. Patients with cystinuria often have other metabolic defects such as hypercalciuria, hypocitraturia, and hyperuricosuria. Therefore, a complete 24-hour urine collection for all stone-forming elements is necessary to treat nephrolithiasis fully in this setting. Restricting dietary sodium is also beneficial.[251]

If these measures are inadequate in controlling stone formation or if the urinary cystine concentration is too high to make adequate fluid intake practical, chelating agents called *cystine-binding thiol drugs* (CBTDs) may be added. Increasing urine pH increases the efficacy of thiol drugs.[250] D-Penicillamine is a CBTD that reduces the cystine concentration by forming a more soluble compound with cystine.[252] However, this medication is associated with numerous serious side effects that limit its use. Other CBTDs, such as tiopronin, α-mercaptoproprionyl glycine, and bucillamine, are now available that reduce the cystine concentration with fewer side effects.[138,253–255]

Physiology of Insulin Secretion

ELE FERRANNINI AND ANDREA MARI

CHAPTER OUTLINE

KEY POINTS

- Beta-cell function is central for glucose homeostasis: insulin secretion is finely regulated by multiple mechanisms to ensure appropriate hormone delivery under changing short-term conditions (e.g., variable nutrient intake) and longer-term circumstances (e.g., obesity, insulin resistance, pregnancy).
- At a cellular level, the current model features different populations of cytoplasmic insulin granules based on their ability to undergo rapid exocytosis. An immediately releasable pool underlies the fast insulin secretion phenomena, and its exocytosis is triggered by membrane depolarization and calcium influx consequent to glucose metabolism. The amplifying role of glucose contributes to sustained insulin secretion and likely involves changes in granule status.
- The insulin secretion response is polymorphic, and its in vivo study requires different tests to assess different response modes.
- The main stimulus for insulin secretion is glucose. Measurement of plasma C-peptide concentrations during an oral (OGTT or mixed meal) or intravenous (hyperglycemic clamp, and graded glucose infusion) glucose tolerance test coupled with mathematical modeling allow recapitulating the main insulin secretion characteristics that are relevant to both normal and impaired glucose tolerance.
- In an oral glucose tolerance test, the insulin secretion excursions parallel those of glucose concentration, thereby defining a dose response relating the two variables, which is the most important beta-cell response mode. Additional modes include an anticipatory secretion phase at rising glucose and potentiation over time.
- An important longer-term insulin secretion adaptative response is the insulin secretion increase with insulin resistance.
- Reduced beta-cell glucose sensitivity and increased absolute insulin secretion characterize the early stages of glucose intolerance and predict progression to overt diabetes.

Introduction

The endocrine pancreas is made up of roughly 3 million islets scattered through the exocrine tissue, for a total weight of about 1 g (under 3% of the pancreas volume).[1] The human islet is populated by beta cells intermingled with α cells, δ cells, γ cells, and ε cells, secreting glucagon, somatostatin, pancreatic polypeptide, and ghrelin, respectively. Beta cells are the most abundant cell type (composing about 60% of islet cells) and represent a higher proportion of all endocrine cells in smaller, compared with larger, islets. Small islets also have a higher insulin content and are in closer contact with blood vessels, thereby representing a functionally distinct subpopulation. The spatial arrangement of cells within the islet is also important for islet function. Although beta cells are irregularly distributed in human islets, when stimulated by glucose, membrane potentials and cytoplasmic Ca^{2+} concentration ($[Ca^{2+}]_c$) show a complex pattern of oscillations in both single beta cells and whole islets.[2] Furthermore, gap junctions provide connectivity, which may be devolved to small clusters of cells with pacemaker properties.[3] The origin and regulation of intrinsic electrical oscillations and hyperspecialized beta-cell subsets are still under investigation, but the heterogeneity of islets, and of beta-cell subsets within them, adds levels of complexity to well-known intra-islet interactions among different cell types (e.g., paracrine inhibition of glucagon secretion by insulin, inhibition of glucagon and insulin secretion by somatostatin). Moreover, endogenous

islet regeneration may occur not only by neogenesis from ductal cells and beta-cell replication but also by transdifferentiation of α cells[4] or δ cells[5] following extreme beta-cell loss.[6] Therefore, a novel concept emerging in beta-cell science is that function is not only the result of mass and quality of beta cells but of the architecture and structural integrity of the islet as an organ.

Beta cells express a large number of transporters and receptors on their plasma membrane; their simultaneous or sequential ligand engagement following a variety of stimuli is eventually integrated into a given secretion rate.[7] Like neurons, whose response to multiple synaptic inputs is an action potential, the beta cell modulates its secretory response in phase and amplitude (i.e., in time course and amount) to precisely fit the stimulus.[8] The overwhelming complexity of stimulatory and inhibitory signals and their intracellular transduction and modulation can be operationally reduced to two main physiologic domains: a triggering pathway, starting at the cell membrane level, and an amplifying pathway, which is mostly intracellular.[9] Thus, glucose enters beta cells via the isoform 2 of the glucose transporter (GLUT2) and is metabolized through the glycolytic pathway and, subsequently, in mitochondria. The first rate-limiting step in this process is the phosphorylation of glucose to glucose-6-phosphate. This reaction is mediated by the enzyme glucokinase, which, by determining the rate of glycolysis, functions as the glucose sensor.[10] Glucose metabolism raises adenosine triphosphate (ATP) production, leading to closure of the ATP-sensitive potassium (K_{ATP}) channel and membrane depolarization. This causes Ca^{2+} entry through the voltage-dependent Ca^{2+} channel and elevation of $[Ca^{2+}]_c$, which initiates exocytosis of the hormone from readily releasable granules. The increase in ATP production is likely due both to nicotinamide adenine dinucleotide production at the glycolytic step of glyceraldehyde-3-phosphate oxidation and to pyruvate oxidation in the tricarboxylic acid cycle in mitochondria. The increase in ATP not only closes K_{ATP} channels but also serves as a major permissive factor for movement of insulin granules and for priming of exocytosis.

The biology of K_{ATP} channels is relevant for beta-cell physiology. These channels include sulfonylurea receptors (SURs) and potassium inward rectifiers (Kir6.1 and Kir6.2), which assemble to form a large octameric channel. In the beta cell, the SUR1/Kir6.2 pairs constitute the K_{ATP} channel, which controls the flux of potassium ions. Importantly, the opening of these channels can reset the resting membrane potential below the threshold for activation of voltage-gated Ca^{2+} channels, thereby aborting insulin secretory bursts. This occurs when plasma glucose levels are low or on insulin stimulation, in the latter case, installing an autocrine control of insulin secretion.[11] Mutations in both components of the beta-cell K_{ATP}—SUR1 (encoded by the *ABCC 8* gene) and Kir6.2—have been shown to lead to hypersecretion of insulin, resulting clinically in either a recessive form of familial hyperinsulinemia or persistent hyperinsulinemic hypoglycemia of infancy.

The amplifying pathway also requires glucose metabolism but is K_{ATP} channel independent. In signal amplification, cyclic adenosine monophosphate (cAMP) plays an important role. This second messenger is generated at the plasma membrane from ATP and potentiates glucose-stimulated insulin secretion, particularly in response to glucagon, glucagon-like peptide 1 (GLP1), and glucose-dependent insulinotropic peptide (GIP). The cAMP–dependent pathways appear to be particularly important in the exocytotic machinery.

More recently, additional molecules have been shown to act as glucose sensors independent of glucose metabolism.[12] In rodent systems, these are cell-surface receptors identified by blocking glucose utilization following the application of a glucose stimulus. They also work by changing the synarchic messengers cAMP and $[Ca^{2+}]_c$. These additional glucose sensors have tentatively been defined as heterodimers of an atypical sweet taste receptor (T1R3) and a calcium-sensitive receptor (CaSR). Their role in human beta cells and in vivo insulin secretion is still under investigation.

Neural Regulation of Beta-Cell Function

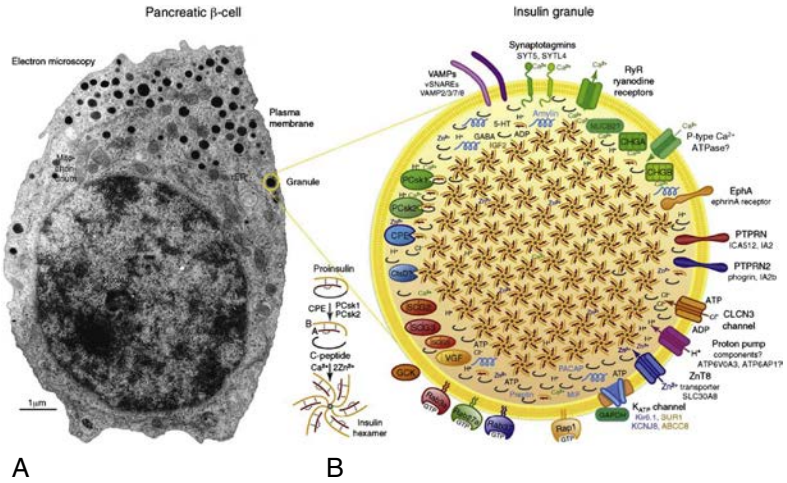
The brain provides supplemental control of insulin and glucagon secretion via efferent nerves penetrating the pancreatic islet.[13] Sympathetic stimulation (through α2 receptor–mediated norepinephrine release) inhibits insulin secretion and potentiates glucagon secretion,[14] whereas parasympathetic stimulation (through M3 muscarinic-mediated acetylcholine release) enhances insulin and glucagon release.[15] These autonomic circuits emanate from hypothalamic regions that differentially control hormone release. In particular, experimentally lowering glucose sensing in glucokinase-expressing neurons of the arcuate nucleus results in deficient glucose-stimulated insulin secretion and glucose intolerance, whereas the same manipulation in the lateral hypothalamic area results in enhanced glucose sensitivity and glucagon response to hypoglycemia.[16] The relative contribution of the brain/islet axis to whole body glucose homeostasis and counterregulation is difficult to quantitate in humans; however, it is interesting that in rodents, islet grafts under the kidney capsule[17] or in the anterior chamber of the eye[18] undergo timed peri-islet and intra-islet reinnervation, a striking example of neuroplasticity.

Beta-Cell Mass

Beta cell mass is the net balance between positive factors, including islet neogenesis, beta-cell proliferation, and beta-cell hyperplasia, and negative factors such as beta-cell apoptosis and dedifferentiation.[6] Despite being a terminally differentiated cell type, β cells are not entirely postmitotic. In humans, most beta-cell neogenesis from ductal epithelial progenitor cells occurs preterm; together with a neonatal burst of β-cell replication (from pancreatic progenitor and/or ductal precursor cells), the full complement of beta-cell mass is established within the first 5 years of life. Thereafter, beta-cell proliferation is very low, with the average lifetime of beta cells extending to about 25 years.[19] However, at the islet periphery, a specialized microenvironment or neogenic niche harbors a population of transcriptionally immature (virgin) beta cells, which constitute a lifelong reservoir of new beta cells.[20] Such cells have an intermediate phenotype between α-cells and mature beta cells and can transdifferentiate to one or the other depending on prevailing signals, such as increased insulin demand (as in obesity, extreme beta-cell loss or pregnancy) or stressors (e.g., hyperglycemia, oxidative overload as in the transition from normal glucose tolerance to type 2 diabetes [T2D]).[4-6] Of note, replicating beta cells upregulate hundreds of proliferation-related genes, but not genes involved in beta-cell function (glucose sensing and insulin secretion), suggesting that the quiescence-proliferation transition involves global amplification of gene expression, except for a subset of tissue-specific genes.[21] Efforts to catalog the transcriptional program of replicating beta cells are key not only to account for the physiologic plasticity of islet cell types but also to identify molecular pathways of beta-cell generation for potential transplant-based therapies.

Beta-Cell Insulin Content

Despite its small size, the endocrine pancreas has a large functional reserve, as pancreatic insulin content has been estimated to be in the range of 200 to 250 units (a 10-day supply for a healthy lean



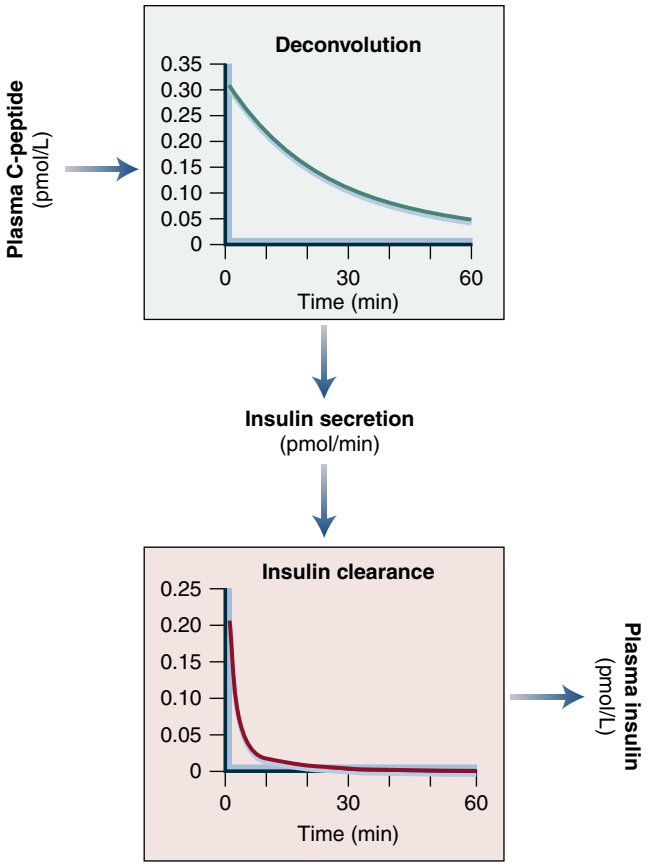
• **Fig. 33.1** (A) Electron micrograph of a human beta cell. The electron-dense spherical bodies in the cytoplasm are insulin granules, some in close proximity of the plasma membrane. Mitochondria and endoplasmic reticulum are also visible. (B) An insulin granule is blown up to schematically highlight its complex structure: in addition to insulin hexamers, receptors, ion channels, transporters, and other proteins are located in the vesicle membrane and within the granule. Also indicated is the maturation of the insulin prohormone proinsulin to insulin (A and B chain) and C-peptide catalyzed by carboxypeptidase E (CPE) and proconvertases (PCsk1 and PCsk2). *5-HT*, 5-Hydroxytryptamine (serotonin); *GABA,* γ–aminobutyric acid; *IAPP,* islet amyloid polypeptide; *IGF2*, insulin-like growth factor 2; *INS,* insulin; *MIF,* macrophage migration inhibitory factor; *PACAP,* pituitary adenylate cyclase-activating polypeptide. (From Suckale J, Solimena M. The insulin secretory granule as a signaling hub. *Trends Endocrinol Metab*. 2010;21[10]:599–609.)

adult). Within the beta-cell cytoplasm, insulin is packaged in 5000 to 8000 secretory granules spatially distributed in age-distinct populations.[22] As shown in Fig. 33.1, each granule (300–350 nm in diameter) contains an electron-dense core composed of tightly packed crystals of insulin hexamers stabilized by one calcium and two zinc ions.[23] Granules are not just delivery depots but dynamic structures containing many proteins, small molecules, and ions in the lumen, as well as several transmembrane proteins, channels, and membrane-associated proteins. Granule turnover and trafficking is a highly regulated process involving relationships with the cytoskeleton, intracellular insulin degradation, mobility (dynamic, restricted, or nearly none), docking, and fusion with the plasma membrane (mediated by soluble N-ethylmaleimide–sensitive factor attachment protein receptor [SNARE] proteins).[22,23] Functionally, the established facts are that (1) only a small fraction (much less than 1%) of granule insulin is secreted in response to acute in vitro glucose stimulation; (2) granule half-life is less than 5 days, with intracellular degradation starting already within about 3 days; and (3) younger granules are fewer but more mobile than older granules even if they come from deep in the cytoplasm and therefore form a readily releasable pool. Which features of secretory granule dynamics—age, position in the cell, and molecular signature—are critical for which aspect of in vivo insulin release dynamics and which steps may be altered in the diabetic state remain to be determined.

