The principal progestogens are C21 steroids and include pregnenolone, progesterone, and 17- hydroxyprogesterone (see Fig. 17.16). Pregnenolone is of primary importance in the ovary because of its key position as a precursor of all steroid hormones.[103] Progesterone, the principal secretory product of the corpus luteum, is responsible for the progestational effects (i.e., cell differentiation and induction of secretory activity in the endometrium of the estrogen-primed uterus).[103] Progesterone is essential for implantation of the fertilized ovum and maintenance of pregnancy. It also induces decidualization of the endometrium, inhibits uterine contractions, increases the viscosity of cervical mucus, promotes lateral (alveolar) development of the breast glands, and increases basal body temperature.[103]

C19 Steroids

The ovary secretes a variety of C19 steroids, including DHEA, androstenedione, and testosterone, all of which primarily serve as distant or immediate precursors for the potent androgen, DHT, or potent estrogen, estradiol (see Fig. 17.16; also see Fig. 17.26, later).[97] C19 steroids are produced by the theca cells and, possibly, to a lesser degree by the ovarian stroma. The major C19 steroid is androstenedione, part of which is secreted directly into plasma, with the remainder converted to estrogen by the granulosa cells.[92] DHEA and androstenedione do not appear to have major androgenic actions. In the ovary and in peripheral tissues, DHEA is converted to androstenedione, which can be converted

to estrone or testosterone.[97] Testosterone is converted locally to DHT at target tissues for full androgenic action or estradiol for estrogenic activity.

C18 Steroids

Estrogen regulates gonadotropin secretion, development of the secondary sexual characteristics of women, uterine growth, thickening of the vaginal mucosa, thinning of the cervical mucus, linear growth of the ductal system of the breast, growth spurt, epiphyseal closure, and bone mineralization.[104] The naturally occurring estrogens are C18 steroids characterized by the presence of an aromatic A ring, a phenolic hydroxyl group at C3, and a hydroxyl group (estradiol) or a ketone group (estrone) at C17.[92,97] Aromatase is the key enzyme for estrogen production in the ovary (see Fig. 17.16).[92] The protein aromatase, encoded by the *CYP19A1* gene, confers the specific activity of the aromatase enzyme complex.

Aromatase mRNA and protein expression and its enzyme activity in the ovarian granulosa cell are regulated primarily by FSH.[92,97] The principal and most potent estrogen secreted by the ovary is estradiol. Although estrone is also secreted by the ovary, another important source of estrone is extraglandular conversion of androstenedione in peripheral tissues.[97] All C18 steroids, including estrone, estradiol, and estriol, are commonly referred to as estrogens. However, estrone is only weakly estrogenic and must be converted to estradiol to show full estrogenic action. At least seven enzymes with overlapping activities are capable of converting estrone to estradiol in the ovary and extraovarian tissues.[105]

Catechol estrogens are formed by hydroxylation of estrogens at the C2 or C4 position. The physiologic role of catechol estrogen is unclear. Estrone sulfate, formed by peripheral conversion of estradiol and estrone, is the most abundant estrogen in blood, but it is not physiologically active. Estrone sulfate is presumed to serve as a reservoir for estrone and eventually estradiol formation in a number of tissues, including those that are targets of estrogen.[97]

Two-Cell Theory for Ovarian Steroidogenesis

The classic two-cell theory is supported by molecular findings. Ovarian steroidogenesis in the preovulatory follicle takes place through LH receptors on theca cells and FSH (possibly also LH) receptors on granulosa cells (see Fig. 17.17). cAMP production and increased SF1 binding to multiple steroidogenic promoters mediate LH action in theca cells.[106] The StAR protein is the primary regulator of production of androstenedione, which subsequently diffuses into granulosa cells to serve as the estrogen precursor.[97] In the preovulatory follicle, cholesterol in theca cells arises from circulating lipoproteins and de novo biosynthesis. FSH is responsible for follicular growth and estrogen formation. FSH induces cAMP formation, activation of protein kinase A and certain MAP kinases, and increased binding activity of LRH1 or SF1 to the *CYP191A1* promoter in preovulatory granulosa cells to form estrone and then estradiol primarily through aromatization of androstenedione (see Fig. 17.17). The relative roles of SF1 and LRH1 in estrogen formation in human ovarian granulosa cells are not well understood.[106]

In the corpus luteum, large stores of cholesterol esters (which provide the yellow color) arise primarily from circulating lipoproteins to support the production of extremely high quantities of progesterone.[107] Other key anatomic events in the formation of the corpus luteum are the disruption of the basement membrane between the granulosa and theca cells and strikingly increased vascularization of granulosa-lutein cells (see Fig. 17.15). Theca-lutein cells possess LH receptors and produce androstenedione. cAMP, SF1, and StAR induced by LH remain as the key regulators for biosynthesis of androstenedione, which serves as the estrogen precursor in neighboring granulosa-lutein cells (see Fig. 17.17).

The granulosa-lutein cell of the corpus luteum is anatomically and functionally different from its counterpart in the preovulatory follicle in several ways. First, these cells are characterized by large and granular cytoplasms, are heavily vascularized, and contain large quantities of cholesterol esters. Second, granulosa-lutein cells contain high levels of LH receptors in addition to FSH receptors. Third, they produce large quantities of progesterone; this function is regulated primarily by LH and StAR. Granulosa-lutein cells also aromatize androstenedione of thecal origin and eventually give rise to estradiol formation through FSH action and CYP19A1. The known mediators of LH and FSH in human granulosa-lutein cells are cAMP and increased LRH1 levels.[106,107] The relative roles of LRH1 and SF1 for progesterone and estradiol production in granulosa-lutein cells are not clear. Specific functions of the two gonadotropins (i.e., differentiation, growth, and progesterone vs estradiol formation) are probably determined by numerous modifying factors (see Fig. 17.17).

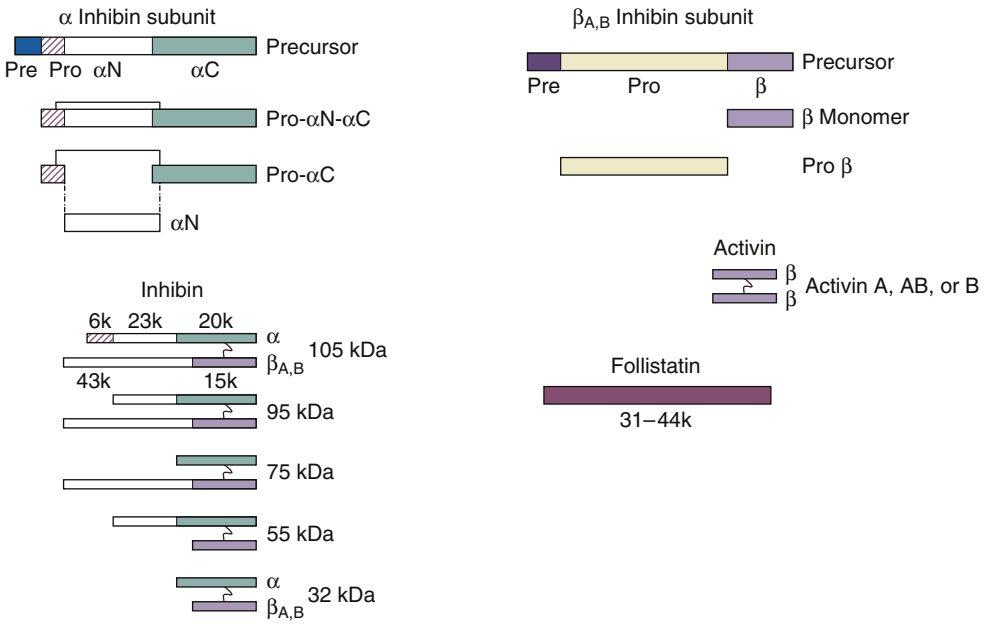
Peptide Hormones Produced by the Ovary

The ovary produces a large number of peptides that can act in an intracrine, autocrine, paracrine, or endocrine fashion.[106,108,109] They include numerous growth factors (e.g., IGFs) and cytokines (e.g., interleukin 1β). IGFs cross-talk with the FSH-dependent signaling cascade to augment the effects of FSH in granulosa cells.[108,109]

Inhibin, activin, and follistatin are produced in ovarian granulosa cells under the control of FSH and LH (Fig. 17.18).[106] Production of inhibin and activin is not limited to the ovary; a number of other tissues, including adrenal, pituitary, and placenta, synthesize these members of the broader TGFβ family of paracrine/endocrine factors. Two isoforms of inhibin have been isolated: inhibin-A and inhibin-B.[106] They contain an identical α-subunit but distinct β-subunits (β_A and β_B), encoded by separate genes. The heterodimers of inhibin, $\alpha\beta_A$ and $\alpha\beta_B$, are called inhibin-A and inhibin-B, respectively (see Fig. 17.18). Although inhibin is produced by a number of tissues in the body, most of it is derived from the gonads. In the ovary, the source of inhibin is granulosa cells. The main role of inhibin is to suppress FSH production in the pituitary.[106]

Although both inhibin isoforms seem to have similar biologic properties, their synthesis is regulated differently during the follicular and luteal phases (see Fig. 17.1A). Under the influence of FSH, inhibin-B is secreted mainly during the early follicular phase, with levels decreasing in midfollicular phase and becoming undetectable after the LH surge.[106] LH-induced inhibin-A levels are low during the first half of the follicular phase but increase gradually during the midfollicular phase and peak during the luteal phase. All three subunits are detected in small antral follicles by immunohistochemistry and in situ hybridization.[106] The α-subunit and β_A-subunit are found in the dominant follicle and in the corpus luteum. All three subunits are expressed in response to gonadotropins or factors that increase intracellular cAMP.[106]

Activin is structurally related to inhibin but exerts opposite actions.[106] Activin contains two subunits that are identical to the β-subunits of inhibin-A and inhibin-B. The three activin isoforms are activin A ($\beta_A\beta_A$), activin B ($\beta_B\beta_B$), and activin AB ($\beta_A\beta_B$). In the pituitary, activin stimulates the release of FSH. In the ovarian follicle, activin enhances FSH action (see Fig. 17.18). As in the case of inhibin, activins are also produced in ovarian granulosa



• **Fig. 17.18** Structures of inhibin subunit precursors and processed forms in serum, the activins and the follistatins. The precise contribution of each molecular-weight form of inhibin to the biologic activity in serum is not known, but it has been established that the 55-kDa and 32-kDa forms are biologically active. *αN,* amino region of alpha-inhibin; *αC,* carboxy region of alpha-inhibin. (Modified from Burger H. Inhibin, activin and neoplasia. In: Yen SC, Jaffe RB, Barbieri RL, eds. *Reproductive Endocrinology*. 4th ed. Philadelphia, PA: Saunders; 1999:669–675.)

cells and pituitary gonadotrophs. Unlike inhibin, locally synthesized activin in the pituitary, rather than the ovarian-derived activin, is responsible for regulating FSH (see Fig. 17.4).[106]

Follistatin is a single-unit peptide that is produced in several human tissues, including the pituitary and ovary (see Fig. 17.18).[106] It binds and neutralizes the biologic functions of activin. It appears that local follistatin levels in tissues modulate the effects of activin. This explains the inhibitory effect of follistatin on pituitary FSH secretion (see Fig. 17.4).[106]

Overview of the Hormonal Changes During the Ovarian Cycle

FSH secretion is suppressed by negative feedback of the ovarian hormones estradiol, inhibin, and progesterone during the early and midluteal phase. The sharp decline of these hormones upon regression of the corpus luteum during the late luteal phase abolishes this negative feedback (see Fig. 17.1A). This permits increased secretion of FSH just before and during menses. This initial increase in FSH is essential for follicle recruitment and growth and steroidogenesis. With continued growth of the follicle, autocrine and paracrine factors produced within the follicle maintain follicular sensitivity to FSH. Continuing and combined action of FSH and activin leads to the appearance of LH receptors on the granulosa cells, a prerequisite for ovulation and luteinization.

Ovulation is triggered by the rapid rise in circulating levels of estradiol. A positive feedback response at the level of the anterior pituitary and possibly at the hypothalamus results in the midcycle surge of LH that is necessary for expulsion of the egg and formation of the corpus luteum (see Fig. 17.1A). A rise in the progesterone level follows ovulation, along with a second rise in the estradiol level, producing the 14-day luteal phase characterized by low FSH and LH levels. Demise of the corpus luteum concomitant with a fall in hormone (progesterone, estradiol, and inhibin-A) levels allows FSH to increase again toward the end of the luteal phase, initiating a new cycle. If pregnancy is established by implantation of a blastocyst, the structural integrity and function (i.e., progesterone and estradiol production) of the corpus luteum are maintained by hCG secreted from the trophoblast. The hCG acts as a surrogate for LH on the corpus luteum.

In addition to FSH and LH, local factors (e.g., activin, inhibin) regulate follicular development and steroidogenesis. In the early follicular phase, activin produced by granulosa cells in immature follicles enhances the action of FSH on aromatase activity and FSH and LH receptor formation while simultaneously suppressing C19 steroid formation in theca cells. In the late follicular phase, increased production of inhibin by the granulosa cells and decreased activin levels promote the synthesis of C19 steroids in the theca layer in response to LH and local growth factors and cytokines; this provides larger amounts of the precursor androstenedione for production of estrone and ultimately of estradiol in the granulosa cells.[110]

LH-mediated androstenedione production in theca cells and FSH-mediated estradiol production in granulosa cells are potentiated by IGFs.[108] The major endogenous IGF produced in the human ovarian follicle is IGF2 (rather than IGF1), which is produced by granulosa and theca cells. The actions of IGF1 and IGF2 are mediated by IGF receptor type I in both cells. IGF receptor type I is structurally similar to the insulin receptor. It appears that gonadotropin-related IGF action in the ovary is regulated primarily by IGF2 and IGF receptor type I.[108,109]

In summary, ovulation is under the control of substances functioning as classic hormones (i.e., FSH, LH, estradiol, and inhibin), which transmit messages between the ovary and the hypothalamic-pituitary axis and of paracrine and autocrine factors such as IGF2, inhibin, and activin, which coordinate sequential activities within the follicle destined to ovulate. The negative feedback relationship between corpus luteum products (i.e., estradiol,

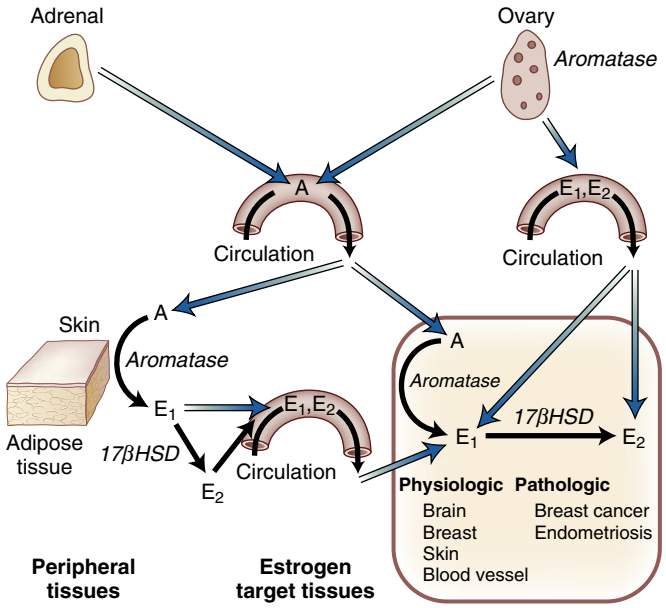
progesterone, and inhibin) and FSH results in the critical initial rise in FSH immediately before and during menses, and the positive feedback relationship between estradiol and LH is responsible for the ovulatory stimulus (see Fig. 17.1). Within the ovary, IGF2, inhibin, and activin modify follicular responses necessary for growth and function. These endocrine, paracrine, and autocrine factors undoubtedly represent only a portion of the complete picture. The causes of anovulation are diverse and may be related to defects in cell surface receptors, intracellular elements of signal transduction, or cell-cell interactions.[111,112]

Extraovarian Steroidogenesis

Estradiol formation takes place in several tissues in the woman of reproductive age, including the ovary, peripheral tissues such as subcutaneous fat and skin, and physiologic and pathologic target sites such as the hypothalamus, breast cancer cells, and the cells of endometriosis (Fig. 17.19).[97] Fat and skin are particularly critical sources of estrogen in anovulatory premenopausal and postmenopausal women. Although only small quantities of estrogen are produced by an individual adipocyte or skin fibroblast in a continuous fashion, these cell types contribute to circulating estradiol levels because of their relative abundance.[97] This effect is more pronounced in obese women because of increased mass of the adipose tissue and skin.[97]

Aromatase (CYP19A1) in adipocytes and skin fibroblasts is responsible for peripheral aromatization of androstenedione that arises from the ovary and the adrenal gland in premenopausal women and primarily from the adrenal in postmenopausal women (see Fig. 17.19).[97] However, the product of this reaction, estrone, is only weakly estrogenic. Estrone is further converted to estrone sulfate, which serves as a reservoir for estrone in blood and other tissues. Estrone (arising from androstenedione and estrone sulfate) is further converted to the biologically active estradiol in target tissues such as the endometrium and breast by a number of enzymatic proteins with overlapping reductive 17βHSD activity (see Fig. 17.19).[97,105] It is likely that local CYP19A1 expression in the hypothalamus is critical for the regulation of gonadotropin secretion.[21,113] Estrogen-dependent pathologic tissues such as those in breast cancer and endometriosis contain extremely high levels of CYP19A1 that enhances tissue growth by increasing local estradiol concentrations (see Fig. 17.19).[97] Circulating androstenedione is the major substrate for aromatase activity in these physiologic and pathologic target tissues.[97]

Significant quantities of circulating androstenedione can also be converted to testosterone in peripheral tissues (discussed later). This is probably accomplished by the presence of multiple 17βHSDs with overlapping reductive activities in peripheral tissues.[105] Androgenic action of testosterone is strikingly amplified by its conversion to DHT in peripheral and target tissues (e.g., skin, prostate). At least two distinct proteins encoded by two separate genes, 5α-reductase type 1 and type 2, catalyze the conversion of testosterone to DHT in liver, prostate, and skin.[98] Local production of DHT in genital skin fibroblasts is critical for normal masculinization of external genitalia of male fetuses in utero.[114] DHT formation in the skin is an important cause of hirsutism.[115]



• **Fig. 17.19** Estrogen biosynthesis in women. The biologically active estrogen, estradiol (E_2), is produced in at least three major sites: (1) by direct secretion from the ovary in reproductive-age women; (2) by conversion of circulating androstenedione (A), originating from the adrenal or ovary or both, to estrone (E_1) in peripheral tissues; and (3) by conversion of A to E_1 in estrogen target tissues. In the latter two instances, estrogenically weak estrone (E_1) is converted to E_2 within the same tissue. The expression of genes that encode the enzymes aromatase and reductive 17β-hydroxysteroid dehydrogenases (17βHSD) is critical for E_2 formation at these sites. Reductive 17βHSD activity in peripheral tissues may be conferred by protein products of several genes with overlapping functions. HSD17B1 is a distinct reductive 17βHSD enzyme that is encoded by a specific gene expressed primarily in the ovary. Aromatase is encoded by a single gene *(CYP19A1)*. E_2 formation by peripheral and local conversion is particularly important in postmenopausal women and in those with estrogen-dependent diseases such as breast cancer, endometriosis, or endometrial cancer.

Endometrium

The endometrium is the mucosal lining of the uterine cavity. The decidua is the highly modified and specialized endometrium of pregnancy. From an evolutionary perspective, the human endometrium is highly developed to accommodate the hemochorioendothelial type of placentation, which requires the presence of spiral arteries (Fig. 17.20). Trophoblasts of the blastocyst invade spiral arteries during implantation and placentation in the establishment of uteroplacental vessels.

Spiral arteries of the human endometrium confer another unique process, *menstruation*. Menstruation is shedding of endometrial tissue with hemorrhage that depends on sex steroid hormone–directed changes in blood flow in the spiral arteries. Spiral arteries are essential for menstruation; only humans and a few other primates that have endometrial spiral arteries experience menstruation. With nonfertile but ovulatory ovarian cycles, menstruation effects desquamation of the endometrium. New endometrial growth and development must be initiated with each ovarian cycle, so endometrial maturation corresponds with the next opportunity for pregnancy. There seems to be a narrow window of endometrial receptivity to blastocyst implantation, comprising the period between days 20 and 24 during a 28-day menstrual cycle.[116]

Functional Anatomy of the Endometrium

The endometrium can be divided morphologically into an upper two-thirds *functionalis* layer and a lower one-third *basalis* layer (see

Fig. 17.20). The purpose of the functionalis layer is to prepare for the implantation of the blastocyst; it is the site of proliferation, secretion, and degeneration. The purpose of the basalis layer is to provide the regenerative endometrium after menstrual loss of the functionalis.[117] Major histologic components of the endometrium include stromal cells, which constitute the skeleton of the tissue; a single layer of epithelial cells, which lines the lumen of the endometrial cavity and invaginations of the stroma; blood vessels; and resident immune cells. The epithelial cells that line the rather deep invaginations of the stroma are also referred to as *glandular cells*. However, these deep crypts represent extensions of the intracavitary lumen and are not true glands. These invaginations lined by epithelial cells extend from the surface of the functionalis layer (i.e., luminal epithelium) deep into the basalis level (i.e., glandular epithelium). After the functionalis layer is shed at the time of menstruation, the tissue stem cells in the basalis layer respond rapidly to estrogen and give rise to a new functionalis layer for the upcoming cycle (Fig. 17.21).[118] In humans and some other primates, the cellular components of the functionalis layer undergo a striking progression during the menstrual cycle, whereas the basalis layer shows only modest alterations.[117,119,120]

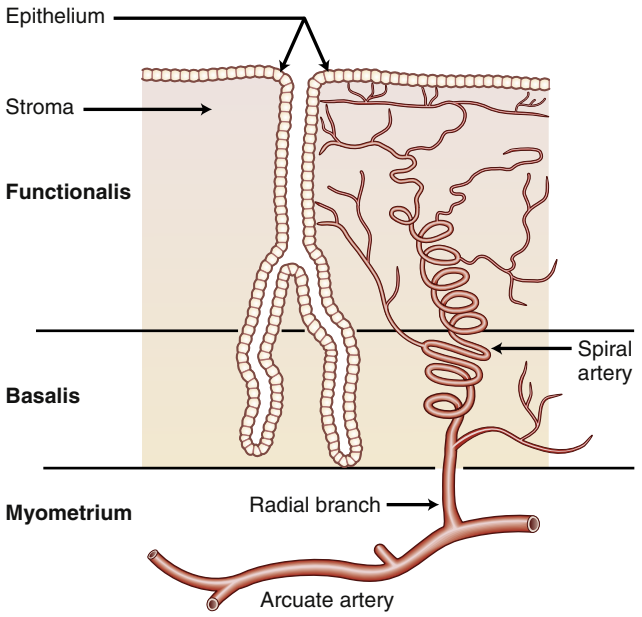
Hormone-Induced Morphologic Changes of the Endometrium

The cyclic changes in endometrial histology are faithfully reproduced during each ovulatory ovarian cycle (see Fig. 17.21). First, during the preovulatory, or follicular, phase of the cycle, estradiol is secreted (principally by a single dominant follicle of one ovary) in increasing quantities until just before ovulation. Second, during the postovulatory, or luteal, phase of the cycle, progesterone is secreted by the corpus luteum in increasing amounts (up to 40–50 mg/day) until the midluteal phase. Third, beginning about 7 to 8 days after ovulation, the rates of progesterone and estradiol secretion by the corpus luteum begin to decline and then diminish progressively before menstruation (see Fig. 17.1).

In response to these cyclic changes in the rates of ovarian sex steroid hormone secretion, there are five main stages of the corresponding endometrial cycle: (1) menstrual-postmenstrual *reepithelialization*; (2) *endometrial proliferation* in response to stimulation by estradiol; (3) abundant *epithelial secretion*, occurring in response to the combined action of estradiol and progesterone; (4) *premenstrual ischemia*, the result of endometrial tissue volume involution, which causes stasis of blood in the spiral arteries; and (5) *menstruation*, which is preceded and accompanied by severe vasoconstriction of the endometrial spiral arteries and collapse and desquamation of all but the deepest layer of the endometrium. In the final analysis, menstruation is the consequence of the withdrawal of factors that maintain endometrial growth and differentiation (see Fig. 17.21).

Commonly, the initiation of menstruation is attributed to progesterone withdrawal. This concept was developed because the administration of estrogen to postmenopausal women and treatment with and then withdrawal of a progestin causes menstruation, even with continued estrogen treatment. Moreover, progesterone facilitates decidualization of the endometrium and the maintenance of pregnancy, whereas progesterone withdrawal favors the initiation of menstruation, lactation, and parturition.

The preovulatory (follicular or proliferative) phase and the postovulatory (luteal or secretory) phase of the ovarian-endometrial cycles are customarily divided into early and late stages (see Fig. 17.21). The normal secretory phase of the menstrual cycle can be subdivided almost daily by histologic criteria, from shortly after ovulation until the onset of menstruation.[121] Some gynecologists use histologic dating of endometrial biopsies obtained during the luteal phase to evaluate ovulation, progesterone production, or the degree of biologic response of the endometrium to progesterone.[121]

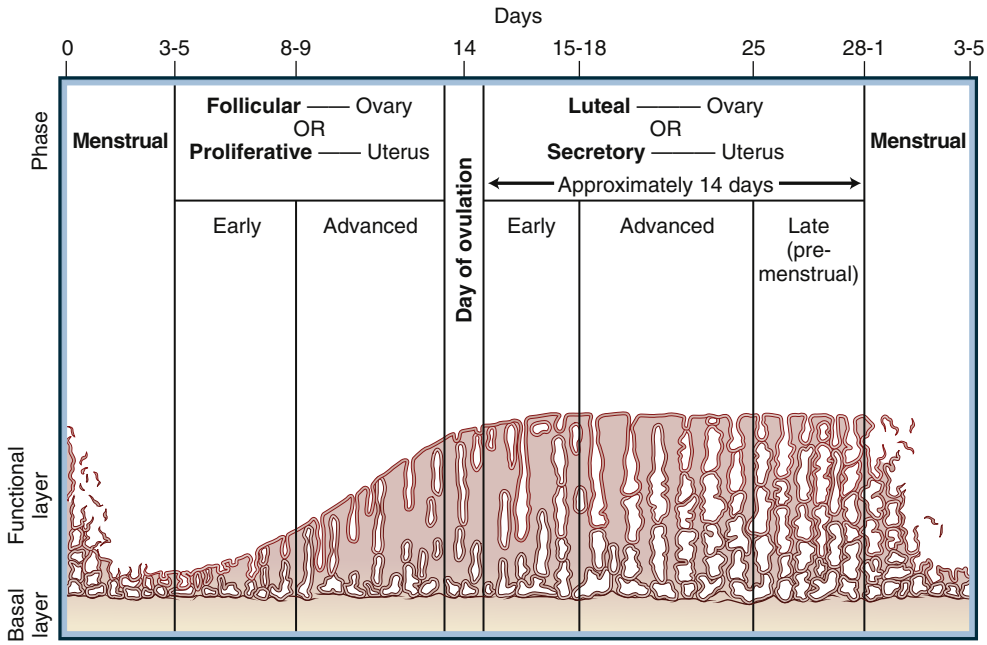


• **Fig. 17.20** Functional anatomy of the endometrium. Endometrium is a multilayered mucosa specialized for implantation and support of pregnancy. A single, continuous layer of epithelial cells lines the surface of the stroma and penetrates the stroma with deep invaginations almost all the way down to the myometrium-endometrium junction. The entire thickness of the endometrium is penetrated by the spiral arteries and their capillaries. Spiral arteries originate from the radial branches of arcuate arteries, which arise from uterine arteries. The superficial layer (functionalis) is shed during menstruation, whereas the permanent bottom layer (basalis) gives rise to the regeneration of endometrium after each menstruation. The striking changes in the spiral arteries (i.e., coiling, stasis, and vasodilatation followed by intense vasoconstriction) are consistently observed before the onset of every menstruation episode. (Courtesy Dr. Kristof Chwalisz, AbbVie, Inc., North Chicago, IL.)

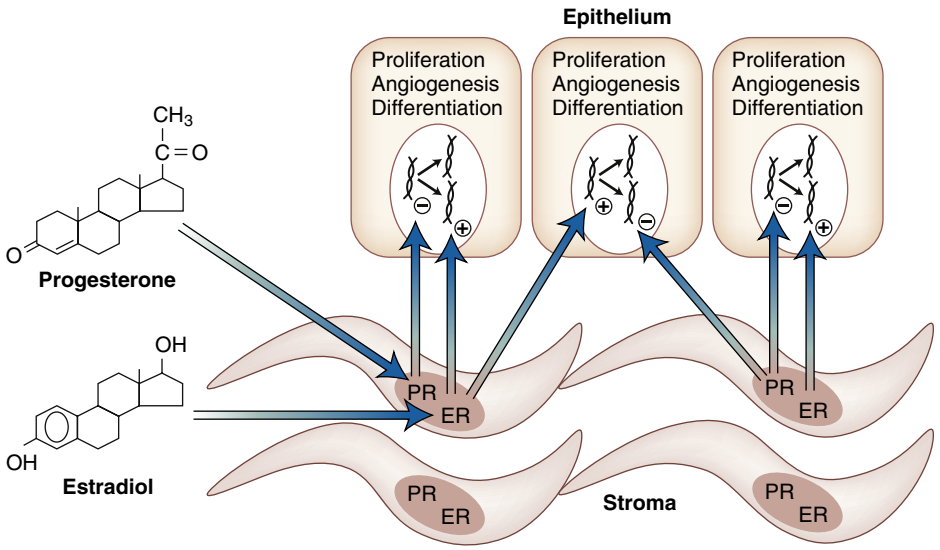
Effects of Ovarian Steroids on Endometrium

The exogenous administration of only estradiol and progesterone is sufficient to prepare the endometrium for implantation in the absence of ovarian function.[122,123] This observation underscores the essential roles of these steroids in uterine physiology. Estradiol or synthetic estrogens such as ethinyl estradiol cause a striking thickening of endometrial tissue. Stromal and epithelial cells of the endometrium proliferate rapidly under the influence of estradiol. Estradiol greatly increases mitotic activity and deoxyribonucleic acid (DNA) synthesis in both cell types (Fig. 17.22). While promoting growth, estradiol also renders endometrial tissue responsive to progesterone by inducing the expression of PRs; progesterone action depends on previous or concurrent estrogen exposure of the endometrium.[124]

In contrast to the proliferative effects of estrogen, progesterone action primarily enables differentiation of the endometrium. Progesterone can inhibit and even reverse the proliferative action of estrogen on epithelial cells in the functionalis layer (see Fig. 17.22). Moreover, progesterone action prepares the endometrium



• **Fig. 17.21** Cyclic changes in thickness and morphologic changes of endometrium and the relationship of these changes to those of the ovarian cycle. (From Cunningham FG, MacDonald PC, Gant NF, et al. The endometrium and decidua: menstruation and pregnancy. In: Cunningham FG, ed. *Williams Obstetrics*. 19th ed. Stamford, CT: Appleton & Lange; 1993:81–109.)



• **Fig. 17.22** Critical epithelial effects of estrogen (i.e., deoxyribonucleic acid [DNA] synthesis, proliferation, and gene expression) are mediated primarily by estrogen receptor-α (ER) in stromal cells in a paracrine manner in the endometrium. This was demonstrated in mice. It was also shown in mice and humans that the antiestrogenic effects of progesterone on epithelial cells (e.g., decreased proliferation, enhanced differentiation) are mediated primarily by progesterone receptors (PRs) in stromal cells.

for implantation of the embryo through differentiation of stromal and epithelial cells. Progesterone induces the production and secretion of a glycogen-rich substance from the epithelial cells. Progesterone also causes an increase in stromal cell cytoplasm, a process called *pseudodecidualization*. The term *decidualization* is reserved for stroma differentiated under the combined influence of progesterone and hCG of placental origin during pregnancy.

Blood vessels that carry estrogen or progesterone come in contact with endometrial stromal cells first. These steroid ligands interact with their nuclear receptors in endometrial stromal cells, which in turn send paracrine signals to neighboring epithelial cells to regulate their functions.[103,124]

Estrogen Action

Estradiol enters endometrial cells from blood by simple diffusion and binds ERs, proteins with a high affinity for estradiol and biologically active synthetic estrogens. Although both ERα and ERβ are present in the endometrium, ERα is the primary mediator of the estrogenic action in that tissue.[125,126] The estradiol-ERα complex is a transcriptional factor that becomes associated

with chromatin.[127] Estradiol-ERα complexes bind thousands of DNA sites across the entire genome and regulate the transcription of hundreds of genes at one time.[127] Most ERα binding sites are outside basal promoters and interact with the transcriptional start sites through DNA looping.[114,127] This interaction brings about ER-specific initiation of gene transcription, which promotes the synthesis of specific mRNAs and, thereafter, specific proteins.[114,127] Estradiol acts in the endometrium and in other estrogen-responsive tissues to promote the responsiveness of that tissue to progesterone via inducing PR expression.[103]

The endometrial epithelial cells are estrogen responsive but probably do not replicate as a result of direct action of estradiol on them. Replication of human endometrial epithelial cells in culture is not increased appreciably, if at all, when estrogen is added to the medium. Estrogen acts on mouse uterine stromal cells to promote the synthesis of growth factors that act on epithelial cells (see Fig. 17.22).[124] These growth factors operate in a paracrine manner to cause increased DNA synthesis and replication in the adjacent epithelial cells.

Progesterone Action

Progesterone enters cells by diffusion and binds to its nuclear receptor (PR). Two PR isoforms, PR-A and PR-B, are present in the human endometrium.[128] Because PR-B but not PR-A levels in the endometrium are tightly regulated during the human menstrual cycle, PR-B is presumed to play a more important biologic role.[128] The cellular content of PRs typically depends on previous estrogen action.

The progesterone-PR complex regulates gene transcription, but the response to progesterone is strikingly different from that evoked by the estradiol-ER complex. Similar to ERα, PR binding sites are also widely distributed across the genome, lie frequently outside basal promoters, and do not involve classically defined progesterone response elements.[129] Interaction of PR binding sites with basal promoters possibly requires DNA looping.[129]

Progesterone acts as an antiestrogen by reducing ERα expression, by decreasing the tissue levels of estradiol through its conversion to estrone via inducing the 17βHSD2 enzyme, and by enhancing estrogen inactivation through sulfation.[130–132] Tissue recombination experiments using uteri of PR knockout and normal mice have demonstrated that many effects of progesterone on epithelial cells are also mediated in a paracrine fashion by PRs in stromal cells but not by those in epithelial cells (see Fig. 17.22).[103,132]

The most striking consequences of progesterone action, stromal predecidualization and epithelial secretion, parallel increased levels of circulating progesterone during the luteal phase. The PR content of human endometrial tissue peaks during the late proliferative phase, just before ovulation, and declines sharply before circulating progesterone levels increase during the luteal phase.[128] This dyssynchrony between endometrial PR expression and circulating progesterone is not well understood. Molecular correlates of progesterone action with respect to differentiation include increased production of lactoferrin and glycodelin in epithelial cells and of prolactin and IGF-binding protein 1 in stromal cells of the endometrium.[103]

The Receptive Phase of the Endometrium for Implantation

Unless the ovum is fertilized within 24 hours after ovulation, it does not survive. Fertilization takes place in the ampullary, the distal one-third of the oviduct. Over the next 2 days, the fertilized ovum remains unattached within the tubal lumen. After this stage, the embryo (which consists of a solid ball of cells called the *morula*) leaves the oviduct and enters the uterine cavity. By this time, endometrial secretions under the influence of luteal progesterone have filled the cavity and bathe the embryo in nutrients. This is the first of many neatly synchronized events that mark the conceptus-endometrial relationship. By 6 days after ovulation, the embryo (now a blastocyst) is ready to implant. It finds an endometrial lining of sufficient depth, vascularity, and nutritional richness to sustain the important events of early placentation that are to follow. Just below the epithelial lining, a rich capillary plexus has been formed and is available for creation of the trophoblast-maternal blood interface. Later, the surrounding superficial portion of the functionalis zone, now occupying more and more of the endometrial cavity, provides a sturdy splint to retain endometrial architecture despite the invasive inroads of the burgeoning trophoblast.

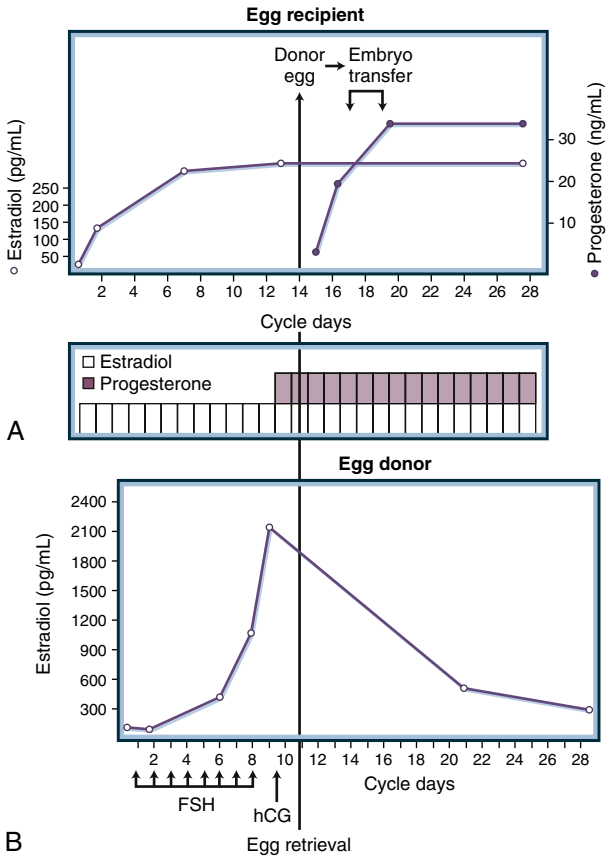
Progesterone is essential for the maintenance of pregnancy. The blastocyst depends on progesterone produced by the corpus luteum at this time. The hCG secreted by the trophoblast acts as a surrogate LH and prevents regression of the corpus luteum that provides a continuous supply of progesterone until the placental tissue starts to produce sufficient quantities of progesterone (6–7 weeks after fertilization).

The receptive phase of the endometrium is the temporal window of endometrial maturation during which the trophectoderm of the blastocyst can attach to the endometrial epithelial cells and proceed to invade the endometrial stroma. The window of uterine receptivity can be inferred from what has been learned from transfer of embryos to uteri of women primed with exogenous estrogen and progesterone preparations (Fig. 17.23). There is a distinct window for embryo transfer leading to implantation, which spans endometrial cycle days 16 to 20. The actual window of implantation follows this window of transfer, because embryos need to develop further, from the four-cell to eight-cell stage to the blastocyst stage, before initiation of attachment and frank invasion can occur. Based on serial measurements of serum hCG as a marker of initial embryonic-maternal interaction, the window of implantation in humans is estimated to be between days 20 and 24 of the cycle.[133] This relatively wide window agrees with the earlier morphologic data.[134]

Control of Endometrial Function With the Use of Exogenous Hormones

The fertility potential of a woman is primarily determined by the biologic quality of her oocytes, reflected in part by a normal chromosomal complement and the capacity of the fertilized ovum to divide at an optimal rate. This biologic quality declines sharply after the age of 35 years. However, the biologic potential of the endometrium for successful implantation remains intact even at advanced ages.[122] Oocyte donation from a fertile woman and fertilization of the donor eggs in vitro with the recipient's male partner's sperm, followed by embryo transfer into the uterine cavity of the recipient woman with nonfunctioning ovaries (e.g., premature ovarian insufficiency [POI]), have been used successfully as a therapeutic strategy to treat infertility (see Fig. 17.23).[122,123] This clinical application has provided unique opportunities to examine the hormonal therapy for endometrial maturation. The success of these procedures (i.e., pregnancy rate) has averaged higher than in conventional IVF.[123]

The follicular phase is mimicked by administration of oral micronized estradiol in daily doses of up to 8 mg for about 10



• **Fig. 17.23** Donation of oocytes by a woman undergoing egg retrieval to a woman with ovarian insufficiency treated with exogenous estrogen and progesterone. The window of implantation in both women is synchronized by different but comparable hormonal treatments. (A) Woman with ovarian insufficiency is initially treated with oral micronized estradiol during days 1 through 14 of the cycle. Exogenous intramuscular progesterone is added to the estradiol treatment on days 15 through 28 and continued if pregnancy is diagnosed. Several donor eggs are fertilized with sperm from the recipient's husband, and one or two embryos are transferred to the uterus on day 16 to 19, depending on the stage of embryo development. These embryos are expected to implant between days 20 and 24. (B) The egg donor is simultaneously treated with human recombinant follicle-stimulating hormone (FSH) with or without menopausal gonadotropin until cycle day 8 to 12, when human chorionic gonadotropin (hCG) is given to induce ovulation, and oocytes are harvested 32 to 36 hours later. One or two fertilized eggs are transferred to the uterus of the recipient. Progesterone supplement to the recipient is started before the embryo transfer. Serum levels of estradiol and progesterone in both women are shown. To convert estradiol values to picomoles per liter, multiply by 3.671. To convert progesterone values to nanomoles per liter, multiply by 3.180.

days. Serum estradiol during the replacement follicular phase reaches sufficiently high levels to stimulate endometrial growth. This is followed by up to 8 mg per day of oral estradiol combined with daily intramuscular (50 mg) or vaginal (200–400 mg) progesterone to promote the secretory transformation. Progesterone supplementation is ordinarily continued until 8 to 10 weeks of gestation.

Mechanism of Menstruation

In the absence of pregnancy, failure of the appearance of hCG despite otherwise appropriate tissue reactions leads to the vasomotor changes associated with estrogen-progesterone withdrawal and menstrual desquamation. A program of endometrial remodeling is initiated; alterations in the extracellular matrix and infiltration of leukocytes lead to hypoxia-reperfusion injury and sloughing of the functionalis, followed by activation of hemostatic and regenerative processes. The main histologic features of the premenstrual phase are degradation of the stromal reticular network, stromal infiltration by polymorphonuclear and mononuclear leukocytes, and secretory exhaustion of the endometrial glands, whose epithelial cells now have basal nuclei. The endometrium shrinks preceding menstruation in part as a result of diminished secretory activity and the catabolism of extracellular matrix.

An ischemic phase caused by vasoconstriction of the arterioles and coiled arteries precedes the onset of menstrual bleeding by 4 to 24 hours.[119] Bleeding occurs after the arterioles and arteries relax, leading to hypoxia-reperfusion injury. The superficial endometrial layers are distended by the formation of hematomas, and fissures develop, leading to the detachment of tissue fragments. Lysis and fragmentation of cells and apoptosis are evident. The menstrual efflux is composed of shed fragments of endometrium mixed with blood and liquefied by the fibrinolytic activity of the cellular debris (see Fig. 17.21). Clots of various sizes may be present if blood flow is excessive. Myometrium contracts to mechanically stop bleeding from the spiral arteries and other endometrial vessels.

Approach to the Woman With Reproductive Dysfunction

Reproductive dysfunction in an adult woman is most often manifested by disruption of cyclic, predictable menses. Efficient diagnosis of the underlying disorder requires a thorough understanding of female reproductive physiology and pathologic conditions and an accurate history and physical examination. Without a critical analysis of clinical findings based on thorough knowledge of normal and abnormal reproductive function, the application of predetermined algorithms of laboratory testing causes unnecessary use of hormone measurements or imaging studies and delays diagnosis.

History

An essential tool for the evaluation of a woman with a reproductive disorder is a carefully recorded history. The history should be obtained from the patient with the aim of assessing the biologic effects of each of the various hormones. Recording the details of pubertal development as a reference for the onset of particular symptoms provides critical clues to the cause of certain reproductive disorders. For example, anovulation manifested by irregular uterine bleeding associated with the polycystic ovary syndrome (PCOS) most often begins during the pubertal years. The early onset of pubic hair and gradually progressing hirsutism at or before the time of puberty suggests nonclassic congenital adrenal hyperplasia or PCOS. In these cases, measurement of serum 17-hydroxyprogesterone may help to differentiate nonclassic congenital adrenal hyperplasia from PCOS. The appearance of hirsutism before puberty or several years after normal pubertal development should alert the clinician to the possibility of ovarian or adrenal neoplasms. Sudden onset of hirsutism at any age or the presence of virilization should prompt the physician to rule out steroid-secreting ovarian or adrenal tumors. Most women with symptomatic endometriosis suffer from severe episodes of painful menses (i.e., dysmenorrhea) that start during pubertal years.

Evaluation of female reproductive function depends on a detailed history of the menses. For example, PCOS is unlikely without a long-standing history of irregular periods since the menarche. A history of a period of cyclic, predictable menses before the onset of menstrual irregularities should draw attention to hypothalamic or other causes of anovulation. The current frequency, regularity, length, and quantity of uterine bleeding should be carefully recorded for several reasons. First, this information reflects tightly regulated interactions of several tissues, including the hypothalamus, pituitary, ovaries, and endometrium. Second, regular, predictable menses imply ovulation. Third, defining the type of menstrual irregularity may help with diagnosis of the underlying cause. For example, prolonged amenorrhea in a thin and estrogen-deficient woman suggests anovulation of hypothalamic origin. Infrequent periods of varying duration and with a varying amount of blood loss in a well-estrogenized, overweight woman suggest a primary ovarian dysfunction such as PCOS. Anovulation in a thin but well-estrogenized woman may also be caused by PCOS. Regular but heavy and prolonged menses with intermittent spotting may result from uterine anatomic disorders such as adenomyosis or leiomyomas. Fourth, neoplastic disorders of the endometrium, including endometrial polyps, hyperplasia, or malignancies, may be manifested by any pattern of irregular bleeding. The combination of vaginal ultrasonography and endometrial biopsy is helpful for the diagnosis of endometrial neoplasia.[135]

Disruption of cyclic and predictable menses is a common and alarming symptom that initially brings the patient to the clinician. After a careful evaluation of the menstrual symptoms, the clinician should identify other obvious symptoms of the endocrine disorder underlying the irregular periods. Pregnancy is the most common cause of amenorrhea (and other menstrual irregularities) in a woman of reproductive age. In a woman presenting with amenorrhea or any other menstrual irregularity, normal pregnancy, ectopic pregnancy, or gestational trophoblastic disease must be excluded at the onset. Careful evaluation of past reproductive history and the patient's sexual activity and contraceptive practices can provide useful indications of the likelihood of pregnancy. The reproductive history may suggest the possibility of Sheehan syndrome of postpartum pituitary necrosis if menses did not resume after a delivery complicated by significant hemorrhage.[136] In such instances, evidence of adrenal and thyroid insufficiency should be sought. A classic symptom of Sheehan syndrome is the absence of postpartum lactation, which is related to prolactin deficiency.

Amenorrhea is traditionally categorized as primary (no history of menstruation) or secondary (cessation of menses after a variable time). The diverse causes of primary amenorrhea are discussed extensively in Chapters 23 and 25. Although the distinction between primary and secondary amenorrhea may be useful for identifying the mechanism of disease and the differential diagnosis, the clinician should be aware that a disorder can initially manifest with either primary or secondary amenorrhea. For example, most women with gonadal dysgenesis have primary amenorrhea, but some patients have residual follicles and ovulate, and in these women with partial gonadal dysgenesis, some menstruation and rare pregnancies may occur before the cessation of ovarian function.[137,138] Patients with PCOS usually have secondary amenorrhea but occasionally have primary amenorrhea. Rarely, pregnancy may manifest as primary amenorrhea.

After pregnancy is ruled out, secondary amenorrhea is most often caused by chronic anovulation, which can be broadly categorized as hypothalamic dysfunction, hyperprolactinemia-associated anovulation, ovarian insufficiency, androgen excess, or chronic illness or primary uterine disease (e.g., intrauterine adhesion formation after a postpartum curettage). Establishing any association of secondary amenorrhea with life events is extremely useful. Strenuous exercise is often associated with amenorrhea. Weight loss often precedes or accompanies secondary amenorrhea and has been suggested as evidence of hypothalamic dysfunction. An unusual dietary history may suggest bulimia or anorexia nervosa. The presence of any signs or symptoms of estrogen deficiency, including painful intercourse, atrophic vagina, emotional lability, and vasomotor instability, suggests anovulation of a central nature with low concentrations of circulating gonadotropins (i.e., hypogonadotropic hypogonadism) or ovarian insufficiency with elevated gonadotropins (i.e., hypergonadotropic hypogonadism).

Galactorrhea in the absence of a recent history of pregnancy suggests a host of diagnostic possibilities and is frequently a manifestation of excessive prolactin secretion, although it may result from increased sensitivity of breast tissue to the hormones necessary for milk production. This history frequently reveals drug ingestion as the cause. Various drugs, including several psychotropic agents, antihypertensive agents, and oral contraceptives, have been implicated. Primary hypothyroidism may be associated with precocious puberty with galactorrhea in the child and with amenorrhea or galactorrhea, or both, in the adult woman. A history of excessive nipple manipulation or chest wall disease should be elicited because it may be the cause of galactorrhea. Prolactinomas, the prolactin-secreting adenomas of the pituitary, are a common cause of galactorrhea related to abnormally high serum levels of prolactin. A history of dilatation and curettage, postpartum endometritis, or disseminated tuberculosis with absent to scant menses suggests the possibility of intrauterine adhesion.[139]

Physical Examination

The quantity and distribution of excessive hair growth should be considered in light of the familial history. Hypertrichosis—excessive growth of hair on the extremities, the head, and the back—must be distinguished from true hirsutism, which is the development of facial hair, chest hair, and a male escutcheon with or without signs of virilization in response to increased production of or sensitivity to biologically active androgens. Some degree of hypertrichosis is not uncommon in women of Mediterranean descent, whereas the occurrence of any facial hirsutism in the relatively hairless Asian woman may require thorough investigation. Hirsutism is best documented and quantified with the help of photographs. Virilization is characterized as deepening of the voice, severe cystic acne, hair loss, increased muscle mass, and clitoromegaly and implies a more severe degree of androgen excess than that found with hirsutism. The syndrome of complete androgen insensitivity is characterized by sparse to absent pubic and axillary hair due to resistance to androgen.

A careful inspection of the breasts is essential for a thorough physical examination. Classification of the stage of breast development according to the method of Marshall and Tanner[140] is a convenient and valuable adjunct. The physician should assess whether the breasts appear to have decreased in size recently (e.g., severe androgen excess), whether the areolae are well formed and pigmented (as they are in pregnancy), and whether a discharge (e.g., galactorrhea) can be expressed.

A woman with PCOS who has never ovulated or taken a progestin-containing medication may have Tanner stage 4 breast development related to adequate estrogen production, whereas the progression to Tanner stage 5 requires exposure to progesterone

through ovulation, ingestion of a progestin (e.g., administration of oral contraceptives), or pregnancy. Chapter 25 discusses Tanner staging of breast development.

The vulva, vagina, and cervix also represent sensitive indicators of gonadal steroid action. Because sensitivity of the genital skin and mucosa to androgen decreases with time from the early stages of fetal development to adulthood, the extent of any virilization can be helpful in suggesting the timing of androgen exposure. The most profound androgenic effects, such as posterior labial fusion with or without formation of a penile urethra, are usually observed in 46,XX fetuses exposed to androgens during the first 8 to 10 weeks of pregnancy. Similar findings have been described in patients with virilizing congenital adrenal hyperplasia, true hermaphroditism, and drug-induced virilization. Postnatal development of significant clitoromegaly in a 46,XX infant requires marked hormonal stimulation and, in the absence of significant exogenous steroids, strongly implicates an androgen-secreting tumor. The size of the glans clitoris can be quantified by determining the clitoral index, which is the product of the sagittal and transverse diameters of the glans. Ninety-five percent of normal women have a clitoral index less than 35 mm^2.

The vagina and uterine cervix are the most sensitive indicators of estrogen action. Under the influence of estrogen, the vaginal mucosa progresses during sexual maturation from a tissue with a shiny, bright red appearance with sparse, thin secretions to a tissue with a dull, gray-pink, rugated surface with copious, thick secretions. Well-estrogenized vaginal mucosa with stretchable cervical mucus (i.e., *spinnbarkeit*) may indicate the proliferative phase of the menstrual cycle in an ovulatory woman or extraovarian estrogen formation in an anovulatory woman with PCOS. The biologic activity of estrogen can also be quantified by vaginal cytologic examination.

To summarize, irregular uterine bleeding is a common symptom that brings the woman with reproductive dysfunction to the physician's office. Various disorders of the hypothalamus, pituitary, ovaries, or uterus or other tissues that affect reproductive function may be responsible for this alarming symptom. After pregnancy is ruled out, a detailed history and physical examination should be carefully recorded. In particular, the physician should pay attention to the salient features in the history and the biologic indicators of hormone action at target tissues during the physical examination. An analysis of these findings most often leads to a tentative diagnosis, which may be confirmed by laboratory testing.

Disorders of the Female Reproductive System

Chronic Anovulation

Chronic anovulation is one of the most common gynecologic problems encountered by the practitioner. Patients may present with secondary amenorrhea, infrequent uterine bleeding (i.e., oligomenorrhea), or irregular episodes of excessive uterine bleeding. Infertility is an obvious consequence of chronic anovulation. Pregnancy, end-organ defects (e.g., intrauterine adhesions, müllerian agenesis), amenorrhea associated with genital ambiguity at birth (e.g., 46,XX, 46,XY, and ovotesticular disorders of sex development), or sexual infantilism due to gonadal dysgenesis should initially be ruled out.

For practical purposes, most of the etiologic factors giving rise to chronic anovulation in a woman of reproductive age fall into five broad categories: hypothalamic anovulation, hyperprolactinemia, androgen excess, POI, and chronic illness (e.g., hepatic or renal insufficiency, acquired immunodeficiency syndrome [AIDS]). Salient features of the history and physical examination help to place a woman with anovulation in one or more of these categories.

One group of anovulatory patients is estrogen deficient. Common disorders in this group include hypothalamic anovulation, galactorrhea-hyperprolactinemia (e.g., hypothyroidism, prolactinoma, nonfunctioning pituitary tumor), and POI in a woman of reproductive age. These patients are usually amenorrheic. All patients present with signs of estrogen deficiency (e.g., vaginal atrophy). Patients with hypothalamic anovulation or galactorrhea-hyperprolactinemia usually do not complain of hot flashes, whereas women with POI present with vasomotor symptoms. One serious consequence of estrogen deficiency is bone loss, giving rise to osteopenia and osteoporosis. If possible, the underlying cause should be corrected. Hormone therapy should be provided if ovulation cannot be restored.

Women with androgen excess constitute the second major group of anovulatory patients. A serious consequence of anovulation in this group is the greater risk for carcinoma of the endometrium because of unopposed action of estrogen formed continuously in extraovarian tissues. The most common disorder of the ovary associated with androgen excess and anovulation is PCOS. Insulin resistance plays a significant role in this condition and, along with hyperandrogenism, increases the risk of developing cardiovascular disease (CVD), diabetes mellitus, or both.[111] The clinician must recognize the long-term impact of PCOS and undertake therapeutic management of these anovulatory patients to avoid unwanted consequences. The clinician should also develop a plan with the patient to address long-term complications of unopposed estrogen formation associated with PCOS (e.g., endometrial neoplasia). Oral contraceptives or periodic progestin supplementation may be provided to prevent endometrial hyperplasia and cancer.

Many mechanisms may be responsible for anovulation in chronic illness. Effective treatment of the primary illness may restore normal menses. Alternatively, anovulatory bleeding may be managed with the use of exogenous hormones in these chronically ill patients (discussed later).

Measurements of FSH and prolactin help to categorize anovulatory patients. An undetectable or low-normal FSH level is consistent with hypothalamic amenorrhea, PCOS, or hyperprolactinemia, whereas high FSH levels suggest ovarian insufficiency. High prolactin levels may indicate a pituitary prolactinoma, pituitary disease, or hypothyroidism. The following sections describe specific disorders that cause chronic anovulation in women of reproductive age.

Hypothalamic Anovulation

Anovulation of hypothalamic origin usually manifests as amenorrhea. The terms *hypothalamic anovulation* and *hypothalamic amenorrhea* are used interchangeably in this chapter. A reduction in GnRH pulse frequency from the characteristic 60 to 120 minutes to intervals longer than 180 minutes leads to lower levels of LH and FSH secretion by the pituitary gland.[13,141] This functional gonadotropin deficiency fails to provide adequate stimulation

to the ovarian follicles, and the normal sequence of follicular growth, maturation, follicular selection, and ovulation becomes attenuated. Downstream ovarian estradiol production remains low, and endometrial growth is reduced or arrested, resulting in a prolonged interval of amenorrhea. The transition from normal menstrual cyclicity to anovulation and amenorrhea can take place gradually and may be characterized by inadequate luteal phases, irregular menstrual bleeding, and amenorrhea. Patients with hypothalamic amenorrhea do not complain of hot flashes, even though circulating levels of estradiol are within the menopausal range. This suggests a significant role for GnRH or gonadotropins in the cause of hot flashes.

Any disorder of the central nervous system that interferes with normal GnRH pulse frequency can cause anovulation. Some of these disorders may be defined genetic or anatomic disorders such as isolated gonadotropin deficiency (with or without anosmia), infection, suprasellar tumors (e.g., pituitary adenomas, craniopharyngioma), and head trauma.[10] These genetic and anatomic disorders affect the function of the hypothalamus, and some of them may be ruled out by the medical history, physical examination, and imaging of the head (Table 17.1).

The most commonly observed form of hypothalamic anovulation is not associated with a demonstrable neuroanatomic finding.[142] This common form is called *functional hypothalamic amenorrhea* because it is presumed to involve aberrant but reversible regulation of otherwise normal neuroendocrine pathways. Other causes of hypothalamic anovulation demonstrable by neuroanatomic or genetic evidence are less common (see Table 17.1).

Functional Hypothalamic Amenorrhea

Anovulation resulting from stress-associated changes is viewed as a functional disorder in which no anatomic or organic abnormalities of the hypothalamic-pituitary-ovarian axis can be identified.[142] This condition typically manifests as amenorrhea of at least a 6-month duration and has also been called *functional hypothalamic amenorrhea*.[142] The overall prevalence of functional hypothalamic amenorrhea among all amenorrhea disorders ranges from 15% to 48%.[143]

Anovulation of hypothalamic origin is characterized by estrogen deficiency and low levels of gonadotropins. No genetic or anatomic disorders are identified in most patients.[142] The concept of functional hypothalamic anovulation (i.e., amenorrhea) was postulated as the failure of the hypothalamic-pituitary pathways to release gonadotropins from the anterior pituitary.[142] Clinical studies have supported this common mechanism associated with an alteration in the pulsatile secretion of GnRH.[14] Diverse etiologic factors such as malnutrition or caloric restriction, depression, psychogenic stress, excessive energy expenditure related to exercise, or combinations of these disorders precede the onset of functional hypothalamic anovulation.[142] Heightened awareness of diet or exercise and unrealistic expectations with respect to body image most likely contributed to the epidemic of this anovulatory disorder.

Diagnosis of Functional Hypothalamic Amenorrhea

Patients most commonly present with secondary amenorrhea characterized by absence of menstrual cycles for longer than 6 months without evidence of an organic disorder. The diagnosis is one of exclusion. There are many neuroanatomic or genetic disorders that can mimic functional hypothalamic anovulation (see Table 17.1), and a careful and complete evaluation is essential to make this diagnosis.

TABLE 17.1 Classification of Anovulation Caused by Disorders of the Hypothalamic-Pituitary Unit

Functional Hypothalamic Anovulation (Amenorrhea)

Stress (psychogenic or physical)
Dieting
Vigorous exercise
Chronic illness (e.g., chronic liver or renal insufficiency, AIDS)

Psychiatric-Medical Emergencies

Anorexia nervosa

Medications

Antipsychotics (e.g., olanzapine, risperidone, amisulpride, clozapine)
Opiates

Hypothyroidism

Anatomically or Genetically Defined Pathologic Conditions of the Hypothalamic-Pituitary Unit

Pituitary tumors
Prolactinoma
Clinically nonfunctioning adenoma
GH-secreting adenoma (acromegaly)
ACTH-secreting adenoma (Cushing disease)
Other pituitary tumors (e.g., metastasis, meningioma)
Pituitary stalk section
Hemorrhagic pituitary destruction, including pituitary apoplexy and Sheehan syndrome
Pituitary aneurysm
Infiltrative disease of the pituitary (e.g., lymphocytic hypophysitis, sarcoidosis, histiocytosis X, tuberculosis)
Empty sella syndrome
Tumors that affect hypothalamic function (e.g., metastasis, craniopharyngioma)
Infiltrative granulomatous disease of the hypothalamus (e.g., sarcoidosis, histiocytosis X, tuberculosis)
Head trauma
Irradiation to the head
CNS infection
Isolated gonadotropin deficiency (including Kallmann syndrome)
Other

ACTH, Adrenocorticotropic hormone; *AIDS,* acquired immunodeficiency syndrome; *CNS,* central nervous system; *GH,* growth hormone.

Women with functional hypothalamic amenorrhea usually present with a history of regular menses for some period after menarche. This period of normal ovulatory function (determined by history) is interrupted by anovulation that usually manifests as secondary amenorrhea. Women with functional hypothalamic anovulation may occasionally present with primary amenorrhea.

Women with functional hypothalamic amenorrhea typically have a normal body weight or are thin. They may be highly driven for success and involved in high-stress occupations. The occupation of the patient (e.g., ballerina, competitive athlete) may be an important clue. A detailed interview may also reveal a variety of emotional crises or stressful events (e.g., divorce, death of a friend) preceding the onset of amenorrhea. During the interview, additional environmental and interpersonal factors may become evident, such as academic pressure, social maladjustment, or psychosexual problems.

When evaluating the patient, the physician should take note of the current diet regimen, the use of any sedatives or hypnotics, and the nature and extent of the patient's exercise habits. Despite

a careful interview, a history of stress, excessive physical exercise, or an eating disorder may not be readily revealed by some women with functional hypothalamic anovulation. These women do not complain of hot flashes, in contrast to women with ovarian insufficiency.

These women usually have normal secondary sexual characteristics. The pelvic examination usually shows a thinning vaginal mucosa accompanied by scant to absent cervical mucus with a normal to small uterus, which are all evidence of estrogen deficiency. Signs of a well-estrogenized vagina and cervix observed during the physical examination make the diagnosis of hypothalamic amenorrhea unlikely. The physician should exclude a possible hyperprolactinemic cause (e.g., prolactinoma, hypothyroidism) and evidence of androgen excess (e.g., PCOS).

Laboratory tests are obtained to exclude other causes of anovulation and secondary amenorrhea. LH and FSH levels are usually lower than the normal values ordinarily found in the early follicular phase. TSH and prolactin levels are obtained to rule out hypothyroidism and hyperprolactinemia. The progestin challenge test (medroxyprogesterone acetate [MPA] at 5 mg/day for 10 days) elicits either a small spotting episode or an absence of withdrawal uterine bleeding in most patients. The administration of combined estrogen (2 mg/day of oral micronized estradiol) with progestin (5 mg/day of MPA for 10 days) will result in endometrial growth followed by vaginal bleeding after one or more cycles of therapy because the uterine compartment remains functionally normal.

These results suggest that there is a scant or absent estrogenic effect on the endometrium, because circulating estradiol levels are typically in the low or early follicular phase range. Measurement of the serum estradiol level is not necessary. Because a suprasellar or large pituitary tumor is in the differential diagnosis, magnetic resonance imaging (MRI) of the head is necessary to rule out these possibilities. Imaging of the head is especially important if amenorrhea develops suddenly or is associated with a neurologic sign, both of which make the presence of a tumor more likely.

Pathophysiology of Functional Hypothalamic Anovulation

A critical defect in hypothalamic amenorrhea is the reduction in GnRH release from the medial basal hypothalamus, which leads to a reduction in GnRH pulse frequency.[14,144] LH pulse frequency is used as a surrogate measure to evaluate GnRH secretion because each GnRH pulse is accompanied by a concomitant LH pulse.[143] A key observation in functional hypothalamic anovulation is the absence of increased gonadotropin secretion despite the lack of inhibitory factors of ovarian origin, such as estradiol and inhibin.

There is considerable variability in the amplitude and frequency of the pulsatile LH secretion in women with functional hypothalamic amenorrhea. When the LH secretory patterns are compared with those of the follicular phase of the menstrual cycle, a characteristic abnormality in LH pulse frequency and amplitude is seen; occasionally, regression to a pronounced variability similar to what is seen in the prepubertal pattern is observed.[14,143,144] In severe cases, the frequency and amplitude of LH pulses are markedly reduced. These LH patterns also suggest that GnRH pulsatile secretion is not altered to the same degree in every patient. During the recovery phase of hypothalamic amenorrhea, reversal to a pattern of LH secretion seen early in puberty often occurs, and it is characterized by a sleep-associated increase in LH amplitude.[143]

The response of the pituitary gland to GnRH with respect to production and release of gonadotropins is not impaired in functional hypothalamic anovulation. Intravenous pulsatile GnRH administration can restore normal levels of LH and FSH.[145]

Norepinephrine, dopamine, and serotonin produced in the brain have been shown to modulate GnRH or LH release in animal studies.[146] Patients receiving medication that alters these neurotransmitters (e.g., sedatives, antidepressants, stimulants, antipsychotics) have presented with abnormalities in their menstrual cycles. These responses to medications provide circumstantial evidence that disruptions of neural pathways can alter GnRH release in humans. It appears that activation of the noradrenergic neurons principally stimulates release of GnRH, whereas dopaminergic and serotoninergic neurons can stimulate or inhibit GnRH-LH secretion.[146]

Another group of substances that have inhibitory influences on GnRH secretion are endogenous opioid peptides.[147,148] Blockade of endogenous opiate receptors by the administration of naloxone, an opiate antagonist, causes an increase in the frequency and amplitude of pulsatile LH release in the majority of women with hypothalamic amenorrhea.[144] Gonadotropin secretion resumes if the activity of the opiate receptor is blocked by long-term naloxone use, and ovulatory function may be regained in some cases.[149] These studies suggest that there is an overall increase in endogenous opiate activity, which can reduce pulsatile GnRH secretion in some cases of functional hypothalamic amenorrhea.

The hypothalamic-pituitary-adrenal axis is dysfunctional in many women with functional hypothalamic amenorrhea, with increased secretion of corticotropin-releasing hormone (CRH), adrenocorticotropic hormone (ACTH), and cortisol. Activation of the pituitary-adrenocortical system is a common response in patients with chronic stress.[150] In functional hypothalamic amenorrhea, stressors such as exercise or emotional distress can chronically activate the hypothalamic-pituitary-adrenal axis and disrupt reproductive function.

Studies have demonstrated an increase in pulsatile ACTH secretion, increased adrenal sensitivity to ACTH, and increased cortisol secretion with a normal diurnal rhythm.[143] Daytime cortisol levels are markedly elevated, and the pituitary response to CRH is blunted.[151] In an animal model, CRH seems to be an important factor in the inhibition of GnRH pulsatility.[152,153] This inhibitory effect can be prevented by coadministration of a CRH antagonist or reversed by the opiate antagonist naloxone, suggesting that cross-talk occurs between the action of CRH and activation of the opioidergic system. Moreover, ACTH administration blocks the pituitary response to GnRH at the pituitary level.[154,155] In summary, overproduction of CRH and other stress-related hormones in the brain and activation of the pituitary-adrenocortical system by chronic stress seem to play causative roles in the inhibition of gonadotropin secretion in functional hypothalamic anovulation.

The roles of energy balance–regulating peptides such as leptin and ghrelin were investigated in the mechanism of hypothalamic amenorrhea.[143] Leptin is a cytokine produced by the adipocytes and is considered to be an appetite-suppressor peptide. Leptin is secreted in a pulsatile manner with a diurnal rhythm. A decrease in total circulating leptin with loss of the normal diurnal rhythm was reported in women with hypothalamic amenorrhea.[156] This relative hypoleptinemia is a common characteristic of several energy-deficient conditions and is associated with slowing of the LH pulse frequency.[156] Leptin administration to correct the relative leptin deficiency in women with hypothalamic amenorrhea was shown to improve reproductive, thyroid, and growth hormone axes and markers of bone formation, suggesting that

leptin, a peripheral signal reflecting the adequacy of energy stores, is required for normal reproductive and neuroendocrine function.[156] In contrast to leptin, ghrelin is an appetite-inducing peptide secreted from the stomach. During the fasting state, ghrelin serves as the hunger signal from the periphery to the hypothalamic arcuate nucleus, a region that is known to control food intake. Ghrelin levels are reported to be elevated in women with hypothalamic amenorrhea.[157]

Hypothalamic Anovulation and Exercise

Regular vigorous exercise can lead to menstrual disturbances, a delay in menarche, luteal phase dysfunction, and secondary amenorrhea. Thirty percent of adolescent ballet dancers have problems with the progression of puberty. The mean age at menarche is delayed until the age of 15 years. Advancement of pubertal stages seems to coincide with times of prolonged rest or after recovery from an injury.[158–161] The intensity, length, and type of the sport determine the severity of the disease. Activities associated with an increased frequency of reproductive dysfunction are those that favor a lower body weight and include middle-distance and long-distance running, competitive swimming, gymnastics, and ballet dancing.

Competitive athletes show endocrine abnormalities in the central nervous system consistent with those in other forms of functional hypothalamic anovulation. Abnormalities include elevations of central CRH and β-endorphin levels.

The management of exercise-related anovulation depends on the patient's choices and expectations. Side effects such as osteoporosis and delay of puberty must be discussed thoroughly with the patient.[162] Decrease in exercise level and behavioral modification may be sufficient for the return of ovulatory function. Hormone therapy should be provided if sufficient results are not achieved. A low-dose oral contraceptive is a suitable option for women younger than 35 years of age.

Hypothalamic Anovulation Associated With Eating Disorders

Two common eating disorders associated with hypothalamic dysfunction are anorexia nervosa and bulimia. Patients with anorexia nervosa have extreme weight loss (>25% of original body weight) and a distorted body image accompanied by a striking fear of obesity. Bulimia is a related disorder characterized by alternating episodes of binge eating followed by periods of food restriction, self-induced vomiting, or excessive use of laxatives or diuretics. Approximately 90% to 95% of these patients are women. The incidence of classic anorexia nervosa is approximately 1 case per 100,000 people in the general population.[163] Among female high school and college students, bulimia is fairly common. The incidence of anorexia nervosa peaks twice during the teen years, at ages 13 and 17. Bulimia usually begins at a later age, between 17 and 25 years. Anorexia nervosa has an extremely high mortality rate of 9% and is a true medical emergency. Death may result from cardiac arrhythmia, which may be precipitated by diminished heart muscle mass and associated electrolyte abnormalities.[164] These patients are also at increased risk for suicide.[165]

Gonadotropin secretion in anorexic women exhibits a prepubertal pattern that is similar to that observed in other forms of hypothalamic anovulation. Transitional patterns of LH secretion are seen with moderate degrees of weight recovery, and there is a normal or supranormal response to GnRH. Anovulation can persist in up to 50% of anorexic patients, even after normal weight is achieved. Anorexic and bulimic patients exhibit hyperactivation of the hypothalamic-pituitary-adrenal system. Although the diurnal variation is maintained, persistent hypersecretion of cortisol occurs throughout the day.[166] Cushingoid features are not present, in part because of mild hypercortisolemia and a reduction of peripheral glucocorticoid receptors. Levels of CRH and β-endorphin are increased in the central nervous system.[167,168]

In anorexia nervosa, basal metabolism is decreased because peripheral conversion of thyroxine (T_4) to biologically potent triiodothyronine (T_3) is decreased. Instead, T_4 is converted to reverse T_3, an inactive isomer. This alteration is also observed in severely ill patients and during starvation.[169] Anorexics have partial diabetes insipidus and are unable to concentrate urine appropriately because of the impaired secretion of vasopressin.[170]

Anorexia nervosa and bulimia are extremely difficult to treat. The most accepted approaches include individual psychotherapy, group therapy, and behavior modification. Patients with eating disorders should have psychiatric consultation and follow-up. This helps with the diagnosis and treatment. For patients who weigh less than 75% of their ideal body weight, immediate hospitalization and aggressive treatment are recommended. Complications of anorexia nervosa include osteoporosis, estrogen deficiency, and generalized effects of malnutrition.[159] Hormone therapy in the form of a low-dose oral contraceptive should be provided until ovulatory function is achieved.

Treatment and Management of Functional Hypothalamic Anovulation

Treatment of chronic anovulation resulting from central nervous system–hypothalamic disorders should be directed at reversal of the primary cause (e.g., stress management, reduction of exercise, correction of weight loss). The importance of successful treatment of this disease state is underscored because these women are prone to the development of osteoporosis. For a considerable number of patients, spontaneous recovery of menstrual function takes place after a modification of lifestyle, psychologic guidance, or accommodation to environmental stress. The initial treatment should be directed to a change in lifestyle and tailored to the individual patient. For individuals who remain amenorrheic, periodic assessment of reproductive status (every 4–6 months) is prudent.

Modification of the stress response through cognitive-behavioral therapy is a logical approach to lowering the endogenous stress levels in women with hypothalamic amenorrhea. This approach was explored in 16 subjects with hypothalamic amenorrhea randomized to cognitive-behavioral therapy or observation for a 20-week period.[171] The therapy design focused on attitudes and habits concerning eating, exercise, body image, problem-solving skills, and stress reduction. The results were encouraging. Approximately 88% of those who underwent cognitive-behavioral therapy had evidence of ovulation, compared with only 25% of those who were observed.[171] These results suggest that endogenous stress is a major factor in the development and maintenance of hypothalamic amenorrhea and that modification of this stress response can restore normal menses.