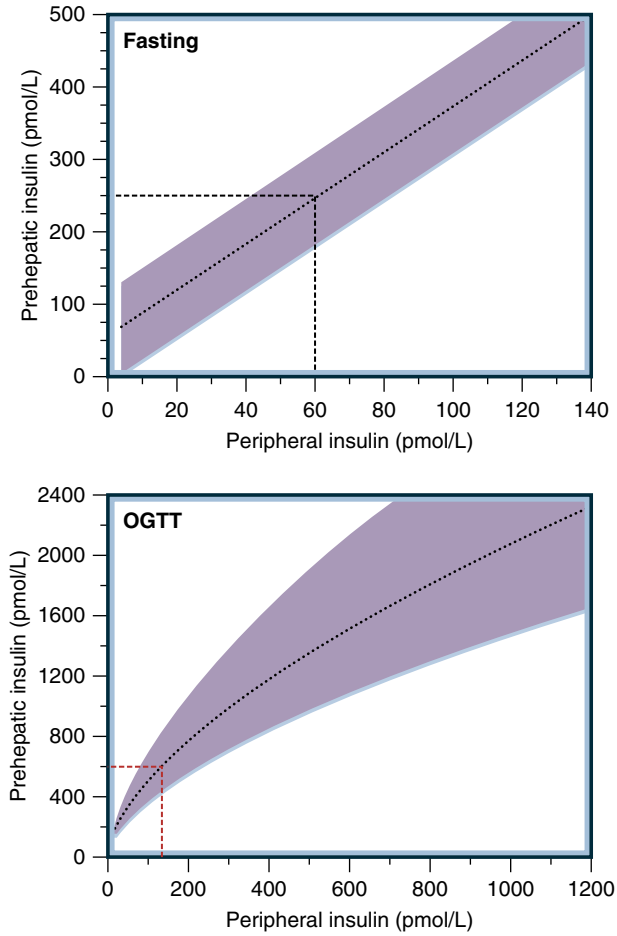
Insulin Secretion Versus Plasma Insulin

Circulating insulin concentrations are a function of secretion and clearance, which is complicated by the appearance of the hormone first into the portal circulation and by substantial hepatic clearance. Insulin secretion normally cannot be measured directly due to the inaccessibility of the portal circulation. Thus, when assessing insulin secretion in vivo, methods based on the measurement of C-peptide currently are state of the art. The principles of this method are that (1) C-peptide is co-secreted with insulin in equimolar amounts as a consequence of proinsulin cleavage, (2) C-peptide is not extracted by the liver, and (3) C-peptide clearance—half of which occurs through the kidney[24]—is approximately constant in any given individual. By this approach, insulin secretion is calculated using a mathematical procedure called *deconvolution*,[25] which reconstructs the pancreatic insulin secretion rate (in pmol/min) as it occurs before hepatic insulin degradation,[26,27] and can be reliably estimated from individual anthropometric data.[28] Thus, transducing plasma C-peptide measures into plasma insulin concentrations involves two catabolic processes (and computational steps) in series with one another (Fig. 33.2). Considering that about 15% of renal C-peptide uptake is excreted intact into the urine (the remainder being degraded),[24] measurements of the ratio of urinary C-peptide to creatinine have been shown to be reasonably well correlated with postprandial plasma C-peptide levels[29] and may therefore be used as indicators of residual beta-cell function in patients with type 1 diabetes.[30]

Because plasma insulin kinetics are fast, insulin secretion rates are quickly reflected in plasma insulin concentrations, which therefore are the prime and most widely used proxy for insulin secretion. However, insulin clearance may vary during stimulation of insulin secretion and may be lower or higher depending on the metabolic status. Hence, insulin concentrations may distort the actual time course of insulin secretion. Insulin clearance occurs through two principal routes depending on the site of entry of the hormone into the circulation: (1) peripheral (or exogenous) insulin clearance ($pMCR_I$), which can be determined experimentally during a euglycemic hyperinsulinemic clamp as the ratio of exogenous insulin infusion rate to arterial plasma insulin concentration at steady state, and (2) prehepatic (or endogenous) insulin



• **Fig. 33.2** The pancreatic insulin secretion rate is reconstructed by deconvolution of plasma C-peptide concentrations by the C-peptide disappearance rate (*green curve*). Secreted insulin then undergoes fast clearance (*red curve*), eventually yielding plasma insulin concentrations.



• **Fig. 33.3** Relationship between calculated prehepatic and measured peripheral plasma insulin concentrations in 1123 normoglycemic subjects (mean fasting plasma glucose of 90 mg/dL [5.0 mmol/L]) after an overnight fast (*fasting*) and during the absorption of a 75-g oral glucose load (OGTT). Note the linear relationship between prehepatic and peripheral insulin levels in the fasting state and the curvilinear relationship during the OGTT, indicating saturation of insulin degradation. The fasting range is plotted on the OGTT range (*dashed lines*). *OGTT,* oral glucose tolerance test. (Data from Ferrannini E, Balkau B, Coppack SW, et al. Insulin resistance, insulin response, and obesity as indicators of metabolic risk. *J Clin Endocrinol Metab*. 2007;92[8]:2885–2892.)

clearance ($eMCR_I$). Direct experimental determination of $eMCR_I$ is hampered by the difficulty of gaining access to the portal vein where pancreatic insulin is secreted. However, endogenous insulin clearance can be calculated as the ratio between endogenous insulin secretion—reconstructed from C-peptide deconvolution—and arterial plasma insulin concentration at steady state.

If both $eMCR_I$ and $pMCR_I$ are known from separate experiments, their fractional difference—for instance, ($eMCR_I$ – $pMCR_I$)/$eMCR_I$)—is an estimate of fractional hepatic insulin extraction. The fraction of portal insulin that is removed by the liver in its first pass is about 65%, ranging between 50% and 70%.[31,32] Once in the systemic circulation, insulin recirculates to, and is further cleared by, the liver and, to a lesser extent, by skeletal muscle and the kidneys. The overall contribution of the liver (first pass plus recirculation) is therefore dominant (approximately 80%). The physiologic characteristics of exogenous insulin clearance ($pMCR_I$ from insulin clamp studies) include large interindividual variability; saturation kinetics[31]; a substantial influence of genetic factors[33,34]; and, to a lesser extent, a negative effect of abdominal obesity and liver fat.[35,36]

By using the C-peptide method to calculate $eMCR_I$ and an estimate of hepatic plasma flow, one can reconstruct prehepatic (70% portal, 30% hepatic arterial) plasma insulin concentrations. As shown in Fig. 33.3, in individuals with normal glucose tolerance, fasting prehepatic insulin concentrations are related to peripheral insulin levels in an approximately linear fashion, with an average ratio of 4:1. In the fed state (e.g., after an oral glucose load), $eMCR_I$ is lower than in the fasting state as a consequence of saturation of liver extraction. The contribution of muscle is reduced,[37] whereas that of the kidney is increased,[31] although together they still contribute no more than 20% to overall insulin clearance. As a consequence, the ratio of prehepatic to peripheral insulin is progressively lower as pancreatic insulin release increases (see Fig. 33.3).

Multiple mechanisms appear to modulate insulin degradation. In mice lacking zinc-transporter 8 (ZnT8), which enriches the insulin vesicles in zinc, the clathrin-dependent insulin endocytosis in the hepatocyte is reduced; individuals with a single nucleotide polymorphism in the gene encoding for this transporter also display an increased insulin clearance during an oral glucose tolerance test (OGTT).[38] Neural inputs[39] and cellular redox state[40] may also influence insulin degradation, whereas gut hormones do not affect this process.[41] Many drugs may interfere with insulin degradation, especially at doses causing a degree of hepatotoxicity. Among antidiabetic agents, sulphonylureas are known to reduce

insulin clearance.[42] Whether this effect is a direct one on the degrading machinery or is secondary to saturation due to insulin hypersecretion is not known.

The role of insulin clearance in the maintenance of glucose homeostasis is complex. A reduction in insulin degradation is commonly interpreted as compensatory, with lower values being observed in individuals who are more insulin resistant and would take advantage of increased insulin levels. On the other hand, experimental animals in which the insulin-degrading enzyme is knocked out develop insulin resistance and diabetes.[43] Similarly, fasting hyperinsulinemia and mild degrees of insulin resistance develop in pancreas-transplanted patients with organ venous drainage into the systemic circulation as compared with those with portal drainage.[44] However, insulin clearance can influence glucose tolerance independently of other factors. For instance, an acute 30% increase in insulin clearance, produced by systemic nitric oxide inhibition, worsens glucose tolerance in normal glucose-tolerant persons.[45] Thus, it is difficult to cleanly dissect out saturation from a bidirectional association of insulin clearance and insulin action. The bulk of evidence, however, indicates that even after accounting for saturation of degrading capacity, insulin clearance is positively associated with insulin sensitivity regardless of the temporal sequence of changes in these two functions.

Characteristics of Insulin Secretion In Vivo

Insulin acts on several target metabolic pathways, such as lipids and amino acids, which also influence its secretion; however, the tightest physiologic feedback is with plasma glucose concentration. In vivo, beta-cell function must supply insulin to body tissues in amounts and time course apt to maintain plasma glucose within a narrow concentration range on a minute-by-minute basis. To this end, insulin output must handle acute challenges, such as size, composition, and appearance rate of meals, and adapt to long-term settings, such as changes in target tissue sensitivity to insulin. In comparison, insulin action, if equally complex at the cellular level, is functionally relatively stable within any given individual. In fact, when measured in vivo by a direct technique (the euglycemic hyperinsulinemic clamp), insulin sensitivity has been shown to vary by 30% to 80% during 24 hours of free living.[46] In most cases, insulin sensitivity can at best double with physiologic or pharmacologic intervention. In contrast, insulin secretion can vary manyfold in the same person in a matter of minutes, as occurs with a large mixed meal, or over years, as happens with weight gain.[47] For example, a lean, insulin-sensitive adult may need as little as 0.5 units of insulin to dispose of an oral load of 75 g of glucose over 2 hours, whereas an obese, insulin-resistant, glucose-intolerant person may require 45 units to perform the same task—an approximate 100-fold span.[48]

Given the highly polymorphic nature of beta-cell responses, absolute insulin secretion is a meaningful index of beta-cell function only in the context of a standardized stimulus (mainly glucose). For this reason, typical protocols employ a controlled stimulus, such as a hyperglycemic clamp (described in the following). When the stimulus is not standardized, the secretory response can be empirically normalized by calculating ratios between insulin (or insulin secretion) and glucose (absolute or incremental values or areas under the response curves). For instance, the time-honored insulinogenic index uses the ratio of 30-minute increments from baseline of insulin and glucose concentrations from an OGTT.

More elaborate approaches rely on mathematical models, which have been widely used to assess beta-cell function from clinical tests—in which glucose levels are not controlled—and also to gain insight into the mechanisms governing insulin secretion.[49] In general, these models relate insulin secretion rates to concomitant plasma glucose concentrations on the basis of a formal description of the secretory machinery. Requisites for such models are a simplified description of the system—to allow robust mathematical identifiability of its parameters—and a realistic congruity with known features of beta-cell function as emerging from cellular physiology.

Modes of Beta-Cell Response

There are multiple in vivo tests of beta-cell function (described later). Each in vivo test of insulin secretion reveals some aspect of beta-cell function; however, alone, none recapitulates the polymorphic nature of insulin's secretory response. The main modes of beta-cell response include (1) first-phase or acute insulin secretion, (2) glucose sensitivity, and (3) potentiation of insulin secretion. These three main features of insulin secretory response were already identified in isolated perfused rat islets more than four decades ago[50] and can be resolved by modern mathematical modeling from multiple types of stimulation.[49,51,52] First-phase insulin release is the sharp and short-lived peak of insulin secretion elicited by a brisk rise in glucose levels. Its magnitude depends on the size of the glucose stimulus and can be also represented as a function of the glucose rate of change (also called *rate sensitivity*, *anticipation*, or *derivative component*). First-phase insulin secretion is rarely observed under free-living conditions, although a biphasic response can be occasionally detected during an OGTT. Despite much investigation, the physiologic interpretation of the biphasic secretory response to a glucose step is still somewhat uncertain. Single-cell electrophysiologic studies have shown that acute exposure to high glucose enhances electrical activity synchronously with spikes in cytosolic calcium concentrations, which parallel insulin release both in terms of glucose dependency and time course.[53] Morphometric studies have shown that the beta cells harbors different populations of secretory granules, in different stages of maturation and in variable spatial array between the trans-Golgi and the plasma membrane, constituting a chain of secretory pools in dynamic exchange with one another.[54] First-phase insulin secretion contributes an estimated one tenth (about 3 nmol/m^2) of suprabasal secretion during a 2-hour OGTT; nevertheless, a prompt stimulation of insulin release as soon as glucose starts to rise is crucial to suppress endogenous glucose production and to prime tissue glucose uptake, thereby curbing subsequent glycemic excursions.[55]

Beta-cell glucose sensitivity measures the increase in secretion rate for any concomitant increase in plasma glucose concentration. This key mode of response determines the amount of insulin secreted during a meal and therefore is a major control of glucose tolerance. In fact, decreased glucose sensitivity is a hallmark of all forms of glucose intolerance.

Potentiation of insulin secretion is an intrinsic feature of beta-cell function. Potentiation occurs when the dose-response relationship between glucose level and insulin secretion is enhanced, as when prior exposure to glucose leads to a greater insulin secretion on subsequent exposure. Potentiation may be generated by a glucose "memory," incretins, or factors such as glucagon, cholinergic stimuli, other nutrients such as fructose, or drugs including sulfonylureas.[56]

From this description, it is clear that maintenance of glucose homeostasis depends not only on the absolute amount of insulin release but also on the time dynamics of the secretory response.

Other clinical tests reveal additional details of beta-cell function. For example, an arginine bolus superimposed on ramping glycemic plateaus explores the effect of an amino acid separately from that of glucose and has been used to estimate maximal secretory capacity.[57] Furthermore, many studies have gauged the influence on insulin secretion of different amino acids,[58] endogenous[59] or exogenous free fatty acids (FFAs),[60] incretin hormones[61] and neural stimuli.[62] These influences depend on stimulus quality, dose, route of delivery, duration (acute or chronic), combination with other stimuli, and simultaneous impact on insulin sensitivity. Ultimately, however, beta cells integrate all inputs and respond in a manner that can be analyzed in quantifiable terms of glucose sensitivity, potentiation, and rate sensitivity. Table 33.1 reports normative values of basic parameters of beta-cell function as measured in a large group of lean (body mass index ≤25 kg/m^2) healthy volunteers with normal glucose tolerance.

Insulin Secretion in the Fasting State

In healthy normoglycemic adults after an overnight (10–14 hours) fast, insulin secretion rates range widely, in rough proportion to the degree of obesity (and insulin resistance, see later discussion) and equally in women and men (Fig. 33.4). In addition to obesity, fasting insulin secretion values are also physiologically dependent on fasting plasma glucose levels. Thus, in hyperglycemic patients (e.g., individuals with impaired glucose tolerance [IGT] or overt T2D), fasting insulin secretion is generally higher than in normoglycemic subjects at each level of obesity.

When frequently sampled from portal vein blood, insulin concentrations oscillate, with detectable pulses at 5- to 14-minute intervals.[63,64] The pulsatility of insulin secretion is intrinsic to the islet and may reflect coupling between slow oscillations of glycolysis and faster oscillations involving Ca^{2+} fluxes.[65] Over 24 hours, slower ultradian cycles occur at 80- to 180-minute intervals; these can be entrained by small subthreshold changes in plasma glucose concentrations.[66] Pulsatile insulin secretion is disrupted in hyperglycemic states,[66,67] but its impact on insulin action on target organs (liver and peripheral tissues) is uncertain.

The ratio of proinsulin to insulin concentration (or the absolute proinsulin concentration adjusted for insulin) in a fasting plasma sample has been proposed as a marker of beta-cell function.[68] In epidemiologic studies, a higher ratio of proinsulin to insulin or proinsulin to C-peptide has been related to incident diabetes.[69]

TABLE 33.1 Insulin Secretion Parameters in Lean Persons With Normal Glucose Tolerance

	Mean	Median	25–75%
Fasting plasma glucose (mmol/L)	4.81	4.90	4.60–5.10
2-hour plasma glucose (mmol/L)	5.18	5.10	4.33–6.00
Fasting plasma insulin (pmol/L)	26	23	17–32
2-hour plasma insulin (pmol/L)	139	119	75–177
Fasting insulin secretion rate (pmol·min^{-1}·m^{-2})	61	58	46–72
Insulin secretion at 5 mM glucose (pmol·min^{-1}·m^{-2})	86	68	48–93
Total insulin output (2 hours) (nmol·m^{-2})	37	36	29–44
Beta-cell glucose sensitivity (pmol·min^{-1}·m^{-2}·mM^{-1})	150	125	91–181
Rate sensitivity (nmol·m^{-2}·mM^{-1})	1.06	0.69	0.01–1.43
Potentiation (ratio)	2.34	1.83	1.26–2.73
Insulin sensitivity (μmol·min^{-1}·kg$_{FFM}$·nM^{-1})	165	155	117–199

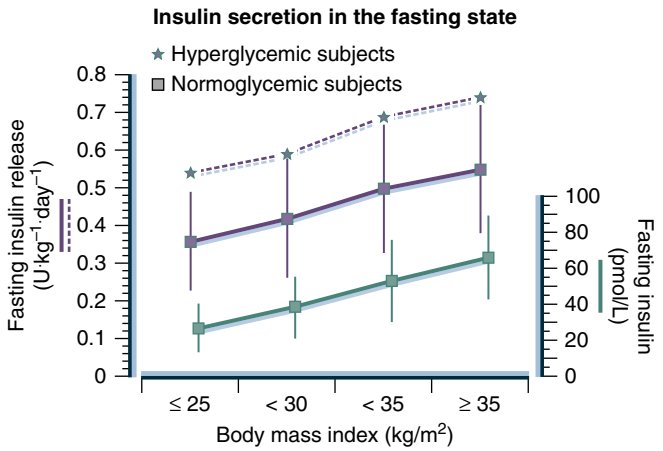
Data from 620 participants in the RISC study.[11]

Insulin Secretory Response to Intravenous Glucose

Various formats of intravenous glucose administration have been used to gauge beta-cell response independently of gastrointestinal influences.

Hyperglycemic Clamp and Biphasic Insulin Secretion

The hyperglycemic clamp protocol has been used in vivo, in the perfused pancreas, and in islet cultures. The rationale of this test is to expose beta cells to a square wave of hyperglycemia, whereby glucose concentration is abruptly raised and kept constant at a preset suprabasal level by means of a controlled variable glucose infusion. The insulin secretory response to this challenge



• **Fig. 33.4** Fasting plasma insulin concentrations and corresponding fasting insulin secretion rates (extrapolated to 24 hours) in 1123 normoglycemic subjects (mean fasting plasma glucose of 90 mg/dL [5.0 mmol/L]) by conventional category of obesity (lean, overweight, moderate, and severe obese). Plots are mean ± 1 standard deviation. Stars indicate mean values of fasting insulin secretion (corresponding insulin concentrations not indicated) in 289 subjects with impaired glucose tolerance or overt diabetes. (Data from Ferrannini E, Balkau B, Coppack SW, et al. Insulin resistance, insulin response, and obesity as indicators of metabolic risk. *J Clin Endocrinol Metab*. 2007;92[8]:2885–2892 and Ferrannini E, Gastaldelli A, Miyazaki Y, et al. Beta-cell function in subjects spanning from normal glucose tolerance to overt diabetes: a new analysis. *J Clin Endocrinol Metab*. 2005;90[1]:493–500.)

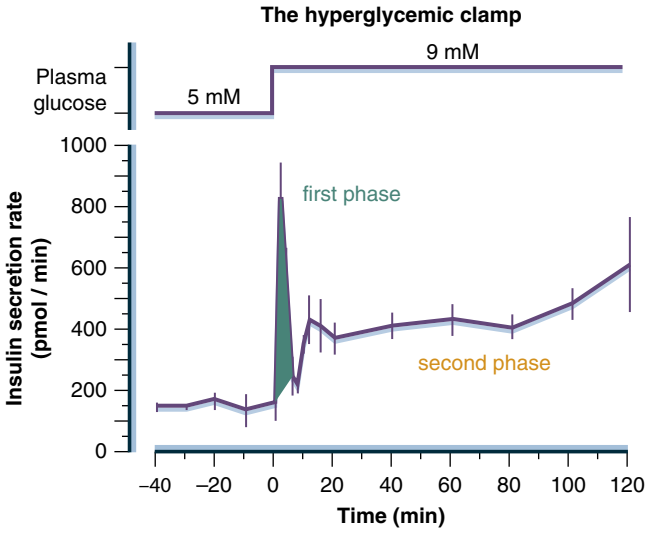
typically is biphasic, with an initial sharp insulin secretory burst lasting about 5 to 8 minutes (first-phase secretion), followed by a transient decrease and then a progressive slow increase, which continues as long as hyperglycemia is maintained (second-phase secretion) (Fig. 33.5).

The amount of insulin secreted during the first phase (also referred to as acute insulin response [AIR]) is dependent on the magnitude of the glucose rise; in a typical + 126 mg/dL (+7 mmol/L) hyperglycemic clamp, it is approximately 4 nmol per square meter of body surface area (~1 unit in a 70-kg adult), representing 10% to 15% of what is secreted per hour during the second phase. Although small, the amount of insulin secreted in the first phase is relevant for at least two reasons. First, although the secretory burst is apparent with a rapid elevation in glucose concentration, the underlying mechanisms appear to operate even for a more gradual rise in glucose concentration. These mechanisms are likely responsible for a response that is anticipated compared with what would be predicted solely on the basis of the dose response. As discussed later, this anticipation has relevant physiologic implications for glucose homeostasis. Second, attenuated first-phase insulin secretion is a very sensitive marker of early beta-cell dysfunction.[70] Impairment of first-phase secretion is already present in individuals at risk of developing diabetes[71] and is predictive of diabetes onset.[72] Because of these relevant characteristics, assessment of first-phase secretion has been widely used.

Higher glycemic plateaus elicit larger secretory responses. However, if multiple glucose steps are applied in sequence, the first-phase response is progressively attenuated while second-phase secretion increases in proportion to the height of the glycemic plateaus.[73] This paradoxical behavior may reflect an inhibitory influence of antecedent glycemia on the subsequent first-phase response or depletion of the pool of readily releasable insulin granules.[51,74]

Intravenous Glucose Tolerance Test

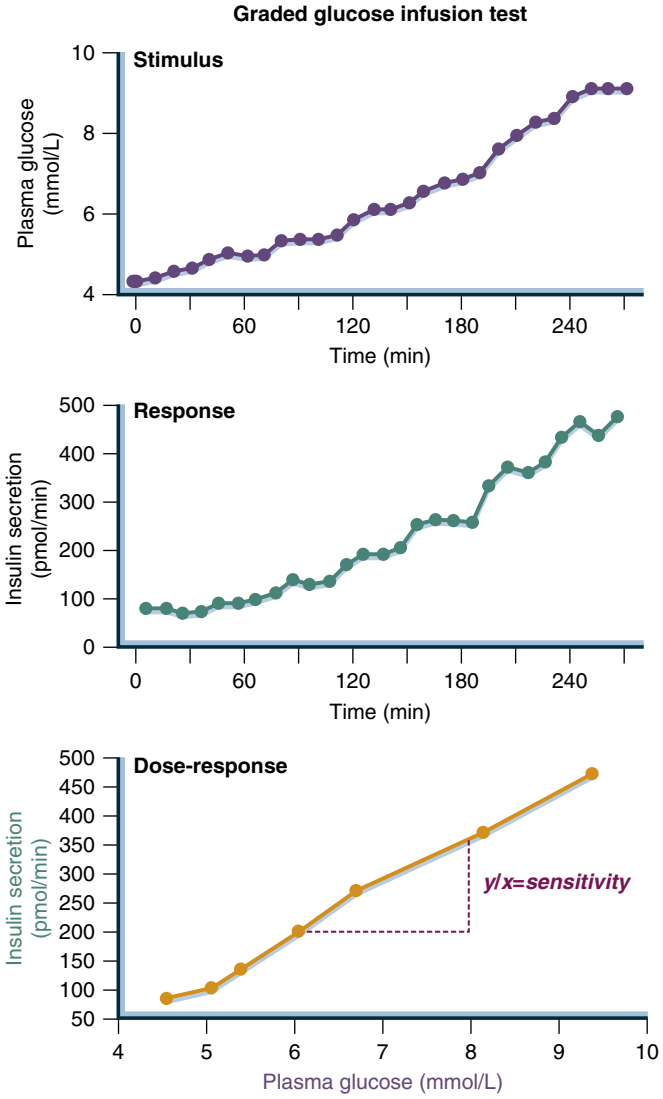
Another clinical test yielding the biphasic insulin response is the intravenous glucose tolerance test (IVGTT). Here, a glucose bolus standardized to body size is injected intravenously, and glucose, insulin and, possibly, C-peptide concentrations are measured. In contrast to the hyperglycemic clamp, glucose concentrations fall rapidly after the initial peak, and second-phase secretion is not sustained but transient with a multiphasic pattern.[25] Thus, the assessment of first-phase secretion is very similar between the hyperglycemic clamp and the IVGTT, whereas second-phase secretion on the IVGTT occurs at variable glucose and is thus less representative. Like the hyperglycemic clamp, the IVGTT has demonstrated the relevance of first-phase secretion as a hallmark of beta-cell function.



• **Fig. 33.5** Biphasic insulin response to a step increase in plasma glucose concentrations from 90 to 162 mg/dL (5–9 mmol/L). Plots are mean ± standard error of the mean. (Personal data.)

Graded Glucose Infusion Test and Beta-Cell Dose Response

In the graded glucose infusion test, glucose is infused at ascending rates to stimulate a progressive increase in insulin secretion. The plot of insulin secretion rates against plasma glucose concentrations represents the beta-cell dose response, whose slope quantifies the sensitivity of the beta cell to glucose (Fig. 33.6). In healthy persons, basal insulin secretion increases by five- to sixfold up to 180



• **Fig. 33.6** The slope (y/x) of the dose-response curve measures beta-cell glucose sensitivity to plasma glucose. Typical data in a normoglycemic subject. (Modified from Byrne MM, Sturis J, Polonsky KS. Insulin secretion and clearance during low-dose graded glucose infusion. *Am J Physiol*. 1995;268[1 Pt 1]:E21–E27.)

mg/dL (10 mmol/L) glucose; correspondingly, beta-cell glucose sensitivity is about 13 $mU \cdot min^{-1} mM^{-1}$ (80 $pmol\ min^{-1} mM^{-1}$). The relationship is fairly linear within this glucose concentration range and up to at least 360 mg/dL (20 mmol/L).[75]

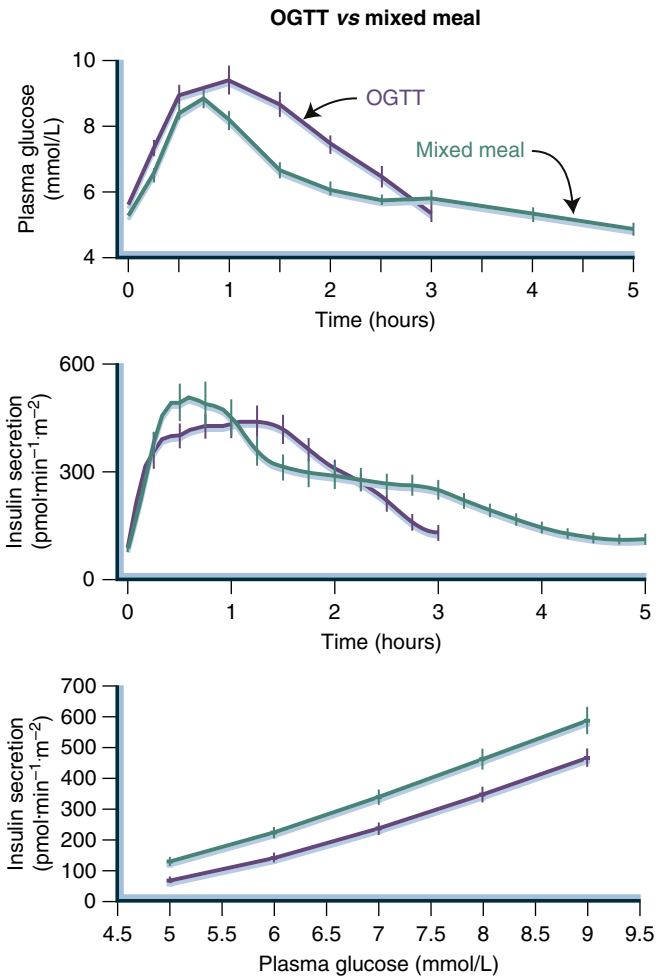
Slow Beta-Cell Response Modes and Adaptation Mechanisms

Under sustained, constant glucose stimulation, insulin secretion continues to rise slightly. This time-dependent potentiation of insulin secretion can be detected in the hyperglycemic clamp (see Fig. 33.5). Similarly, prolonged (2–4 days) exposure to mild hyperglycemia markedly enhances insulin secretion, with a steepening of the dose-response curve, as shown in hyperglycemic clamp[76] and graded glucose infusion studies.[75] Thus, the healthy beta cell is constitutively capable of potentiating its response when a chronic condition of mild hyperglycemia is induced by intravenous glucose administration.

Insulin Secretory Response to Oral Stimuli

When glucose is ingested, the biphasic pattern of insulin response seen with intravenous glucose is substantially spread out over the time of glucose absorption, with plasma glucose levels typically peaking at 0.5 to 1.0 hour and returning to baseline by 2 hours post ingestion. Insulin secretion rates rise and fall in close synchrony with plasma glucose levels. When a mixed meal containing the same amount of glucose (75 g as in a conventional OGTT) is ingested, glycemic excursions are smoothed out, but insulin secretion is enhanced due to the direct or indirect insulin-stimulating effect of protein and fat (Fig. 33.7). When four successive mixed meals with a high carbohydrate content are fed over a 14-hour period, insulin output appears to max out at 70 to 85 units in nondiabetic insulin-sensitive persons and at 140 to 170 units in insulin-resistant individuals, which highlights the large functional secretory reserve of the endocrine pancreas.[77] With consecutive nutrient loads, the plasma glucose and insulin secretory responses are attenuated during the second, as compared with the first, meal (Staub-Traugott effect); this phenomenon, which is also observed in patients with diabetes, is due to persistent suppression of endogenous glucose production by the hyperglycemia and hyperinsulinemia induced by the first load and to enhanced potentiation of insulin release.[78]

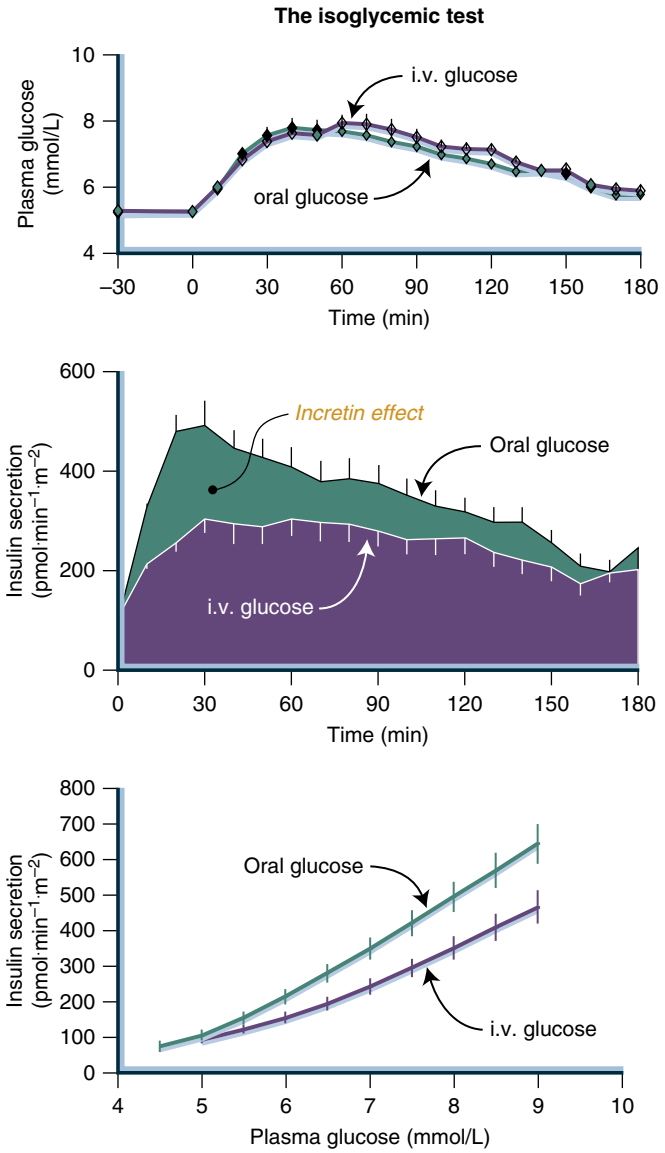
Notably, circulating insulin levels are reduced during starvation but quickly rebound on refeeding.[79] This transition, which is key to survival with the paleolithic hunter-gatherer lifestyle, requires a major, rapid adaptation of islet function. In rats subjected to prolonged (72 hours) fast, beta cells show marked degranulation and blunted in vivo insulin secretion. In contrast, autophagolysomal and lysosomal organelles are upregulated, the Golgi apparatus is expanded, and (pro)insulin biosynthetic capacity is enhanced. Within 4 to 6 hours of refeeding, proinsulin biosynthesis, cellular ultrastructure, in vivo insulin secretion, and glucose tolerance all recover, indicating a rapid replenishment of insulin secretory capacity.[80] Likewise, in obese nondiabetic individuals, plasma insulin concentrations drop by about 40% (and plasma glucagon levels rise) following a 14-day fast along with a 50% reduction in insulin sensitivity; 10 days of refeeding return all of these changes to baseline.[81] Thus, the beta cell protects against hypoglycemia during a prolonged fast but retains the potential



• **Fig. 33.7** Plasma glucose concentrations and insulin secretion rates in response to a standard (75-g) OGTT and to a mixed meal test (75 g of glucose plus 40 g of parmesan cheese and one 50-g egg, for a total of 500 kcal) in 22 normoglycemic subjects. The bottom panel shows the insulin secretion dose response to glucose: note the upward shift with the mixed meal versus oral glucose alone. Plots are mean ± standard error of the mean. *OGTT,* oral glucose tolerance test. (Personal data.)