If anovulation persists for longer than 6 months or if reversal of the primary cause is not practical (e.g., professional athletes, ballerinas), a major concern is the long-term effect of hypoestrogenism, especially on bone metabolism. In addition to estrogen deficiency, IGF1 deficiency, hypercortisolism, and nutritional factors may contribute to bone loss in this disorder.[172] However, epidemiologic data on the risk of fractures and the benefits of hormone therapy are scant.[162,172] On the basis of studies of reproductive-age women who were ovariectomized or underwent treatment with GnRH agonist for endometriosis, bone density is expected

to decrease significantly, even within the first 6 months of amenorrhea. Because these patients are often reluctant to take medications, serial bone density studies of the lumbar spine and femur may be necessary to convince them of the necessity to begin estrogen replacement therapy. If the patient is not at risk for thromboembolism and does not smoke cigarettes, a low-dose combination oral contraceptive is a reasonable replacement option. Alternatively, a combination of conjugated equine estrogens (0.625 mg) and MPA (2.5 mg) daily may be administered to provide estrogenic support. The progestin (MPA) is added solely to prevent endometrial hyperplasia.

If the patient desires ovulation to achieve pregnancy, the most physiologic approach is ovulation induction with pulsatile GnRH. This is the best physiologic means of induction because the cause of the anovulatory state is decreased endogenous GnRH secretion. Pulsatile intravenous GnRH (5 μg every 90 minutes) was shown to be effective.[173] Monitoring of serum estradiol levels or follicular development can be minimized because the ovarian follicular response and gonadotropin output mimic the natural menstrual cycle. In these patients, continuation of pulsatile GnRH or hCG (1500 units administered intramuscularly every 3 days for a total of four doses) can support the function of the corpus luteum. Intravenous GnRH treatment results in ovulation rates of approximately 90%, pregnancy rates of up to 30%, and hyperstimulation rates of less than 1% per treatment cycle. Because the intravenous GnRH pump is not a practical choice for many women, an alternative strategy is the use of subcutaneous recombinant FSH for the development of one to three follicles and the induction of ovulation with intramuscular hCG followed by luteal support using intramuscular hCG or progesterone in oil.

Chronic Anovulation Associated With Pituitary Disorders

The most common pituitary-related causes of anovulation are associated with hyperprolactinemia caused by prolactinomas or other functional or anatomic disorders of the pituitary. These disorders are frequently associated with dysregulation of gonadotropin secretion. Hyperprolactinemia and other pituitary disorders and their relation to reproduction are discussed in Chapter 9.

Chronic Anovulation Associated With Androgen Excess

The most common ovary-related disorder of chronic anovulation is PCOS. Irregular periods or amenorrhea and androgen excess are the most commonly observed features of PCOS. Other causes of ovary-related anovulation include steroid-secreting ovarian tumors and POI. Androgen excess arising from extraovarian sources (e.g., adrenal disorders) is also associated with anovulation.

Approach to the Patient With Androgen Excess

Two natural androgens are testosterone, which is transported to target tissue by the circulation, and DHT, which is produced primarily by target tissues. Increased levels of these androgens can lead to hirsutism, which is excessive androgenic hair growth, or to virilization, a more severe form of androgen excess. Emerging evidence also suggest that the adrenal steroid 11-hydroxyandrostenedione may be converted to 11-ketotesosterone and 11-keto-DHT in peripheral or target tissues.[174,175] These latter steroids may act as potent androgens.[174,175]

Hirsutism is defined as the presence of terminal (coarse) hair in locations at which hair is not commonly found in women, including facial hair on the cheek, above the upper lip, and on the chin (Fig. 17.24 A and B). The presence of midline chest hair is also significant (see Fig. 17.24C). A male escutcheon, hair on the inner aspects of the thighs, and midline lower back hair entering the intergluteal area are hair growth patterns compatible with androgen excess. A moderate amount of hair on the forearms and lower legs by itself may not be abnormal, although it may be viewed by the patient as undesirable and may be mistaken for hirsutism. Numerous scoring systems are available for quantifying hirsutism. One of the most detailed scales was proposed by Ferriman and Gallwey.[176] A practical and clinically useful means of quantifying hirsutism is recording the hair growth in detail using simple drawings and photographs. In particular, photographs are invaluable for documenting hirsutism accurately.

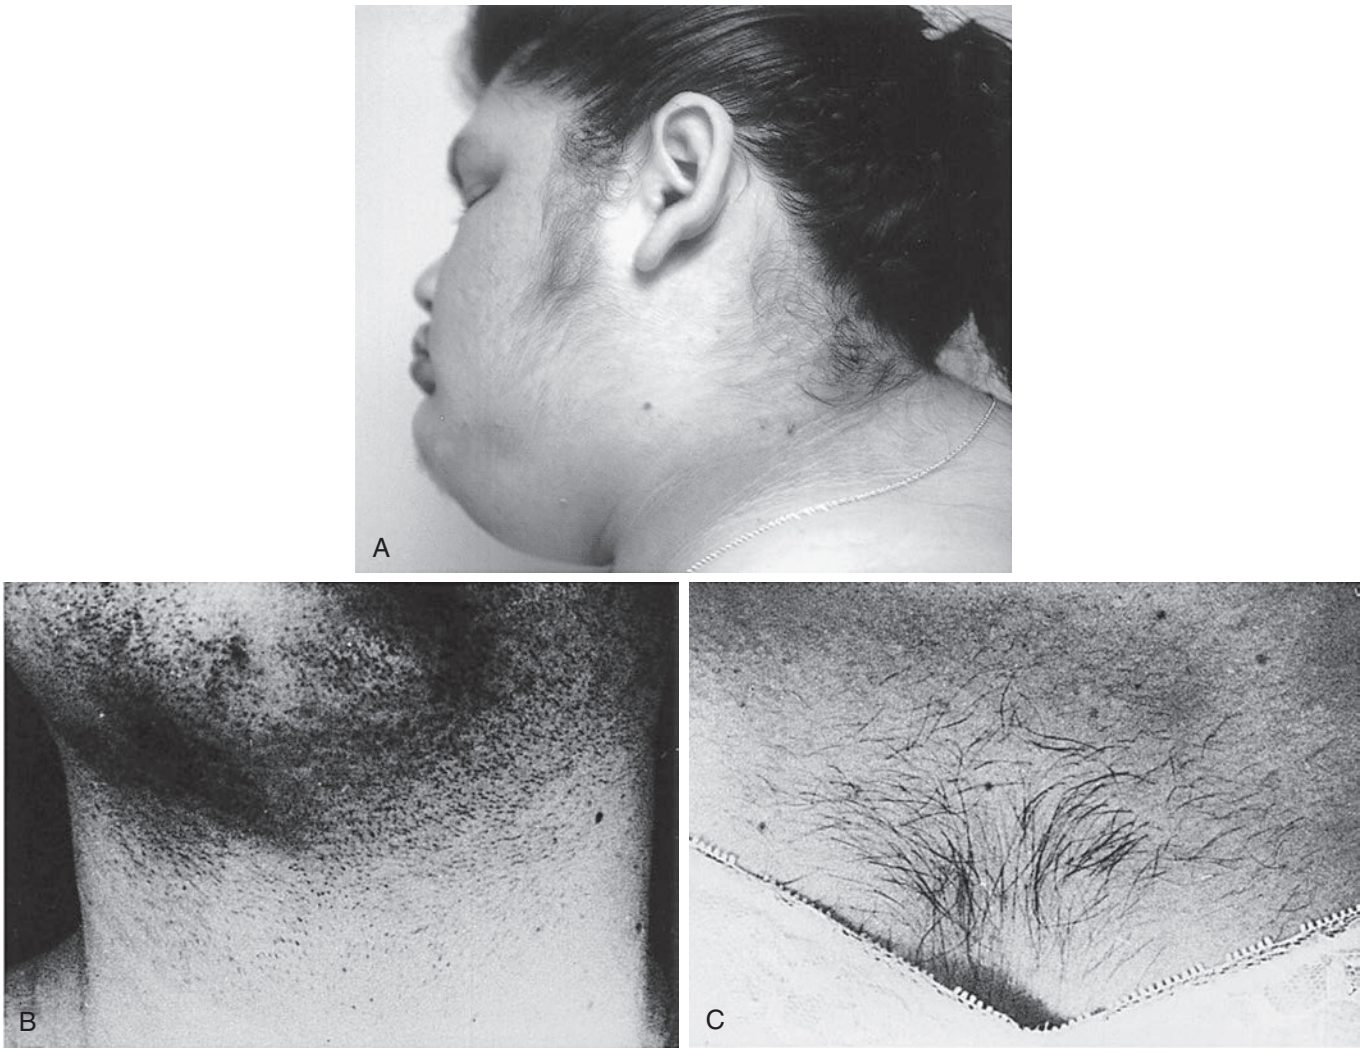
Compared with hirsutism, virilization is a more severe form of androgen excess and implies significantly higher rates of testosterone production. Its manifestations include temporal balding, deepening of voice, decreased breast size, increased muscle mass, loss of female body contours, and clitoral enlargement (Fig. 17.25). Even if testosterone levels are moderately increased (<1.5 ng/mL), temporal balding and clitoromegaly may be observed after a long period (>1 year) in the presence of persistent androgen excess. A marked increase in androgen secretion, such as that which may occur from production by neoplasms, leads to a more full-blown picture of virilization in less than a few months (see Fig. 17.25).

Measurements of an enlarged clitoris may be used for the quantification of virilization. A clitoral length greater than 10 mm is considered abnormal (see Fig. 17.25). Clitoral length is quite variable, however. An increase in clitoral diameter is a much more sensitive indicator of androgen action. Normal values for clitoral diameter are less than 7 mm at the base of the glans (see Fig. 17.25). The most accurate definition of clitoromegaly involves use of the clitoral index (the product of the sagittal and transverse diameters of the glans clitoris). A clitoral index greater than 35 mm^2 is abnormal and correlates statistically with androgen excess.[177]

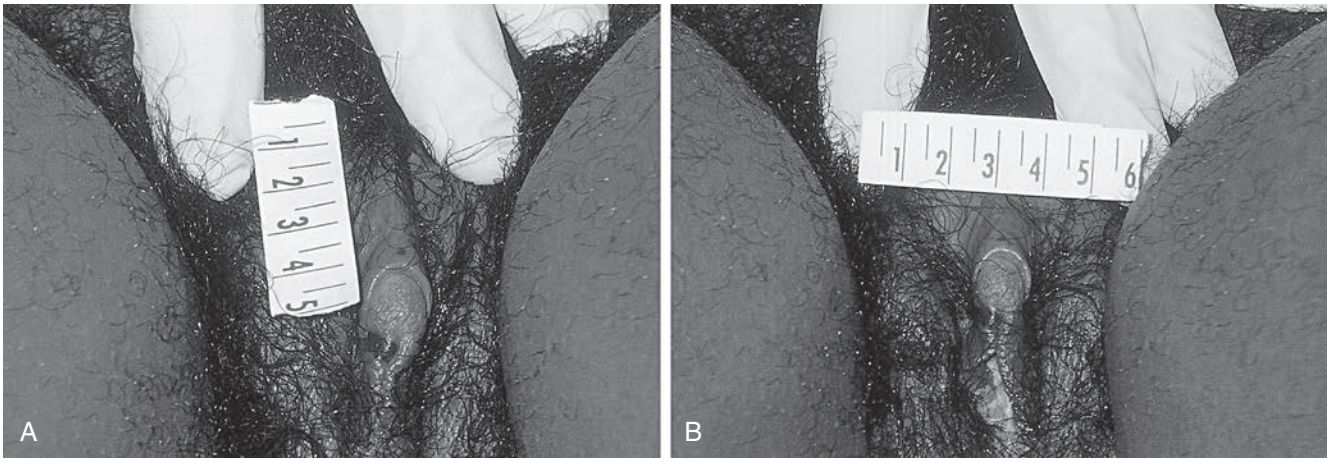
Origins of Androgens

Among the natural C19 steroids, DHT is a biologically potent androgen that is capable of acting through androgen receptors on target cells. Almost all testosterone target tissues contain 5α-reductase activity, which converts testosterone to DHT, or aromatase activity, which produces estradiol in an intracrine fashion. There is no convincing evidence that the other C19 steroids, including androstenedione, DHEA, and dehydroepiandrosterone sulfate (DHEAS), are biologically active.

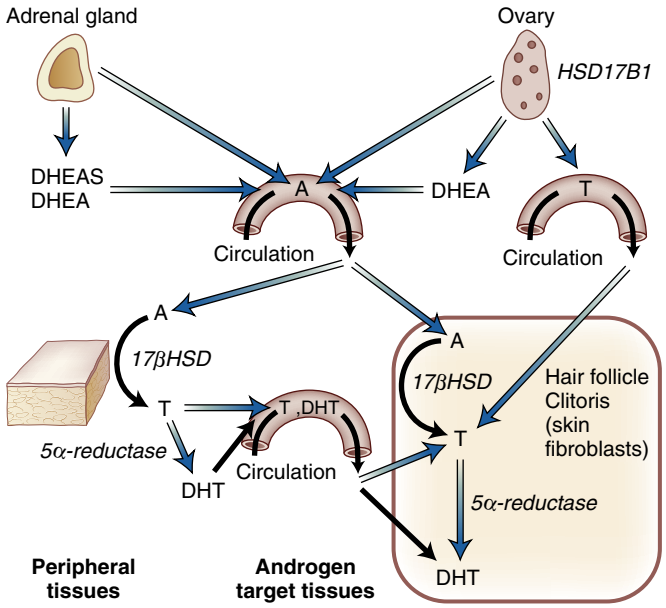
Testosterone in reproductive-age women is produced by two major mechanisms: direct secretion by the ovary, which accounts for roughly one-third of testosterone production, and conversion of the precursor, androstenedione, to testosterone in the peripheral (extragonadal) tissues, which accounts for two-thirds of testosterone production (Fig. 17.26).[178] These peripheral tissues include the skin and adipose tissue. Androstenedione, the direct precursor of testosterone, is produced in the ovary and the adrenal gland. The C19 steroids DHEAS and DHEA of adrenal origin, and DHEA of ovarian origin, indirectly contribute to testosterone formation by first being converted to androstenedione, which is subsequently converted to testosterone (see Fig. 17.26). Androstenedione is the major precursor that is converted directly to testosterone. The conversion fraction of circulating androstenedione to testosterone in extragonadal tissues is about 5% in both men and women.



• **Fig. 17.24** Hirsutism. (A) Mild facial hirsutism. (B) Severe facial hirsutism (chin), which requires regular shaving. (C) Severe hirsutism on chest. (B and C, from Dunaif A, Hoffman AR, Scully RE, et al. The clinical, biochemical and ovarian morphologic features in women with acanthosis nigricans and masculinization. *Obstet Gynecol.* 1985;66:545–552.)



• **Fig. 17.25** Severe clitoromegaly resulting from a testosterone-secreting ovarian tumor. (A) The entire length of the clitoris is approximately 4 cm (normal, <1 cm). (B) The transverse diameter of the clitoris measures 1.5 cm (normal, <0.7 cm).



• **Fig. 17.26** Androgen biosynthesis in women. Depending on the menstrual cycle phase or postmenopausal status, 20% to 30% of testosterone (T) is secreted by the ovary. The rest is accounted for by the conversion of circulating androstenedione (A) to T in various peripheral tissues. Both the adrenal gland and the ovary contribute to circulating A directly or indirectly, depending on the cycle phase or postmenopausal status and chronologic age. T may also be formed locally in androgen target tissues. T is converted to the biologically potent androgen dihydrotestosterone (DHT) within the target tissues and cells. For example, local conversion of T to DHT by 5α-reductase activity, which is conferred by products of at least two genes, in sex skin fibroblasts and hair follicles plays a key role in clitoral enlargement and hirsutism. The enzyme activity of 17βHSD in peripheral tissues may be conferred by protein products of several genes with overlapping functions; HSD17B1, a distinct reductive 17βHSD enzyme, is encoded by a specific gene expressed primarily in the ovary. *DHEAS,* dehydroepiandrosterone sulfate; *17βHSD,* reductive 17β-hydroxysteroid dehydrogenase.

Testosterone is converted to a potent steroid, DHT, to exert full androgenic effects on certain target tissues such as hair follicles and external genitalia.[98,115] This conversion is catalyzed by the enzyme 5α-reductase and takes place in the liver for systemic DHT production and within androgen target cells such as sex skin fibroblasts for an intracrine effect.[98]

The androgenic effects of testosterone in target tissues are determined by the level of local 5α-reductase activity and the androgen receptor content (see Fig. 17.26). Androgen receptors mediate androgenic action in critical target tissues.[115,179] Other local enzymes at target tissues (e.g., aromatase, oxidative 17βHSD) also regulate hormone action by metabolizing testosterone to the androgenically inactive androstenedione or to estradiol, a potent estrogen. There appears to be a balance between potent androgen action when DHT is formed and reduction of androgenicity when inactive C19 steroids or estradiol is formed from testosterone in target tissues and other extragonadal tissues. This may be particularly relevant for androgen-dependent disorders (e.g., hirsutism, virilization) and estrogen-dependent disorders such as malignancies of breast and endometrium (see Figs. 17.19 and 17.26).

Laboratory Evaluation of Androgen Action

Testosterone circulates in three forms: that which is bound to sex hormone–binding globulin (SHBG), the portion not bound to SHBG but loosely associated with albumin, and the fraction not bound by SHBG or albumin (i.e., free or dialyzable testosterone). The blood testosterone that is available to diffuse into target tissues includes the free and albumin-bound fractions and is referred to as bioavailable or non–SHBG-bound testosterone. The remainder is tightly bound to the protein SHBG.

SHBG is one of the primary regulators that determine the amounts of circulating bound and bioavailable testosterone available to act on target tissues. Conditions that decrease SHBG binding (e.g., androgen excess, obesity, acromegaly, hypothyroidism, liver disease) also increase bioavailable testosterone, augmenting the effect of testosterone. SHBG also regulates the circulating amounts of bioavailable estradiol by binding a significant fraction of circulating estradiol. Conditions that decrease SHBG levels give rise to increased bioavailable (non–SHBG-bound) estradiol.

The measurement of non–SHBG-bound (bioavailable) forms of testosterone has been advocated for states of androgen excess to detect more accurately subtle forms of hirsutism. Although the diagnostic yield of this measurement is superior to that of total serum testosterone, the correlation between total and non–SHBG-bound testosterone is excellent, so that bioavailable testosterone can usually be predicted from the total testosterone and SHBG levels.[180] The purpose of measuring serum testosterone is to establish the presence of circulating androgen excess and to detect extremely high values that may originate from an androgen-secreting neoplasm.

The normal serum levels of androgens, especially free testosterone determined by radioimmunoassay (RIA) or other direct methods, vary from laboratory to laboratory. A group of investigators compared serum-free testosterone levels measured by equilibrium dialysis with those measured by direct RIA and with those calculated from the free androgen index (100 × testosterone/SHBG), a simple index that correlates with the free testosterone level.[181] Calculated values for free testosterone using the free androgen index correlated well with those obtained from equilibrium dialysis. In contrast, the direct free testosterone measurements had unacceptably high systematic bias and random variability and did not correlate as well with equilibrium dialysis values. Moreover, the lower limit of detection was higher for the direct RIA than for equilibrium dialysis or calculated free testosterone.[181] The clinician should be aware of the limitations of direct free testosterone measurements performed without rigorous quality control.

Measuring the levels of all C19 steroids is not clinically necessary for most patients presenting with androgen excess. The most useful initial test is a serum total testosterone level. An abnormal level in the presence of hirsutism or virilization may be associated with PCOS, hyperthecosis, nonclassic congenital adrenal hyperplasia, or an androgen-secreting neoplasm. Most androgen-secreting tumors are of ovarian origin. The likelihood of a neoplasm correlates roughly with increasing testosterone levels. The following tests may be added on the basis of the clinical presentation: serum 17-hydroxyprogesterone (i.e., nonclassic congenital adrenal hyperplasia), serum prolactin and TSH (i.e., mild androgen excess associated with hyperprolactinemia), serum FSH and LH (i.e., elevated LH/FSH ratio in PCOS), serum DHEAS (i.e., adrenal tumors), and imaging of ovaries and adrenals (i.e., PCOS and steroid-secreting tumors).

Causes of Androgen Excess

Several disorders give rise to androgen excess. They include unusual causes such as iatrogenic or drug-induced androgen excess, congenital genital ambiguity (e.g., excessive in utero androgen formation

TABLE 17.2 Causes of Androgen Excess in Women of Reproductive Age

Ovarian

Polycystic ovary syndrome (PCOS)
Hyperthecosis (a severe PCOS variant)
Ovarian tumor (e.g., Sertoli-Leydig cell tumor)

Adrenal

Nonclassic congenital adrenal hyperplasia
Cushing syndrome
Glucocorticoid resistance
Adrenal tumor (e.g., adenoma, carcinoma)

Specific Conditions of Pregnancy

Luteoma of pregnancy
Hyperreactio luteinalis
Aromatase deficiency in fetus

Other Causes

Hyperprolactinemia, hypothyroidism
Medications (danazol, testosterone, anabolizing agents)
Idiopathic hirsutism (normal serum testosterone in an ovulatory woman)
Idiopathic hyperandrogenism (patients who do not fall into any of the other categories listed)

in 46,XX disorders of sex development), and conditions unique to pregnancy (e.g., luteoma of pregnancy, hyperreactio luteinalis). These uncommon causes and relatively more prevalent disorders associated with androgen excess are listed in Table 17.2. The term *extraovarian steroid formation* is used synonymously with *extraglandular*, *extragonadal*, or *peripheral steroid formation* in this text.

Overall, the prevalence of androgen-excess disorders was found to be as follows: 72.1% for PCOS (anovulatory patients, 56.6%; mildly affected ovulatory patients, 15.5%), 15.8% for idiopathic hyperandrogenism, 7.6% for idiopathic hirsutism, 4.3% for 21-hydroxylase-deficient nonclassic congenital adrenal hyperplasia, and 0.2% for androgen-secreting tumors.[182]

In most hyperandrogenic disorders, androgen originates from more than one source (see Fig. 17.26). For example, testosterone secretion is somewhat increased from the ovary in PCOS, but the bulk of testosterone comes from extraovarian conversion of significantly elevated circulating androstenedione of ovarian origin to testosterone. Patients with PCOS also show increased adrenal output of DHEAS, which (after peripheral conversion to DHEA that is further converted to androstenedione) contributes indirectly to extraovarian testosterone formation.

If androgen excess is associated with primary amenorrhea, abnormal in utero sexual differentiation should be strongly suspected. These disorders are discussed in Chapter 23. Before embarking on a major workup for hirsutism or virilization, the physician is well advised to rule out exogenous androgen use. It is best to ask the patient to list all prescriptions and over-the-counter medications that she takes on her own, including injections. This is usually more rewarding than asking the patient whether she takes any androgens. Medications that can cause hirsutism or virilization are related to testosterone and include anabolic steroids and similar compounds.

The most common identifiable cause of androgen excess is PCOS, which is discussed elsewhere in this chapter. In this section, we first define some of the other disorders associated with hirsutism or virilization. This is followed by a simplified treatment strategy that may be applied to most hirsute patients within the categories of PCOS, nonclassic congenital adrenal hyperplasia, and idiopathic hirsutism.

Idiopathic Hirsutism

Hirsutism is defined subjectively as the presence in a woman of terminal hair growth in a male-distribution pattern that affects quality of life sufficiently to prompt her to seek medical advice. Hirsutism should be distinguished from hypertrichosis, in which the excessive hair growth is not restricted to androgen-dependent areas and comprises vellus or lanugo-type hair. Hypertricosis is considered to be a phenotype not associated with male pattern hair growth and is unlikely to be modified by the known treatments of hirsutism.

Idiopathic (constitutional) hirsutism is characterized by excessive hair growth in the absence of elevated circulating androgen levels in ovulatory women, and it occurs more frequently in certain ethnic populations, particularly in women of Mediterranean ancestry.[115] It is defined as hirsutism in conjunction with regular menstrual cycles and normal levels of serum testosterone. Idiopathic hirsutism is not associated with any signs of virilization. Its cause is not understood completely. It has been proposed that women with idiopathic hirsutism have significantly increased cutaneous 5α-reductase activity,[183] but this association has not been confirmed. It is also unclear whether a certain 5α-reductase isoenzyme (type 1 or 2) is involved in the development of idiopathic hirsutism.[115]

Idiopathic hirsutism is diagnosed in women who have hirsutism,[115] normal ovulatory function, and normal total or free testosterone levels. Cyclic predictable menses are usually indicative of regular ovulation. If in doubt, ovulatory function may be verified by a luteal phase day 7 progesterone level, which should be at least 5 ng/mL. Luteal phase day 7 corresponds to cycle day 17 for 24-day intervals, cycle day 21 for 28-day intervals, and cycle day 28 for 35-day intervals. The presence of oligo-ovulation or anovulation in hirsute women after exclusion of related disorders (e.g., hypothyroidism, hyperprolactinemia, nonclassic congenital adrenal hyperplasia) is consistent with the diagnosis of PCOS.[115] Thyroid dysfunction or hyperprolactinemia should be excluded by the measurements of TSH and prolactin. The follicular-phase basal 17-hydroxyprogesterone level should be measured to exclude 21-hydroxylase–deficient, nonclassic congenital adrenal hyperplasia. The use of exogenous androgens should also be excluded. In summary, the diagnosis of idiopathic hirsutism is one of exclusion in which ovulatory dysfunction, elevated circulating testosterone levels, and other causes of androgen excess are ruled out.

Androgen-Secreting Tumors of the Ovary and Adrenal

Most androgen-secreting tumors arise from the ovary and secrete large quantities of testosterone or its precursor, androstenedione. These include Sertoli-Leydig cell tumors, hilus cell tumors, lipoid cell tumors, and (infrequently) granulosa-theca tumors. Steroidogenically inert ovarian neoplasms such as epithelial cystadenomas or cystadenocarcinomas may produce factors that stimulate steroidogenesis in adjacent nonneoplastic ovarian stroma and induce production of sufficient amounts of androgen precursors such as androstenedione to give rise to clinically detectable androgen excess. Approximately 5% of androstenedione is converted to testosterone in extraovarian tissues, ultimately producing androgen excess (see Fig. 17.26).

Sertoli-Leydig cell tumors, which account for fewer than 1% of all solid ovarian tumors, tend to occur during the second to fourth

decades of life, whereas hilus cell tumors occur more frequently in postmenopausal women. By the time the signs and symptoms of androgen excess cause the patient to seek medical assistance, Sertoli-Leydig cell tumors are usually so large that they are readily palpable on pelvic examination, whereas hilus cell tumors are still small. In women with either type of tumor, the serum testosterone level is markedly elevated. Granulosa-theca tumors primarily produce estradiol but may occasionally produce testosterone.

Rapidly progressing symptoms of androgen excess suggest the presence of an androgen-producing tumor unless proven otherwise. This rapid progression is typical of both ovarian and adrenal androgen-producing tumors. Progression is usually associated with defeminizing signs, such as loss of female body contour, increased muscle mass, and decreased breast size. As the tumor continues to grow, more and more testosterone is produced, resulting in rapidly worsening hirsutism and progressive virilization. Elevated serum testosterone levels are characteristically associated with ovarian tumors. This change may be mediated by production and secretion of testosterone directly by the tumor or by secretion of large quantities of androstenedione that are converted to testosterone in extragonadal tissues. The testosterone levels produced by certain ovarian tumors (e.g., Sertoli-Leydig cell tumors) may be suppressed by GnRH agonists,[184] so use of a GnRH agonist cannot be relied on to differentiate a neoplasm from another functional state.

In interpreting testosterone levels, the clinician should be familiar with the normal ranges of the clinical laboratory used. A value of three times the upper-normal range (or >2 ng/mL) suggests a neoplasm, particularly if the clinical history supports this diagnosis. Lower serum testosterone levels occasionally may be associated with virilizing ovarian tumors. If an androgen-secreting tumor is suspected, measurement of androstenedione is clinically useful. A severely elevated level of androstenedione is not diagnostic but consistent with an ovarian or adrenal tumor. When an elevated level of testosterone is associated with suggestive clinical history, meticulously performed transvaginal ultrasonography is the most sensitive method to detect an ovarian tumor.

In contrast to testosterone-secreting tumors of the ovary, testosterone-secreting tumors of the adrenal are rare. The cells of some testosterone-producing adrenal tumors may resemble ovarian hilus cells, which are analogous to Leydig cells. These tumor cells produce testosterone and may be stimulated by LH or hCG. In patients with testosterone-producing adrenal adenomas, testosterone secretion usually decreases after LH suppression and increases after hCG stimulation. Testosterone-secreting adrenal carcinomas also have been reported.[185]

Virilizing adrenal tumors commonly secrete large quantities of DHEAS, DHEA, and androstenedione, and testosterone is usually produced by extraovarian conversion of these precursors. Levels of serum DHEAS are highly elevated in most patients with virilizing adrenal tumors.[186] If DHEAS levels exceed 8 μg/mL, adrenal imaging by computed tomography (CT) or MRI should be ordered. Occasionally, such high levels of DHEAS are associated with a functional abnormality such as congenital adrenal hyperplasia caused by an enzymatic defect or an unexplained hyperfunctional adrenal state that is commonly associated with PCOS. These circumstances may explain a negative CT or MRI result, which warrants further investigation.

Levels of a variety of adrenal steroids, including corticosteroids, may be elevated in various combinations in the presence of an adrenal tumor. It is not possible to describe a particular pattern of hormones that defines an adrenal tumor.[186] Very high levels of serum DHEAS (>8 μg/mL) suggest an adrenal tumor. Virilizing ovarian tumors are encountered much more frequently than those of adrenal origin. If the presentation is compatible with an androgen-secreting tumor and the ovaries are normal by transvaginal ultrasonography, the adrenals should be evaluated next by imaging.

Testosterone levels three times the upper-normal range (i.e., >2 ng/mL) and DHEAS levels higher than 8 μg/mL have been used traditionally as guidelines to investigate further whether neoplasms of the ovary or adrenal are the sources of androgen excess. These numbers are provided only as guidelines, not as rules, and there are exceptions. First, because tumors secrete androgens episodically, more than one measurement may be required to detect a significantly elevated level.[187] Second, other precursor steroids are often elevated as well (particularly androstenedione), and their measurement should be considered. Third, some tumors may give rise to milder elevations of DHEAS and testosterone levels. Even mild elevations in a postmenopausal woman are highly suspicious for an androgen-secreting tumor. By the same token, greatly elevated serum testosterone levels may be observed in women with severe ovarian hyperthecosis (a severe variant of PCOS) in the absence of a tumor.

Virilization of recent onset and short duration warrants immediate investigation, even if testosterone and DHEAS levels are mildly elevated. With improvements in imaging techniques—vaginal ultrasonography for the ovary; abdominal ultrasonography, CT, and MRI for the adrenal glands—the diagnosis of even a small ovarian or adrenal tumor may be made. If no neoplasm can be localized, imaging of the ovary or adrenal after intravenous administration of radiolabeled iodomethylnorcholesterol (NP59), which detects active steroid-producing tumors, has proven useful.[188] These diagnostic studies should be pursued aggressively before surgical exploration of a suspected tumor.

The clinician should question whether an ovarian or adrenal tumor detected by imaging is the actual source of androgen excess before resorting to its surgical resection. Occasionally, a hemorrhagic corpus luteum cyst of the ovary may mimic an androgen-secreting tumor, or a woman with androgen excess may have an adrenal incidentaloma, which does not secrete androgen. Intraoperative selective ovarian or adrenal vein catheterization may be considered as a last resort to demonstrate significant steroid gradients before surgical exploration of an adrenal or ovary for a small tumor is undertaken, especially if the clinical picture is not certain.[189]

Nonneoplastic Adrenal Disorders and Androgen Excess

Adrenal disorders such as classic congenital adrenal hyperplasia, Cushing syndrome, and glucocorticoid resistance give rise to androgen excess related to overproduction of testosterone precursors from the adrenal gland. These disorders are discussed elsewhere in this text. In this chapter, we discuss nonclassic congenital adrenal hyperplasia.

The diagnosis and prevalence of nonclassic congenital adrenal hyperplasia continue to be debated, although the disorder clearly exists. Other terms that have been used to describe this syndrome include late-onset, adult-onset, attenuated, incomplete, and cryptic adrenal hyperplasia. This form of adrenal hyperplasia is caused by a partial deficiency in 21-hydroxylase activity. Although deficiencies in 11β-hydroxylase and 3βHSD may result in the disorder, defects in 21-hydroxylase account for more than 90% of cases.[190]

The clinical presentation is almost identical to that of patients with PCOS. The prevalence of this disorder varies according to ethnic background, and the prevalence reported by different

investigators has varied widely. The characteristic presentation consists of anovulatory uterine bleeding and progressive hirsutism of pubertal onset. These individuals are born with normal genitalia, do not exhibit salt wasting, and many have premature pubarche and accelerated linear growth with advanced bone age. Patients of northern European ancestry have a low frequency of this disorder, whereas Ashkenazi Jews, Hispanics, and patients of central European ancestry have a much higher prevalence.[191] The patient with androgen excess from a high-risk ethnic group should be screened. (See Chapter 15 for more complete discussion.)

Screening may first be carried out by obtaining an 8 AM serum level of 17-hydroxyprogesterone in an anovulatory patient on any day. Although most women with nonclassic congenital adrenal hyperplasia are anovulatory, some women with this disorder present with regular periods and hirsutism of pubertal onset or with only unexplained infertility and frequent miscarriage.[190] If nonclassic congenital adrenal hyperplasia is suspected in an ovulatory patient on the basis of clinical presentation, an 8 AM serum level of 17-hydroxyprogesterone should be obtained during the follicular phase, because 17-hydroxyprogesterone levels are higher in the luteal phase in ovulatory women.[190] A level of less than 2 ng/mL effectively rules out this diagnosis.[190]

The diagnosis of nonclassic congenital adrenal hyperplasia can be made if the basal 17-hydroxyprogesterone level is higher than 10 ng/mL. No further testing is required in these cases. Values between 2 and 10 ng/mL are considered increased but not diagnostic of nonclassic congenital adrenal hyperplasia. For example, disease-free women and patients with PCOS may also have basal levels of 17-hydroxyprogesterone in this indeterminate range.[190] In these circumstances, an ACTH stimulation test should be used to distinguish nonclassic congenital adrenal hyperplasia from PCOS.[190] A rise of the 17-hydroxyprogesterone level to at least 10 ng/mL 60 minutes after intravenous injection of ACTH is considered diagnostic of nonclassic adrenal hyperplasia.[192] A higher basal level of 17-hydroxprogesterone within the range of 2 to 10 ng/mL is associated with a higher likelihood of nonclassic congenital adrenal hyperplasia. For example, an 8 AM 17-hydroxyprogesterone level higher than 4 ng/mL had a sensitivity of 90% for the diagnosis of nonclassic congenital adrenal hyperplasia.[190]

In an androgen excess patient from a high-risk ethnic group, a baseline level of 17-hydroxyprogesterone should be measured at 8 AM. A screening baseline level of 17-hydroxyprogesterone should be obtained for patients with premature pubarche, those with androgen excess of early pubertal onset, women with progressive hirsutism or virilization, and patients with strong family histories of severe androgen excess.

Laboratory Testing to Aid the Differential Diagnosis of Androgen Excess

Algorithms exist for the differential diagnosis of anovulation associated with hirsutism or virilization or both. Salient clinical features are of paramount importance to guide laboratory testing. The most important features are the onset and severity of the signs and the rapidity with which they progress. Rapidly progressing severe androgen excess implies an androgen-secreting tumor until proven otherwise. The possibility of a tumor is further underscored in a postmenopausal woman or in a reproductive-age woman with a recent history of cyclic, predictable periods. Ovarian hyperthecosis, a severe variant of PCOS, also gives rise to severe androgen excess that may progress rapidly, especially at the time of expected puberty. Androgen excess emerging at the time of puberty may be indicative of PCOS or nonclassic congenital adrenal hyperplasia.

TABLE 17.3 Laboratory Tests for the Differential Diagnosis of Androgen Excess

Initial Testing
Total testosterone
Prolactin
Thyroid-stimulating hormone
Further Testing Based on Clinical Presentation[a]
17-Hydroxyprogesterone (8 AM)
17-Hydroxyprogesterone 60 min after intravenous ACTH
Cortisol (8 AM) after 1 mg dexamethasone at midnight
DHEAS
Androstenedione
Imaging of ovaries (transvaginal ultrasonography)
Imaging of adrenal glands (abdominal ultrasonography, CT, MRI)
Nuclear imaging after intravenous administration of radiolabeled cholesterol

[a]See text.

ACTH, Adrenocorticotropic hormone; *CT,* computed tomography; *DHEAS,* dehydroepiandrosterone sulfate; *MRI,* magnetic resonance imaging.

The most useful initial test to evaluate androgen excess is the serum level of total testosterone (Table 17.3). Testosterone levels in most normal ovulatory women are lower than 0.6 ng/mL, although the value may vary from laboratory to laboratory. Women with idiopathic hirsutism have cyclic menses and normal testosterone levels. No further testing for androgen excess is required in this group.

If the testosterone level is elevated in an anovulatory woman, serum levels of TSH and prolactin should be obtained to rule out anovulation associated with hyperprolactinemia. Ultrasonography of the ovaries also can help to identify an ovarian tumor or polycystic ovaries. If the ethnic background of the patient (i.e., Ashkenazi Jews, Hispanics, and those of central European ancestry), onset of hirsutism (i.e., puberty), or family history suggests nonclassic congenital adrenal hyperplasia, a baseline serum level of 17-hydroxyprogesterone should be obtained at 8 AM. Rare causes of androgen excess include an adrenal tumor, Cushing syndrome, and glucocorticoid resistance. A serum level of DHEAS and adrenal imaging are required to assess the presence or absence of an adrenal tumor. CT, MRI, or abdominal ultrasonography may be used to assess the adrenals, depending on the expertise of the local radiology laboratory. A screening test for Cushing syndrome and glucocorticoid resistance may be performed to explore rare adrenal causes of androgen excess (see Chapter 15).[193]

Most women with chronic anovulation and mild to moderate hirsutism of pubertal onset fall into the category of PCOS. These women usually have high-normal or mildly elevated testosterone levels and may not have any other laboratory abnormalities. After other diagnoses are ruled out by laboratory testing or on clinical grounds, a diagnosis of PCOS can be made.

Treatment of Hirsutism

Therapy for androgen excess should be directed toward its specific cause and suppression of abnormal androgen secretion. Neoplasms warrant surgical intervention and are not discussed in greater detail here. Suppression with a GnRH analogue may be tried initially for ovarian hyperthecosis. However, bilateral oophorectomy may become necessary to control androgen excess arising from hyperthecosis (see later discussion). Patients with adrenal disease are treated specifically. For Cushing syndrome, treatment correlates with the

source of hypercortisolism. When treating androgen excess associated with nonclassic congenital adrenal hyperplasia, an antiandrogen (e.g., spironolactone) in combination with an oral contraceptive is used. Although a glucocorticoid may be considered, particularly if fertility is desired, the doses of glucocorticoids needed to suppress the adrenal can cause symptoms and signs of glucocorticoid excess during long-term treatment. Thus a combination oral contraceptive plus spironolactone is favored to treat androgen excess if the patient responds to this treatment with decreased hirsutism. Several classes of medications are reviewed in detail later in the chapter for the treatment of androgen excess and hirsutism.

Oral Contraceptives

Oral contraceptives reduce circulating testosterone and androgen precursors by suppression of LH and stimulation of SHBG levels, thereby reducing hirsutism in hyperandrogenic patients.[115] Oral contraceptives decrease circulating androgen in patients with PCOS and synergize with the effects of antiandrogens. Oral contraceptives may further improve the results of antiandrogen therapy in patients with idiopathic hirsutism or nonclassic congenital adrenal hyperplasia. It is advisable to use an oral contraceptive containing 30 or 35 μg of ethinyl estradiol to achieve effective suppression of LH.[115] A meta-analysis showed that treatment with oral contraceptives for 6 months reduced Ferriman-Gallwey scores of hirsutism by an average of 27%.[194]

Spironolactone

The most commonly used androgen blocker for the treatment of hirsutism in the United States is spironolactone, an aldosterone antagonist structurally related to progestins. Spironolactone is effective for abnormal hair growth associated with PCOS, nonclassic congenital adrenal hyperplasia, or idiopathic hirsutism. Treatment with spironolactone for 6 months reduces Ferriman-Gallwey scores of hirsutism by an average of 38.4%.

Because spironolactone acts through mechanisms different from those of oral contraceptives, overall effectiveness is improved by combining these two medications in patients with hirsutism, including those with PCOS, idiopathic hirsutism, or nonclassic congenital adrenal hyperplasia. Apart from inhibiting steroidogenesis and acting as an androgen antagonist, spironolactone has a significant effect in inhibiting 5α-reductase activity.[115,195] Basic experimental and several clinical studies have confirmed the efficacy of spironolactone for hyperandrogenism and suggest that the principal effect is related to its ability to block peripheral androgen production and action.[115]

Doses of spironolactone used in clinical studies have varied from 50 to 400 mg daily. Although doses of 100 mg/day are usually effective for the treatment of hirsutism, higher doses (200–300 mg/day) may be preferable in extremely hirsute or markedly obese women.[115,195] The initial recommended dosage is 100 mg/day, which is gradually increased by increments of 25 mg/day every 3 months up to 200 mg/day on the basis of the response. This approach may be helpful to minimize side effects such as gastritis, dry skin, and anovulation. In patients with normal renal function, hyperkalemia is almost never seen. Hypotension is rare except in older women. Monitoring for electrolytes and blood pressure is imperative within the first 2 weeks at each dose level. Adjustments in dose should be made only after 3 to 6 months, as with other antiandrogens, to account for the slow changes in the hair cycle.

Patients usually notice an initial transient diuretic effect. Some women with normal cycles complain of menstrual irregularity with spironolactone; this is remedied by a downward dose adjustment or the addition of an oral contraceptive. The mechanism for abnormal bleeding is unclear. In women with oligomenorrhea, such as those with PCOS, resumption of normal menses may occur. This change may be caused in part by an alteration in levels of circulating androgens; LH levels have only occasionally been reported to decrease.[196] Another important consideration is the potential in utero feminizing effect of this antiandrogen on the genitalia of a 46,XY fetus. Effective contraception should always be provided in women taking spironolactone.

Cyproterone Acetate

Cyproterone acetate is a 17-hydroxyprogesterone acetate derivative with strong progestagenic properties. Cyproterone acetate acts as an antiandrogen by competing with DHT and testosterone for binding to the androgen receptor. There is also some evidence that cyproterone acetate and ethinyl estradiol in combination can inhibit 5α-reductase activity in skin.[197] Cyproterone acetate is not available in the United States but has been used in other countries. The drug is usually administered daily in doses of 50 to 100 mg on days 5 through 15 of the treatment cycle. Because of its slow metabolism, it is administered early in the treatment cycle; when ethinyl estradiol is added, it is usually administered in 50-μg doses on days 5 through 26. This regimen is needed for menstrual control and is usually referred to as the *reverse sequential regimen*. Cyproterone acetate in doses of 50 to 100 mg/day, combined with ethinyl estradiol at 30 to 35 μg/day, is as effective as the combination of spironolactone (100 mg/day) and an oral contraceptive in the treatment of hirsutism.[115] In smaller doses (2 mg), cyproterone acetate has been administered as an oral contraceptive in daily combination with 50 or 35 μg of ethinyl estradiol. This regimen is primarily suited for individuals with a milder form of hyperandrogenism.[115]

Finasteride

Finasteride inhibits 5α-reductase activity and has been used primarily for the treatment of prostatic hyperplasia. It can also be used in the treatment of hirsutism.[198,199] At a dose of 5 mg/day, a significant improvement of hirsutism is observed after 6 months of therapy, without significant side effects. In hirsute women, the decline in circulating DHT levels is small and cannot be used to monitor therapy. Although this treatment regimen increases testosterone levels, SHBG levels remain unaffected.[198] A meta-analysis showed that finasteride treatment for 6 months reduced Ferriman-Gallwey scores of hirsutism by an average of 20.3%.[194]

Finasteride primarily inhibits 5α-reductase type 2. Because hirsutism results from the combined effects of type 1 and type 2, this agent is only partially effective. Although prolonged experience with finasteride is lacking, one of the potential advantages of this agent is its benign side effect profile. One study showed efficacy with 1 year of hirsutism treatment.[200] It was also reported that finasteride is less effective than spironolactone with respect to the reduction of hirsutism in women.[115] Nevertheless, finasteride at a dose of 5 mg/day for prolonged periods represents a useful option because of its benign side effect profile and good tolerance by patients. Like spironolactone, finasteride may cause congenital genital ambiguity in a 46,XY fetus, and effective contraception should be provided during its use.

Flutamide

Flutamide is a potent antiandrogen used in the treatment of prostate cancer. It has been shown to be effective in the treatment of

hirsutism.[201,202] The mean Ferriman-Gallwey score is reduced by 41.3%.[194] Nevertheless, occasional severe hepatotoxicity makes this drug unsuitable for the indication of hirsutism.[203]

Metformin and Thiazolidinediones

Because PCOS is often associated with insulin resistance, drugs that mitigate insulin resistance have been used in this disorder.[110] Metformin (1500–2700 mg/day) for 6 months significantly reduces hirsutism by 19.1% as assessed by the Ferriman-Gallwey scoring system.[194] In obese adolescent women with PCOS, metformin in combination with lifestyle modification (i.e., diet with a 500 kcal/day deficit and exercise 30 minutes/day) and oral contraceptives reduced the total testosterone level and waist circumference.[204] The thiazolidinediones (4 mg/day of rosiglitazone or 30 mg/day of pioglitazone) also reduced Ferriman-Gallwey scores significantly.[194] These studies suggested that insulin-sensitizing agents may be used in the treatment of hirsutism of PCOS, especially for women who do not wish to use other oral agents.

Lifestyle Modification

In obese adolescent women with PCOS, lifestyle modification (i.e., diet with a 500 kcal/day deficit and exercise 30 minutes/day) alone resulted in a 59% reduction in the testosterone/SHBG ratio, with a 122% increase in SHBG.[204] A moderate diet and exercise program should be recommended as part of hirsutism management, particularly for obese women.

A Comprehensive Treatment Strategy for Hirsutism

The medications described in the previous paragraphs may be effective when administered as individual treatments. Patients with the most common form of hirsutism (i.e., PCOS, nonclassic congenital adrenal hyperplasia, or idiopathic hirsutism) are often initially treated with a combination of two agents, one that suppresses the ovary (e.g., an oral contraceptive) and another that suppresses the extraovarian (peripheral) action of androgens (e.g., spironolactone). An oral contraceptive containing 30 to 35 μg of ethinyl estradiol combined with spironolactone (100 mg/day) is the initial treatment of choice. Even in women with idiopathic hirsutism, the addition of an oral contraceptive to the antiandrogen spironolactone can improve efficacy and prevent abnormal bleeding. For women with only minor complaints of hirsutism, the use of an oral contraceptive alone may be an appropriate first approach. Moderate lifestyle modification (i.e., diet with a 500-kcal/day deficit and 30 minutes/day of exercise) should be a part of hirsutism management in obese patients.

Because the growth phase of body hair lasts 3 to 6 months, a response should not be expected before 6 months after onset of treatment. Objective means should be used to assess changes in hair growth. Scoring systems and evaluation of anagen hair shafts are difficult; taking photographs is the simplest and most objective tool. Patients are often unaware that change is taking place unless there is some objective measurement. Pictures of the face and selected midline body areas before and during therapy are especially useful for the encouragement of the patient and compliance with the treatment.

Suppression of androgen production and action inhibits only new hair growth. Existing coarse hair should be removed mechanically. Plucking, waxing, and shaving are ineffective for hair removal and cause irritation, folliculitis, and ingrown hairs. Electrolysis and laser epilation are more effective and preferred methods.[115]

Most patients with PCOS, nonclassic congenital adrenal hyperplasia, or idiopathic hirsutism respond to this strategy within 1 year. Patients should be encouraged to continue treatment for at least 2 years. Then, depending on the wishes and clinical responses of patients, therapy can be stopped and the patient reevaluated. Many patients require continuous treatment for suppression of hirsutism. Patients with clitoromegaly may be referred to a urologist for clitoral reduction surgery after the source of virilization has been effectively eliminated.

Polycystic Ovary Syndrome

PCOS is the most common form of chronic anovulation associated with androgen excess; it occurs in perhaps 5% to 10% of reproductive-age women.[205] The diagnosis of PCOS is made by excluding other hyperandrogenic disorders (e.g., nonclassic congenital adrenal hyperplasia, androgen-secreting tumors, hyperprolactinemia) in women with chronic anovulation and androgen excess.[205]

During the reproductive years, PCOS is associated with important reproductive morbidity, including infertility, irregular uterine bleeding, and increased pregnancy loss. The endometrium of the patient with PCOS must be evaluated by biopsy because long-term unopposed estrogen stimulation leaves these patients at increased risk for endometrial cancer. PCOS is also associated with increased metabolic and cardiovascular risk factors.[206] These risks are linked to insulin resistance and are compounded by the common occurrence of obesity, although insulin resistance also occurs in nonobese women with PCOS.[111]

PCOS is considered to be a heterogeneous disorder with multifactorial causes. PCOS risk is significantly increased with a positive family history of chronic anovulation and androgen excess, and this complex disorder may be inherited in a polygenic fashion.[207,208]

Historical Perspective

In their pioneering studies, Stein and Leventhal described an association between the presence of bilateral polycystic ovaries and signs of amenorrhea, oligomenorrhea, hirsutism, and obesity (Fig. 17.27).[209] At the time, these signs were strictly adhered to in the diagnosis of what was then known as *Stein-Leventhal syndrome*. These investigators also reported the results of bilateral wedge resection of the ovaries, in which at least half of each ovary was removed as a therapy for PCOS; most of their patients resumed menses and achieved pregnancy after ovarian wedge resection. The exact mechanism responsible for the therapeutic effect of removal or destruction of part of the ovarian tissue is still not well understood.

On the basis of Stein and Leventhal's original work, a primary ovarian defect was inferred. Subsequent clinical, morphologic, hormonal, and metabolic studies uncovered multiple underlying pathologies, and the term *polycystic ovary syndrome* was introduced to reflect the heterogeneity of this disorder. One of the most significant discoveries regarding the pathophysiology of PCOS was the demonstration of a unique form of insulin resistance and associated hyperinsulinemia.[111,209]

Diagnosis of Polycystic Ovary Syndrome and Laboratory Testing

One of the most prominent features of PCOS is the history of ovulatory dysfunction (i.e., amenorrhea, oligomenorrhea, or other forms of irregular uterine bleeding) of pubertal onset. A clear history of cyclic predictable menses of menarchal onset makes the diagnosis of PCOS unlikely. Acquired insulin resistance associated

(B) Sectioned polycystic ovary with numerous follicles. (C) Histologic section of a polycystic ovary with multiple subcapsular follicular cysts and stromal hypertrophy at low power *(left)*. At higher power (×100), islands of luteinized theca cells are visible in the stroma *(right)*. This morphologic change is called *stromal hyperthecosis*, and it appears to correlate directly with circulating insulin levels. (C, from Dunaif A. Insulin resistance and the polycystic ovary syndrome: mechanism and implications for pathogenesis. *Endocr Rev.* 1997;18:774–800. Copyright © 1997 by The Endocrine Society.)

with significant weight gain or an unknown cause may induce the clinical picture of PCOS in a woman with a history of previously normal ovulatory function. Hirsutism may develop prepubertally or during adolescence, or it may be absent until the third decade of life. Seborrhea, acne, and alopecia are other common clinical signs of androgen excess. In extreme cases of ovarian hyperthecosis (a severe variant of PCOS), clitoromegaly may be observed. Nonetheless, a history of rapid progression of androgenic symptoms and virilization is unusual. Some women may never have signs of androgen excess because of hereditary differences in target tissue sensitivity to androgens.[115] Infertility related to the anovulation may be the only presenting symptom.

During the physical examination, it is essential to search for and document signs of androgen excess (hirsutism, virilization, or both), insulin resistance (acanthosis nigricans) (Fig. 17.28), and the presence of unopposed estrogen action (well-rugated vagina and stretchable, clear cervical mucus) to support the diagnosis of PCOS. None of these signs is specific for PCOS, and each may be associated with any of the conditions listed in the differential diagnosis of PCOS (Table 17.4).

PCOS was previously defined according to the proceedings of an expert conference sponsored by the National Institutes of Health (NIH) in 1990, which described the disorder as including hyperandrogenism or hyperandrogenemia (or both), oligo-ovulation, and exclusion of known disorders of androgen excess and anovulation (Table 17.5).[210,211] Another expert conference held in Rotterdam in 2003 defined PCOS, after the exclusion of related disorders, by the presence of two of the following three features: oligo-ovulation or anovulation, clinical or biochemical signs of hyperandrogenism (or both), and polycystic ovaries (Fig. 17.29).[212] In essence,

Idiopathic hirsutism
Hyperprolactinemia, hypothyroidism
Nonclassic congenital adrenal hyperplasia
Ovarian tumors
Adrenal tumors
Cushing syndrome
Glucocorticoid resistance
Other rare causes of androgen excess

TABLE 17.5 Criteria for the Definition of Polycystic Ovary Syndrome (PCOS)

NIH Statement (1990)[211]

To include all of the following:
1. Hyperandrogenism and/or hyperandrogenemia
2. Oligo-ovulation
3. Exclusion of related disorders[a]

ESHRE/ASRM Statement (Rotterdam, 2003)[212]

To include two of the following, in addition to exclusion of related disorders[a]:
1. Oligo-ovulation or anovulation (e.g., amenorrhea, irregular uterine bleeding)
2. Clinical and/or biochemical signs of hyperandrogenism (e.g., hirsutism, elevated serum total or free testosterone)
3. Polycystic ovaries (by ultrasonography)

AES Suggested Criteria for the Diagnosis of PCOS (2006)[213]

To include all of the following:
1. Hyperandrogenism: hirsutism and/or hyperandrogenemia
2. Ovarian dysfunction: oligo-anovulation and/or polycystic ovaries
3. Exclusion of other androgen excess or related disorders[a]

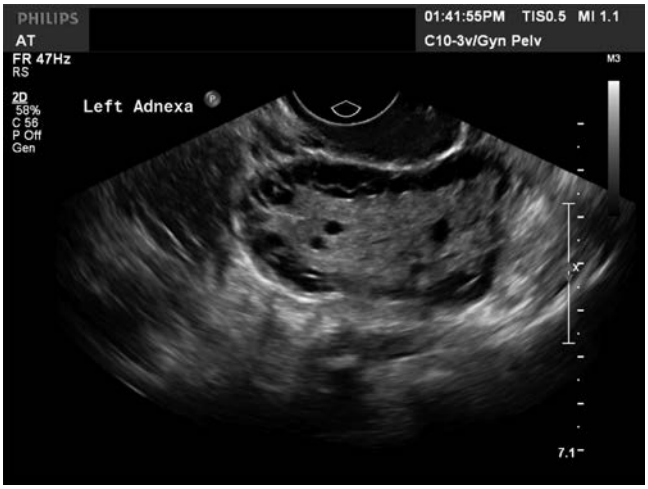
[a]Including but not limited to 21-hydroxylase-deficient nonclassic adrenal hyperplasia, thyroid dysfunction, hyperprolactinemia, neoplastic androgen secretion, drug-induced androgen excess, the syndromes of severe insulin resistance, Cushing syndrome, and glucocorticoid resistance. Superscript numbers in table indicate references at the end of the chapter.

AES, Androgen Excess Society; *ASRM,* American Society for Reproductive Medicine; *ESHRE,* European Society for Human Reproduction and Embryology; *NIH,* National Institutes of Health.

the Rotterdam 2003 criteria expanded the NIH 1990 definition by creating two new phenotypes: ovulatory women with polycystic ovaries plus hyperandrogenism and oligo-anovulatory women with polycystic ovaries but without hyperandrogenism. The clinical usefulness of including these new groups with respect to increased risk of infertility, insulin resistance, and long-term metabolic complications is not clear at this time.[213] More recently, the Androgen Excess Society published a broad consensus statement that included discussions of the merits and disadvantages of the NIH and Rotterdam criteria and suggested a practical definition that integrates both sets of diagnostic criteria (see Table 17.5).[212]

The exclusion of hyperprolactinemia, hypothyroidism, nonclassic congenital adrenal hyperplasia, and tumors requires a careful history, physical examination, and laboratory testing, as detailed previously (see Table 17.4). Cushing syndrome and glucocorticoid resistance may give rise to androgen excess and anovulation after a period of normal ovulatory function in teens. An 8 AM cortisol level after dexamethasone (1 mg) administration at midnight is a useful screening test for both conditions. Cushing syndrome may be recognized by its typical signs, whereas 8 AM and 4 PM cortisol levels are essential to confirm the diagnosis of glucocorticoid resistance.[193] Glucocorticoid resistance is characterized by preserved diurnal rhythm despite significantly elevated cortisol, ACTH, and adrenal C19 steroid levels and absence of cushingoid symptoms and signs.[193]

Elevated total testosterone is the most direct evidence for androgen excess. Various levels of testosterone are found in women with PCOS. Rarely, serum testosterone levels higher than 2 ng/mL may be encountered in association with the most severe form of PCOS, ovarian hyperthecosis. Overall, it is much more common to observe high-normal levels or borderline elevations of testosterone in women with PCOS.



• **Fig. 17.29** Transvaginal ultrasound image of a polycystic ovary. Notice the multiple, midsized follicles in the periphery and the increased solid area in the middle.

Prolactin and TSH concentrations should be measured routinely to rule out mild androgen excess and anovulation that may be associated with hyperprolactinemia. If basal LH levels are used as a marker for PCOS, a significant number of patients will slip through the cracks because they do not manifest elevated LH levels or increased LH/FSH ratios. The NIH-sponsored consensus conference on diagnostic criteria for PCOS in 1990 recommended that LH and the LH/FSH ratio are not required for the diagnosis of PCOS.[211,214] The heterogeneity of LH values in PCOS may be caused by the pulsatile nature of LH secretion and negative effects of obesity on LH levels. An elevated LH/FSH ratio supports the diagnosis of PCOS and may be useful in differentiating mild cases of nonobese PCOS without prominent androgen excess from hypothalamic anovulation. However, failure to exhibit an elevated LH level is of no diagnostic value. By definition, nonclassic congenital adrenal hyperplasia does not manifest as congenital virilization of external genitalia. Hyperandrogenic symptoms most commonly appear peripubertally or postpubertally. The clinical evaluation and laboratory-based diagnosis of nonclassic congenital adrenal hyperplasia were discussed earlier. Chapter 15 describes the ACTH stimulation test. A screening test for Cushing syndrome or glucocorticoid resistance should be performed as clinically indicated (see Chapter 15).

Serum DHEAS levels may be increased (up to 8 μg/mL) in about 50% of anovulatory women with PCOS. DHEAS originates almost exclusively from the adrenal gland.[215] The cause of adrenal hyperactivity in PCOS is unknown. Obtaining a DHEAS level routinely in a patient with PCOS is not recommended because it does not change the diagnosis or management. If an adrenal tumor is suspected, a DHEAS level should be obtained. DHEAS levels higher than 8 μg/mL may be associated with steroidogenically active adrenal tumors, and imaging is then indicated.

The Rotterdam 2003 criteria include the use of ultrasound as a diagnostic tool. The use of ultrasonography in the diagnosis of PCOS must be tempered by an awareness of the broad spectrum of women with ultrasonographic findings characteristic of polycystic ovaries. The typical polycystic-appearing ovary may emerge in a nonspecific fashion when a state of anovulation of any cause persists for any length of time (see Fig. 17.29).[216] Thus the polycystic-appearing ovary is the result of a functional derangement but not a specific central or local defect.

Biochemical evidence of insulin resistance or glucose intolerance is not necessary for the diagnosis of PCOS. Nonetheless, glucose intolerance should be investigated. Plasma glucose levels should be measured after a 75-g glucose load as a screen for glucose intolerance.

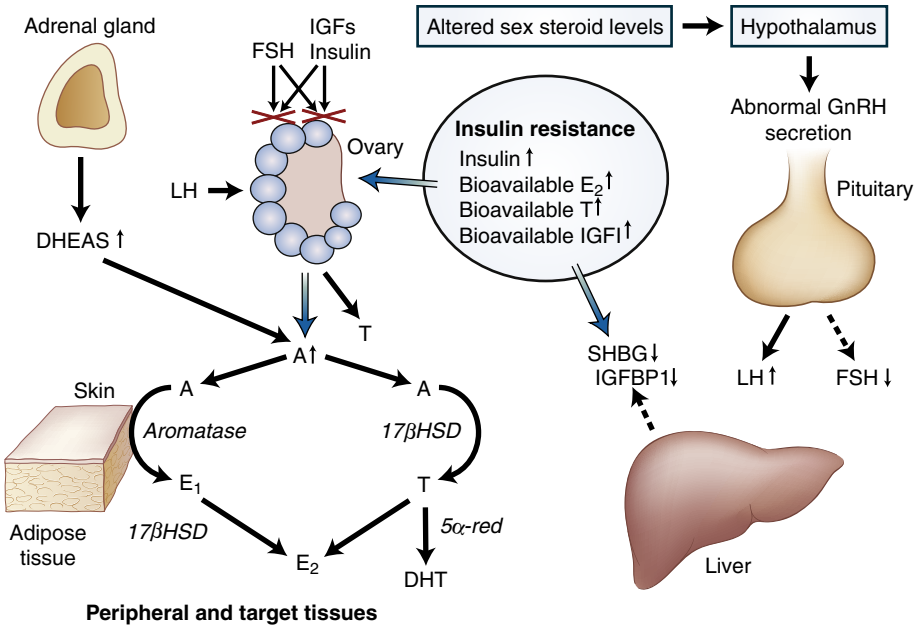
Women with PCOS commonly present with irregular uterine bleeding in the form of infrequent periods (i.e., oligomenorrhea) or amenorrhea. It is not necessary to document anovulation by ultrasonography, progesterone levels, or otherwise, especially if menstrual cycles are irregular with periods of amenorrhea. To confirm the diagnosis of chronic anovulation and unopposed estrogen exposure, most clinicians perform a progestin challenge test after a negative urine pregnancy test. Because endometrium is exposed to estradiol chronically in PCOS, these women respond to a challenge with a progestin (e.g., 5 mg/day of MPA given orally for 10 days) by uterine bleeding within a few days after the last pill of progestin. Reasons for lack of uterine bleeding after a progestin challenge include pregnancy, insufficient prior estrogen exposure of the endometrium, or an anatomic defect. If uterine bleeding does not follow progestin challenge, pregnancy should be ruled out again, along with other causes of chronic anovulation, as described in this chapter. An anatomic defect such as intrauterine adhesions may be ruled out with a hysterosalpingogram or hysteroscopy.

During the initial workup, an endometrial biopsy specimen should be obtained with the use of a plastic minisuction cannula (e.g., Pipelle) in the physician's office. If chronic anovulation persists, endometrial biopsies should be repeated periodically. Pregnancy should be ruled out by a urine or serum pregnancy test before each biopsy. Response to oral contraceptives or periodic progestin treatment with predictable withdrawal bleeding episodes is reassuring, and patients with predictable bleeding patterns do not need endometrial sampling during these treatments. In untreated patients, the risk of endometrial hyperplasia and malignancy is significantly increased even in young women with PCOS because of unopposed estrogen exposure.

Gonadotropin Production in Polycystic Ovary Syndrome

Women with PCOS have higher mean concentrations of LH but low or low-normal levels of FSH compared with levels found in normal women in the early follicular phase.[217] The elevated LH levels in PCOS are presumed to be primarily caused by accelerated GnRH-LH pulsatile activity (Fig. 17.30).[218–220] Central opioid tone appears to be suppressed because the pattern of LH secretion does not change in response to naloxone.[221] The enhanced pulsatile secretion of GnRH has been attributed to a reduction in hypothalamic opioid inhibition caused by the chronic absence of progesterone.[189] An increase in amplitude and frequency of LH secretion also correlates with steady-state levels of circulating estrogen.

In obese women with PCOS, LH levels may not be increased. The increase in LH pulse frequency is characteristic of the anovulatory state regardless of body fat content.[222] LH pulse amplitude, however, is comparatively normal in overweight women with PCOS, whereas it is increased in nonobese women with PCOS.[223] The overall LH reduction in obese women with PCOS may result from factors other than changes in LH pulse amplitude.[224] A low



• **Fig. 17.30** Pathologic mechanisms in polycystic ovary syndrome (PCOS). A deficient in vivo response of the ovarian follicle to physiologic quantities of follicle-stimulating hormone (FSH), possibly because of an impaired interaction between signaling pathways associated with FSH and insulin-like growth factors (IGFs) or insulin, may be an important defect responsible for anovulation in PCOS. Insulin resistance associated with increased circulating and tissue levels of insulin and bioavailable estradiol (E_2), testosterone (T), and IGF1 gives rise to abnormal hormone production in a number of tissues. Oversecretion of luteinizing hormone (LH) and decreased output of FSH by the pituitary, decreased production of sex hormone–binding globulin (SHBG) and IGF-binding protein 1 (IGFBP1) in the liver, increased adrenal secretion of dehydroepiandrosterone sulfate (DHEAS), and increased ovarian secretion of androstenedione (A) all contribute to the feed-forward cycle that maintains anovulation and androgen excess in PCOS. Excessive amounts of E_2 and T arise primarily from the conversion of A in peripheral and target tissues. T is converted to the potent steroids estradiol or DHT (dihydrotestosterone). Reductive 17β-hydroxysteroid dehydrogenase (17βHSD) enzyme activity may be conferred by protein products of several genes with overlapping functions; 5α-reductase (5α-red) is encoded by at least two genes, and aromatase is encoded by a single gene. *GnRH,* gonadotropin-releasing hormone.

LH value does not rule out the diagnosis of PCOS, whereas a high LH-FSH ratio supports this diagnosis in an anovulatory woman.

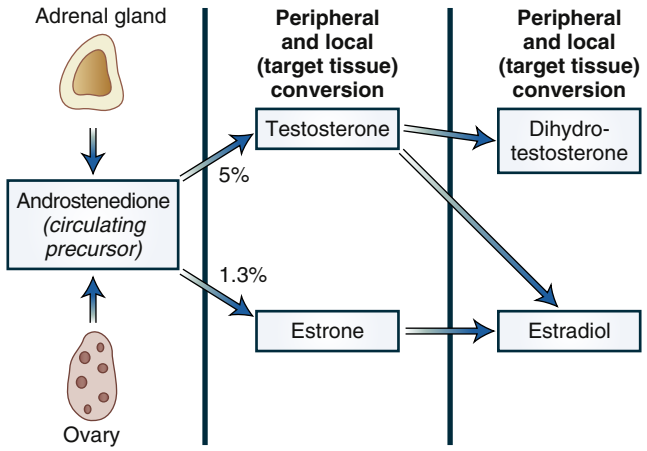
Insulin has been implicated as a potential regulator of LH secretion in PCOS. Insulin enhances the transcription of the LHβ gene *(LHB)*.[225,226] This laboratory observation was supported by an in vivo human study showing that insulin infusion suppresses pituitary response to GnRH in normal women and in women with PCOS.[227] These studies support the concept that insulin resistance or hyperinsulinemia may be responsible for abnormal gonadotropin release (see Fig. 17.30).

Steroid Production in Polycystic Ovary Syndrome

Ovulatory cycles are characterized by cyclic fluctuating hormone levels that regulate ovulation and menses (see Fig. 17.1A). Anovulation in women with PCOS is associated with steady-state levels of gonadotropins and ovarian steroids. In patients with persistent anovulation, the average daily production of estrogen and androgens is increased and depends on LH stimulation (see Fig. 17.30).[228] This is reflected in higher circulating levels of testosterone, androstenedione, DHEA, DHEAS, 17-hydroxyprogesterone, and estrone.[229] Testosterone, androstenedione, and DHEA are secreted directly by the ovary, whereas DHEAS, which is elevated in about 50% of anovulatory women with PCOS, is almost exclusively an adrenal contribution.[215] Circulating levels of androstenedione, secreted by polycystic ovaries, are particularly high.

Local conversion of steroid precursors to estradiol is an important physiologic process for certain estrogen target tissues, such as normal breast and genital skin, and can also promote the growth of pathologic estrogen-dependent tissues, such as endometrial or breast cancer (Fig. 17.31).[97,105,229–231] Androstenedione of ovarian origin is the most strikingly elevated steroid in PCOS. Androstenedione is not biologically active but serves as a dual precursor for androgen (i.e., testosterone that is further converted to the biologically far stronger androgen DHT) and estrogen (i.e., estrone that is further converted to biologically active estradiol in target tissues) (see Fig. 17.31). Increased androstenedione of ovarian origin in women with PCOS gives rise to circulating levels of estradiol higher than those measured during the first few days of an ovulatory cycle.

Estradiol is an extremely potent steroid. Biologically effective circulating levels of estradiol are measured in units of picograms per milliliter (pg/mL) or picomoles per liter (pmol/L); biologically effective levels of testosterone are measured in units of nanograms per milliliter (ng/mL) or nanomoles per liter (nmol/L) and circulate at 10 to 100 times the physiologic levels of estradiol. Even small rates of conversion of androstenedione to estrone may have a significant biologic impact, whereas markedly elevated production of androstenedione is required to produce significant amounts of testosterone and manifestations of androgen excess (see Fig. 17.31). Because elevated production of androstenedione does occur in PCOS,



• **Fig. 17.31** Extraovarian conversion of androstenedione to androgen and estrogen. Androstenedione of adrenal or ovarian origin, or both, acts as a dual precursor for androgen and estrogen. Approximately 5% of circulating androstenedione is converted to circulating testosterone, and approximately 1.3% of circulating androstenedione is converted to circulating estrone in peripheral tissues. Testosterone and estrone are further converted to biologically potent steroids, dihydrotestosterone and estradiol, in peripheral and target tissues. Biologically active amounts of estradiol in serum are measured in picograms or picomoles per milliliter (pg/mL or pmol/L), whereas biologically active levels of testosterone in serum are measured in nanograms or nanomoles per milliliter (ng/mL or nmol/L). The 1.3% conversion of normal quantities of androstenedione to estrone may have a critical biologic impact in settings such as postmenopausal endometrial or breast cancer. Significant androgen excess is observed in conditions with abnormally increased androstenedione formation (e.g., polycystic ovary syndrome).

extraovarian production of testosterone is biologically significant in this disease. In postmenopausal women, who have much lower levels of androstenedione, extraovarian production of testosterone is less important. Relatively small quantities of estrone (and estradiol) produced primarily by peripheral aromatization of androstenedione have a biologic impact in men and postmenopausal women.

Production of Sex Hormone–Binding Globulin in Polycystic Ovary Syndrome

SHBG binds testosterone and estradiol and decreases their biologic activities. In PCOS, the net production of androgen and estrogen is increased. Amplified estrogenic and androgenic effects in PCOS also are caused by a decreased SHBG concentration, giving rise to increased free or biologically active circulating levels of estradiol and testosterone (see Fig. 17.30). The levels of SHBG are controlled by a balance of hormonal influences on its synthesis in the liver. Testosterone and insulin inhibit, and estrogen and thyroid hormone stimulate, SHBG formation.[232] In anovulatory women with PCOS, circulating levels of SHBG are reduced by approximately 50%; this effect may be a hepatic response to increased circulating levels of testosterone and insulin (see Fig. 17.30).[232]

Testosterone decreases serum SHBG levels, giving rise to a vicious feedback circle favoring low SHBG and high bioavailable testosterone levels (see Fig. 17.30). Insulin directly decreases serum SHBG concentrations in women with PCOS independent of any action of sex steroids.[232] Insulin increases free testosterone levels in PCOS by two mechanisms: increasing ovarian secretion of testosterone precursors (e.g., androstenedione) and suppressing SHBG.[232]

Follicular Fate in Polycystic Ovary Syndrome

Under the influence of relatively low but constant levels of FSH, follicular growth is continuously stimulated, although not to the point of full maturation and ovulation.[233] Although full growth potential is not realized, the follicular life span may be extended by several months in the form of multiple follicular cysts. Most of these follicles in polycystic ovaries are 2 to 10 mm in diameter, and some can be as large as 20 mm. Hyperplastic theca cells, often luteinized in response to the high LH levels, surround these follicles (see Fig. 17.27). The accumulation of follicles arrested at various stages of development allows increased and relatively constant production of steroids in response to steady-state levels of gonadotropins.

These follicles are subject to atresia and are replaced by new follicles of similar limited growth potential. Steady-state turnover of stromal cells contributes to the stromal compartment of the ovary, and it is sustained by tissue derived from follicular atresia. A degenerating granulosa compartment, leaving the theca cells to contribute to the stromal compartment of the ovary, accompanies atresia (see Fig. 17.27). This functioning stromal tissue secretes significant amounts of androstenedione under the influence of increased LH. Androstenedione, by the mechanisms discussed previously, leads to increases in free testosterone and free estradiol levels and decreases in SHBG concentrations (see Fig. 17.30). From the point of view of steroidogenesis and steroid action, PCOS is the result of a complex vicious circle that includes a number of positive and negative feedback mechanisms.

Fig. 17.30 summarizes the postulated mechanisms underlying PCOS. Because FSH, insulin, and IGF pathways can synergize, it was postulated that this synergy does not occur in the presence of insulin resistance and might lead to relative resistance of the ovarian follicle to FSH. However, in vitro studies provide mixed results with respect to this hypothesis. For example, cultured granulosa cells obtained from the small follicles of polycystic ovaries produce negligible amounts of estradiol but show a dramatic increase in estrogen production when FSH or IGF1 is added to the culture medium. When FSH and IGF1 were added together in vitro, they synergized to increase estrogen biosynthesis in granulosa cells from polycystic ovaries.[234]

Induction of ovulation in PCOS is achieved by increasing FSH levels that are hypothesized to overcome this postulated in vivo block to FSH at the granulosa cell level. Two popular treatments, oral clomiphene citrate and injectable recombinant FSH, can provide increased levels of endogenous or exogenous FSH that may lead to ovulation at various doses. Some PCOS patients require large doses of clomiphene citrate or FSH to achieve ovulation. Paradoxically, the polycystic ovary may overreact to pharmacologic levels of FSH by recruiting a large number of developing follicles at once; this occasionally gives rise to the ovarian hyperstimulation syndrome (OHSS) (discussed later).[235] The therapeutic window between ovarian nonresponsiveness and hyperreactivity is usually narrow. There are significant gaps of knowledge that do not permit reconciliation of clinical postulates derived from in vitro or in vivo studies of PCOS.