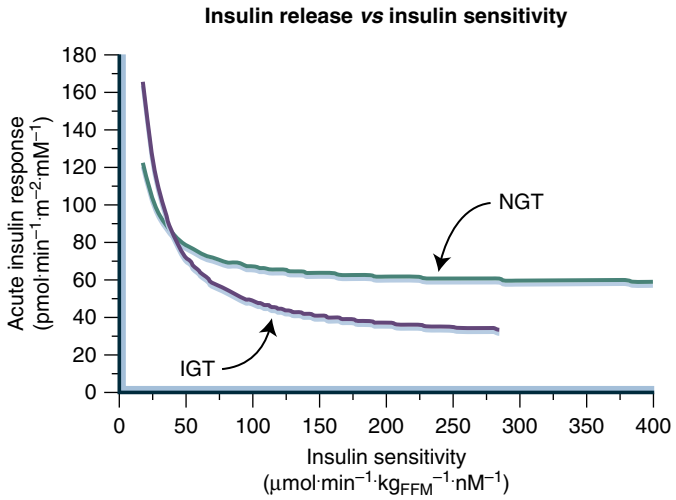
to efficiently increase insulin production on refeeding. With the present-day lifestyle, the fasting-feeding cycle is much shorter, but the coordinate regulation of beta-cell function and insulin sensitivity during the transition phase is the same. This is the basis for the recommendation that oral glucose (or mixed meal) tolerance tests be carried out in settings of an adequate carbohydrate load to prevent spurious glucose intolerance.

It has long been known that if glucose is ingested rather than infused, insulin secretion is higher at the same glucose levels.[82] GIP and GLP1, which are released by the intestinal epithelium in response to nutrient ingestion, are mainly responsible for the higher insulin release and have therefore been collectively termed *incretins*. The classical test to unveil and quantify the incretin effect is based on a standard OGTT and a separate test in the same subject, in which the time course of glucose concentration observed with the OGTT is reproduced by a controlled intravenous glucose infusion (also called *isoglycemic glucose infusion*).[83] As illustrated in Fig. 33.8, insulin secretion is considerably potentiated by the oral route of glucose entry, thereby resulting in an increase in slope of the beta-cell dose response, as estimated by modeling analysis.[56] The relative role of GIP and GLP1 in this



• **Fig. 33.8** Matching the plasma glucose response to oral glucose with a controlled i.v. glucose infusion reveals the incretin effect, namely the potentiation of insulin secretory response due to the oral route of glucose entry. The corresponding dose-response curves highlight the enhanced beta-cell sensitivity to oral, as compared with i.v., glucose. *i.v.,* intravenous. (Personal data.)

potentiation during physiologic stimulation, the interrelationships of the two hormones, and their relation to a host of other hormones secreted by islets (glucagon, somatostatin, ghrelin), as well as extrapancreatic tissues (leptin, obestatin), form a network whose nodes and links are difficult to dissect out in human experiments. The features of the in vivo incretin effect that are reasonably well established are the following: (1) GLP1 and GIP are released in phase with insulin and glucose concentrations; (2) when gastric emptying is accelerated (e.g., following gastric bypass surgery[47]), both the glucose and insulin peaks are anticipated and GLP1 levels are much higher if still synchronous with insulin; (3) glucose-induced and incretin-induced potentiation of insulin secretion—as resolved by modeling of isoglycemic experiments[56]—have different time courses and relation to glucose tolerance; and (4) strength of potentiation depends on the stimulus and the quality of beta-cell function.



• **Fig. 33.9** Nonlinear relationship between the acute insulin response to intravenous glucose (during an intravenous glucose tolerance test) and insulin sensitivity (separately measured by a euglycemic hyperinsulinemic clamp) in subjects with NGT (n = 1123) and individuals with IGT (n = 156). IGT, impaired glucose tolerance; NGT, normal glucose tolerance. (Modified from Mari A, Tura A, Natali A, et al. Impaired beta cell glucose sensitivity rather than inadequate compensation for insulin resistance is the domina;nt defect in glucose intolerance. *Diabetologia*. 2010;53[4]:749-756.)

Insulin Secretion and Insulin Sensitivity

A separate important aspect of beta-cell function is its relation to insulin sensitivity. In insulin-resistant states, more insulin needs to be secreted at the same glucose levels to maintain glucose tolerance. Evidence for this phenomenon dates back to the infancy of the insulin assay.[84] More systematic investigations have been carried out using the IVGTT, as this test allows the simultaneous assessment of the AIR and insulin sensitivity. The reciprocal relationship between AIR and insulin sensitivity likely reflects adaptation of the beta cell to impaired insulin action, which sets in as a steep increment in secretion as insulin sensitivity declines (Fig. 33.9). By fitting equilateral hyperbola on these IVGTT data, it has been proposed that a more appropriate index of intrinsic beta-cell function is the product of the insulin secretion and sensitivity indices, or disposition index.[85] The paradigm is commonly assumed to apply to other indices of insulin secretion, such as those obtained from an OGTT.[86] This, however, is only partly the case, as a similar relation of insulin sensitivity exists with postprandial insulin output (or fasting insulin secretion) but not with beta-cell glucose sensitivity.[87] Furthermore, in individuals with IGT, the curve is displaced as shown in Fig. 33.9, indicating that compensation is reduced until insulin sensitivity drops below approximately 50 $\mu mol \cdot min^{-1} \cdot kg_{FFM} \cdot nM^{-1}$, at which level AIR rises back to normal, very probably as a consequence of the mild hyperglycemia of these individuals.[88,89] The physiologic interpretation of these interrelationships is that insulin resistance raises the setpoint of beta-cell function, whereby absolute measures of insulin secretion (fasting, AIR, and postglucose) are chronically upregulated. However, the secretory mechanisms that control postprandial glucose excursions are less influenced by this form of adaptation. The anatomic counterpart of this phenomenon is the expansion of beta-cell mass in obese individuals,[90] in many of whom beta-cell glucose sensitivity and glucose tolerance are normal.

Genetic Influences on Insulin Secretion

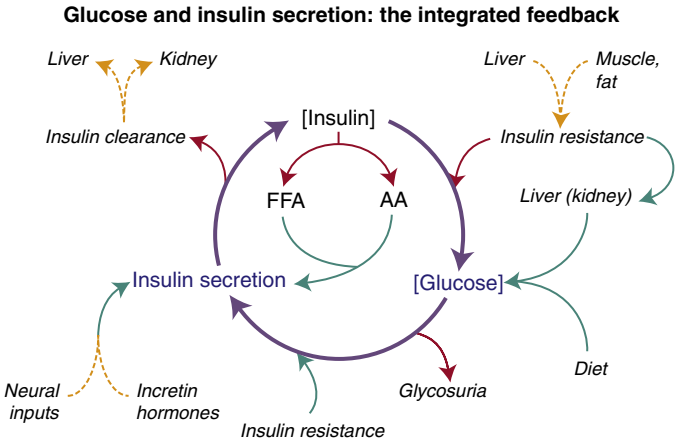
The large interindividual variability of beta-cell secretory outputs even in a very selected clinical phenotype (see Table 33.1) per se suggests that multiple influences are at play. Most of the more than 150 polymorphisms shown by genome-wide scans to be associated with diabetes or glycemic traits have been linked with defects in insulin secretion.[91] Even when tested in mendelian randomization studies,[92] the effect size of several of these risk variants is small, and they explain only a small proportion of the total heritability of T2D. Nevertheless, some interesting mechanistic information is emerging. For example, genetics variants of *TCF7L2*, a transcription factor that mediates the wingless/integrated (Wnt) pathway,[93] have been associated with impaired incretin-induced insulin secretion.[94] Other gene variants (*GIPR*, *WFS1*, *KCNQ1*) have also been shown to affect GIP- or GLP1-mediated insulin secretion.[95] In the future, it is likely that more and more knockout and knock-down experiments will add cellular and molecular granularity to these associations.

More detailed information on insulin secretion pattern is available in monogenic forms of diabetes, particularly in maturity-onset diabetes of the young (MODY). Mutations in one of at least six different genes (inherited by an autosomal dominant mode) result in hyperglycemia of variable severity in young, nonobese subjects (typically younger than 25 years) with a multigenerational family history of diabetes. As all these genes are expressed in beta cells, their mutation causes beta-cell dysfunction. In MODY 2, a heterozygous private mutation of the gene (*GCK*) encoding glucokinase results in partial enzyme deficiency and a loss of beta-cell glucose sensitivity, evidenced by a rightward shift in the dose response on a graded glucose infusion test.[96] Coexpression of the transcription factors (hepatic nuclear factor) *HNF1α*, *HNF1β*, and *HNF4α* controls gene expression during embryonic development and adulthood; in beta cells, they regulate the expression of the insulin gene and genes encoding proteins involved in glucose transport and metabolism.[97,98] Mutations in *HNF4α* (MODY 1) or *HNF1α* (MODY 3) also cause loss of beta-cell glucose sensitivity on a graded glucose infusion test[96] and rapidly progressing hyperglycemia. Interestingly, associated abnormalities include a deficient insulin secretory response to arginine and reduced glucagon release but not insulin resistance.[99] Mutations in other MODY-related genes (*insulin promoter factor 1* [or MODY 4], *HNF1β* [or MODY 5], and *neurogenic differentiation 1 transcription factor* [*BETA2*, or MODY 6]) expressed in beta cells likewise cause diabetes related to beta-cell dysfunction. Because these transcription factors are also expressed in other tissues (liver and kidney), the mutations produce a clinical phenotype in which islet dysfunction is associated with other abnormalities, particularly microvascular complications.

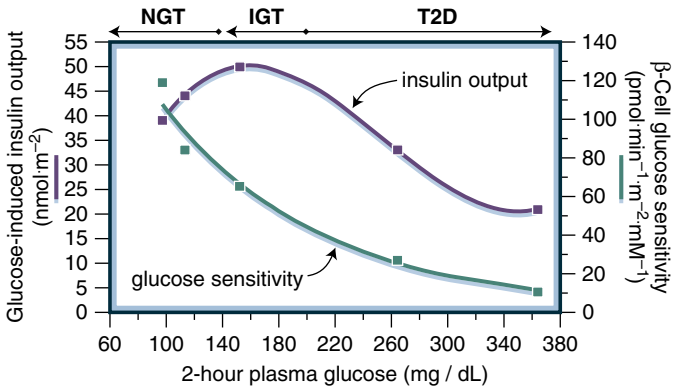
Insulin Secretion, Insulin Action, and Glucose Homeostasis

The information derived from clinical tests carried out across different conditions can be assembled into a simplified resume of beta-cell physiology (Fig. 33.10). Under most circumstances, the primary feedback is between glucose concentrations and insulin secretion rates: insulin decreases glucose and glucose increases insulin secretion. Several major processes modulate this feedback. Insulin secretion is potentiated by nonglucose substrates (FFAs and amino acids); incretin hormones; and, to a lesser extent, neurotransmitters. Insulin clearance—predominantly hepatic—translates secretion rates into circulating insulin concentrations; this step is modulated by an intrinsic saturation of liver-degrading capacity and by insulin resistance. Plasma insulin lowers plasma glucose by promoting tissue glucose uptake; this step is gated by insulin resistance. Plasma insulin also restrains lipolysis[100] and protein breakdown,[101] thereby lowering circulating FFAs and amino acids; this closes a secondary feedback loop modulating insulin secretion. Endogenous glucose production—enhanced by insulin resistance—and dietary carbohydrate independently contribute to plasma glucose levels, whereas glycosuria dampens them when the renal threshold for glucose reabsorption is exceeded. The cycle is completed by the stimulatory effect of glucose on insulin secretion, with a chronic effect of insulin resistance to raise the beta-cell set-point.

Diabetes and obesity can also be represented within this schematic: the presence and severity of insulin resistance affect insulin secretion by increasing baseline secretory activity and by incrementing the stimulatory signals (i.e., glucose, FFAs, and amino



• **Fig. 33.10** Integrated control of in vivo insulin secretion. The *square brackets* stand for plasma concentration, the *purple line* encircles the primary feedback, the *green arrows* indicate stimulation, and the *red arrows* indicate inhibition. *AA,* amino acids; *FFA,* free fatty acid.



• **Fig. 33.11** Median values of total insulin output over the 2 hours of a standard oral glucose tolerance test (*blue squares*) and beta-cell glucose sensitivity (*green squares*) are plotted against the 2-hour plasma glucose concentrations to highlight the different behavior of absolute insulin release and beta-cell function across progressive stages of glucose intolerance. NGT, normal glucose tolerance; IGT, impaired glucose tolerance; T2D, type 2 diabetes. (Data from Mari A, Tura A, Natali A, et al. acids). Genetic makeup (and epigenetic modifications), chronic hyperglycemia, and other acquired insults impair beta-cell secretory dynamics (glucose sensitivity and potentiation) and compromise islet structure and cellular phenotype through the expression of risk gene variants; glucose- and lipotoxicity; and, quite possibly, insulin resistance itself.[102-104]

An important concept is the opposite behavior of absolute insulin release and the glucose sensitivity of the beta cell across stages of glucose intolerance as reconstructed by physiologic modeling of OGTT data (Fig. 33.11). In the conventional diagnostic categories of impaired fasting glycemia and IGT, insulin release is increased (to compensate for the insulin resistance), whereas beta-cell glucose sensitivity is already markedly decreased and continues to decline monotonically throughout progressive hyperglycemia in overt T2D. In impaired fasting glycemia, for example, insulin output is increased by 15%, insulin sensitivity (on an insulin clamp) is only slightly impaired, but glucose sensitivity is 30% lower[105] (Table 33.2). Concordant with these cross-sectional data is the finding that beta-cell glucose sensitivity is a powerful negative predictor of incident T2D in nondiabetic cohorts above and beyond the impact of conventional risk factors (sex, age, body mass index, family history, etc.). In these models, insulin output typically features as an independent positive predictor[106] (it is reduced only in long-standing, severely hyperglycemic T2D patients). Also of note is that the model-derived potentiation factor picks up the incretin defect that is consistently observed in patients with T2D and, to a lesser extent, in IGT individuals. Thus, the pathogenesis and natural history of human diabetes can be construed as a recapitulation of the physiology of insulin secretion.

Pathophysiology of Type 2 Diabetes Mellitus

C. RONALD KAHN, HEATHER A. FERRIS, AND BRIAN T. O'NEILL

CHAPTER OUTLINE

KEY POINTS

- Type 2 diabetes mellitus (T2DM) is one of the most common health problems facing mankind and is a major public health problem. The International Diabetes Federation estimated in 2017 that 425 million people have diabetes worldwide and that by 2045 this number will rise to 629 million.
- T2DM is the predominant form of diabetes worldwide, accounting for 90% to 95% of cases globally.
- The pathogenesis of T2DM is complex and involves the interaction of genetic and environmental factors.
- Several environmental factors have been shown to play critical roles in the development of T2DM, particularly excessive caloric intake, a sedentary lifestyle, and increases in fat mass.
- The clinical presentation is heterogeneous, with a wide range in age at onset, severity of hyperglycemia, degree of obesity, and severity of other associated metabolic abnormalities.
- From a pathophysiologic standpoint, persons with T2DM consistently demonstrate three cardinal abnormalities:
  - Resistance to the action of insulin in peripheral tissues, particularly muscle, fat, and liver
  - Defects in insulin secretion, particularly in response to a glucose stimulus
  - Increased glucose production by the liver.
- Although more than 100 genetic variants have been linked with risk for T2DM, these variants collectively account for 5% to 10% of the overall familial risk for disease, suggesting the importance of epigenetic effects, as well as environmental influences.
- Insulin receptors are nearly ubiquitously expressed, yet the physiologic actions of insulin are highly tissue specific, promoting calorie storage in the postprandial state via pleotropic effects on growth, metabolism, and cell survival.

Epidemiology

Type 2 diabetes mellitus (T2DM) is the predominant form of diabetes worldwide, accounting for 90% to 95% of cases globally. An epidemic of T2DM is under way in both developed and developing countries. The International Diabetes Federation estimated in 2017 that 425 million people have diabetes worldwide and that by 2045 this number will rise to 629 million. Of those with diabetes currently, 79% live in low- and middle-income countries. The largest percentage of increases in diabetes cases are predicted for Africa, the Middle East, and Southeast Asia, where the greatest numbers of people are moving from low to middle income.[1] In the United States, the Centers for Disease Control and Prevention estimated in 2017 that 30.3 million people, or 9.4% of the population, had diabetes and that 7.2 million of them (23.8%) were undiagnosed. Based on fasting glucose or hemoglobin A_{1c} levels, they also estimated that 84 million people (34% of adults older than 20 years) had prediabetes and thus were at high risk of developing diabetes.[2]

The economic burden of diabetes is enormous. The International Diabetes Federation estimated that in 2017, diabetes-related health expenditures amounted to $727 billion.[1] The American Diabetes Association estimated that in the United States alone in 2017, diabetes accounted for $237 billion in direct health care expenditures and an additional $90 billion in lost productivity. Average expenditures per person, adjusted for age and gender, were 2.3-fold higher compared with the nondiabetic US population. The increased spending was driven by both the increased prevalence of the disease and the costs associated with care.[3] In addition, the high cost of diabetes medications, including insulin, leaves many patients in the United States unable to afford the medications they are prescribed.

TABLE 34.1 Epidemiologic Determinants of and Risk Factors for Type 2 Diabetes Mellitus

Genetic Factors
Genetic markers
Family history
Demographic Characteristics
Age
Ethnicity
Behavioral and Lifestyle-Related Risk Factors
Obesity (including distribution of obesity and duration)
Physical inactivity
Diet
Stress
Westernization, urbanization, modernization
Medications
Shift work
Metabolic Determinants and Intermediate-Risk Categories of Type 2 Diabetes
Impaired glucose tolerance
Insulin resistance
Gestational diabetes
Offspring of women with diabetes during pregnancy
Intrauterine malnutrition or overnutrition
Microbiome composition

Considerable information is available on the factors that are responsible for the development of T2DM, and these determinants are summarized in Table 34.1.[4,5] T2DM is thought to occur in genetically predisposed persons who are exposed to a series of environmental influences that precipitate the onset of clinical disease. Although T2DM is strongly associated with a high body mass index (BMI), there are clear differences in fat distribution and the degree of excess fat that is required to drive susceptibility to T2DM.[6] For example, individuals with high levels of visceral fat (central obesity) are clearly more insulin resistant and at higher risk for T2DM than those with high levels of peripheral, mainly subcutaneous, fat. Likewise, individuals from Southeast Asia are at high risk of developing T2DM at lower BMIs than other ethnicities due to greater proportional visceral adipose stores. Historically, when ethnicities prone to developing T2DM at lower BMIs migrate to the United States, they see weight gain and a rapid rise in the rate of T2DM with the change to a Western diet.[7,8] Not surprisingly, as many people in Asia adopt a more Western diet, the rates of T2DM increase even within those countries with previously low incidence rates, and there is no longer a migration effect because the diet had already changed.[9] In the United States, the prevalence of T2DM varies by race and ethnicity, with Native American populations having twice the rate of diabetes at 15.1% than non-Hispanic whites at 7.4%[2] (Fig. 34.1).

Historically, T2DM was viewed as a disorder of aging. Although this remains true today, the prevalence of obesity and T2DM in children has risen dramatically over the past decade. Thus, in the past, the overwhelming majority of children with diabetes had type 1 diabetes mellitus (T1DM), with only 1% to 2% of diabetic children considered to have T2DM or other rare forms of diabetes. Recent reports suggest that as many as 20% to 25% of children in the United States with newly diagnosed diabetes have non-T1DM, i.e., non–immune-mediated, forms of the disease. Most of these children have T2DM, but the rarer monogenic types are also being increasingly identified. Nevertheless, T2DM in children remains relatively rare, with an estimated prevalence of 5 cases per 10,000 children.[2,10]

Pathogenesis

The pathogenesis of T2DM is complex and involves the interaction of genetic and environmental factors. Several environmental factors have been shown to play a critical role in the development of the disease, particularly excessive caloric intake leading to obesity and a sedentary lifestyle (Fig. 34.2). Other environmental factors that impact obesity and T2DM development, including epigenetics, medications, inflammation, circadian rhythm disruptions, and the microbiome, also need to be considered. The clinical presentation of T2DM is heterogeneous, with a wide range in age at onset, severity of associated hyperglycemia, and degree of obesity. From a pathophysiologic standpoint, persons with T2DM consistently demonstrate three cardinal abnormalities:

- Resistance to the action of insulin in peripheral tissues, particularly muscle, fat, and liver (the classical tissues of insulin action).
- Defective insulin secretion, particularly in response to a glucose stimulus, although absolute levels may be high, low, or normal
- Increased glucose production by the liver leading to hyperglycemia in the fasting state.

In addition, people with T2DM may have hyperglucagonemia, alterations in incretin hormone secretion or action, accelerated lipolysis in the fat cell, increased renal tubular reabsorption, and abnormalities in central nervous system (CNS) regulation of metabolism.[11]

From a pathophysiologic standpoint, many argue that it is the inability of the pancreatic beta cell to adapt to the reductions in insulin sensitivity that precipitates the clinical onset of T2DM. What is clear is that the earliest detectable abnormality in those predisposed to T2DM is insulin resistance. Indeed, insulin resistance may precede T2DM by many years.[12] The most common factors that place an increased secretory burden on the beta cell are additional insulin resistance factors such as puberty, pregnancy, a sedentary lifestyle, and overeating leading to weight gain. An underlying genetic predisposition appears to be a factor in determining the frequency with which beta-cell failure occurs, although like T2DM itself, no single genetic alternation has been identified as the driver of beta-cell failure.

Genetic Factors in the Development of Type 2 Diabetes Mellitus

The precise way in which genetic, environmental, and pathophysiologic factors interact to lead to the clinical onset of T2DM is complex and may vary from individual to individual. The common forms of T2DM are polygenic in nature and are caused by an interaction between these genes and multiple environmental factors (known and unknown), as well as epigenetic factors. Therefore, it is not surprising that the individual genes involved in the common polygenic forms of T2DM have been difficult to identify and their contribution to disease development modest. The monogenic forms, although relatively uncommon, are important to recognize because they have led to important insights about normal physiology; if identified early, they may be important in selecting appropriate therapy. Several genes involved in monogenic forms have been identified and characterized.

Monogenic Forms of Diabetes Associated With Insulin Resistance

In the monogenic forms of diabetes, the gene involved is both necessary and sufficient to cause disease. In other words, environmental factors play little or no role in determining whether a

• **Fig. 34.2** Genetics, the environment, diet, and the gut microbiome are among many interacting factors influencing the development of obesity, insulin resistance, and diabetes.

genetically predisposed person develops clinical diabetes, although there is some variation in penetrance of disease among individuals with the same genetic defect. The monogenic forms of diabetes are usually diagnosed in younger patients, often in the first two to three decades of life; however, if only mild, asymptomatic elevations in blood glucose occur, the diagnosis may be missed until later in life. The monogenic forms of diabetes can be divided into those in which the mechanism is a defect in insulin secretion and those that involve defective responses to insulin or insulin resistance. In this chapter, we will discuss the forms associated with insulin resistance.

Mutations in the Insulin Receptor

Numerous mutations have been identified in the insulin receptor gene in various insulin-resistant patients. Although there is a spectrum of disorders, at least three clinical syndromes caused by mutations in the insulin receptor gene have been described. *Type A insulin resistance* is defined by the presence of insulin resistance, acanthosis nigricans, and hyperandrogenism. Most often, these patients are identified as adolescents or young adults, often based on the acanthosis nigricans and/or signs of hyperandrogenism, rather than by their disturbances in glucose metabolism, even though insulin resistance can be very severe and accompanied by marked hyperinsulinemia.[13] Patients with *Donohue syndrome* (formerly called *leprechaunism*), however, have multiple early abnormalities, including severe intrauterine growth retardation, abnormal facies leading to the name of the syndrome, and death within the first 1 to 2 years of life.[14-16] Interestingly, the patients may have episodes of hypoglycemia despite their severe insulin resistance. *Rabson-Mendenhall syndrome* is associated with short stature, protuberant abdomen, and abnormalities of teeth and nails; pineal hyperplasia was a characteristic in the original description of this syndrome.[17]

These mutations impair receptor function by several different mechanisms. The majority of mutations associated with type A insulin resistance are in the intracellular tyrosine kinase domain, whereas in Donohue and Rabson-Mendenhall syndromes, the mutations are more frequently found in the extracellular domain, causing impairment in ligand binding, or the FnIII domains, which are key for receptor folding.[18] As noted earlier, the insulin resistance that is associated with these insulin receptor mutations is usually severe, manifesting in the neonatal period (e.g., Donohue and Rabson-Mendenhall syndromes), or it can occur in a milder forms in adulthood, and is often most easily detected biochemically by marked hyperinsulinemia and clinically by acanthosis nigricans often in the absence of obesity. Some individuals with insulin receptor mutations are able to remain normoglycemic due to massive elevations of endogenous insulin secretion, whereas others have presented with hyperglycemia that fails to respond to insulin therapy sometimes in doses exceeding 10,000 units/day.[13]

Lipodystrophic Diabetes

Lipodystrophic diabetes syndromes, which can either be genetic or acquired, are syndromes of severe insulin resistance associated with lipoatrophy (loss of fat) and lipodystrophy (loss and maldistribution of fat). These forms of diabetes are characterized by a paucity of fat, insulin resistance, and hypertriglyceridemia. The genetic forms can be divided into generalized lipodystrophies or partial lipodystrophies; however, within each of these categories, mutations in many different genes have been identified. The gene

mutations that cause lipodystrophy control a variety of functions including insulin signaling (AKT2, PIK3R1), caveolins (CAV1, PTRF), phospholipid biosynthesis (AGPAT2, PCYT1A), lipid droplet morphology (LMNA, BSCL2, ZMPSTE24), adipogenesis (CIDEC, PPARG), and lipolysis (LIPE, PLIN1).[19] Depending on the gene mutation and the particular mutation within the gene, the associated syndrome may be confined to loss of fat and the associated metabolic abnormalities or may cause a syndrome with a wider array of phenotypes. For example, mutation in the lamin A gene (*LMNA*) can cause either the face-sparing familial partial lipodystrophy commonly referred to as Dunnigan syndrome or through a different mutation in the same gene can cause mandibuloacral dysplasia syndrome, resulting in a partial lipodystrophy, accompanied by postnatal growth retardation, and craniofacial and skeletal malformations.[20,21] The generalized lipodystrophies are quite rare but easily diagnosed by the loss of subcutaneous fat throughout the entire body. These syndromes cause severe metabolic abnormalities, including severe fatty liver disease, sometimes leading to ascites and esophageal varices. Generalized lipodystrophy is also associated with very low levels of the adipose tissue–derived hormones leptin and adiponectin.[22] Leptin-replacement therapy improves glycemic control, decreases fatty liver disease, and decreases circulating triglyceride levels in patients with lipodystrophy and leptin deficiency.[23]

In contrast, the partial lipodystrophies are frequently missed, and thus the incidence is unknown. The phenotypes of the partial lipodystrophies vary significantly by mutation and gender. Leptin levels may be in the normal range or slightly below the normal range but do not show the elevations generally seen with obesity.[24] Diagnosis is made by clinical phenotype, with genetic testing generally only performed in research settings.

Acquired generalized lipodystrophy (also known as Seip-Lawrence syndrome) is a rare condition that may appear during childhood, adolescence, or young adulthood, characterized by fat loss affecting large areas of the body, initially usually the face, arms, and legs. Acquired generalized lipodystrophy is thought to be an autoimmune disorder with secondary destruction of the adipose organ, but definitive proof of autoimmunity is lacking.

Genetics of the Polygenic Forms of Type 2 Diabetes Mellitus

The common polygenic form of T2DM has complex pathophysiology, with genetic and environmental factors playing major roles. The phenotypic manifestations of the disease are also complex and include resistance to the action of insulin in the muscle, fat, and liver and defects in insulin secretory responses from the pancreatic beta cell. Together, these lead to reduced glucose uptake and increased hepatic glucose production. However, the primary defect or defects responsible for the development of the syndrome remain elusive. Indeed, with more than 100 genes linked to T2DM, the role of these genes and the nature of the gene-environment interactions that are ultimately responsible for development of the disorder in predisposed persons remain unknown.

Insulin resistance is present in persons predisposed to T2DM long before the onset of hyperglycemia, and this finding has been interpreted by some to indicate that insulin resistance is the primary abnormality responsible for the development of T2DM. Since some patients with severe insulin resistance can mount extreme hyperinsulinemic responses, it seems likely that in typical T2DM with less profound insulin resistance, defective beta-cell function is also present before the onset of T2DM, as impaired glucose tolerance (IGT) develops. In fact, altered insulin secretion has been reported in first-degree relatives of persons with T2DM who have normal plasma glucose concentrations.[12] Therefore, although there is still controversy about whether insulin resistance or abnormal insulin secretion represents the primary defect in T2DM, there is general consensus that both defects are present in essentially all subjects with the disorder at clinical presentation.

Over the past decade, there have been dramatic advances in understanding the role of genes in T2DM. Earlier genetic studies relied either on the candidate gene approach, in which the search for diabetes genes is dictated by the prevailing understanding of the pathways involved in glucose regulation, or on linkage studies, which involve identifying regions of chromosomal DNA that are shared to excess by affected family members. Although these approaches did allow identification of important diabetes genes, especially in monogenic forms of the disease, more recent studies have focused on the application of genome-wide associations (GWAS). These GWAS use an unbiased interrogation of the entire genome comparing cases and controls to determine which single-nucleotide polymorphisms (SNPs) are *associated* with disease. The location of the SNP can suggest associated genes in the region, but often SNPs are in noncoding intragenic regions, making the causative gene unclear. The genes that have been implicated in the pathogenesis of T2DM are depicted in Fig. 34.3. The following sections provide a summary of some of the genes that have strong evidence in the pathogenesis of T2DM.

Insulin Receptor Substrate 1 Gene

The first polymorphism identified for T2DM was Gly972Arg in *IRS1*, a key protein in the canonical insulin signaling pathway. This common polymorphism was detected by direct sequencing of 86 patients with T2DM and 76 controls, with three times as many cases present in cases than controls.[25] Subsequent studies demonstrated that this polymorphism results in impaired insulin-stimulated phosphatidylinositol 3-kinase signaling.[26] As genomic information expanded, it became clear that this polymorphism plays only a minor role in overall T2DM risk; however, this initial finding provided the first evidence of the genetic association with T2DM.