Ovarian Hyperthecosis

Ovarian hyperthecosis is a severe variant of PCOS. The term refers to significantly increased stromal tissue with luteinized theca-like cells scattered throughout large sheets of fibroblast-like cells. The clinical and histologic findings and pathophysiology represent an exaggerated version of PCOS.[236] This diagnosis can be made on clinical grounds; an ovarian biopsy is not necessary except to rule out an ovarian tumor.

Increased androgen production leads to the clinical picture of more intense androgenization. The higher testosterone levels may also lower LH levels by blocking estrogen action at the hypothalamic-pituitary level.[224] The severity of hyperthecosis correlates with the degree of insulin resistance.[224] Because insulin and IGF1 stimulate proliferation of thecal interstitial cells, hyperinsulinemia may be an important pathophysiologic factor in the cause of hyperthecosis.

It is not uncommon to encounter markedly high levels of testosterone, even above 2 ng/mL, in patients with ovarian hyperthecosis. Virilization is common. These patients do not usually ovulate in response to clomiphene or recombinant FSH. It is usually difficult to suppress testosterone production, even using a GnRH analogue. Bilateral oophorectomy should be a last resort, but it may be necessary to control testosterone production in some of these patients.

Genetics of Polycystic Ovary Syndrome

The strong trend of PCOS to aggregate in families suggests an underlying genetic basis.[237,238] Some key clinical features of PCOS are genetically transmitted. In particular, there is familial aggregation of hyperandrogenemia (with or without oligomenorrhea) in PCOS kindreds, suggesting that it is a genetic trait.[208] Another study showed that hyperinsulinism may be a familial characteristic in daughters of women with PCOS.[239]

The PCOS phenotype is a consequence of genes and environment. For example, obesity associated with unhealthy lifestyle choices aggravates the PCOS phenotype in genetically susceptible women. The variable PCOS phenotypes add further challenge to genetic studies of PCOS. Several genomic loci have been proposed to account for the PCOS phenotype. These include *CYP11A1*, the insulin gene, and the follistatin gene; however, no convincing evidence regarding any of these loci has been published.[240] Although independent studies identified a dinucleotide repeat marker near the insulin receptor gene that maps to chromosome 19p13.2, the particular PCOS gene in this locus has not been isolated.[241] In the Han Chinese population, genome-wide PCOS association signals showed evidence of enrichment for candidate genes related to insulin signaling *(INSR)*, gonadotropin receptors *(FSHR, LHCGR),* and type 2 diabetes *(HMGA2, THADA, DENND1A)*.[242]

Insulin Resistance and Polycystic Ovary Syndrome

Insulin resistance is a major factor in the pathogenesis of non–insulin-dependent diabetes mellitus (NIDDM). The term *insulin resistance* can be defined as impaired whole-body insulin-mediated glucose disposal, as determined with the use of techniques such as the hyperinsulinemic glucose clamp technique.[111] Insulin resistance is defined clinically as the inability of a known quantity of exogenous or endogenous insulin to increase glucose uptake and use in an affected individual as much as it does in a normal person. Insulin resistance is frequently observed in lean and obese women with PCOS. More severe degrees of insulin resistance or impaired glucose tolerance are more common in obese women with PCOS.[111]

Androgen excess and insulin resistance are often associated with acanthosis nigricans. Acanthosis nigricans is a gray-brown, velvety discoloration and increased thickness of the skin, usually seen at the neck, groin, and axillae and under the breasts; it is a marker for insulin resistance (see Fig. 17.28). Hyperkeratosis and papillomatosis are the histologic characteristics of acanthosis nigricans. Acanthosis nigricans in hyperandrogenic women depends on the presence and severity of hyperinsulinemia and insulin resistance.[243] The mechanism responsible for the development of acanthosis nigricans is uncertain. This abnormal growth response of the skin may be mediated through receptors for various growth factors, including those for insulin and IGF1. Acanthosis nigricans can also be observed in the absence of insulin resistance or androgen excess.

Insulin resistance is characterized by an impaired glucose response to a specific amount of insulin. In many of these patients, normal glucose levels are maintained at the expense of increased circulating insulin to overcome the underlying defect. More severe forms of insulin resistance in PCOS range from impaired glucose tolerance to frank NIDDM. Resistance to insulin-stimulated glucose uptake is a relatively common phenomenon in the general population and is sometimes referred to as *syndrome X* or *metabolic syndrome*. The fundamental abnormality leading to the manifestations that make up the metabolic syndrome is resistance to insulin-mediated glucose uptake in muscle and increased lipolysis, which produces elevated levels of circulating free fatty acids.[244] These individuals also have dyslipidemia, hypertension, and increased risk of developing CVD. Not surprisingly, the incidences of dyslipidemia and cardiovascular risk are increased significantly in women with PCOS.[245,246] The incidence of hypertension increases significantly after menopause in women with a history of PCOS.[111] There is a significant clinical and pathologic overlap between the metabolic syndrome and PCOS.[247]

The clinical presentation of patients with insulin resistance depends on the ability of the pancreas to compensate for the target tissue resistance to insulin. During the first stages of this condition, compensation is effective, and the only metabolic abnormality is hyperinsulinemia. In many patients, the beta cells of the pancreas eventually fail to meet the challenge, and declining insulin levels lead to impaired glucose tolerance and eventually to frank diabetes mellitus. Beta-cell dysfunction is demonstrable in women with PCOS before the onset of glucose intolerance.[248]

Studies of well-characterized causes of hyperinsulinemia and androgen excess have illuminated various mechanisms of insulin resistance. Factors such as a decrease in insulin binding related to autoantibodies to insulin receptors, postreceptor defects, and a decrease in insulin receptor sites in target tissues are all involved in insulin resistance.[249] These rare syndromes are found in an extremely small portion of women with anovulation, androgen excess, and insulin resistance, leaving most PCOS patients without any demonstrable abnormalities in the number or quality of receptors or in antibody formation. The exact nature of insulin resistance in most women with PCOS is not well understood.

To understand the molecular defect underlying insulin resistance in PCOS, Dunaif and coworkers studied the differences between skin fibroblasts from women with and without PCOS with respect to insulin-dependent signal transduction.[111] The fibroblasts of women with PCOS showed no change in insulin binding or receptor affinity, but a postreceptor defect was observed in one-half of the women with PCOS.[111] This defect is characterized by increased basal insulin receptor serine phosphorylation and decreased insulin-dependent tyrosine phosphorylation of the insulin receptor.[111] At about the same time, Miller and coworkers evaluated whether post-translational modification of the product of the *CYP17A1* gene alters the ratio of its hydroxylase to lyase activity; they found that serine phosphorylation of CYP17A1 dramatically increases the enzyme's 17,20-lyase but not its 17α-hydroxylase activity. These observations led the investigators to hypothesize that a dominantly inherited aberrant kinase

activity phosphorylates serine residues at the insulin receptor-β and CYP17A1 product, leading to insulin resistance and increased androgen production, respectively. The cause of this abnormal phosphorylation pattern and consequences for insulin action and androgen production are important topics for further study.[250]

Within the context of a unified hypothesis, insulin resistance seems to be a critical defect that explains most of the endocrine abnormalities observed in PCOS (see Fig. 17.30). Insulin resistance is associated with abnormal responses of the ovarian follicle to FSH, which lead to anovulation and androgen secretion. This results in noncyclic formation of estrogen from androgens in peripheral tissues. Estradiol together with elevated androgen and insulin levels gives rise to abnormal gonadotropin secretion. This creates an anovulatory state favoring continuous excess of LH, steroid precursors, androgen, and estrogen (see Fig. 17.30).

Role of Obesity in Insulin Resistance and Anovulation

Increased waist-to-hip ratio compounded by significantly increased body mass index is called *android obesity* because this type of adipose tissue distribution is observed more commonly in men. Overweight women with anovulatory androgen excess commonly have this particular body fat distribution.[251] Android obesity is the result of fat deposition in the abdominal wall and in visceral mesenteric locations. This fat is more sensitive to catecholamines, less sensitive to insulin, and more active metabolically. Android obesity is associated with insulin resistance, glucose intolerance, diabetes mellitus, and an increase in androgen production rate and results in decreased levels of SHBG and increased levels of free testosterone and estradiol.[251] Android obesity is associated significantly with cardiovascular risk factors, including hypertension and dyslipidemia, and it has been tied to a notable increase in the risk of poor-prognosis breast cancer.[252,253] However, no direct association has been reported between PCOS and breast cancer risk.[254]

Although the combination of insulin resistance and androgen excess is often observed in obese women overall, women with android-type obesity appear to be at a significantly higher risk for insulin resistance and androgen excess. However, insulin resistance and androgen excess are not confined to obese anovulatory women but also occur in nonobese anovulatory women.[222] Although obesity by itself causes insulin resistance, the combination of insulin resistance and androgen excess is a specific feature of PCOS. Not surprisingly, the combination of obesity and PCOS is associated with more severe degrees of insulin resistance than those found in nonobese women with PCOS.[222,255] Android-type obesity, in contrast to general obesity, is a more specific risk factor for PCOS.

Laboratory Evaluation of Metabolic Syndrome in PCOS

In everyday clinical practice, the criteria for diagnosing insulin resistance in an individual patient have not been standardized and present extremely complex issues. One-fourth of the normal population has fasting and glucose-stimulated insulin levels that overlap with those of insulin-resistant individuals because of the great variability of insulin sensitivity in normal subjects.[111] Clinically available measures of insulin action, such as fasting or glucose-stimulated insulin levels, do not correlate well with more detailed measurements of insulin sensitivity in research settings.

In view of these constraints, it is reasonable to consider all women with PCOS at risk for insulin resistance and the associated abnormalities of the metabolic syndrome—dyslipidemia, hypertension, and CVD.[247] A lipid profile should be obtained in all cases of PCOS. Especially for obese women with PCOS, fasting glucose levels and glucose levels 2 hours after a 75-g glucose load should be obtained as a screen for glucose intolerance. The clinician should encourage the patient to take every possible measure (e.g., weight reduction, exercise) to reduce insulin resistance.

Use of Antidiabetic Drugs to Treat Anovulation and Androgen Excess

A logical approach to the management of PCOS includes using medications that improve insulin sensitivity in target tissues, achieving reductions in insulin secretion, and stabilizing glucose tolerance. Antidiabetic medications in the classes of biguanides (metformin) and thiazolidinediones (pioglitazone and rosiglitazone) have been used to reduce insulin resistance. Although metformin appears to influence ovarian steroidogenesis directly, this effect does not appear to be primarily responsible for the attenuation of ovarian androgen production in women with PCOS. Rather, metformin inhibits the output of hepatic glucose, necessitating a lower insulin concentration and thereby probably reducing androgen production by theca cells.[256]

Metformin at a dose of 500 mg three times daily reduced hyperinsulinemia, basal and stimulated levels of LH, and free testosterone concentrations in overweight women with PCOS.[257,258] Some anovulatory women ovulated and achieved pregnancy; however, clomiphene is superior to metformin in achieving live births in infertile women with PCOS.[259–261] Among published studies of metformin use in women with PCOS, subject characteristics and control measures for effects of weight change, dose of metformin, and outcome vary widely. A meta-analysis of 13 studies in which metformin was administered to 543 participants reported that patients taking metformin had an odds ratio for ovulation of 3.88 (95% confidence interval [CI], 2.25–6.69) compared with placebo and an odds ratio for ovulation of 4.41 (95% CI, 2.37–8.22) for metformin plus clomiphene compared with clomiphene alone.[262] Although the addition of metformin to clomiphene seems to increase the ovulation rate, it does not result in a higher rate of live births.[260] Metformin also improved fasting insulin levels, blood pressure, and levels of LDL cholesterol. These effects were judged to be independent of any changes in weight that were associated with metformin treatment, but controversy persists about whether the beneficial effects of metformin are entirely independent of the weight loss that is typically seen early in the course of therapy.[261,262]

The thiazolidinediones are pharmacologic ligands for the nuclear receptor PPARγ. They improve the action of insulin in the liver, skeletal muscle, and adipose tissue and have only a modest effect on hepatic glucose output. As with metformin, the thiazolidinediones are reported to affect ovarian steroid synthesis directly, although most evidence indicates that the reduction in insulin levels is responsible for decreased concentrations of circulating androgen.[256]

Women with PCOS who took troglitazone had consistent improvements in insulin resistance, pancreatic beta-cell function, hyperandrogenemia, and glucose tolerance.[263,264] In a double-blind, randomized, placebo-controlled study, ovulation was significantly greater for women with PCOS who received troglitazone than for those who received placebo; free testosterone levels decreased, and levels of SHBG increased in a dose-dependent fashion.[265] Although troglitazone is no longer available because of its hepatotoxicity, subsequent studies using rosiglitazone and pioglitazone had similar results.[266–268] Because of concern about the use of thiazolidinediones in pregnancy and recent evidence

linking these drugs to serious side effects such as heart failure and stroke, they have been less readily adopted for routine treatment of PCOS. The success of the strategy of reversing insulin resistance as a way to correct the critical abnormalities in PCOS argues for this defect as central to the pathogenesis of the disorder.

Management of Long-Term Deleterious Effects of Polycystic Ovary Syndrome

The long-term consequences of PCOS include irregular uterine bleeding, anovulatory infertility, androgen excess, chronically elevated levels of free estrogen associated with an increased risk of endometrial cancer, and insulin resistance associated with an increased risk of CVD and diabetes mellitus. Treatment must aid in achieving a healthy lifestyle and normal body weight, protect the endometrium from the effects of unopposed estrogen, and reduce testosterone levels.

Any woman with PCOS should be counseled to maintain a healthy lifestyle. In obese PCOS women, permanent lifestyle modification should be emphasized as the primary preventive measure to minimize short-term and long-term deleterious effects. Simple measures such as decreasing daily food intake by 500 kcal and introducing any type of moderate exercise for 30 minutes daily for 6 months can decrease hyperandrogenemia and diastolic blood pressure.[204] Because insulin resistance contributes to the abnormal lipid profile and increased cardiovascular risk in women with PCOS, weight loss is a high priority for patients who are overweight.[269] Insulin resistance and androgen excess can be reduced with a weight reduction of at least 5%.[270,271] Significant weight loss has also resulted in ovulation and pregnancy in a number of patients with PCOS.[272] Nutritional counseling and an emphasis on lifestyle changes are essential components of the long-term management of PCOS.

If the patient does not wish to become pregnant, medical therapy is directed toward the interruption of the effect of unopposed estrogen on the endometrium. Nonfluctuating levels of unopposed estradiol in the absence of progesterone cause irregular uterine bleeding, amenorrhea, and infertility and increase the risk of endometrial cancer. Anovulatory women with PCOS may have endometrial cancer even in their early 20s.[273] Endometrial biopsy should be performed periodically in untreated women with PCOS regardless of age. Pregnancy should be ruled out before each endometrial biopsy. The uterine bleeding pattern should not influence the decision to perform an endometrial biopsy. The presence of amenorrhea does not rule out endometrial hyperplasia. The critical factor that determines the risk of endometrial neoplasia is the duration of anovulation and exposure to unopposed estradiol. Long-term treatment with a progestin or oral contraceptive significantly decreases the risk of endometrial cancer.

One of the simplest and most effective ways to administer a progestin in the long term is to use an oral contraceptive. Oral contraceptives provide two additional benefits: reduction of androgen excess and contraception. Oral contraceptive pills reduce circulating androgen levels through suppression of circulating LH and stimulation of SHBG levels, and they have been shown to reduce hirsutism.[152] Oral contraceptive treatment for anovulation and hyperinsulinemia in women with androgen excess does not increase cardiovascular risk.[274]

For the patient who does not complain of hirsutism but is anovulatory and has irregular bleeding, treatment with progestin alone may be attempted as an alternative to oral contraceptive use. Progestin therapy is directed toward interruption of the chronic exposure of endometrium to unopposed effects of estrogen. MPA may be administered intermittently (e.g., 5 mg daily for the first 10 days of every other month) to ensure withdrawal bleeding and prevent endometrial hyperplasia. This treatment does not decrease androgen excess, nor does it provide contraception. Because an oral contraceptive with an ethinyl estradiol content of 30 μg or less can suppress androgen excess of ovarian origin, provide contraception, and protect the endometrium and does not increase insulin resistance, a low-dose oral contraceptive is the treatment of choice for nonsmokers with PCOS. An oral contraceptive together with the antiandrogen spironolactone (100 mg/day) is the recommended starting treatment for a hirsute woman with PCOS. The dose of spironolactone can be increased in increments to suppress hair growth, as described earlier.

Treatment with an oral contraceptive, with or without spironolactone, may not be effective in androgen suppression in severe cases of PCOS. In patients resistant to oral contraceptives, suppression of the ovary using a depot GnRH agonist may be required. Spironolactone does not affect insulin sensitivity in anovulatory women and can be used safely without causing adverse effects on carbohydrate or lipid metabolism.[275]

The clinician must counsel women with PCOS regarding their increased risk of future diabetes mellitus. The age at onset of NIDDM is significantly earlier in these women than in the general population.[206] Women with PCOS are more likely to experience gestational diabetes.[276] Long-term follow-up studies have shown a significantly increased risk for frank diabetes mellitus in anovulatory patients with PCOS.[111] It is therefore important to monitor glucose tolerance with periodic measurements of glucose levels after fasting and after a 75-g glucose load. The place of metformin in the long-term treatment of PCOS remains to be determined.[261,277]

The physician should alert the patient with PCOS that up to one-half of first-degree relatives and sisters may be affected by PCOS or at least by androgen excess in the presence of regular menses.[208] These individuals may be at higher than average risk for CVD and may benefit from preventive measures that reduce this risk.

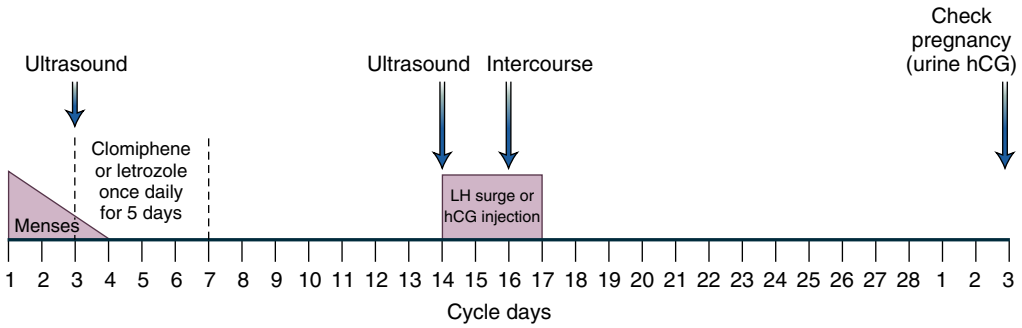
Ovulation Induction in Polycystic Ovary Syndrome

When pregnancy is achieved, patients with PCOS appear to have an increased risk of spontaneous miscarriage.[278] This increased risk may be related to elevated levels of LH that may produce an adverse environment for the oocyte and the endometrium. LH levels should be suppressed with oral contraceptives before ovulation is induced. Suppression can be achieved in most patients with PCOS by the use of an oral contraceptive for 4 to 6 weeks before ovulation induction with clomiphene citrate, an aromatase inhibitor, or recombinant FSH.

To induce ovulation in women with PCOS, FSH levels may be increased by oral administration of an antiestrogen (clomiphene citrate) or an aromatase inhibitor (letrozole, anastrozole) or by subcutaneous injection of recombinant FSH. Presumably, pharmacologic levels of FSH overcome the ovarian defect that is responsible for anovulation in PCOS.

Clomiphene Citrate

Clomiphene citrate is a nonsteroidal, ovulation-inducing ER ligand with mixed agonistic-antagonistic properties.[279] Acting as an antiestrogen, clomiphene citrate is thought to displace endogenous estrogen from hypothalamic ERs, thereby removing the negative feedback effect exerted by endogenous estrogens. The resultant change in pulsatile GnRH release is thought to normalize the release



• **Fig. 17.32** Monitoring of clomiphene citrate or letrozole-initiated ovulation. On cycle day 2 or 3, a baseline ultrasound examination is performed to rule out any large ovarian follicular cyst. Oral administration of clomiphene citrate or letrozole is started on day 3 of the cycle and continued for 5 days. Ultrasonography is performed on cycle day 13 or 14 to ensure follicular development. Upon observing at least one mature follicle by ultrasound, ovulation may be triggered by a human chorionic gonadotropin (hCG) injection followed by intercourse in 24 to 34 hours. Alternatively, the patient may be encouraged to have intercourse every other day during the 12-day period after the last clomiphene citrate or letrozole dose. Urinary hCG levels are checked to determine whether pregnancy has occurred. *LH,* luteinizing hormone.

of pituitary FSH and LH, which is followed by follicular recruitment and selection, assertion of dominance, and ovulation.[279]

Clomiphene citrate treatment can be started at any time to induce ovulation in an amenorrheic and anovulatory patient provided that a pregnancy test is performed beforehand (Fig. 17.32). Alternatively, uterine bleeding may be induced after a 10-day treatment with a combination oral contraceptive or MPA (5 mg/day). On cycle day 2 or 3 (day 1 is the first day of uterine bleeding), a baseline ultrasound study is performed to rule out any ovarian follicular cyst of more than 25-mm average diameter. If one or more large cysts are seen, ovulation induction should be delayed until after gonadotropin suppression by continuous oral contraception treatment for 4 to 6 weeks to eliminate these cysts or decrease their size. Clomiphene citrate is started at 50 mg/day orally on day 3 of the cycle and continued for 5 days. Ultrasonography is performed on cycle day 13 or 14 to ensure follicular development (i.e., at least one new follicle measuring at least 16 mm in diameter). The patient should be encouraged to have intercourse every other day during the 10-day period following the last clomiphene citrate dose. Alternatively, measurement of urinary LH to detect an LH surge can be used to time intercourse. Intercourse is recommended on the day of a positive urinary LH peak and on the next day. If an hCG injection is used to induce ovulation, intercourse is recommended within 24 to 34 hours after the injection.

If follicular development does not occur after the first course of therapy with clomiphene citrate at 50 mg/day, a second course of 100 mg daily for 5 days may be started. Lack of response at doses of 150 to 200 mg daily for 5 days should be an indication for a change of treatment. Most patients destined to conceive do so with the starting dose of clomiphene citrate (50 mg/day for 5 days). Most clomiphene citrate–initiated conceptions occur within the first 6 ovulatory cycles.[279] The incidence rate for multiple gestation in clomiphene citrate–induced pregnancies is 6% (4% for twins and 2% for triplets).[260] Failure to achieve pregnancy after three clomiphene cycles despite sonographic evidence of follicular development should prompt the clinician to perform a comprehensive infertility workup, including a semen analysis and evaluation of the uterine cavity and tubal patency.

Aromatase Inhibitors

Via decreasing aromatization of the estrogen precursor steroids in the brain and other body sites, aromatase inhibitors reduce hypothalamic-pituitary estrogen feedback, and this leads to increased GnRH secretion, concomitant elevations in LH and FSH, and increased ovarian follicular development in premenopausal women.[104,280] The gonadotropin-stimulating aromatase inhibitors letrozole and anastrozole have been used off-label in the treatment of patients with ovulatory dysfunction, such as PCOS, and for increasing the number of ovarian follicles recruited for ovulation in women who are already ovulatory.[281] Oral administration of letrozole (2.5 or 5 mg/day) or anastrozole (1 mg/day) on days 3 to 7 after uterine bleeding is effective for ovulation induction in women with anovulatory infertility (see Fig. 17.32).[281,282] In a randomized study, as compared with clomiphene (50 mg/day), letrozole (2.5 mg/day) was associated with higher live-birth and ovulation rates among infertile women with PCOS.[282] A retrospective study did not show any difference in the overall rates of major and minor congenital malformations among newborns from mothers who conceived after letrozole or clomiphene treatment.[283]

Metformin

Head-to-head randomized trials showed that clomiphene alone is clearly superior to metformin only with respect to achieving ovulation and live births in women with PCOS.[260] However, the ovulatory response to clomiphene was increased in obese women with PCOS by decreasing insulin secretion with the addition of metformin.[277] Another randomized study showed that the higher rate of ovulation in the users of clomiphene plus metformin seemed to be offset by a higher rate of pregnancy losses, producing similar live-birth rates in clomiphene-only and clomiphene plus metformin groups.[260] The benefit of the addition of metformin to clomiphene in obese clomiphene-nonresponders with PCOS needs to be assessed further.

Low-Dose Gonadotropin Therapy

For women who do not ovulate in response to clomiphene citrate or letrozole, FSH injections are started on day 3 of spontaneous or progestin-induced uterine bleeding. Recombinant FSH is administered subcutaneously starting with a daily dose of 75 IU for up to 10 days, if necessary, and using small incremental dose increases (12.5–37.5 IU) from then on at intervals of 3 to 7 days until serum estradiol concentrations begin to increase. The dose is then maintained until follicular rupture, which is induced by

subcutaneous injection of recombinant hCG (250 μg). Follicular growth is monitored by transvaginal ultrasonography and blood estradiol levels, which serve as biochemical markers for the granulosa cell mass in the growing follicle.[235] This regimen induces development of a single follicle in most cycles and has succeeded in reducing the rate of multiple pregnancies to as low as 6% in some series.[235] The low-dose regimen also practically eliminated the complication of severe OHSS.[235] Conception rates are comparable to those achieved with conventional therapy. The miscarriage rate remains somewhat higher than that after spontaneous conceptions (20–25%).

Conventional-dose gonadotropin therapy (starting FSH dose, 150 IU daily) should not be used as first-line treatment in patients with PCOS because it causes an alarming number of multiple pregnancies (14–50% of treatment cycles) and a significantly increased risk of OHSS (1.3–9.4% of treatment cycles).[284] OHSS is a more common complication of conventional-dose compared with low-dose gonadotropin treatment. Milder forms are relatively common and are characterized by weight gain, abdominal discomfort, and enlarged ovaries. Home bed rest and increased oral intake of fluids are sufficient to manage this form. Severe OHSS occurs in 0.1% to 0.2% of stimulation attempts and is accompanied by severe ascites, pleural effusion, electrolyte imbalance, and hypovolemia with oliguria. The most dreaded complication is deep venous thrombosis and embolism. Its cause is poorly understood. Large numbers of follicles, peak estradiol levels greater than 2000 pg/mL, and pregnancy are associated with a higher likelihood of OHSS. Prevention includes withholding of the hCG injection and intrauterine insemination. Treatment of severe OHSS includes hospitalization, maintenance of fluid and electrolyte balance, prophylaxis for thromboembolism by heparin, and drainage of severe ascites or pleural effusions. Frequently, supportive measures are sufficient to manage this self-limited condition.

Premature Ovarian Insufficiency

On average, menopause occurs at the age of 50 years, with 1% of women continuing to menstruate beyond the age of 60 years and another 1% whose menopause occurs before age 40 years. Premature menopause or ovarian insufficiency has been arbitrarily defined as the cessation of menses before 40 years of age.[285]

POI, which is defined as early depletion of ovarian follicles (before the age of 40 years), is a state of hypergonadotropic hypogonadism. These patients go through a normal puberty and a variable period of cyclic menses followed by oligomenorrhea or amenorrhea accompanied by hot flashes and urogenital atrophy. POI should always be included in the differential diagnosis of chronic anovulation. History and physical examination may reveal menstrual irregularity or secondary amenorrhea accompanied by symptoms and signs of estrogen deficiency, such as hot flashes and urogenital atrophy.[286]

The cause or genetic basis of POI is not well understood. Two genetic syndromes associated with POI are gonadal dysgenesis with primarily mosaic X-chromosome defects and *FMR1* gene premutation, a variant of fragile X syndrome.[287] Syndromes resulting from single-gene mutations (e.g., blepharophimosis-ptosis-epicanthus inversus syndrome [*FOXL2* mutation], galactosemia [*GALT* mutation]) may be associated with POI.[287] However, the cause of POI remains unknown in most cases.

The underlying ovarian defect may manifest at various ages, depending on the number of functional follicles left in the ovaries. If loss of follicles occurs rapidly before puberty, primary amenorrhea and lack of secondary sexual development ensue. The degree to which the adult phenotype develops and the age at which secondary amenorrhea actually occurs depend on whether follicle loss took place during or after puberty. In cases of primary amenorrhea associated with sexual infantilism, the ovarian remnants exist as streaks, and transvaginal ultrasonography usually cannot detect any ovaries. Many gene defects (e.g., *FSHR*, *CYP17A1*, *CYP19A1*) involve ovarian failure at the expected time of puberty, and the phenotypes manifest with primary amenorrhea and lack of secondary sexual development (see Chapter 25).[287]

POI can also result from an autoimmune process and may be associated with an autoimmune polyendocrine syndrome.[288] Other causes of premature insufficiency can be related to the sudden destruction of follicles by chemotherapy, irradiation, or infections such as mumps oophoritis. The effect of irradiation depends on the patient's age and the x-ray dose.[289] Steroid levels begin to fall and gonadotropins rise within 2 weeks after irradiation of the ovaries. Younger women exposed to radiation are less likely to have permanent ovarian insufficiency because of the higher number of oocytes present at earlier ages. When the radiation field excludes the pelvis or the ovaries are transposed out of the pelvis by laparoscopic surgery before irradiation, the risk for POI is minimized.[290] Most chemotherapeutic agents used for eradication of malignancies are toxic to the ovaries and cause ovarian insufficiency.[291] Resumption of menses and pregnancy have been reported after radiotherapy or chemotherapy,[292] but POI may occur years after these therapies.[272]

Diagnosis and Management of Premature Ovarian Insufficiency

POI should be suspected in a woman younger than 40 years of age who presents with amenorrhea, oligomenorrhea, or another form of menstrual irregularity accompanied by hot flashes. Menopausal serum FSH levels (40 IU/L) on at least two occasions are sufficient for the diagnosis of POI.

Case reports of pregnancies in affected women occurring during hormone replacement therapy have been published.[293,294] In particular, young women with POI may experience intermittent periods of ovarian function, with antral follicles present at ovarian ultrasonography and ovulation described in cases that followed up with regular endocrine assessments. A randomized trial of hormone therapy in this setting showed that folliculogenesis occurred often but was less frequently followed by ovulation and even less frequently by pregnancy (up to 14%); conventional-dose estrogen therapy did not improve the rate of folliculogenesis, ovulation, or pregnancy.[286] Later pilot studies or case reports suggested that lowering FSH levels to less than 15 IU/L by use of high-dose estrogen or a GnRH antagonist in young women with POI may trigger ovulation or permit ovulation induction and pregnancy in a small number of patients.[295,296]

The clinician should inform patients diagnosed with POI that there is a small but significant likelihood of spontaneous pregnancy or pregnancy after ovulation induction. Women who desire pregnancy are still best served by assisted reproductive technology using donor oocytes, because the probability of pregnancy with an autologous egg is low. Use of donor oocytes followed by IVF with the partner's sperm and intrauterine embryo transfer after synchronization of the recipient patient's endometrium with the donor's cycle using exogenous estrogen and progesterone is offered to the patient who wishes to carry a pregnancy in her uterus (see Fig. 17.23). This approach offers an excellent chance of achieving live birth (>50% per donor oocyte IVF cycle).

Patients with POI have an increased incidence of an abnormal complement of chromosomes.[297] The risk of having an abnormal karyotype increases with decreasing age at onset of the POI. A chromosomal analysis is recommended for the POI patients younger than 30 years of age because of the increased risk of a gonadal tumor associated with the presence of a Y chromosome.[298] It is extremely rare to encounter a gonadal tumor in patients with POI after the age of 30 years.[299]

Mosaicism that includes a Y chromosome has been associated with a high incidence of gonadal tumors.[298] These malignant tumors arise from germ cells and include gonadoblastomas, dysgerminomas, yolk sac tumors, and choriocarcinoma. Secondary virilization in patients with karyotypic abnormalities and POI is associated with a significantly increased risk of a gonadal tumor. The precise risk of a tumor in various subsets of these patients is not well known because a significant number of women carrying a Y chromosome do not have symptoms of virilization. The frequency of Y chromosomal material determined by polymerase chain reaction is high in those with Turner syndrome (12.2%), but the occurrence of a gonadal tumor among these Y-positive patients is about 7% to 10%.[300]

Fragile X–associated disorders are caused by a CGG trinucleotide repeat expansion in the promoter region of the *FMR1* gene. Expansion of the CGG trinucleotide repeats to more than 200 copies induces methylation of the *FMR1* gene, with an outcome of transcriptional silencing.[301] This so-called full mutation was linked to mental retardation or autism. Individuals who carried the premutation (defined as >55 but <200 CGG repeats) have increased *FMR1* mRNA levels with decreased levels of fragile X mental retardation protein (FMRP). Convincing evidence relates the *FMR1* premutation to altered ovarian function and loss of fertility.[302] The natural history of the altered ovarian function in women who carry the *FMR1* premutation is still not well understood. Women with POI are at increased risk for an *FMR1* premutation and should be informed of the availability of fragile X testing.

POI usually occurs as an isolated autoimmune disorder. Rarely, it may be associated with hypothyroidism, diabetes mellitus, hypoadrenalism, hypoparathyroidism, or systemic lupus erythematosus (SLE).[303] It can be part of an autoimmune polyendocrine syndrome.[288] Thyroid insufficiency, adrenal insufficiency, and diabetes mellitus are the endocrine disorders most frequently associated with POI.[304] Periodic endocrine testing for glucose intolerance, adrenal or parathyroid function, and autoimmune disease (e.g., SLE) should be considered based on the clinical presentation (Table 17.6). Because hypothyroidism is more commonly found than other endocrine disorders associated with POI, this author prefers to check a TSH level during the initial evaluation (see Table 17.6).

Treatment of POI should be directed toward its specific cause. In most cases, however, it is not possible to identify a specific cause if there are no karyotypic anomalies. Besides infertility, long-term ovarian steroid deficiency has far-reaching health implications. Early menopause has been associated with increased cardiovascular mortality and stroke, bone fracture, and colorectal cancer risks.[287] Despite reduced risks for development of breast cancer, overall quality of life and life expectancy decline with early menopause.[287] Hormone therapy, using combined estrogen and progestin or a low-dose oral contraceptive, is the cornerstone of the management for these women. The added value of androgen replacement remains uncertain.[287]

Diagnosis and Management of Anovulatory Uterine Bleeding

Acyclic production of estrogen during anovulatory cycles gives rise to irregular shedding of the endometrium. These bleeding manifestations of anovulatory cycles in the absence of uterine pathology or systemic illness are commonly referred to as *dysfunctional uterine bleeding*. Anovulatory uterine bleeding, which is the most common cause of chronic menstrual irregularities, is a diagnosis of exclusion. Pregnancy, uterine leiomyomas, endometrial polyps, and adenomyosis should be ruled out as anatomic causes of irregular or excessive uterine bleeding. Malignancies of the vagina, cervix, endometrium, myometrium, fallopian tubes, and ovaries or coagulation abnormalities should also be ruled out before a diagnosis of anovulatory uterine bleeding is made.

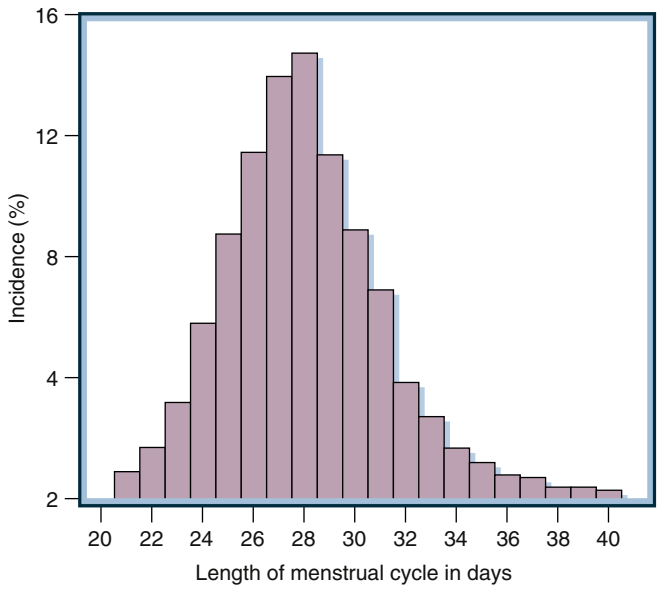
Anovulatory uterine bleeding can be managed without surgical intervention by either restoring ovulation or mimicking the ovulatory hormonal profile by providing exogenous steroids. The rationale for use of exogenous steroids is based on the knowledge of predictable responses of the endometrium to estrogen and progesterone. Physiologic responses of the endometrium to natural ovarian steroids have been uncovered by observation of the gross and microscopic changes occurring in the endometrium during thousands of normal ovulatory cycles in humans and other primates.[119,120,305] The pharmacologic application of exogenous estrogens and progestins in women with anovulatory bleeding aims to correct the production of local tissue factors that mediate physiologic steroid action and reverse the excessive and prolonged flow typical of anovulatory cycles.

Clinical management of irregular uterine bleeding with exogenous hormones is a time-honored method, and it has diagnostic value. Failure to control vaginal bleeding with hormonal therapy, despite appropriate application and use, makes the diagnosis of anovulatory uterine bleeding considerably less likely. In such cases, attention is directed to an anatomic pathologic entity within the reproductive axis as the cause of abnormal bleeding.

Heavy but regular menstrual bleeding (i.e., hypermenorrhea) can be encountered in ovulatory women. It may have an anatomic cause, such as a leiomyoma impinging on the endometrial cavity or the diffuse and pathologic presence of benign endometrial glands in the myometrium (i.e., adenomyosis). In the absence of a specific pathologic cause, it is presumed that hypermenorrhea reflects subtle disturbances in the endometrial tissue mechanism. In essentially all cases, evaluation and treatment are identical to the approach detailed in this section.

Characteristics of Normal Menses

Normal menstruation takes place about 14 days after each ovulation episode as a consequence of postovulatory estrogen-progesterone



• **Fig. 17.33** Variation of the duration of the menstrual cycle in women with regular cycles. (From Cunningham FG, MacDonald PC, Gant NF, et al. The endometrium and decidua: menstruation and pregnancy. In: Cunningham FG, ed. *Williams Obstetrics*. 19th ed. Stamford, CT: Appleton & Lange; 1993:81–109.)

withdrawal. The quantity and duration of bleeding are quite reproducible. This predictability leads many women to expect a certain characteristic flow pattern. Any slight deviations, such as plus or minus 1 day in duration or minor deviation from expected tampon use, are causes for major concern in the patient. Most women of reproductive age can predict the timing of their flows so accurately that even minor variability may require reassurance by the clinician. Although variability of menstrual cycles is a common feature during the teenage years and perimenopausal transition, the characteristics of menstrual bleeding do not undergo appreciable change between ages 20 and 40.[306]

For ovulatory women, the changes in the length of the menstrual cycle over the period of reproductive age are predictable. Between menarche and age 20, the cycle length for most ovulatory women is relatively longer. Between 20 and 40 years, there is increased regularity as cycles shorten. In the 40s, cycles begin to lengthen again. The highest incidence of anovulatory cycles occurs before age 20 and after age 40.[307] In these age groups, the average length of a cycle is between 25 and 28 days. Among ovulatory women, the frequency of a cycle of less than 21 days or more than 35 days is rare (<2%).[308] Overall, most women have cycles that last 24 to 35 days (Fig. 17.33).[306] Between ages 40 and 50, menstrual cycle length increases and anovulation becomes more prevalent.[309]

The average postovulatory bleeding lasts from 4 to 6 days. The normal volume of menstrual blood loss is 30 mL. More than 80 mL is considered abnormal. Most of the blood loss occurs during the first 3 days of a period, so excessive flow may exist without prolongation of flow.[310,311]

During an ovulatory cycle, the duration from ovulation to menses is relatively constant and averages 14 days (see Fig. 17.1A). Greater variability in the length of the proliferative phase, however, produces a distribution in the duration of the menstrual cycle. Menstrual bleeding more often than every 24 days or less often than every 35 days requires evaluation.[306,309] Flow that lasts 7 or more days also requires evaluation. A flow that totals more than 80 mL/month usually leads to anemia and should be treated.[312] In clinical practice, however, it is difficult to quantify menstrual flow because evaluation and treatment are based solely on the patient's perceptions regarding the duration, amount, and timing of her menstrual bleeding. Despite this difficulty in quantifying menstrual blood loss, the clinician should evaluate the cause of excessive uterine bleeding. Anemia should be ruled out by a complete blood cell count.[313] A low hemoglobin value accompanied by microcytic and hypochromic red blood cells suggests excessive blood loss during menses. These patients should be provided with iron supplementation. The likely presence of coagulation defects, uterine leiomyomas, or adenomyosis underlying prolonged menses should be evaluated in anemic patients through a meticulous history and physical examination followed by relevant laboratory tests.

Terminology Describing Abnormal Uterine Bleeding

Oligomenorrhea is defined as intervals between episodes of uterine bleeding longer than 35 days, and the term *polymenorrhea* is used to describe intervals shorter than 24 days. *Hypermenorrhea* refers to regular intervals (24–35 days) but excessive flow or duration of bleeding, or both. An alternative term for hypermenorrhea is *menorrhagia*. *Hypomenorrhea* refers to diminution of the flow or shortening of the duration of regular menses, or both.

Uterine Bleeding in Response to Steroid Hormones

Estrogen Withdrawal Bleeding

Uterine bleeding follows acute cessation of estrogen support to the endometrium. This type of uterine bleeding can occur after bilateral oophorectomy, irradiation of mature follicles, or administration of estrogen to a woman who previously underwent removal of both of her ovaries, followed by discontinuation of therapy. Similarly, the bleeding that occurs after bilateral removal of ovaries can be delayed by concomitant estrogen therapy. Flow occurs on discontinuation of exogenous estrogen. Estrogen withdrawal by itself (in the absence of progesterone) almost invariably causes uterine bleeding.

Estrogen Breakthrough Bleeding

Chronic exposure to various quantities of estrogen stimulates the growth of endometrium continuously in the absence of progesterone, as in the case of excessive extragonadal estrogen production in PCOS. After a certain point, the amount of estrogen produced in extraovarian tissue remains insufficient to maintain structural support for the endometrium. This gives rise to unpredictable episodes of shedding of the surface endometrium. Relatively low doses of estrogen yield intermittent spotting that may be prolonged, but the quantity is light. High levels of estrogen and sustained availability lead to prolonged periods of amenorrhea followed by acute, often profuse episodes of bleeding with excessive loss of blood.

Progesterone Withdrawal Bleeding

Typical progesterone withdrawal bleeding occurs after ovulation in the absence of pregnancy. Removal of the corpus luteum also leads to endometrial desquamation. Pharmacologically, a similar event can be achieved by administration and then discontinuation of progesterone or a synthetic progestin. Progesterone withdrawal

bleeding occurs only if the endometrium is initially primed by endogenous or exogenous estrogen. If estrogen therapy is continued as progesterone is withdrawn, the progesterone withdrawal bleeding still occurs. Only when estrogen levels are increased markedly is progesterone withdrawal bleeding delayed.[314] Progesterone withdrawal bleeding is quite predictable in the presence of previous or concomitant estrogen exposure.

Progestin Breakthrough Bleeding

The pharmacologic phenomenon of breakthrough bleeding occurs in the setting of an unfavorably high ratio of progestin to estrogen. In the absence of sufficient estrogen, continuous progestin therapy leads to intermittent bleeding of variable duration, similar to the low-dose estrogen breakthrough bleeding described previously. This type of bleeding is associated with combination oral contraceptives that contain low-dose estrogen and the long-acting, progestin-only contraceptive methods such as Norplant and Depo-Provera.[315] Progestin breakthrough bleeding is highly unpredictable and is characterized by extensive variability among women.

Causes of Irregular Uterine Bleeding

The most common cause of disruption of a normal menstrual pattern is pregnancy or a complication of pregnancy. Pregnancy and pregnancy-related problems such as ectopic pregnancy or spontaneous miscarriage are extremely common causes of abnormal uterine bleeding (Table 17.7). Pregnancy should be ruled out by a urine test in any woman of reproductive age who presents with irregular bleeding (Table 17.8).

Anovulatory uterine bleeding is a diagnosis of exclusion for several reasons. Vulvar, vaginal, or uterine malignancies or an estrogen-secreting or androgen-secreting ovarian tumor may cause abnormal uterine bleeding (see Table 17.7). Anovulatory uterine bleeding arising from responses of the endometrium to inappropriate production of ovarian steroids has also been called *dysfunctional uterine bleeding* because treatments that restore ovulatory function potentially reverse the irregular bleeding pattern. Common examples of anovulatory bleeding include those associated with exercise-related anovulation, hyperprolactinemia, hypothyroidism, or PCOS.[316] In these cases, restoration of ovulatory menses by correction of the underlying disorder or use of exogenous hormones can achieve predictable uterine bleeding.

Another common cause of irregular uterine bleeding is observed in oral contraceptive users in the form of progestin breakthrough bleeding. Progestin breakthrough bleeding during postmenopausal hormone therapy is also common. Patients may be unknowingly using other hormonal medications with an impact on the endometrium. For example, the use of ginseng, an herbal root, has been associated with estrogenic activity and abnormal bleeding.[317] Although uterine bleeding is a common benign side effect of various long-term hormone treatments, the clinician should always be convinced first that no other pathologic condition is present. Anatomically demonstrable pathologic disorders of the menstrual outflow tract include endometrial hyperplasia and cancer, endometrial polyps, uterine leiomyomas, adenomyosis, and endometritis. Irregular uterine bleeding may be associated with chronic illness, such as renal insufficiency, liver insufficiency, or AIDS. Careful examination may discover genital injury or a foreign object (see Table 17.7).

At puberty, the most common cause of irregular uterine bleeding is anovulation. Approximately 20% of adolescents with excessive

TABLE 17.7 Causes of Irregular Uterine Bleeding

Complications of Pregnancy
- Threatened miscarriage
- Incomplete miscarriage
- Ectopic pregnancy

Anovulation
- Physiologic
  - Uncomplicated pregnancy (amenorrhea)
  - Pubertal (postmenarchal) anovulation
  - Anovulation immediately before menopause
- Medications (e.g., oral contraceptives, GnRH agonists, danazol)
- Hypothalamic (frequently presents as amenorrhea)
  - Functional (e.g., diet, exercise, stress)
  - Anatomic (e.g., tumor, granulomatous disease, infection)
- Hyperprolactinemia, other pituitary disorders
  - Prolactinoma
  - Other pituitary tumors, granulomatous disease
  - Hypothyroidism
  - Medications
  - Other
- Androgen excess
  - PCOS, hyperthecosis
  - Ovarian tumor (e.g., Sertoli-Leydig cell tumor)
  - Nonclassic congenital adrenal hyperplasia
  - Cushing syndrome
  - Glucocorticoid resistance
  - Adrenal tumor (e.g., adenoma, carcinoma)
  - Medications (e.g., testosterone, danazol)
  - Other
- Premature ovarian insufficiency (frequently presents as amenorrhea)
- Chronic illness
  - Liver insufficiency
  - Renal insufficiency
  - AIDS
- Other

Anatomic Defects Affecting the Uterus
- Uterine leiomyomas
- Endometrial polyps
- Adenomyosis (usually manifests as hypermenorrhea)
- Intrauterine adhesions (usually manifests as amenorrhea)
- Endometritis
- Endometrial hyperplasia, cancer
- Chronic estrogen exposure (e.g., PCOS, medication, liver insufficiency)
- Estrogen-secreting ovarian tumor (e.g., granulosa cell tumor)
- Advanced cervical cancer
- Other

Coagulation Defects (Usually Manifest as Hypermenorrhea)
- Von Willebrand disease
- Factor XI deficiency
- Other

Extrauterine Genital Bleeding (May Mimic Uterine Bleeding)
- Vaginitis
- Genital trauma
- Foreign body
- Vaginal neoplasia
- Vulvar neoplasia
- Other

AIDS, Acquired immunodeficiency syndrome; *GnRH*, gonadotropin-releasing hormone; *PCOS*, polycystic ovary syndrome.

TABLE 17.8 Diagnostic Tests to Evaluate Irregular Uterine Bleeding

Commonly Used Tests

Urine hCG test
Serum hCG level (incomplete miscarriage, ectopic pregnancy)
Transvaginal pelvic ultrasonography (intrauterine or ectopic pregnancy, uterine leiomyoma, endometrial polyp or neoplasia, ovarian tumor)
Serum FSH, LH (anovulation; ovarian insufficiency)
Serum prolactin, TSH (anovulation; hyperprolactinemia)
Complete blood count, PT, PTT (evaluation for anemia, coagulation defect)
Liver and renal functions, HIV (anovulation; chronic disease)
Endometrial biopsy (endometrial disease; polyp, neoplasia, endometritis)

Less Commonly Used Tests

Evaluation for PCOS, ovarian or adrenal tumor, nonclassic congenital adrenal hyperplasia, Cushing syndrome, and glucocorticoid resistance (androgen excess)
Head CT or MRI scan (hypothalamic anovulation, hyperprolactinemia)
Pelvic MRI scan (adenomyosis, uterine leiomyoma)
Hysterosonography with intrauterine saline instillation (endometrial polyp, uterine leiomyoma)
Hysteroscopy (endometrial polyp, uterine leiomyoma)
Dilatation and curettage (endometrial disease not diagnosed by ultrasonography or biopsy)

CT, Computed tomography; *FSH,* follicle-stimulating hormone; *hCG,* human chorionic gonadotropin; *HIV,* human immunodeficiency virus; *LH,* luteinizing hormone; *MRI,* magnetic resonance imaging; *PCOS,* polycystic ovary syndrome; *PT,* prothrombin time; *PTT,* partial thromboplastin time; *TSH,* thyroid-stimulating hormone.

irregular uterine bleeding have a coagulation defect.[318,319] Among all women of reproductive age with hypermenorrhea, the prevalence of a coagulation disorder is 17%; von Willebrand disease is the most common defect, and factor XI deficiency is the second most common diagnosis. Bleeding because of a coagulation defect usually consists of a heavy flow with regular, cyclic menses (i.e., hypermenorrhea), and the same pattern can be seen in patients being treated with anticoagulants.[320] Bleeding disorders are usually associated with hypermenorrhea since menarche and a history of bleeding with surgery or trauma. Hypermenorrhea may be the only sign of an inherited bleeding disorder.[321]

Early pregnancy or its complications should always be ruled out first by a sensitive urine hCG measurement in any reproductive-age woman presenting with irregular bleeding. Other tests should be ordered on the basis of the initial clinical evaluation, including tests to evaluate anovulatory disorders of various causes (see Table 17.8). In patients with a history of prolonged heavy menses (i.e., hypermenorrhea) of pubertal origin, coagulation studies (e.g., prothrombin time, partial thromboplastin time, bleeding time) and a complete blood cell count should be obtained.

Pelvic ultrasonography through a vaginal probe is an extremely useful test for the evaluation of normal or abnormal pregnancy, uterine leiomyomas, endometrial neoplasia, and ovarian tumors (see Table 17.8). Other imaging studies may be used judiciously to rule out pathologic involvement of the hypothalamus, pituitary, and adrenal (discussed earlier). Pelvic MRI or ultrasound is used to assess adenomyosis, a uterine disorder characterized by the abnormal presence of diffuse endometrial tissue in the myometrial layer. Advanced adenomyosis is associated with diffuse enlargement of the uterus, hypermenorrhea, and anemia.

Endometrial histologic evaluation should be determined by an endometrial biopsy performed in the physician's office in patients at risk for endometrial hyperplasia or cancer (e.g., PCOS, liver insufficiency, obesity, diabetes mellitus, hormone therapy). A benign endometrial polyp or a uterine leiomyoma protruding into the uterine cavity can be diagnosed by hysterosonography using intrauterine saline installation or by hysteroscopy. Hysterosonography and hysteroscopy are not appropriate tests to evaluate endometrial hyperplasia or cancer because these procedures may cause dissemination of malignant cells. If malignancy is suspected, it should be ruled out by an office endometrial biopsy (see Table 17.8). Occasionally an office endometrial biopsy cannot be performed or is not diagnostic of endometrial neoplasia. In these rare instances, endometrial curettage under anesthesia is performed for a reliable tissue diagnosis.

A careful history and physical examination may eliminate the need for most of these diagnostic tests. Before ordering a certain diagnostic study, it is useful to consider whether a particular test result would alter the ultimate clinical management.

Management of Anovulatory Uterine Bleeding

If ovulatory function can be restored, anovulatory bleeding usually gives way to predictable cyclic periods. Because restoration of ovulatory function may not be possible or practical in many of these women, exogenous estrogen and progestin are administered for several purposes. The indications for hormonal treatment of uterine bleeding include the need to stop acute uterine bleeding, to maintain predictable bleeding episodes, or to prevent endometrial hyperplasia.

Anovulatory uterine bleeding is a diagnosis of exclusion. Various anatomically demonstrable pathologic involvements of the genital tract (see Table 17.7) should be ruled out before administration of estrogen, progestin, or GnRH analogues.

Oral Contraceptives

Use of combination oral contraceptives in an acute or chronic fashion is the most common treatment for irregular uterine bleeding. The estrogen component of the combination pill stabilizes the endometrial tissue and stops shedding within hours; it decreases ovarian secretion of sex steroids by suppression of gonadotropins within several days. The progestin component of the pill directly affects endometrial tissue to decrease shedding over days and potentiates ovarian suppression induced by estrogen. The progestin (in the presence of estrogen) induces differentiation of the endometrial tissue into a stable form called *pseudodecidua*. Typically, a monophasic oral contraceptive preparation that contains 30 or 35 μg of ethinyl estradiol is preferred. Triphasic oral contraceptives and those with less than 30 μg of ethinyl estradiol are not suitable for the treatment of excessive anovulatory uterine bleeding. A combination oral contraceptive in high doses (two or three pills per day) can be used for short intervals (i.e., weeks) to treat an acute episode of excessive uterine bleeding. The usual dose of one pill per day may be administered for years to manage chronic anovulatory bleeding associated with PCOS or hyperprolactinemia.

Oral Contraceptives and Acute Excessive Uterine Bleeding Associated With Anemia

Unopposed estrogen exposure in women with anovulatory uterine bleeding is commonly associated with chronic endometrial buildup and heavy bleeding episodes. Therapy is administered as

one combination oral contraceptive pill twice daily for 1 week. In obese women, the oral contraceptive may be given three times daily. This therapy is maintained despite cessation of flow within 2 days. If flow does not abate, other diagnostic possibilities (e.g., previously missed diagnosis of polyps, incomplete abortion, or neoplasia) should be reevaluated. In case of anovulatory bleeding, the flow does diminish rapidly within 2 days after the beginning of high-dose oral contraceptive treatment (i.e., one pill two or three times daily). Specific causes of anovulation and possible coagulation disorders should be evaluated during the next few days. The physician should also consider whether blood replacement or initiation of iron therapy is necessary. The patient should also be warned of possible nausea that may be caused by high-dose oral contraceptive treatment.

At the end of a week of high-dose oral contraceptive treatment, the pill is stopped temporarily. A heavy flow usually starts within a few days. On the third day of this withdrawal bleeding, a regular dose of combination oral contraceptive medication (one pill/day) is started. This is repeated for several 3-week treatments interrupted by 1-week withdrawal intervals. A decrease in volume with each successive cycle is expected. Oral contraceptives reduce menstrual flow by more than one-half in most women.[322]

Because oral contraceptive use does not treat the underlying cause of anovulation but provides symptomatic relief by directly affecting the endometrium, its cessation results in the return of erratic uterine bleeding. Regardless of the requirement for contraception, use of oral contraceptives represents the best choice for hormonal management of heavy anovulatory bleeding and should be offered as long-term management.

Oral Contraceptives and Chronic Irregular Uterine Bleeding

PCOS is a common form of anovulation associated with chronic steady-state levels of unopposed estrogen that may give rise to endometrial hyperplasia and cancer (discussed earlier). Hypothalamic anovulation and hyperprolactinemia are associated with low estrogen levels that are insufficient to prevent bone loss. A combination oral contraceptive is a suitable long-term treatment for both forms of chronic anovulation.

Before the administration of an oral contraceptive, pregnancy should be ruled out. One pill per day is ordinarily administered for 3-week periods interrupted by 1-week hormone-free intervals. Withdrawal bleeding is expected during the hormone-free interval. The progestin component serves to prevent endometrial hyperplasia associated with steady-state unopposed estrogen exposure in PCOS. In cases of anovulation associated with hypoestrogenism (e.g., hypothalamic anovulation, hyperprolactinemia), the estrogen component of the pill provides sufficient replacement to prevent bone loss. The risk of thromboembolism, stroke, or myocardial infarction associated with long-term administration is extremely low in current nonsmokers and in the absence of a history of thromboembolism. Provided that the oral contraceptive controls the abnormal uterine bleeding effectively, a chronically anovulatory woman can continue this regimen until menopause.

Synthetic Progestins

Synthetic progestins enhance endometrial differentiation and antagonize the proliferative effects of estrogen on the endometrium (see Fig. 17.22).[130,323] The effects of progestins or natural progesterone include limitation of estrogen-induced endometrial growth and prevention of endometrial hyperplasia. The absence of naturally synthesized progesterone in anovulatory states is the rationale for administering a progestin.

The most common indication for long-term cyclic progestin administration is to prevent endometrial malignancy in a patient with PCOS and unopposed chronic estrogen exposure of the endometrium. A combination oral contraceptive is the treatment of choice in these cases. If the patient cannot use an oral contraceptive for some reason (e.g., history of thromboembolism), a progestin may be administered in a cyclic fashion to prevent endometrial hyperplasia. Before the administration of a progestin (or oral contraceptive), pregnancy should be ruled out. In the treatment of oligomenorrhea associated with PCOS, orderly, limited withdrawal bleeding can be accomplished by administration of a progestin such as MPA (5 mg/day) for at least 10 days every 2 months. Alternatively, norethindrone acetate at 5 mg/day or megestrol acetate at 20 mg/day may be administered for 10 days every 2 months. Absence of withdrawal bleeding requires further workup.

In the treatment of excessive uterine bleeding (i.e., hypermenorrhea or polymenorrhea), these progestins at higher daily doses (20 mg/day of MPA, 10 mg/day of norethindrone acetate, or 40 mg/day of megestrol acetate) are prescribed for 2 weeks to induce predecidual stromal changes in the endometrium. A heavy progestin withdrawal flow usually follows within 3 days after the last dose is administered. Thereafter, repeated progestin treatment (5 mg/day of MPA, 5 mg/day of norethindrone acetate, or 20 mg/day of megestrol acetate) is offered cyclically for at least the first 10 days of every other month to ensure therapeutic effect. Failure of progestin to correct irregular bleeding requires diagnostic reevaluation such as endometrial biopsy. Predictable withdrawal bleeding within several days after each cycle of progestin administration suggests the absence of endometrial malignancy.

High-Dose Estrogen for Acute Excessive Uterine Bleeding

An oral contraceptive given two or three times daily is the treatment of choice to stop heavy anovulatory bleeding. A high-dose oral contraceptive regimen should be offered to women with heavy uterine bleeding with or without asymptomatic anemia after anatomically demonstrable pathology of the genital tract has been ruled out (see Table 17.7). A patient with acute and severe anovulatory bleeding accompanied by symptomatic anemia represents a medical emergency. These patients should be hospitalized immediately and offered a blood transfusion. After genital tract disease has been ruled out by history, physical examination, and pelvic ultrasonography, intravenously administered high-dose estrogen is the treatment of choice to stop life-threatening bleeding. A well-established regimen is to administer 25 mg of conjugated estrogen intravenously every 4 hours until bleeding markedly slows down or for at least 24 hours.[324] Estrogen most likely acts on the capillaries to induce clotting.[325] Before intravenous estrogen treatment is discontinued, an oral contraceptive pill is started three times daily. Oral contraceptive treatment is then continued as described previously.

Because high-dose estrogen is a risk factor for thromboembolism, taking two or three oral contraceptive pills per day for a week or large doses of intravenous conjugated equine estrogens for 24 hours should be regarded as presenting a significant risk. However, no data are available to evaluate any risk associated with this type of acute use of hormonal therapy for such short intervals. The physician and patient should make a decision regarding high-dose hormone therapy after considering its risks and benefits. Alternative treatment options may be offered to patients with significant risk factors. Exposure to high doses of estrogen should be avoided in women with a past episode or a strong family history of

idiopathic venous thromboembolism. High-dose hormone treatment should also be avoided in women with severe chronic illness such as liver insufficiency or renal insufficiency. One alternative for these patients is dilatation and curettage, followed by treatment with an oral contraceptive (one pill per day) until the uterine bleeding is under control.

Gonadotropin-Releasing Hormone Analogues for Excessive Anovulatory Uterine Bleeding

A GnRH analogue may be given to women with excessive anovulatory bleeding or hypermenorrhea related to severe chronic illness such as liver insufficiency or coagulation disorders. Monthly depot injections of GnRH agonists are not effective for acute excessive uterine bleeding and may increase uterine bleeding for the first 2 weeks. GnRH antagonists downregulate FSH and LH without a delay and achieve amenorrhea more rapidly. The GnRH agonist leuprolide acetate depot (3.75 mg/month intramuscularly) may be administered for 6 months or longer to control uterine bleeding due to chronic illness. GnRH antagonists can probably be used to halt acute or chronic anovulatory bleeding; however, insufficient published data are available to provide dose recommendations. Long-term side effects of GnRH analogues, including osteoporosis, make this an undesirable choice for long-term therapy. If long-term treatment with GnRH analogues is chosen, norethindrone acetate (2.5 mg daily) should be added back. This add-back regimen is usually sufficient to prevent osteoporosis and does not ordinarily worsen the uterine bleeding.

Hormone-Dependent Benign Gynecologic Disorders

Endometriosis

Endometriosis is defined as the presence of endometrium-like tissue in ectopic sites outside the uterine cavity, primarily on pelvic peritoneum and ovaries, and it is associated with chronic pelvic pain, pain during intercourse, and infertility.[326] This estrogen-dependent inflammatory disease affects 5% to 10% of US women of reproductive age.[326] This classic presentation may represent a common phenotype resulting from diverse anatomic or biochemical aberrations of uterine function. As cellular and molecular mechanisms in endometriosis are uncovered, this condition is coming to be viewed as a systemic and chronic complex disease, much like diabetes mellitus or asthma.[327] Endometriosis may be inherited in a polygenic manner, because its incidence is increased by up to sevenfold in relatives of women with endometriosis.[328]

Pathology

There are three clinically distinct forms of endometriosis: endometriotic implants on the surface of pelvic peritoneum and ovaries (i.e., peritoneal endometriosis); ovarian cysts lined by endometrioid mucosa (i.e., endometriomas); and a complex, solid mass composed of endometriotic tissue blended with adipose and fibromuscular tissue and residing between rectum and vagina (i.e., rectovaginal nodule). These three types of lesions may be variant phenotypes of the same pathologic process, or they may be caused by different mechanisms.[329,330] Their common histologic characteristic is the presence of endometrial stromal or epithelial cells, along with chronic bleeding and inflammatory changes. These lesions may occur singly or in combination and are associated with significantly increased risk of infertility and chronic pelvic pain.[329,330] The inflammatory process in endometriosis may stimulate nerve endings in the pelvis to cause pain, impair the function of the uterine tubes, decrease receptivity of the endometrium, and negatively affect development of the oocyte and embryo. Endometriosis may also cause infertility by physically blocking the tubes. An ovarian endometrioma may decrease the quality of the eggs or become sufficiently large to interfere with the ovulation process.

Clinical evidence points to a deleterious effect of uninterrupted ovulatory cycles on the development and persistence of endometriosis.[327] First, symptoms of endometriosis usually appear after menarche and vanish after menopause. Occasionally, a rectovaginal nodule remains symptomatic in a postmenopausal woman, suggesting that its persistence is independent of ovarian estrogen. Second, multiparity is associated with a decreased risk of endometriosis. Third, disruption of ovulation by GnRH analogues, oral contraceptives, or progestins reduces pelvic disease and associated pain. In line with these observations, basic and clinical research findings indicate major roles of the ovarian steroids estrogen and progesterone in the pathologic development of endometriosis. In humans and primate models, estrogen stimulates the growth of endometriotic tissue, whereas aromatase inhibitors that block estrogen formation and antiprogestins are therapeutic.[327] Levels of nuclear receptors for estrogen and progesterone in endometriotic tissue are strikingly different from those in normal endometrium.[327] Fourth, biologically significant quantities of progesterone and estrogen are produced locally by an abnormally active steroidogenic cascade that includes aromatase.[327]

Mechanism of Disease

A number of hypotheses have been proposed regarding the histologic origin of endometriosis. Sampson suggested that fragments of menstrual endometrium pass retrograde through the tubes and then implant and persist on peritoneal surfaces.[331] This mechanism has been demonstrated in primate models and observed naturally in human disease, and it is supported by the observation that spontaneous endometriosis occurs exclusively in species that menstruate. Alternatively, the coelomic-metaplasia hypothesis describes the genesis of endometriotic lesions within the peritoneal cavity by differentiation of mesothelial cells into endometrium-like tissue. A third hypothesis argues that menstrual tissue from the endometrial cavity reaches other body sites through veins or lymphatic vessels.[327] Finally, it has been proposed that circulating blood cells originating from bone marrow differentiate into endometriotic tissue at various body sites.[332] Sampson's implantation hypothesis offers a plausible mechanism for most endometriotic lesions but does not explain why only some women develop endometriosis. Although most women of reproductive age have reflux menstruation into the peritoneal cavity, endometriosis is encountered in only 5% to 10% of this population.

Two possible mechanisms may explain the successful implantation of refluxed endometrium on the peritoneal surface or in a hemorrhagic corpus luteum cyst of the ovary. First, the eutopic endometrium of women with endometriosis exhibits multiple subtle but significant molecular abnormalities, including activation of oncogenic pathways or biosynthetic cascades favoring increased production of estrogen, cytokines, prostaglandins, and metalloproteinases.[327] When this biologically distinct tissue attaches to mesothelial cells, the magnitude of these abnormalities is amplified dramatically to enhance implant survival.[327] A second mechanism suggests that a defective immune system fails to clear implants off the peritoneal surface.[327] It is possible that both mechanisms may contribute to the same phenotype.

Clear molecular distinctions, such as overproduction of estrogen, prostaglandins, and cytokines, are observed between endometriotic tissue and endometrium (Fig. 17.34).[327] Subtler forms of these abnormalities are also observed in endometrium from a patient with endometriosis compared with endometrium from a disease-free woman. Inflammation is a hallmark of endometriotic tissue that overproduces prostaglandins, metalloproteinases, cytokines, and chemokines.[327] Increased levels of acute inflammatory cytokines such as interleukin 1β (IL1β), IL6, and tumor necrosis factor (TNF) likely enhance adhesion of shed endometrial tissue fragments on peritoneal surfaces, and proteolytic membrane metalloproteinases may further promote their implantation.[327] Monocyte chemoattractant protein 1, IL8, and RANTES (i.e., *r*egulated on *a*ctivation, *n*ormal *T* cell *e*xpressed and *s*ecreted) attract the granulocytes, natural killer cells, and macrophages typically observed in endometriosis.[333] Autoregulatory positive feedback loops ensure further accumulation of these immune cells, cytokines, and chemokines in established lesions.

Basic biologic functions such as inflammation, immune response, angiogenesis, and apoptosis are altered in favor of survival and replenishment of endometriotic tissue.[327] These functions depend in part on estrogen or progesterone action. Excessive formation of estrogen and prostaglandin and development of progesterone resistance have emerged as clinically useful concepts, because targeting of aromatase in the estrogen biosynthetic pathway, cyclooxygenase 2 (COX2) in the prostaglandin pathway, or the PR significantly reduces laparoscopically visible endometriosis and pelvic pain (see Fig. 17.34).[327] These three critical mechanisms have been linked by specific epigenetic (hypomethylation) defects that cause overexpression of the nuclear receptors SF1 and ERβ.[327] The genome-wide unique epigenetic fingerprint in endometriosis suggests DNA methylation is an integral component of the disease and identifies a novel role for the GATA family as key regulators of uterine physiology; aberrant DNA methylation in endometriotic cells correlates with a shift in GATA isoform expression that facilitates progesterone resistance and disease progression.[334]

Diagnosis

A history of severely painful menses during the teenage years, which eventually progressed into chronic pelvic pain experienced both during and between periods, is suggestive of endometriosis. Reliable diagnosis of peritoneal endometriosis can be made only by direct visualization of these lesions by laparoscopy or laparotomy. Ovarian endometriotic cysts filled with a thick, bloody fluid (i.e., endometriomas) can be diagnosed accurately by vaginal ultrasonography.

Treatment

Treatment of infertility caused by endometriosis consists of surgical removal with or without assisted reproductive technology, whereas pain is usually treated with a combination of medical suppression of ovulation and surgery. Peritoneal implants are resected or vaporized by electric current or laser. Ovarian endometriomas and rectovaginal endometriotic nodules may be effectively removed only by full dissection. Epidemiologic and laboratory data suggest a link between ovarian endometriosis and distinct types of ovarian cancers.[327]

Although current hormonal therapy for infertility associated with endometriosis is not of proven value, it is somewhat successful for pelvic pain associated with endometriosis. Various agents used are comparable in terms of efficacy. Most of the current medical treatments were designed to suppress ovulation (e.g., GnRH agonists and antagonists, oral contraceptives, danazol, progestins). A possible alternative mechanism of action of the androgenic steroid danazol or a progestin is a direct growth-suppressive effect on endometriotic tissue.

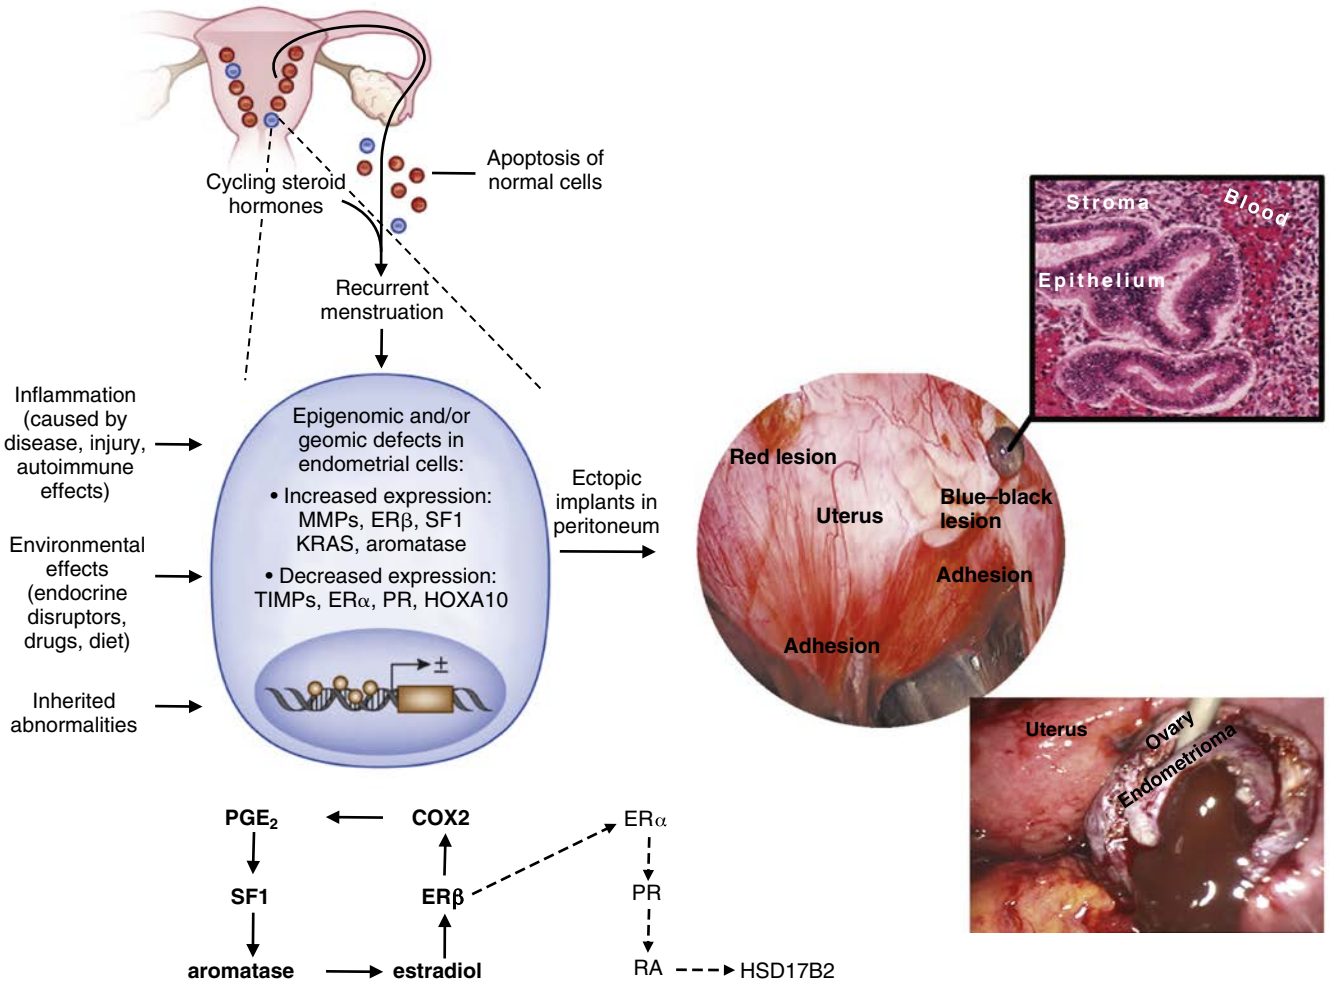
Many patients and physicians do not favor danazol because of its anabolic and androgenic side effects of weight gain and muscle cramps and occasional irreversible virilization (e.g., clitoromegaly, voice changes).[335] Up to 50% of patients with endometriosis fail to complete 6 months of treatment with danazol.[336] The rest of the hormonal agents—oral contraceptives, progestins, and GnRH agonists—show comparable efficacy for control of endometriosis-associated pain.[337–339] A 6-month course using any one of these agents results in a significant reduction of pain in more than 50% of patients.[337–339] Induction of pain relief with a continuously administered oral contraceptive or progestin takes longer than with a GnRH agonist. Recently, an oral GnRH antagonist, elagolix, has been introduced to treat endometriosis-associated pain.[2] Both higher and lower doses of elagolix decreased dysmenorrhea and nonmenstrual pelvic pain and were approved in 2018 for 6-month and 24-month periods, respectively, in women with endometriosis-associated pain. Greater duration is not recommended due to a dose-dependent decrease in bone mineral density. Both doses of elagolix were also associated with other hypoestrogenic adverse effects.[2]

There is a high incidence of recurrence or persistence of the disease and pain after all of these medical therapies.[340] Thus successful medical management of pain requires long-term ovarian suppression for years. Because it is practical to maintain these patients on a combination oral contraceptive for years with a relatively benign side effect profile, birth control pills as a class has been the most suitable long-term management option.[34]

We are still far from the cure of endometriosis, and current treatments are not satisfactory for effective control of pain. The radical treatment is removal of both ovaries, and even this was not found to be effective in a number of cases of postmenopausal endometriosis.[341] New alternative strategies are needed to offer women with endometriosis a reasonable chance to live without suffering from chronic pelvic pain for decades.

There are two important caveats about ovulation suppression–based treatments. First, large quantities of estrogen can be produced locally within the endometriotic cells. This represents an intracrine mechanism of estrogen action, in contrast to ovarian secretion, which is an endocrine means of supplying this steroid to target tissues (see Fig. 17.19).[97,338] Second, estradiol produced in peripheral tissue sites (e.g., adipose tissue, skin fibroblasts) may give rise to pathologically significant circulating levels of estradiol in a subset of women.[97] GnRH agonists do not inhibit peripheral estrogen formation or local estrogen production within the estrogen-responsive lesion. Moreover, endometriosis is resistant to selective effects of progesterone and progestins.[327]

Aromatase inhibitors and selective progesterone response modulators are candidate therapeutic agents for endometriosis refractory to existing treatment options. Aromatase expression and local estrogen biosynthesis in endometriotic implants prompted pilot studies to target aromatase in endometriosis using its third-generation inhibitors. Among these inhibitors, anastrozole and letrozole were used successfully to treat endometriosis in postmenopausal and premenopausal women.[336,342–345] An aromatase inhibitor is the medical treatment of choice for persistent postmenopausal endometriosis. Use of aromatase inhibitors in premenopausal women with endometriosis requires concomitant



• **Fig. 17.34** Molecular mechanisms in endometriosis. Endometriosis is defined as the presence of endometrium-like tissue on the pelvic peritoneum (red and blue-black lesions) or in the ovary (blood-filled cyst, i.e., endometrioma). These lesions are thought to originate from abnormal endometrial tissue stem cells *(blue),* which have migrated retrograde during menstruation. Normal endometrial cells *(red)* without such survival capabilities are thought to go through apoptosis in the peritoneal or ovarian environments. It is possible that women with endometriosis have higher numbers of the abnormal cells in their eutopic endometrial tissues. Thus recurrent menstruation seems to be a significant risk factor for developing endometriosis. These abnormal cells *(blue)* contain genome-wide epigenetic abnormalities, such as DNA methylation, that affect the expression of a wide variety of genes. These epigenetic abnormalities may be inherited or caused by environmental influences such as inflammation and endocrine disruptors. Two nuclear receptors, steroidogenic factor 1 (SF1) and estrogen receptor-β (ERβ), play significant roles in the pathology of endometriosis. In normal endometrial stromal cells, cytosine-phosphate-guanine islands located at the SF1 and ERβ promoters are robustly methylated and silenced. A lack of promoter methylation is associated with promoter activation and the presence of extraordinarily large quantities of these nuclear receptors in endometriotic stromal cells. Prostaglandin E_2 (PGE_2) induces multiple steroidogenic genes, including aromatase, and formation of estradiol from cholesterol. SF1 mediates this steroidogenic action of PGE_2. ERβ suppresses ERα and progesterone receptors (PR). This results in defective retinoic acid *(RA)* production and action, leading to 17β-hydroxysteroid dehydrogenase 2 (HSD17B2) deficiency and failure to metabolize estradiol. ERβ also induces cyclooxygenase 2 (COX2) and formation of PGE_2. Estradiol and PGE_2 are produced in large quantities and enhance cell survival and inflammation in endometriotic tissue. *HOXA10,* homeobox A10; *KRAS,* V-Ki-ras2 Kirsten rat sarcoma viral oncogene homologue; *MMPs,* matrix metalloproteinases; *TIMPs,* tissue inhibitors of metalloproteinases.

ovarian suppression by the addition of a GnRH analogue, progestin, or combination oral contraceptive.

For the medical management of pain in premenopausal women with endometriosis, this author favors the following simple algorithm. Unless contraindicated, the continuous use of a combination oral contraceptive is the initial treatment of choice. The patient is reassured that the majority of women will have minimal or no breakthrough bleeding after 6 months of continuous oral contraceptive treatment. If pain relief is adequate, the patient can remain on this regimen for years. If adequate pain relief is not achieved after 6 months of use, a daily oral aromatase inhibitor (anastrozole 1 mg/day or letrozole 2.5 mg/day) is added to the

continuous oral contraceptive regimen. This combination may be maintained for at least 1 year. If pain relief is still not satisfactory, conservative laparoscopic surgery is considered.

Uterine Leiomyomas

Uterine fibroids (leiomyomas) represent the most common tumor in women.[346] These lesions disrupt the functions of the uterus and cause excessive uterine bleeding, anemia, defective implantation of an embryo, recurrent pregnancy loss, preterm labor, obstruction of labor, pelvic discomfort, and urinary incontinence and may mimic or mask malignant tumors. By the time they reach 50 years of age, nearly 70% of white women and more than 80% of black women will have had at least one fibroid; severe symptoms develop in 15% to 30% of these women. Uterine fibroids in black women are significantly larger at diagnosis than those in white women, are diagnosed at an earlier age, and are characterized by more severe symptoms and a longer period of sustained growth. Approximately 200,000 hysterectomies, 30,000 myomectomies, and thousands of selective uterine-artery embolizations and high-intensity focused ultrasound procedures are performed annually in the United States to remove or destroy uterine fibroids.[346]

Each fibroid seems to originate from the transformation and monoclonal expansion of a single somatic stem cell of the myometrium under the influence of ovarian hormones. Human uterine fibroid tissue contains fewer stem cells than normal myometrium. However, stem cells derived from fibroid tissue—not the myometrium—carry *MED12* mutations, which suggests that at least one genetic hit initially transforms a myometrial stem cell, which subsequently interacts with the surrounding myometrial tissue to give rise to a fibroid tumor.[346] Each fibroid tumor seems to contain a unique driver mutation. *MED12* mutations are found in approximately 70% of the fibroids.[346] Somatic mutations that affect the *HMGA2* gene represent the second most common genetic disruption in a fibroid tumor.[346]

Estrogen stimulates the growth of uterine fibroids through its receptor ERα. The primary roles of estrogen and ERα in fibroid growth are permissive in that they enable tissue to respond to progesterone by inducing the expression of PR, which is essential and sufficient for tumor growth, as indicated by the stimulation of cell proliferation, the accumulation of extracellular matrix, and cellular hypertrophy.[346] Since the stem cell population expresses much lower levels of PR than the population of mature cells but serves as the key source of tissue growth, a paracrine signal originating from PR-rich differentiated cells may mediate the proliferative effects of progesterone on fibroid stem cells.[346]

Diagnosis can be made by abdominal or transvaginal ultrasonography. Transvaginal ultrasonography is a sensitive method for determining the size, number, and location of uterine leiomyomas.

The therapeutic choices depend on the goals of therapy, with hysterectomy most often used for definitive treatment and myomectomy used when preservation of childbearing capability is desired. Intracavitary and submucous leiomyomas can be removed by hysteroscopic resection. Laparoscopic myomectomy is technically possible but involves an increased risk of uterine rupture during pregnancy. The overall recurrence rate after myomectomy varies widely, from 10% to 50%. Other FDA-approved treatment options include selective uterine artery embolization and extracorporeal ablation of uterine fibroids with MRI-guided, high-intensity, focused ultrasound.[347]

Although GnRH agonist–induced hypogonadism can reduce the overall volume of the uterus containing leiomyomas and tumor vascularity, the severe side effects and prompt recurrences make GnRH agonists useful only for short-term goals such as reducing anemia related to uterine bleeding or decreasing tumor vascularity before hysteroscopic resection. Trials have consistently demonstrated that treatment with an antiprogestin such as mifepristone or ulipristal acetate reduces fibroid size.[346] This observation underscores the role of progesterone in the cause of uterine fibroids and opens a new area of therapeutic investigation.[346]

Management of Menopause

Consequences of Menopause

Perimenopause Stage

Menopause is the cessation of ovulatory menses as a result of the irreversible loss of a number of ovarian functions, including ovulation and estrogen production. Perimenopause is a critical period of life during which striking hormonal, somatic, and psychologic alterations occur in the transition to menopause. Perimenopause encompasses the change from ovulatory cycles to cessation of menses and is marked by irregularity of menstrual bleeding.

The most sensitive clinical indication of perimenopause is the progressively increasing occurrence of menstrual irregularities. The menstrual cycle for most ovulatory women lasts 24 to 35 days, and approximately 20% of all reproductive-age women experience irregular cycles.[306] When women are in their 40s, anovulation becomes more prevalent and the menstrual cycle length increases, beginning several years before menopause.[309] The median age at the onset of perimenopause is 47.5 years.[348] Regardless of the age at onset, menopause (i.e., cessation of menses) is consistently preceded by a period of prolonged cycle intervals.[349] Elevated circulating levels of FSH mark this menstrual cycle change before menopause and are accompanied by decreased inhibin levels, normal levels of LH, and slightly elevated levels of estradiol.[350] These changes in serum hormone levels reflect a decreasing ovarian follicular reserve and can be detected most reliably on day 2 or 3 of the menstrual cycle.

Serum estradiol levels do not begin to decline until less than a year before menopause. The average circulating estradiol levels in perimenopausal women are estimated to be somewhat higher than those in younger women because of an increased follicular response to elevated FSH levels.[351] The decline in inhibin production by the follicle, which allows a rise in FSH levels, in the later reproductive years reflects diminishing follicular reserve and competence. Ovarian follicular output of inhibin begins to decrease after 30 years of age, and this decline becomes much more pronounced after age 40. These hormonal changes parallel a sharp decline in fecundity, which starts at age 35.

Perimenopause is a transitional period during which postmenopausal levels of FSH can be observed despite continued menses; LH levels remain in the normal range. Pregnancy is still possible in the perimenopausal woman, because occasional ovulation and functional corpus luteum formation can occur. Until complete cessation of menses is observed or FSH levels higher than 40 IU/L are measured on two separate occasions, some form of contraception should be recommended to prevent unwanted pregnancy.

Perimenopause represents an optimal period in which to evaluate the general health of the mature woman and introduce measures to prepare her for the striking physiologic changes that come with menopause. The patient and her clinician should attempt to achieve several important aims during perimenopause. The long-term goal is to maintain an optimal quality of physical and social

life. Another immediate objective is the detection of any major chronic disorders that occur with aging. The benefits and risks of hormone therapy should be discussed thoroughly at this time.

Menopause Features

The median age at menopause is approximately 51 years.[352] The age at menopause is probably determined in part by genetic factors, because mothers and daughters tend to experience menopause at about the same age.[353–355] Environmental factors may modify the age at menopause. For example, current smoking is associated with an earlier menopause, whereas alcohol consumption delays menopause.[352] Oral contraceptive use does not affect the age at which menopause begins.

The symptoms frequently seen and related to decreased estrogen production in menopause include irregular frequency of menses followed by amenorrhea, vasomotor instability manifested as hot flashes and sweats, urogenital atrophy giving rise to pain during intercourse and a variety of urinary symptoms, and consequences of osteoporosis and CVD. The combination and extent of these symptoms vary widely for each patient. Some patients experience multiple severe symptoms that may be disabling, whereas others have no symptoms or only mild discomfort associated with perimenopause.

Biosynthesis of Estrogen and Other Steroids in the Postmenopausal Woman

No follicular units can be detected histologically in the ovaries after menopause. In reproductive-age women, the granulosa cell of the ovulatory follicle is the major source of inhibin and estradiol. In the absence of these factors that inhibit gonadotropin secretion, FSH and LH levels increase sharply after menopause. These levels peak a few years after menopause and decrease gradually and slightly thereafter.[356] The postmenopausal serum level of either gonadotropin may be more than 100 IU/L. FSH levels are usually higher than LH levels because LH is cleared from the blood much more quickly and possibly because the low levels of inhibin in menopause selectively lead to increased FSH secretion. Nevertheless, increased LH is a major factor that maintains significant quantities of androstenedione and testosterone secretion from the ovary, although the total production rates of both steroids decline after menopause.

The primary steroid products of the postmenopausal ovary are androstenedione and testosterone.[97] The average premenopausal rate of production of androstenedione of 3 mg/day is decreased by one-half to approximately 1.5 mg/day.[97] The decrease primarily results from a substantial reduction in the ovarian contribution to the circulating androstenedione pool. Adrenal secretion accounts for most of the androstenedione production in the postmenopausal woman, with a smaller amount secreted from the ovary.[97] DHEA and DHEAS originate almost exclusively from the adrenal gland and decline steadily with advancing age independent of menopause. The serum levels of DHEA and DHEAS after menopause are about one-fourth of those in young adult women.[357]

Testosterone production is decreased by approximately one-third after menopause.[97] Total testosterone production can be approximated by the sum of ovarian secretion and peripheral formation from androstenedione (see Fig. 17.26). In the premenopausal woman, significant amounts of testosterone are produced by conversion of androstenedione in extraovarian tissues. Because ovarian androstenedione secretion is substantially decreased after menopause, the decrease in postmenopausal testosterone production is accounted for in large measure by a decrease in the relative contribution of extraovarian sources.[97] With the disappearance of follicles and decreased estrogen, the elevated gonadotropins drive the remaining stromal tissue in the ovary to maintain testosterone secretion at levels observed during the premenopausal years. The contribution of the postmenopausal ovary to the total testosterone production is increased in the presence of seemingly unaltered ovarian secretion.

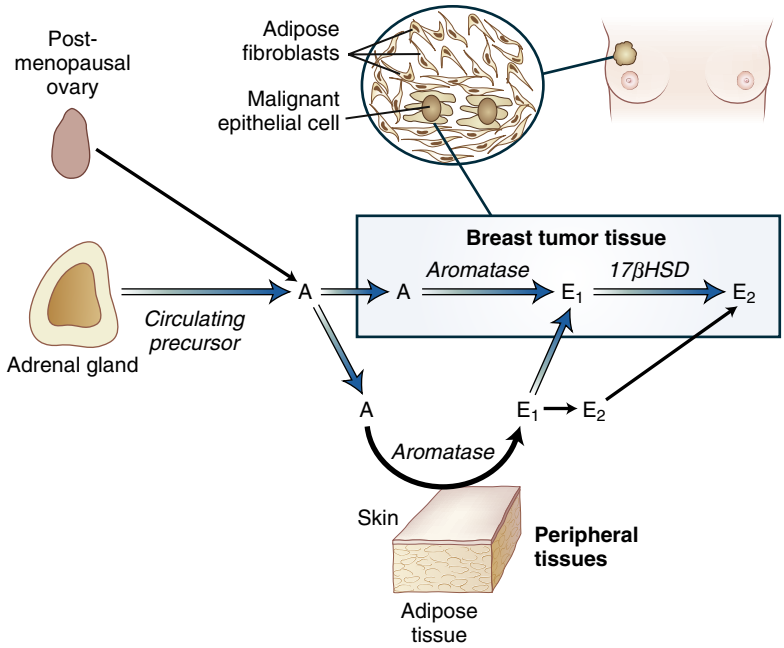
The most dramatic endocrine alteration of perimenopause involves the decline in the circulating level and production rate of estradiol. The average menopausal level of circulating estradiol is less than 20 pg/mL. The estradiol and estrone levels in postmenopausal women are usually slightly less than those in adult men. Circulating estradiol in postmenopausal women (and men) is derived from the peripheral conversion of androstenedione to estrone, which is converted peripherally to estradiol (see Fig. 17.19).[97] The mean circulating level of estrone in postmenopausal women (37 pg/mL) is higher than that of estradiol. The average postmenopausal production rate of estrone is approximately 42 μg every 24 hours. After menopause, almost all estrone and estradiol is derived from the peripheral aromatization of androstenedione. There is a dramatic change in the androgen-to-estrogen ratio because of the sharp decrease in estradiol level and the only slightly reduced testosterone. The frequent onset of mild hirsutism after menopause reflects this striking shift in the hormone ratio. During the postmenopausal years, DHEAS and DHEA levels continue to decline steadily with advancing age, whereas serum androstenedione, testosterone, estrone, and estradiol levels do not change significantly.[356]

The aromatization of androstenedione to estrone in extraovarian tissues correlates positively with weight and advancing age (see Figs. 17.19 and 17.31).[97] Body weight correlates positively with the circulating levels of estrone and estradiol. Because aromatase enzyme activity is present in significant quantities in adipose tissue, increased aromatization of androstenedione in overweight individuals may reflect the increased bulk of tissue containing the enzyme.[97] There is a twofold to fourfold increase in the specific activity of aromatase per cell with advancing age.[97] An increased overall number of adipose fibroblasts with aromatase activity and a decrease in the levels of SHBG increase the free estradiol level and contribute to the increased risk of endometrial cancer in obese women.[97]

In postmenopausal women, estrogen produced from androstenedione peripherally in fat and skin and locally in breast cancer tissue promotes the growth of this malignancy (Fig. 17.35).[97] The clinical relevance of extraovarian estrogen formation is exemplified by the successful use of aromatase inhibitors as the current endocrine treatment for postmenopausal breast cancer.[97]

Postmenopausal Uterine Bleeding

Perimenopausal or postmenopausal bleeding can be caused by hormone administration or excessive extraovarian estrogen formation. Irregular uterine bleeding is commonly observed during the perimenopausal transition as anovulatory cycles alternate with ovulatory cycles. Uterine bleeding after menopause is less common if the patient is not receiving hormone therapy. Obese women are more likely to experience postmenopausal bleeding because of increased peripheral aromatization of adrenal androstenedione. Patients receiving a continuous combination regimen of hormone therapy may experience unpredictable uterine bleeding. The major objective in these circumstances is to rule out endometrial malignancy. This can be best achieved by tissue diagnosis through an office endometrial biopsy using a plastic cannula.



• **Fig. 17.35** Tissue sources of estrogen in postmenopausal breast cancer. The important pathologic roles of extraovarian (peripheral) and local estrogen biosynthesis are shown for an estrogen-dependent disease in postmenopausal women. The estrogen precursor androstenedione (A) originates primarily from the adrenal gland in the postmenopausal woman. Aromatase expression and enzyme activity in extraovarian tissues such as fat increase with advancing age. The aromatase activity in skin and subcutaneous adipose fibroblasts gives rise to formation of systemically available estrone (E_1) and, to a smaller extent, estradiol (E_2). The conversion of circulating A to E_1 in undifferentiated breast adipose fibroblasts compacted around malignant epithelial cells and subsequent conversion of E_1 to E_2 in malignant epithelial cells provide high tissue concentrations of E_2 for tumor growth. The clinical relevance of these findings is exemplified by the successful use of aromatase inhibitors to treat breast cancer in postmenopausal women. *17βHSD,* reductive-type 17β-hydroxysteroid dehydrogenase.

Transvaginal ultrasonographic measurement of endometrial thickness may be used in postmenopausal women to avoid unnecessary biopsies.[135] A biopsy is required if an endometrial thickness of 5 mm or greater is observed.

Unpredictable irregular uterine bleeding is observed in approximately 20% of postmenopausal women receiving a long-term (>1 year) continuous estrogen-progestin combination. Before using ultrasonography and endometrial biopsy to explore the cause of bleeding that is assumed to arise from the intrauterine cavity, the clinician should rule out diseases of the vulva, vagina, and cervix.[135] Careful inspection of these organs along with a normal cervical Papanicolaou (Pap) smear within the past year is sufficient to rule out the vulva, vagina, and cervix as potential sources of bleeding. The causes of postmenopausal uterine bleeding are benign most of the time. Endometrial malignancy is encountered in patients with bleeding in only about 1% to 2% of postmenopausal endometrial biopsies.[358] Approximately three-fourths of endometrial biopsies from postmenopausal women reveal no pathologic change or an atrophic endometrium. Other histologic findings include hyperplasia (15%) and endometrial polyps (3%). Persistent unexplained uterine bleeding requires repeated evaluation, biopsy, hysteroscopy, or dilatation and curettage.

Hot Flashes

The most frequent and striking symptom during perimenopause is the hot flash. It typically occurs during the transition from perimenopause to postmenopause. The hot flash is also a major symptom of postmenopause, and it can occur up to 5 years after menopause.[359] More than four-fifths of postmenopausal women experience hot flashes within 3 months after the cessation of ovarian function, whether natural or surgical in origin. Of these women, more than three-fourths have hot flashes for more than 1 year, and approximately one-half have them for up to 5 years.[359] Hot flashes lessen in frequency and intensity with advancing age, unlike other sequelae of menopause, which progress with time.

A hot flash is a subjective sensation of intense warmth of the upper body, which typically lasts for approximately 4 minutes but may range in duration from 30 seconds to 5 minutes. It can follow a prodrome of palpitations or headache and is frequently accompanied by weakness, faintness, or vertigo. The episode usually ends in profuse sweating and a cold sensation. Hot flashes may occur rarely or recur every few minutes. At night, hot flashes are more frequent and can be severe enough to awaken a woman from sleep. They are also more intense during times of stress. In a cool environment, hot flashes are fewer, less intense, and shorter in duration than in a warm environment.[360]

The hot flash results from a sudden reduction of estrogen levels rather than from hypoestrogenism itself. Regardless of the cause of menopause—natural, surgical, or estrogen withdrawal caused by a GnRH agonist—hot flashes are associated with an acute and significant drop in estrogen level. The consistent association between the onset of flashes and acute estrogen withdrawal is supported by the effectiveness of estrogen therapy and the absence of flashes in prolonged hypoestrogenic states, such as gonadal dysgenesis or hypothalamic amenorrhea. Hypogonadal women experience

hot flashes only after estrogen is administered and withdrawn.[361] Higher body mass index, and body fat in particular, is associated with greater vasomotor symptom reporting, primarily hot flashes.[362]

Other conditions cause symptoms similar to the menopausal hot flash. Sudden episodes of sweating and/or flushing may be caused by catecholamine-secreting or histamine-secreting tumors (e.g., pheochromocytoma, carcinoid), hyperthyroidism, or chronic infection (e.g., tuberculosis). The hot flash may also be psychosomatic in origin. In these circumstances, the clinician should obtain a serum FSH level to confirm perimenopause or menopause before initiating hormone therapy.

Urogenital Atrophy

The urogenital sinus gives rise to development of the lower vagina, vulva, and urethra during embryonic development, and these tissues are estrogen responsive. The decrease in estrogen at menopause causes the vaginal walls to become pale because of diminished vascularity and to thin down to only three or four squamous epithelial cell layers. Loss of this protective mechanism leaves the thin, friable tissue vulnerable to infection and ulceration. The vagina also loses its rugae and becomes shorter and inelastic. Postmenopausal women may complain of symptoms caused by vaginal dryness, such as pain during intercourse, vaginal discharge, burning, itching, or bleeding. Genitourinary atrophy leads to a variety of symptoms that affect the ease and quality of living. Intravaginal estrogen treatment can effectively alleviate these vaginal symptoms in the postmenopausal patient.[363]

Postmenopausal Osteoporosis

Osteoporosis is a disorder characterized by low bone mass and microarchitectural deterioration of bone tissue, leading to enhanced bone fragility and a consequent increase in fracture risk. The World Health Organization criteria for defining and diagnosing osteoporosis in postmenopausal women is the finding of a T-score of –2.5 or lower at the lumbar spine, femur neck, or total hip by bone mineral density (BMD) testing.[364] Osteoporosis is a public health concern that is associated with more than 2 million fractures per year in the United States.[364] The most frequent sites of fracture are the vertebral bodies, distal radius, and femoral neck. Most osteoporotic patients are postmenopausal women.

Osteoporosis in postmenopausal women is a function of advancing age and estrogen deficiency. Seventy-five percent or more of the bone loss in women during the first 15 years after menopause is attributed to estrogen deficiency rather than to aging.[365,366] For the first 20 years after the cessation of ovarian estrogen secretion, postmenopausal osteoporosis accounts for a 50% reduction in trabecular bone and 30% loss of cortical bone.[365,366] Vertebral bone is especially vulnerable because the trabecular portion of the vertebral bodies is metabolically very active and decreases dramatically in amount in response to estrogen deficiency. Vertebral bone mass is already significantly decreased in perimenopausal and early postmenopausal women who have rising FSH and decreasing estrogen levels, whereas bone loss from the radius is not detected until at least 1 year after menopause.[366]

The risk of fracture depends on two factors: the peak bone mass achieved at maturity (at approximately age 30) and the subsequent rate of bone loss. An accelerated rate of bone loss after menopause strongly predicts an increased risk of fracture. The unfavorable effects of low premenopausal bone mass and accelerated loss of bone after menopause are additive, and these individuals are at the highest risk for fracture. An increased rate of average bone loss during menopause is an indicator of lower endogenous estrogen levels, possibly because postmenopausal bone loss is considerably slower in women with increased adipose tissue mass and consequent increased peripheral estrogen formation.[230]

Numerous studies showed that hormone therapy started at perimenopause prevents postmenopausal bone loss.[367] Hormone therapy started at any age in a postmenopausal woman prevents additional bone loss. The Women's Health Initiative (WHI) trial results revealed the most conclusive evidence for a decreased number of vertebral and hip fractures in the group of postmenopausal women receiving estrogen plus progestin (E+P) or estrogen (E) only.[368] The risk reductions were attenuated in both trials after the intervention was stopped; however, a significant hip fracture benefit persisted over 13 years for women assigned to conjugated equine estrogens (CEEs) plus MPA.[368]

Postmenopausal Hormone Therapy

A key and complex decision facing postmenopausal women is whether to use menopausal hormone therapy (HT). HT is the most effective treatment for vasomotor symptoms and may also improve vaginal dryness, sleep, and quality of life.[369] Postmenopausal women who have undergone a hysterectomy ordinarily receive HT with estrogen only (HT-E). A progestin is added to estrogen (HT-EP) in the postmenopausal woman with a uterus to prevent endometrial hyperplasia and cancer. Although either form of HT was originally prescribed primarily to treat vasomotor symptoms, starting from the 1950s, HT-E and later HT-EP had been increasingly viewed as a way to forestall many chronic diseases of aging, including CVD, cognitive impairment, and osteoporotic fractures. Approximately 40% of postmenopausal women in the United States were using HT shortly before the publication of the initial findings from the WHI.[368,370] A number of observational studies had suggested benefits of HT for CVD, including coronary heart disease (CHD) and all-cause mortality, and an overall favorable benefit-risk profile.[371] There had been, however, no large-scale randomized prevention trials to address the balance of risks and benefits of HT. In these observational studies, the apparent benefits of HT may result in part from differences between women who choose to take postmenopausal HT and women who do not; HT users tend to be healthier and have better access to medical care.[372]

Until the late 1990s, the most common practice was to treat all women disturbed by the symptoms of hormone deprivation (e.g., hot flashes) with HT and to use long-term hormonal prophylaxis against osteoporosis. The assumption that HT was cardioprotective played an important role in encouraging postmenopausal women to stay on this regimen indefinitely.[373] This trend changed dramatically in the early 2000s, after publication of the principal results of two large randomized trials, the Heart and Estrogen/Progestin Replacement Study (HERS) in 1998 and the WHI trial in 2002.[374–376] The WHI results constituted the direct cause of discontinuation of HT in approximately 30% of postmenopausal women.[376] Debate continues regarding the applicability of the WHI results to all or various subsets of postmenopausal women.[373] Although the use of HT has dramatically decreased, the WHI trials raised a number of important issues that require further studies to address.[373,377]

The WHI investigators sought to determine the benefits and risks of HT taken for chronic disease prevention in predominantly

healthy postmenopausal women aged 50 to 79 years at enrollment.[368,370] The WHI trials elected to include the most popular HT formulations in the United States at that time, which were CEEs (0.625 mg/day) plus MPA (2.5 mg/day) and CEEs (0.625 mg/day) alone.[368,370] Starting from 2002, a large number of original and review articles came from the WHI trials. A comprehensive integrated overview of findings from the two WHI HT trials with extended postintervention follow-up for a median of 13 years was published.[368] Here the WHI investigators reported the key outcomes and stratified results by age and by time since menopause onset.[368] A discussion of the WHI and other large trials and how they changed HT practices is provided next.

The Long-Term Benefits and Side Effects of Hormone Therapy

Unless there are contraindications, HT should be offered to every menopausal woman suffering from vasomotor symptoms, vulvovaginal atrophy, or dyspareunia. For these indications, HT may be maintained for up to 5 years based on the preference of the woman appropriately informed of the risks and benefits.

Menopause is also associated with increased risks for chronic disorders, including heart disease, osteoporosis, cognitive impairment, or certain malignancies. Previously, hormone therapy was used for the primary prevention of these chronic conditions, but results from the WHI and other randomized clinical trials provided a clearer picture regarding the benefits and risks of HT and have provided insights to improve decision making in HT practices.[368,370,373–376] A number of clinical characteristics are useful in identifying postmenopausal women for whom benefits of HT are likely to outweigh the risks.[368] Age and time since menopause were considered as predictors of risks of HT.[368] The role of age was particularly prominent in the HT-E (estrogen only, for women without uteri) trial.[368] Younger women (50–59 years) taking HT-E had more favorable results for all-cause mortality, myocardial infarction, and the global index but not for stroke and venous thrombosis.[368] The influence of age was less clear for HT-EP (women with intact uteri, taking estrogen/progestin), owing to increased risks of breast cancer, stroke, and venous thrombosis in all age groups. Overall, risks of adverse events were lower in younger than in older women among both HT-E and HT-EP users.[368]

A recent benefit versus harm analysis of 18 recent trials, including the two WHI trials (HT-EP and HT-E), is summarized in Table 17.9, showing intervention-phase findings such as absolute risks per 10,000 women per year, rate differences, and relative risks for a wide range of chronic disease outcomes.[378] HT-E users compared with placebo had significantly lower risks, per 10,000 person-years, for diabetes (–19 cases [95% CI, –34 to –3]) and fractures (–53 cases [95% CI, –69 to –39]). On the other hand, increased risks for HT-E users (per 10,000 person-years) included gallbladder disease (30 more cases [95% CI, 16–48]), stroke (11 more cases [95% CI, 2–23]), venous thromboembolism (11 more cases [95% CI, 3–22]), and urinary incontinence (1261 more cases [95% CI, 880–1689]) (see Table 17.9).[378]

HT-EP users compared with placebo had lower risks, per 10,000 person-years, for colorectal cancer (–6 cases [95% CI, –9 to –1]), diabetes (–14 cases [95% CI, –24 to –3), and fractures (–44 cases [95% CI, –71 to –13).[378] Increased risks for HT-EP users, per 10,000 person-years, included invasive breast cancer (9 more cases [95% CI, 1–19]), probable dementia (22 more cases [95% CI, 4–53]), gallbladder disease (21 more cases [95% CI, 10–34]), stroke (9 more cases [95% CI, 2–19]), urinary incontinence (876 more cases [95% CI, 606–1168]), and venous thromboembolism (21 more cases [95% CI, 12–33]).[378] The authors of this recent meta-analysis and review, including 18 trials (including the WHI trials), stated "the available evidence regarding benefits and harms of early initiation of hormone therapy is inconclusive."[378]

An analysis of WHI results indicated that neither HT modality altered the mortality rate.[368,370] Interestingly, breast cancer findings were divergent between the two trials, and for both cancer and CVD outcomes, results tended to be more adverse for HT-EP than for HT-E.[368,370] There was a clear and sizable benefit for reducing vasomotor symptoms; the results for other quality of life measures, however, varied widely.[368,370]

The age of the woman and time since menopause seemed to be the key modifiers of most of the WHI results.[368,370] In the HT-E trial, younger women 50 to 59 years of age had more favorable results for all-cause mortality, myocardial infarction, colorectal cancer, and the global index.[368] Age, however, did not affect increased risks of stroke, venous thrombosis, gallbladder disease, or urinary incontinence associated with both HT regimens. Among HT-EP users, breast cancer was an additional adverse effect. Although risk of myocardial infarction varied by time since menopause, the overall risks of chronic disease events outweighed benefits across all age groups for HT-EP.[368] In general, variations in hazard ratios by age were more apparent among the HT-E users than in the HT-EP users.[368,370] However, risks of unfavorable outcomes were much lower in younger women than in older women in both HT-E and HT-EP trials. Absolute risks measured by the global index per 10,000 women per year on HT-EP varied from 12 excess cases for ages 50 to 59 years to 38 excess cases for ages 70 to 79 years and, for HT-E, from 19 fewer cases for ages 50 to 59 years to 51 excess cases for the age group 70 to 79 years.[370] Overall, findings from both WHI trials suggest that HT has a harmful effect on CHD risk in older women and those at higher baseline risk of CVD, whereas the results in younger and low-risk women tend to be neutral for HT-EP and in a favorable direction for HT-E.[370] HT use had a negative impact on cognitive function among women older than 65 years, whereas HT effect was neutral for women younger than 55 years of age.[370,379]

Risks and Contraindications of Hormone Therapy

Coronary Heart Disease

Data suggest that initiation of HT many years after menopause is associated with excess CHD risk, whereas HT given for a limited period soon after menopause is not. HT-EP or HT-E does not prevent CHD as was previously proposed. To the contrary, there may be a small but significant increase in the rate of CHD among HT-EP users; these women with preexisting CHD and healthy women are at risk.[368,380] HT-E, on the other hand, does not increase the risk for CHD in healthy women.[368]

Stroke

Another outcome that was consistent across the two WHI trials and HERS is the increased risk of stroke among women assigned to HT-E or HT-EP. Increased stroke risk may be attributable to the estrogen component of the hormone regimen because its increase is statistically significant among both HT-E and HT-EP users.[368,370,380]

Pulmonary Embolism

A pattern of increased pulmonary embolism was observed in all randomized studies, although the risk was attenuated and was not statistically significant in the WHI HT-E trial.[368,370,380]

TABLE 17.9 Absolute Risk Reductions or Increases for Women Treated With Estrogen Alone and With Estrogen Plus Progestin

ESTROGEN ALONE				
Outcome	**No. of Trials**	**Strength of Evidence**	**RR (95% of CI)**	**Absolute Risk Difference, Events per 10,000 Women (95% CI)**
Breast cancer (invasive)	1	Moderate	0.79 (0.61–1.01)	-52 (-97–3)
Colorectal cancer	1	Low	1.15 (0.81–1.63)	16 (-20–73)
Lung cancer	1	Low	1.04 (0.73–1.48)	5 (-30–54)
Coronary heart disease	3	High	0.95 (0.79–1.14)	-20 (-82–55)
Dementia (probable)	1	Low	1.49 (0.84–2.66)	63 (-21–213)
Diabetes	1	Moderate	0.87 (0.77–0.98)	-137 (-242–-21)
Fractures (osteoporotic)	1	High	0.73 (0.65–0.80)	-382 (-495–-283)
Gallbladder disease	1	Moderate	1.63 (1.33–2.00)	213 (111–338)
Stroke	1	Moderate	1.33 (1.06–1.67)	79 (14–160)
Urinary incontinence	1	Moderate	1.53 (1.37–1.71)	1261 (880–1689)
Venous thromboembolism	1	Moderate	1.43 (1.11–1.85)	78 (20–153)
All-cause mortality	3	High	1.01 (0.88–1.17)	6 (-74–96)
ESTROGEN + PROGESTIN				
Outcome	**No. of Trials**	**Strength of Evidence**	**RR (95% of CI)**	**Absolute Risk Difference, Events per 10,000 Women (95% CI)**
Breast cancer (invasive)	1	High	1.27 (1.0–1.56)	52 (6–107)
Cervical cancer	1	Low	1.52 (0.50–4.66)	3 (-3–23)
Colorectal cancer	1	Moderate	0.64 (0.44–0.91)	-33 (-52–-8)
Endometrial cancer	1	Low	0.86 (0.51–1.44)	-5 (-18–6)
Lung cancer	1	Moderate	1.06 (0.77–1.46)	5 (-20–40)
Ovarian cancer	1	Low	1.43 (0.76–2.69)	9 (-5–33)
Coronary heart disease	3	High	1.23 (1.00–1.52)	41 (7–93)
Dementia (probable)	1	Moderate	1.97 (1.16–3.33)	88 (15–213)
Diabetes	1	Moderate	0.84 (0.72–0.97)	-77 (-135–-15)
Fractures (osteoporotic)	5	High	0.80 (0.68–0.94)	-221 (-353–-66)
Gallbladder disease	1	Moderate	1.59 (1.29–1.97)	116 (57–190)
Stroke	1	High	1.39 (1.09–1.77)	53 (12–104)
Urinary incontinence	1	Moderate	1.39 (1.27–1.52)	876 (606–1168)
Venous thromboembolism	1	Moderate	1.95 (1.54–2.47)	120 (68–185)
All-cause mortality	3	Moderate	1.01 (0.88–1.17)	4 (-48–68)

Modified from Gartlehner G, Patel SV, Feltner C, et al. Hormone therapy for the primary prevention of chronic conditions in postmenopausal women: evidence report and systematic review for the us preventive services task force. *JAMA*. 2017;318(22):2234–2249. © 2017 American Medical Association.

Breast Cancer

Findings of the WHI HT-E trial were markedly different from those of the HERS and WHI HT-EP trials with respect to breast cancer risk.[370] The WHI HT-E trial indicated a trend, albeit statistically not significant, toward a lower breast cancer risk during the intervention phase. This protective effect was statistically significant during cumulative (intervention plus postintervention) follow-up (HR 0.79, CI 0.65–0.97).[368] This result was in contrast to findings of an observational literature that mostly reports a moderate increase in risk with estrogen-alone preparations.[381]

However, after control for prior use of postmenopausal HT and additional control for time from menopause to first use of postmenopausal HT, the hazard ratios agreed closely between the observational and randomized trial data.[381] Nonetheless, the higher risk for breast cancer observed in the HT-EP trials probably represents a harmful additional effect of MPA, the progestin used in these studies.[368] The increased breast cancer risk was statistically significant in the WHI HT-EP trial, which demonstrated an attributable risk of 9 cases per 10,000 person-years during the 5.6-year intervention phase.[368] This risk persisted and remained significant during the postintervention phase, giving rise to an overall risk of 9 cases per 10,000 person-years during the 13 years of cumulative follow-up.[368] This result was matched by a trend of the same magnitude in the HERS study and was supported by evidence from large observational studies suggesting that the addition of MPA or another progestin to estrogen may significantly increase the risk for breast cancer (see Table 17.9).[382]

Dementia

In postmenopausal women 65 years of age or older, HT-EP significantly increased risk and resulted in an additional 23 cases of probable dementia per 10,000 women per year.[383] Alzheimer disease was the most common classification of dementia. A similar trend was observed for HT-E but did not reach statistical significance.[383] When the data were pooled, HT significantly increased probable dementia risk.[383]

Hypertriglyceridemia

Worsening of hypertriglyceridemia is a rare side effect of HT, particularly in patients with severe familial hypertriglyceridemia. An oral estrogen regimen can hasten development of severe hypertriglyceridemia in women with previously elevated triglyceride levels, which can precipitate pancreatitis.[384] Estrogen replacement is relatively contraindicated in women with substantially increased triglyceride levels.

Gallbladder Disease

Both WHI trials (HT-E and HT-EP) showed substantially greater risk for any gallbladder disease or surgery with estrogen.[385] Both trials indicated a higher risk for cholecystitis and for cholelithiasis. Women on either HT regimen were more likely to undergo cholecystectomy.[368,370] These data suggest an increase in risk of biliary tract disease among postmenopausal women using estrogen therapy. The morbidity and cost associated with these outcomes may need to be considered in decisions regarding the use of estrogen therapy. Preexisting gallbladder disease is a relative contraindication for estrogen replacement.

Urinary Incontinence

Both HT-E and HT-EP users are at strikingly higher risk for urinary incontinence.[378] The type of incontinence or the underlying mechanisms for this side effect are not well understood. Thus, until these issues are resolved, urinary incontinence should be considered at least a relative contraindication.

Indications for Hormone Therapy

Hot Flashes

HT-E or HT-EP reliably treats hot flashes in most women.[386] Currently, hot flashes constitute the most common indication for a short course of HT (<5 years).

Fractures

HT-EP or HT-E significantly decreased the incidence of hip, vertebral, and other osteoporotic fractures.[368] In this case, the results of observational studies of estrogen and fracture risk and of trials using a surrogate endpoint (i.e., BMD) agree with the results of clinical trials of fracture prevention.[378]

Diabetes

Diabetes was significantly less common with both HT-E and HT-EP users.[368,370,378] Thus diabetes prevention should be considered in menopausal women starting either form of HT.[378]

Post-WHI Recommendations for Hormone Therapy

A number of publications with flow charts are available to clinicians for decision making about HT use.[370] Here, a number of useful principles are offered to guide the clinician and the patient for an optimal plan that suits her short-term and long-term needs and expectations. Decision making for women interested in HT involves balancing the potential benefits of HT against the potential risks.[370,387] HT is extremely effective for treatment of hot flashes, and for this indication women with intact uteri should receive HT-EP, whereas women without uteri should be prescribed HT-E because the only known benefit of adding a progestin is to prevent endometrial cancer. Overall, HT-E seems to be associated with less risk than HT-EP.[386] Nonetheless, HT-E also has adverse effects, and it is prudent to keep the dose low and the duration of treatment short for all HT regimens.[386]

Many clinicians and epidemiologists agree that short-term estrogen therapy using the lowest effective estrogen dose is a reasonable option for recently menopausal women who have moderate to severe symptoms and no previous history or elevated risk of CHD, stroke, breast cancer, or venous thromboembolism.[370,387] HT usually lasts for 2 to 3 years but rarely more than 5 years, because menopausal symptoms diminish after several years, whereas the risk of breast cancer increases with longer duration of HT.[386]

A small group of women may need long-term therapy for severe, persistent symptoms after stopping HT. These few women may be encouraged to first try nonhormonal options such as selective serotonin reuptake inhibitors (SSRIs); estrogen treatment should be resumed only if these alternatives are not helpful.[369,386] For isolated symptoms of genitourinary atrophy, low-dose vaginal estrogen with relatively lesser systemic absorption or endometrial effects is highly beneficial.[387]

In the absence of evidence for an overall net benefit of postmenopausal treatment with HT-E and with the evidence that HT-EP is harmful, neither therapy should be used for preventing CHD or improving mental function.[378]

Target Groups for Hormone Therapy

In women with gonadal dysgenesis and surgical menopause, the duration of estrogen deprivation is prolonged. Estrogen replacement is recommended for these patients for reduction of hot flashes and for long-term prophylaxis against osteoporosis and target organ atrophy. A low-dose contraceptive may be offered to nonsmoking women until the age of 45 years. After that point,

doses of estrogen equivalent to 0.625 mg of conjugated equine estrogens may be more appropriate because of a sharp age-related increase in risk for thromboembolic events. The physician should recommend a continuous or cyclical estrogen-progestin combination to those women with a uterus and an estrogen-only regimen to women without a uterus.

During perimenopause, hot flashes can be suppressed with an estrogen-progestin combination. Because bone loss related to estrogen deprivation also begins during this period, a benefit for women who take HT to prevent hot flashes is that bone loss will not start for the few years of therapy.[388] In perimenopausal women, unexplained uterine bleeding should be evaluated with an endometrial biopsy before the start of HT.

Estrogen Preparations and Beneficial Dose of Estrogen

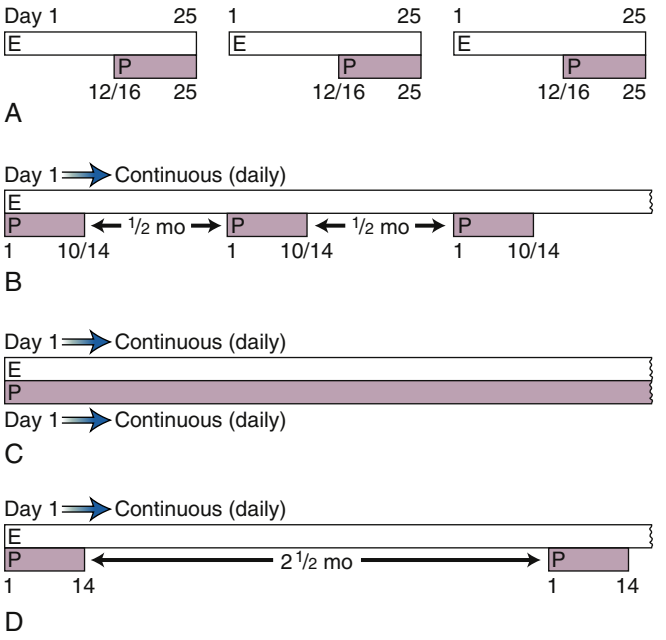
Oral Estrogens: Combined Conjugated Equine Estrogens

The amount of estrogen that provides effective treatment for hot flashes varies. For this purpose, it is reasonable to start with CEEs at 0.3 mg/day (or micronized estradiol at 0.5 mg/day) and gradually increase this dose to CEEs at 0.625 mg/day (equivalent to micronized estradiol at 1 mg/day) and 1.25 mg/day (equivalent to micronized estradiol at 2 mg/day). If hot flashes in a postmenopausal woman are not alleviated by 1.25 mg/day of CEEs or an equivalent transdermal estradiol dose, it is unlikely that higher doses will be effective. In this case, alternative diagnoses (e.g., tuberculosis, depression, thyroid disease) should be ruled out.

Low-dose estrogen (0.3 mg/day of CEEs or 0.5 mg/day of micronized estradiol) maintains blood estradiol levels between 17 and 32 pg/mL (average, 22 pg/mL) and may be sufficient for preserving bone density and for alleviating menopausal symptoms in early postmenopausal women.[389] Osteoporosis and fracture risk should be assessed via periodic dual-energy x-ray absorptiometry (DXA) scans, especially because low-dose estrogen preparations may not prevent bone loss. The effect of estrogen on arterial thrombosis is probably dose related.[389] When choosing a dose for HT, it is imperative to achieve and maintain the lowest beneficial levels of circulating estradiol and to avoid higher levels to minimize the risk of thrombosis.

The addition of a progestin, either cyclically or continuously, to concomitant estrogen replacement reduces the risk of estrogen-induced endometrial hyperplasia or carcinoma but poses additional problems, which include regular withdrawal bleeding in up to 90% of women treated with cyclic therapy and irregular spotting in 20% of women treated with continuous estrogen plus progestin.[390] Progestins appear to reduce the beneficial effects of estrogen on high-density lipoprotein (HDL) and LDL cholesterol and to increase the risks of pulmonary embolism, CHD, and breast cancer.[368,370,380]

A time-honored sequential regimen involves oral administration of 0.625 mg of CEEs or the equivalent dose of a variety of available products on days 1 through 25 of each month (Fig. 17.36). A daily dose of 5 mg of MPA is added on days 12 through 25 or on days 16 through 25. Withdrawal bleeding is expected on or after day 26 of each month. Another common cyclic regimen involves continuous oral administration of 0.625 mg of CEEs or the equivalent daily dose (see Fig. 17.36). A daily dose of 5 mg of MPA is added for the first 10 to 14 days of every month. One-year randomized trial data indicate that the 5-mg dose protects the endometrium as well as the 10-mg dose does.[391] Progestin



• **Fig. 17.36** Regimens of hormone therapy. Estrogen (E) is replaced in a postmenopausal woman to prevent osteoporosis, urogenital atrophy, and hot flashes. In the postmenopausal woman with a uterus, a progestin (P) should be added to estrogen to prevent endometrial hyperplasia and cancer. E and P can be administered in several ways. (A, B) Postmenopausal women receiving hormone therapy have predictable withdrawal bleeding episodes after each P course. (C) E and P are administered together. After a year of continuous combination therapy, the rate of unpredictable breakthrough spotting is 20%. (D) This relatively new regimen was introduced to minimize the harmful effects of a progestin. Its long-term safety for endometrial hyperplasia or cancer risk is unknown. Predictable bleeding after each P course every 3 months is presumed to be reassuring.

withdrawal bleeding occurs in 90% of women with a sequential or cyclic regimen.[392,393] These regimens can also cause adverse symptoms related to the relatively high daily doses of progestin, including breast tenderness, bloating, fluid retention, and depression. The lowest possible dose of a progestin is recommended.

The continuous combined method of treatment has the potential benefit of reduced bleeding and amenorrhea, but it is occasionally complicated by breakthrough bleeding (see Fig. 17.36).[392,393] In this regimen, a combination of 0.625 mg of CEEs and 2.5 mg of MPA is given orally every day. The continuous combination regimen is simple and convenient, and it is associated with an incidence of amenorrhea in 80% of patients after at least 6 months of use. The other 20% of patients continue to experience some degree of unpredictable spotting. Overall compliance is much better in users of the continuous combination regimen. Moreover, the lower daily dose of MPA is associated with a lower incidence of breast tenderness with this regimen. Other estrogen-progestin combinations are also available for similar continuous use.

Cyclic progestin has also been used at less frequent intervals, such as every 3 to 6 months. When added to standard-dosage estrogen, 10 mg of MPA every 3 months for 14 days produced a 1.5% rate of hyperplasia (a rate low enough to be interpreted as endometrial protection), and long-term use of MPA at 6-month intervals was associated with a low rate of endometrial cancer.[394,395] However, clinicians have not determined the optimal progestin dosage and schedule to use with low-dosage estrogen. Low-dosage estrogen use can reasonably be assumed to require less progestin for protection of the endometrium.

Most postmenopausal women can switch their HT regimen from standard-dosage HT to low-dosage estrogen combined with a 15-day MPA treatment at 3-month intervals or start HT at this low dose.[389] Although its long-term safety has not been proven with respect to endometrial hyperplasia, the following regimen appears to be a reasonable compromise for treating hot flashes and preventing osteoporosis while minimizing the harmful effects of progestins and high-dose estrogen[389]: 0.3 mg/day of CEEs or 0.025 mg of transdermal estradiol is administered continuously. Every 3 months, a 14-day course of 5 mg of MPA is added (see Fig. 17.36D). Endometrial biopsy is not required in the presence of withdrawal bleeding after each periodic progestin intake and in the absence of irregular bleeding. This regimen may be continued for up to 5 years. After discontinuation of HT, the postmenopausal woman can be switched to a bisphosphonate or a selective estrogen receptor modulator (SERM) for bone protection if needed.

Transdermal Estrogen

Transdermal estrogen preparations appear to be as effective as oral estrogens for treating hot flashes and maintaining BMD, but they have different metabolic profiles. Oral estrogens seem to have favorable effects on lipoprotein profiles. However, oral estrogens are associated with several disadvantages, including unfavorable changes in serum levels of triglycerides, C-reactive protein, fibrinogen, factor VII, and plasminogen activator inhibitor type 1.[387] A meta-analysis of clinical trials suggested a higher risk of venous thromboembolic events among oral HT users compared with transdermal estrogen users.[387] Clinical trial data that address the effect of transdermal estrogen on CHD and stroke risk are limited.[387]

A daily dose of 0.05 mg of transdermal estradiol is equivalent to 0.625 mg of oral CEEs or 1 mg of oral micronized estradiol. A lower-dose transdermal preparation includes 0.025 mg of estradiol (equivalent to 0.3 mg of oral CEEs). An ultralow-dose transdermal estradiol preparation (0.014 mg) is also available. In women with symptoms not responding to smaller doses, high-dose transdermal estradiol at 0.1 mg/day (equivalent to CEEs at 1.25 mg/day) may be used. For the average menopausal woman with hot flashes, it is reasonable to start with a daily dose of 0.025 mg, which should be accompanied by a progestin in a woman with a uterus.

Vaginal Estrogen

Vaginal estrogen formulations are the first choice for the initial management of menopause-related vaginal atrophy symptoms. Low-dose vaginal tablets, rings, and creams administered via the vagina are equally effective when used for relief of vulvovaginal symptoms. A usual starting dose is 0.625 mg CEEs (in 1 g cream) applied vaginally daily for 1 week; the following maintenance dose is twice weekly. A 12-week study designed to elucidate the lowest effective dose of estradiol cream for relieving vaginal symptoms reported that 100% of women responded to the lowest dose tested (10 μg daily). Circulating estradiol levels remained in the postmenopausal range (3–10 pg/mL, 13.6–36.7 pmol/L) using a highly sensitive assay, and improvements in vaginal cytologic features and decreases in vaginal pH were significant. No endometrial hyperplasia was noted during the course of the study.[396]

Management of Breakthrough Bleeding During Postmenopausal Hormone Therapy

Approximately 90% of women receiving estrogen plus cyclic administration of a progestin have monthly progestin withdrawal bleeding in a predictable fashion. Continuous combined estrogen-progestin therapy causes breakthrough bleeding in approximately 40% of women during the first 6 months, with the remaining 60% being amenorrheic. The pattern of vaginal bleeding in women taking the continuous combined regimen is unpredictable and causes anxiety in most patients, but the incidence of breakthrough bleeding decreases to 20% after 1 year of treatment.[392,393,397] Nevertheless, breakthrough bleeding remains the most important reason for discontinuance of this therapy. A significant number of patients find it unacceptable and prefer to switch to a cyclic progestin regimen or to discontinue HT altogether. There is no effective pharmacologic method to manage the breakthrough bleeding associated with continuous combined estrogen-progestin regimens. The physician can only reassure the patient that the bleeding is likely to subside within 1 year from the start of HT. If breakthrough bleeding continues beyond 1 year, the regimen may be changed to daily estrogen plus cyclic progestin.

HT can be started in the amenorrheic postmenopausal patient at any time. Perimenopausal women with oligomenorrhea, hot flashes, or other associated symptoms can also be treated with HT. In the oligomenorrheic patient, an HT regimen may be initiated on day 3 of one of the infrequent menses. If the candidate for HT does not have irregular uterine bleeding, it is not essential to perform an endometrial biopsy routinely before beginning treatment. Studies indicate that asymptomatic postmenopausal women rarely have endometrial abnormalities.[341,397,398] Pretreatment biopsies using a thin plastic biopsy cannula in the office may be limited to patients who are at higher risk for endometrial hyperplasia (e.g., unpredictable uterine bleeding, history of PCOS or chronic anovulation, obesity, liver disease, diabetes mellitus).

Prescribing a combined estrogen-progestin regimen does not preclude the development of endometrial cancer.[399] Therefore it is necessary to rule out endometrial malignancy in women receiving HT who are experiencing irregular uterine bleeding. The important task is to differentiate breakthrough bleeding from bleeding induced by hyperplasia or cancer. Because breakthrough bleeding is extremely common, many biopsies must be performed to detect a rare case of endometrial abnormality during HT. To decrease the number of endometrial biopsies, a screening method using transvaginal ultrasonography has been introduced.[135] The thickness of the postmenopausal endometrium as measured by transvaginal ultrasonography in postmenopausal women correlates with the presence or absence of pathologic changes.[135] Patients receiving a cyclic or daily combination HT regimen who have an endometrial thickness of less than 5 mm can be managed conservatively.[400–402] An endometrial thickness equal to or greater than 5 mm requires biopsy. Based on this algorithm, it is estimated that 50% to 75% of bleeding patients receiving HT and evaluated by ultrasonography require biopsy.[135]

Management of Menopausal Symptoms in Breast Cancer Survivors

Vasomotor symptoms constitute a major problem for survivors of breast cancer. Approximately 65% of women become symptomatic with hot flashes (mostly severe) after treatment for breast cancer.[403] Hot flashes are encountered more frequently among tamoxifen users and women treated with chemotherapy. Up to 90% of premenopausal women who receive chemotherapy and tamoxifen have vasomotor symptoms.[403]

Breast cancer survivors often seek relief from hot flashes.[404] HT is typically withheld from women with breast cancer because of concerns that estrogen may stimulate recurrence. One randomized

study showed that after extended follow-up, there was a statistically significant increased risk of a new breast cancer event in survivors who took HT.[405] In this randomized, non–placebo-controlled study, 442 women assigned to receive HT-EP/HT-E or best symptomatic management without hormones were followed for a median of 4 years. Thirty-nine of the 221 women in the HT arm and 17 of the 221 women in the control arm had a new breast cancer diagnosed (hazard ratio, 2.4; 95% CI, 1.3–4.2). Cumulative breast cancer incidences at 5 years were 22.2% in the HT arm and 8% in the control arm. No difference in mortality rate from breast cancer was found.[405]

Because of higher breast cancer recurrence associated with HT, many breast cancer survivors have sought nonhormonal alternatives, including other pharmaceutic agents, herbal or dietary remedies, and mind-body or behavioral therapies.[403] Mind-body or behavioral treatments for hot flashes are particularly attractive to survivors of breast cancer because they do not have the side effects caused by pharmaceutic agents, but it is not yet known whether they are effective.[386,403,404]

Several nonhormonal pharmaceutic agents have been used off-label for women who cannot take or elect not to take HT. Among the non-HT treatments, SSRIs, serotonin-norepinephrine reuptake inhibitors (SNRIs), clonidine, and gabapentin were found to be more effective than placebo.[387] Although all of these nonsteroidal medications could reduce the number of hot flashes per day, their beneficial effects were far less than what has been observed with estrogen, and these drugs are all associated with significant side effects that can limit their use in some women. Extracts of black cohosh or red clover were found to be ineffective, and the results for soy isoflavone extracts were mixed.[387] The beneficial doses for hot flashes include paroxetine (an SSRI) at 10 to 20 mg/day, paroxetine controlled release at 12.5 to 25 mg per day, venlafaxine (an SNRI) at 75 mg/day, desvenlafaxine (a SNRI) at 100 mg/day, and gabapentin at 900 mg/day.[386] Gabapentin should be started with a smaller dose given at bedtime, and the dose should be gradually increased. Paroxetine reduces the metabolism of tamoxifen to its most active metabolite, endoxifen, and should be avoided in women with breast cancer who are receiving tamoxifen.[387]

For long-term prophylaxis against osteoporosis in breast cancer survivors, tamoxifen, raloxifene, or a bisphosphonate are viable options. However, tamoxifen and raloxifene intensify hot flashes.[404]

Selective Estrogen Receptor Modulators and Bisphosphonates for Osteoporosis Prevention

Postmenopausal women who are at risk for osteoporosis should be screened at least once for osteoporosis by DXA scan. Based on the initial results and other risk factors, DXA should be repeated periodically, preferably annually or every other year, to monitor the effectiveness of osteoporosis treatment and prevention.[406]

SERMs are compounds that act like estrogen in some target tissues but antagonize estrogenic effects in others (see Chapter 29).[407] One of the first SERMs was tamoxifen, for which estrogen-like agonist activity on bone was observed to occur simultaneously with estrogen antagonist activity on the breast.[407] Tamoxifen had been approved initially for treatment and prevention of breast cancer. An unwanted effect of tamoxifen is its estrogen-like action on the endometrium. Second-generation compounds have since been developed, most notably raloxifene, which has estrogen-like actions on bone, lipids, and the coagulation system; estrogen antagonist effects on the breast; and no detectable action in the endometrium.[408] In 2007 the FDA approved raloxifene for reducing the risk of invasive breast cancer in postmenopausal women with osteoporosis and in postmenopausal women who are at high risk for invasive breast cancer. Raloxifene is most often used to prevent and treat osteoporosis in postmenopausal women.[409]

In placebo-controlled trials, raloxifene reduced vertebral fractures, whereas tamoxifen reduced nonvertebral fractures.[408] Tamoxifen and raloxifene had similar effects on fractures at multiple sites in a randomized, head-to-head trial.[408] Neither drug has been shown to prevent hip fractures, however. Tamoxifen or raloxifene reduced risk for invasive breast cancer compared with placebo by approximately 7 to 10 cases per 1000 women per year.[408] Tamoxifen and raloxifene reduced ER-positive breast cancer but not ER-negative breast cancer, noninvasive breast cancer, or mortality rate.[408] Tamoxifen and raloxifene increase thromboembolic events by 4 to 7 cases per 1000 women per year; raloxifene causes fewer events than tamoxifen. Tamoxifen increases risk for endometrial cancer compared with placebo by 4 cases per 1000 women per year and causes cataracts.[408] Raloxifene use is not associated with endometrial cancer or cataract risk.[408] The most common side effects for tamoxifen are hot flashes and other vasomotor symptoms and vaginal discharge, itching, or dryness. For raloxifene, vasomotor symptoms and leg cramps are most common. In a head-to-head trial, raloxifene users reported more musculoskeletal problems, dyspareunia, and weight gain, whereas tamoxifen users had more gynecologic problems, vasomotor symptoms, and bladder control symptoms.[408] Tamoxifen and raloxifene may be used to reduce the incidence of vertebral fractures and invasive breast cancer in postmenopausal women. The major drawbacks include hot flashes and increased thromboembolic events for both drugs and endometrial cancer for tamoxifen.

SERMs are effective for managing certain aspects of estrogen deficiency in postmenopausal women, but recent data suggest that pairing a SERM with estrogens may provide a more optimal therapeutic profile for women with a uterus. The drug combination bazedoxifene/CEE is a medication approved by the FDA in 2013 for the treatment of menopause symptoms and the prevention of postmenopausal osteoporosis but not for the treatment of osteoporosis.[409] It is a fixed-dose combination drug containing the SERM bazedoxifene and CEE.[410] This new agent demonstrated efficacy in postmenopausal women with a uterus, while allowing these women to avoid progestins and their possible adverse effects.[410]

The major treatment goal in postmenopausal osteoporosis is to prevent fractures by maintaining or increasing BMD and reducing excessive bone turnover.[411] Bisphosphonates suppress resorption by inhibiting the attachment of osteoclasts to bone matrix and enhancing programmed cell death in osteoclasts. They have increased BMD and reduced the risk for osteoporotic fractures in numerous clinical trials.[411] The FDA has approved a number of bisphosphonates for treatment. Oral alendronate and oral risedronate were approved in 1995 and 2000, respectively. In 2003, oral ibandronate was approved, followed by intravenous ibandronate in 2006. Intravenous zoledronic acid was approved in 2007. A 5-mg dose of zoledronic acid is infused over 15 minutes once each year.[409] Alendronate is given as a once-weekly 35-mg or 70-mg tablet or a once-daily 5-mg or 10-mg tablet; risedronate is given as a once-daily 5-mg tablet, a once-weekly 35-mg tablet, or a once-monthly 150-mg tablet; ibandronate is given as a once-monthly 150-mg tablet or as 3 mg intravenously every 3 months.[412]

Compared with placebo control subjects, all approved bisphosphonates reduce the relative risk of new vertebral fractures by on

average 50% in women with postmenopausal osteoporosis.[412,413] Alendronate, risedronate, and zoledronic acid reduce the relative risk of new nonvertebral and hip fractures.[411] Clinical trial extensions of up to 10 years with alendronate and 7 years with risedronate have shown that efficacy is maintained during long-term treatment.[411] Moreover, discontinuation of long-term (≥5 years) alendronate therapy results in minimal bone loss over the ensuing 3 to 5 years.[414] As in the case of SERMs, definitive data are lacking on optimal doses, duration, timing, long-term effects, and effects in nonwhite women. Once-yearly zoledronic acid infusions appear to be an attractive choice because of better compliance and lack of esophagitis, a side effect associated with oral bisphosphonates.[404]

Osteonecrosis of the jaw is a rare but serious side effect of bisphosphonate therapies. Bisphosphonate users who plan to undergo tooth extraction should discuss this side effect with their dental surgeons, because tooth extraction may predispose them to osteonecrosis of the jaw.[415] In premenopausal patients with estrogen-responsive early breast cancer, the addition of zoledronic acid to adjuvant endocrine therapy reduced disease recurrence in all body sites and improved disease-free survival.[416] Further studies are required to explore the potential of bisphosphonates in preventing breast cancer in postmenopausal women with no previous history of breast cancer.

A number of case reports and a recent retrospective study suggested that the risk of esophageal cancer increased with oral bisphosphonate use over about a 5-year period. In Western countries, the incidence of esophageal cancer in patients over the age of 60 is estimated to increase from 1 to 2 per 1000 population with 5 years' use of an oral bisphosphonate.[417,418] Another retrospective study, however, did not find such a link.[419] Until more accurate data are available, health care providers should avoid prescribing oral bisphosphonates to patients with Barrett esophagus, a known risk factor for esophageal cancer.[417]

Tibolone for Osteoporosis Prevention

Tibolone, a synthetic steroid with estrogenic, androgenic, and progestagenic properties, is approved in many countries for the treatment of menopausal symptoms and prevention of osteoporosis. Tibolone preserves BMD, reduces hot flashes, and may increase libido and vaginal lubrication in postmenopausal women.[420] A randomized study showed that tibolone reduced the risks of fracture and breast cancer and possibly colon cancer but increased the risk of stroke in older women with osteoporosis.[420] Tibolone should not be used in breast cancer survivors, as it increases breast cancer recurrence.[404,421] Tibolone is not available in the United States.

Hormonal Contraception

REBECCA H. ALLEN, ANDREW M. KAUNITZ, MARTHA HICKEY, AND ANNABELLE BRENNAN

CHAPTER OUTLINE

KEY POINTS

- Reducing health care system barriers to contraceptive initiation and continuation is important to reduce unintended pregnancy rates. Such barriers include requiring unnecessary health screenings, waiting until menstruation to begin methods, inappropriate contraindications, and failure to provide adequate refills for prescription-based methods. The US Selected Practice Recommendations for Contraceptive Use from the Centers for Disease Control and Prevention offers evidence-based guidelines to assist providers in caring for women who need contraception.
- Long-acting reversible contraceptive methods, which include the copper intrauterine device (IUD), the levonorgestrel IUD, and the etonogestrel subdermal implant, provide superior contraceptive effectiveness, equivalent to sterilization, and higher continuation and satisfaction rates compared with shorter-acting methods. These methods can be offered to all women, including adolescents seeking contraception.
- Emergency contraception should ideally be available to women at risk for unplanned pregnancy. The copper IUD is the most effective emergency contraceptive, followed by oral ulipristal acetate and oral levonorgestrel.
- Besides offering highly effective contraception, the higher-dose levonorgestrel IUD represents a first-line treatment for heavy menstrual bleeding and an effective alternative to endometrial ablation and hysterectomy.
- Pregnancy in women with underlying medical conditions is associated with higher risks of maternal and perinatal morbidity and mortality; therefore, achieving effective preconception and family planning care is particularly important in this setting. Health care providers should consult the US Medical Eligibility Criteria for Contraceptive Use from the Centers for Disease Control and Prevention when caring for these women.

Prevention of unplanned pregnancy continues to challenge women, couples, and clinicians in developed and developing countries. For all couples, access to contraception is critical to be able to plan the timing and spacing of their childbearing for social, economic, and health reasons.[1] Most women in the United States and other developed countries desire to have two children.[2] Therefore, on average, sexually active women devote more than three decades of their lives to avoiding unintended pregnancy. However, nearly half (45%) of all pregnancies in the United States are unintended.[3] Women who use contraception consistently and correctly account for only 5% of unintended pregnancies, but women who use contraception inconsistently or incorrectly account for 41%, and women who do not use any method of contraception account for 54% of unintended pregnancies. Pregnancies that are unintended or too closely spaced can lead to adverse maternal and child health outcomes.[4] In developing countries, childbirth and unsafe abortion are important causes of maternal death and morbidity, and the unintended pregnancy rate is estimated at 65 per 1000 women.[5]

Contraceptive advice and provision should start before the commencement of sexual activity and continue through the reproductive years. Although the incidence is declining, the United States still has one of the highest teenage pregnancy rates in the developed world.[6] Teenage parenting can have adverse consequences for the adolescent, as well as the adolescent's children and family.[7] Programs to prevent unplanned pregnancy by promoting abstinence have largely been ineffective. Nonhormonal contraceptives, such as male condoms, may offer benefits in terms of protection against sexually transmitted infection (STI) but are highly user dependent and do not reliably prevent unplanned pregnancy in many populations. Female hormonal contraception, along with the copper intrauterine device (IUD), represents the most effective and acceptable reversible contraceptive options; male hormonal contraception has not achieved this goal. The ideal contraceptive would be safe, highly effective, discreet, inexpensive, long acting, easily reversible, and under the woman's control. It would not need to be activated at or around the time of intercourse. The

ideal contraceptive would also protect against STIs. Because an ideal contraceptive does not exist, the challenge for clinicians is to tailor available methods to the medical, personal, and social needs of the woman and her partner and changing approaches when necessary as these needs evolve throughout her reproductive life span. The clinician must also learn to recognize and address barriers to safe and effective implementation of the selected methods. Hormonal contraceptives are most effectively used by women who are well informed about the advantages and common side effects of the method, and who have actively participated in selecting the method. Guidance on medical eligibility for contraceptives can be found in two companion documents from the Centers for Disease Control and Prevention (CDC), entitled "U.S. Selected Practice Recommendations for Contraceptive Use, 2016"[8] and "U.S. Medical Eligibility Criteria for Contraceptive Use, 2016."[9]

In addition to enhancing quality of life by allowing couples to choose whether and when they wish to bear children, effective contraception lowers health care costs.[10] Male and female sterilization and long-acting reversible methods (e.g., IUDs, subdermal implants) constitute the most cost-effective contraceptive options, followed by other hormonal methods (e.g., oral contraceptives). Depot medroxyprogesterone acetate (DMPA) injection is more cost effective than oral contraception. Barrier and behavioral methods (i.e., male condom and withdrawal, respectively) are the least cost effective compared with other contraceptive options. Nevertheless, when compared with no method, they still prevent a large number of unintended pregnancies, leading to important cost savings.

Choosing a Contraceptive Method

Given the number of contraceptive options available to women, it is important providers concentrate their efforts on helping women choose the best contraceptive method for them and focus on counseling that helps improve continuation. The best birth control method is one that provides the safest and most effective contraceptive for a woman and is the method she chooses to use and has access to. This approach not only places a strong value on medical considerations but also includes consideration of a woman's preferences, values, and level of prevention desired, as well as the affordability of the method given her access to health insurance or ability to pay. When helping women make sound contraceptive decisions, clinicians should consider the patient's age, lifestyle, and other relevant circumstances, including the recognition that contraceptive needs are likely to change during different phases of reproductive life, and that the risks and benefits may alter according to age and background health factors. For those considering pregnancy in the future, contraceptive reversibility and time to return of fertility should be discussed. Affordability must be considered, because it may affect continuation rates and therefore affect efficacy.

Long-acting reversible contraceptives (i.e., IUDs and the implant) offer women the advantages of high contraceptive efficacy and high rates of continuation. When discussing contraception, clinicians should present all suitable options to their patients but outline the options in terms of tiers of effectiveness (Fig. 18.1). Tier 1 includes long-acting reversible contraception and sterilization. Tier 2 includes combined methods (pill, patch, and ring), DMPA, and the progestin-only pill (POP). Tier 3 includes barrier methods, and tier 4 includes withdrawal and use of spermicides.

As with all medications, contraceptives have potential side effects. Candid discussion of these effects and other areas of anticipatory guidance may increase acceptability. The clinician should offer information about adverse events that are individualized and provided in the context of how they compare with the effects of an unplanned pregnancy. Information about contraceptive failure and access to emergency contraception should be given. For those at risk for STIs, clinicians should encourage consistent condom use and minimizing the number of partners, regardless of contraceptive choice. No method of contraception is perfect. Each woman must consider the advantages and disadvantages of each method in making her decision. The most effective method is likely to be the one that she can use successfully.

Combined Estrogen and Progestin Contraceptives

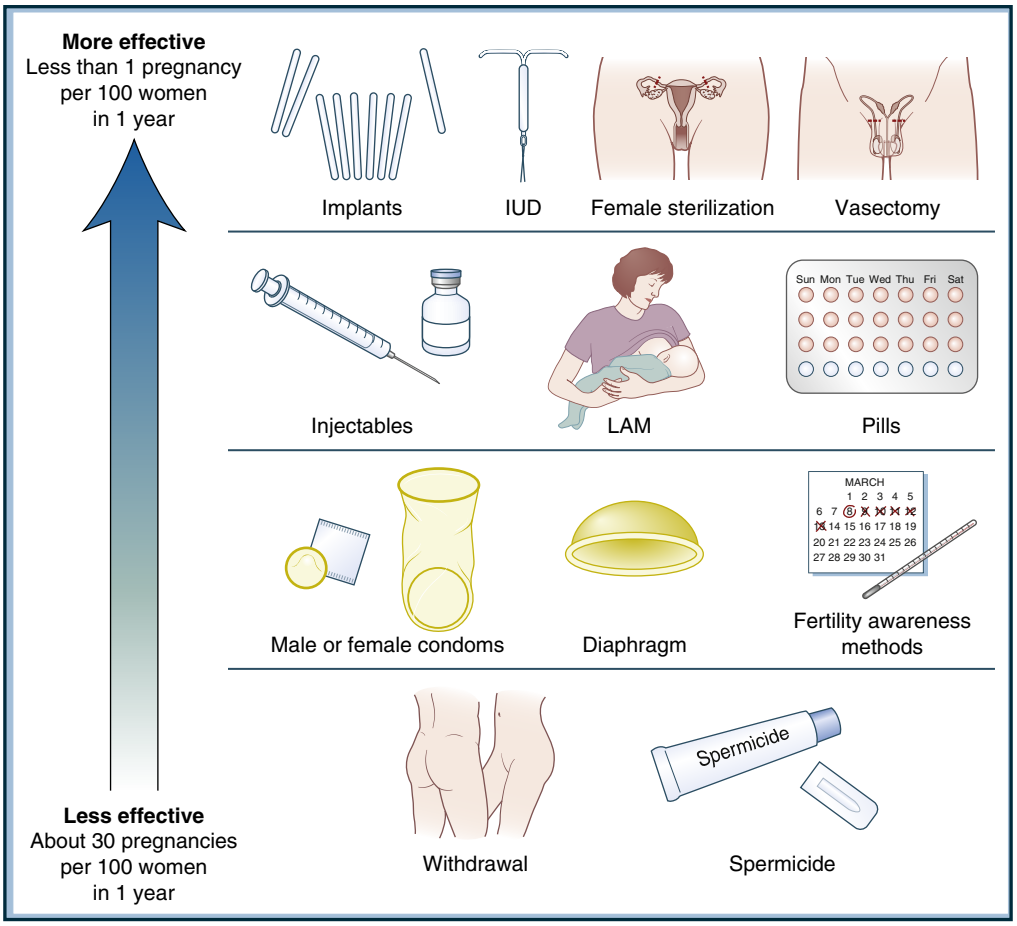
Methods combining estrogen and progestin offer the advantage of relatively regular bleeding patterns and high efficacy if used consistently. These combined methods are available in oral, transdermal, and transvaginal preparations providing increased flexibility in choice of delivery system.