Transcription Factor 7–Like 2 Gene

Grant and colleagues[27] genotyped 228 microsatellite markers in Icelandic patients with T2DM and in control subjects. A microsatellite, DG10S478, in intron 3 of the transcription factor 7–like 2 gene (*TCF7L2*; formerly *TCF4*) was associated with T2DM. This was replicated in a Danish cohort and in a US cohort. Compared with noncarriers, heterozygous and homozygous carriers of the at-risk alleles (38% and 7% of the population, respectively) have relative risks of 1.45 and 2.41 for development of T2DM. Follow-up studies showed that specific polymorphisms in *TCF7L2* increase the risk of progression from IGT to T2DM, and this effect is associated with a reduction of glucose-induced insulin secretion.[28] The *TCF7L2* gene product is a high-mobility group box containing transcription factor previously implicated in colon cancer. In T2DM, it has been suggested to act through regulation of proglucagon gene expression in enteroendocrine cells by impacting on the Wnt signaling pathway. Of the common variants that determine diabetes risk, variants at the *TCF7L2* locus have the greatest impact. However, the diabetes-associated polymorphism marks an intronic variant, and how or if this affects expression or function of the *TCF7L2* mRNA or protein remains unknown.

KATP Channel Genes: *KCNJ11* and *ABCC8*

The beta-cell K_{ATP} channel is composed of two subunits, Kir6.2 (*KCNJ11*) and SUR1 (*ABCC8*). Kir6.2 is the pore-forming

component of the potassium channel, whereas SUR1 is the sulfonylurea receptor that regulates opening of the channel. Opening of the channel results in potassium efflux from the beta cell, causing insulin secretion. Mutations in these genes are the most common cause of neonatal diabetes. Identification of these patients is important because these forms of neonatal diabetes are generally treatable with sulfonylureas rather than insulin.[29] The two genes are located adjacent to each other on chromosome 11, and SNPs within both genes are associated with an increased risk of diabetes.[30] A missense mutation Glu23Lys (E23K) in *KCNJ11* has also been associated with increased risk of typical adult-onset T2DM by an average of 13%, and the KK homozygote is at greatest risk (relative risk, 1.28).[31] A recent study suggests that, like neonatal diabetes caused by mutations in *KCNJ11* and *ABCC8*, polymorphisms in these genes, which increase the risk for T2DM, may be more readily treated with sulfonylureas.[32]

Peroxisome Proliferator-Activated Receptor γ Gene

PPARγ is a member of the PPAR subfamily of nuclear receptors. It is an important regulator of lipid and glucose homeostasis and cellular differentiation. Although PPARγ is most abundantly expressed in adipose tissue, it is also expressed in muscle and in the pancreatic beta cell. Targeted elimination of the receptor in muscle alters muscle fatty acid oxidation,[33] and knockout in the beta cell leads to a blunting of the normal increase in beta-cell mass that occurs on a high-fat diet.[34] Meta-analyses show that the common missense mutation Pro12Ala (P12A) in *PPARG* (the gene encoding PPARγ2) is associated with decreased risk for T2DM (estimated risk ratio for the alanine allele, 0.79).[35] People homozygous for the Pro12 allele are more insulin resistant than those with one Ala12 allele and have a 1.25-fold increased risk of diabetes. A second polymorphism, C161→T, has been linked to insulin resistance in Hispanic and non-Hispanic white women.[36] Loss of function mutations in PPAR cause familial partial lipodystrophy type 3 (FPLD3), and these patients may show dramatic improvement when treated with the thiazolidinedione PPAR agonists.[37]

Hepatocyte Nuclear Factor 4α Gene

Despite its name, HNF4A was the first discovered MODY (Maturity Onset Diabetes of the Young) gene, where it leads to abnormalities in insulin secretion.[38] HNF4α is also active in the liver, where it is upregulated by an alternative promoter from the pancreas and is important for gluconeogenesis. Patients with the risk alleles have increased hepatic glucose production, not impaired insulin secretion, confirming the liver-specific impact of the polymorphisms in the alternative hepatic promoter.[39] Several clinical studies have demonstrated that genetic variation in this liver-specific promoter for the *HNF4A* gene is associated with increased risk of T2DM.[39-42]

Kruppel-like Factor 14 (*KLF14*)

Kruppel-like factor 14 (*KLF14*) is a maternally imprinted transcription factor. Noncoding polymorphisms in the *KLF14* gene are associated with increased fasting insulin, waist-to-hip ratio, and T2DM.[43,44] Regulatory variants of *KLF14* appear to influence T2DM risk by causing a redistribution of fat from gynoid to visceral depots and increasing adipocyte size.[43] Accompanying in vitro experiments demonstrated that these changes are mediated, in part, by an increase in preadipocyte proliferation but impairment in lipogenesis. Interestingly, these effects only occur when the polymorphism is inherited from mother to daughter.

Diabetes Genes Identified by Genome-Wide Association Studies

GWAS continue to identify variants that determine genetic risk of T2DM and to define the genetic architecture of the disease. Fig. 34.3 depicts the intersection between loci associated at genome-wide significance with T2DM and five metabolic traits strongly associated with T2DM, including BMI, waist circumference, waist-to-hip ratio, fasting insulin, and fasting glucose. Note that there is substantial, but not complete, overlap in the loci significantly associated with these traits. For example, a variant in the gene *CREBRF*, found almost exclusively in the Samoan population, is associated with a large (1.4 kg/m^2) increase in BMI per risk allele and is also associated with a paradoxical decrease in odds ratio of 0.6 for the development of T2DM.[45] The mechanisms driving the increase in BMI but protection from T2DM are still to be elucidated but suggest that the increase in adipose tissue is confined to metabolically healthy subcutaneous tissues rather than pro-inflammatory visceral adipose tissue.

Based on these advances, the following general comments can be made regarding the genetics of T2DM:

1. The genes identified to date individually lead to a modest increase in the risk of diabetes. Persons with these individual polymorphisms have odds ratios between 1.10 and 1.45 when compared with individuals who do not have the at-risk polymorphisms.
2. The presence of multiple at-risk polymorphisms in a single individual substantially increases the risk of developing diabetes.
3. Although early GWAS suggested that a substantial proportion of the genetic variants associated with increased risk for diabetes were in genes that might alter insulin secretion, in recent studies the number of SNPs associated with decreased insulin sensitivity have increased, and at least some of these effects on insulin sensitivity appear to be independent of obesity.[43,46,47]
4. The majority of the SNPs associated with risk of T2DM appear to reside in noncoding regions of the chromatin. Studies have shown that some of these allelic variations exist in open chromatin regions alternatively called *stretch enhancers*,[48] which appear to be bound by proteins. Stretch enhancers across the genome are cell type specific and are located near and associated with increased expression of genes involved in cell-specification, as opposed to housekeeping, processes.
5. A large number of genes are associated with increased susceptibility to this disease. Whereas the total number of loci linked to T2DM is large, they account for a small proportion (estimated at no more than 5–10%) of the total genetic risk for diabetes in the population. In the search for this missing heritability, increasing attention is being given to the *rare variant hypothesis*, which states that common diseases are due to multiple, but rare, variants with large effects. Alternatively, there is new evidence that T2DM can be divided into multiple phenotypic subgroups with distinct genetic signatures that were difficult to identify when all of these subtypes were grouped together in previous studies.[49,50] Finally, the high familial risk of T2DM may be due to some element of shared environment or epigenetic effects (see the following discussion).

Epigenetic Risk of Diabetes

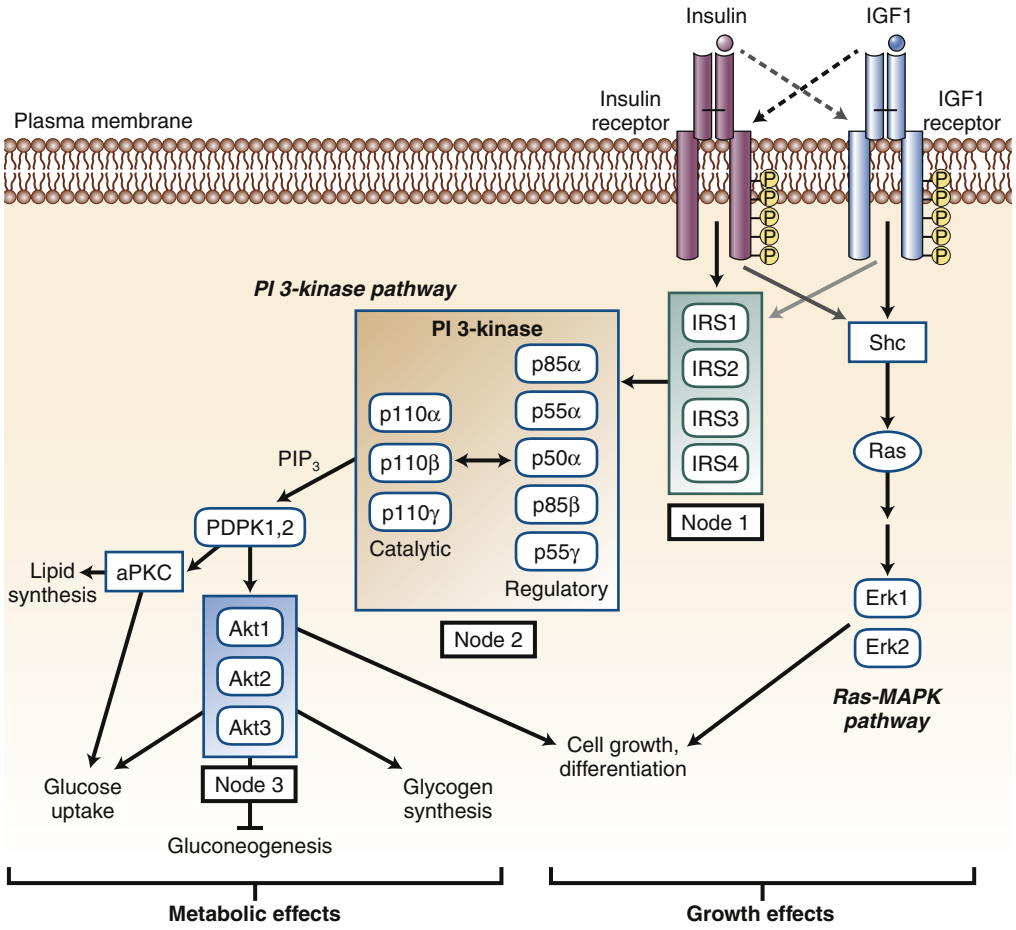
In addition to variations in the sequence of genes conferring risk of T2DM, epigenetic marks, which influence the expression of genes, can also influence disease risk. Detrimental epigenetic marks can be created in the developing fetus by both over- and undernutrition.[51,52] The idea that perinatal nutrition could influence the risk for obesity in offspring came from the observation of children born of pregnancies during the Dutch Hunger Winter, a period of starvation in the Netherlands during World War II. During this period, all Dutch citizens, including pregnant mothers, were restricted to as little as 400 to 800 calories per day. It was subsequently noted that the offspring of these pregnancies were more likely to become obese than same sex siblings conceived during normal food availability. This is attributed to epigenetic marks that persisted 60 years beyond the neonatal exposure.[53] Evidence of the same phenomena has been documented following several other famines around the world. These human observations have since been replicated in mouse models of undernutrition, which not only demonstrate the passage of obesity risk from mother to offspring, but that risk can be perpetuated for an additional generation by male offspring of undernourished mothers due to epigenetic changes to primordial sperm.[54] Similar to undernutrition, evidence also exists that overnutrition during pregnancy can cause epigenetic changes that predispose offspring to obesity and T2DM for multiple generations.[55,56]

Insulin Signaling

Insulin signaling is initiated through binding and activation of its tyrosine kinase cell-surface receptor. This initiates a cascade of phosphorylation and dephosphorylation events, generation of second messengers, and protein-protein interactions that result in diverse metabolic events in almost every tissue. Insulin receptors are ubiquitously expressed, yet insulin action is highly tissue specific due to the varied composition of downstream targets of insulin signaling. The insulin receptor consists of two insulin-binding α-subunits and two catalytically active β-subunits. Like insulin itself, the α- and β-subunits are derived from a single chain precursor or prereceptor. Once the subunits are formed, they are disulfide linked into an $\alpha_2\beta_2$ heterotetrameric complex. Insulin binds to the extracellular α-subunits, activating the intracellular tyrosine kinase domains of the β-subunits that phosphorylate intracellular partners on specific tyrosine residues.[57] On phosphorylation of the receptor, multiple classes of adapter proteins including insulin receptor substrates (IRSs), Src homology 2 domain containing (Src), growth factor receptor–bound protein (Grb), and others[58] can associate with the receptor and propagate the downstream signal resulting in modulation of cellular metabolism, stimulation of mitogenesis,[59] and receptor internalization.[60]

Downstream Events After Insulin Receptor Phosphorylation

IRS, phosphoinositide 3-kinase (PI3K), and Akt represent three critical nodes of insulin signaling that regulate a majority of the metabolic and transcriptional effects downstream of insulin activation (Fig. 34.4). The IRS proteins are critical adaptors that mediate



• **Fig. 34.4** Insulin signaling activates three critical nodes of regulation to mediate most of its metabolic actions across tissues. Node 1 contains the insulin receptor substrate (IRS) isoforms 1 through 4. Node 2 is phosphatidylinositol-3-kinase (PI3K), which is comprised of a p85 or p55 regulatory subunit and a p110 catalytic subunit. Node 3 contains three isoforms of Akt. These three signaling nodes regulate lipid and glucose metabolism, as well as cell growth and differentiation, and run parallel to the Ras-mitogen–activated protein kinase (MAPK) pathway with some crosstalk. *aPKC,* atypical protein kinase C; *ERK,* extracellular signal–regulated kinase; *IGF1,* insulin-like growth factor 1; *MAPK,* mitogen-activated protein kinases (MEK, MAPK/ERK); *PDPK,* phosphoinositol-3-phosphate–dependent kinase; *Ras,* rat sarcoma oncogene; *Shc,* SH3-containing protein.

many of the key metabolic actions of insulin across multiple tissues. IRSs have multiple functional domains, including pleckstrin homology (PH), phosphotyrosine binding (PTB), and Src homology (SH) domains that allow for interaction with phosphorylated tyrosine residues on the insulin receptor and the closely related insulin-like growth factor 1 (IGF1) receptor, allowing for docking with downstream effectors, such as PI3K.[61] There are four IRS isoforms (IRS1-IRS4), with IRS1 and IRS2 being ubiquitously expressed. Although there is evidence for functional overlap, IRS1 and IRS2 do display unique roles in growth and metabolism across tissues. Disruption of IRS1 in mice resulted in mild insulin resistance and growth retardation, whereas disruption of IRS2 resulted in beta-cell failure and secondary insulin resistance.[62]

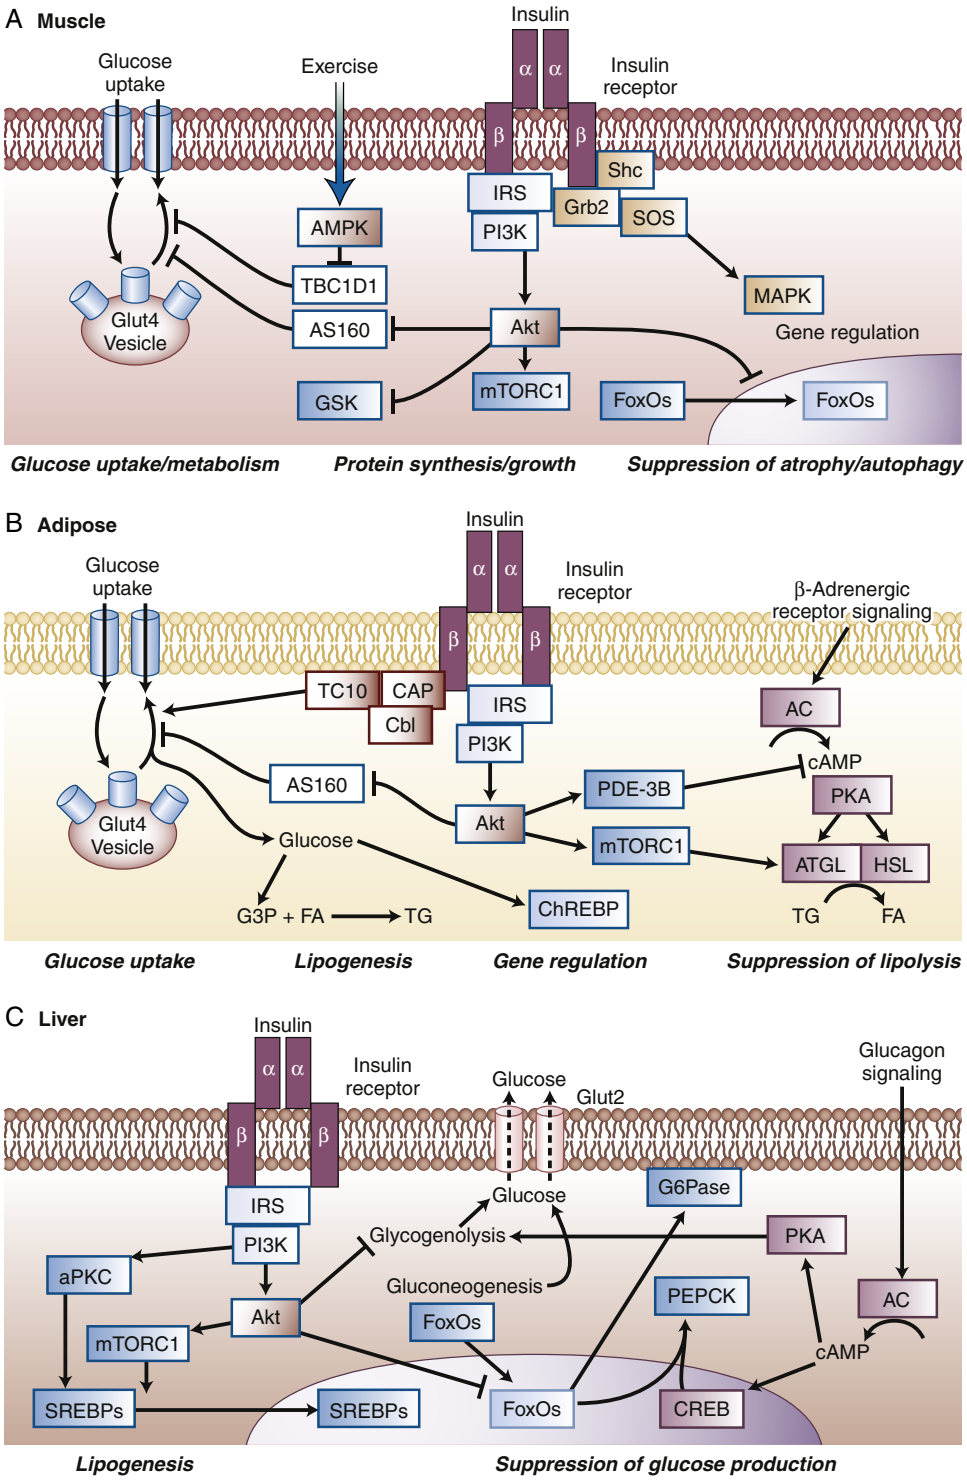
PI3K generates phosphatidylinositol 3,4,5-triphosphate (PIP3), which activates several PIP3-dependent serine-threonine kinases, such as PI-dependent protein kinases 1 and 2 (PDPK1 and PDPK2), which in turn activate Akt isoforms, atypical PKCs, wortmannin-sensitive and insulin-stimulated serine kinase, and others.

Akt kinase (also known as protein kinase B) exists as three distinct isoforms that are activated by phosphorylation on specific threonine and serine residues.[63,64] Full activation of Akt requires PDPK1-directed phosphorylation at threonine 308 (T308) in the kinase domain (KD) followed by phosphorylation at serine 473 (S473) in the hydrophobic motif (HM) of Akt by the rictor-containing complex, mTOR complex 2 (mTORC2).[64] Activated Akt has the ability to phosphorylate proteins that regulate lipid synthesis, glycogen synthesis, protein synthesis, and apoptosis. Disruption of Akt1 results in growth retardation,[65] whereas disruption of Akt2 results in insulin resistance and diabetes in mice.[66] Several investigators have examined the role of PI3K and Akt in persons with insulin resistance. Studies have shown a decrease in IRS-associated PI3K[67] and Akt[68] activity in insulin-resistant skeletal muscle; however, in some patients with reduced PI3K activity, there was normal activation of Akt.[69]

Tissue-Specific Actions of Insulin

Mechanisms of Insulin-Mediated Glucose Uptake in Muscle and Fat

A primary effect of insulin in skeletal muscle and adipose tissue is to stimulate glucose uptake by translocation of GLUT4 from an intracellular pool to the surface of cells[70] (Fig. 34.5A). Indeed,



• **Fig. 34.5** Tissue-specific insulin signaling. Insulin binds to the insulin receptor, allowing for docking and activation of multiple signaling molecules, most notably insulin receptor substrates (IRS), phosphatidylinositol-3-kinase (PI3K) and Akt, which can mediate different physiologic effects, depending on the tissue. (A) In muscle, insulin action increases glucose uptake/metabolism, promotes protein synthesis and suppresses atrophy, some of which can also be mediated by exercise. (B) In adipose, insulin increases glucose uptake and lipogenesis while suppressing lipolysis. (C) In liver, insulin promotes lipogenesis and counters the actions of glucagon, thereby suppressing glucose production. *AC,* adenylate cyclase; *AMPK,* adenosine monophosphate (AMP)–activated kinase; *aPKC,* atypical protein kinase C; *AS160,* Akt substrate of 160 kilodaltons (also TBC1D4); *ATGL,* adipose triglyceride lipase; *CAP,* Cbl-associated protein; *Cbl,* Cas-Br-M (murine) ectopic retroviral transforming sequence; *ChREBP,* carbohydrate response element–binding protein; *CREB,* cyclic AMP (cAMP) response element–binding protein; *FA,* fatty acid; *FoxO,* forkhead box O; *G3P,* glycerol-3-phosphate; *G6Pase,* glucose-6-phosphatase; *Glut,* glucose transporter; *Grb2,* growth factor receptor–bound protein 2; *GSK3,* glycogen synthase kinase 3; *HSL,* hormone-sensitive lipase; *MAPK,* mitogen-activated protein kinases (MEK, MAPK/ERK kinases); *mTORC1,* mammalian target of rapamycin complex 1; *PEPCK,* phosphoenolpyruvate carboxykinase; *PDE-3B,* phosphodiesterase 3B; *PKA,* protein kinase A; *Shc,* SH3-containing protein; *SOS,* son of sevenless; *SREBP,* sterol responsive element–binding protein; *TBC1D1,* tre-1/USP6 BUB2 cdc16 domain family member 1; *TC10,* small GTP-binding protein TC10; *TG,* triglyceride.

disruption of GLUT4 in muscle or adipose tissue causes an insulin-resistant phenotype.[71,72] Akt substrate of 160 kDa (AS160, also known as TBC1D4) and TBC1D1 are paralog Rab family guanosine triphosphatase (GTPase)-activating (Rab GAP) proteins that have been proposed to inhibit the translocation of GLUT4 to the plasma membrane through interaction with insulin-responsive aminopeptidase (IRAP).[73] AS160 activity is suppressed by Akt phosphorylation in response to insulin stimulation and mediates translocation of GLUT4-containing vesicles to the plasma membrane to increase glucose uptake in muscle and adipose tissue.[73,74] TBC1D1, however, is phosphorylated by adenosine monophosphate–activated kinase (AMPK) and appears to play a key role in exercise-regulated increases in muscle glucose uptake, which remain intact in patients with T2DM.[75-77] On phosphorylation of the Rab GAPs, the inhibition of GLUT4 translocation by AS160 and/or TBC1D1 is relieved, contributing to the increased glucose uptake. Although the composition and signaling pathways that converge on the intracellular GLUT4-containing vesicles to cause GLUT4 translocation are still not fully understood, it appears that the number of glucose transporters in skeletal muscle of insulin-resistant persons is not changed, but the ability of insulin to effect GLUT4 translocation is disrupted.[78-80] In adipose tissue, PI3K-independent mechanisms also play a role in mediating glucose uptake. Insulin receptors can associate with Cbl-associated protein (CAP) and the E3 ubiquitin-protein ligase Cbl to activate TC10, an actin remodeling enzyme.[81] This interaction occurs in lipid rafts on the plasma membrane, contributing to GLUT4 vesicle translocation in the absence of IRS-PI3K-Akt activation. A similar mechanism of actin remodeling to regulate GLUT4 trafficking occurs in striated muscle, but this is via Rac proteins and is not dependent on TC10.[82]

In addition to its regulation of glucose metabolism, insulin also has profound effects on protein homeostasis (proteostasis).[83] In muscle, insulin promotes hypertrophy by both enhancing protein synthesis and suppressing protein degradation pathways including proteasome and autophagy (see Fig. 34.5A). Insulin, via Akt, activates mTOR complex 1 (mTORC1) to promote protein synthesis and cellular growth.[84] At the same time, insulin suppresses forkhead box O (FoxO) transcription factor activation, a master regulator of protein degradation pathways.[83,85] Mouse models with muscle-specific deletion of insulin receptor, or both insulin receptor and IGF1 receptor, show profound muscle atrophy,[86] but the atrophy is completely rescued by deletion of FoxOs.[87] This increased protein degradation is also seen in rodent models of T1DM[88] and in patients with T1DM when insulin is withdrawn for as little as 8 hours.[89,90] Thus, insulin coordinates muscle protein turnover, and this regulation is dependent on suppression of FoxO-regulated protein degradation.

Insulin Regulation of Lipolysis and Lipogenesis

Insulin plays a critical role in regulating lipid storage. The liver is the primary site for de novo lipogenesis of fatty acids and triglycerides, whereas adipose tissue serves as the primary storage depot for triglycerides. Insulin signaling enhances lipid storage in adipose by both stimulating triglyceride synthesis and suppressing lipolytic triglyceride breakdown (see Fig. 34.5B). First, insulin stimulates rapid and potent increases in adipose tissue glucose uptake that is then converted into glycerol-3-phosphate, used to synthesize triglycerides from fatty acids. Fatty acid transport into adipose is also increased by insulin, which likely involves translocation of fatty acid transporters, including FATP1 and CD36,[91] and/or increases in lipoprotein lipase expression and activity.[92-94] In addition to providing substrates for triglyceride synthesis, glucose also activates carbohydrate response element–binding proteins to upregulate glycolytic and lipogenic genes in adipocytes.[95] This pathway to enhance lipid storage is critical for metabolic homeostasis, as overexpression of GLUT4 in adipose protects against insulin resistance caused by diet-induced obesity, but deletion of carbohydrate response element–binding protein prevents this effect.[95,96]

Insulin potently suppresses adipose tissue lipolysis, which, when combined with the enhanced lipid uptake in adipose, can significantly reduce circulating fatty acid content.[97] Insulin regulates lipolysis at multiple levels (see Fig. 34.5B). β-adrenergic signaling enhances cyclic adenosine monophosphate (cAMP)-induced protein kinase A activation, which in turn activates two of the principal lipases in fat cells: adipose tissue triglyceride lipase (ATGL) and hormone-sensitive lipase. Insulin activates PDE-3B, which reduces cAMP levels and inhibits protein kinase A–mediated activation of ATGL and hormone-sensitive lipase.[98,99] Two further mechanisms by which insulin suppresses lipolysis are by increases in ATGL mRNA and by increased expression of FSP27, a lipid droplet stabilizing protein.[100-102] These actions of insulin to suppress lipolysis are clinically important in T1DM because newly diagnosed T1DM patients show a rapid gain of fat during the first year of insulin therapy.[103,104]

Regulation of fat distribution by insulin is also important in metabolic health. A recent genomic analysis found strong associations between reduced adiposity in peripheral compartments, severe insulin resistance, and SNPs in 53 genes, among which insulin receptor (INSR), IRS1, and a regulatory subunit of PI3K (PIK3R1) were identified.[105] The 53 genes also correlated highly with familial partial lipodystrophy type 1 (FPLD1). These studies agree with data from rodent models that indicate deletion of insulin receptors in adipocytes leads to rapid decreases in adipose tissue mass, redistribution of body fat to liver, and lipodystrophic diabetes.[106-108] Thus, insulin regulation of lipolysis and lipogenesis in adipose plays a critical role in storage of lipids, maintaining whole-body insulin sensitivity, and preventing metabolic disease.

Insulin also regulates hepatic lipogenesis, the primary site of de novo lipogenesis in the body.[97] SREBP transcription factors are master regulators of lipogenic genes including fatty acid synthase, lipoprotein lipase, acetyl coenzyme A carboxylase (ACC), and stearoyl coenzyme A (CoA) desaturase isoforms, and are regulated by insulin at multiple levels in liver (see Fig. 34.5C). Through activation of atypical PKC isoforms λ/ζ (aPKC), expression of sterol regulatory element-binding transcription factor 1c (SREBP1c) is increased by insulin in liver.[109,110] Furthermore, SREBP1c requires proteolytic cleavage to enter the nucleus and activate transcription of lipogenic genes. This processing of SREBP1c is regulated by mTORC1 signaling downstream of the IRS-PI3K-Akt pathway,[111] and mTORC1 activation can also promote mRNA stability of SREBP1 target genes.[112] Studies in mice and humans with insulin receptor mutations show that reduced insulin signaling in the liver protects against hepatic steatosis.[113,114] However, patients with T2DM and metabolic syndrome have a paradoxical upregulation of hepatic lipogenesis and dyslipidemia that is observed in the context of muscle and adipose insulin resistance, altered CNS signaling to the liver, and increased nutrient supply. Although the exact mechanisms have not been elucidated, the upregulation of hepatic lipogenesis in insulin-resistant states is proposed to be due to either a selective postreceptor insulin resistance[113-115] or a combination of insulin resistance with altered substrate supply and extrahepatic signaling.[116-118]

Insulin Regulation of Hepatic Carbohydrate Metabolism

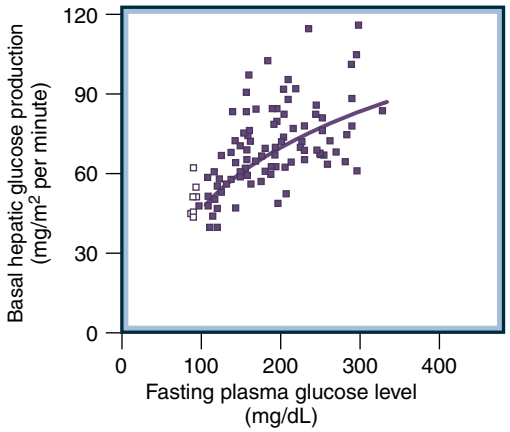
The production of glucose by the liver is regulated primarily by a balance between the actions of insulin to suppress glucose production

and glucagon to activate glucose production, with insulin being dominant over glucagon (see Fig. 34.5C). The sympathetic nervous system[119] and glucose autoregulation also play roles in hepatic glucose production but are probably less important.[120] The ability of insulin to reduce hepatic glucose output is an important mechanism for maintaining normal fasting blood glucose and normal glucose tolerance.[121,122] Insulin also suppresses glucose release from the liver by inhibiting glycogenolysis.[123] As with gluconeogenesis, the effect of insulin to suppress hepatic glycogenolysis is dominant over glucagon.[124] Glucagon increases glycogenolysis by activation of the classic protein kinase A cascade involving cAMP and also increases gluconeogenesis in part by increasing transcription of phosphoenolpyruvate carboxykinase (PEPCK) by means of cAMP response element–binding protein (CREB).[122,125]

Data suggest that the regulatory mechanisms triggered by cAMP are much more complex, with the CREB transcriptional coactivator, TORC2, playing an important role. TORC2 is specifically dephosphorylated in response to cAMP; this results in translocation of the TORC2 protein to the nucleus, allowing activation of CREB-dependent transcription of gluconeogenic enzymes.[126] In addition, CREB may increase transcription of PPARγ coactivator 1α (PGC1α), which serves as a critical coactivator of the transcription factor forkhead box protein O1 (FoxO1). FoxO1 plays a role in the transcriptional activation of various genes associated with gluconeogenesis, including PEPCK and glucose-6-phosphorylase.[125] Indeed, deletion of FoxO isoforms in the liver can restore glucose levels to normal in mice with insulin receptor knockout.[127,128] Deacetylation of transcription factors and coactivators can also regulate gluconeogenesis. The sirtuin, SIRT1, deacetylates PGC1α[129] and histone deacetylases and sirtuins can deacetylate FOXOs,[130,131] increasing their nuclear localization and interaction with HNF4A. The PGC1α/FOXO1/HNF4A complex is a potent activator of gluconeogenic gene transcription.[125]

Insulin decreases endogenous glucose production by direct and indirect mechanisms.[132] In its direct action, portal insulin suppresses glucose production by inhibiting glycogenolysis and gluconeogenesis by insulin receptor activation (see Fig. 34.5C). The indirect or peripheral effect of insulin in controlling glucose production by the liver is twofold. First, insulin profoundly decreases glucagon secretion by the alpha cell of the pancreas through systemic and paracrine effects.[133,134] The decrease in glucagon secretion decreases the activation of glycogenolysis and gluconeogenesis. The second important peripheral action of insulin is to decrease substrates for gluconeogenesis, such as alanine from muscle protein degradation,[83] and glycerol and free fatty acid levels, by suppressing lipolysis in adipose tissue[135] (see Fig. 34.5A,B). When the reduction in plasma fatty acids during a hyperinsulinemic clamp is prevented by infusion of triglyceride emulsions with heparin (which produces increased fatty acid levels through activation of lipoprotein lipase), insulin-mediated suppression of hepatic glucose output is reduced.[136] The suppression of glucagon secretion and the decrease in gluconeogenic substrate delivery to the liver are additive in reducing liver glucose production.[137]

Clinically, hepatic insulin resistance plays an important role in the hyperglycemia of T2DM,[138,139] and the impaired suppression of hepatic glucose output appears to be quantitatively similar to, or even larger than, the defect in stimulation of peripheral glucose disposal.[140] Defects in the direct effect of insulin to suppress hepatic glucose production in humans appear to be caused by a large rightward shift in the steep dose-response curve for insulin's inhibition of glycogenolysis.[141] There is a direct relationship between increased hepatic glucose output and fasting hyperglycemia[142] (Fig. 34.6). Insulin-mediated suppression of hepatic glucose output is impaired



• **Fig. 34.6** The relationship between fasting hepatic glucose output and fasting plasma glucose levels. *Open squares* represent nondiabetic control subjects; *closed squares* represent diabetic subjects. (From Maggs DG, Buchanan TA, Burant CF, et al. Metabolic effects of troglitazone monotherapy in type 2 diabetes mellitus: a randomized, double-blind, placebo-controlled trial. *Ann Intern Med.* 1998;128:176–185. © American College of Physicians, used with permission.)