The Combined Oral Contraceptive Pill

Combined oral contraceptives (COCs) offer safe, reversible, and convenient birth control that is highly effective for those who take pills correctly and consistently. In many settings, oral contraception provides important noncontraceptive benefits (mentioned later) that should be discussed during counseling.[11] By individualizing counseling and follow-up strategies based on relevant behavioral and medical considerations, clinicians can help women maximize efficacy of COCs. COCs have been available for more than 50 years and have gradually been refined to improve safety, efficacy, and acceptability. COCs are used by almost 10 million women in the United States, making them the most widely used hormonal contraceptive method.[12] Currently used methods contain estrogen, usually as ethinyl estradiol, at doses of 10 to 35 μg/day and progestins in different forms and doses. This section describes COCs available in the United States, focusing on education, counseling, and management measures to maximize contraceptive efficacy.

Composition and Formulations

Over time, the dose of estrogen and progestin in COCs has gradually decreased, and the types of progestins have changed. Currently, the highest-dose formulations marketed in the United States contain 50 μg of estrogen, but the great majority of COCs prescribed contain 35 μg or less. Most modern COCs formulated with 35 μg of estrogen or less use ethinyl estradiol, which is a potent synthetic estrogen with long half-life and slow metabolism and similar metabolic effects (e.g., liver protein production) regardless of the route of administration (oral, transdermal, or vaginal ring).[13] Estradiol valerate has been marketed as a component of one newer COC, Natazia (Bayer Healthcare Pharmaceuticals, Wayne, NJ). Estradiol valerate is a synthetic hormone extensively metabolized to estradiol and valeric acid before reaching the systemic circulation. A dose of estradiol valerate (2 mg daily) has biologic effects on the uterus, ovary, and hypothalamic-pituitary-ovarian axis similar to those of a 20-μg dose of ethinyl estradiol.[14] A COC formulated with micronized estradiol (1.5 mg) and the progestin nomegestrol acetate has been approved for use in some European countries but is not currently marketed in the United States.[15] Older COC preparations marketed in the United States contain one of five progestins: norethindrone, norethindrone acetate, ethynodiol diacetate, norgestrel, or levonorgestrel. Newer formulations contain more potent progestins: norgestimate, desogestrel, drospirenone, and dienogest.



• **Fig. 18.1** Comparing effectiveness of family planning methods. *IUD,* intrauterine device; *LAM,* lactational amenorrhea method. (Redrawn from World Health Organization Department of Reproductive Health and Research (WHO/RHR) and Johns Hopkins Bloomberg School of Public Health/Center for Communication Programs (CCP), Knowledge for Health Project. Family Planning: A Global Handbook for Providers (2011 update). Baltimore and Geneva: CCP and WHO; 2011.)

Many COC formulations are marketed in the United States (Table 18.1). These products do not appear to be different in terms of safety or efficacy if used correctly.[16] COCs were originally formulated to mimic the normal menstrual cycle by providing 21 days of combined estrogen and progestin, followed by a 7-day hormone-free interval (HFI) when withdrawal bleeding occurred. Although there is no evidence that an HFI provides any health benefits, most modern COCs continue to follow this approach and contain active pills for 21 to 24 days in each 28-day pack; in most formulations, pills containing no active medication are taken during the HFI.[17] Less pituitary-ovarian activity during the HFI is noted in the 24/4 regimen compared with the 21/7 regimen.[18,19] COC formulations with a shorter HFI allow less opportunity for follicle development and possible ovulation; accordingly, such formulations may be more effective.[20] Some women may ovulate if the HFI is extended beyond 7 days.[20,21]

The HFI can be modified (shortened to 4 days) or eliminated to reduce hormone-withdrawal symptoms including pelvic pain, breast tenderness, and mood symptoms, and to improve treatment of problems such as dysmenorrhea, pelvic pain, and anemia. This approach may enhance convenience for some women.[22] A recent meta-analysis showed lower rates of menstrual-related symptoms, including headache, bloating, and pelvic pain with extended-dosing regimens.[17] Extended oral contraceptive formulations are available as packs of 84 pills, followed by 7 days of inert tablets or tablets containing ethinyl estradiol 10 μg in place of the conventional HFI. These formulations offer women only four scheduled withdrawal bleeds per year. In addition, a continuous COC with no HFI is available.

COC regimens also differ with respect to the dose of sex steroid and whether these remains constant throughout the hormonally active pills. Monophasic preparations have a constant dose of estrogen and progestin in each of the 21 or 24 active hormone tablets in each cycle pack. Phasic preparations alter the dose of the progestin and, in some formulations, the estrogen component within the active tablets. There is no evidence phasic preparations are superior to monophasic formulations in terms of efficacy or bleeding patterns.[23-25]

Mechanism of Action, Efficacy, Administration, and Effect on Pregnancy

Estrogen and progestin components of COCs contribute to inhibition of ovulation through suppression of the hypothalamic-pituitary-gonadal axis. Suppression of pituitary release of follicle-stimulating hormone and luteinizing hormone (LH) discourages folliculogenesis and prevents ovulation. Additionally, the exogenous progestin increases cervical mucous viscosity, causes endometrial atrophy, and impairs function of the fallopian tube cilia to prevent fertilization.[16]

TABLE 18.1 Oral Contraceptive Formulations Available in the United States

Description	Name	Estrogen	Progestin	Progestin Dose (mg)

[a]Generic versions available.

[b]Indicated for the treatment of acne in women desiring to use oral contraception.

[c]Indicated for the treatment of premenstrual dysphoric disorder in women desiring to use oral contraception.

[d]Indicated for the treatment of heavy menstrual bleeding in women desiring to use oral contraception.

EE, Ethinyl estradiol; *EV*, estradiol valerate.

Daily use is critical to contraceptive efficacy of COC, so failure rates are largely attributable to poor adherence but may also be influenced by age and frequency of sexual intercourse. The Pearl index is a method of measuring contraceptive effectiveness in clinical trials, with a lower Pearl index representing a lower chance of unintended pregnancy. Failure rates range from less than 1 per 100 woman-years (Pearl index) with excellent adherence to more than 15 pregnancies per 100 woman-years with low adherence. Typical first-year combination oral contraception failure rates are estimated at 7 per 100 women.[26] There does not appear to be any significant difference in contraceptive efficacy of COCs formulated with different progestins.[27]

Traditionally, COCs have been started on the first day of menses, but the pills can be safely started at any time if pregnancy has been excluded (the quick-start method).[8] It is unclear whether this approach reduces unplanned pregnancies occurring while women are waiting until menses to start the pills.[28] If the COCs are inadvertently taken during pregnancy, they do not appear to increase the rate of miscarriage or adversely affect the developing fetus.[29] Of course, use of COCs may delay the diagnosis of an early pregnancy.

The importance of daily administration for contraceptive efficacy must be communicated to patients. Some women link pill taking with a daily ritual (e.g., tooth brushing) or use daily reminders through email or text messaging. Clear instructions for managing missed pills are an essential component of COC counseling. If a woman misses one tablet, she should take the missed pill as soon as possible even if it means taking two pills on the same day. She should then continue to take one tablet daily; no additional contraceptive protection is needed.[8] If she has missed two or more consecutive tablets, she should take the most recent pill and continue taking the remaining pills at the usual time, even if it means taking two pills on the same day. In this instance, she should also use an additional form of contraception (e.g., condoms) for 7 days. If two or more pills are missed in the third week of the 28-day pack, she can omit the HFI in the current pack and start a new pack. Emergency contraception can also be considered in these cases. These instructions also apply to women with vomiting and severe diarrhea while taking COCs. COCs are not suitable for women who consistently miss pills, because this undermines contraceptive efficacy. In these cases, a method that does not require daily adherence (e.g., contraceptive rings; patches; an injectable, intrauterine, or implantable method) should be considered.

After discontinuation of COCs, most women rapidly resume ovulation. In some women, ovulation may be temporarily delayed for several months after discontinuing oral contraception; however, 12-month conception rates are no different in former pill users compared with women who discontinue other contraceptive methods.[30]

Noncontraceptive Health Benefits

Educating women regarding potential noncontraceptive benefits of COC can assist patients in making a prudent contraceptive choice and can increase oral contraception adherence and continuation. For many users, COCs offer substantial noncontraceptive health benefits, including enhanced menstrual regularity; improved pelvic pain; reduced premenstrual symptoms; reduction in benign breast diseases, including fibroadenoma and fibrocystic changes; management of acne; and preservation of bone mineral density (BMD).[11,31] The benefits to bone health are an important consideration in perimenopause for women who have been hypoestrogenic and those with hypothalamic amenorrhea, where accelerated bone loss occurs in addition to the need for contraception.[32] As with most contraceptives, COC use reduces the incidence of ectopic pregnancy, which is a common and potentially life-threatening condition.[33]

Reducing the risk of epithelial ovarian and endometrial cancer is an important noncontraceptive benefit of COC use. Although the incidence is low, ovarian cancer is the most common cause of death from gynecologic malignancy and the fifth most common cause of overall cancer death in women in the United States.[34] Meta-analysis data of cohort and case-control studies demonstrated a reduction in ovarian cancer risk in women who have ever used COC, although 185 women needed to use COC to prevent one ovarian cancer. COC use of more than 10 years appeared to reduce the incidence of ovarian cancer by more than 50%. These results do not appear to be dependent on the dose of sex steroids administered.[35] COCs appear to reduce risk of ovarian cancer in women at increased inherited risk of ovarian cancer through *BRCA1* and *BRCA2* genes.[36-40] However, this benefit must be carefully weighed against the possible increase in breast cancer risk associated with COC use in *BRCA1* and *BRCA2* carriers, which is discussed further in the following.

Endometrial adenocarcinoma is the most common gynecologic cancer in US women, and rising obesity rates put more women at risk. The risk of endometrial adenocarcinoma is reduced with COC use, with several meta-analyses demonstrating reduced risk of more than 50%.[41-43] This protective effect appears to be time dependent, with risk of endometrial cancer reduced by almost 70% with 8 years of COC use and with protection persisting for at least 20 years after oral contraception discontinuation.[43] It is unclear whether the level of protection varies among distinct COC formulations.

Around 6% of reproductive-age women meet diagnostic criteria for polycystic ovary syndrome (PCOS), and prevalence is likely to be higher in women considering COC use due to clinical features such as irregular menstruation and hyperandrogenism.[44] Use of COC leads to more regular vaginal bleeding patterns, prevents endometrial hyperplasia, and may reduce clinical and biochemical hyperandrogenism in PCOS women.[45] The impact of COC on carbohydrate metabolism and cardiovascular risk in this population is unclear.

Side Effects

Contrary to popular perception, randomized, placebo-controlled trials have not shown COCs to cause weight gain, nausea, breast tenderness, or mood changes.[46,47] Consequently, COCs are well tolerated by most users. Nevertheless, some individuals report side effects they attribute to COCs that may affect quality of life, contraceptive continuation, and patient satisfaction. Therefore, counseling about side effects or lack thereof is an important aspect of contraceptive care and may improve patient tolerance and adherence to COCs when they occur.[48]

Unscheduled vaginal bleeding is a common side effect attributable to COC. Unscheduled bleeding affects 30% to 50% of COC users during the initial 3 months of use, but the incidence declines with ongoing use. Unscheduled bleeding is more common with lower-dose (20 μg) than standard-dose (30 or 35 μg) ethinyl estradiol preparations, which increases discontinuation rates.[49] The influence of progestin type is unclear. In addition, unscheduled bleeding is more common in women using extended COC formulations in early cycles, but this bleeding will lessen over time. If unscheduled bleeding during extended COC use is bothersome, women may opt to stop active tablets for 3 days, thereby inducing

withdrawal bleeding, and then continue with active pills. This strategy has been shown to reduce subsequent unscheduled bleeding in this setting.[50]

Irregular bleeding may be a manifestation of pregnancy or disease such as cervical or endometrial infection, polyps, or neoplasia. Persistent or new-onset bleeding should therefore be investigated. Amenorrhea (absence of withdrawal bleeding) may occur with long-term COC use, and it may be more acceptable with counseling that provides appropriate reassurance.[48] Women who experience absence of withdrawal bleeding or who for other reasons suspect that they could be pregnant should use a urine pregnancy test.

Headaches are common, but there is a lack of high-quality evidence that COC use contributes to headaches.[51] Some users may experience headaches in early cycles, which tend to improve with ongoing use. Furthermore, estrogen withdrawal headaches that occur during the HFI may respond to a shorter duration HFI of 3 days.[52,53] Any new-onset or worsening headache with COC use must be evaluated. A history of migraine with aura is a contraindication for use of COC because of increased risk of stroke (described in the following).[54] COC use in women with a history of migraine without aura should be avoided in women with other risk factors for stroke.[52] Similarly, any COC users who experience increased frequency or intensity of any type of migraine headache should discontinue estrogen-containing contraceptives.

Health Risks

Extensive studies in large populations have established the risks and benefits of COCs for most women.[55] For the majority of women, use of COCs represents a safe contraceptive choice. However, clinicians should be aware of circumstances in which COC may pose health risks. The US Medical Eligibility Criteria for Contraceptive Use (USMEC), most recently updated in 2016,[9] were adapted from the World Health Organization (WHO) document *Medical Eligibility Criteria for Contraceptive Use*, 5th edition (Tables 18.2 and 18.3).[55a] The guidelines provide evidence-based advice on eligibility for use of hormonal contraceptives. Although the WHO document covered many conditions, such as postpartum status, breastfeeding, smoking, obesity, cardiovascular disease, diabetes, and cancer, the USMEC added new categories: endometrial hyperplasia, rheumatoid arthritis, solid organ transplantation, inflammatory bowel disease, bariatric surgery, and peripartum cardiomyopathy. The USMEC assists providers in deciding what contraceptive methods are appropriate for their patients to improve access to contraception, especially among women with medical problems for which providers may have been hesitant to prescribe contraception in the past.[9]

The safety of contraception in the USMEC is considered in four categories:

1. Conditions with no restriction on the use of the contraceptive method.
2. Conditions in which the advantages of the method usually outweigh the theoretical or proven risks. The method can generally be used, but careful follow-up may be required.
3. Conditions in which the theoretical or proven risks usually outweigh the advantages; examples of estrogen-containing methods include current gallbladder disease, diabetes with end-organ damage, controlled hypertension, and taking medications that may interfere with COC efficacy. The method is generally not recommended unless other more appropriate methods are not available or acceptable.
4. Conditions that present an unacceptable health risk if the contraceptive method is used; examples of estrogen-containing methods include delivery during the past 21 days, a personal history of deep venous thrombosis or pulmonary embolism, ischemic heart disease, stroke, known thrombogenic mutations, and migraine headaches with aura or other neurologic signs.

TABLE 18.2 US Medical Eligibility Criteria (USMEC) for Contraceptive Use Categories for the Use of Estrogen-Containing Contraception According to Medical Condition

Condition	USMEC
Smoking age ≥35 years	
<15 cigarettes/day	Risks outweigh benefits
≥15 cigarettes/day	Unacceptable risk
Obesity (body mass index ≥30)	Benefits outweigh risks
Hypertension	
Controlled hypertension	Risks outweigh benefits
Elevated blood pressure	
Systolic 140–159 mm Hg or diastolic 90–99 mm Hg	Risks outweigh benefits
Systolic ≥160 mm Hg or diastolic ≥100 mm Hg	Unacceptable risk
Vascular disease	Unacceptable risk
Diabetes	
No vascular disease	Benefits outweigh risks
Vascular disease or >20 years' duration	Either risks outweigh benefits or unacceptable risk (based on severity of condition)
Stroke	Unacceptable risk
Current or history of ischemic heart disease	Unacceptable risk
Multiple risk factors for cardiovascular disease (older age, smoking, obesity, diabetes, hypertension)	Either risks outweigh benefits or unacceptable risk (based on severity of condition)
Breast cancer	
Current	Unacceptable risk
Past and no evidence of disease for 5 years	Risks outweigh benefits
Migraines	
Without aura	Benefits outweigh risks
With aura	Unacceptable risk

Thromboembolic Disease

The established increased risk of venous thromboembolism (VTE) is related to the estrogenic component, and although modern low-dose preparations (≤35 μg) carry a lower risk than the original oral contraceptives, the incidence of VTE is still increased.[56] COC use increases risk of VTE by more than twofold, with an incidence of approximately 9 to 10 per 10,000 women per treatment year[57]

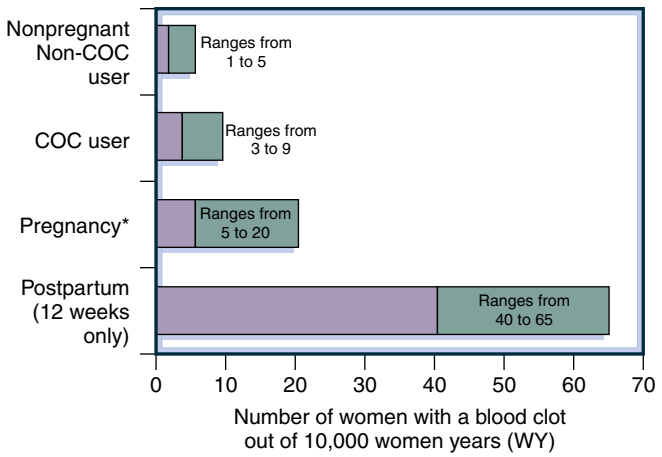
TABLE 18.3 US Medical Eligibility Criteria for Contraceptive Use Categories for the Use of Progestin-Only Methods of Contraception According to Medical Condition

Condition	POP	DMPA	Implant	Levonorgestrel IUD
Smoking age ≥35 years	No restriction	No restriction	No restriction	No restriction
Obesity ≥30 BMI	No restriction	No restriction	No restriction	No restriction
Menarche to age 18 years and ≥30 BMI	No restriction	Benefits outweigh risks	No restriction	No restriction
Hypertension				
Controlled hypertension	No restriction	Benefits outweigh risks	No restriction	No restriction
Elevated BP				
Systolic 140–159 mm Hg or diastolic 90–99 mm Hg	No restriction	Benefits outweigh risks	No restriction	No restriction
Systolic ≥160 mm Hg or diastolic ≥100 mm Hg	Benefits outweigh risks	Risks outweigh benefits	Benefits outweigh risks	Benefits outweigh risks
Vascular disease	Benefits outweigh risks	Risks outweigh benefits	Benefits outweigh risks	Benefits outweigh risks
Diabetes				
No vascular disease	Benefits outweigh risks	Benefits outweigh risks	Benefits outweigh risks	Benefits outweigh risks
Vascular disease or >20 years' duration	Benefits outweigh risks	Risks outweigh benefits	Benefits outweigh risks	Benefits outweigh risks
Stroke	I: Benefits outweigh risks C: Risks outweigh benefits	Risks outweigh benefits	I: Benefits outweigh risks C: Risks outweigh benefits	Benefits outweigh risks
Current or history of ischemic heart disease	I: Benefits outweigh risks C: Risks outweigh benefits	Risks outweigh benefits	I: Benefits outweigh risks C: Risks outweigh benefits	I: Benefits outweigh risks C: Risks outweigh benefits
Multiple risk factors for cardiovascular disease (older age, smoking, obesity, diabetes, hypertension)	Benefits outweigh risks	Risks outweigh benefits	Benefits outweigh risks	Benefits outweigh risks
Breast cancer				
Current	Contraindicated	Contraindicated	Contraindicated	Contraindicated
Past and no evidence of disease for 5 years	Risks outweigh benefits	Risks outweigh benefits	Risks outweigh benefits	Risks outweigh benefits
Migraines				
Without aura	No restrictions	No restrictions	No restrictions	No restrictions
With aura	No restrictions	No restrictions	No restrictions	No restrictions

BMI, Body mass index; *BP*, blood pressure; *C*, continuation; *DMPA*, depot medroxyprogesterone acetate; *I*, initiation; *IUD*, intrauterine device; *POP*, progestin-only pill.

(Fig. 18.2). Comparatively, in otherwise healthy reproductive-age women, the risk of VTE ranges from 1 to 5 per 10,000 women per year, whereas VTE risk in pregnancy is almost 29 per 10,000 women per year and even higher in the postpartum period.[58] Other risk factors for VTE include, but are not limited to, age, obesity, smoking, and thrombogenic mutations.[59-61] The best-quality prospective epidemiologic studies have not shown any increased risk of VTE with newer progestins (desogestrel and drospirenone) and the vaginal ring (etonogestrel) compared with older progestins (levonorgestrel and norethindrone).[62-65] These prospective cohort studies addressed important baseline confounders, including age, family history, and body mass index (BMI); categorized contraceptives users by duration of use; maintained regular contact with users; and individually validated each diagnosis of VTE.[66-68] Because COCs containing estradiol valerate are relatively new, there is limited data on their effects on risk of VTE.

National guidelines contraindicate COC use in those at increased risk for VTE, including those with a personal history of VTE, women immediately after delivery, women undergoing surgery with prolonged immobilization, and those with known inherited thrombophilic conditions.[9] In the context of inherited thrombophilias, clinicians need to consider VTE risk based on the type of thrombophilia present and its association with other risk factors, such as coexistence of multiple thrombophilias, obesity, age, and any VTE events during prior periods of hormonal exposure, such as pregnancy and estrogen-containing contraceptives.[69] Routine screening of the general population for familial thrombophilic markers is not recommended before initiating COC use.[9]



• **Fig. 18.2** Venous thromboembolism risk among women of reproductive age by various conditions. Pregnancy data based on actual duration of pregnancy in the reference studies. Based on a model assumption that pregnancy duration is 9 months, the rate is 7 to 27 per 10,000 women-years. *COC,* combined oral contraceptives. (From U.S. Food and Drug Administration. FDA Drug Safety Communication: Updated information about the risk of blood clots in women taking birth control pills containing drospirenone. Available at https://www.fda.gov/drugs/drug-safety-and-availability/fda-drug-safety-communication-updated-information-about-risk-blood-clots-women-taking-birth-control.)

Myocardial Infarction and Thrombotic Stroke

Although arterial events are substantially less common than VTE in reproductive-age women, the sequelae of strokes and myocardial infarctions are more devastating than those of VTE. The risk of arterial thrombosis including myocardial infarction and stroke is increased with COC use. The risk is estrogen dose dependent, with a 1.6-fold increase in thromboses with estrogen doses of 20 μg and up to a 2.4-fold increase in risk with estrogen doses greater than 50 μg; risk appears to be unrelated to progestin type.[70,71] This effect is estimated to account for 19 thrombotic strokes and seven myocardial infarctions per 100,000 women per treatment year.[71] Risk of arterial thrombosis does not appear to be increased with past COC use.[72]

The absolute risk of myocardial infarction and stroke increases with age. Therefore, COC should be avoided in women older than 35 years with risk factors for myocardial infarction or stroke, including smoking, hypertension, long-standing diabetes, and migraine headache with aura.[9]

Breast Cancer

Findings that exogenous estrogen-progestin combination hormone therapy increases breast cancer risk in postmenopausal women raises concerns that COCs may increase breast cancer risk in premenopausal women. Recent findings from a large national registry in Denmark including approximately 1.8 million women 15 to 49 years of age over a period of almost 11 years reported a modest increased relative risk of invasive breast cancer in current hormonal contraception users (most of which were COC users) of 1.20 (95% confidence interval [CI], 1.14–1.26) compared with never users.[73] The absolute increased risk of breast cancer was small, translating into approximately one extra breast cancer for every 7690 women using hormonal contraception for 1 year. The study adjusted for duration of hormonal contraceptive use, age, calendar year, education level, parity, PCOS, endometriosis, and family history of breast or ovarian cancer. However, methodologic limitations should be considered when interpreting these findings. The Danish researchers utilized a database that did not include information addressing several potential confounders, including age at menarche, history of breastfeeding, and alcohol consumption. In addition, investigators did not address possible differences between users and nonusers in breast cancer surveillance, such as screening mammography. Although the database had information on women 15 to 79 years of age, the analysis was limited to women younger than 50 years. This is unfortunate given that more than three quarters of invasive breast cancers are diagnosed in women age 50 years and older; not including this population eliminated the opportunity to assess the potential association of hormonal contraceptive use and risk of breast cancer during women's postmenopausal years.[74] A large prospective cohort study in the United Kingdom including more than 46,000 women followed for more than 40 years also reported an increased risk of breast cancer but also a reduced overall cancer risk (lower rates of colorectal, endometrial, ovarian, hematopoietic cancers) in ever users of COC compared with nonusers.[75] The authors concluded that most women who choose to use oral contraceptives do not expose themselves to long-term cancer harms; instead, with some cancers, many women benefit from important reductions of risk that persist for many years after stopping. These findings are consistent with a systematic review of oral contraceptive use and cancer risk that reported a reduction in cancer risk.[41]

In women with a family history of breast cancer, a systematic review of retrospective cohort studies and case-control studies show that COC use does not confer an increased risk of breast cancer.[76] However, recent data suggest that COC use may increase risk of early-onset breast cancer in women carrying *BRCA* gene mutations,[77] although previous reports have not found this association.[37,78] According to the current USMEC guideline, there are no restrictions on use of hormonal contraception in women with a family history of breast cancer or women with breast cancer susceptibility genes (e.g., *BRCA1* and *BRCA2*).[9]

Cervical Cancer

For current COC users, the risk of invasive cervical cancer increases with increasing duration of use (relative risk for ≥5 years' use vs. never use is 1.90; 95% CI, 1.69–2.13), as demonstrated in a meta-analysis of pooled data from 24 studies including more than 16,000 women with cervical cancer and 35,000 without cervical cancer. The risk declined after use ceased; however, after 10 or more years, it returned to the risk level of never users. A similar pattern of risk was seen for invasive and in situ cancer, as well as for women who tested positive for high-risk human papillomavirus strains.[79]

A more recent meta-analysis of case-control and cohort studies demonstrated an increased risk of cervical cancer beyond 5 years of treatment, but the effect was not statistically significant and the evidence was of insufficient strength.[41] Regular cervical cancer screening according to national protocols is advised for all sexually active women, regardless of contraceptive use. A history of cervical intraepithelial neoplasia or genital human papillomavirus infection is not a contraindication for COC use.[9]

Use of Concomitant Medications With Combined Oral Contraceptives Pills

Certain anticonvulsants (phenytoin, carbamazepine, barbiturates, primidone, topiramate, and oxcarbazepine) that induce hepatic

enzymes may reduce contraceptive efficacy of COCs.[9] Rifamycin antibiotics, including rifampicin and rifabutin, can also interact with contraceptive hormones and reduce the efficacy of the contraceptive during and up to 4 weeks after use.[80] With the exception of those in the rifamycin class, concomitant use of antibiotics has not been found to reduce efficacy of any hormonal contraceptives.[81] In addition, antiretrovirals may reduce efficacy of hormonal contraception, including some non-nucleoside reverse transcriptase inhibitors (efavirenz) and some ritonavir-boosted (/r) protease inhibitors (darunavir/r, fosamprenavir/r, lopinavir/r, saquinavir/r, and tipranavir/r).[9] If oral contraceptives are used with these medications, a formulation containing at least 30 μg of ethinyl estradiol and backup contraception in the form of condoms should be used.[9] Alternatively, high-dose progestin-only methods such as DMPA or intrauterine contraceptives may be preferable because their efficacy is not reduced by medications that induce liver enzymes.

Contraceptive Vaginal Ring and Transdermal Patch

The transdermal and transvaginal routes are safe and acceptable alternatives to COCs to deliver combined estrogen-progestin contraception. The contraceptive patch (Xulane, Mylan Pharmaceuticals, Morgantown, WV) and the contraceptive vaginal ring (NuvaRing, Merck & Co. Inc., Rockville, MD) offer women combination estrogen-progestin contraception without the need to take pills daily. In consistent users, contraceptive failure rates with the patch and ring are similar to those for oral contraceptives.[82] There is currently insufficient evidence to determine how body weight affects the contraceptive efficacy of the vaginal ring and contraceptive patch.[83]

It is important to note that all ethinyl estradiol contraceptives elevate VTE risk, regardless of whether the route of administration is oral, vaginal, or transdermal.[84] The contraceptive patch generates higher circulating levels of ethinyl estradiol than either COC or the vaginal ring.[85] It is uncertain whether use of the patch is associated with a higher risk of VTE than use of COC.[67,86] Contraindications to the patch and the vaginal ring are the same as those for COCs. In the absence of adequate evidence to determine how risks and noncontraceptive benefits of the patch and the ring compare with those of COC, they are usually considered to be equivalent.

As with COC pills, the contraceptive patch and vaginal ring act primarily by suppression of ovulation. The patch and ring are immediately effective if commenced within the first 5 days of the onset of menstruation, but because therapeutic steroid levels are achieved over the course of several days, starting at any other time requires 7 days of backup contraception, such as condoms or abstinence.[8]

Transdermal Contraceptive Patch

Xulane, the only contraceptive patch available in the United States, is a 4.5-cm tan square that releases 20 μg of ethinyl estradiol daily along with norelgestromin, the biologically active metabolite of the progestin norgestimate[87] (Fig. 18.3). A new patch is applied each week on the same day for 3 weeks, followed by a patch-free week, during which withdrawal bleeding is anticipated. Sweating associated with vigorous exercise, swimming, and use of a hot tub or sauna should not result in patch detachment. Unscheduled bleeding in patch users is similar to that seen with COCs.[82] Although patch users are more compliant than pill users, they are more likely to report breast discomfort, dysmenorrhea, nausea, and vomiting.[82,88] Mild local skin reactions are common. An investigational contraceptive patch is being developed that releases less ethinyl estradiol than the Xulane transdermal contraceptive.[89]

• **Fig. 18.3** The contraceptive patch.

• **Fig. 18.4** The contraceptive vaginal ring.

Contraceptive Vaginal Ring

The vaginal mucosa offers excellent absorption of sex steroids. The only contraceptive vaginal ring available in the United States is the NuvaRing, a flexible plastic ring that is 4 mm thick and has an outside diameter of 54 mm.[90] The ring releases 15 μg of ethinyl estradiol daily along with etonogestrel, the biologically active metabolite of the progestin desogestrel (Fig. 18.4). The contraceptive vaginal ring is inserted in the vagina for 3 weeks and then withdrawn for 1 week, during which withdrawal bleeding is anticipated. A new ring is required every 4 weeks. The ring does not require individual fitting; as long as it remains in the vagina, appropriate absorption of steroids occurs. The ring is well tolerated, with increased physiologic vaginal discharge being the main bothersome side effect.[88] Rates of unscheduled bleeding and spotting are lower with the ring than with oral COC.[82] Spontaneous expulsion is uncommon. The ring can also be used in extended-cycle regimens.[91]

Women's interest in using a contraceptive vaginal ring varies; some women are highly motivated and comfortable with this method. Some users keep the ring in place during sexual relations; in this setting, male discomfort is uncommon. Other users prefer to remove the ring before intercourse, and removal for less than 48 hours does not appear to impair efficacy.[8] However, frequent removal for long periods is not recommended, and the label states a maximum of 3 hours is allowed.[92] Backup contraception is required for 7 days if the ring is removed for 48 hours or longer.

Progestin-Only Contraceptive Methods

Progestin-only contraceptives offer many advantages over estrogen-containing methods. There are fewer contraindications to progestin-only contraception (see Table 18.3). Progestin-only contraceptives may be appropriate for many women with contraindications to contraceptive doses of estrogen, including those at elevated baseline risk for VTE, women 35 years or older who smoke, who have hypertension, or who have long-standing diabetes. In addition, they can be used immediately after delivery, whether or not the patient is breastfeeding.

Progestin-only methods include the following:

- the POP (minipills),
- DMPA injections (DMPA-IM [Depo-Provera, Pfizer, New York, NY], DMPA-SC [Depo-subQ Provera]),
- the etonogestrel implant (Nexplanon [Merck & Co., Whitehouse Station, NJ]), and
- levonorgestrel IUDs (LNG IUDs; the larger-frame devices Mirena [Bayer Healthcare Pharmaceuticals] and Liletta [Medicines360, San Francisco, CA] and the smaller-frame devices Kyleena and Skyla [Bayer Healthcare Pharmaceuticals]).

These methods comprise various types of progestins, doses, and routes of administration. The dose of progestin in the "minipill" available in the United States (0.35-mg norethindrone) is one third that typically found in combined hormonal contraceptives formulated with this progestin. A stable serum concentration of 150 to 200 pg/mL of levonorgestrel occurs after insertion of the 52-mg LNG IUD,[93] a concentration substantially lower than that seen in women using a 150-µg levonorgestrel-containing oral contraceptive pill (6.2 ng/mL).[94]

Although POPs, implants, and the LNG IUD do not appear to increase risk of VTE, data for DMPA are less clear.[95-99] A twofold increased risk of VTE with progestin-only injectables was found in meta-analysis[96] based on two studies; however, residual confounding weakens the result.[100-102] If DMPA does increase VTE risk, the magnitude of this increase is likely less than that seen with COCs. The USMEC allows the use of DMPA in women with VTE and those at elevated risk for thromboembolism.

Progestin-Only Oral Contraceptive Pill

Only one POP formulation is marketed in the United States: norethindrone in 0.35-mg tablets (e.g., Micronor, Nor-QD, and generics). The progestin dose is lower than the dose in any combination oral contraceptive. Due to the short half-life of POPs, serum steroid levels decline to near baseline as quickly as 24 hours after administration, and a dose is considered missed if it has been more than 3 hours beyond an expected dose.[8] Norethindrone POPs are dispensed in packs of 28 active pills, which are taken continuously (i.e., no HFI) (Table 18.4). Contraindications to POPs are few (see Table 18.3).

TABLE 18.4 Summary and Recommendations for Progestin-Only Oral Contraceptive Use

1. Progestin-only contraception is an option for women in whom an estrogen-containing contraceptive is either contraindicated or causes additional health concerns.
2. Ovulation is not consistently suppressed; the main contraceptive actions of progestin-only oral contraception are effects on cervical mucus and the endometrium.
3. The typical user failure rate with progestin-only oral contraception is estimated to be more than 7%. Women choosing progestin-only oral contraception are often subfertile as a result of breastfeeding or older reproductive age, so the failure rate in these populations may be lower than in more fertile populations.
4. It is essential that the pill be taken at the same time each day to maximize contraceptive efficacy.
5. Menstrual irregularities are common in users of progestin-only oral contraception and represent the most frequent cause for contraceptive discontinuation.

Mechanism of Action

The mechanism of action of progestin-only oral contraceptives may include suppression of ovulation, thickening of cervical mucus, and induction of endometrial atrophy. Unlike with COCs, ovulation is not consistently suppressed with the 0.35-mg norethindrone POP, and the progestin effects on cervical mucus and the endometrium are critical factors in preventing conception.[103] Within hours of administration, progestin-only oral contraceptives thicken cervical mucus, which acts as a barrier to stop sperm at the cervical canal; 48 hours of norethindrone POP use is necessary to achieve full contraceptive effects on cervical mucus.[8] In European countries, a POP containing 75 µg of desogestrel is available. In contrast with the norethindrone POP available in the United States, the desogestrel POP inhibits ovulation, and contraceptive efficacy is as high as with COCs.[104]

Efficacy

The efficacy of progestin-only oral contraceptives is not well established.[105] National survey data used to estimate contraceptive failure rates with typical use have failed to distinguish between COCs (the larger group) and POPs. A potential confounding factor is that women using progestin-only oral contraceptives may have reduced fertility as a result of breastfeeding or older reproductive age. It is possible that the typical first-year failure rates (7%) with progestin-only oral contraceptives are higher than those seen with COCs.[26] In general, norethindrone 0.35-mg POPs should not be considered a first-line contraceptive except in women who should not or do not wish to use estrogen. Given concerns regarding the efficacy of norethindrone 0.35-mg pills in women with normal fertility, some experts recommend that women with normal fertility who choose to use POPs (e.g., a 35-year-old hypertensive woman) take *two* daily tablets (two tablets as a single dose, off-label). A tablet combining 1 mg of norethindrone acetate and 5 µg of ethinyl estradiol is marketed for treatment of menopausal symptoms.[106] This dose of norethindrone acetate appears adequate to consistently suppress ovulation; in addition, the dose of estrogen is small. Accordingly, some clinicians prescribe this combination medication off-label to women requiring contraception who medically are not candidates for conventional combination estrogen-progestin contraceptives. Such patients should be advised that the 1-mg norethindrone acetate/5-µg ethinyl estradiol combination is not approved for contraceptive use, and condom backup is

recommended. Of note is that the progestational impact of 1-mg norethindrone acetate is similar to that of 1-mg norethindrone.

Starting the Progestin-Only Pill

Progestin-only oral contraceptives can be initiated within the first 5 days of menses, without need for backup contraception. Some clinicians initiate progestin-only oral contraceptives at any time in the cycle, as long as the clinician is reasonably certain that the patient is not pregnant. With this strategy, backup contraception should be used for the first 2 days of use.[8] Because of the short duration of action and the short half-life of POPs, the pill must be taken at the same time each day to maximize contraceptive efficacy. A backup contraceptive (e.g., condoms) should be used for at least 2 days if the progestin-only oral contraceptive is taken more than 3 hours late or forgotten on any day. The patient should also resume taking daily progestin-only oral contraceptives as soon as possible. Progestin-only oral contraceptives may be initiated immediately or within 7 days after induced or spontaneous abortion. If not administered immediately after abortion, the woman must use alternative contraception or abstinence for 2 days. After delivery, POPs can be started at any time, including immediately postpartum in breastfeeding and nonbreastfeeding women.[107] If the woman is more than 21 days postpartum and is not using POPs to augment lactational amenorrhea, then backup contraception should be used for 2 days.[8]

Side Effects of Progestin-Only Oral Contraceptives

Sonographic studies have shown that prominent ovarian follicular activity is more common among progestin-only oral contraceptive users than among other women, but this may wax and wane over time.[108] Transvaginal ultrasound follow-up of women during a 3-year clinical trial of the small-frame LNG IUD (Skyla) found that ovarian cysts (defined as >3 cm) were present in 1.6% of participants at screening and 1.1% to 2.4% of participants at each subsequent visit. Eighty-eight percent of these cysts were 5 cm or less; none were greater than 8 cm. No ovarian cysts persisted beyond 9 months, which is consistent with a functional etiology.[109] Other than reassurance and sonographic follow-up, no intervention is required in asymptomatic women found to have asymptomatic incidental ovarian cysts during use of progestin-only contraceptives. If a follow-up sonogram in 6 to 8 weeks demonstrates resolution or decrease in size of ovarian cysts, no further evaluation is required.

Side effects with POPs other than changes in bleeding patterns are relatively uncommon.[103] Weight gain has not been objectively documented, and headaches are uncommon. Unscheduled bleeding, spotting, and amenorrhea are common menstrual patterns during progestin-only oral contraceptive use, and users should be counseled accordingly. Interpreting signs and symptoms of pregnancy, whether intrauterine or extrauterine, can be challenging. Pregnancy testing is appropriate for POP users experiencing nausea, breast tenderness, a change in menstrual pattern, or lower abdominal pain (see Table 18.2).

Other Effects

Most studies have reported that progestin-only oral contraceptives have little impact on carbohydrate metabolism.[110] However, one study conducted in Latina women observed that lactating women with a history of gestational diabetes who used progestin-only oral contraceptives after delivery had an almost tripled risk of diabetes compared with those who used low-dose COCs.[111] All women with gestational diabetes, regardless of contraceptive used, should be screened for diabetes postpartum with a 75-g, 2-hour oral glucose tolerance test.[112]

As with all contraceptives, POPs lower overall risk for ectopic pregnancy. A history of ectopic pregnancy does not contraindicate progestin-only oral contraceptive use. However, if pregnancy occurs, the likelihood that the pregnancy is ectopic is higher in POP users than in nonusers of contraceptives.[103] Bone density does not appear to be adversely affected by the POP. The only study assessing skeletal health in progestin-only oral contraceptive users was conducted in breastfeeding women; progestin-only oral contraceptives, in fact, protected against small, reversible losses in BMD occurring during lactation.[113] Finally, progestins usually suppress endometrial growth.[108] However, few epidemiologic data address the effect of progestin-only oral contraceptives on endometrial cancer risk or on any cancer risk.

Progestin-Only Oral Contraceptives During Lactation

Progestin-only oral contraceptives do not interfere with the quality or quantity of breast milk.[107] Very little progestin is passed from nursing mothers into their breast milk, and no adverse impact on infant growth has been observed. Package labeling advises delaying administration in lactating women until 6 weeks after delivery. A trial conducted in the United States randomized breastfeeding women to initiate progestin-only compared with combination estrogen-progestin oral contraceptives 2 weeks postpartum. At 8 weeks postpartum, approximately two-thirds of women continued to breastfeed in both groups.[114] Based on the absence of data suggesting harm to the infant or mother and the contraceptive benefits of early initiation, some experts recommend initiation of POPs before hospital discharge and no later than the third postpartum week, regardless of lactation status.

Depot Medroxyprogesterone Acetate for Contraception

DMPA is an injectable, progestin-only contraceptive that provides effective, private, and reversible contraception. It is discrete, avoids the need for user action daily or near the time of sexual intercourse, and avoids the need for partner cooperation (Table 18.5).

Formulations and Pharmacology

DMPA is available in two formulations: 150 mg/1 mL for intramuscular injection and 104 mg/0.65 mL for subcutaneous injection. The injections can be given every 3 months because low solubility of the microcrystals at the injection site allows pharmacologically active drug levels to persist for several months. DMPA primarily acts by inhibiting follicular maturation and ovulation through inhibition of gonadotropin secretion. Unlike other progestin-only contraceptives, mean estradiol levels may be lower than normal for cycling premenopausal women.[115]

DMPA is an effective contraceptive. Following a 150-mg intramuscular injection, failure rates in clinical trials have ranged from 0.0 to 0.7 per 100 woman-years. In clinical practice, typical-user failure rates are 4 failures per 100 woman-years, reflecting the fact that some users do not return for their injections as scheduled.[26] Because progestin levels are high, efficacy is not reduced by obesity or use of concurrent medications, such as anticonvulsants. For the 104-mg subcutaneous injection, no contraceptive failures were reported in phase III clinical trials.[116] This formulation is relatively new, so typical-user failure rates are not available, but they are expected to be similar to those for the intramuscular preparation.

TABLE 18.5 Summary and Recommendations for DMPA Use

1. DMPA is an excellent method of contraception for women who desire a long-term, reversible contraceptive method.
2. DMPA primarily acts by inhibiting follicular maturation and ovulation through inhibition of gonadotropin secretion; it also affects cervical mucus.
3. DMPA is available in two formulations: 150 mg/1 mL for IM injection and 104 mg/0.65 mL for SC injection.
4. DMPA can be administered as long as the provider is reasonably certain the patient is not pregnant. The dose is repeated every 3 months (13 weeks), with a 2-week grace period.
5. Although DMPA does not permanently affect endocrine function, return of fertility may be delayed.
6. Thorough, candid counseling about side effects is important. Women who are well informed when they choose this method of contraception are much more likely to become highly satisfied users with high continuation rates.
7. Menstrual changes occur in all women using DMPA and are the most frequent cause for discontinuation.
8. Because DMPA induces amenorrhea, it can be used for managing a variety of gynecologic and nongynecologic disorders, such as heavy menstrual bleeding, dysmenorrhea, and iron deficiency anemia.
9. There is no high-quality evidence that use of DMPA increases the risk of developing cancer, cardiovascular disease, or sexually transmitted infection. DMPA use significantly reduces the risk of developing endometrial cancer.
10. There is an association between current DMPA use and decreased bone mineral density; losses in bone mineral density are temporary, reverse after discontinuation of DMPA, and have not been linked to postmenopausal osteoporosis or fractures.

DMPA, Depot medroxyprogesterone acetate; *IM*, intramuscular; *SC*, subcutaneous.

Although users may be hypoestrogenic, vasomotor symptoms and vaginal atrophy are uncommon. Because of its progestin effect, DMPA also causes changes in cervical mucus that are hostile to sperm migration and endometrial atrophy. The newer subcutaneous injection is less painful and is available in a prefilled syringe, offering the potential for self-administration.[117] Intramuscular DMPA is available as a generic formulation that is less costly than subcutaneous DMPA. Otherwise, benefits and risks are similar for intramuscular and subcutaneous administration.[118]

Administration of DMPA

Starting Injections

The ideal time to initiate DMPA is within 7 days of the onset of menses.[8] This approach ensures that the patient is not pregnant at the time of injection and prevents ovulation during the first month of use, so backup contraception is unnecessary. Most women have pharmacologically active drug levels and a poor cervical mucus score within 24 hours after injection.[119] The "same-day," "quick-start," or "Depo-now" approach when a pregnancy test result is negative facilitates DMPA initiation for many users, and it may prevent some pregnancies.[120] However, there is a small possibility of undiagnosed pregnancy despite a negative pregnancy test result. When the quick-start approach is used for initiating DMPA, backup contraception or abstinence should be used for 7 days and a repeat pregnancy test should be performed in 2 to 4 weeks. Nevertheless, DMPA given inadvertently during pregnancy does not appear to be teratogenic.[121] DMPA may be initiated immediately after spontaneous or induced abortion or within the first 7 days.[8] If given in the first 7 days after the event, then backup contraception should be used. After delivery, DMPA can be started at any time, including immediately postpartum in breastfeeding and nonbreastfeeding women.[107,122] If the woman is more than 21 days postpartum and not breastfeeding exclusively, backup contraception should be used for 7 days after the first DMPA injection.[8]

Repeat Injections

Repeat injections of DMPA should be scheduled every 3 months (13 weeks). After a 150-mg injection, ovulation does not occur for at least 14 weeks. A 2-week grace period (repeat injection without pregnancy testing, up to 15 weeks following the prior injection) is appropriate for women receiving injections every 3 months.[8] In women more than 2 weeks late for an injection, a urine pregnancy test should be performed before administering further DMPA, and backup contraception for 7 days is advised.

Side Effects of DMPA

Candid counseling regarding the side effects of DMPA and the need for timed injections must be provided. Women who are well informed when they choose this method of contraception are more likely to become satisfied users with high continuation rates.[123] Menstrual changes occur in almost all women using DMPA and are the most frequent cause for discontinuation of injectable and all other progestin-only contraceptives.[124] Proactive patient education before the initiation of DMPA and supportive follow-up can improve tolerance of menstrual changes. During the first months of use, episodes of unpredictable bleeding and spotting lasting 7 days or longer are common. Bleeding decreases with longer duration use, and at 1 year, 50% of women experience amenorrhea; this rate increases to 75% with long-term use.[115] Similar bleeding patterns are reported with the subcutaneous preparation.[125] Many women view amenorrhea (along with a reduction or elimination of menstrual cramps) as one of the advantages of using this method.

There are no established methods for predicting, preventing, or treating unscheduled bleeding in DMPA users. Small studies have shown that estrogen supplements (e.g., 1.25 mg of conjugated estrogen orally, 1–2 mg of micronized estradiol orally, or 0.1-mg estradiol patches for 10–20 days) may terminate a bleeding episode.[126] Another treatment option endorsed by the US Selected Practice Recommendations for Contraceptive Use is nonsteroidal anti-inflammatory drugs for 5 to 7 days. However, a systematic review concluded that there is a lack of high-quality data to support routine clinical use of any interventions to treat persistent unscheduled bleeding with progestin-only contraceptives.[125]

Observational studies have not reported any consistent effects of DMPA on mood.[127] Progestins may cause or exacerbate depressive symptoms in certain subpopulations of women, including those with a history of premenstrual syndrome or mood disorders. However, depression is not a contraindication to DMPA use.[128] The impact of DMPA on weight has been controversial.[129] Randomized controlled trials, although limited, fail to show that DMPA causes weight gain.[115,130] Observational studies are difficult to interpret given that individuals tend to gain weight over time irrespective of contraceptive use. On average, the weight gain with DMPA use is small (2 kg); however, there is marked individual variation. Weight gain with the use of DMPA may be associated with user subgroups at particular risk for obesity, including adolescents and ethnic minorities.[131] In the US CHOICE study, women who chose DMPA were more likely to be African-American

than those who chose other contraceptives. Weight changes varied among women choosing different progestin-only methods; however, being of the black race predicted weight gain regardless of the contraceptive chosen.[132,133] It is reasonable to monitor weight over time in women using DMPA.[8]

Risks and Benefits of DMPA

DMPA has been used to manage a variety of gynecologic and nongynecologic disorders. The tendency of DMPA to cause amenorrhea makes it a particularly appropriate contraceptive choice for women with heavy menstrual bleeding, dysmenorrhea, or irondeficiency anemia. DMPA is a useful means of suppressing menstrual bleeding and managing menstrual hygiene in individuals with special needs (e.g., cognitive impairment, military personnel, wheelchair-bound individuals).[115,134]

Progestins inhibit endometriotic tissue growth by directly causing initial decidualization and eventual atrophy, and by inhibiting pituitary gonadotropin secretion and ovarian estrogen production. Randomized trials show that DMPA is more effective than oral contraceptives and danazol and as effective as leuprolide injections for treatment of pain associated with endometriosis.[130] In the United States, subcutaneous DMPA is approved for the treatment of pain associated with endometriosis.

Effect on Cancer Risk

Large case-control studies conducted by the WHO have shown that use of DMPA is associated with an 80% reduced risk of endometrial cancer and does not affect the incidence of cervical cancer.[135-137] A more recent Thai case-control study found that use of DMPA is associated with protection against epithelial ovarian cancer, similar to that seen with use of COCs.[138] Multicountry data from the WHO and data from the United States, South Africa, and New Zealand provide reassurance that use of DMPA is not associated with an increased risk of breast cancer.[139]

Effect on Cardiovascular Risk

DMPA has an adverse effect on circulating lipids but does not increase production of coagulation factors and has no adverse effect on blood pressure. No adverse clinical effects on cardiovascular disease have been observed.[102] Based on these findings, the USMEC allows DMPA and other progestin-only contraceptives for use in women with a history of VTE and those in whom use of combination estrogen-progestin contraceptive is contraindicated.[9] This recommendation is different from package labeling for DMPA (written in the 1960s), which indicates that a prior history of VTE is a contraindication to DMPA use. In women with multiple risk factors for cardiovascular disease (e.g., smoking, older age, hypertension, diabetes), the USMEC classifies DMPA as category 3 (see Table 18.3), indicating that the risks of use may exceed the benefits. The basis for this caution, which the authors do not support, seems to be the hypoestrogenic effects of DMPA and reduced high-density lipoprotein (HDL) levels. In addition, the effects of DMPA might persist for some time after discontinuation, so it would not be immediately reversible if there were an adverse event.

Effect on Skeletal Health

DMPA's impact on BMD has generated much controversy. *Bone mineral density* is defined as the amount of mineral matter per volume of bone and directly correlates with bone strength.[140] DMPA injections suppress the secretion of gonadotropins, decreasing ovarian production of estrogen, which results in a decline in BMD. In 2004, the US Food and Drug Administration (FDA) added a "black box" warning to DMPA labeling about declines in BMD, which might discourage health care providers from initiating DMPA or limit long-term use.[141] Pregnancy, breastfeeding, menopause, and use of hormonal contraceptives can all impact BMD by affecting sex hormones.

Both cross-sectional and longitudinal studies using dual-energy x-ray absorptiometry technology to evaluate current users of DMPA have observed lower BMD in current DMPA users compared with nonusers.[142-149] Longitudinal studies report BMD losses of –3.1% to –5.8% and –4.1% to –5.7% at the hip and spine, respectively, after 2 years of use, and losses of –4.5% to –7.7% and –4.9% and –6.6% after 4 years of use.[147,148] Most of the decline in BMD is observed within the first 2 years of use, suggesting that longer use may not progressively increase risk of osteoporosis.[147] Decline in BMD appeared to be substantially or completely reversible, as seen in studies including both adults and adolescents, with a duration of DMPA use of 2 to 5 years and follow-up to 5 years after discontinuation.[145,147,150-152]

DMPA use and breastfeeding are both accompanied by hypoestrogenemia. The reversible declines in BMD associated with DMPA use, followed by recovery when the DMPA is discontinued, parallels the BMD trends seen with breastfeeding.[153,154] Cross-sectional studies demonstrate that BMD in adult women who previously used DMPA is similar to that of women who never used injectable contraception, an observation that provides further reassurance that loss of BMD associated with DMPA use is reversible.[155-157]

Changes in BMD resulting from use of DMPA are clinically important if they increase risk for fracture. No published data address whether premenopausal DMPA impacts subsequent fracture risk in postmenopausal women. Although the association between decline in BMD and risk of fracture is well established in postmenopausal women,[158] the association is less robust in healthy premenopausal women.[134] Observational studies have mixed findings on the association of DMPA use and fracture risk in reproductive-age women. Three observational studies used large national databases to examine the association between DMPA or LNG IUD use and fracture.[159-161] Two of these were based on the same large United Kingdom database.[159,160] Using case-control methods, ever users of DMPA had a higher risk of fracture compared with never users (odds ratio [OR], 1.44).[159] Using the same British database but a retrospective cohort analysis, a second group also observed that DMPA users had an increased risk for fracture (OR, 1.41). However, this second report noted that the elevated risk was present at baseline, *prior* to DMPA use; accordingly, the elevated fracture risk could not have been caused by DMPA.[160] A Danish case-control study also noted that ever use of DMPA was associated with increased risk for fracture (OR, 1.44). However, the authors of this Danish report suggested that the subgroup of women choosing DMPA, 0.1% of the study sample, were not representative of the larger Danish population, limiting attribution of their findings.[161] These British and Danish studies raise the issue that women who choose DMPA are different from women who choose other methods of contraception (as noted also in the US CHOICE study[132]) and hypothesize that fracture risk associated with DMPA exposure may be due to unmeasured confounders in women who choose injectable contraception, including behavioral differences. For example, authors of the Danish study point out the prevalence of alcoholism (a condition known to be associated with fractures from motor vehicle and other accidents) in women using DMPA was 14%, sevenfold higher than in women

not using DMPA; furthermore, the Danish investigators note that cases with fractures were some threefold more likely to be classified as alcoholics as control women.

When counseling women considering initiation or continuation of injectable contraception, clinicians should discuss the benefits and the risks of DMPA, including the FDA black box warning, and use clinical judgment and shared decision making to assess appropriateness of use. The effect of DMPA on BMD on skeletal health should not prevent clinicians from recommending DMPA initiation or continuing use beyond 2 years (USMEC category 2 for adolescents <18 years of age and women >45 years of age; category 1 for women age 18–45 years).[9] Routine assessment of BMD is not recommended in adolescents and young women using DMPA. Although low-dose estrogen supplementation has been observed to limit BMD loss in adolescent DMPA users,[162,163] estrogen supplementation during DMPA use is not recommended due to potential adverse effects and a paucity of data from clinical trials assessing skeletal health outcomes.

For patients with comorbidities and conditions that may impact skeletal health, including an elevated risk of falls, wheelchair use, chronic corticosteroid use, renal disease, or malabsorption, individualized counseling and clinical management along with shared decision making is appropriate. Age-appropriate calcium and vitamin D dietary intake, regular weight-bearing exercise, and smoking cessation should be encouraged for all women. Although these recommendations may benefit the health of patients in general, studies demonstrating that these measures will improve skeletal health outcomes in women using injectable contraception are lacking.

Effect on Sexually Transmitted Infections

The association between use of DMPA and risk of STIs is uncertain. Some studies show an increased risk of STI in DMPA users compared with other contraceptives, but it is unclear whether this reflects differences in sexual practices, such as lower condom use, in DMPA users.[164,165] The relationship between DMPA use and human immunodeficiency virus (HIV) acquisition and transmission is also unclear, but several clinical trials show an increased risk.[166] There are several plausible biologic mechanisms through which DMPA may increase HIV transmission risk.[167,168] DMPA is widely used in the areas of high HIV prevalence where alternative contraceptive options are limited. A systematic review of progestin injectables found a possible increased risk for HIV acquisition (adjusted hazard ratio, 1.4; 95% CI 1.2–1.6) among women at increased risk.[166] It is unknown whether this association is due to a real biologic effect, because there were methodologic issues causing the evidence to be inconclusive. The current USMEC recommendation states that the advantages of DMPA continue to outweigh the theoretical or proven risks (USMEC category 2) among women at high risk for HIV infection but that women should be counseled regarding these issues.[165] The USMEC emphasizes that women should not be denied DMPA because of these concerns, as there is a very real risk that unintended pregnancies and maternal morbidity and mortality would result. Women with HIV or those at risk for HIV should be counseled to always use condoms to prevent HIV and other STI transmission.[165]

Effect on Return of Fertility

Although DMPA does not permanently impact endocrine function, return of fertility may be delayed after stopping DMPA use. Within 10 months of the last injection, 50% of women who discontinue DMPA to become pregnant will conceive. However, in some women, fertility is not reestablished until up to 18 months after the last injection.[115] The persistence of ovulation suppression after DMPA discontinuation is not related to the duration of use, but it is related to weight, as clearance is slower in heavier women.[169] Before initiating DMPA contraception, clinicians should counsel candidates about the possible prolonged duration of action. Women who may want to become pregnant within the next year should choose an alternative contraceptive.

Progestin-Releasing Intrauterine Devices

LNG IUDs provide highly effective, safe, convenient, and reversible contraception.[170] In the 1980s, intrauterine contraception use in the United States fell dramatically after earlier flawed studies reported an association between intrauterine contraception use and later tubal infertility. It is now acknowledged that modern intrauterine contraception not only is highly effective but also is safe for most women to use.[171] Use of IUDs has increased in the United States, with the prevalence of use rising from 2% to more than 10% from 2002 to 2012 among women using contraception. Most IUDs used by US women are progestin-releasing devices.[172] The addition of progestin to the IUD increases contraceptive efficacy, and the 52-mg LNG IUD is approved in the United States not only for contraception but also for treatment of heavy menstrual bleeding. The LNG IUD provides other off-label therapeutic benefits, including treatment of pain associated with endometriosis, treatment of symptoms associated with uterine adenomyosis, treatment of endometrial hyperplasia or carcinoma, and protection of the endometrium in women during use of menopausal estrogen therapy.

Contraceptive Uses

Mirena, Liletta, Kyleena, and Skyla are the four LNG IUDs marketed in the United States. Mirena and Liletta are larger higher-dose T-shaped devices with a reservoir containing 52 mg of levonorgestrel. These devices deliver 20 μg of levonorgestrel per day. Although Mirena is approved for up to 5 years of use, it provides contraceptive efficacy for a longer duration. In a US study of 496 women who had used the LNG IUD for 5 years, overall, two pregnancies occurred in the LNG IUD group during the sixth and seventh years of use. The failure rate in the sixth year of use was 0.25 per 100 women-years (95% CI, 0.04–1.42); in the seventh year of use, the failure rate was 0.43 per 100 women-years (95% CI, 0.08–2.39).[173] Accordingly, women, particularly women older than 35 years, can be offered the opportunity to retain their 52-mg LNG IUDs for up to 6 or 7 years of use, recognizing that such use is off-label.[174] Although Liletta is approved for up to 4 years of use (as of early 2018) but given that it has the same quantity of levonorgestrel as Mirena, it is expected to eventually be approved for 5 or more years of use.

Kyleena and Skyla are smaller and lower-dose LNG IUDs, containing 19.5 mg and 13.5 mg and releasing 17.5 μg/day and 14 μg/day of levonorgestrel, respectively. Kyleena and Skyla are approved for up to 5 and 3 years of use, respectively. These small-frame devices are distinguished from Mirena and Liletta by their smaller size (30 mm × 28 mm compared with 32 mm × 32 mm) and a silver ring at the top of the vertical stem (visible with ultrasound). The inserter diameter is also narrower than Mirena (3.8 mm vs. 4.5 mm). The smaller dimensions of the Kyleena and

Skyla devices make them particularly suitable for women with smaller uterine cavities or tight cervices.[175] Data from large international studies confirm extremely low pregnancy rates with the various LNG IUD devices, ranging between 0.1 and 0.3 per 100 woman-years.[26,176,177]

Despite endometrial suppression, fertility returns rapidly after contraceptive removal.[178] The high contraceptive efficacy of LNG IUDs reflects the thickening cervical mucus and profound endometrial suppression caused by locally high concentrations of progestin. Most LNG IUD users continue to ovulate, even when amenorrhea is present.[176] There are few contraindications to IUDs, and most women are appropriate candidates—including adolescents and nulliparous women.[170] Contraindications to IUD use are pregnancy, active cervicitis or uterine infection, malignancy in the uterus or cervix, a distorted uterine cavity, unexplained abnormal bleeding, and adverse reaction to product ingredients.[179] Although systemic concentrations of levonorgestrel are very low in LNG IUD users, use of hormonal contraceptives is generally avoided after breast cancer.

Expanding the Use of IUDs

There is growing consensus that women in the United States will benefit from broader use of IUDs, including the LNG IUD.[171] The Contraceptive CHOICE Project in St. Louis, Missouri, provided women (n = 5000) who did not desire pregnancy for at least 1 year with free reversible contraceptives for up to 3 years. This project has shown that with standardized counseling and no financial barriers to contraceptive acquisition, the majority of women (68%) will choose long-acting reversible contraceptive methods (45% LNG IUD, 10% copper IUD, and 13% etonogestrel implant).[180] Continuation rates at 12 and 24 months were 88% and 79% for the LNG IUD, 84% and 77% for the copper IUD, and 83% and 69% for the etonogestrel implant, respectively.[181] Satisfaction rates were also higher for long-acting reversible methods compared with other methods of contraception, such as oral contraceptives and the injectable DMPA. In addition, among women participating in the Contraceptive CHOICE Project, rates of unintended pregnancy, birth, and abortion were substantially lower than for other women in St. Louis and compared with women in the United States overall.[182] Adolescents in this study also frequently chose either IUDs or implants.[183] With appropriate counseling and management regarding STI prevention and anticipated side effects, it is now accepted that IUDs can be used safely and effectively in adolescents.[184,185] Adolescents and young women have higher continuation rates and lower repeat unintended pregnancy rates when using a method that does not require ongoing adherence.[132] Additionally, the use of long-acting reversible contraception immediately after abortion has been shown to decrease repeat abortion rates.[186,187]

Abnormal Bleeding, Expulsion, and Uterine Perforation

As with DMPA and other progestin-only contraceptives, unpredictable uterine bleeding is the most common reason for discontinuation of LNG IUDs.[188] Unscheduled bleeding is most common during the early months of LNG IUD use and tends to resolve with time. By 12 months, up to 50% of women have amenorrhea or infrequent bleeding. With the Kyleena and Skyla LNG IUD, by 12 months, approximately 38% and 26% of women have amenorrhea or infrequent bleeding, respectively.[189,190] Addressing patient preferences and assessing acceptance of menstrual disturbances are integral to efforts aimed at reducing early discontinuation rates. Adequate and specific counseling about likely changes in bleeding patterns before placement is essential for increasing patient acceptability.

Expulsion is the most common cause of IUD failure. The cumulative expulsion rate was 10.2 per 100 IUD users over 36 months and did not vary among LNG and copper IUDs in a US study.[191] Increased risk for expulsion occurs in nulliparous women, women with severe dysmenorrhea or uterine adenomyosis, those with uterine cavity abnormalities, and women with insertions immediately after delivery. The authors' anecdotal impression is that appropriate high fundal IUD insertion minimizes the likelihood of expulsion.

The USMEC allows immediate insertion after first-trimester (category 1) and second-trimester (category 2) abortions.[9] Postpartum insertion is recommended after a 4-week interval (category 1). Immediate postpartum insertion (following vaginal or cesarean birth) is also an option (category 2) within 10 minutes of placental delivery as long as there is no evidence of chorioamnionitis or puerperal sepsis.[192] Expulsion rates with immediate postpartum insertion range from 10% to 20%, with lower rates seen after cesarean delivery. Because expulsion usually occurs within the first few months, women are encouraged to follow up with their care provider within 12 weeks of insertion.

Uterine perforation is an uncommon but potentially serious complication of LNG IUD placement. A large European prospective cohort study found a perforation incidence of 0.6 for nonlactating women and 4.5 for lactating women per 1000 insertions.[193] No perforations caused injury of intra-abdominal or pelvic structures or serious morbidity.[194]

Upper Genital Tract Infection and Infertility

The use of intrauterine contraception does not increase the risk of pelvic infection.[195] Similarly, there is no evidence intrauterine contraception increases the risk of subsequent infertility.[196] Intrauterine methods are suitable for nulliparous and adolescent women.[184] Prophylactic antibiotics are not recommended for IUD insertion. A clinical history (including sexual history) should be taken as part of the routine assessment for intrauterine contraception to identify women at high risk for STIs; testing before insertion should be performed selectively, not routinely. Even among high-risk women, testing on the same day of insertion was found to be as safe as testing prior to insertion in terms of subsequent pelvic inflammatory disease (PID) risk.[197] An IUD should not be inserted in women with current PID, purulent cervicitis, or current chlamydial or gonorrheal infection.[9] However, cervical or vaginal infection is not an indication to remove an IUD.[8] If a woman contracts gonorrhea, chlamydia, or PID with an LNG IUD in place, treatment follows the CDC Sexually Transmitted Diseases Treatment guidelines, and if the patient responds to therapy, the IUD can remain in place.[198]

Metabolic and Systemic Effects

Low but detectable circulating levels of progestin in LNG IUD users have raised concerns that glucose control, the lipid profile, and blood pressure may be negatively affected. However, these concerns have not been substantiated in high-quality clinical trials.[176] The data support that the LNG IUD is safe to use in patients with diabetes, hyperlipidemia, or hypertension. Progestins are not thought to increase the risk of thromboembolic disease, and the LNG IUD has not been associated with venous or arterial events.[102]

Noncontraceptive Uses of the Levonorgestrel-Releasing Intrauterine System

Heavy Menstrual Bleeding

The high-dose LNG IUD is a well-established and highly effective treatment intervention for heavy menstrual bleeding. In comparative studies, it offers efficacy equal to or greater than other surgical uterine-conserving treatments (e.g., global endometrial ablation, transcervical endometrial resection), is an acceptable alternative to hysterectomy for many women, and offers comparable improvement in health-related quality of life for menstrual disorders.[199-202] Although up to 43% of women using the LNG IUD to treat abnormal uterine bleeding will eventually undergo hysterectomy, the system still offers lower direct and indirect health care costs at 5 years compared with immediate hysterectomy.[201,203]

Symptomatic Fibroids and Uterine Adenomyosis

Data support that the LNG IUD is also an effective treatment for heavy menstrual bleeding associated with uterine fibroids.[204,205] However, submucous fibroids may be more likely to cause heavy bleeding and are more likely to lead to LNG IUD expulsion because they distort the uterine cavity.[206] Therefore, effectiveness of the LNG IUD likely depends on fibroid number, size, and location in the uterus.

Uterine adenomyosis also is a common, benign condition that may be associated with heavy menstrual bleeding and pelvic pain. Limited data suggest that the LNG IUD reduces bleeding and pain in women with this condition.[207-209] As with uterine fibroids, expulsion rates appear elevated when IUDs are placed in women with uterine adenomyosis.[200]

Endometriosis

A Cochrane review concluded that the 52-mg LNG IUD reduces pelvic pain and dysmenorrhea associated with endometriosis.[210] Advantages of the LNG IUD in this setting include the absence of hypoestrogenic effects associated with the use of gonadotropin-releasing hormone agonists, as well as lower medication costs. Disadvantages of the LNG IUD include irregular bleeding associated with this approach.

Endometrial Protection With Estrogen Replacement Therapy

Good-quality evidence supports long-term use of the LNG IUD for endometrial suppression during estrogen replacement therapy, and it is approved for this indication in other countries.[211,212] However, the 52-mg LNG IUD is relatively large and may be more difficult to insert into a postmenopausal woman's uterus. The two smaller LNG IUDs may be better choices in menopausal women. Acceptability studies are needed, and more studies are necessary to determine the lowest effective dose of levonorgestrel required to achieve effective endometrial suppression.[213]

Endometrial Protection With Tamoxifen Use

Tamoxifen is commonly used as adjuvant endocrine therapy in the treatment of estrogen receptor–positive breast cancer in premenopausal women and in selected postmenopausal women. In postmenopausal women, tamoxifen increases the risk of endometrial polyps, hyperplasia, and cancer. A systematic review of the 52-mg LNG IUD for prevention of endometrial disease in tamoxifen users concluded that the device reduced the risk of endometrial polyps, but it is not known whether LNG IUD reduces the risk of endometrial hyperplasia or cancer.[214] LNG IUD users had a higher incidence of unscheduled bleeding, which may increase the need for diagnostic intervention in this high-risk group. The FDA lists a personal history of breast cancer as a contraindication to use of all progestational medications, including the LNG IUD. Reflecting the uncertain safety of LNG IUD use in women with breast cancer, guidance released in 2014 from the American College of Obstetricians and Gynecologists does not recommend that this intrauterine system be used in this patient population.[215]

Treatment for Endometrial Hyperplasia or Carcinoma

Although hysterectomy represents the best treatment for early endometrial cancer, progestins are sometimes used to treat endometrial hyperplasia with atypia or early endometrial cancer in women who wish to preserve future fertility or who represent poor surgical candidates due to comorbidities. The 52-mg LNG IUD reverses endometrial neoplastic changes in most women with complex atypical hyperplasia and early-grade endometrial cancer.[216]

Contraceptive Implants

Contraceptive implants provide long-acting, highly effective, convenient, and reversible contraception. All subdermal contraceptive implants for clinical use in humans employ progestins. These methods offer an excellent contraceptive option for women who have contraindications to combined hormonal methods and an option for any woman who desires long-term protection against pregnancy that is rapidly reversible. The only subdermal implant currently available to women in the United States is Nexplanon (Fig. 18.5), released in 2006 as Implanon. In 2011, Nexplanon (a radiopaque implant) replaced Implanon.

Nexplanon contains 68 mg of etonogestrel as a single-rod subdermal implant.[217] The device is approved for 3 years' duration, provides excellent efficacy throughout its use, and is easy to insert and remove by trained practitioners. Nexplanon can be used during lactation; may improve dysmenorrhea; does not significantly affect weight, acne, lipids, or liver enzymes; and has only modest effects on BMD.[218] Like other progestin-only contraceptives, the etonogestrel implant commonly causes irregular vaginal bleeding.

• **Fig. 18.5** The subdermal etonogestrel implant.

Description and Pharmacology

The Nexplanon rod releases the gonane progestin etonogestrel, formerly known as 3-ketodesogestrel, the biologically active metabolite of desogestrel.[218] Desogestrel is used in some oral contraceptives, and etonogestrel is the same progestin used in the contraceptive vaginal ring. The implant is 4 cm long and 2 mm in diameter, is radiopaque, and has a core made from a nonbiodegradable solid composed of ethylene vinyl acetate impregnated with 68 mg of etonogestrel (see Fig. 18.5). The ethylene vinyl acetate copolymer of Nexplanon allows controlled hormone release over at least 3 years of use. Each implant is provided in a disposable sterile inserter for subdermal application. Maximum serum concentrations of etonogestrel are usually seen by day 4 after implant insertion. Etonogestrel levels decrease slightly by 1 year and further by 3 years but remain above the threshold needed to suppress ovulation.[217] After removal, serum levels are undetectable by 1 week in most users, who resume ovulation within 6 weeks of implant removal. Despite effective suppression of ovulation, estradiol levels only fall into the early follicular level range, and the implant does not cause hypoestrogenism. Consistent with that observation, based on limited data from clinical trials, there does not appear to be a clinically significant adverse effect of the etonogestrel implant on BMD.[218]

Mechanism of Action and Efficacy

Nexplanon prevents fertilization primarily by inhibiting ovulation, although some thickening of cervical mucus may also occur.[219] The etonogestrel implant provides highly effective contraception. In an integrated analysis of 11 international clinical trials that included more than 900 healthy women between 18 and 40 years old, no pregnancies were reported while the etonogestrel implants were in place. Six pregnancies occurred during the first 14 days after etonogestrel implant removal. Including these six pregnancies, the cumulative Pearl index (number of pregnancies per 100 woman-years) was 0.38 (Pearl indices were 0.27 and 0.30 at 1 and 2 years, respectively).[219] After the implant has been removed, normal ovulation and fertility rapidly return. Reported pregnancies among implant users have primarily been due to unrecognized pregnancies at the time of insertion and failure to insert the device. Postmarketing data regarding the etonogestrel implant from Australia found a real-world failure rate of 1.07 per 1000 insertions.[220] Of the 218 pregnancies identified in the Australian study, data were insufficient to assess the reason for contraceptive failure in 45 women, and 46 women were determined to have been already pregnant prior to implant insertion. Of the remaining 127 cases, failure to insert the implant resulted in pregnancies in 84 women. Other reasons for contraceptive failure included incorrect timing of insertion (19 cases), expulsion of the implant out of the insertion site (3 cases), and interaction with hepatic enzyme–inducing medications (8 cases). The remaining 13 cases were classified as product failures. However, even when these method failures are accounted for, Nexplanon continues to have one of the highest efficacies of any available reversible or permanent contraceptive.

There are reports of implant failure in women using anticonvulsants, particularly carbamazepine. Accordingly, contraceptive implants are not recommended in women taking anticonvulsants, certain antiretrovirals, or other medications that induce hepatic enzymes.[220-222] Overweight and obese women were not included in the trials for approval of the etonogestrel implant. However, a prospective cohort study that examined 1168 women (28% overweight and 35% obese) found that failure rates were not impacted by BMI.[223]

Package labeling indicates that Nexplanon can be used for up to 3 years. However, the implant appears to retain its efficacy for up to 5 years.[224] In a US study among 291 women who had used the implant for 3 years, no pregnancies occurred during a fourth or fifth year of use.[173] Accordingly, and recognizing that such use is off-label, individuals can be offered the opportunity to extend use to as long as 5 years.

Safety and Side Effect Profile

Nexplanon users commonly experience irregular and unpredictable bleeding patterns, similar to the experience of users of other continuous progestin-only contraceptives. Combined data from 11 clinical trials show that the most common bleeding patterns with the etonogestrel implant are amenorrhea (22%), infrequent bleeding (34%), frequent bleeding (7%), and frequent or prolonged bleeding or both (18%).[225] The number of bleeding days are usually not increased, but the pattern is unpredictable. Of clinical relevance is that bleeding patterns experienced during the initial 3 months predict future patterns for most women. Women with favorable bleeding patterns during the first 3 months tend to continue this pattern throughout the first 2 years of use. Women with unfavorable initial patterns have at least a 50% chance that the pattern will improve. Only 11.3% discontinue use because of bleeding irregularities, mainly because of prolonged flow and frequent irregular bleeding.[225] Most women (77%) with baseline dysmenorrhea experience complete resolution of symptoms due to ovulation suppression. Effective preinsertion counseling on the possible changes in bleeding patterns may improve continuation rates.[126,226] A small, short-term clinical trial found that adding COCs reduces bothersome bleeding in implant users.[227] If a patient using a contraceptive implant desires treatment to reduce bothersome irregular bleeding, the US Selected Practice Recommendations for Contraceptive Use present two options: (1) nonsteroidal anti-inflammatory drugs for 5 to 7 days, or (2) low-dose COCs or estrogen for 10 to 20 days.[8] These treatments may shorten bleeding episodes and offer temporary relief but do not change long-term bleeding patterns. In selected patients experiencing bothersome bleeding due to the contraceptive implant and without contraindications to COC use, the authors recommend long-term use of COCs to reduce such bleeding if the patient desires this therapy.

Several studies observe a small (<1 kg) weight increase in etonogestrel implant users.[219] However, only 3% to 7% of women choose to remove the implant because of weight changes. Similar to the effect seen in women using POPs, ovarian cysts occur in up to 15% of users. Most cysts regress spontaneously and do not need additional treatment.[228]

Nexplanon appears safe for use during lactation.[108] A 2015 Cochrane review did not identify concerns regarding milk volume or composition of infant growth in implant users.[229] Likewise, a Brazilian randomized trial of breastfeeding women found that infant growth was similar with early (prior to hospital discharge) implant placement compared with delayed placement, and that Nexplanon does not appear to change the content of breast milk and does not influence infant growth up to 3 years.[230]

Lipid measurements demonstrate an overall decrease in serum total cholesterol, HDL cholesterol, and low-density lipoprotein cholesterol. Some studies also find a decrease in triglyceride levels. Minor reductions in the HDL/low-density lipoprotein ratio have been observed, although not into ranges thought to be clinically significant. Etonogestrel implant use does not significantly increase the risk of cardiovascular disease.[231]

Migration of contraceptive implants to the systemic vasculature, particularly the pulmonary artery, represents a rare complication of implant placement. Proper superficial placement of implants represents the key to avoiding this serious complication.[232,233]

Patient Selection

Before recommending the contraceptive implant, providers should review the indications and contraindications for its use. Contraindications to etonogestrel implant use are few and include breast cancer, use of hepatic enzyme–inducing drugs, unexplained and unevaluated abnormal vaginal bleeding, severe cirrhosis, systemic lupus erythematosus (SLE) with positive or unknown antiphospholipid antibodies, and liver tumors.[9] There are also reports describing etonogestrel implant failure in a woman taking the antiretroviral drug efavirenz.[234] When counseling women regarding the etonogestrel implant, the clinician should address concerns and fears a woman may have about this method of contraception. Women may have particular concerns about implant removal, although removal problems with single-rod devices such as Nexplanon are uncommon. Side effects (particularly irregular bleeding) should be discussed, as an unexpected side effect may cause women to request early removal of the implant. The implant does not provide protection against STIs. Accordingly, and as is appropriate for all sexually active women, implant users should be reminded about safe sexual practices. Appropriate candidates for implantable contraception are women who desire long-term reversible birth control, have no contraindications to etonogestrel implant use, accept implant insertion and removal, and are ready to accept a change in menstrual bleeding patterns.

Insertion and Removal

Proper insertion and removal techniques are essential for clinical efficacy and for prevention of complications. Timing of insertion depends on the patient's prior use of contraception and the clinician's evaluation of the appropriateness for the individual.[8] In the United States, Nexplanon has been made available only to clinicians who have completed insertion and removal training provided by the manufacturer. Proper training of clinicians reduces the incidence of complications at insertion and removal. Complications of Nexplanon insertion are rare (<2%) but may include local pain, infection, and bleeding. Migration of the implant into the systemic vasculature is described earlier.[232,233] A follow-up visit following implant placement is not routinely indicated.

Before removal, the clinician needs to palpate the implant. Under sterile conditions and after injection of a local anesthetic, a 2- to 3-mm incision is made vertically over the implant. The rod is then removed using the pop-out technique described by Pymar and associates[235] for Norplant System removal. If inserted correctly, removal is usually simple and should take less than 5 minutes. The most common reason for difficulty in removal is placement of the implant too deeply. If the clinician cannot palpate the implant, imaging techniques may be necessary before proceeding.

Emergency Contraception

Emergency contraception (EC) is defined as a drug or device used to prevent pregnancy after unprotected sexual intercourse (including sexual assault) or after a recognized contraceptive failure.[236] Although EC is sometimes called the morning-after pill, this label is confusing because it implies that EC can be taken only the morning after unprotected sexual intercourse. EC, or postcoital contraception, can actually reduce the risk of unintended pregnancy up to 5 days after unprotected sex.

Oral EC is intended as a backup method for occasional use rather than a regular method of contraception. Discussions with patients regarding EC offer an opportunity to discuss longer-term contraception, sexual health and safety, and other preventative women's health measures such as Papanicolaou smears. EC should be readily available to all women at risk for unplanned pregnancy, including adolescents and victims of sexual assault.

Research shows that increased access to EC improves use, but it is not yet clear whether this access translates into a reduction in unintended pregnancy or abortion.[237] Although access is an important factor, how women use EC may be a stronger determinant of its ultimate effect. Even when women have EC at home, they often fail to use it after unprotected sexual intercourse. The most common reason for this is a lack of recognition of the risk of pregnancy or neglect of the perceived risk.[238] Although increasing knowledge of and access to EC is a public health priority, use of regular, ongoing contraception is a more effective way to reduce unplanned pregnancy and abortion.

Emergency Contraception Regimens

The EC currently available to women in the United States includes 1.5-mg levonorgestrel (Plan B One-Step [Duramed Pharmaceuticals, Pomona, NY], Next Choice [Watson Laboratories, Inc., Corona, CA]), 30-mg ulipristal acetate (UPA, Ella, Afaxys Pharma, LLC., Charleston, SC), and the copper T 380A IUD (Paragard [CooperSurgical, Trumbull, CT]).

In 2009, a one-dose 1.5-mg levonorgestrel tablet was introduced (preferred over the previous 0.75-mg two-dose regimen), which should be taken as soon as possible after unprotected intercourse and is labeled for use up to 72 hours following intercourse.[236] The medication is available without a prescription. A prescription was previously required for those younger than 17 years, but there are now no age restrictions for access to levonorgestrel EC without a prescription following FDA approval in 2014. The progestin-only oral EC regimen is better tolerated than the older Yuzpe method of EC that used high doses of COCs.

UPA was approved in 2010 for EC in the United States and is marketed as Ella.[239] UPA is a progesterone receptor modulator in the same class as mifepristone and is more effective than levonorgestrel EC.[236] UPA requires a prescription, and although it should be taken as soon as possible after unprotected intercourse, it has been shown to be effective for up to 5 days.[240]

The copper T 380A IUD may be inserted for EC up to 5 days after unprotected intercourse, although some evidence suggests that it may still be effective when inserted up to 10 days post intercourse.[241-243] Although the copper T is a highly effective form of EC, with the advantage of providing ongoing longer-term contraception for women,[244] the requirement for specialist insertion and the cost of the device may act as a barrier to access.

Mechanism of Action

The mode of action of hormonal EC is multifactorial and not completely understood. Because sperm are viable in the female reproductive tract for up to 5 days but eggs can be fertilized only within 1 day of ovulation, the mechanism of action depends on when the oral EC regimen is given in relation to the time of intercourse and time of ovulation.

Levonorgestrel EC prevents or delays ovulation if administered before the commencement of the LH surge and is ineffective if taken afterward.[236,245] UPA is a selective progesterone receptor modulator with different proposed mechanisms when taken at different times of the menstrual cycle. UPA administered before the commencement of the LH surge inhibits follicular development, and when taken during the LH increase but prior to the peak, it delays follicular rupture.[246] Neither oral agent has been shown to interfere with implantation directly. Therefore, they are not considered abortifacients or teratogenic to a developing pregnancy.[247,248]

The mechanism of action of the copper IUD is thought to be the release of copper ions toxic to sperm function while associated inflammation potentially impairs transport of ovum or implantation of the fertilized egg.[249]

Efficacy

The effectiveness of EC depends on the mechanism of action and when the EC regimen is given in relation to the time of unprotected intercourse. The probability of pregnancy after a single act of unprotected intercourse varies (3–8%) according to the day of the menstrual cycle and the couple's fertility status.[250] Calculating the efficacy of EC is complex because it is impossible to know how many pregnancies would otherwise have occurred. Therefore, an estimation of efficacy is the failure rate of the contraceptive method—that is, the rate of pregnancy following administration.

The most effective EC is the copper IUD, with a failure rate of less than 0.1%.[241] With regard to oral EC, UPA has greater efficacy over levonorgestrel because it more effectively delays follicular rupture and has a longer action well into the LH surge.[251] A recent systematic review directly comparing UPA and levonorgestrel demonstrated that UPA almost halved the risk of pregnancy compared with levonorgestrel when given within 120 hours of unprotected sexual intercourse; the failure rate of UPA when administered within 120 hours is 1.3%.[252] Moreover, when given within 24 hours of intercourse, UPA reduces the risk of pregnancy by almost two thirds compared with levonorgestrel, with a failure rate of 0.9%.[253]

After a single episode of unprotected intercourse, the use of levonorgestrel-only EC is more effective than no treatment at all.[254] Taking a total of 1.5 mg of levonorgestrel in a single dose is as effective as the 0.75-mg split dose, and single dosing is more user-friendly.[252] The timing of levonorgestrel EC influences its effectiveness. Waiting 12 hours to initiate treatment after unprotected intercourse increases the odds of pregnancy by almost 50%, and its efficacy decreases linearly with time.[255]

The efficacy of oral EC may be reduced with increased BMI. One study used a subanalysis to demonstrate the effect of BMI on contraceptive efficacy; levonorgestrel was shown to be ineffective in overweight women (with a BMI >26 kg/m^2) compared with UPA, which was ineffective in obese women (with a BMI >35 kg/m^2).[256] Women should not be denied access to EC based on BMI, but the potential impact of weight on EC efficacy should be discussed and considered in agent selection. Some European authorities have recommended increasing the dose of levonorgestrel EC to 3 mg in the setting of obesity and also when a woman is taking concomitant liver enzyme–inducing drugs.[257] The efficacy of the copper IUD is not affected by BMI.

Indications

EC is indicated for any woman at risk for unintended pregnancy from an episode of contraceptive failure or unprotected intercourse. Experts recommend the advance provision of EC to women.[258] However, surveys have found that the level of knowledge and use of EC in the United States by women and their health care providers is low.[259]

No clinical examination or pregnancy testing is required before using oral hormonal EC.[9] Given the infrequent use and short duration of action of EC, the medical contraindications to regular oral contraceptives are not applicable. USMEC recommendations state that women with previous ectopic pregnancy, cardiovascular disease, migraines, or liver disease can use EC.[9] Current guidelines advise that breastfeeding should be avoided for 1 week after using UPA; breastfeeding women should continue to express and discard milk during this time.[260]

The only contraindication to the oral EC regimens is allergy to the active substance. Pregnancy is a relative contraindication because EC is ineffective if a pregnancy is already established; as discussed earlier, there is no evidence demonstrating teratogenicity to a developing pregnancy. There may be reduced efficacy of oral EC in women with severe malabsorption syndromes and those taking hepatic enzyme–inducing drugs and certain antiretroviral drugs. Contraindications for the copper IUD for EC are the same as those for regular contraceptive use.[9]

Side Effects

The FDA has determined that levonorgestrel EC is safe enough to be available without a prescription in states with direct pharmacy access. UPA has an excellent safety profile and is available over the counter throughout Europe but requires a prescription in the United States. The side effects of the copper IUD for EC are the same as those for its use for long-term contraception.

No deaths or serious complications have been directly linked to EC. The most common short-term side effects of oral EC include nausea, vomiting, and irregular bleeding, which affect up to 20% of users. Irregular bleeding caused by hormonal EC typically resolves by the next menstrual cycle. Other minor adverse effects reported by women in clinical trials include dizziness, fatigue, breast tenderness, headache, and abdominal pain.[252] If vomiting occurs within 3 hours of taking oral EC, most experts recommend that the dose be repeated.[236]

After hormonal EC is taken, menses usually occurs within 1 week before or after the expected time. Women using levonorgestrel are more likely to experience early menstruation, whereas women using UPA are more likely to experience delayed menstruation.[252] If the delay in the onset of menses is greater than 1 week or if the expected menses is lighter than usual, a pregnancy test should be performed. A woman should also be advised to seek medical attention for continued irregular bleeding or abdominal pain, as these symptoms may be a sign of a spontaneous abortion or ectopic pregnancy.

Ongoing Contraception

As outlined previously, hormonal EC can postpone ovulation, making a woman vulnerable to pregnancy later in the cycle. Women should therefore be counseled to begin a regular method of contraception after using EC. However, there is preliminary data demonstrating that hormonal contraception, particularly oral progestins, could reduce the efficacy of UPA.[261] Further research is needed into the mechanism and risk profiles of various therapies. It has been suggested that commencement of regular hormonal contraception should be delayed for 5 days after the administration of UPA, and that women should either abstain from sexual intercourse or use barrier protection for that duration.[8,261,262]

Clinical Challenges in Contraceptive Care

Hormonal Contraception for Adolescents

Although on the decline, rates of teenage pregnancy are higher in the United States than in other Western industrialized countries.[6,263] Approximately 75% of these pregnancies are unplanned, of which about 38% end in induced abortion.[3] Teenage pregnancy and parenting are risk factors for adverse medical, educational, and psychosocial outcomes for mother and child.[264] Children of teenage mothers are at greater risk for preterm birth, low birth weight, neonatal death, and later behavioral problems and poor academic performance.[265] Teenage parenting contributes to the intergenerational transmission of poverty.[266] Sexually active adolescents are more motivated to use contraception if they are academically successful, believe that pregnancy would be an impediment to their goals, and are involved in a stable relationship with a sexual partner.[267]

Considerations for clinicians advising adolescents about contraception should include the potentially high fertility rates in these young women, their high rates of unprotected intercourse, elevated risk of sexual assault, and increased risk of STIs.[268] Consistent and correct use of contraceptive methods can be challenging for adolescents, and long-acting methods increase efficacy.[132] These methods, including the DMPA injection, contraceptive implants, and IUDs, should be made available to teens.[184,269] With proper patient selection and counseling, IUDs and implants can be successful contraceptive options for adolescents.[184,270] Clinicians should also be aware of the legal conditions surrounding prescribing contraception to minors in the state in which they are practicing.

Sexually active adolescents benefit from health guidance annually regarding responsible health behaviors, including abstinence, latex condoms to prevent STIs, and appropriate methods of birth control, along with instructions on ways to use them effectively.[268] Adolescents should also be counseled in a nonjudgmental manner about the need to use condoms for all types of intercourse, including anal and oral intercourse. Barriers to effective contraception use by adolescents include lack of forward planning, nonconsensual intercourse, lack of confidential care, fear of disapproval by parents and doctors, absence of adolescent-friendly services, language and cultural barriers, fear of pelvic examination, and cost.[271] Misconceptions about contraception, including effects on weight gain, future fertility, acne, and risk of cancer, may also prevent adolescents from using effective contraception and should be addressed in counseling. The National Campaign to Prevent Teen and Unplanned Pregnancy, now called *Power to Decide*, operates a website that provides excellent information, decision tools, and reminders specifically designed for young women at https://www.bedsider.org.

Combined Hormonal Contraceptives in Adolescents

Although COCs, the patch, and the ring represent safe and effective methods for adolescents, many young women are not effectively educated about correct use and anticipated side effects. They may use these short-acting hormonal contraceptives inconsistently, which will lead to very high pregnancy rates.[271] During counseling, it is important to provide clear oral and written instructions about initiating these methods, ways to ensure correct use, and what to do if one or more pills are missed or if the patch or ring is not used correctly. By the same token, POPs are not favored for adolescents because they require stricter adherence for efficacy.

Initiating or continuing hormonal contraception does not require pelvic examination, cervical cancer screening, or STI screening in adolescents or older reproductive-age women.[8] A history excluding contraindications, blood pressure measurement, and being reasonably sure the patient is not pregnant is sufficient before initiating hormonal contraception.[272] Age-appropriate screening for STIs or cervical cancer should be considered regardless of contraceptive use. Screening for chlamydial infection and gonorrhea, as recommended by the CDC for women under the age of 26 years, can be accomplished through urine tests or a vaginal swab without a speculum.[198] The use of condoms should be encouraged in conjunction with the use of hormonal contraceptives to prevent STIs.

Initial follow-up should be 8 to 12 weeks after commencing the COCs to monitor correct use and adverse events and should be done thereafter at 6- to 12-month intervals. Education and ongoing counseling are essential to ensure correct usage. Many adolescents are concerned that the COCs will cause weight gain or acne, and these issues should be directly addressed.[271] Chewable pills are available and may be more acceptable to young women who find it difficult to swallow pills. Unscheduled bleeding may be less acceptable to adolescents than adult women. Clinicians must consider the possibility that unscheduled bleeding represents cervicovaginal infection in this high-risk population and investigate and treat it accordingly.

Injectable Contraceptives in Adolescents

Discontinuation rates for DMPA in adolescents are high, with half of adolescents discontinuing the method by 12 months.[273] However, because DMPA suppresses ovulation for an extended period of time, prior use of DMPA protects many adolescents from unintended pregnancy despite inconsistent use. Weight gain is the most commonly cited reason for adolescents to discontinue DMPA, and it may be more common in obese adolescents.[115] Although loss of bone density has been a concern in adolescents using DMPA, the position statement of the Society for Adolescent Medicine is that DMPA represents an extremely effective contraceptive, and that clinical concerns about loss of BMD must be placed within the context of likely bone recovery on discontinuation, low risk of fractures, and benefits of preventing unintended pregnancy among adolescents.[274]

Hormonal Contraception in Postpartum and Lactating Women

The postpartum period is a critical time period for initiating contraception to help women achieve optimal interpregnancy intervals.[275] The immediate postpartum period offers an ideal time for women to initiate contraception because of patient access and convenience. Delaying initiation of contraception until the standard 6-week postpartum visit places many women at risk for unintended pregnancy. By 6 weeks postpartum, up to 40% of women will have had unprotected intercourse, and nearly 50% will have ovulated if they are not breastfeeding.[276,277] Furthermore, not all women seek postpartum medical care, resulting in a large proportion of women with unmet contraceptive needs.[278] Return of fertility is, of course, postponed in breastfeeding women who meet criteria for the lactational amenorrhea method of contraception.

Postpartum women remain in a hypercoagulable state for weeks after childbirth.[279,280] This elevated risk does not resolve until 12 weeks postpartum, although after 6 weeks the risk is low (22 cases per 100,000 deliveries within 6 weeks and falling to three cases

per 100,000 deliveries in weeks 7–12).[281] Risk factors for VTE in the postpartum period include age 35 years or older, previous VTE, thrombophilia, immobility, transfusion at delivery, peripartum cardiomyopathy, BMI 30 kg/m^2 or higher, postpartum hemorrhage, cesarean delivery, preeclampsia, and smoking.[282] The USMEC recommends deferring use of estrogen-containing methods (category 4) until 3 weeks after delivery in all women and until 4 weeks in breastfeeding women.[9] The guidelines further state that the risks of using estrogen-containing methods outweigh the benefits in those with risk factors for VTE starting 6 weeks postpartum.

Traditionally, combined hormonal contraception has not been recommended as the first choice for lactating women because of concerns that the estrogenic component can reduce the volume of milk production and the caloric and mineral content of breast milk.[229] However, use of COCs by well-nourished breastfeeding women does not appear to result in problems with infant development. Data regarding this concern is limited and inconsistent, with two recent systematic reviews unable to draw firm conclusions regarding the effect of COCs on breastfeeding duration and infant outcomes.[229,283] On an individual level, it is important to note that some women might be at risk for breastfeeding difficulties, and if full breastfeeding is desired, counseling regarding these concerns is warranted. USMEC guidelines allow use of estrogen-containing methods after 30 days postpartum in breastfeeding women without risk factors for VTE.[9]

Evidence from limited studies suggests that progestin-only contraception does not interfere with lactation or infant development and does not increase risk of thromboembolic disease.[102,107] It appears reasonable to initiate progestin-only contraception, including DMPA, POPs, and implants, immediately after delivery, regardless of whether mothers are nursing their infants. There is a theoretical concern, nevertheless, that initiation of progestin methods immediately postpartum could preempt lactogenesis, given that progesterone withdrawal after delivery of the placenta is thought to trigger prolactin secretion.[229] Although long-term data are limited, observational studies of progestin-only contraceptives suggest that they have no effect on successful initiation and continuation of breastfeeding or on infant growth and development even when started immediately postpartum.[107] IUDs are also an option either immediately after delivery of the placenta or as an interval insertion (4–6 weeks postpartum) provided that there is no evidence of chorioamnionitis or postpartum endometritis or sepsis. Higher risk of expulsion with postplacental IUD insertion compared with interval insertion should be balanced against the benefit of immediate access to a highly effective contraceptive method, especially in women at risk for not returning for postpartum follow-up.[284]

Hormonal Contraception in Women Older Than 35 Years

There are no contraindications to use of hormonal contraceptives on the basis of age alone.[9] However, risks associated with the use of some methods may increase with age and additional comorbid conditions. For example, although the incidence of VTE, myocardial infarction, and stroke is low, these risks increase with age, obesity, smoking, diabetes, migraine headaches with aura, and hypertension.[72,285] However, because lean, healthy, nonsmoking women are at low risk for these rare events, they can use any method, including combined (estrogen-progestin pills, patch, and vaginal ring) methods, until menopause.[286] Large US population-based case-control studies have found no increased risk of myocardial infarction or stroke among healthy, nonsmoking women older than 35 years who use COCs formulated with less than 50 μg of estrogen.[287,288] Perimenopausal women may benefit from a positive effect on BMD,[289] abnormal uterine bleeding,[290] and a reduction in vasomotor symptoms[291] offered by COCs. In addition, COC use is associated with a reduced risk of endometrial cancer and ovarian cancer, which is of particular importance to older reproductive-age women. Progestin-only hormonal contraceptives and IUDs are preferred for older women at elevated risk for VTE, myocardial infarction, and stroke.[292-294] It is unknown if long-term older DMPA users can regain BMD levels to baseline before entering menopause. For this reason, DMPA in women older than 45 years is USMEC category 2, and the other progestin-only methods are category 1. The LNG IUD is particularly effective for perimenopausal bleeding.[295,296]

Discontinuation of Hormonal Contraception at Menopause

When deciding to stop use of a contraceptive method, the benefits and risks of the method must be evaluated in the context of the diminishing risk of pregnancy as the woman ages. The median age of menopause in North America is 51 years, and about 90% of women will have reached menopause by age 55.[297] Although pregnancy is uncommon after age 44, spontaneous conception can occur. Assessment of follicle-stimulating hormone levels to determine when hormonal contraceptive users have become menopausal and thus no longer need contraception may be misleading and should not be routinely performed.[8] Until a well-validated tool to confirm menopause is available, it is appropriate for healthy, nonsmoking women using a hormonal contraceptive to continue until age 50 to 55 years, after weighing the risks and benefits.[9] Thus, most women will be able to use contraception safely until they are assured of menopause. At the time they discontinue hormonal contraception, some midlife women will choose to initiate menopausal hormonal therapy.

Contraception in Women With Underlying Medical Conditions

Because pregnancy in women with underlying medical conditions is associated with higher risks of maternal and perinatal morbidity and mortality, achieving effective contraception is particularly important in this setting[298] (Table 18.6). Providers should remember that the risk of using a contraceptive must be balanced with the risk of pregnancy. Although numerous studies have addressed safety and effectiveness of hormonal contraceptive use in healthy women, data unfortunately are far less complete for women with underlying medical problems or other special circumstances. The US Medical Eligibility Criteria for Contraceptive Use from the CDC provides an important evidence-based resource for clinicians.[9]

Decisions regarding contraception for women with coexisting medical problems may be complicated. In some cases, medications taken for certain chronic conditions may alter the effectiveness of hormonal contraception, and pregnancy in these cases may pose substantial risks to the mother and her fetus. Differences in content and delivery methods of hormonal contraceptives may affect patients with certain conditions differently. Because transdermal and vaginal ring contraception are relatively new, less data address their use in women with medical concerns. In the absence

TABLE 18.6 Conditions Associated With Increased Risk for Adverse Health Events as a Result of Unintended Pregnancy

- Breast cancer
- Complicated valvular heart disease
- Diabetes: insulin dependent; with nephropathy/retinopathy/neuropathy or other vascular disease; or of >20 years' duration
- Endometrial or ovarian cancer
- Epilepsy
- Hypertension (systolic >160 mm Hg or diastolic >100 mm Hg)
- History of bariatric surgery in the past 2 years
- HIV/AIDS
- Ischemic heart disease
- Malignant gestational trophoblastic disease
- Malignant liver tumors (hepatoma) and hepatocellular carcinoma of the liver
- Peripartum cardiomyopathy
- Schistosomiasis with fibrosis of the liver
- Severe (decompensated) cirrhosis
- Sickle cell disease
- Solid organ transplantation within the past 2 years
- Stroke
- Systemic lupus erythematosus
- Thrombogenic mutations
- Tuberculosis

AIDS, Acquired immunodeficiency syndrome; *HIV*, human immunodeficiency virus.

From Curtis KM, Tepper NK, Jatlaoui TC et al. US medical eligibility criteria for contraceptive use, 2016. *MMWR Recomm Rep*. 2016;65:1–104.

of more extensive data, contraindications to the use of estrogen-progestin COCs should also be considered as contraindications to the use of transdermal and vaginal ring contraception. Practitioners should recognize that use of nonhormonal forms of contraception, such as the copper IUD, remain a safe, effective choice for many women with medical conditions.

Hormonal Contraception in Obese Women

The proportion of American adult women who are obese (BMI of 30 kg/m^2 or higher) has increased to 38%.[299] Studies show that obese women have similar levels of sexual activity and unintended pregnancy compared with normal weight women.[300] No methods of contraception are contraindicated in obese women.[9,301] As noted earlier, oral EC may be less effective in obese women. Although the efficacy of oral contraceptives and the transdermal patch in obese women has been questioned, a 2016 Cochrane review found that there was generally no association between BMI and the effectiveness of hormonal contraceptives.[302] Similarly, the overall risk for unintended pregnancy in women using the combined hormonal pill, patch, or ring was not significantly different across BMI categories, with an overall range of 8.4% to 11.0% at 3 years of use in a prospective cohort study of 1500 women.[303] This study was not able to evaluate efficacy separately among pill, patch, and ring users.[304] A recent large, prospective cohort study of more than 52,000 women reported a slight increase in failure rates of COCs as BMI increased (hazard ratio of 1.5 for BMI higher than 35; 95% CI, 1.3–1.8), adjusting for age, parity, and education.[20] However, this difference disappeared when evaluating pills dosed in a 24/4 fashion compared with 21/7 regimens. The ability to detect small differences in contraceptive efficacy between normal weight and obese women may be obscured by adherence issues with short-term methods.[305]

Efficacy of COCs, contraceptive rings, and transdermal patches primarily reflects suppression of ovulation resulting from the dose of progestin. Pharmacokinetic studies show that, compared with normal weight women, it takes twice as long for obese women to reach steady-state therapeutic levels of contraceptive steroids when starting the pill or after the HFI due to changes in clearance.[306,307] Therefore, these episodes might represent a vulnerable time period for this population. It is possible that continuous oral contraceptive use or oral contraceptives with a shorter HFI may be more effective in obese women. Evidence evaluating the effectiveness of the patch and vaginal ring among obese women is limited, but both provide more effective contraception than barrier methods alone.[89,301,308,309] Among overweight and obese women, higher pregnancy rates have not been observed with use of the 150-mg intramuscular DMPA or 104-mg subcutaneous formulations[116,310] or the etonogestrel implant.[311] Considering that IUDs work locally on the uterus and do not rely on systemic drug levels, their efficacy is not affected by BMI.[305]

Combined hormonal contraceptives are rated USMEC category 2 for obese women due to theoretical concerns about arterial and VTE. Although obesity and use of combined hormonal contraceptives represent independent risk factors for VTE,[285,312,313] the absolute risk of VTE with combined contraceptives in obese women is still less than the risk of VTE during pregnancy and the puerperium in obese women.[314,315] The evidence of an increased risk of acute myocardial infarction or stroke in obese users of COC is conflicting,[316] but the overall absolute risk of these events in reproductive-age women is low.[72] That being said, obese women are more likely to have other comorbidities, such as hypertension, hypercholesterolemia, and diabetes. No published studies address the safety of combined hormonal contraceptives in obese women with these comorbidities. Accordingly, consideration should be given to progestin-only and intrauterine methods when counseling obese individuals regarding contraceptive choices, particularly when such patients are older than 35 years. Because obese women experience an elevated risk for abnormal uterine bleeding and endometrial neoplasia, use of the LNG IUD represents a particularly sound choice in this patient population.[317,318]

Individuals who undergo bariatric surgery that may compromise the absorption of oral medications (Roux-en-Y gastric bypass or biliopancreatic diversion) should use oral contraceptives with caution (USMEC category 3).[319] There are no similar concerns for women who have had restrictive types of bariatric surgery (vertical banded gastroplasty, laparoscopic adjustable gastric band, or laparoscopic sleeve gastrectomy).

Hormonal Contraception in Women Taking Antiepileptic Drugs

Effective contraception is a critical component in management of the female patient with epilepsy because of increased risk of seizures in pregnancy, teratogenic effects of some antiepileptic drugs (AEDs), and the multitude of interactions between AEDs and hormonal contraception.[320] AEDs that induce hepatic enzymes can decrease serum concentrations of one or both of the estrogen or progestin component of oral contraceptives.[321] Risk of COC failure may be increased in the presence of CYP3A4 enzyme inducing, such as carbamazepine, felbamate, lamotrigine, phenobarbital, phenytoin, oxcarbazepine, primidone, topiramate, and rufinamide. Concomitant use of AEDs that induce hepatic enzymes with combined hormonal contraceptives is rated USMEC category 3, given that the increased risk of pregnancy

generally outweighs the benefits. Lamotrigine is a special case in that estrogen-containing contraceptives increase metabolism of lamotrigine, reducing drug levels.[322,323] Therefore, dose adjustments of lamotrigine will be needed if the two medications are used together. In addition, during the HFI, lamotrigine levels may increase.

As a high-dose contraceptive, injectable contraception (DMPA) appears effective with concomitant AED use, and IUDs are highly effective in women taking anticonvulsants. The USMEC recommends that when women taking liver enzyme–inducing medications use COC, a formulation containing a minimum of 30 μg of ethinyl estradiol should be used. In addition, expert opinion recommends selecting an oral contraceptive with a progestin that has a longer half-life (drospirenone, desogestrel, levonorgestrel) or using formulations with HFIs shorter than 7 days, or active pills in a continuous fashion, to potentially improve efficacy.[20,324] Given that the norethindrone POP available in the United States is dosed too low to consistently suppress ovulation, this contraception does not represent a sound choice for women taking enzyme-inducing AEDs. Data are limited for the contraceptive patch and vaginal ring. Contraceptive failures have also been reported in women taking enzyme-inducing AEDs and using the etonogestrel implant system (Nexplanon).[220-222]

Hormonal Contraception in Women Taking Antibiotics

Although there have been many retrospective case series and anecdotal reports of COC failure in women taking concomitant antibiotics, pharmacokinetic evidence of lower serum steroid levels exists only for rifampin.[80,81] Women taking rifampin should not rely on oral, transdermal, vaginal ring, or implantable contraception alone for protection. In contrast to rifampin, use of ampicillin, doxycycline, fluconazole, metronidazole, miconazole, quinolones, and tetracycline have not lowered steroid levels in women using COCs. The use of combined hormonal methods is not restricted among women taking broad-spectrum antibiotics, antifungals, or antiparasitics.[9]

Hormonal Contraception in HIV-Positive Women

More than 17 million women, many of reproductive age, are infected with HIV.[325] HIV transmission increasingly is linked to heterosexual intercourse. The role of hormonal contraception in HIV-positive women has been controversial. There may be an increased risk for acquiring or transmitting HIV in DMPA users, but DMPA is a needed contraceptive in areas of high HIV prevalence (sub-Saharan Africa) where there are limited alternative contraceptive options.[166] The USMEC recently revised its recommendation for the use of DMPA among women at increased risk for HIV acquisition based on a systematic review of progestin injectables that found a possible increased risk for HIV acquisition (adjusted hazard ratio 1.4; 95% CI, 1.2–1.6) in this population.[166] The current recommendation is that the advantages of DMPA still outweigh the theoretical or proven risks (category 2) among women at high risk for HIV infection, but women should be counseled regarding these issues.[165] POPs, combined hormonal methods, and implants are safe (category 1) for women at high risk for HIV infection or infected with HIV. Hormonal contraceptives, including DMPA, do not appear to have an impact on HIV disease progression.[326] For women on antiretroviral therapy, it is important to note there are several drug-drug interactions with hormonal contraceptives (particularly some non-nucleoside reverse transcriptase inhibitors and ritonavir-boosted protease inhibitors). These interactions might alter the safety and efficacy of both the hormonal contraceptive and the antiretroviral drug. The website https://www.hiv-druginteractions.org is kept up to date as new evidence emerges and new drugs are released. Case reports suggest that the antiretroviral drug efavirenz reduces contraceptive implant protection; IUDs and DMPA represent preferable contraceptive choices for women taking this medication or others that induce hepatic enzymes.[234]

IUDs are allowed by the USMEC for women with HIV (category 1), as there is no evidence that they are at higher risk for infectious complications than HIV-uninfected women.[166] The IUD has not been shown to affect disease progression or increase risk of transmission to sex partners. For women with acquired immunodeficiency syndrome, IUDs can be used if they are clinically well on antiretroviral therapy (category 1) and also considered if they are not (category 2). All IUD users with acquired immunodeficiency syndrome should be closely monitored for pelvic infection.

Hormonal Contraception and Chronic Hypertension

Blood pressure should be measured prior to initiating combined hormonal contraceptives.[8,327] Although few women develop overt hypertension after starting combined hormonal contraceptives, blood pressure should be checked at follow-up visits.[328] Modern low-dose COCs may increase systolic and diastolic blood pressure, on average, by 8 and 6 mm Hg, respectively.[329] This increase is thought to be secondary to increased activation of the renin-angiotensin system.[330] Nevertheless, a systematic review of the literature found that only a small percentage of women developed incident hypertension in up to 2 years of follow-up after starting a COC.[331]

For women with preexisting hypertension, the concern with combined hormonal methods is the increased risk of arterial thrombosis leading rarely to myocardial infarction and stroke. In women with stage 1 hypertension (systolic 140–159 mm Hg or diastolic 90–99 mm Hg), combined hormonal contraceptives should not be used unless no other method is appropriate or acceptable to the patient (USMEC category 3).[9] Women with stage 2 hypertension (systolic ≥160 mm Hg or diastolic ≥100 mg Hg) or vascular disease should not use combined hormonal contraceptives (USMEC category 4). Women on antihypertensive medication represent a separate category (see Table 18.2). Although the risk of cardiovascular disease in women with hypertension adequately controlled with medications should be reduced, there are no data on the use of combined hormonal contraceptives in this population. Therefore, use of combined hormonal contraceptives in these women requires clinical judgment (USMEC category 3). Women with well-controlled and monitored hypertension who are age 35 years or younger may be appropriate candidates for a trial of combined contraceptives, provided that they are otherwise healthy, show no evidence of end-organ vascular disease, and do not smoke cigarettes. If blood pressure remains well controlled with careful monitoring several months after contraceptive initiation, use can be continued.

Progestin-only contraceptives, such as DMPA, POPs, the etonogestrel implant, or the LNG IUD, are appropriate options in women with hypertension. Unlike other progestins, the use of DMPA in women with stage 2 hypertension (systolic ≥160 mm Hg or diastolic ≥100 mm Hg) is generally not

advised because of the theoretical risk of unfavorable lipoprotein changes (USMEC category 3).[9] However, risks and benefits of the method need to be weighed against risks of adverse pregnancy outcomes in women with hypertension. Blood pressure measurement prior to or during the use of progestin-only methods is not necessary.[8]

Hormonal Contraception in Women With Diabetes

A systematic review concluded that hormonal contraceptives have limited effect on carbohydrate metabolism in women without diabetes.[332] Likewise, COCs do not appear to impair carbohydrate metabolism or affect vascular disease in diabetic women. A history of gestational diabetes is not a contraindication to hormonal contraceptives. However, studies are limited and do not inform the management of diabetic women who are overweight.[333] Additionally, clinicians should consider the presence of other cardiovascular risk factors in a diabetic patient, such as obesity, smoking, hypertension, and age, when evaluating for hormonal contraception.

For women with diabetes of more than 20 years' duration or evidence of microvascular disease (retinopathy, nephropathy, or neuropathy), combined hormonal contraceptives are generally contraindicated (USMEC category 3 or 4 depending on the severity of the condition).[9] Due to the concern about possible hypoestrogenism during use of injectable contraception and effect on HDL levels,[334] DMPA is given a category 3 rating for women with diabetes of more than 20 years or evidence of microvascular disease, indicating that the risks usually outweigh the benefits.

The POP, IUDs, and implant are suitable for women with diabetes. A clinical trial found that metabolic control was similar in women with uncomplicated diabetes randomized to a copper IUD or the LNG IUD.[335]

Hormonal Contraception in Women Awaiting Surgery

VTE with pulmonary embolism remains a major cause of fatalities associated with surgical (including gynecologic) procedures.[336] There is concern that combined hormonal contraception use around the time of surgery may increase this risk. The procoagulant changes of COCs take 6 weeks or longer to resolve after discontinuation.[337] The benefits associated with stopping combined hormonal contraceptives 1 month or more before major surgery should be balanced against the risks of an unintended pregnancy. The USMEC recommends that COCs be discontinued before major surgery with an anticipated prolonged immobilization postoperatively (category 4).[9] In addition, patients with risk factors for VTE, such as prior VTE or undergoing high-risk procedures (e.g., major abdominal-pelvic surgeries, major orthopedic surgeries, or cancer surgery), may consider discontinuing COCs. Otherwise, for any major surgery for which the patient is expected to be ambulatory immediately after surgery, it is not necessary to discontinue combined hormonal contraceptives. Because of the low perioperative risk of VTE, it is not considered necessary to discontinue combined hormonal contraceptives before laparoscopic tubal sterilization or other minor surgical procedures not known to be associated with an elevated VTE risk. Progestin-only and intrauterine contraceptives are not expected to be associated with an increased risk of perioperative VTE.

Hormonal Contraception in Women With a History of Thromboembolism

Women with an acute deep vein thrombosis or pulmonary embolism, documented history of unexplained VTE, recurrent VTE or VTE associated with pregnancy, exogenous estrogen use, known thrombophilia or antiphospholipid antibody syndrome, or active cancer should not use combined hormonal contraceptives (USMEC category 4).[9,338] With respect to women not using anticoagulants, the risk of recurrent VTE depends on whether the initial deep vein thrombosis was associated with a permanent (e.g., factor V Leiden) or reversible (e.g., surgery) risk factor.[339] Therefore, a COC candidate who had experienced a single episode of VTE years earlier associated with a nonrecurring risk factor (e.g., VTE occurring after immobilization following a motor vehicle accident) may not currently be at increased risk for VTE. Accordingly, the decision to initiate estrogen-containing contraceptives in such patients can therefore be individualized. Most studies have not found an increased VTE risk with use of progestin-only contraception; therefore, these methods and IUDs are not contraindicated in women at increased risk of thromboembolism.[102]

Hormonal Contraception in Women Taking Anticoagulation Therapy

Long-term risks of warfarin for reproductive-age women include heavy or prolonged menstrual bleeding and rarely include hemoperitoneum after rupture of ovarian cysts. Warfarin is also a teratogen. Because the risk of recurrent thrombosis is reduced in women on therapeutic anticoagulation, some authorities recommend that use of estrogen-containing contraceptives can be considered for anticoagulated women with a prior history of venous thrombosis on a case-by-case basis, especially if alternative methods are not acceptable to the woman or contraindicated and they have a low risk of recurrence (USMEC category 3).[340] Among women with a history of thromboembolic disease participating in clinical trials of anticoagulants, use of hormonal contraceptives, including combination methods, does not elevate the risk of recurrent thrombosis among women using anticoagulants.[340] Accordingly, among chronically anticoagulated women, use of combination hormonal contraceptives may be appropriate. Because of its high contraceptive efficacy and ability to suppress uterine bleeding, use of LNG IUDs also represents a useful option for some anticoagulated women and is preferred over the copper IUD in this setting.[341-345] Intramuscular injection of DMPA consistently suppresses ovulation, and limited evidence has not revealed injection site problems, such as hematoma, in anticoagulated women.[346] Similar injections (e.g., influenza vaccine) in anticoagulated women have not shown risk of hematoma.[347] Accordingly, DMPA represents a useful contraceptive for anticoagulated women. There are no data on the risk of hematoma formation at the insertion site of contraceptive implants; however, it is unlikely to be a greater risk than that associated with intramuscular DMPA injections.

Hormonal Contraception for Women With Migraine Headaches

Headaches are common in women of reproductive age. Most of these headaches are tension headaches, not migraines.[348] Some women with migraines experience improvement in their symptoms with use of hormonal contraceptives, and some women's symptoms worsen. Because the presence of true migraine

headaches with aura affects the decision to use estrogen-containing contraception, careful consideration of the diagnosis is important. Most migraines occur without aura. Nausea, vomiting, photophobia, phonophobia, or visual blurring occurring before or during a migraine headache do not constitute aura. According to the International Headache Society, an aura is the complex of neurologic symptoms that occurs usually before the headache, but it may begin after the headache has begun.[349] A typical aura is reversible, lasts less than 60 minutes, and can consist of visual symptoms such as a zigzag figure (fortification spectrum, so named due to its resemblance to the walls of a medieval fortress) spreading across the visual field, sensory symptoms such as pins and needles, speech disturbances, or motor weakness.

Although the absolute risk of ischemic stroke is low in women of reproductive age, migraine with aura is an independent risk factor for stroke. Most studies note a higher risk of stroke in women who have migraine with aura than in those who have migraine without aura.[350,351] The assumption is that aura is associated with ischemic changes.[352] Use of combined hormonal contraception by itself also increases the risk of stroke in women, although the absolute risk is still low.[353] The elevated risk of ischemic stroke is likely due to the hypercoagulable state caused by estrogen. The risk of stroke among women using combined hormonal contraception rises with increasing age from 3.4 per 100,000 women-years in adolescents to 64.4 events per 100,000 women-years among women age 45 to 49 years.[72] In a recent case control study, investigators found combined hormonal contraceptive use by women with migraines with aura synergistically increased the risk of stroke.[54] In contrast, use of combined hormonal contraception by women with migraines without aura did not increase the risk over baseline. Although cerebrovascular events occur rarely among women with migraine with aura who use COCs, the impact of a stroke can be so devastating that clinicians should consider the use of progestin-only or intrauterine contraceptives in this setting. According to the USMEC, estrogen-containing contraceptives are contraindicated (category 4) in women migraine sufferers with aura and should be discontinued in patients suffering from migraine without aura if aura symptoms appear. Of note, some headache specialists are suggesting that today's ultralow-dose COC formulations (e.g., the COC formulated with ethinyl estradiol dosed at 10 μg) may be safe and also useful in preventing menstrual-related migraines in migraineurs who are otherwise healthy, normotensive nonsmokers.[354] There are no contraindications to the use of any progestin-only method or IUD in women with migraines with or without aura (USMEC category 1).[9]

Hormonal Contraception in Women With Systemic Lupus Erythematosus

Although effective contraception is important for women with lupus, concerns about increasing disease activity and thrombosis have resulted in clinicians rarely prescribing combination estrogen-progestin oral contraceptives to women with this disease. Indeed, women with SLE are at higher risk for ischemic heart disease, stroke, and VTE, especially in the presence of antiphospholipid antibodies.[355-357] Prior to initiating contraceptives in women with SLE, the level of disease activity and presence of antiphospholipid antibodies and thrombocytopenia should be established. Combined hormonal contraception is contraindicated in women with SLE and positive antiphospholipid antibodies due to the increased risk of venous and arterial thromboembolism (USMEC category 4). In other SLE patients, decisions regarding use of combined hormonal contraceptives should consider the presence of other cardiovascular disease risk factors (e.g., older age, smoking, hypertension, diabetes, and hypercholesterolemia) and is rated USMEC category 2. Use of COC does not appear to worsen disease activity in women with inactive or stable active disease.[358] Although progestin-only methods are not considered to increase the risk of VTE, they are all rated category 3 (risks outweigh benefits) for SLE patients with antiphospholipid antibodies. This is because the propensity for VTE is quite high in these patients, and one randomized controlled trial reported the development of thrombosis in two such women taking POPs.[359,360] Although the category 3 classification also applies to the LNG IUD, systemic drug levels with this device would be minimal. In other SLE patients without antiphospholipid antibodies, progestin-only methods are rated USMEC category 2. There are no restrictions on the use of the copper IUD in women with SLE and positive antiphospholipid antibodies. For women with thrombocytopenia, the LNG IUD is preferred over the copper IUD. Many women with SLE take immunosuppressant medications, and, in the past, the use of IUDs among immunocompromised women has been controversial. However, immunosuppression is no longer considered a contraindication to IUD use.[361,362]

Hormonal Contraception in Women With Sickle Cell Disease

Similar to pregnancy in SLE patients, pregnancy in women with sickle cell disease increases maternal and fetal morbidity and mortality rates. The safety of hormonal contraceptives in women with homozygous (SS) sickle cell disease has been controversial.[363] Only one small randomized controlled trial has addressed this issue. Twenty-five patients were given DMPA or intramuscular saline placebo injections once every 3 months in a crossover design. DMPA users were less likely to experience painful sickle episodes (OR, 0.23; 95% CI, 0.05–1.02).[364] No randomized studies have addressed estrogen-containing products.[365] These limited data suggest that DMPA and other progestin-only methods are a safe contraceptive option for women with sickle cell disease.[363]

No well-controlled study has assessed whether VTE risk in oral contraception users with sickle cell disease is higher than in other combination oral contraception users. However, a small case-control study conducted in the United States found that COC use was associated with a nonsignificantly elevated risk of VTE.[366] Cross-sectional studies of women with sickle cell disease have observed no differences in markers for platelet activation, thrombin generation, fibrinolysis, or red blood cell deformability between users of combination oral contraception methods, users of progestin-only methods, and nonusers of hormonal contraception.[367] On the basis of these observations, studies of pregnant women with sickle cell disease, and small observational studies of women with sickle cell disease who use COCs, and on theoretical considerations, the USMEC concludes that pregnancy carries a greater risk than estrogen-containing contraceptive use.[9] This recommendation would change, however, if the woman had concomitant cardiovascular risk factors or pulmonary hypertension—a complication of sickle cell disease.

Although the lack of evidence on IUD use among women with sickle cell disease represents a major gap in the literature, theoretical concerns about IUD use in this population are few. There is no current evidence to support limiting IUD use among women with sickle cell disease.[363] The USMEC rates the LNG IUD category 1, indicating that there are no restrictions for this method in women with sickle cell disease. The copper IUD is considered category 2,

in which benefits outweigh risks, because of the theoretical concern about increased blood loss with menstruation.

Hormonal Contraception in Depression

Depression and mood disorders are extremely common in women of reproductive age.[128] The issues to consider are the impact of hormonal contraceptives on mood and the potential impact of treatments for depression on contraceptive efficacy. The use of any method of contraception is acceptable for women who suffer from depression, and there are no contraindications (USMEC category 1).[9] There is no evidence that hormonal contraception including DMPA worsens a woman's mood, regardless of whether or not she has baseline depression.[127,368] Selective serotonin reuptake inhibitors and serotonin norepinephrine reuptake inhibitors, the most commonly used antidepressants, do not appear to interact with hormonal contraceptives.[369,370] In contrast, a clinical trial observed that use of the herbal remedy St. John's wort, a hepatic enzyme inducer, increased progestin and estrogen metabolism, as well as breakthrough bleeding and the likelihood of ovulation, in women using COCs.[371,372] For this reason, concomitant use of St. John's wort is rated USMEC category 2 for combined hormonal contraception, POPs, and the etonogestrel implant.

Testicular Disorders

ALVIN M. MATSUMOTO AND BRADLEY D. ANAWALT

CHAPTER OUTLINE

KEY POINTS

- The testes are critical for normal development of internal and external genitalia in the fetus; for secondary sexual characteristics, sexual function, and initiation of spermatogenesis during puberty; and for development and maintenance of adult male phenotype, sexual function, and fertility.
- Knowledge of the anatomy, physiology, and regulation of the hypothalamic-pituitary-testicular axis forms the basis for understanding the clinical manifestations, diagnosis, and management of the main disorders of testis function, androgen deficiency and infertility.
- Male hypogonadism is a clinical syndrome that results from the failure of the testes to produce adequate amounts of testosterone (androgen deficiency) and sperm, or from an isolated impairment of spermatogenesis.
- The consequences of androgen deficiency vary depending on the stage of sexual development. In the fetus, androgen deficiency causes ambiguous genital development; in the child, it causes delayed puberty or eunuchoidism; and in adults, it causes sexual dysfunction, gynecomastia, infertility, and changes in body composition, muscle mass and strength, and bone density and strength that adversely affect health.
- Male hypogonadism is common, but the diagnosis should only be made in men with symptoms and signs of androgen deficiency and consistently low serum testosterone concentrations, in the absence of conditions that transiently suppress testosterone.
- In men with low serum total testosterone concentrations and conditions that alter sex hormone–binding globulin, an accurate assessment of serum free testosterone is useful.
- In men with hypogonadism, gonadotropin concentrations should be measured to distinguish between primary and secondary hypogonadism.
- Primary hypogonadism is associated with infertility that cannot be treated with medical therapy.
- Men with secondary hypogonadism should be evaluated for causes of hypothalamic or pituitary dysfunction, such as hyperprolactinemia, Cushing syndrome, sella mass, and iron overload syndromes.
- Gonadotropin replacement therapy generally improves spermatogenesis and fertility in men with secondary hypogonadism.
- Prior to initiating testosterone replacement in men with obesity or metabolic syndrome, low serum testosterone concentrations, and symptoms of possible androgen deficiency, it is important to initiate lifestyle changes for weight loss. Drugs that might suppress the hypothalamic-pituitary-testicular axis should be stopped, if possible.
- Efficacy and safety monitoring should be performed during testosterone treatment.

The testes have critical physiologic roles during various stages of development. During early fetal life, production of testosterone and antimüllerian hormone (AMH) by the fetal testes is required for the differentiation and development of normal male internal and external genitalia. During puberty, activation of the hypothalamic-pituitary-testicular axis and testosterone production by the testes are necessary for the induction of secondary (adult) male sexual characteristics, stimulation of sexual function, and initiation of sperm production. In adults, testis production of testosterone is required for the maintenance of adult male characteristics (virilization), sexual function, spermatogenesis, and fertility potential. Therefore, disorders of the testis may result in abnormalities in sexual development and function, body habitus and function, and fertility that have profound effects on health and well-being.

Disorders of the testis are common. Klinefelter syndrome is the most common human sex chromosome abnormality and the most common cause of primary hypogonadism, occurring in 1 in 500 to 600 male births.[1,2] Isolated disorders of sperm production are the main causes of male infertility, affecting approximately 5% to

6% of otherwise healthy men in the reproductive age group.[3] Testicular disorders resulting in testosterone deficiency may contribute to complaints of reduced libido (sexual interest and desire), erectile dysfunction, gynecomastia (benign breast enlargement), and reduced bone mass (osteoporosis), all of which are common in men, particularly as they age. Finally, disordered hypothalamic-pituitary-testicular function is commonly associated with chronic systemic illnesses, wasting syndromes, morbid obesity, chronic use of certain medications (e.g., opioids and glucocorticoids), and aging. These conditions often result in testosterone deficiency that, if severe and prolonged, may contribute to clinical manifestations and morbidity.[4,5]

The treatment of testicular disorders usually results in significant clinical improvements in function and quality of life. In prepubertal boys and adults with severe testosterone deficiency, testosterone therapy results in dramatic transformations in body composition and function.[6] In men with low serum testosterone, infertility, and impaired spermatogenesis due to gonadotropin deficiency, gonadotropin replacement therapy generally increases sperm and testosterone production and restores fertility. Finally, advances in assisted reproductive technology (ART) have permitted previously infertile men with testicular disorders to have children. For example, although men with Klinefelter syndrome and azoospermia (no spermatozoa in their ejaculate) were once thought to have untreatable infertility, testicular sperm extraction (TESE) using microsurgical techniques combined with intracytoplasmic sperm injection (ICSI) may permit some of these men to father children.[7]

Functional Anatomy and Histology

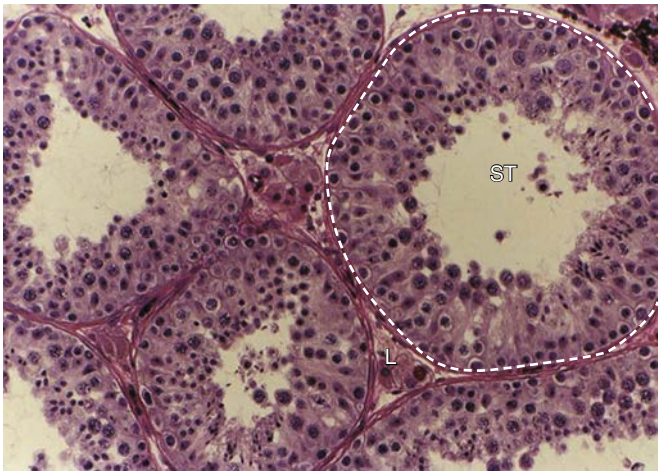
The Testis

Adult testes are paired, ovoid organs that hang from the inguinal canal by the *spermatic cord* (which is composed of a neurovascular pedicle, vas deferens, and cremasteric muscle); they are located outside the abdominal cavity within the scrotum. The left testis hangs lower in the scrotum than the right in about 60% of men, and the right testis hangs lower in approximately 30% of men. Each testis has a volume of 15 to 30 mL and measures 3.5 to 5.5 cm in length by 2.0 to 3.0 cm in width.[8,9]

The testis comprises two structurally and functionally distinct compartments: the *seminiferous tubule compartment*, which is composed of Sertoli cells and developing germ cells at various stages of spermatogenesis and accounts for 80% to 90% of the volume of the testis, and the *interstitial compartment*, which is composed of Leydig cells that secrete testosterone, the main male sex steroid hormone, as well as peritubular myoid cells, fibroblasts, neurovascular cells, and macrophages[10] (Fig. 19.1). Because germ cells constitute most of the testis volume, small testes are usually an indication of significantly impaired spermatogenesis.

The testis is surrounded by a fibrous capsule, the *tunica albuginea.* Fibrous septa that emanate from the tunica albuginea separate the parenchyma of the testis into lobules. The arterial blood supply of the testes is derived primarily from the testicular (internal spermatic) arteries that arise from the abdominal aorta and descend through the inguinal canal in the spermatic cord. Collateral blood supply is provided by the cremasteric and deferential arteries. This collateral supply permits survival of the testis after a testicular artery ligation associated with surgical fixation of a high undescended testis into the scrotum (orchiopexy). However, twisting of the spermatic cord, known as *testicular torsion*, results in strangulation of the blood supply to the testis and causes testicular necrosis and infarction after 6 to 8 hours, making this condition a surgical emergency.[11] A testis that has a *bell-clapper deformity* (i.e., is not attached to the scrotal wall) is more susceptible to testicular torsion. Lymphatic drainage from the testes follows the testicular arteries to periaortic lymph nodes; this is a common route for metastasis of testicular cancer.

A network of veins that compose the pampiniform plexus provides venous drainage from the testes. The pampiniform plexus coalesces into the testicular (internal spermatic) vein. The right testicular vein drains into the inferior vena cava, and the left testicular vein empties at a right angle into the left renal vein. One-way valves in testicular veins prevent backflow of blood into the scrotum. Abnormal enlargement of the venous plexus draining a testicle, known as a *varicocele*, occurs if valves are defective or absent or if there is extrinsic venous compression impeding normal venous drainage.[12] Increased pressures associated with the backflow of blood and altered temperature regulation may contribute to testicular dysfunction associated with a varicocele. Ninety-eight percent of varicoceles occur in the left scrotum, possibly because of absent or defective valves in the left testicular vein. The presence of a prominent unilateral right-sided varicocele or new-onset varicocele on either side should prompt evaluation for venous obstruction by an abdominal or pelvic malignancy (e.g., renal cell carcinoma) or lymphadenopathy; a chronic right-sided varicocele may also indicate *situs inversus*. Rarely, an anatomic anomaly of the superior mesenteric artery that compresses the left renal vein causes a left-sided varicocele; this is known as the *nutcracker syndrome*.



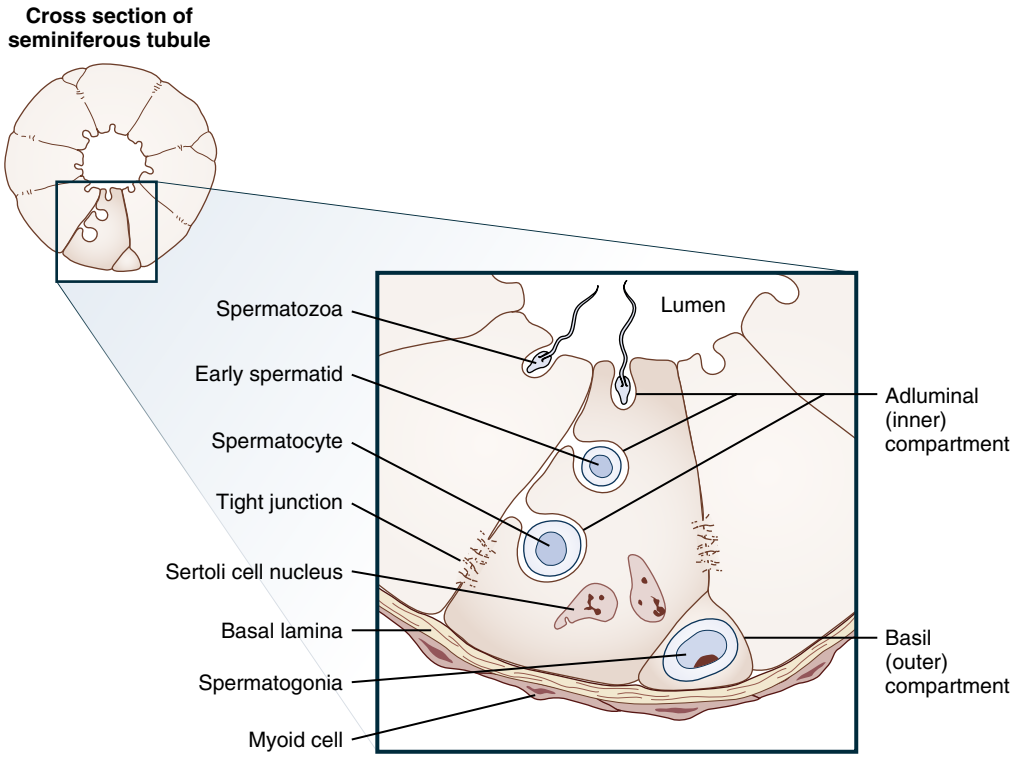
• **Fig. 19.1** Light photomicrograph of the seminiferous tubule and interstitial compartments of the human testes. The seminiferous tubule (ST) compartment makes up the majority of the testis and is composed of developing germ cells enveloped by Sertoli cells. Spermatogonia line the basal lamina of the seminiferous tubules, spermatocytes at various stages of development are present in the middle layers of the tubules, and spermatids at various steps of maturation are present in the luminal aspect of the seminiferous tubules. Within each tubule, there are germ cells at different stages of spermatogenesis. In the interstitial compartment, there are prominent clusters of Leydig cells (L) nestled between seminiferous tubules, peritubular myoid cells within the basal lamina of the tubules, and scattered blood vessels and macrophages. (From Matsumoto AM. Spermatogenesis. In: Adashi EY, Rock JA, Rosenwaks Z, eds. *Reproductive Endocrinology, Surgery, and Technology.* Philadelphia, PA: Lippincott-Raven; 1996:359–384.)

Because the testes are located outside the abdominal cavity, they are exposed to temperatures approximately 2°C lower than core body temperature. The position of the testes within the scrotum and the testicular temperature are regulated by the cremasteric muscle. The cremasteric muscle contracts when warming is needed, resulting in shortening of the spermatic cord and drawing of the testis toward the abdomen; when cooling is needed, the muscle relaxes, resulting in lowering of the testis into the scrotum. In addition, the pampiniform venous plexus provides a countercurrent heat exchange mechanism to cool the testis by surrounding the testicular artery with cooler venous blood. A testis temperature slightly lower than core body temperature is important for normal spermatogenesis. Exposure of the testes to higher temperatures, such as with failure of the testes to descend normally into the scrotum (*cryptorchidism*) or excessive external heat exposure due to frequent, prolonged hot tub use may impair spermatogenesis.

Seminiferous Tubule

Seminiferous tubules contain epithelium consisting of Sertoli cells that envelop and support germ cells undergoing progressive differentiation and development into mature spermatozoa. Once released into the lumen, mature spermatozoa are transported within seminiferous tubules, which measure up to 70 cm in length and are tightly coiled within lobules of the testis, to the rete testis, the efferent ducts, the epididymis, and, finally, the vas deferens for ejaculation. The seminiferous tubules are surrounded by a basal lamina composed of an extracellular matrix that serves to separate them from the interstitial compartment, provides structural integrity to the tubules, and regulates the function of cells in contact with it. Histologic examination of a testis biopsy specimen in cross section reveals many different seminiferous tubules surrounded by basal lamina and clusters of Leydig cells in the interstitial compartment between each tubule[10] (see Fig. 19.1).

Sertoli cells extend from the basal lamina to the lumen of tubules, and adjacent Sertoli cells envelop and provide a structural scaffold for germ cells as they differentiate within the tubule[9] (Fig. 19.2). Undifferentiated spermatogenic stem cells, called *spermatogonia*, lie along the basal lamina at the periphery of tubules, interspersed between Sertoli cells. Adjacent Sertoli cells surround spermatogonia and form specialized junctional complexes or tight junctions that divide the seminiferous tubule into the *basal compartment*, in which spermatogonia reside, and the *adluminal compartment*, which is occupied by differentiating germ cells. Sertoli cell tight junctions impede the passage of large molecules, steroids, and ions into the seminiferous tubule and constitute the cytologic basis of the *blood-testis barrier*, analogous to the blood-brain barrier. In the adluminal compartment, *spermatocytes* derived from spermatogonia in the basal compartment undergo meiosis to form *spermatids* that progressively mature (*spermiogenesis*), with



• **Fig. 19.2** Schematic diagram of the cells in the seminiferous tubule (*top*). The seminiferous tubule consists of Sertoli cells that surround developing germ cells (*middle*). Sertoli cells extend from the basal lamina to the lumen. Tight junctions between adjoining Sertoli cells separate the seminiferous tubule into basal and adluminal compartments and are the anatomic basis for the blood-testis barrier (*bottom*). The basal compartment, which contains spermatogonia lining the basal lamina and peritubular myoid cells, is exposed to the interstitial compartment, which contains Leydig cells and blood vessels that deliver endocrine regulators of testis function (e.g., gonadotropins). The adluminal compartment contains developing spermatocytes, spermatids, and mature spermatozoa that are released into the lumen of the seminiferous tubule. (From Matsumoto AM. The testis. In: Felig P, Frohman LA, eds. *Endocrinology and Metabolism.* 4th ed. New York, NY: McGraw-Hill; 2001:635–705.)

the more mature germ cells occupying positions closer to the lumen, until mature spermatozoa are released into the lumen of the tubule (*spermiation*).

Because of the blood-testis barrier, only Sertoli cells and spermatogonia are directly accessible to endocrine and paracrine regulation from the circulation and cells of the interstitial compartment, respectively. Sertoli cells need to synthesize and secrete many products, some of which are present in the circulation but not accessible to developing germ cells in the adluminal compartment, to nurture and regulate spermatogenesis. Sertoli cells contain receptors for follicle-stimulating hormone (FSH) and androgens, and they mediate the regulation of spermatogenesis by circulating FSH and testosterone produced locally by Leydig cells in response to stimulation from circulating luteinizing hormone (LH). Sertoli cells produce extracellular matrix components and AMH that causes regression of müllerian ducts and prevents the development of female accessory sex organs in the male fetus and inhibin B, which is the most important testicular contributor to negative feedback suppression of FSH.

Spermatogenesis

In male humans, the process of spermatogenesis supports a production rate of approximately 120 million mature spermatozoa per day by the testis (approximately 1000 per heartbeat!).[13] Spermatogenesis, the process by which stem cells (spermatogonia) differentiate into mature spermatozoa, proceeds in three functionally distinct phases: (1) the *mitotic* or *proliferative phase*, during which the majority of spermatogonia undergo mitosis to renew the stem cell pool and a minority become committed to further differentiation to produce spermatocytes; (2) the *meiotic phase*, during which spermatocytes undergo successive meiotic divisions to produce haploid germ cells (spermatids); and (3) *spermiogenesis*, during which immature, round spermatids differentiate into mature spermatozoa[10,14] (Fig. 19.3).

Proliferative Phase

Based on chromatin staining and pattern, spermatogonia may be classified as A dark (A_d), A pale (A_p), or B spermatogonia. Because of their relatively low mitotic rate, A_d spermatogonia are thought to be the spermatogonial stem cells. A_d spermatogonia are relatively resistant to external insults (e.g., ionizing radiation), and in response to such insults, they undergo mitotic proliferation. However, severe or complete depletion of A_d spermatogonia, such as that which occurs with high-dose x-irradiation or vascular compromise, results in irreversible impairment or loss of sperm production.

A small number of A_d spermatogonia undergo mitotic divisions to form A_p and then B spermatogonia. In humans, the rate of formation of B spermatogonia is low, so only a small number of B spermatogonia are available to enter meiosis and undergo further differentiation.[15] This rate limits the efficiency of spermatogenesis in humans. B spermatogonia are the most sensitive germ cells to the effects of ionizing radiation, and their numbers are reduced after irradiation of the testes.[16]

B spermatogonia that become committed to further differentiation undergo mitotic division to form *preleptotene* or *resting* spermatocytes, which enter a prolonged meiotic phase of 24 days. Spermatogonia do not completely separate after mitosis (*incomplete cytokinesis*). Groups of spermatogonia remain connected via cytoplasmic bridges, forming a syncytium, and undergo meiosis and spermiogenesis in synchrony.

Meiotic Phase

Preleptotene primary spermatocytes contain a diploid complement of chromosomes (46 chromosomes or 2N, where N is the number of haploid chromosomes), and they are the last germ cells to undergo DNA synthesis. Preleptotene spermatocytes undergo an initial round of meiotic division (*meiosis I*), lasting longer than 2 weeks, to form secondary spermatocytes that contain a haploid complement of chromosomes (1N). Secondary spermatocytes, which are present for only about 8 hours, undergo a second meiotic division (*meiosis II*) to form haploid spermatids.

Improper segregation of chromosomes (*meiotic nondisjunction*) resulting in an abnormal number of chromosomes (*aneuploidy*) occurs in 0.7% of live births and 50% of first-trimester abortuses.[17,18] Klinefelter syndrome is classically associated with a 47,XXY karyotype caused by paternal meiotic nondisjunction in 50% of cases.[19,20]

Spermiogenesis

The final phase of spermatogenesis is the maturation of spermatids from round to elongated spermatids and then to mature spermatozoa; this process, known as spermiogenesis, is followed by release of spermatozoa into the lumen of seminiferous tubules (spermiation). The major changes that occur during spermiogenesis include formation of the sperm head with condensation of chromosomes (DNA and nucleoproteins) and formation of the *acrosomal cap*, which contains proteolytic enzymes needed for sperm penetration of the ovum; formation of the sperm tail or *flagellum* (pointing into the lumen) that permits motility; phagocytic removal of excess spermatid cytoplasm (known as the *residual body*) by Sertoli cells; and release of mature spermatozoa into the lumen. Progressive maturation of spermatids is accompanied by progressive movement of more mature spermatids toward the lumen of the seminiferous tubule. Under the regulation of FSH and intratesticular testosterone, Sertoli cells nurture spermiogenesis by supporting spermatid maturation.

Germ Cell Loss

Compared with most other species, the efficiency of spermatogenesis in humans is relatively poor, and the germ cell degeneration and loss that occur predominantly during mitosis and meiosis are major contributors to the low efficiency of sperm production.[21] Significant degrees of germ cell degeneration occurring during meiosis results in a loss of about 60% during formation of spermatids from preleptotene spermatocytes. As men age, increased germ cell degeneration may result in lower daily sperm production. It is hypothesized that germ cell degeneration prevents abnormal germ cells from further development, thereby serving an important quality control function.

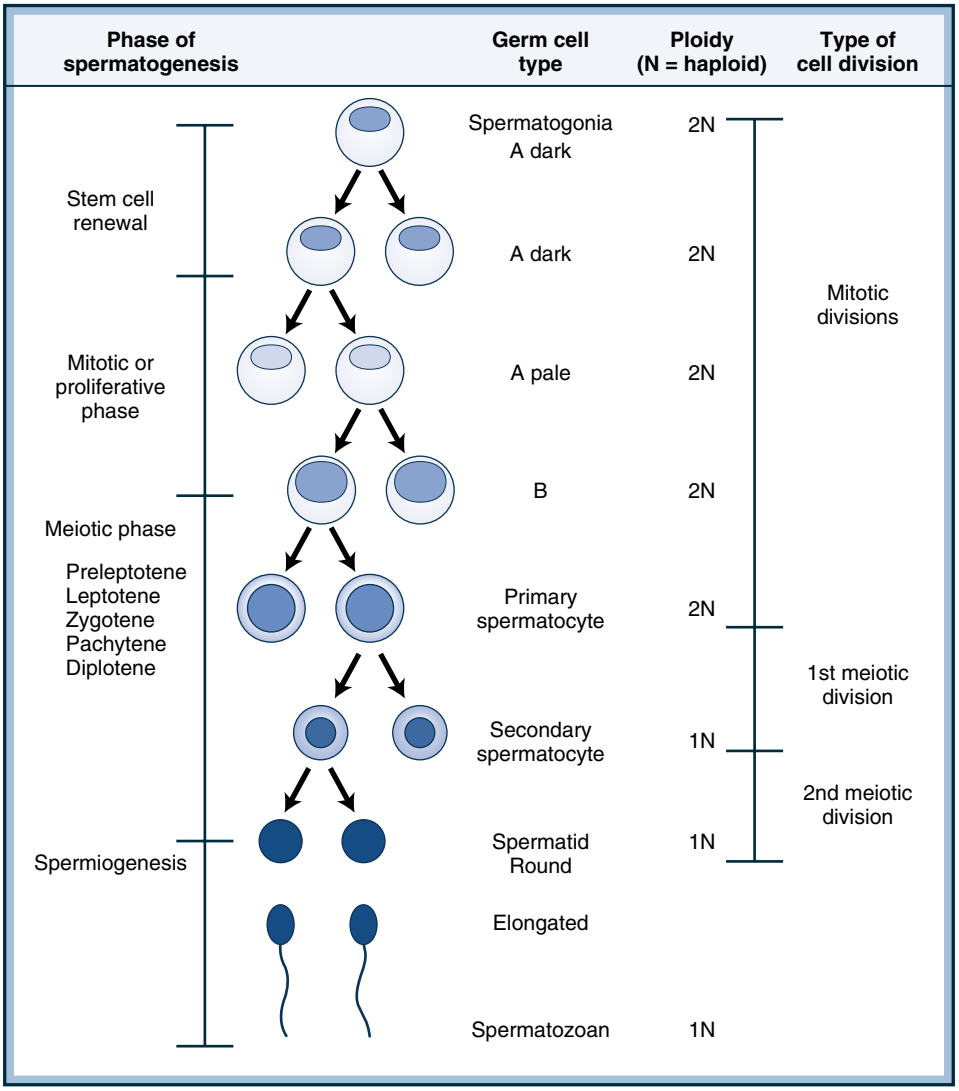
Organization of Spermatogenesis

Histologic examination of a human testis in cross section reveals that germ cells at particular phases of development cluster in six cellular associations, referred to as *stages*, which together constitute a complete *cycle* of spermatogenesis. In most mammals, stages are organized sequentially along the longitudinal axis of the tubules so that all of the germ cells present in a cross section of a tubule are in the same stage of spermatogenesis.[22,23] In contrast, three or more different stages of a cycle may variably be present in a cross section of human testis. Although some have proposed a helical pattern of stages along the tubule to explain this seemingly chaotic arrangement, this has not been confirmed by others.