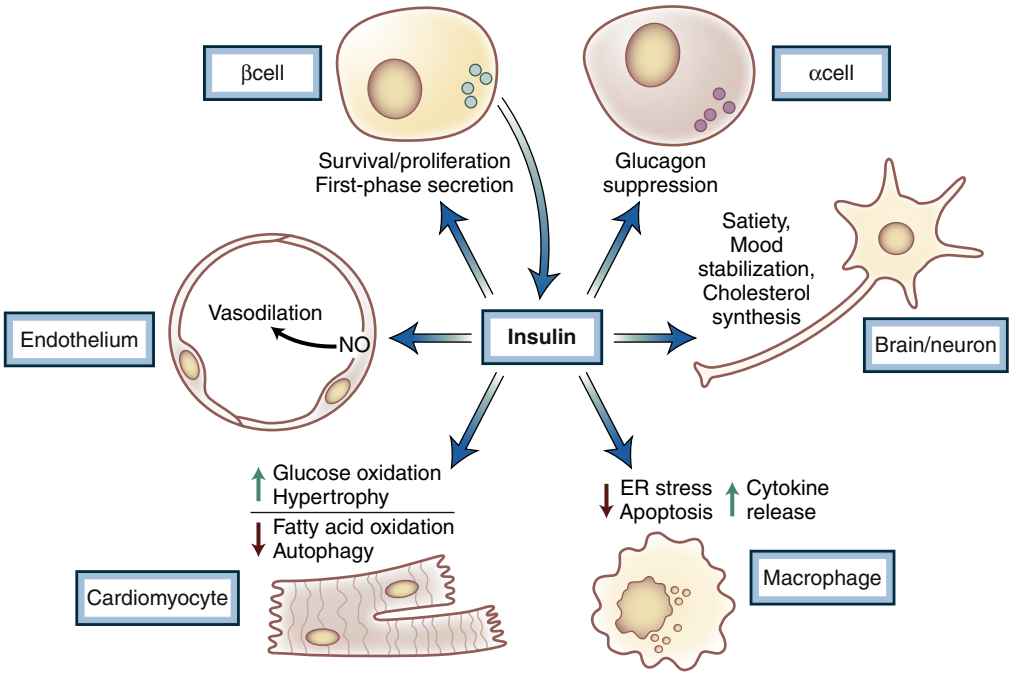
at both low and high plasma insulin levels in T2DM[140,143]; hepatic glucose production is elevated early in the course of the disease[144,145] but may be normal in lean, relatively insulin-sensitive T2DM.[146] Treatment of patients with metformin, which suppresses hepatic glucose production, results in improved glucose tolerance.[145]

Expanding Collection of Insulin-Sensitive Tissues

Although much of our understanding of insulin action on metabolism involves the insulin-sensitive metabolic tissues of muscle, liver, and adipose, insulin receptors are ubiquitously expressed and insulin action on other "nonclassic" tissues plays an important role in health (Fig. 34.7). Insulin signaling in beta cells is critical for adaptive survival and proliferation of these cells. Insulin secretion and beta-cell mass both increase in response to chronic mild hyperglycemia, and the ability to upregulate beta-cell mass influences the development of T2DM. Interestingly, when insulin receptors are deleted from beta cells, first-phase insulin secretion is lost and compensatory growth of beta cells is impaired in response to diet-induced obesity and hepatic insulin resistance,[147,148] indicating an unexpected autocrine loop. Furthermore, FoxO transcription factors, which are downstream targets of insulin action, are important for maintenance of beta-cell function and identity,[149] and beta cells appear to de-differentiate when FoxOs are deleted.[150] Evidence that beta-cell dedifferentiation occurs in insulin-resistant states in humans are emerging,[151] but the degree to which this phenomenon accounts for beta-cell failure in T2DM and whether this process can be intervened upon is still under investigation.

Insulin action on glucagon-producing alpha cells suppresses glucagon secretion and maintains glucose homeostasis. This was demonstrated by deletion of insulin receptors on alpha cells of mice, which leads to mild glucose intolerance, increased glucagon secretion, and progressive hyperinsulinemia,[134] all of which are features of metabolic syndrome and T2DM. Thus, insulin signaling on alpha and beta cells in islets is important for metabolic health and glucose homeostasis.

Vascular complications are a major contributor to morbidity and mortality in diabetes. Thus, it may not be surprising that vascular endothelium and cardiomyocytes are exquisitely insulin



• **Fig. 34.7** The expanding collection of insulin-sensitive tissues. Insulin receptors are ubiquitously expressed, and thus insulin controls pleotropic effects on numerous "nonclassical" tissues that play an important role in health. *ER,* endoplasmic reticulum.

responsive. In endothelial cells, insulin action promotes vasodilation via nitric oxide production, which is impaired in insulin resistant states.[152-154] Endothelial insulin sensitivity is also important for transendothelial transport of insulin to peripheral tissues,[155,156] and the relative permeability of the endothelial barrier in various tissues plays an important role in timing of insulin action in those tissues after a bolus of insulin.[157] Endothelial insulin signaling also plays a major role in the development of atherosclerosis. Insulin receptor knockout in endothelial cells caused a two- to threefold increase in atherosclerotic lesions in an atherogenic mouse model.[158] Conversely, enhancing downstream activation of insulin signaling by either overexpression of IRS or inhibition of FoxOs improves vascular endothelial function and can prevent atherosclerosis.[159,160] In cardiomyocytes, the insulin signaling cascade controls growth and metabolism in both physiologic and pathologic conditions.[161,162] The heart has a remarkable ability to utilize a wide variety of substrates for energy production, but under fasted states, fatty acids are preferentially metabolized. On insulin stimulation, glucose oxidation is increased and fatty acid oxidation is suppressed, but in insulin-resistant or diabetic states, this metabolic flexibility is lost.[163] Insulin also plays an important role in postnatal cardiac growth by suppression of autophagy.[164] These signals in the cardiovascular system integrate with insulin action in other tissues and metabolic flux to coordinate cardiovascular health. Disruption of the tissue cross talk during obesity and insulin resistance results in features of metabolic syndrome, which increase cardiovascular risk.[165]

Insulin can also affect cardiovascular risk by its action on immune cells, particularly macrophages. Macrophages play an important role in the development of atherosclerosis by formation of foam cells within atherosclerotic plaques, enhanced inflammation, and apoptosis leading to a necrotic core that is susceptible to rupture.[166] Mouse models with loss of insulin signaling in macrophages show mild protective effects on atherosclerotic lesion size[167] but also show worsening of the necrotic core, likely due to enhanced macrophage apoptosis from endoplasmic reticulum (ER) stress.[168] This observation also extends to obesity and aging models of atherosclerosis[169,170] indicating that insulin resistance in macrophages contributes to plaque progression in the context of metabolic syndrome.[171]

Insulin Signaling in the Central Nervous System

Although previously considered insulin independent, it is now clear that the brain is an important site for insulin signaling. Insulin action is not required for glucose uptake in the brain because it predominantly expresses the insulin-independent glucose transporters Glut1 and Glut3. The insulin receptor is expressed throughout the brain. Brain-specific knockout of the receptor in mice results in a variety of abnormalities including increased body weight, hypothalamic hypogonadism, increased hepatic glucose production, and a depression-like phenotype.[172] The impact of insulin signaling in the brain is cell-type specific. Although neuronal insulin receptor appears to be key for regulation of hepatic glucose production,[173] astrocyte insulin receptor signaling is vital for insulin-mediated effects on mood.[174] Activation of the brain insulin receptor can lead to improved synaptic transmission through cholesterol synthesis; proliferation through mitogen-activated protein kinase; axon growth and neuroplasticity through glycogen synthase kinase 3β (GSK3β); gene transcription and neuronal polarity through FOXO; and autophagy, protein synthesis, and neuronal plasticity through mTORC1.[175,176] Insulin entry into the brain shows regional differences and in some areas is dependent on a receptor-mediated transcytosis process.[157,177] Systemic insulin resistance results in lower than expected cerebrospinal fluid insulin levels due to decreased transport across the blood-brain barrier.[178] Brain-specific resistance to both insulin and IGF1 signaling in humans is associated with Alzheimer disease, but the significance of these findings to disease progression remains uncertain.[179]

The insulin receptor has two isoforms: IR-A is missing exon 11, whereas IR-B includes exon 11. Isoform A has a higher affinity for insulin-like growth factor 2 binding than isoform B. In contrast to most other tissues in the body, the brain predominantly expresses isoform A. Other unique aspects of brain insulin signaling include a unique glycosylation pattern of the brain insulin receptor and the propensity for insulin receptor to form heterodimers with the more abundant IGF1 receptor, which appears to favor IGF1 signaling over insulin signaling.[180] Greater understanding of the relative impacts of insulin and IGF1 signaling on the various cell types of the brain may prove critical as clinical trials are under way in testing the efficacy of insulin delivered to the brain intranasally to treat such diverse disorders as Alzheimer disease, depression, and obesity.

Insulin Resistance and the Risk of Type 2 Diabetes Mellitus

Insulin Resistance

The term *insulin resistance* indicates the presence of an impaired biologic response to either exogenously administered or endogenously secreted insulin. Insulin resistance is primarily manifested by decreased insulin-stimulated glucose transport and metabolism in skeletal muscle, impaired insulin suppression of adipocyte lipolysis, and impaired ability of insulin to suppress hepatic glucose output. However, given the pleiotropic actions of insulin, it is clear that insulin resistance could lead to disorders of multiple metabolic pathways involving amino acids, glucose, and lipid metabolism.

Insulin resistance can be measured using a variety of techniques. The gold standard for determining insulin sensitivity/resistance in an individual is a hyperinsulinemic euglycemic clamp. In this technique, developed by DeFronzo, a patient is given a constant infusion of insulin to produce hyperinsulinemia. A second infusion containing glucose is given concurrently and adjusted to produce euglycemia. Since the individual is in steady state, the glucose infusion rate represents the rate of glucose uptake/disposal into muscle, fat, and other tissues under hyperinsulinemic conditions (i.e., the insulin sensitivity of the patient).[181] When conducted with tracers, one can also measure the hepatic glucose production rate as a measure of liver insulin sensitivity. Because this technique is costly, invasive, and time consuming, alternative approaches have been developed to estimate insulin resistance, such as the steady-state plasma glucose method of Reaven[182] or the Bergman minimal model of glucose disposal assessed using a frequently sampled intravenous glucose tolerance test.[183] When coupled with insulin levels, one can also obtain the Disposition Index, which is a combined measure of insulin sensitivity and insulin secretion.[184,185] For large cohort studies or a simple measure in an outpatient setting, HOMA-IR (homeostatic model assessment of insulin resistance) can be calculated using just fasting glucose and insulin levels. It correlates favorably with a hyperinsulinemic euglycemic clamp with an R_s of 0.88.[186] Others favor the use of QUICKI (quantitative insulin-sensitivity check index), as an alternative mathematical model, also based on the reciprocal of the logarithm of HOMA-IR.[187]

Insulin sensitivity is influenced by several factors, including age, weight, ethnicity, body fat (especially intra-abdominal obesity), physical activity, dietary intake, gut microbiota, and medications. Substantial data indicate that insulin resistance plays a major role in the development of IGT and diabetes. Insulin resistance is a consistent finding in patients with T2DM, and resistance is present years before the onset of diabetes.[188-191] Prospective studies have shown that insulin resistance predicts the onset of diabetes.[189,190] There is also a strong influence of environmental factors on the genetic predisposition to insulin resistance and therefore to diabetes.[192,193]

The molecular mechanisms of insulin resistance are initiated by various pathophysiologic processes that feed back on the insulin receptor and its adapter proteins (Fig. 34.8). The insulin receptor β-subunit has been shown to undergo serine/threonine phosphorylation, which might decrease the ability of the receptor to autophosphorylate. The activities of several serine/threonine protein kinases that catalyze inhibitory phosphorylation of the insulin receptor or IRS proteins are elevated in animal models of insulin resistance and in insulin-resistant humans.[194,195] Interventions that decrease serine phosphorylation (inhibitory signal) of the insulin receptor result in increased insulin signaling.[196] Furthermore, enhanced tyrosine dephosphorylation by protein tyrosine phosphatases can attenuate insulin signaling. Two protein tyrosine phosphatases that have been shown to negatively regulate insulin signaling, PTP1B and LAR (leukocyte antigen related), have been reported to be elevated in insulin-resistant patients.[197,198] Conversely, disruption of PTB1B in mice resulted in a marked increase in insulin sensitivity and resistance to diet-induced obesity.[199]

As mentioned previously, mutations in the insulin receptor are associated with rare forms of insulin resistance. In addition, individuals may develop autoantibodies to the insulin receptor, which induce severe insulin resistance (type B insulin resistance and acanthosis nigricans).[13,200]

Obesity and Type 2 Diabetes Mellitus

The association of obesity with T2DM has been recognized for decades (Fig. 34.9). Central (also referred to as intra-abdominal or visceral) adiposity is more strongly linked to insulin resistance and to several important metabolic variables, including elevated plasma glucose, insulin, total plasma cholesterol and triglyceride concentrations, and decreased plasma high-density lipoprotein cholesterol concentration, than is total adiposity.[201-207] Indeed, some studies have suggested that subcutaneous fat may actually be protective against insulin resistance.[208] As a result, the association between abdominal fat and glucose tolerance is independent of total adiposity.[209,210] The reason for the relationship between intra-abdominal fat and abnormal metabolism is not clearly defined, but several hypotheses have been proposed and may interact in this association. Abdominal fat is more lipolytically active than subcutaneous fat, perhaps because of its greater complement of adrenergic receptors.[211] In addition, the abdominal adipose store is resistant to the antilipolytic effects of insulin,[212] including alterations in lipoprotein lipase activity; this leads to increased lipase activity and a greater flux of fatty acids into the circulation, with the portal circulation receiving the greatest fatty acid load. Conversely, subcutaneous fat makes and releases more adiponectin, which is a beneficial adipokine. Finally, the high levels of 11β-hydroxysteroid dehydrogenase type 1 (HSD11B1) in intra-abdominal fat could result in enhanced conversion of inactive cortisone to active cortisol, resulting in increased local cortisol production. This might change adipocytes to increase lipolysis and alter the production of adipokines, which may directly modulate glucose metabolism.

Hyperinsulinemia and Insulin Resistance

Hyperinsulinemia can cause insulin resistance. Elevated concentrations of insulin downregulates insulin receptors and desensitizes postreceptor pathways.[213] Del Prato and colleagues[214] showed that 24 and 72 hours of sustained physiologic hyperinsulinemia