In humans, the time for completion of spermatogenesis (from A_p spermatogonia to release of mature spermatozoa) is 74 ± 4 days.[24] The epididymal transit time of spermatozoa is approximately 12 to 21 days.[25] Therefore, external insults to the testis (e.g., ionizing radiation) or induction of gonadotropin deficiency (e.g., by male hormonal contraceptive regimens) that inhibits early germ cell development and reduces spermatogenesis are not reflected in reduced sperm counts in the ejaculate for 3 months or more.

Sperm Transport and Fertilization

Mature spermatozoa released into the lumen of the seminiferous tubule are transported to the rete testis, to the efferent ducts of the testis, and then to the caput epididymis primarily by peristaltic contractions and intratubular fluid flow. In the epididymis, sperm undergo biochemical and functional modifications that result in the capacity for sustained forward motility. After ejaculation from the vas deferens and penis into the female reproductive tract, human sperm interact with uterine secretory products and undergo *capacitation* in the uterus; the resulting biochemical alterations in the acrosomal cap increase the sperm membrane fluidity, calcium influx, and sperm motility ("hyperactivation") so that the spermatozoa acquire the capacity to fertilize an ovum.[26,27] After capacitation, as the spermatozoon meets an ovum in the ampulla of the fallopian tube, the sperm binds to the egg and releases hyaluronidase to penetrate the zona pellucida that surrounds the ovum, a process known as the *acrosome reaction*. Fertilization then occurs as the plasma membranes of sperm and ovum fuse.

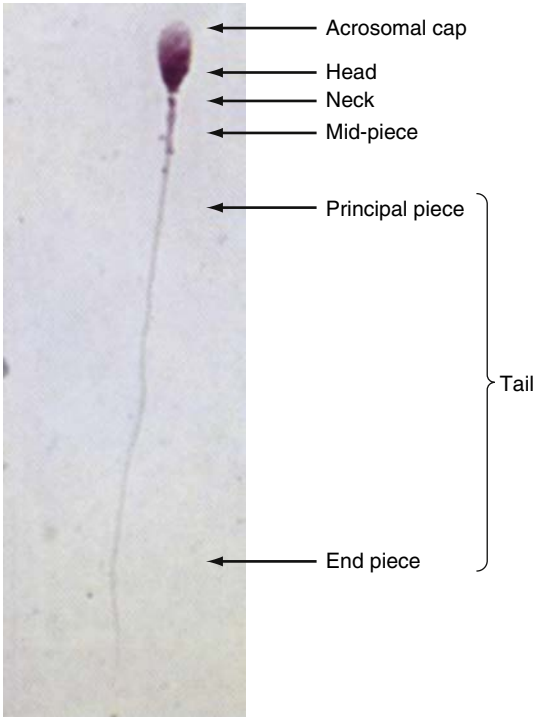


• **Fig. 19.3** Schematic diagram of human spermatogenesis. Spermatogonial stem cells undergo self-renewal by mitotic division. At the initiation of spermatogenesis, some spermatogonia undergo differentiation into primary spermatocytes, which contain a diploid number of chromosomes (2N = 46 chromosomes). The primary spermatocytes then undergo two successive meiotic divisions to form spermatids, which contain a haploid number of chromosomes (1N = 23 chromosomes). Spermatids undergo spermiogenesis from round to elongated spermatids to form mature spermatozoa, which also contain a haploid number of chromosomes. (Modified from Matsumoto AM. Spermatogenesis. In: Adashi EY, Rock JA, Rosenwaks Z, eds. *Reproductive Endocrinology, Surgery, and Technology.* Philadelphia, PA: Lippincott-Raven; 1996:359–384.)

Spermatozoa

Morphologically, most ejaculated human spermatozoa are composed of an oval-shaped head that contains condensed chromatin and nucleoproteins, an acrosomal cap that covers approximately the anterior two thirds of the head, a short neck that contains centrioles important for attachment of the tail and cleavage of the zygote after fertilization, a middle piece that consists of axial filaments surrounded by a spiral of mitochondria containing oxidative enzymes that provide energy for motility, and a long tail or flagellum that permits normal progressive forward motility of the spermatozoa[10] (Fig. 19.4). The flagellum consists of a microtubule-based cytoskeleton, the *axoneme*, which has a characteristic structure composed of two central microtubules surrounded by nine microtubule doublets (9 × 2 + 2 pattern) that serves as a scaffold for motor protein complexes (i.e., *dynein arms*).[28]

In humans, the normal sperm concentration in the ejaculate is greater than 15 million/mL, with 4% or more having normal morphologic appearance by strict criteria (≥30% by previous criteria) and 40% or more having total motility, according to the most recent World Health Organization (WHO) criteria.[29,30] Men with infertility may exhibit morphologic abnormalities of the sperm head (tapered, amorphous, or double-headed forms) or of the tail (coiled forms) and reduced or absent motility. Alterations in the structural or functional components of the axoneme (e.g., absence of dynein arms) result in altered motility, and deficiency of dynein adenosine triphosphatase results in primary ciliary dyskinesia (also known as immotile cilia syndrome), a syndrome associated with lung disease, recurrent sinusitis, and otitis media, as well as male infertility.[31]



• **Fig. 19.4** Light photomicrograph of an ejaculated mature human spermatozoon, composed of a head, neck, mid-piece, and tail (principal piece and end piece). (From Matsumoto AM. Spermatogenesis. In: Adashi EY, Rock JA, Rosenwaks Z, eds. *Reproductive Endocrinology, Surgery, and Technology.* Philadelphia, PA: Lippincott-Raven; 1996:359–384.)

Interstitium

The interstitial compartment of the testis contains clusters of Leydig cells, the primary sex steroid–producing cells of the testis, which make up only about 5% of testis volume[23,32] (see Fig. 19.1). Leydig cells produce testosterone, which acts as a paracrine regulator within the seminiferous tubules of the testis on Sertoli cells in close proximity to stimulate spermatogenesis. Testosterone is secreted into adjacent testicular capillaries and then into the general circulation to act as an endocrine signal on androgen target organs throughout the body. Leydig cells also produce *insulin-like factor 3* (INSL3), a peptide hormone in the relaxin-insulin family, which plays an important role in the first phase of testicular descent from the abdomen into the scrotum during development.[33] INSL3 also may be an important autocrine regulator of Leydig cells and a paracrine regulator of germ cells directly.[34]

Peritubular myoid cells that surround the seminiferous tubules are contractile, smooth muscle-like cells that serve to facilitate forward transport of spermatozoa and testicular fluid within the tubular lumen, provide structural integrity to the tubule, secrete extracellular matrix components and putative regulatory factors such as growth factors, and are involved in retinol metabolism.[23,35] These cells contain androgen receptors (ARs) and are thought to mediate some of the paracrine effects of testosterone on Sertoli cells within the seminiferous tubules, but their precise role in human testicular physiology remains unclear.

The interstitial compartment also contains macrophages that may regulate Leydig cell steroidogenesis by secretion of cytokines and may play a role in phagocytosis of degenerating cells and necrotic debris. The interstitium contains arterioles and a rich network of capillaries that permit secretion of testosterone and other products into the circulation and delivery of circulating gonadotropins (e.g., LH and FSH).

Testis Development

Fetal Development

During embryogenesis, the Y chromosome directs the development of the testis from an undifferentiated anlage that has the potential to develop into either a testis or an ovary.[36] The *SRY (sex-determining region of the Y chromosome) gene*, located on the pseudoautosomal region of the Y chromosome, encodes a transcription factor that increases the expression of SRY-box 9 (*SOX9*), which in turn drives the formation of Sertoli cells and testis differentiation. *SRY* gene expression is activated by several factors, including steroidogenic factor 1 and the DNA-binding protein GATA4.[37] *SRY*-independent *SOX9* expression may also be driven by steroidogenic factor 1. *SOX9* directs the expression of other genes that are essential in testis differentiation, such as fibroblast growth factor 9 (*FGF9*) and *AMH*, and in repression of ovarian differentiation, such as *WNT4* and *NR0B1* (formerly known as *DAX1*). In the absence of *SRY* or *SRY* action, *SOX9* is repressed by many factors, including *β-catenin*, and development of the follicular cells and ovaries follows.

Primordial germ cells originate in the yolk sac and migrate to the genital ridges. Together with coelomic epithelial and mesenchymal cells that eventually differentiate, respectively, into Sertoli cells and interstitial cells (Leydig and peritubular myoid cells), they form the *genital blastema* by 6 weeks of gestation. Primordial germ cells that fail to migrate normally explain the location of extragonadal germ cell cancers in men. Under the influence

of gene products activated by *SRY*, primordial germ cells become surrounded by primitive Sertoli cells to form seminiferous or sex cords that eventually develop into seminiferous tubules.

Under the influence of maternal human chorionic gonadotropin (hCG) initially and later LH and FSH from the fetal pituitary gland, immature Leydig cells, Sertoli cells, and germ cells undergo differentiation, proliferation, and organization. Testosterone production from fetal Leydig cells increases progressively and induces development of the epididymis, vas deferens, and seminal vesicles from wolffian or mesonephric ducts. Conversion of testosterone to 5α-dihydrotestosterone (DHT) in the urogenital tract leads to the formation of the prostate from the urogenital sinus, the penis from the genital tubercles and folds, and the scrotum from the urogenital swelling.[38] In the absence of testosterone production or action, female internal and external genitalia develop. AMH secretion from the fetal Sertoli cells causes regression of the müllerian or paramesonephric ducts and prevents the formation of a uterus and fallopian tubes.

Male phenotypic development is complete by about 15 weeks of gestation, after which the proliferation of Sertoli and germ cells arrests. The Leydig cells produce testosterone in the third trimester when fetal gonadotropin secretion rises, and this phase of androgen action is required for normal penis size at birth.

Testis Descent

The developing testis is attached to the diaphragm by the craniosuspensory ligament and anchored to the inguinal region by a caudal ligament known as the *gubernaculum*. Descent of the testis occurs in two phases.[33] During the initial *transabdominal phase*, the testis descends within the abdomen to the inguinal region; this occurs between 10 and 23 weeks of gestation. Studies in animals suggest that testis descent during this phase depends on two processes: (1) regression of the craniosuspensory ligament, induced by testosterone, which frees the testes to descend, and (2) thickening of the gubernaculum, which is controlled by INSL3 and its cognate receptor, relaxin-family peptide receptor 2 (RXFP2, also known as leucine-rich repeat–containing G protein–coupled receptor 8 or G protein–coupled receptor affecting testis descent). During the *inguinoscrotal phase*, which begins at 26 to 28 weeks of gestation, the testis descends into the scrotum; this process is largely controlled by the effects of testosterone on gubernacular shortening and contractions. The effects of testosterone may be mediated in part by the neurotransmitter, calcitonin gene–related peptide, which is released by the genitofemoral nerve. The importance of testosterone, gonadotropins, and INSL3 in testis descent in humans is suggested by the occurrence of undescended testes (cryptorchidism) associated with fetal androgen deficiency or resistance, gonadotropin deficiency, and *INSL3* or *RXFP2* mutations.[34]

Testis descent is usually complete, with the testes entirely within the scrotum, by 7 months of gestation to birth. During testis descent, a herniation of the abdominal cavity, the *processus vaginalis*, develops along the course of the gubernaculum, forming the inguinal ring and canal and descending with the testis into the scrotum. As the abdominal wall and muscles develop, the inguinal rings close, and the processus vaginalis obliterates to form the *tunica vaginalis*, which covers the anterior and lateral portion of the testes. Incomplete closure of the inguinal ring predisposes an individual to *inguinal hernia*, and incomplete obliteration of the processus vaginalis with accumulation of serous fluid results in a *hydrocele*; either of these conditions can manifest as a scrotal mass.

Postnatal Development

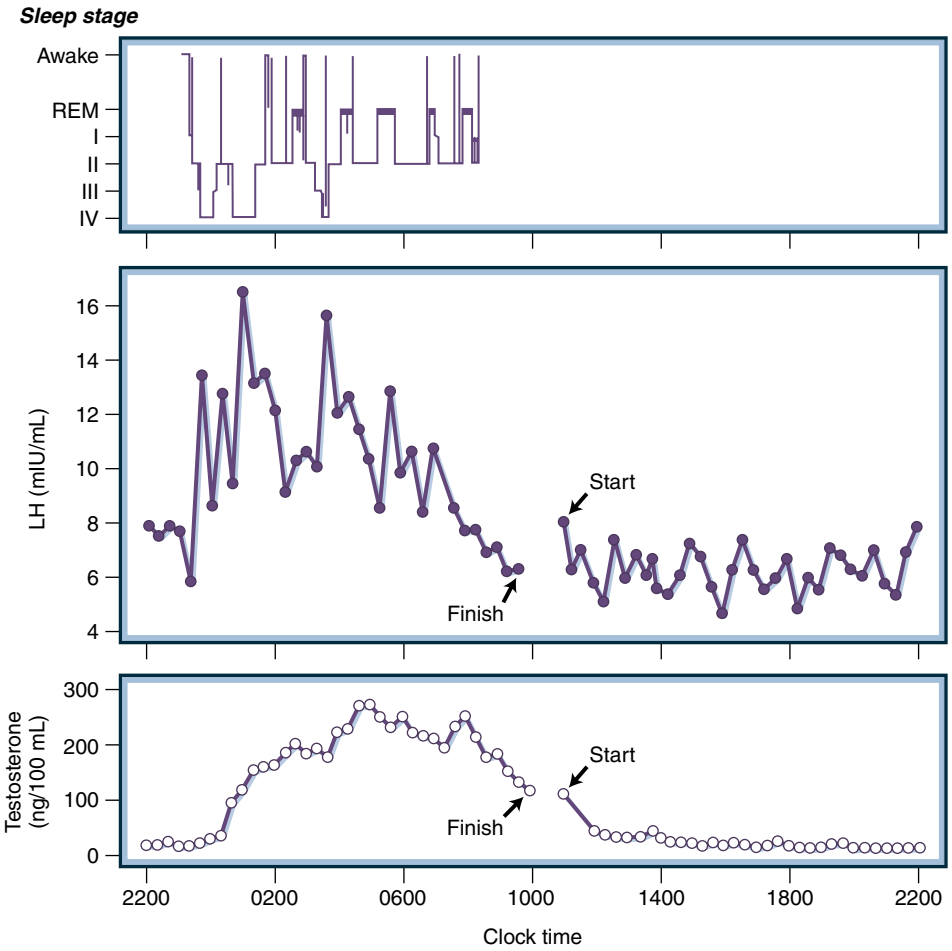
During late gestational life, the male fetus is exposed to high concentrations of maternal estrogens from the placenta. With the decline in estrogen concentrations after birth, the hypothalamic-pituitary-testicular axis is released from negative feedback suppression, resulting in a postnatal surge of gonadotropin that stimulates the testes to produce testosterone and inhibin B.

LH and testosterone concentrations begin to increase at about 1 week of life and peak 1 to 2 months later, reaching the equivalent of adolescent concentrations in association with an increase in the number of Leydig cells; LH and testosterone then decline to prepubertal concentrations by about 6 months of age. Infants with complete androgen insensitivity who lack androgen action due to an AR mutation (see later discussion) do not demonstrate a postnatal gonadotropin surge and have low or undetectable LH and testosterone concentrations postnatally, suggesting that AR expression is required for the surge.[39] In humans, there is no evidence that the postnatal surge of LH and testosterone has an effect on adult Leydig cell function. However, in infants with hypogonadotropic hypogonadism, the lack of third trimester fetal gonadotropins and the neonatal surge in testosterone play an important role in the development of micropenis and cryptorchidism.[40,41] In infants with micropenis, postnatal hormone testing may permit early identification and possible treatment of isolated hypogonadotropic hypogonadism or hypopituitarism.

FSH and inhibin B concentrations also begin to rise at 1 week of life, in association with an increase in proliferation of Sertoli cells, and peak at 3 months. FSH declines to prepubertal concentrations by 9 months of age. Because Sertoli cells continue to proliferate for some time after FSH declines, the inhibin B concentration declines more slowly and plateaus at approximately 15 months of age. Sertoli cell number determines spermatogenic potential, and the postnatal gonadotropin surge is likely important for quantitatively normal sperm production in adults. The postnatal testosterone surge also increases the formation of A_d spermatogonia (spermatogonial stem cells) from gonocytes during the first 3 months and increases testis size and seminiferous tubule length during the first year of life, providing further evidence for the importance of the gonadotropin surge on normal spermatogenesis and fertility as an adult. In male infants with congenital gonadotropin deficiency, the lack of a postnatal surge in serum gonadotropin concentrations results in lower numbers of Sertoli cells and spermatogonia. The lack of a postnatal gonadal surge explains why gonadotropin replacement therapy fails to produce normal sperm counts in the majority of men with congenital forms of hypogonadotropic hypogonadism who are treated as adults.

Pubertal Development

At the onset of puberty, reactivation of hypothalamic GnRH secretion stimulates pituitary LH and FSH, initially only during nocturnal sleep (Fig. 19.5) and subsequently throughout the day.[42,43] Increased circulating LH increases Leydig cell secretion of testosterone that induces male secondary sexual characteristics. Increased serum LH and intratesticular testosterone concentrations together with increased FSH concentrations stimulate Sertoli cells to initiate spermatogenesis. With increasing germ cell numbers and expansion of seminiferous tubules, testis size increases progressively. Increase in testis size is the first clinical sign of puberty. In addition, with the release of mature spermatozoa into the lumen of seminiferous tubules and transport of sperm to



• **Fig. 19.5** Sleep-associated secretion of luteinizing hormone (LH) (*middle*) and testosterone (*bottom*) related to sleep stage (*top*) in a boy entering puberty. *REM,* rapid eye movement sleep. (From Boyar RM, Rosenfeld RS, Kapen S, et al. Human puberty: simultaneous augmented secretion of luteinizing hormone and testosterone during sleep. *J Clin Invest.* 1974;54:609–618.)

the genitourinary tract, sperm begin to appear in the urine (*spermarche*) during early puberty (usually at 12–15 years of age).[44]

Adult Physiology

Hypothalamic-Pituitary-Testicular Axis

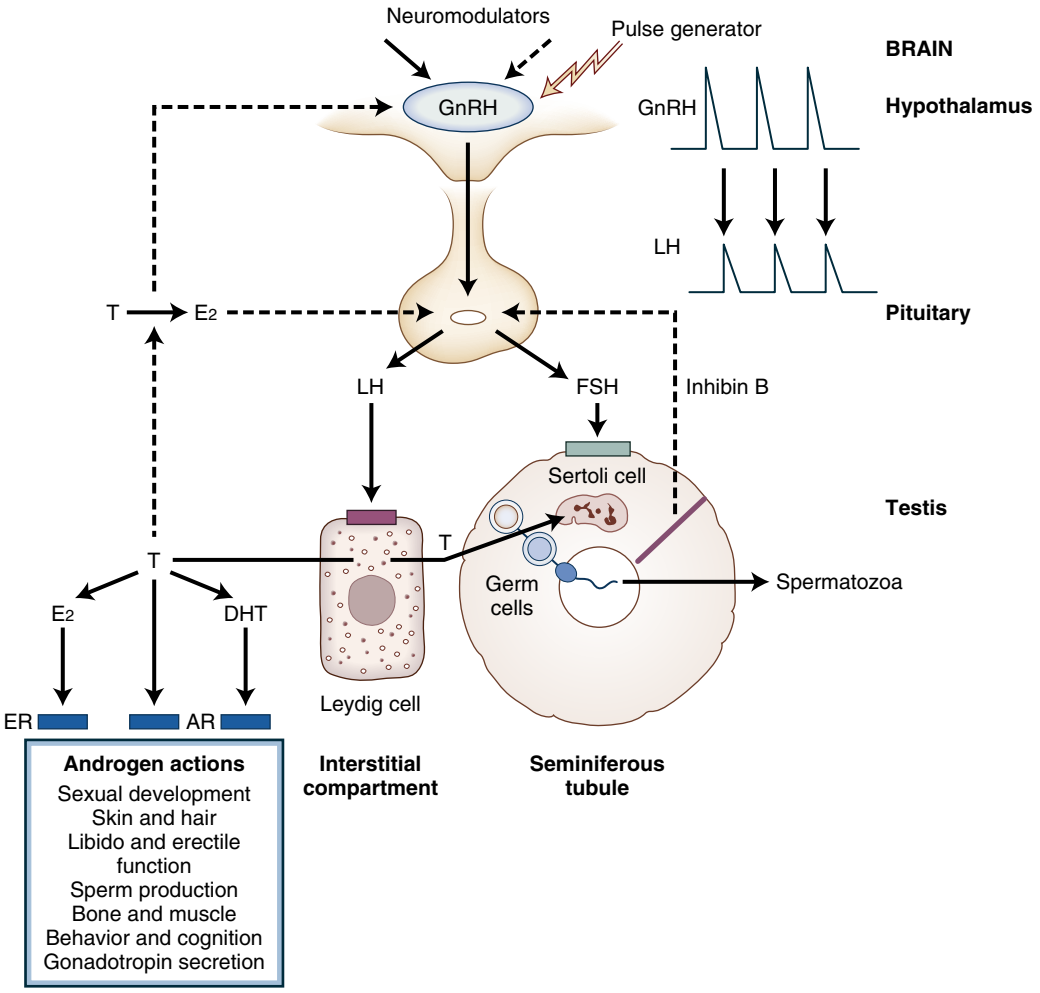
The testis is controlled by classic positive feed-forward and negative feedback mechanisms (Fig. 19.6). The major positive regulators of testis function are LH and FSH, which are synthesized and secreted from the anterior pituitary gland. Secretion of LH and, to a lesser extent, FSH, is pulsatile and driven primarily by episodic release of GnRH from neurons in the hypothalamus.[45] GnRH stimulates gonadotropin-producing cells of the anterior pituitary (gonadotrophs) to secrete LH and FSH every 90 to 120 minutes in men.

LH acts on Leydig cells of the testes to stimulate production of testosterone, the main sex steroid hormone in males. In concert with FSH, testosterone acts locally on Sertoli cells within the seminiferous tubules of the testes to initiate and maintain spermatogenesis. Testosterone secreted into the circulation acts to mediate and promote androgen action on almost every tissue in the body, including negative feedback inhibition of pituitary LH and FSH secretion (primarily via conversion to estradiol) and suppression of GnRH production by the hypothalamus. FSH stimulates Sertoli cells to produce inhibin B, a peptide hormone that causes negative feedback inhibition of FSH secretion by the anterior pituitary.

Knowledge of the hypothalamic-pituitary-testicular axis is essential in understanding the causes, classification, differential diagnosis, clinical consequences, and treatment of testicular disorders.

Central Nervous System Regulation of Gonadotropin-Releasing Hormone Secretion

The brain plays a vital role in regulation of the testis and of reproductive function through production of the decapeptide, gonadotropin-releasing hormone (GnRH), by a relatively small number of neurons located primarily in the arcuate nucleus of the medial basal hypothalamus. GnRH is released episodically from axon terminals in the median eminence into capillaries of the hypothalamic hypophyseal portal system, through which it is carried to the anterior pituitary to stimulate synthesis and the release of LH and FSH. Like all hypothalamic trophic hormones, the concentration of GnRH in portal blood is low. As a result, GnRH concentration in peripheral blood is very low and cannot be measured for clinical purposes (e.g., to diagnose GnRH deficiency).

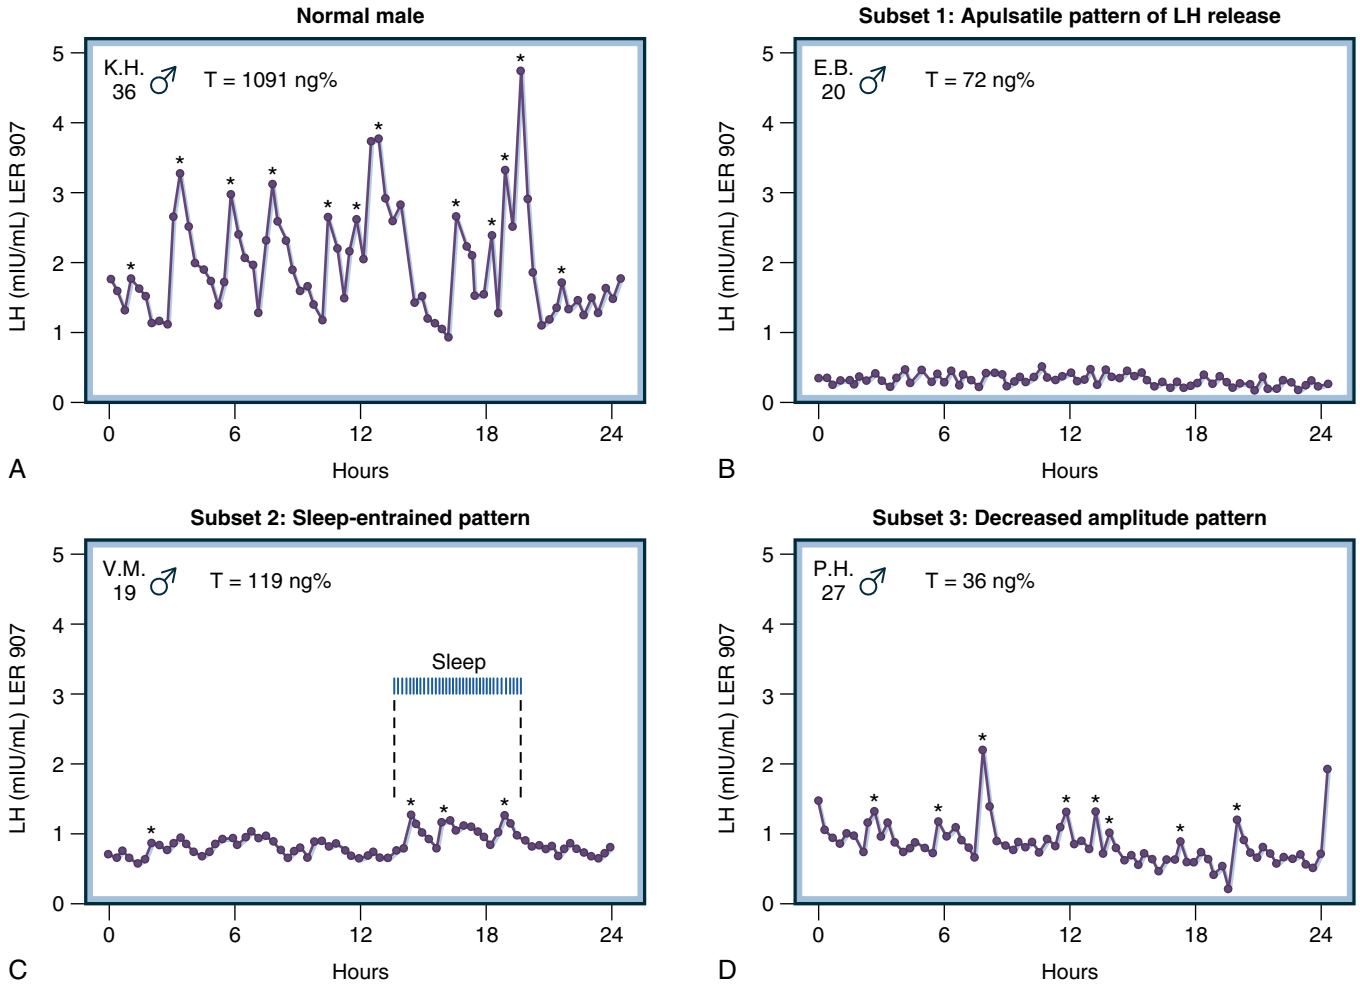


• **Fig. 19.6** Schematic diagram of the hypothalamic-pituitary-testicular axis. Hypothalamic gonadotropin-releasing hormone (GnRH) stimulates the pituitary to produce luteinizing hormone (LH) and follicle-stimulating hormone (FSH). LH stimulates *(solid lines)* Leydig cells of the testes to produce testosterone (T), which is actively metabolized to estradiol (E_2) and dihydrotestosterone (DHT), which interact with androgen receptor (AR) and estrogen receptor (ER), respectively, resulting in several direct and indirect androgen actions. FSH stimulates Sertoli cells of the testes, which, together with LH-stimulated testosterone, increases spermatogenesis. LH-stimulated testosterone and E_2 exert negative feedback suppression *(dashed lines)* of GnRH production at the hypothalamus and LH and FSH production at the pituitary, and FSH-stimulated inhibin B exerts negative feedback suppression on FSH secretion by the pituitary. (Modified from Matsumoto AM. The testis. In: Felig P, Frohman LA, eds. *Endocrinology and Metabolism.* 4th ed. New York, NY: McGraw-Hill; 2001:635–705.)

The precise mechanism of synchronous episodic release of GnRH from many separate GnRH neurons into the hypophyseal portal system to provide pulsatile stimulation of pituitary gonadotrophs is not clear. There is evidence that pulse generation is a direct consequence of intrinsic periodicity of GnRH or other neurons that synapse on GnRH neurons within the medial basal hypothalamus, such as neurons containing kisspeptin or excitatory or inhibitory neurotransmitters.

The frequency of pulsatile GnRH secretion is temporally coupled with the episodic release of LH, free α-subunit (co-secreted with intact gonadotropins), and FSH.[46] Because the half-lives of LH and free α-subunit in the circulation are shorter than that of FSH, concentrations of LH and α-subunit demonstrate discrete pulses, which are evident with frequent blood sampling (e.g., every 10 minutes for 12–24 hours), whereas FSH pulses are not as apparent. The frequency of LH or free α-subunit pulses reflects GnRH pulse frequency and serves as an indicator of synchronous GnRH neuronal activity (pulse generation) in the brain. The amplitude of LH or free α-subunit pulses reflects both the amplitude of GnRH pulses and the responsiveness of the gonadotrophs to GnRH stimulation. Normal men usually demonstrate 12 to 16 LH pulses of varying amplitude over 24 hours (Fig. 19.7). In men with GnRH deficiency (congenital hypogonadotropic hypogonadism [CHH], also referred to as idiopathic hypogonadotropic hypogonadism [IHH]), there is an absence of LH pulses (most commonly) or abnormalities in LH pulsatility.[47]

Treatment of men who have GnRH deficiency with low-dose pulsatile GnRH normalizes LH and FSH secretion and testicular function. In contrast, continuous low-dose GnRH administration does not stimulate normal gonadotropin secretion in these men.[48] Administration of potent GnRH receptor agonists providing continuous, high-dose GnRH stimulation of the pituitary initially



• **Fig. 19.7** Endogenous pulsatile secretion of luteinizing hormone (LH) in a normal man (A) and in men with idiopathic hypogonadotropic hypogonadism (B–D), assessed by blood sampling every 20 minutes for 24 hours. In normal men (A), discrete pulses (*) of LH occur approximately every 2 hours, reflecting pulsatile release of gonadotropin-releasing hormone from the hypothalamus, and stimulate normal adult concentrations of testosterone (T). Most men with idiopathic hypogonadotropic hypogonadism (B) demonstrate no detectable LH pulses and have prepubertal testosterone concentrations. Others exhibit primarily sleep-entrained LH pulses of reduced amplitude without significant LH pulsatility during the waking hours (C) or LH pulses of reduced amplitude throughout sleep and waking hours (D) with pubertal or prepubertal testosterone concentrations, respectively. (From Santoro N, Filicori M, Crowley WF Jr. Hypogonadotropic disorders in men and women: diagnosis and therapy with pulsatile gonadotropin-releasing hormone. *Endocr Rev.* 1986;7:11–23.)

stimulates but then downregulates and profoundly suppresses gonadotropin secretion and testosterone production. This effect has been the basis for the use of potent GnRH agonists to produce medical castration (androgen deprivation therapy) in men with advanced prostate cancer. These findings underscore the critical importance of pulsatile GnRH control of reproductive function in men.

GnRH neurons receive many excitatory and inhibitory inputs from other brain regions (e.g., from kisspeptin neurons), as well as feedback signals from the testes and other circulating endocrine signals. Therefore, the GnRH neuronal system serves an important integrative role in the regulation of reproductive and testis function. A large and complex ensemble of neuroregulators mediates GnRH secretion, acting directly on GnRH neurons themselves or indirectly on other neurons that in turn regulate GnRH neurons to stimulate or inhibit GnRH secretion. These central nervous system (CNS) neuromodulatory systems, together with peripheral endocrine regulators, provide the means by which GnRH secretion and testicular function may be altered by environmental factors such as stress (e.g., via corticotropin-releasing hormone, glucocorticoids), nutritional compromise (e.g., via leptin), and medications (e.g., opioid drugs).

During embryogenesis, GnRH and olfactory neurons originate outside the CNS in the olfactory placode and migrate together along olfactory axons through the cribriform plate of the ethmoid bone to the olfactory bulb, where GnRH neurons diverge and continue to migrate to the medial basal hypothalamus.[49] Abnormalities in the development of the olfactory bulbs and migration of these neurons explain the association between CHH due to GnRH deficiency and the loss or impairment of the sense of smell (anosmia or hyposmia, respectively) that occurs in patients with Kallmann syndrome. Loss-of-function mutations occur in

genes that play important roles in the migration and embryologic development of GnRH neurons, such as the genes for Kallmann syndrome 1 (*ANOS1*), *KAL2* (now called *fibroblast growth factor receptor 1* [*FGFR1*]), and prokineticin receptor 2 (*PROKR2*) and its ligand, prokineticin 2 (*PROK2*). Similarly, genes that are important in the regulation of GnRH neurons may sustain loss-of-function mutations; examples include the genes for kisspeptin 1 receptor (*KISS1R* [formerly *GPR54*]) and its ligand, kisspeptin 1 (*KISS1*), also called *metastin*; the neurokinin B (tachykinin 3) receptor (*TACR3*) and its ligand (*TAC3*); and the GnRH receptor (*GNRHR*) and its ligand (*GNRH*). All of these defects result in isolated GnRH deficiency associated with impaired pubertal development, often in combination with anosmia or hyposmia or other morphologic defects.[50]

GnRH Regulation of Gonadotropin Secretion

GnRH released from the hypothalamus into the hypophyseal portal system binds to G protein–coupled GnRH receptors on anterior pituitary gonadotrophs.[51] In humans, GnRH receptors are coupled primarily to $G_{q/11}$ proteins, which activate phospholipase C-β to produce 1,2-diacylglycerol and inositol 1,4,5-trisphosphate (IP3). Diacylglycerol activates protein kinase C (PKC), and IP3 mobilizes intracellular calcium, which binds to the calcium-binding protein, calmodulin. Both PKC and calmodulin-dependent kinases phosphorylate and activate several transcription factors, resulting in increased synthesis of the gonadotropin subunits LHβ, FSHβ, and the common α-subunit and release of intact LH and FSH and free α-subunits into the circulation. The GnRH receptor may also be coupled to G_s protein, which activates protein kinase A (PKA), resulting in the synthesis and release of gonadotrophs.

LH and FSH, together with another anterior pituitary hormone, thyroid-stimulating hormone (TSH), and a placental hormone, hCG, are members of the glycoprotein hormone family. Glycoprotein hormones are heterodimers in which a common α-subunit is noncovalently linked to a unique β-subunit; this structure confers their ability to bind to their cognate receptors and their biologic specificity. In the pituitary gonadotroph, the common α-subunit and the LHβ- and FSHβ-subunits are products of different genes that are synthesized and regulated differentially.[52] After the subunits are synthesized, an α-subunit combines noncovalently with either an LHβ- or FSHβ-subunit. After translation, the heterodimer undergoes variable glycosylation wherein oligosaccharide chains (glycans) are attached covalently to specific amino acids, resulting in LH and FSH molecules with a high degree of microheterogeneity (i.e., many LH and FSH isoforms characterized by different glycosylation patterns). The gonadotropin α-subunit is produced in excess relative to the LHβ- and FSHβ-subunits; it too is glycosylated, and free α-subunit is cosecreted into the circulation with LH and FSH. Many nonfunctional and gonadotropin-secreting pituitary adenomas secrete excessive amounts of free α-subunit into the circulation.[53]

The degree of glycosylation of gonadotropins and other glycoprotein hormones alters their clearance rate from the circulation and their signal transduction after receptor binding, thereby affecting their biologic activity in vivo. The half-life in the circulation of gonadotropins increases with greater degrees of glycosylation: hCG > FSH > LH > free α-subunit. In humans, the initial half-life of disappearance for LH is about 40 minutes, and the secondary half-life of disappearance is about 120 minutes; for FSH, these periods are approximately 4 and 70 hours, respectively.[54,55]

Variations in glycosylation of LH and FSH result in substantial microheterogeneity among circulating gonadotropin isoforms, which vary in half-life and biologic activity and may be altered by particular physiologic conditions, such as during puberty, with aging, and with androgen deprivation.

Clinically, serum LH and FSH concentrations are measured with rapid, nonradioactive, highly sensitive immunoassays that use monoclonal antibodies recognizing two separate epitopes on the gonadotropin molecule. Gonadotropin measurements are essential in the evaluation of men with hypogonadism to distinguish those who have a primary testicular disorder (*primary hypogonadism*, in which gonadotropins are high) from those who have a secondary hypothalamic or a pituitary disorder (*secondary hypogonadism*, in which gonadotropins are low or normal). Specific immunoassays for free α-subunit are used to diagnose and monitor patients with nonfunctional and gonadotropin-secreting pituitary adenomas.

Gonadotropin Control of Testicular Function

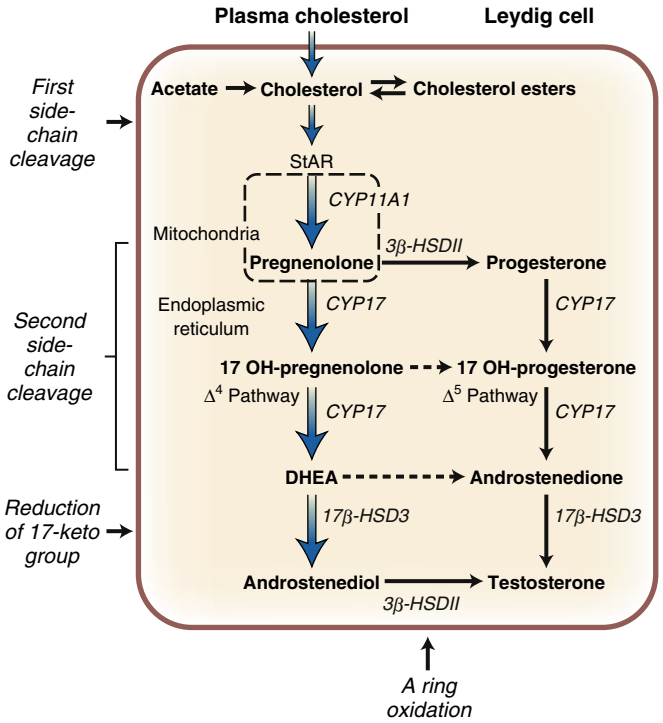
LH Regulation of Leydig Cells

Circulating LH binds to the G protein–coupled receptor for LH and hCG (termed *LHCGR*) on the surface of Leydig cells, resulting in receptor aggregation and a conformational change that activates G_s protein. G_s protein, in turn, results primarily in cyclic adenosine monophosphate (cAMP)-dependent activation of PKA.[56] Activated PKA increases the production of proteins that regulate steroidogenesis and testosterone biosynthesis (Fig. 19.8). The main proteins regulated by LH-stimulated PKA are as follows:

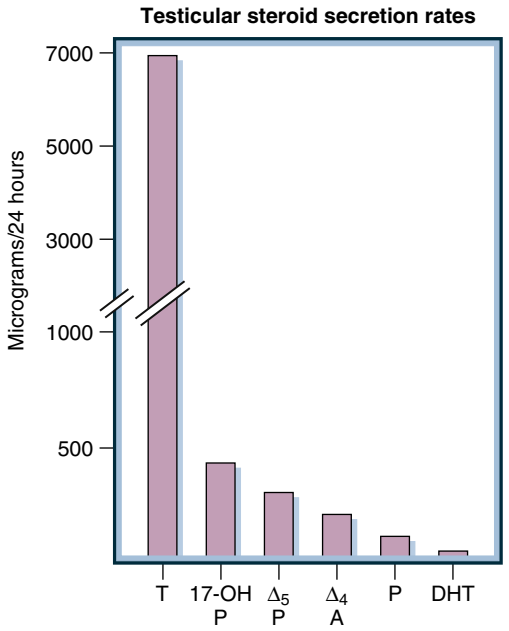
1. *Steroidogenic acute regulatory protein* (StAR), a transport protein that regulates transfer of cholesterol from the outer to the inner mitochondrial membrane—the rate-limiting step for steroid production
2. *Cytochrome P450 isoenzyme 11A1 (P450 11A1)*, also called *cholesterol side-chain cleavage enzyme*, within the inner mitochondrial membrane, which catalyzes the conversion of cholesterol delivered by StAR protein to pregnenolone—the first and rate-limiting enzymatic step in steroidogenesis
3. *P450 17A1*, also called *17α-hydroxylase/17,20-lyase* in the endoplasmic reticulum, which catalyzes the conversion of pregnenolone to 17α-hydroxypregnenolone—the second enzymatic step in testosterone biosynthesis.[57]

In humans, cholesterol is synthesized within Leydig cells from acetate by *3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase*, or it is derived from circulating low-density lipoprotein (LDL) cholesterol.

Clinically, rare inactivating mutations of the LHCGR cause Leydig cell hypoplasia, resulting in impaired male genital development and *46,XY disorder of sex development* (46,XY DSD, previously known as male pseudohermaphroditism; see Chapter 23) resulting from insufficient testosterone production during fetal development.[58] Rare LHβ mutations cause failure of normal male pubertal development with micropenis but otherwise normal genital development at birth, evidence that normal endogenous LH secretion is not required for male sexual differentiation during fetal development and that hCG stimulation of testosterone production by fetal Leydig cells is the main driver.[59] Activating mutations of the LHCGR have been found in boys with familial precocious puberty (*testotoxicosis*).[60] Inhibitors of HMG-CoA reductase (statins) used to treat hypercholesterolemia do not significantly affect serum testosterone concentrations.



• **Fig. 19.8** Testosterone biosynthetic pathways in the Leydig cell of the human testis. Cholesterol may be synthesized de novo from acetate within the Leydig cell or derived from hydrolysis of cholesterol esters or circulating cholesterol. Cholesterol is transported into the inner mitochondrial membrane by steroidogenic acute regulatory protein (StAR); there it is converted to pregnenolone by the cholesterol side-chain cleavage enzyme P450 11A1 (CYP11A1). Biosynthesis of testosterone in the human testis proceeds predominantly through the Δ^5 pathway in the endoplasmic reticulum, where pregnenolone is converted to 17-hydroxypregnenolone and then to dehydroepiandrosterone (DHEA) by 17α-hydroxylase/17,20 lyase P450 17A1 (CYP17), which is converted to androstenediol by 17β-hydroxysteroid dehydrogenase type 3 (17β-HSD3 or HSD17B3) and then to testosterone by 3β-hydroxysteroid dehydrogenase type II (3β-HSDII or HSD3B2). In the Δ^4 pathway, pregnenolone is converted successively to 17-hydroxyprogesterone, androstenedione, and testosterone. (Modified from Bhasin S. Testicular disorders. In: Kronenberg HM, Melmed S, Polonsky KS, et al, eds. *Williams Textbook of Endocrinology,* 11th ed. Philadelphia, PA: Elsevier; 2008:645–698.)



• **Fig. 19.9** Relative steroid hormone secretion rates from the human testis. Secretion rates were calculated from arteriovenous (AV) differences across the testis of testosterone and other steroids, assuming a testosterone secretion rate of 7000 μg per 24 hours and using the following formula: Secretion rate = Assumed testosterone secretion rate/Testosterone AV difference × AV difference of steroid in question. Testosterone (T) is the main steroid secreted by the testis; much lower amounts of 17-hydroxyprogesterone (17-OHP), pregnenolone (Δ^5P), androstenedione (Δ^4A), progesterone (P), and dihydrotestosterone (DHT) are also secreted. (From Hammond GL, Ruokonen A, Kontturi M, et al. The simultaneous radioimmunoassay of seven steroids in human spermatic and peripheral venous blood. *J Clin Endocrinol Metab.* 1977;45:16–24.)

Leydig Cell Production of Testosterone and INSL3

In the human testis, LH-stimulated transport of cholesterol into the inner mitochondrial membrane is followed by conversion of cholesterol to pregnenolone by CYP11A1 and conversion of pregnenolone to 17α-hydroxypregnenolone by CYP17A1. Testosterone biosynthesis then proceeds via a series of further enzymatic steps in the endoplasmic reticulum, initially through the Δ^5 steroid biosynthesis pathway[57,61] (see Fig. 19.8).

The *17,20-lyase (desmolase)* activity of P450 17A1 catalyzes the further conversion of 17α-hydroxypregnenolone to DHEA. DHEA then is converted to Δ^5-androstanediol by *17β-hydroxysteroid dehydrogenase 3* (*17β-HSD3* or *HSD17B3*). DHEA and Δ^5-androstanediol are converted to the Δ^4 steroids, Δ^4-androstenedione and testosterone, respectively, by the enzyme *3β-hydroxysteroid dehydrogenase/Δ^{5-4} isomerase type 2* (*3β-HSD2* or *HSD3B2*).

The early steroid precursors, pregnenolone and 17α-hydroxypregnenolone, may also be converted to progesterone and 17α-progesterone, respectively, by HSD3B2 and then proceed down the Δ^4 pathway to testosterone synthesis. However, in the human testis, the Δ^5 pathway is the predominant steroid biosynthetic pathway for testosterone production. Testosterone may be converted in the testes to the active metabolites, estradiol and DHT, by the enzymes *aromatase* (*P450 19A1*) and *steroid 5α-reductase type 1* (*SRD5A1*, the predominant isoform found in the testes), respectively.

Mutations in testosterone biosynthetic enzymes result in abnormalities of sexual differentiation and varying degrees of 46,XY DSD, depending on the severity of androgen deficiency.[62]

Testosterone is the major androgen produced by the testis. In humans, the average secretion rate of testosterone is approximately 7000 μg/day. The testes also secrete significant but quantitatively smaller amounts of 17α-hydroxyprogesterone, pregnenolone, Δ^4-androstenedione, and progesterone. Very little estradiol (about 10 μg/day) or DHT (about 69 μg/day) is secreted by the testes[9,63] (Fig. 19.9).

In response to pulsatile LH stimulation, testosterone is secreted episodically into the spermatic vein and then into the general circulation. However, testosterone pulses are less discrete, relatively low in amplitude, and concordant with LH pulses only after a lag time of 80 to 120 minutes, suggesting a relatively sluggish response of Leydig cells to LH stimulation.[45] In addition to this ultradian variation, testosterone concentrations in young men exhibit a circadian variation characterized by a maximum excursion of 140 ng/dL, with peak testosterone concentrations occurring at approximately 8 AM and nadir concentrations at 8 PM.[64] The circadian variation in testosterone concentrations is blunted

but still present in older men, with a maximum excursion of 60 ng/dL. The testosterone response to hCG (LH-like) stimulation is greater in the morning than in the evening, suggesting that diurnal variation in Leydig cell responsiveness may contribute to the circadian variation in testosterone concentrations.[65] Both the ultradian and the circadian variation in testosterone concentrations contribute to the variability in testosterone measurements within an individual; together with assay variability, this underscores the importance of repeating testosterone measurements during the clinical evaluation of patients with clinical manifestations of male hypogonadism.

INSL3 is a peptide hormone in the relaxin-insulin family that is produced by Leydig cells and secreted into the circulation.[66] Serum concentrations of INSL3 reflect the number and differentiation status of Leydig cells. During puberty, LH induces proliferation and differentiation of Leydig cells and production of INSL3. Serum INSL3 concentrations increase progressively during puberty, reaching adult concentrations at about 18 years of age and remaining stable until 35 to 40 years of age, after which they decline steadily with age.

Men with anorchia and bilateral orchidectomy, in whom Leydig cells are absent, and men with chronic gonadotropin suppression induced by GnRH analogues or androgens have undetectable or very low concentrations of INSL3. In men with hypogonadotropic hypogonadism, INSL3 concentrations are undetectable; in these patients, hCG (LH-like) stimulation increases serum testosterone concentrations within 72 to 96 hours but has no stimulatory effect on INSL3 concentrations. However, chronic hCG treatment, presumably because of induction of Leydig cell differentiation by longer-term LH-like stimulation, increases both testosterone and INSL3 concentrations in these men.[67] In men with unilateral orchidectomy, INSL3 concentrations are intermediate between those in men with bilateral orchidectomy and those in normal men, but testosterone concentrations are normal, supporting the importance of Leydig cell number for circulating INSL3 concentrations.

FSH and Testosterone Regulation of Sertoli Cells

Circulating FSH binds to G protein–coupled FSH receptors on the surface of Sertoli cells, activating G_s protein that increases cAMP production.[68] cAMP then activates PKA and other signal-transduction proteins (e.g., phosphatidylinositol 3-kinase, phospholipase A_2, calcium channel proteins, mitogen-activated protein kinase [MAPK]). Activated PKA activates many proteins, including the transcription factor, *cAMP response element–binding protein*; these proteins, in turn, regulate gene expression and production of Sertoli cell proteins that play important roles in supporting and regulating spermatogenesis within the seminiferous tubules. In rodents, the expression of FSH receptors in Sertoli cells varies cyclically with the stage of spermatogenesis, being highest in stages XIII through I and lowest in stages VII and VIII.[69] The precise roles of Sertoli cell products in human spermatogenesis are poorly understood and derive from studies using Sertoli cells obtained primarily from immature animals, mostly rodents.

Testosterone produced locally by Leydig cells binds to intracellular ARs in the cytoplasm of Sertoli cells; ligand-bound AR translocates to the nucleus, where it binds to androgen response elements and interacts with coregulator proteins to regulate gene expression and production of Sertoli cell proteins that play vital roles in supporting and regulating spermatogenesis. The expression of the AR also varies cyclically with the stage of spermatogenesis, being highest in stage VII, when FSH receptor expression is the lowest.[70]

The major functions of Sertoli cells[71,72] are (1) to maintain seminiferous tubule structure and compartmentalization; (2) to provide nutrients and growth factors to developing germ cells and spermatozoa; (3) to translocate, sculpt, and release developing germ cells; (4) to secrete seminiferous tubule fluid; and (5) to produce reproductive hormones.

Maintenance of Seminiferous Tubule Structure and Compartmentalization

The blood-testis barrier is formed by basal tight junctions between adjacent Sertoli cells; these serve to compartmentalize the seminiferous tubule into basal and adluminal compartments. Compartmentalization provides an environment in which developing germ cells are protected from external insults and the immune system.

Sertoli cells produce many junctional complex, structural, and extracellular matrix proteins, such as cell adhesion molecules (e.g., claudin 3, which is particularly important for the integrity of Sertoli cell tight junctions), cadherins, laminins, type I and type IV collagen, and proteoglycans including chondroitin and heparin. These proteins are important in maintaining the structural integrity and support for developing germ cells, forming the blood-testis barrier, mediating cell-to-cell interactions, and maintaining polarized secretion of products by Sertoli cells.

Provision of Nutrients and Growth Factors to Developing Germ Cells and Spermatozoa

Although it is protective, the blood-testis barrier also isolates developing germ cells from nutrients, hormones, and growth factors that are present in the systemic circulation. The Sertoli cell has an essential role in producing vital nutrients, cofactors, and proteins that are needed for the normal progression of spermatogenesis and support of spermatozoa being transported within the seminiferous tubule lumen. Sertoli cells produce pyruvate and contain lactate dehydrogenase, which catalyzes the conversion of pyruvate to lactate, the preferred energy substrate of germ cells.

Most of the proteins produced by Sertoli cells are binding or transport proteins for substances (e.g., metals, vitamins, sphingolipids, androgens, hormones, growth factors) that serve as cofactors and regulators of germ cell development within the seminiferous tubule. Binding proteins produced by Sertoli cells include transferrin, an iron-binding protein; ceruloplasmin, a copper-binding protein; glycosphingolipid-binding protein; sulfated glycoprotein 2, also called *clusterin*, a lipid-binding protein with other biologic activities; androgen-binding protein (ABP); α_2-macroglobulin, which serves as a binding protein for inhibin and activin; follistatin, a potent binding protein for activin; and insulin-like growth factor–binding proteins (IGFBPs), which bind insulin-like growth factor type 1 (IGF1).

ABP is a testicular homologue of *sex hormone–binding globulin* (SHBG), the major circulating ABP, which is synthesized by the liver and encoded by the same gene.[73] Based on studies in rodents, ABP is thought to play a role in regulating local testosterone concentrations in the seminiferous tubule and epididymis. However, one study reported that human SHBG is expressed in germ cells but not in Sertoli cells and that a smaller isoform of SHBG is located between the outer acrosomal membrane and the sperm plasma membrane and is released during capacitation.[74] These findings suggest a potentially different role of SHBG/ABP in humans and rodents and underscore the hazard of extrapolating results from animal studies.

The Sertoli cell also produces several growth factors, such as IGF1, basic fibroblast growth factor, activin A, transforming

growth factor-α (TGFα) and TGFβ, interleukin 1α (IL1α) and IL6, stem cell factor (the c-KIT ligand), glial cell–derived neurotrophic factor, and polyamines (putrescine, spermine, and spermidine), which act both as paracrine regulators of stem cell renewal, germ cell development, and Leydig cell and peritubular myoid cell function and as autocrine regulators.

Translocation, Sculpting, and Release of Developing Germ Cells

Sertoli cells actively move developing germ cells from the basal compartment through the adluminal compartment and release spermatozoa from the seminiferous epithelium into the lumen (spermiation). During translocation, Sertoli cells remove degenerating germ cells, residual cytoplasm from late elongated spermatids (residual body), and seminiferous tubule fluid and contents by phagocytosis and pinocytosis. The Sertoli cell produces proteases and protease inhibitors (e.g., testibumin or sulfated glycoprotein 1, tissue plasminogen activators, type IV collagenase, cystatin, α_2-macroglobulin) that are involved in germ cell translocation, removal of degenerating germ cells, and spermiation.

Secretion of Seminiferous Tubule Fluid

Seminiferous tubule fluid serves important roles in the delivery of nutrients to developing germ cells within the seminiferous epithelium, transportation of regulatory factors and nutrients within the seminiferous tubule lumen, and transportation of spermatozoa released into the seminiferous tubule lumen to the rete testis, efferent ducts, and epididymis.

Production of Reproductive Hormones

Sertoli cells produce hormones that are important in male reproductive differentiation and function. These include AMH, which causes regression of the müllerian ducts, preventing uterine and fallopian tube formation during embryogenesis; inhibin B and activin A, peptide hormones that, respectively, participate in negative feedback regulation of FSH secretion and potentially act as a paracrine regulator of spermatogenesis; and estradiol, a potent estrogen that is produced via aromatization of testosterone in immature Sertoli cells.

FSH acts directly and testosterone (secreted by Leydig cells in response to LH) acts directly and also indirectly (e.g., by stimulating peritubular myoid cells) to control Sertoli cell function and regulate spermatogenesis. Gene expression profiling studies using microarray analysis in rat Sertoli cells treated with FSH, in Sertoli cell–specific AR mutant mice, and in GnRH-mutant mice treated with testosterone have provided insight into specific Sertoli cell genes that are regulated directly by FSH and testosterone.[75] However, similar studies in humans investigating the regulation of Sertoli cell gene expression, specifically by FSH and testosterone, have yet to be performed.

Paracrine and Autocrine Regulation of Testis Function

As described earlier, with regard to testicular function, gonadotropins, LH, and FSH secreted by the pituitary are the major endocrine regulators, and testosterone produced by Leydig cells in response to LH stimulation is the main paracrine regulator. However, there is evidence, mostly from studies in experimental animals and in vitro studies using isolated testis cell types from animals, that Leydig, Sertoli, and peritubular myoid cells and macrophages in the testis secrete other paracrine and autocrine factors that may be important modulators of testosterone and sperm production.

One of the most important examples of paracrine regulation within the testis is the effect of testosterone, produced locally by Leydig cells, on Sertoli cell function and spermatogenesis. There is evidence that testosterone has both a direct effect on Sertoli cell function and spermatogenesis and an indirect effect on peritubular myoid cell ARs. In GnRH- and gonadotropin-deficient *hpg* mice in which the AR has been knocked out specifically in Sertoli cells, DHT treatment is not able to stimulate spermatogenesis, suggesting that direct androgen action on Sertoli cells is needed to stimulate spermatogenesis.[76] Animals with a peritubular myoid cell–specific AR knockout demonstrate impaired Sertoli function (i.e., reduced seminiferous tubule fluid and Sertoli cell androgen-dependent gene expression), azoospermia, and infertility not explained by alterations in testosterone, LH, and FSH concentrations.[77] These findings suggest that the paracrine effect of Leydig cell–produced testosterone on Sertoli cell function and regulation of spermatogenesis is mediated in part by androgen-driven interactions between peritubular myoid cells and Sertoli cells. Whether these stromal-epithelial cell interactions occur in humans is not known. At present, the roles of paracrine and autocrine factors other than testosterone in the regulation of human testis function are not clear.

Hormonal Control of Spermatogenesis

LH and FSH are the main hormonal regulators of spermatogenesis in humans. The effect of FSH on spermatogenesis is mediated by a direct endocrine action on Sertoli cells, whereas that of LH is mediated by an action on Leydig cells to produce testosterone, which in turn acts locally within the testes in a paracrine manner, with direct effects on Sertoli cells and possibly indirect effects through peritubular myoid cell regulation of Sertoli cells. The gonadotropin requirements necessary for the initiation of spermatogenesis at the time of puberty differ from those needed for the maintenance of sperm production, once initiated, in adults.[10,78]

Initiation of Spermatogenesis

Usually, both LH and FSH are required to initiate spermatogenesis at the time of puberty. In men with prepubertal gonadotropin deficiency (e.g., CHH), treatment with LH (hCG) is needed to stimulate sufficient intratesticular testosterone production to support spermatogenesis and seminal fluid production by accessory sex glands (seminal vesicles and prostate gland). However, most such patients also require FSH treatment to initiate and complete the first wave of spermatogenesis and to produce sperm in the ejaculate.[79] In some men with incomplete gonadotropin deficiency (usually with evidence of endogenous FSH secretion, e.g., larger testis volume), LH treatment alone is sufficient to initiate and complete spermatogenesis. FSH treatment without LH (hCG) does not stimulate sperm production in men with prepubertal complete gonadotropin deficiency—but might be sufficient in men with partial gonadotropin deficiency.

Natural inactivating mutations of gonadotropin β-subunits and receptors provide some insight into the roles of LH and FSH in initiating spermatogenesis. Men with inactivating mutations of LHβ usually have a lack of pubertal development and arrested spermatogenesis or azoospermia and infertility.[59] Recently, however, a man with an LHβ mutation resulting in a partially active LH molecule (as evidenced by expression of steroidogenic enzymes in a few mature Leydig cells and low intratesticular testosterone concentrations) was reported to have complete and quantitatively normal spermatogenesis.[80] This finding suggests that complete spermatogenesis may be initiated by low concentrations of LH

and intratesticular testosterone in the presence of high serum FSH concentrations, as were present in this case.

Men with inactivating LH receptor mutations present with varying degrees of impaired sexual differentiation or 46,XY DSD, ranging from ambiguous genitalia to perineoscrotal hypospadias, and azoospermia, although defects in sperm production are confounded by the presence of cryptorchidism in many of these men.[58] Recently, a man with a partially inactivating mutation of the LH receptor was reported to have micropenis, delayed puberty, low serum testosterone concentrations, and normal FSH concentrations but bilaterally normal-size, descended testes and normal sperm production, albeit with low sperm concentration (oligozoospermia).[81] This finding suggests that spermatogenesis may be initiated qualitatively by very low LH activity and intratesticular testosterone in the presence of normal FSH concentrations.

Men with inactivating mutations of FSHβ have been found generally to have azoospermia with low or low-normal testosterone and high LH concentrations.[82-85] In contrast, men with inactivating FSH receptor mutations have been reported to have moderate to severely reduced sperm counts (but not azoospermia) with normal testosterone and normal to high LH concentrations.[58,86] The reason for the apparent discrepancy in degree of spermatogenic impairment exhibited by men with FSHβ versus FSH receptor mutations is not clear. It is possible that residual receptor function in men with FSH receptor mutations results in persistent small amounts of FSH signaling or that men with FSHβ mutations have greater Leydig cell dysfunction, as evidenced by lower serum concentrations of LH and intratesticular testosterone that result in greater impairment of spermatogenesis.

In summary, findings from the small number of reports of men with inactivating mutations of gonadotropin β-subunits and receptors suggest that initiation of the first wave of spermatogenesis may require only very low concentrations or activity of either LH (intratesticular testosterone) or FSH in the presence of adequate amounts of the other gonadotropin. Clinically, however, most men with prepubertal gonadotropin deficiency require treatment with both LH and FSH to initiate spermatogenesis during puberty. Because FSH stimulates Sertoli cell proliferation and number during testis development, it plays a vital role in determining the capacity for quantitatively normal spermatogenesis.

Maintenance of Spermatogenesis

In men with prepubertal gonadotropin deficiency (e.g., CHH), once spermatogenesis has been initiated with LH (hCG) and FSH treatment, sperm production may be maintained with LH treatment alone without continued FSH administration.[79] However, spermatogenesis is not stimulated by administration of FSH in combination with testosterone (that maintains normal concentrations of serum testosterone but with continued low LH and intratesticular testosterone concentrations) in men with CHH. Spermatogenesis may be reinitiated with LH (hCG) alone in previously gonadotropin-treated men with CHH after a period of gonadotropin deficiency associated with exogenous testosterone replacement therapy. Furthermore, in men with gonadotropin deficiency and azoospermia acquired as an adult (e.g., secondary to a pituitary adenoma), spermatogenesis may be reinitiated and maintained with LH (hCG) treatment alone.[79]

In normal men with experimental gonadotropin deficiency induced by high-dose testosterone administration, spermatogenesis may be reinitiated and maintained by either LH or hCG alone, despite markedly suppressed FSH concentrations, or by FSH alone, despite severely suppressed LH (and presumably low intratesticular testosterone) concentrations. However, sperm production was not stimulated by either LH or FSH alone to the baseline concentrations that existed before experimental gonadotropin suppression.[87] In this model of gonadotropin deficiency, treatment with both LH (hCG) and FSH restored sperm counts fully to baseline values. Finally, in support of the ability of FSH alone to stimulate sperm production, spermatogenesis was maintained despite undetectable serum gonadotropin concentrations in a hypophysectomized man who had an activating FSH receptor mutation.[88]

Together, these findings suggest that a normal concentration of either FSH or LH is sufficient for maintenance of qualitatively normal sperm production, but both gonadotropins are necessary for quantitatively normal spermatogenesis in male humans.

The effect of gonadotropins on specific stages of spermatogenesis has been studied in normal men with experimental gonadotropin suppression induced by the administration of high-dose progestin and testosterone. In these gonadotropin-deficient men, selective replacement of either FSH or LH (increasing intratesticular testosterone) supported all stages of spermatogenesis, including spermatogonial maturation, meiosis, spermiogenesis, and spermiation, but each agent had predominant actions on specific stages.[89] FSH exerted a relatively greater effect on maturation of spermatogonia (conversion of spermatogonia A_p to spermatogonia B), early meiosis, and maintenance of pachytene spermatocytes (conversion of spermatogonia to pachytene spermatocytes). LH (stimulating intratesticular testosterone) had predominant effects on the completion of meiosis (conversion of pachytene spermatocytes to round spermatids) and on spermiation (release of mature spermatozoa). LH and FSH (intratesticular testosterone) exert similar effects on spermiogenesis (conversion of round to elongated spermatids).

In normal men, LH stimulates intratesticular testosterone concentrations that are approximately 100- to 200-fold higher than serum testosterone concentrations and correlate with circulating LH concentrations. Administration of various combinations of exogenous testosterone, progestin, and GnRH antagonist to induce gonadotropin deficiency in male contraception trials suppressed intratesticular testosterone by 98%, to concentrations comparable to those in serum, and reduced sperm production, producing severe oligozoospermia or azoospermia.[90] Short-term administration of hCG (LH-like activity) in normal men with experimental gonadotropin deficiency resulted in a dose-dependent increase in intratesticular testosterone.[91]

Testosterone replacement therapy in gonadotropin-deficient men does not increase intratesticular testosterone sufficiently to support spermatogenesis. In fact, testosterone treatment suppresses endogenous gonadotropin concentrations and may suppress sperm production. However, this cannot be assumed to occur in all testosterone-treated gonadotropin-deficient men, especially if testosterone replacement is not adequate. In one study involving a small number of men with acquired hypogonadotropic hypogonadism due to hypothalamic-pituitary disease, half had detectable sperm counts ranging from very low (1 million/mL) to normal (120 million/mL) on testosterone replacement therapy, mostly because of incomplete gonadotropin suppression associated with an subtherapeutic testosterone regimen (200–250 mg given by intramuscular [IM] injection every 3–4 weeks).[92]

Spermatogenesis is maintained with intratesticular testosterone concentrations that are 10% of normal, but the minimum concentration needed to support sperm production is not known. Intratesticular testosterone is converted within the testes to its

active metabolites, estradiol and DHT, by P450 19A1 (aromatase) and 5α-reductase (SRD5A1), respectively. As with testosterone, intratesticular concentrations of estradiol are about 100-fold higher than serum estradiol concentrations; however, intratesticular concentrations of DHT are only approximately 15-fold higher than concentrations in the circulation.[93] The roles of these relatively high concentrations of estradiol and DHT within the testes in the maintenance of spermatogenesis are not clear.

Negative Feedback Regulation of Gonadotropin Secretion

As described earlier, the feed-forward regulation of testicular function involves hypothalamic GnRH stimulation of pituitary gonadotropin secretion, which in turn stimulates the testes to secrete testosterone and increase sperm production (see Fig. 19.6). An important aspect of hypothalamic-pituitary-testicular axis regulation is the negative feedback suppression of hypothalamic GnRH and pituitary gonadotropin secretion by steroid and peptide hormones produced by the testes. Testosterone, produced by Leydig cells of the testis, and estradiol, its active metabolite, act at both the hypothalamus and the pituitary gland to inhibit GnRH and gonadotropin secretion. Inhibin B, produced by Sertoli cells within seminiferous tubules of the testis, acts primarily on the pituitary to suppress FSH secretion.

In a series of elegant prospective studies, normal men and GnRH-deficient men with CHH treated with physiologic doses of pulsatile GnRH (i.e., a GnRH clamp) underwent medical castration induced by high-dose ketoconazole and treatment with physiologic doses of testosterone or estradiol. The effects of these interventions on production of LH and FSH were measured. These studies have helped to define the relative roles of testosterone and estradiol in regulating gonadotropin secretion and the sites of negative feedback by these steroids.[94,95] It appears that both testosterone and estradiol (derived from aromatization of testosterone) exert negative feedback effects at the hypothalamus to suppress pulsatile GnRH secretion. These studies also demonstrated that negative feedback inhibition of pituitary LH and FSH secretion by testosterone requires aromatization of testosterone to estradiol. The suppression of FSH by estradiol is modest when inhibin B concentrations are normal and testes are normal, suggesting that inhibin B is the main physiologic negative feedback regulator of FSH secretion.[96] When inhibin B concentrations are low, as in men with seminiferous tubule failure or anorchia, the negative feedback effect of estradiol derived from testosterone assumes a greater role in suppressing FSH.

Although active metabolism of testosterone to estradiol is important in the negative feedback actions of testosterone, conversion of testosterone to DHT by 5α-reductase types 1 and 2 does not play a major role in steroid feedback. Men with mutations in *SRD5A2* exhibit only modest elevations in gonadotropins and increases in LH pulse amplitude but not frequency.[97] Men with benign prostatic hyperplasia (BPH) and normal men treated with finasteride (an SRD5A2 inhibitor) or dutasteride (an SRD5A1 and SRD5A2 inhibitor) do not demonstrate increases in serum LH and FSH concentrations.[98] These findings suggest a relatively minor role for DHT in physiologic negative feedback regulation of gonadotropins. However, administration of supraphysiologic amounts of DHT does suppress concentrations of LH (by 30–60%) and FSH (by 15–30%).[99]

The pituitary gonadotrophs contain estrogen receptor α (ERα), but GnRH neurons appear to lack both ERα and AR. The negative feedback actions of testosterone and estradiol are thought to be mediated indirectly by other neuronal systems that relay steroid feedback signals to GnRH neurons. Studies in animals suggest that neurons that produce *kisspeptin*, a 54–amino acid peptide product of the *KISS1* gene, may be candidate mediators of steroid negative feedback.[100,101] These neurons interact directly with GnRH neurons in the medial basal hypothalamus, the majority of which contains the kisspeptin receptor, *KISS1R*, and the release of kisspeptin thereby stimulates GnRH secretion. Kisspeptin neurons may also interact with other neurons (e.g., γ-aminobutyric acid neurons) to indirectly regulate GnRH secretion. Kisspeptin neurons contain both AR and ERα. In experimental animals, castration increases kisspeptin expression, coinciding with an increase in GnRH and gonadotropin secretion; sex steroid treatment with testosterone, estradiol, or DHT reverses these changes, and kisspeptin antagonists block the postcastration increase in LH secretion. In humans, mutations in *KISS1* or *KISS1R* cause hypogonadotropic hypogonadism and impaired pubertal development,[102] and there is accumulating evidence in animals that kisspeptin may have a key role in the initiation of puberty.

Inhibins are heterodimeric glycoproteins belonging to the TGFβ superfamily of proteins, which includes activins, inhibins, TGFβ, bone morphogenetic proteins, and growth and differentiation factors such as AMH and myostatin.[103] Inhibins are composed of an α-subunit connected by a disulfide bridge to either a β_A or a β_B subunit to form inhibin A or inhibin B, respectively. *Inhibin B* (α-β_B heterodimer) is the physiologically relevant inhibin species in humans. Unlike most proteins in the TGFβ family, which act as local paracrine or autocrine regulators of diverse cellular functions, inhibin B acts as a circulating hormone. Inhibin B is produced by the Sertoli cell in response to FSH stimulation. It binds to a coreceptor composed of the type III TGFβ receptor (TGFBR3 or betaglycan) and the type IIB activin receptor (ACVR2B) and is thought to be the main endocrine negative feedback suppressor of FSH secretion by pituitary gonadotrophs.

In humans, inhibin B concentrations rise progressively at the time of puberty, correlating with FSH concentrations and FSH-stimulated Sertoli cell proliferation.[103] Adult concentrations are reached by midpuberty. At that time, Sertoli cell function becomes intimately linked to the onset of spermatogenesis, and inhibin B concentrations assume an inverse relationship with FSH concentrations as the inhibin B–mediated negative feedback regulation becomes activated. For example, in boys with Sertoli cell–only syndrome, inhibin B concentrations are normal before puberty as a function of Sertoli cell proliferation but become undetectable at the time of puberty, reflecting the absence of germ cells and Sertoli cell dysfunction. In adults, inhibin B concentrations are inversely related to the degree of germ cell damage or loss and Sertoli cell dysfunction. This relationship suggests that germ cells regulate Sertoli cell function, although the precise cellular and molecular mechanisms underlying this regulation are not clear. Inhibin B concentrations have been used as biomarkers of spermatogenesis and Sertoli cell function in research and by some practitioners, but they have not yet been used in routine clinical practice.

Activins include homodimers consisting of two β_A subunits (activin A) or two β_B subunits (activin B) and a heterodimer of one β_A and one β_B subunit (activin AB).[103,104] Activins are produced by gonadotrophs and bind to ACVR2B receptors. They act primarily as autocrine regulators to stimulate FSHβ synthesis and sensitize gonadotrophs to GnRH stimulation, resulting in increased FSH secretion. Inhibin B acts as a selective antagonist of activins in gonadotrophs by binding to ACVR2B receptors.

Follistatins are glycoproteins produced by gonadotrophs and by folliculostellate cells of the pituitary gland that bind and antagonize the actions of activin. They act as autocrine and paracrine regulators of FSH secretion. Activins and follistatins are also produced in Sertoli cells and germ cells and may act as autocrine and paracrine regulators of testis function.

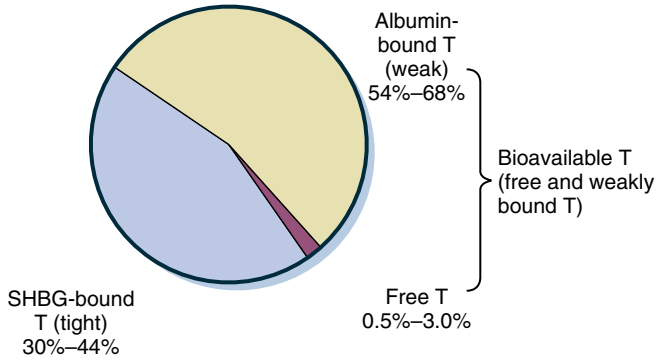
Negative feedback suppression of gonadotropin production (by pharmacologic doses of androgens or combinations of androgens and progestins or by GnRH antagonists) that is sufficient to result in suppression of sperm production has been the basis for male hormonal contraceptive development strategies.[105]

Testosterone Transport, Metabolism, and Actions

Circulating Testosterone

Like other steroid and thyroid hormones, testosterone secreted into the circulation by Leydig cells is mostly bound to plasma proteins, primarily to SHBG and albumin. In the circulation, *total testosterone* is composed of 0.5% to 3.0% *free testosterone* unbound to plasma proteins, 30% to 44% SHBG-bound testosterone, and 54% to 68% albumin-bound testosterone[106,107] (Fig. 19.10).

Clinically, biologic actions of testosterone, like those of other steroid hormones, are thought to conform to the free hormone hypothesis—that is, the biologic activity of testosterone is mediated only by its free (unbound) concentration or the concentration that is easily dissociable from plasma proteins in the circulation.[107,108] Testosterone is tightly bound to SHBG with such high affinity (1.6×10^{-9} mol/L) that it is not easily dissociable and available to target tissues for biologic action. In contrast, testosterone is loosely bound to albumin, with a binding affinity (1.0×10^{-4} mol/L) that is several orders of magnitude less than that of SHBG binding. Therefore, albumin-bound testosterone is dissociable and available to target tissues for action. Together, free testosterone and albumin-bound testosterone are referred to as *bioavailable testosterone*, because these fractions are available to diffuse into target tissues, bind AR, and affect gene transcription, resulting in androgen action in those tissues. One case was reported of a man who had undetectable SHBG and very low total testosterone concentrations due to a missense mutation of the *SHBG* gene that blocked its secretion.[109] His free testosterone and gonadotropin concentrations and semen analysis were normal, and he had normal objective evidence of sexual development. Although he did have subtle symptoms of male hypogonadism (sexual dysfunction, weakness, and fatigue), the overall findings in this man provide support for the free hormone hypothesis. In addition, data from the European Male Aging Study, a longitudinal cohort study, indicate that low serum free testosterone concentrations are associated with symptoms and objective findings of male hypogonadism in men with normal total testosterone concentrations.[110] In addition, incident symptoms of hypogonadism occur in men who have low serum free testosterone and total testosterone concentrations but not in obese men with normal serum free testosterone and low serum total testosterone concentrations.[111] Although the free testosterone hypothesis remains controversial, the limited available data generally support it.[112]



• **Fig. 19.10** Fractions of circulating testosterone in blood. The majority of circulating testosterone (T) is bound to serum proteins: approximately 54% is weakly bound to albumin, and 44% is tightly bound to sex hormone–binding protein (SHBG). Only about 2% of circulating T is free of protein binding. The combination of free and weakly bound (albumin-bound) T is referred to as bioavailable testosterone.

SHBG, which is synthesized by hepatocytes of the liver, is a homodimeric β-globulin protein composed of a heavy and a light subunit that are identical in peptide sequence and encoded by a single gene but differ in their degree of glycosylation.[73] The *SHBG* gene is also expressed in the testes and in most mammals, Sertoli cells produce a homologue of SHBG, known as ABP, under the control of FSH. In the human testis, however, *SHBG* appears to be expressed in germ cells rather than Sertoli cells and to produce a truncated form of SHBG (not ABP) that localizes to the acrosome of spermatozoa.[74] SHBG has two binding sites per monomer; these sites bind DHT and testosterone with high affinity and estradiol less avidly. Previous studies have assumed identical binding affinities of SHBG monomers for testosterone and other ligands. Recent studies suggest that binding of testosterone to one monomer of the SHBG dimer affects the binding affinity of testosterone to the second monomer and that binding can only be characterized by a complex dynamic, multistage, allosteric model.[113] Glycosylation of SHBG is not involved in steroid binding but may prolong the plasma half-life of the protein in the circulation. SHBG production by the liver is increased under the influence of estrogens and thyroxine and decreased by androgens and insulin.

Counter to the free hormone hypothesis, there is evidence that testosterone bound to SHBG may affect androgen action in some target tissues. In some tissues, such as the human prostate, SHBG may bind to a cell surface receptor; testosterone then binds to the SHBG-receptor complex, activating cAMP and affecting target organ function.[114] Glycosylation of SHBG may be important for the interaction of steroid-SHBG complexes with plasma membranes. *Megalin* is a member of the LDL receptor superfamily of proteins that serve as endocytic proteins facilitating the entry of steroids into cells (most notably 25-hydroxyvitamin D into proximal tubule cells of the kidney). Megalin is found in the kidney and also in the epididymides, prostate, ovaries, and uterus. In vitro studies in cells that expressed megalin but no other endocytic receptors found that testosterone, DHT, and estradiol bound to SHBG were endocytosed into cells and activated AR-mediated transcription; these effects were blocked by a megalin antagonist.[115] Furthermore, megalin-knockout mice demonstrated impaired testicular descent, an androgen-mediated process. These findings suggest that megalin may be important in mediating cellular uptake of androgens into some tissues. However, the importance of testosterone bound to SHBG or endocytic proteins such as megalin in human physiology remains to be determined.

In normal men with an intact hypothalamic-pituitary-testicular axis, alterations in SHBG concentrations and testosterone bound to SHBG do not influence the physiology and action of androgens at steady state. Any acute effects on free testosterone

concentration caused by changes in SHBG would alter the negative feedback regulation of gonadotropins, resulting in normalization of free testosterone concentrations. For example, an acute increase in SHBG concentrations may transiently decrease free testosterone concentrations, but the consequent decrease in testosterone negative feedback increases pituitary LH secretion, which increases testosterone production by the testes to restore normal free testosterone concentrations. In contrast, alterations in SHBG concentrations may alter free testosterone concentrations in men with reproductive disorders who have impaired negative feedback regulation or are receiving testosterone replacement therapy.

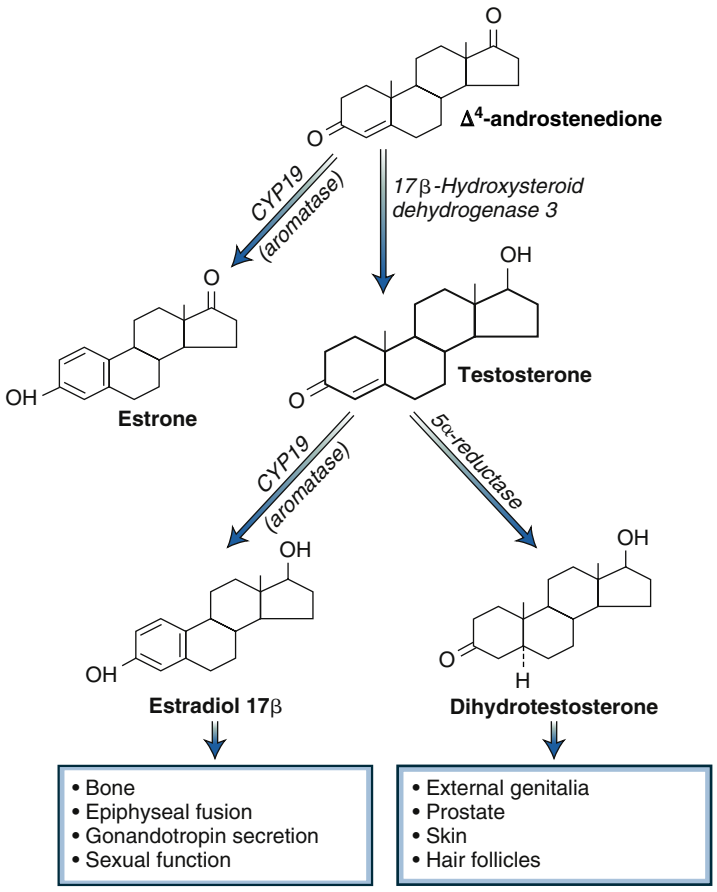
SHBG concentrations may be decreased or increased in a variety of commonly encountered clinical conditions.[116] Clinically, alterations in SBHG are extremely important to consider in the diagnosis of male hypogonadism (see later discussion). Because serum total testosterone measurements are affected by changes in SHBG concentrations, accurate measurements of free or bioavailable testosterone are needed to assess the adequacy of Leydig cell function, to determine whether a patient is hypogonadal, and to monitor testosterone replacement in patients with alterations in circulating SHBG concentrations.

Active Metabolism and Catabolism of Testosterone

An important aspect of the effects of testosterone action on target tissues is its active metabolism to *17β-estradiol* (estradiol) by P450 19A1 and to *DHT* by SRD5A1 and SRD5A2; these are the most potent of the endogenous estrogens and androgens[9] (Fig. 19.11). Many of the biologic actions of testosterone are mediated by these active metabolites, acting through mechanisms that are dependent on ERα and ERβ (estradiol) or on AR (DHT). These active metabolites are formed and act locally as paracrine or autocrine regulators, and they also are secreted and act as endocrine regulators of target tissue function.

Aromatization of Testosterone to Estradiol

Aromatase (P450 19A1) catalyzes the conversion of testosterone to estradiol, as well as the conversion of the weaker androgen, Δ^4-androstenedione, to the weaker estrogen, estrone. In men,



• **Fig. 19.11** Active metabolism of testosterone. Testosterone may be converted to the potent estrogen 17β-estradiol by the enzyme aromatase or P450 19A1 (CYP19) or to the more potent androgen dihydrotestosterone (DHT) by the enzyme 5α-reductase. The effects of testosterone on external genital differentiation, prostatic growth, skin, and hair follicles in androgen-sensitive areas require 5α-reduction of testosterone to DHT. The effects of testosterone that require aromatization to estradiol are prevention of bone resorption, increase in bone mineral density, epiphyseal fusion, and gonadotropin secretion. Testosterone and DHT, but not estradiol, increase and maintain muscle mass and strength; testosterone, DHT, and estradiol play a role in normal male sexual function; and testosterone and DHT have opposing effects to estradiol on high-density lipoprotein cholesterol concentrations. (Modified from Bhasin S. Testicular disorders. In: Kronenberg HM, Melmed S, Polonsky KS, et al, eds. *Williams Textbook of Endocrinology,* 11th ed. Philadelphia, PA: Elsevier; 2008:645–698.)

these conversions occur predominantly in adipose tissue but also in other tissues, including brain, bone, breast, liver, blood vessels, and testes (Sertoli cells and Leydig cells). Approximately 40 to 50 μg of estradiol is produced daily, primarily by extratesticular aromatization of testosterone to estradiol and of Δ^4-androstenedione to estrone (which is then converted to estradiol by various isoforms of the 17β-HSD enzymes). Approximately 15% to 25% of circulating estradiol is produced by the testes, primarily by Leydig cells.[117]

Aromatization of testosterone to estradiol mediates the effects of testosterone on epiphyseal closure at the time of puberty, inhibition of bone resorption and maintenance of bone mineral density (BMD), regulation of fat mass accumulation, negative feedback suppression of hypothalamic GnRH secretion and pituitary gonadotropin secretion, sexual function, and possibly regulation of high-density lipoprotein (HDL) cholesterol concentrations and some aspects of cognitive function and mood.[118,119] Healthy young to middle-age men with experimental hypogonadism induced by a GnRH agonist were treated with placebo or various dosages of testosterone with or without coadministration of an aromatase inhibitor to investigate the relative effects of experimental androgen and estrogen deficiency, respectively.[120,121] Decreases in lean body mass, muscle size, and strength were induced by androgen deficiency; fat mass accumulation and bone loss was induced by estrogen deficiency; and decline in sexual function was induced by both androgen and estrogen deficiency. In addition, estradiol deficiency appears to be the primary cause of vasomotor symptoms (hot flashes) in men with acute severe hypogonadism.[122]

In men, circulating estradiol is regulated primarily by the amount of androgen substrates, testosterone and Δ^4-androstenedione, and by aromatase activity in adipose tissue and other peripheral tissues. Aromatase activity in Leydig cells is controlled primarily by LH. Stimulation of aromatase activity in gonadotropin-deficient men treated with hCG may result in relatively higher concentrations of serum estradiol compared with testosterone and may contribute to benign breast tenderness and enlargement (gynecomastia) during treatment. As in women, men with ER-positive breast cancer may be treated with aromatase inhibitors to reduce estrogen synthesis.

The few men reported with inactivating mutations of the aromatase gene (*CYP19A1*) have demonstrated tall stature, persistent linear growth after puberty, eunuchoidal body proportion, delayed bone age, osteopenia or osteoporosis and progressive *genu valgum*, and variable impairments in glucose and lipid metabolism, including insulin resistance, elevated triglyceride and low HDL cholesterol concentrations, abnormal liver enzymes and fatty liver, variably low sperm counts and infertility, and undetectable estradiol concentrations with normal to elevated serum testosterone and gonadotropin concentrations.[123] Furthermore, estradiol treatment results in closure of the epiphyses, increased BMD, and increased bone age. Men with a rare inactivating mutation of ERα had a similar phenotype, but in contrast to men with aromatase deficiency, they had high serum estradiol, testosterone, and gonadotropin concentrations, consistent with estrogen resistance.[118] These findings support potentially important roles of estradiol in bone, glucose, and lipid metabolism; liver function; and pituitary and testis function.

5α-Reduction of Testosterone to DHT

Testosterone is converted to DHT, an androgen that is 2.5 to 3.0 times more potent than testosterone, by SRD5A1 and SRD5A2. These two isoenzymes of 5α-reductase differ in the optimal pH for their activity and in their expression patterns.[124] SRD5A2 is expressed most highly in prostate, epididymis, seminal vesicles, genital skin, and liver and at lower concentrations in other tissues, such as certain brain regions, nongenital skin, testis, and kidney. SRD5A1 is expressed most highly in nongenital skin (hair follicles), liver, and certain brain regions and at lower concentrations in prostate, epididymis, seminal vesicles, genital skin, testis, adrenal, and kidney. Approximately 200 to 300 μg of DHT is produced daily, mostly from 5α-reduction of testosterone in peripheral tissues (predominantly skin and liver). The prostate and testis contribute relatively little to concentrations of DHT in blood.

Men with inactivating mutations of *SRD5A2* are born with severe 46,XY DSD with ambiguous genitalia (clitoris-like phallus, bifid scrotum, pseudovaginal hypospadias, and rudimentary prostate gland) but normal wolffian duct differentiation (normal seminal vesicles, epididymides, and vas deferens) and no müllerian duct structures, supporting the vital role of DHT in external genital differentiation and prostate development.[125] Individuals with SRD5A2 deficiency are usually raised as girls. With the onset of puberty and increase in testosterone to adult male concentrations, the phallus grows, the scrotum develops, libido and erections are stimulated, and the gender role may change from female to male. Cryptorchidism is common but not invariable and is associated with oligozoospermia or azoospermia. Testes may descend at the time of puberty. Normal sperm counts may occur in individuals with descended testes, and fertility has been reported in men with SRD5A2 deficiency. However, in adults, the prostate remains underdeveloped and is not palpable, facial and body hair are diminished, sebum is not produced, and male-pattern baldness does not occur, supporting the importance of normal SRD5A2 activity and DHT for hair growth, sebaceous function, and prostate development. Serum DHT concentrations are low, testosterone concentrations are normal to slightly elevated, and gonadotropin concentrations are normal to modestly elevated.

Within the prostate gland, conversion of testosterone to DHT produces concentrations of DHT that are approximately 10-fold higher than those in serum, serving to amplify androgen activity in the prostate. Intraprostatic androgen concentrations may contribute to prostate disease, such as BPH or prostate cancer.[126]

Inhibitors of SRD5A2 (finasteride) or of both SRD5A1 and SRD5A2 (dutasteride) are used to treat lower urinary tract symptoms (LUTS), improve urinary flow, and prevent complications related to BPH, as well as to treat male-pattern baldness and androgenic alopecia.[127] Treatment with finasteride or dutasteride reduces, respectively, the prevalence or the incidence of prostate cancer found on biopsy but is possibly associated with a greater number of cancers with high Gleason grade.[128,129] An important aspect of the effect of androgens on the prostate is that intraprostatic androgen concentrations are not reflected in serum concentrations, underscoring the importance of local paracrine and autocrine actions of androgens in the physiology and pathology of the prostate and probably other androgen target tissues.

Catabolism of Testosterone

The primary site of catabolism of circulating testosterone and 5α-DHT is the liver.[130] Testosterone and 5α-DHT are taken up in the liver, and testosterone is converted to an inactive metabolite, 5β-DHT, by the enzyme 5β-reductase. Both 5α- and 5β-DHT then undergo 3α-reduction by the 3α-HSD enzymes to form 3α,5α-androstanediol (also called *3α-diol*) and 3α,5β-androstanediol, respectively; this is followed by 17β-oxidation by the enzyme 17β-HSD type 2 to form androsterone and etiocholanolone as

catabolic products. In peripheral tissues such as skin, 5α-DHT may also be converted to 3α-diol, which is further metabolized in the liver.

In the liver, testosterone, DHT, androsterone, etiocholanolone, and the 3α-androstanediols undergo glucuronidation and, to a lesser degree, sulfation, to form more hydrophilic conjugates that are released into the circulation and excreted in urine and bile. Metabolic inactivation of testosterone primarily involves its conversion to metabolites such as androstenedione (about 50%), androsterone (20%), and etiocholanolone (20%) glucuronides (as well as sulfates) and lesser conversion to 3α-diol glucuronides (3α-diol Gs). Because 3α-diol comes mostly from skin, blood and urine measurements of 3α-diol G have been used as a marker of peripheral androgen action.[130] In men with 5α-reductase deficiency, 3α-diol G concentrations are reduced. The amount of body hair and acne correlates with 3α-diol G concentrations.

Epitestosterone (17α-hydroxy-4-androsten-3-one) is a biologically inactive 17α-hydroxy epimer of testosterone (17β-hydroxy-4-androsten-3-one) that is produced by the testes in response to LH.[131] The production rate of epitestosterone is about 3% that of testosterone, but its clearance rate is 33% that of testosterone, and there is no interconversion of epitestosterone and testosterone. Like testosterone, epitestosterone is conjugated in the liver, primarily to glucuronides and sulfates, and excreted in the urine. Because epitestosterone conjugates are rapidly cleared in the urine, excretion rates of testosterone and epitestosterone are similar, and the ratio of urinary testosterone to epitestosterone (T/E ratio) is approximately 1:1.

Measurements of the T/E ratio and other metabolites in urine by sensitive gas chromatography/mass spectrometry methods are used to detect androgenic anabolic steroid doping, particularly testosterone, by competitive athletes.[131] Administration of exogenous testosterone suppresses LH and the production and clearance of epitestosterone relative to the administered testosterone, resulting in an elevated T/E ratio in urine. The World and United States Anti-Doping Agencies have set a threshold T/E ratio of greater than 4:1 as suspicious for testosterone doping.

Testosterone is glucuronidated primarily by the enzyme uridine diphosphate glucuronyl transferase 2B17 (UGT2B17), whereas epitestosterone is glucuronidated mostly by another UGT isoform, UGT2B7. Although testosterone may be glucuronidated by other UGT isoforms (e.g., UGT2B15), individuals with deletion of UGT2B17 (common in Asian populations) have reduced testosterone glucuronidation and clearance, resulting in lower T/E ratios with testosterone administration.[130-133] Realization that there were populations with naturally low T/E led to a reduction in the T/E ratio cutoff from the previous threshold for suspicion of doping of (>6:1) to the present one (>4:1). In addition, there are individuals with naturally high T/E ratios, perhaps because of other genetic polymorphisms or environmental factors, such as excessive alcohol consumption, that may increase T/E ratio transiently, particularly in women.[134] In the absence of environmental perturbations, the T/E ratio in a single individual is remarkably stable over time, and longitudinal measurements of urinary T/E ratio are used to detect illicit androgen use (known as the athlete biologic passport). Coadministration of epitestosterone with testosterone (to maintain a normal T/E ratio) has been used by athletes to avoid detection.

If a urinary T/E ratio is suspicious for doping, exogenous androgen use is confirmed by gas chromatography combustion isotope ratio mass spectrometry, which can detect small differences in the ratio of carbon-13 to carbon-12 ($^{13}C/^{12}C$) isotopes of testosterone or its metabolites.[131] Because synthetic androgens are synthesized from plant sources (yams or soy), their $^{13}C/^{12}C$ ratio is lower than that of endogenously produced testosterone and other steroids that reflect an animal source or dietary ingestion of both animal and plant products. However, $^{13}C/^{12}C$ isotope ratio mass spectrometry will not detect doping by administration of hCG or LH-like activity to stimulate endogenous testosterone production or administration of androgens derived from animal sources that have a $^{13}C/^{12}C$ ratio like that of endogenous testosterone.

Mechanisms of Androgen Action

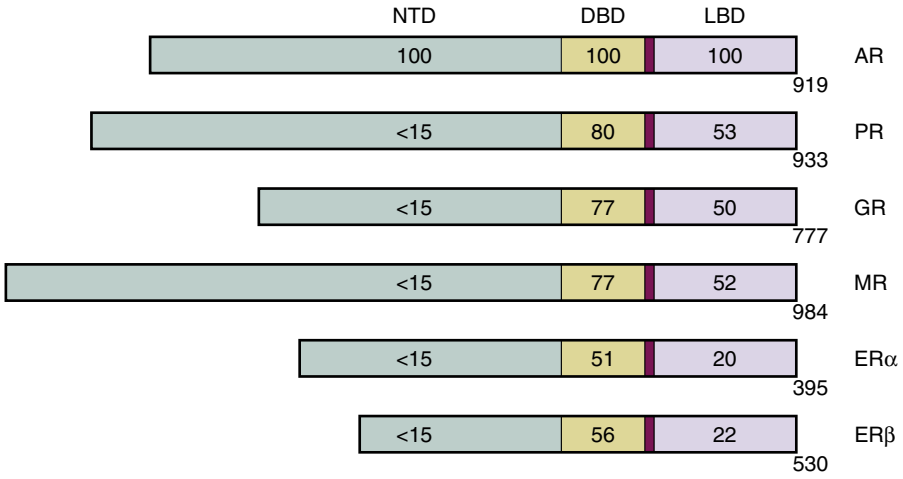
In androgen target tissues, testosterone and DHT in the circulation diffuse through the plasma membrane and bind to intracellular ARs.[135] Binding of androgen to the AR induces a conformational change in the AR that causes dissociation of heat shock proteins bound to AR, permitting translocation into the nucleus, induction of phosphorylation and homodimerization, and interaction with DNA, specifically on androgen response elements located in regulatory sites of target genes. The AR dimer actively recruits tissue-specific coregulators (coactivators and corepressors) to form the transcriptional apparatus necessary to control androgen-regulated gene transcription and subsequent androgen-regulated protein synthesis.

The *AR* gene is located on the long arm of the X chromosome (Xq11-12). *AR* is organized into functional domains[135] (Fig. 19.12): (1) an *N-terminal domain* comprising two transactivation domains (AF1 and AF5) that mediate the majority of *AR* transcriptional activity and coregulator interaction and two trinucleotide repeat segments (CAG and GGN, encoding polyglutamine and polyglycine tracts, respectively) of varying number that modify *AR* transactivation; (2) a *DNA-binding domain* comprising two zinc finger motifs, the first mediating DNA recognition and binding and the second stabilizing DNA interaction and mediating dimerization of *AR*; (3) a small *hinge region* (H); and (4) a *ligand-binding domain* that mediates high-affinity binding of androgen to the AR and also contains another transactivation domain (AF2).

The AR is a member of the nuclear receptor superfamily that includes other steroid hormone receptors. It shares approximately 80% sequence homology in the DNA-binding domain and 50% in the ligand-binding domain, with its most closely related steroid receptors being the progesterone receptor, the glucocorticoid receptor, and the mineralocorticoid receptor.[135] This similarity may explain why, for example, some progestins (e.g., medroxyprogesterone acetate) have AR agonist activity, others (e.g., cyproterone acetate) have AR antagonist activity, and a mineralocorticoid antagonist, spironolactone, has AR antagonist activity. Compared with the binding of testosterone, DHT binds to AR with higher affinity, greater stability, and a slower rate of dissociation, conferring greater androgen activity to DHT, the most potent endogenous androgen in humans.

Inactivating mutations of the *AR* may cause qualitative or quantitative abnormalities of receptor function, resulting in variably impaired androgen action.[136] *AR* mutations manifest phenotypic variability, ranging from that of a 46,XY phenotypic female with normal female external genitalia and breast development (*complete androgen insensitivity*, formerly *testicular feminization*), which occurs in individuals with complete androgen insensitivity or resistance, to that of an otherwise normal male with incomplete hypospadias, mild undervirilization, or infertility.

In a normal population, the number of trinucleotide CAG repeats in the first exon of the *AR* gene varies from 11 to 35. In



• **Fig. 19.12** Schematic diagram of the structure of the human androgen receptor (AR) gene and homology to other steroid hormone receptors: progesterone receptor (PR), glucocorticoid receptor (GR), mineralocorticoid receptor (MR), estrogen receptor α (ERα), and estrogen receptor β (ERβ). The AR is a 919–amino acid protein that is composed of three functional domains: a ligand-binding domain (LBD), a DNA-binding domain (DBD), and an N-terminal transactivation domain (NTD). The DBD shares the greatest degree of homology (>51% vs. AR) and the NTD the least degree of homology (<15% vs. AR) among steroid hormone receptors. (From Li J, Al-Azzawi F. Mechanism of androgen receptor action. *Maturitas.* 2009;63:142–148.)

general, the number of CAG repeats appears to correlate inversely with AR function and action, both in vitro and in vivo, in transgenic mice and humans. *Kennedy disease*, or *X-linked spinal and bulbar muscular atrophy*, is a rare adult-onset neurodegenerative disease of motor neurons that results in progressive muscle weakness; it is associated with a markedly expanded number of CAG repeats, varying from 40 to 62, which does not overlap with the normal population.[137] Neurodegeneration in this disorder is thought to be caused by toxicity from intracellular aggregation of the AR and associated cofactors that is worsened by androgen binding to the mutant AR and translocation into the nucleus.

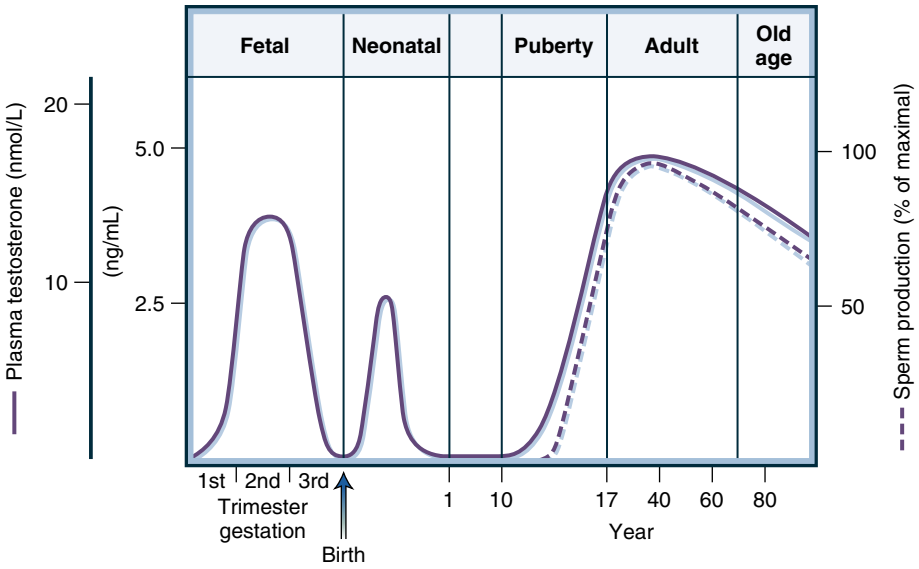
Most men with Kennedy disease also manifest clinical findings of partial androgen resistance, including gynecomastia, reduced libido, erectile dysfunction, decreased facial hair, testicular atrophy, and oligozoospermia or azoospermia in association with high testosterone and high or normal gonadotropin concentrations.[138] The severity of the latter biochemical indices of androgen insensitivity is directly related to CAG repeat length. Although it is not found consistently, some studies have reported an association between CAG repeat number and manifestations of androgen action in normal men.[139] In these studies, a low number of CAG repeats within the normal range was associated with higher androgenicity (e.g., earlier onset of prostate cancer, male-pattern baldness, lower HDL cholesterol), and a high number of repeats within the normal range was associated with lower androgenicity (e.g., gynecomastia, impaired spermatogenesis, lower bone density, depressive symptoms). CAG repeat number also seems to be associated with the clinical manifestations of men with androgen deficiency due to Klinefelter syndrome and their response to testosterone treatment; men with Klinefelter syndrome with higher CAG repeat numbers require relatively high doses of testosterone for full androgen effects.

Studies in vitro and in experimental animals suggest that some actions of androgens may occur within seconds to minutes, too rapidly to be caused by classic genomic effects of androgens acting through the AR on gene transcription and subsequent protein synthesis, which usually take hours to produce effects.[140] Rapid, nongenomic (also called *nonclassical*) effects of androgens may be mediated by cell surface interactions and receptors and by the activation of conventional signal transduction mechanisms, including activation of PKA and PKC, which increase intracellular calcium and MAPK pathways. Binding of androgen to intracellular AR may also activate coregulators that do not require gene transcription to signal, such as the tyrosine kinases (e.g., MAPK, ERK, and Akt) that are AR coactivators. Nongenomic actions of androgens have been described in testis (Sertoli cells), brain, muscle, cardiovascular tissue, prostate, and immune cells. In humans, the rapid vasodilatory effect of testosterone on myocardial ischemia in patients with coronary artery disease is attributed to a direct nongenomic effect of androgens (or estrogenic metabolites) on vascular cells.

Androgen Effects at Various Stages of Sexual Development

Concentrations of testosterone and its actions differ at various stages of sexual development[141] (Fig. 19.13). During *fetal life*, testosterone is secreted by the fetal testis beginning at 7 weeks of gestation.[36] Testosterone secretion is primarily under the control of maternal hCG, initially, and then LH secreted by the fetal pituitary. During this time, testosterone concentrations increase to almost adult male concentrations, and testosterone and its conversion to DHT are critical for normal male internal and external genital differentiation (e.g., development of primary sexual characteristics). Testosterone concentrations remain elevated through most of the second trimester and decline in the third trimester.

Shortly after birth, during *neonatal life*, LH secretion increases and stimulates a second rise in testosterone concentrations, almost to adolescent concentrations, between 3 and 6 months of age; this is followed by a fall to low prepubertal concentrations.[142] The neonatal surge in testosterone concentrations may have a role in the development of normal phallus size and completion of testicular descent. The neonatal increase in testosterone and FSH concentrations at this time also stimulates Sertoli cell proliferation and



• **Fig. 19.13** Schematic diagram of changes in serum testosterone concentration and sperm production during different phases of life. During fetal life, testosterone concentrations increase almost to adult male concentrations, peaking during the first trimester and remaining elevated throughout the second trimester, after which they decline. During neonatal life, testosterone increases almost to adolescent concentrations at 3 to 6 months of age, then declines to prepubertal concentrations. During puberty, testosterone concentrations and sperm production increase to adult male concentrations over several years. With aging, there is a variable, gradual, and progressive decline in serum testosterone concentrations and sperm production, beginning at age 40 years. (From Griffin JE, Wilson JD. The testis. In: Bondy PK, Rosenberg LE, eds. *Metabolic Control and Disease,* 8th ed. Philadelphia, PA: WB Saunders; 1980:1535–1578.)

spermatogonial development, which may play a role in determining spermatogenic capacity.

During *puberty*, testosterone concentrations increase to adult male concentrations (or higher) in response to activation of hypothalamic GnRH secretion and its stimulation of pituitary gonadotropin secretion.[43,143] The progressive increase in testosterone and its active metabolites, estradiol and DHT, is responsible for the development of secondary sexual characteristics (*virilization* or *masculinization*) and other changes. Pubertal changes induced by testosterone may be categorized as those related to body, brain, and sexual function.

Body function changes mediated by testosterone and its active metabolites include the following:

- Growth and development of the penis and scrotum and the appearance of rugal folds and pigmentation in scrotal skin
- Enlargement of the prostate and seminal vesicles and production of accessory sexual gland secretion and seminal fluid
- Androgen-dependent hair growth and development of a male hair distribution—facial (moustache and beard), external auditory canal, chest, axillary, pubic and lower abdomen (male escutcheon), perianal, inner thigh, and leg and arm hair growth and frontal scalp hair recession
- Increase in sebum production
- Stimulation of IGF1 production together with that of growth hormone (GH)
- Long bone growth and eventually closure of long bone epiphyses resulting in cessation of growth
- Increase in BMD and accretion of peak bone mass
- Increase in skeletal muscle mass and strength, especially in shoulder and pectoral muscles
- Decrease and redistribution of body fat
- Enlargement of the larynx and thickening of vocal cords, resulting in a lower-pitched voice
- Stimulation of erythropoiesis resulting in an increase in hematocrit, primarily by direct bone marrow induction of erythroid differentiation and stimulation of erythropoietin secretion
- Reduction of HDL cholesterol.

Brain function changes mediated by testosterone and its active metabolites include stimulation of libido (sexual interest, desire, and motivation); increase in motivation, initiative, and social aggressiveness; and increase in aspects of cognitive function (e.g., visuospatial abilities). *Sexual function changes* mediated by testosterone and its active metabolites include initiation of spermatogenesis and acquisition of fertility potential and increase in spontaneous erections.

In *adult life*, normal adult male concentrations of testosterone serve to maintain many of the changes induced during puberty. This includes maintenance of body function changes such as normal amounts of androgen-dependent hair and male hair distribution, sebum production, BMD, muscle mass and strength, hematocrit in the male range (higher than the female range), and HDL cholesterol in the male range (lower than the female range); brain function changes such as libido, motivation, initiative, social aggressiveness, energy and vitality, mood, and possibly some aspects of cognitive function (e.g., visuospatial ability); and sexual function changes such as sperm production and fertility potential and spontaneous erections. Some of the masculinizing changes induced by testosterone during puberty are permanent. Once some body changes are developed, testosterone is not necessary for maintenance of penis size, scrotal development, linear growth, laryngeal size, vocal cord thickness, or voice pitch.[116]

With *aging*, there is a gradual and progressive decline in serum testosterone concentrations associated with reductions in muscle mass and strength, BMD, libido, energy and vitality, mood,

aspects of cognitive function, sperm production and fertility, and erections.[144] However, the contribution of the age-related decline in testosterone concentrations to these age-associated changes in function is not clear.

Male Hypogonadism

The two major functions of the testis are to produce sufficient amounts of testosterone and of sperm to support the development and maintenance of male sexual function, body function, and fertility. *Male hypogonadism* is a clinical syndrome that results from a failure of the testes to produce adequate amounts of testosterone; this syndrome is almost always associated with impaired sperm production (*androgen deficiency and impairment of sperm production*), or an *isolated impairment of sperm production or function* with normal testosterone production. Hypogonadism is the most common disorder of testis function encountered in clinical practice.

Because testis function is controlled by the hypothalamus and the pituitary, male hypogonadism may be caused by a primary disorder of the testis (*primary hypogonadism*); it may be secondary to a disorder of the pituitary or hypothalamus (*secondary hypogonadism*); or in some instances, there may be defects at both levels (*combined primary and secondary hypogonadism*).

Identifying men with secondary hypogonadism has important clinical implications that may affect management.[116] For example, secondary hypogonadism can be caused by a pituitary adenoma that may be associated with clinical manifestations related to tumor mass (e.g., headaches, visual field defects), to deficiency or excessive secretion of other anterior pituitary hormones, or to diabetes insipidus (polyuria) resulting from hypothalamic antidiuretic hormone deficiency. Such patients require management of the underlying hypothalamic or pituitary disorder in addition to testosterone replacement therapy. Secondary hypogonadism may be reversible with treatment of the underlying condition (e.g., nutritional deficiency) or discontinuation of an offending medication (e.g., glucocorticoids, opioids), or it may be associated with a chronic systemic illness that is not curable, such as chronic kidney disease (CKD). Impaired spermatogenesis and infertility caused by gonadotropin deficiency in men with secondary hypogonadism may be treated with gonadotropin or GnRH therapy, and sperm production and fertility may be restored. In contrast, infertility caused by primary testicular disease is usually not treatable with hormone therapy and requires other fertility options, such as the use of donor sperm, ART (e.g., ICSI), or adoption.

Clinical Manifestations

Because testosterone has different roles during fetal, prepubertal, and adult life, the manifestations of androgen deficiency differ depending on the stage of sexual development.[9,116]

Fetal Androgen Deficiency

During fetal development, testosterone and its conversion to DHT have vital roles in directing male internal and external genital differentiation and development. Fetal androgen deficiency (e.g., from congenital defects in testosterone biosynthesis enzymes) or androgen resistance/insensitivity (e.g., from AR mutations or 5α-reductase deficiency) manifests at birth with varying degrees of ambiguous genitalia and 46,XY DSD[32,62,145] (Table 19.1). Depending on the severity of androgen deficiency or resistance/insensitivity, the phenotype of individuals with these disorders may range from that of a normal female to that of an otherwise normal male with microphallus, pseudovaginal perineoscrotal hypospadias, bifid scrotum, and/or cryptorchidism of varying severity. These disorders are described in greater detail in Chapter 23.

Prepubertal Onset of Androgen Deficiency

The increase in testosterone concentrations that occurs at the time of puberty is responsible for development of secondary sexual characteristics; an increase in muscle mass and reduction and redistribution of body fat; long bone growth and eventually closure of epiphyses resulting in cessation of growth; stimulation of sexual interest (libido), spontaneous erections, and sexual activity; and initiation of spermatogenesis and seminal fluid production.[146,147] Prepubertal onset of androgen deficiency causes *eunuchoidism*[146,147] (Fig. 19.14; see Table 19.1), which is characterized most notably by infantile genitalia with a small penis and a poorly developed scrotum that lacks rugal folds and pigmentation. The testes are small, usually less than 2 cm in length and from 2 mL to less than 4 mL in volume. Hair is thin and fine, and there is a lack of androgen-dependent hair growth (i.e., absence of a male hair pattern in all body areas) and no temporal hair recession. The pubic hair pattern is more typical of females, with the shape of an inverted triangle in the pubic area (female escutcheon) rather in a diamond shape with hair extending from the pubic area to the umbilicus (male escutcheon), and there is little hair extending to the thighs. Acne does not develop because sebum production is not stimulated due to androgen deficiency.

Eunuchoidism is typified by a distinctive body habitus, characterized by poor muscle mass development (especially in the shoulders and chest), prepubertal fat distribution (predominantly in the face, chest, and hips), and excessively long arms and legs relative to height. Arm span exceeds height by greater than 5 cm, and the distance from the symphysis pubis to the floor exceeds the distance from the crown of the head to the symphysis pubis by greater than 5 cm. The voice is high pitched in the absence of androgen-dependent laryngeal enlargement and vocal cord thickening. Relatively long arms and legs result from a failure of long bone epiphyses to close; epiphyseal closure is mediated normally by increased estradiol derived from aromatization of the increased testosterone produced at the time of puberty. In preliminary studies, aromatase inhibitors that inhibit the conversion of testosterone to estradiol and delay epiphyseal closure have been used in combination with GH treatment in boys with idiopathic short stature; however, the long-term risks and benefits of this approach are not known.[148]

Androgen deficiency of prepubertal onset may not be recognized or diagnosed until adulthood. Compromise in peak bone mass accrual due to androgen deficiency may manifest as low BMD for age, and prolonged severe androgen deficiency increases the risk of osteoporosis and fractures as these men become older. Despite the absence of pubertal development, these individuals may develop gynecomastia (benign breast enlargement) that is caused by androgen deficiency rather than by the relatively high production of estradiol concentrations associated with pubertal gynecomastia. (Both prepubertal and pubertal gynecomastia result from relatively high ratios of serum estradiol to testosterone concentrations but by different mechanisms.) Psychological motivation and initiative may be reduced and, together with poor muscle mass and strength, may contribute to poor physical performance (e.g., in athletics or the military). These men have reduced sexual interest or desire (libido) and lack spontaneous erections at night or on awakening in the morning. Hematocrit

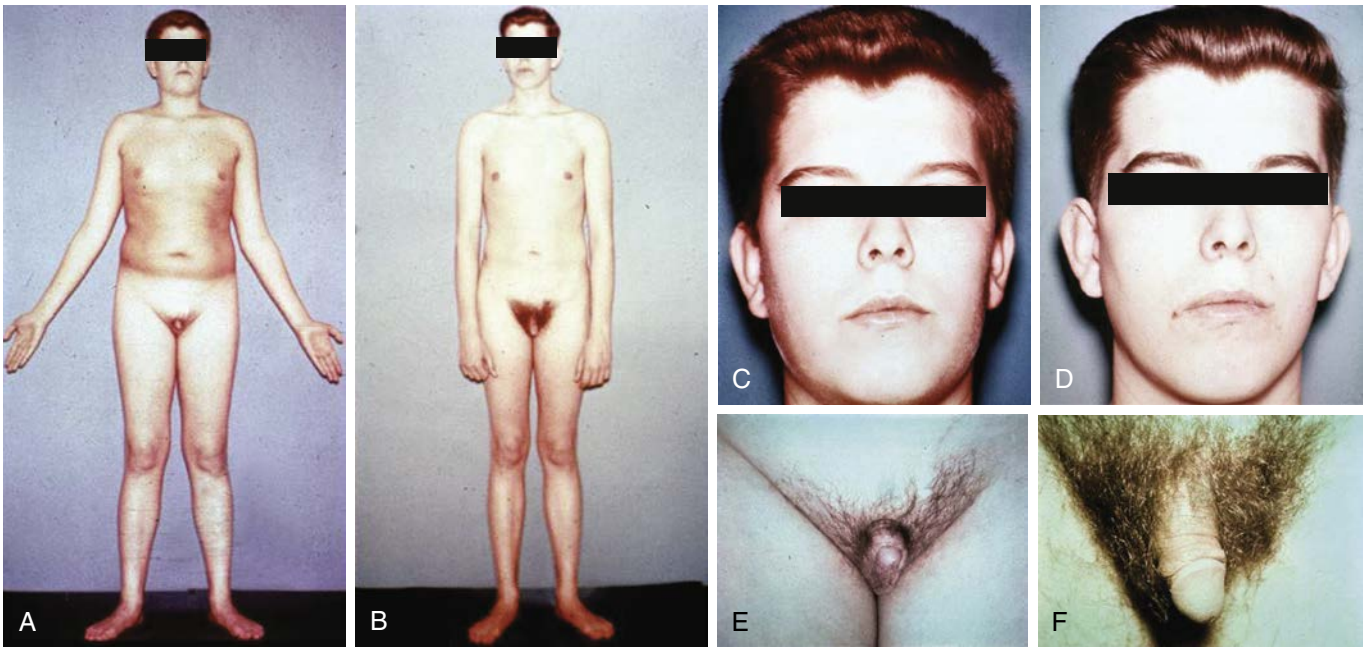
TABLE 19.1 Clinical Manifestations of Androgen Deficiency

FETAL ANDROGEN DEFICIENCY	
Symptoms	**Signs**
Ambiguous genitalia	Ambiguous genitalia (46,XY DSD) Normal female genitalia Microphallus (resembling clitoromegaly) Pseudovaginal perineoscrotal hypospadias Bifid scrotum Cryptorchidism

ANDROGEN DEFICIENCY OF PREPUBERTAL ONSET	
Symptoms	**Signs**
Delayed puberty	Eunuchoidism
Lack of sexual interest or desire (libido)	Infantile genitalia
Reduced nighttime or morning spontaneous erections	Small testes
Breast enlargement and tenderness	Lack of male hair pattern growth, no acne
Reduced motivation and initiative	Disproportionately long arms and legs relative to height
Diminished strength and physical performance	Prepubertal fat distribution
No ejaculate or ejaculation (spermarche)	Poorly developed muscle mass
Inability to father children (infertility)	High-pitched voice Reduced peak bone mass, osteopenia or osteoporosis Gynecomastia Small prostate gland Aspermia, severe oligozoospermia or azoospermia

ADULT ANDROGEN DEFICIENCY	
Symptoms	**Signs**
Incomplete sexual development	Eunuchoidism
Lack of sexual interest or desire (libido)	Small or shrinking testes
Reduced nighttime or morning spontaneous erections	Loss of male hair (axillary and pubic hair)
Breast enlargement and tenderness	Gynecomastia
Inability to father children (infertility)	Aspermia or azoospermia or severe oligozoospermia
Height loss, history of minimal-trauma fracture	Low bone mineral density (osteopenia or osteoporosis)
Hot flushes, sweats	Height loss, minimal-trauma or vertebral compression fracture
Reduced shaving frequency	Unexplained reduction in prostate size or PSA
Less Specific Symptoms	**Less Specific Signs**
Decreased energy, vitality	Mild normocytic, normochromic anemia (normal female range)
Decreased motivation, self-confidence	Depressed mood, mild depression or dysthymia
Feeling sad or blue, irritability	Reduced muscle bulk and strength
Weakness, decreased physical or work performance	Increased body fat or body mass index
Poor concentration and memory	Fine facial skin wrinkling (lateral to orbits and mouth)

DSD, Disorder of sex development; *PSA,* prostate-specific antigen.



• **Fig. 19.14** A 19-year-old patient with androgen deficiency of prepubertal onset caused by congenital anorchia before (A, C, and E) and after (B, D, and F) 5 years of testosterone treatment. Before testosterone treatment, the patient had features of eunuchoidism, characterized by infantile genitalia (small penis and poorly developed scrotum); lack of chest, pubic, and facial hair; long arms and legs relative to height; and poorly developed muscle mass in the upper body with accumulation of fat in the face, chest, and hips. After testosterone treatment, there was an increase in penis size; an increase in chest, pubic, and facial hair with scalp recession and development of acne; an increase in muscle mass, particularly in the upper body; and loss of fat in the face, chest, and hips. (From Matsumoto AM. The testis. In: Felig P, Frohman LA, eds. *Endocrinology and Metabolism.* 4th ed. New York, NY: McGraw-Hill; 2001:635–705.)

remains in the female range due to inadequate androgen stimulation of erythropoiesis. The prostate and seminal vesicles remain small without androgen stimulation, and seminal fluid production is absent, resulting in aspermia (lack of ejaculate) and failure to undergo spermarche (first ejaculation). Seminal fluid may be present in men with mild or partial androgen deficiency of prepubertal onset or in those treated with androgens. However, these men usually have severe oligozoospermia or azoospermia, and most are infertile.

Adult Androgen Deficiency

Some individuals with androgen deficiency of prepubertal onset who are not diagnosed or are inadequately treated as boys present as adults with features of eunuchoidism and other manifestations of androgen deficiency of prepubertal onset (see Table 19.1). Their condition is usually clinically obvious because of inadequate sexual development for their chronologic age.

In adults, testosterone is needed to maintain sexual function, some secondary sexual characteristics, muscle and bone mass, and sperm production. Clinical manifestations of androgen deficiency are nonspecific and may be modified by the severity and duration of androgen deficiency, the presence of comorbid illnesses, previous testosterone treatment, or variations in target-organ sensitivity to androgens. Therefore, the clinical diagnosis of androgen deficiency acquired as an adult can be challenging, particularly in older men.[116]

Some clinical symptoms and signs are suggestive of androgen deficiency. Adults most commonly present with *sexual dysfunction* (diminished libido as manifested by reduced sexual interest or desire, reduced spontaneous and sexually evoked erections, and erectile dysfunction), *gynecomastia* (benign breast enlargement that may be accompanied by tenderness), and *infertility* (inability to father children despite unprotected intercourse) associated with oligozoospermia or azoospermia and small or shrinking testes with severe impairment in spermatogenesis. Secondary sexual characteristics do not regress to a prepubertal state; however, with long-standing, severe androgen deficiency, there may be loss of androgen-dependent hair, such as reduced facial hair associated with reduced shaving frequency and loss of axillary and pubic hair (Fig. 19.15). Men with rapid and profound decreases in testosterone concentrations (e.g., from GnRH agonist treatment of prostate cancer) may have hot flushes and sweats due to vasomotor instability (like those experienced by menopausal women) due mostly to low estradiol production related to extremely low testosterone concentrations. Because testosterone and its active metabolite, estradiol, have an important role in the maintenance of bone mass, men with chronic androgen deficiency may present with osteopenia or osteoporosis on BMD measurement (e.g., by dual-energy x-ray absorptiometry scanning) or with a minimal-trauma bone or vertebral compression fracture that may be associated with height loss. An unexplained reduction in prostate size or in the level of prostate-specific antigen (PSA) is uncommon but may occur as a result of long-term, severe acquired androgen deficiency.

Other symptoms and signs are much less specific for androgen deficiency but may occur, commonly in conjunction with clinical manifestations described previously that are more suggestive of androgen deficiency. Men with low testosterone

• **Fig. 19.15** A 54-year-old man with adult androgen deficiency caused by hypopituitarism who presented with sexual dysfunction (reduced libido and erectile dysfunction); loss of chest, axillary, and pubic hair (A, B, and C); and gynecomastia (A). His penis and testes were normal in size (B). He had normal facial hair (C), but his shaving frequency was less.

concentrations often complain of diminished energy and vitality, poor motivation and social aggressiveness, depressed mood and irritability, or poor concentration and memory. Men with severe androgen deficiency may have a mild hypoproliferative normocytic, normochromic anemia within the female range in the absence of androgen stimulation of erythropoiesis. With long-standing deficiency, reduced muscle bulk and strength associated with weakness and reduced physical and work performance may occur. The latter symptoms may occur in conjunction with an increase in body fat, but androgen deficiency is not a cause of clinically obvious obesity per se. Skin changes and reduced sebum production with severe, long-standing androgen deficiency may be associated with fine facial wrinkling that is particularly noticeable on the lateral corners of the orbits (lateral canthus) and mouth. Testis size may be small, especially with severe impairment of spermatogenesis, but in most men with acquired adult androgen deficiency, testis size is normal to slightly reduced.

Because clinical manifestations are nonspecific, older men may have several medical or comorbid conditions and medications that contribute to symptoms and signs that are consistent with androgen deficiency, presenting a particular diagnostic challenge (Fig. 19.16). Symptoms and signs of comorbid illnesses may mask, mimic, or contribute to clinical manifestations of androgen deficiency in older men. Elderly men may present with muscle loss and mobility impairment, fragility fracture or osteoporosis, and reduced vitality and depressed mood. On close examination, however, older men with severe, long-standing androgen deficiency usually manifest objective evidence of androgen deficiency.

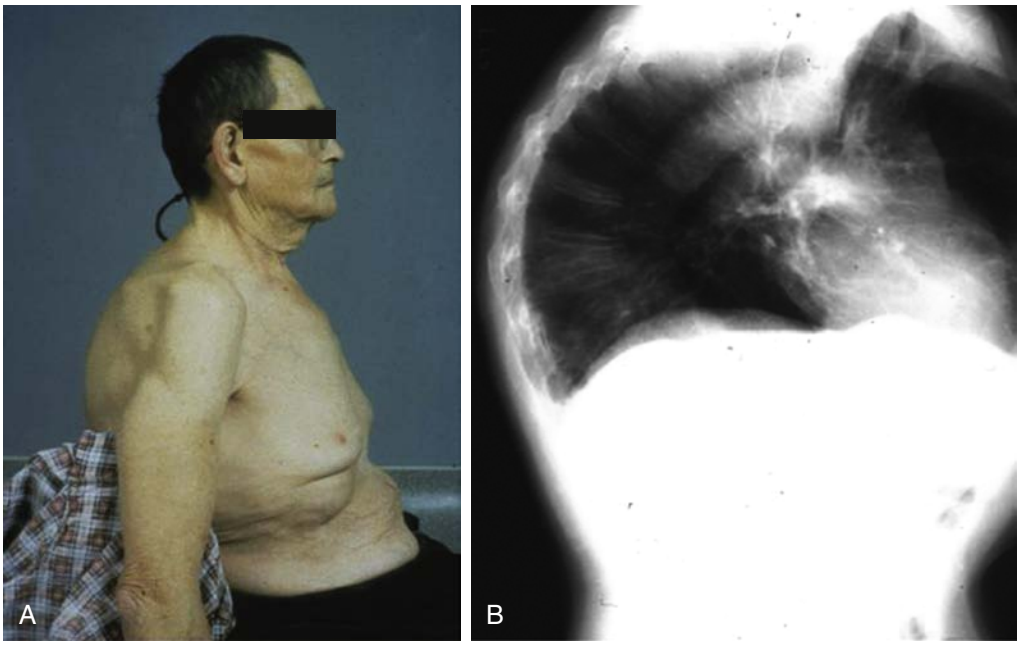
Isolated Impairment of Sperm Production or Function

Most men with male infertility have hypogonadism manifested by an isolated impairment of sperm production with normal androgen production. These men present as adults with infertility and demonstrate oligozoospermia or azoospermia, sperm with abnormal morphologic appearance (*teratospermia*) or reduced or absent motility (*asthenospermia*), or a combination of abnormalities on seminal fluid analysis. They do not have manifestations of androgen deficiency, and serum testosterone concentrations are normal. Testes may be small (if spermatogenesis is severely impaired) or normal size. Testes may not be palpable if cryptorchidism or anorchia is present.

History and Physical Examination

Clinical evaluation of male hypogonadism involves a careful history and physical examination directed at determining whether there are symptoms and signs of androgen deficiency or isolated impairment of sperm production and at identifying potential common causes of hypogonadism.[9] Because adults with androgen deficiency commonly present with sexual dysfunction, gynecomastia, and infertility, the differential diagnosis of these conditions and causes other than hypogonadism of these presenting complaints should be considered. Laboratory evaluation of serum testosterone, gonadotropins, and seminal fluid (in men who are concerned with infertility) are performed to confirm the diagnosis of hypogonadism and to determine whether there is predominantly primary or secondary hypogonadism.

The *history* should include inquiry regarding symptoms of androgen deficiency. Questions about the onset of these symptoms may be useful in determining whether the cause of androgen



• **Fig. 19.16** A 70-year-old man with severe androgen deficiency caused by Kallmann syndrome (hypogonadotropic hypogonadism and anosmia) who presented to a geriatric evaluation and management unit with functional and mobility disability caused by upper (A) and lower extremity muscle wasting and severe back pain from multiple vertebral compression fractures (B) due to osteoporosis. He was noted to have gynecomastia and absence of chest, axillary, and pubic hair.

deficiency occurred before birth, between birth and puberty, or after puberty. Note that symptoms or signs that suggest reduced androgen effect compared with baseline generally indicate postpubertal-onset of hypogonadism. These questions may be grouped in the following areas:

1. *Development:* Developmental markers of congenital androgen deficiency include a history of genital abnormalities (hypospadias, microphallus, cryptorchidism); developmental markers of congenital or androgen deficiency of prepubertal onset include a history of delayed sexual development or growth and testosterone therapy to induce puberty; family history of delayed puberty or reproductive disorders; psychological impact of delayed puberty or growth; difficulty in school or learning disability (often associated with Klinefelter syndrome); inability or reduced ability to smell (suggesting CHH due to Kallmann syndrome)
2. *Sexual function:* Poor erections; reduced spontaneous, nighttime, or morning erections; inability to perform sexually; decreased sexual activity; inability to father children despite unprotected sexual intercourse (>1 year); small (suggesting congenital or prepubertal onset of hypogonadism) or shrinking testes
3. *Brain function:* Poor general well-being; reduced sexual desire, interest, and motivation (libido); poor energy and vitality and excessive fatigue; poor motivation and initiative, passivity, low self-confidence, and low self-esteem; depressed mood and irritability; difficulty sleeping; hot flashes and sweats; poor concentration and memory
4. *Body function:* Decreased muscle bulk and strength; reduced physical activity or performance; breast enlargement or tenderness, especially if recent in onset; height loss, history of low-trauma or vertebral compression fractures, osteopenia, or osteoporosis; body hair loss (chest, axillary, or pubic); reduced beard growth and shaving frequency.

The initial history may also include inquiry concerning the potential cause of hypogonadism. With *primary hypogonadism*, there may be a history of mumps involving the testes; testicular trauma, irradiation, or surgery; complications of pelvic or scrotal surgery; medication use (spironolactone, ketoconazole, cytotoxic agents); or chronic liver or kidney failure. With *secondary hypogonadism*, headaches, visual complaints or reduced peripheral vision, history of pituitary disease, chronic lung disease or congestive heart failure (CHF), wasting conditions (e.g., acquired immunodeficiency syndrome [AIDS], cancer), nutritional deficiencies, recent acute illness, morbid obesity, or use of certain medications (e.g., opioids, glucocorticoids, anabolic steroids, megestrol acetate, medroxyprogesterone acetate, nutritional supplements) may be noted.

The patient should be questioned regarding conditions that are relative or absolute contraindications to testosterone treatment, including a history of severe BPH and LUTS as assessed by the American Urological Association (AUA) symptom score or International Prostate Symptom Score (IPSS), history of prostate or breast cancer, history or symptoms of untreated obstructive sleep apnea syndrome (daytime sleepiness, snoring with sleep disruption, witnessed apnea episodes), history of CHF, and polycythemia.

In patients with suspected androgen deficiency of prepubertal onset, *physical examination* should include measurements of total arm span, height, and the distances from the crown of the head to the symphysis pubis and from the symphysis pubis to the floor to determine whether the patient has excessively long arms and legs (see Fig. 19.14). Eunuchoidal body proportions are characterized by an arm span that is at least 5 cm greater than height and a symphysis-to-floor distance that is at least 5 cm greater than crown-to-symphysis distance; such proportions are indicative of androgen deficiency of prepubertal onset. Men with Klinefelter syndrome may have disproportionately long legs relative to arms

and a greater ratio of lower- to upper body segment measurements but a relatively normal ratio of arm span to height. Eunuchoidism is also characterized by infantile genitalia (micropenis or small penis, unrugated and nonpigmented scrotum); small testes or, rarely, absence of the testes; cryptorchidism; sparse or absent facial, axillary, chest, extremity, and pubic hair; poorly developed upper body musculature; fat predominance in the face, chest, and hips; and gynecomastia. Patients with Kallmann syndrome may have anosmia or hyposmia that may be tested with an odor identification and threshold test using readily identifiable, common household odorants (e.g., peppermint, cinnamon, cocoa, coffee, cigarette, orange, soap), or more formally, such as with the University of Pennsylvania scratch and sniff test.

The physical findings of androgen deficiency acquired in adulthood are usually subtler than those of androgen deficiency of prepubertal onset (see Fig. 19.15). In patients with severe, long-standing adult androgen deficiency, there may be loss of androgen-dependent facial, axillary, chest, extremity, and pubic hair; however, there are ethnic variations in body hair in androgen-dependent areas (e.g., less in Asians and Hispanics). The skin may be dry, and there may be fine wrinkling lateral to orbits or the mouth in patients with severe, long-standing androgen deficiency. Patients should be carefully examined for the presence of palpable breast tissue or gynecomastia; presence, size, and consistency of the testes; and palpable abnormalities in the scrotum, such as varicocele, epididymal enlargement, or tenderness or absence of the vas deferens. In older men, particularly those at high risk for prostate cancer (e.g., African-American ethnicity, family history of prostate cancer), a digital rectal examination (DRE) to screen for prostate cancer should be offered. If performed, the focus of the examination is to detect palpable abnormalities, such as a prostate nodule or induration and to assess the size of the prostate. Careful examination for kyphosis and measurement of height are useful for detecting significant height loss (>5 cm) associated with osteoporotic vertebral compression fractures that may be asymptomatic.

Proper technique is needed to examine the male breast. The thumb and index finger (or the fingers of both hands) are used to grasp and gently grasp the periareolar area of the breast and to palpate glandular breast tissue, which is rubbery in consistency and firmer than the surrounding adipose tissue (Fig. 19.17). Breast tissue is generally discoid and has a firm edge that can be palpated and "flipped up" to distinguish it from adipose tissue. With this technique, gynecomastia can usually be distinguished from excessive breast adipose tissue, called *pseudogynecomastia*, which is often associated with generalized obesity. Gynecomastia is usually bilateral and relatively symmetric, but occasionally it is asymmetric and more prominent on one side. If present, asymmetric gynecomastia may suggest breast carcinoma, which is usually rock hard and irregular and may be associated with skin dimpling (*peau d'orange*), nipple retraction or discharge, and axillary lymphadenopathy. The diameter of palpable breast tissue is used as an objective measure of gynecomastia. Gynecomastia of recent onset is usually tender on palpation, and men usually complain of nipple irritation associated with rubbing against clothing.

Examination of the testes and scrotum may be performed with the patient either lying on his back or standing, but the latter position is preferred because it relaxes the scrotum, making some abnormalities (e.g., varicocele) easier to detect. In patients with retractile testes positioned high in the scrotum, it may be possible to palpate the testes only after placing the scrotum in warm water, after a warm bath, or by having the patient assume a squatting position. The testes may be very difficult to examine and palpate in morbidly obese men who have excessive folds of fat overlying the scrotum, in the presence of a large hydrocele, if the testis is tender (e.g., with epididymo-orchitis or testicular torsion), or occasionally in some men who are sensitive to palpation for unclear reasons. In these instances, testicular ultrasound may be required to confirm the presence of the testis, estimate its size, and detect abnormalities.

• **Fig. 19.17** The proper method of examining the male breast is to use the thumb and index finger to grasp the periareolar area of the breast and to gently pinch the thumb and index finger together on either side of the breast toward the nipple. Glandular breast tissue feels like a rubbery disc of tissue that extends concentrically from under the nipple and subareolar area and is firmer than the surrounding adipose tissue. The size of gynecomastia is estimated by measurement of the diameter of palpable breast tissue. (From Matsumoto AM. The testis. In: Felig P, Frohman LA, eds. *Endocrinology and Metabolism.* 4th ed. New York, NY: McGraw-Hill; 2001:635–705.)

• **Fig. 19.18** The assessment of testis size using a Prader orchidometer in a man with classic 47,XXY Klinefelter syndrome is characteristically very small (e.g., 2 mL). Care must be taken not to include the head of the epididymis when estimating testis size.

Although ultrasonographic size estimates are more accurate, testis size can be estimated by measuring the length and width with a ruler or calipers or by comparing testis volume with that of ellipsoid models of known volume (Prader orchidometer) (Fig. 19.18). Normal testis size varies with age and ethnicity. Normal prepubertal testis size is approximately 1.6 to 2.9 cm in length and 1.0 to 1.8 cm in width, or 1 to 4 mL in volume. Testis size greater

than 3 mL (by orchidometer) suggests the onset of puberty.[149] In adults, normal testes usually measure 3.5 to 5.5 cm in length and 2.0 to 3.0 cm in width or 15 to 30 mL in volume.[8,9] In addition to size, testes should be palpated for consistency or firmness and for presence of a mass representing a benign or malignant testicular tumor. The testicular examination in men with classical Klinefelter syndrome is notable for very small (usually <3 mL), firm testes.

Differential Diagnosis

Because sexual dysfunction, gynecomastia, and infertility are often presenting complaints in adults with androgen deficiency, it is important to consider the differential diagnosis of these conditions and to be familiar with other common causes of these manifestations when evaluating men who present with these complaints.

Sexual Dysfunction

Normal sexual function requires successive, coordinated physiologic events—libido, erection, ejaculation, orgasm, and detumescence—that occur in a defined sequence and require normal psychological, CNS, peripheral nerve, vascular, and genital function.[150]

Sexual dysfunction may involve specific disorders of libido or sexual desire, erectile dysfunction, ejaculatory disorders, orgasmic dysfunction, or failure of detumescence. These components may occur in isolation, but specific disorders of sexual function commonly occur together because these processes are interrelated and because a specific cause (e.g., testosterone and/or estrogen deficiency due to hypogonadism) can affect more than one of the physiologic processes that mediate normal sexual function. Male sexual dysfunction is detailed in Chapter 20. Men with androgen deficiency often present with sexual dysfunction, and it is important to consider the differential diagnosis of this complaint in the evaluation.

Androgen deficiency often results in reduced libido or sexual desire (hypoactive sexual desire disorder); loss or reduction of spontaneous evening and morning or sexually stimulated erections (erectile dysfunction); and, if severe, reduced or absent ejaculation. In many men with androgen deficiency, erectile response to intense erotic stimuli (and, occasionally, spontaneous erections) may be preserved, suggesting that the androgen requirement for sexual function is variable.[151] However, persistent erectile dysfunction may cause performance anxiety, and, together with hypoactive sexual desire and depressed mood associated with androgen deficiency, this may contribute to the eventual loss of erotically stimulated erections and, secondarily, to orgasmic dysfunction. Androgen deficiency may also affect nitric oxide (NO) production and maximal smooth muscle relaxation and vasodilatation within the penis, reducing the ability to produce an erection that is sufficient to satisfactorily complete sexual intercourse and further contributing to the severity of erectile dysfunction.[152,153]

Clinically, men with androgen deficiency most commonly present with hypoactive sexual desire disorder and erectile dysfunction. Men with severe androgen deficiency may present with reduced ejaculation, but these individuals usually also complain of hypoactive sexual desire disorder and erectile dysfunction.

Hypoactive Sexual Desire Disorder and Erectile Dysfunction

Libido, the desire or drive for sexual activity, is generated by external visual, auditory, and tactile stimuli, as well as internal psychic stimuli acting on cortical and subcortical brain regions such as the limbic system (amygdala, hippocampus, anterior thalamic nuclei, and prefrontal cortex) and the temporal lobe. Stimuli from these areas are relayed to the medial preoptic area, which serves to integrate central inputs and sends impulses to the paraventricular nuclei; these, in turn, send projections to the thoracolumbar and sacral spinal cord centers that regulate penile erection. This neural pathway explains why brain disorders that cause hypoactive sexual desire disorder are usually accompanied by varying degrees of erectile dysfunction (see later discussion).[150] In particular, there is a loss of the spontaneous evening and morning erections that are associated with brain activation of sexual neural pathways during rapid eye movement sleep and dreaming. Clinically, libido may be influenced by previous or recent sexual activity and by experiences, psychosocial background, overall state of general health, androgen sufficiency, and brain function.

The neurotransmitter systems that regulate the physiology of normal libido are not precisely known. However, there is evidence that central dopamine neurotransmission may be important in mediating CNS regulation of sexual desire and erections. In humans, treatment with dopamine receptor agonists (e.g., bromocriptine, pergolide) may stimulate spontaneous erections (and even hypersexual behavior), and in 20% to 30% of men with Parkinson disease, levodopa therapy is associated with stimulation of libido and spontaneous erections. The use of pharmacologic agents with dopamine receptor antagonist activity is frequently associated with reduced libido and erectile dysfunction. However, these agents also affect many other neurotransmitter systems. Dopamine antagonism (e.g., by neuroleptic or antipsychotic agents) results in elevated prolactin concentrations that suppress endogenous gonadotropin and testosterone secretion and may contribute to reduced libido and erectile dysfunction.

Hypoactive sexual desire disorder is defined as persistent or recurrent deficiency or absence of desire for sexual activity resulting in marked personal distress, interpersonal difficulty, or both[150,154,155] and is estimated to affect more than 15% of men. The causes of hypoactive sexual desire disorder are primarily disorders that affect normal brain function and are usually associated with erectile dysfunction, particularly with the loss of spontaneous evening or morning erections (Table 19.2). *Erectile dysfunction* is defined as the inability to achieve or maintain penile erection that is adequate for completion of satisfactory sexual intercourse or activity.[156] Erectile dysfunction is a common condition that increases with aging. It is estimated to affect fewer than 10% of men younger than 40 years of age but approximately 50% of men between 40 and 70 years of age, with 35% of men in the latter age group having moderate or complete erectile dysfunction.

Hypoactive Sexual Desire Disorder and Erectile Dysfunction Due to Brain Disorders. *Psychogenic disorders* commonly cause hypoactive sexual desire and erectile dysfunction. These disorders include stress or preoccupation associated with life circumstances or situations, illness, marital discord, or underlying maternal transference or gender identity issues; performance anxiety associated with fear of failure or preoccupation with the adequacy of erections during sexual intercourse; major depression or dysthymia (moderate or complete erectile dysfunction occurs in 60% to 90% of men with moderate to severe depression); and major psychiatric illness such as psychotic or personality disorders.[150,154,155]

Chronic systemic illness (chronic heart disease, respiratory illness, kidney or liver failure, or cancer) and poor general health are usually associated with reduced libido and spontaneous erections.[150,154,155] Several *CNS-active medications* may cause hypoactive sexual desire disorder and erectile dysfunction, including alcohol, centrally acting antihypertensive medications, narcotics,

TABLE 19.2 Causes of Hypoactive Sexual Desire Disorder and Erectile Dysfunction

Cause	Examples
Brain Disorders	
Psychogenic disorders	Stress or preoccupation, performance anxiety, depression, major psychiatric illness
Chronic systemic illness	Heart, respiratory, kidney, or liver failure; cancer
CNS-active drugs	Alcohol; antihypertensive, narcotic, sedative-hypnotic, anticonvulsant, antidepressant, antipsychotic medications
Structural brain disease	Temporal lobe or limbic system disorders, Parkinson or other neurodegenerative brain disease, vascular brain disorders
Androgen deficiency	Primary and secondary hypogonadism
Other endocrine disorders	Hyperprolactinemia, Cushing syndrome, hyperthyroidism, hypothyroidism
Spinal Cord and Peripheral Disorders	
Spinal cord disorders	Trauma, vascular compromise, spinal stenosis, epidural abscess, tumor, transverse myelitis, multiple sclerosis, other spinal cord lesions
Peripheral nerve disorders	Diabetes mellitus; pelvic, prostate, or retroperitoneal surgery or damage; other causes of peripheral neuropathy
PNS-active drugs	Anticholinergic, antihistamine, antidepressant, sympathomimetic, α-adrenergic agonist, β-adrenergic antagonist medications
Peripheral vascular disease	Aortoiliac atherosclerosis, diabetes mellitus, trauma, surgery, vasculitis, venous incompetence (venous leakage), smoking
Antihypertensive drugs	Diuretics, β-adrenergic antagonists, calcium channel antagonists
Penile abnormalities	Peyronie disease, chordee, trauma, priapism, phimosis

CNS, Central nervous system; *PNS*, peripheral nervous system.

sedative-hypnotic drugs, anticonvulsants, antidepressants, and antipsychotic medications. In addition to their direct effects on brain neurotransmitter function, both chronic illness and CNS-active medications may also be associated with androgen deficiency. *Structural brain disease*, such as infiltrative or destructive lesions of the temporal lobe or limbic system, Parkinson or other neurodegenerative brain disease, or vascular brain disorders such as stroke or vasculitis, may reduce libido and spontaneous erections.

Androgen deficiency is commonly associated with reduction or loss of libido and spontaneous erections.[157,158] Sexual dysfunction is usually a prominent presenting complaint in young men who are severely androgen deficient and in older men who are treated with medical therapies (e.g., GnRH agonist treatment) or surgical castration for advanced prostate cancer. In contrast, older men with less severe androgen deficiency may have sexual dysfunction that is also related to underlying depression, chronic systemic illness, or use of certain medications.[159] Comorbid conditions contribute to the nonspecificity of presenting complaints of androgen deficiency (e.g., sexual dysfunction) as men age. Testosterone treatment of severe androgen deficiency in young men usually improves sexual desire, interest, and thoughts; attentiveness to erotic stimuli; and the frequency, duration, and rigidity of spontaneous evening and morning erections.[158,160,161] In older hypogonadal men with reduced libido, 1 year of a physiologic dose of transdermal testosterone improved sexual activity and desire compared with placebo.[162]

Other endocrine disorders can cause hypoactive sexual desire disorder and erectile dysfunction; examples include hyperprolactinemia, Cushing syndrome (glucocorticoid excess), hyperthyroidism, and hypothyroidism. In addition to their direct effects on brain function, hyperprolactinemia and glucocorticoid excess also suppress GnRH and gonadotropin secretion and induce androgen deficiency that contributes to sexual dysfunction. Anecdotally, some men with androgen deficiency due to severe hyperprolactinemia who are treated with testosterone alone do not fully recover sexual function and may require additional therapy with dopamine receptor agonists, but this has not been demonstrated conclusively. Dopamine receptor agonists lower elevated prolactin concentrations and may also have direct affects in the brain to activate neuronal systems involved in stimulating libido and erections.

Erectile Dysfunction Due to Spinal Cord or Peripheral Disorders. External and internal erotic stimuli from the brain are relayed via descending neural pathways in the lateral spinal columns to stimulate the parasympathetic sacral (S2-S4) spinal erection center, resulting in *psychogenic erections*. Efferent parasympathetic nervous system stimulation from the sacral center travels via the nervi erigentes (pelvic splanchnic nerve) and the pelvic plexus and enters the penis via the cavernosal nerve. This stimulation causes relaxation of the smooth muscles that form sponge-like interconnected trabecular spaces within the corpora cavernosa of the penis and vasodilation of the cavernosal arterioles and vascular sinusoids. As a result, blood flow and pressure into the trabecular spaces within the corpora increase several fold and cause engorgement of the penis (tumescence). Expansion of the trabecular spaces against the thick fibrous sheath (tunica albuginea) surrounding the corpora compresses subtunical venules and impedes venous outflow, resulting in sustained penile tumescence (i.e., an erection).[150,156]

Afferent somatic (via the pudendal nerve) and parasympathetic impulses in response to sensory stimulation of the penis with sexual intercourse or masturbation also act to stimulate erections via a reflex arc through the sacral spinal erection center, resulting in *reflexogenic erections*. Pudendal nerve stimulation also triggers the reflex contraction of the ischiocavernosus and bulbocavernosus muscles, resulting in vascular compression at the base of the penis, further increasing cavernosal blood pressure and maximal penile rigidity, leading to the plateau phase of erection.

The primary neurotransmitter that mediates penile smooth muscle relaxation and erection is NO. In response to parasympathetic cholinergic (acetylcholine-mediated) stimulation, NO is synthesized from its precursor, L-arginine, by the enzyme nitric oxide synthase and is released by corporal sinusoidal endothelial cells and postganglionic noncholinergic, nonadrenergic nerve terminals. NO then enters adjacent smooth muscle cells, where it activates guanylyl cyclase and increases intracellular cyclic guanosine monophosphate (cGMP). cGMP activates cGMP-dependent protein kinase, which phosphorylates many proteins, including myosin light chains and ion channels that ultimately decrease intracellular calcium concentrations, causing smooth

muscle relaxation, increase in penile blood flow, and erection. cGMP is primarily hydrolyzed and inactivated by the enzyme phosphodiesterase type 5 (PDE5). In addition to cGMP, other neurotransmitters induce cavernosal smooth muscle relaxation, including prostaglandin E_1 (PGE_1) that activates adenylyl cyclase and increases cAMP and cAMP-dependent protein kinase.

Knowledge of the neurotransmitter systems that control erections has been used to design pharmacologic treatments for erectile dysfunction[156,163,164] (detailed in Chapter 20). The most commonly used treatments are oral PDE5 inhibitors, such as sildenafil, vardenafil, and tadalafil, which act to inhibit the breakdown of cGMP, resulting in more sustained smooth muscle relaxation and improved penile erection after erotic stimulation. Injection of intracavernosal alprostadil (PGE_1) or insertion of intraurethral alprostadil pellets acts to increase cavernosal cAMP concentrations and induce smooth muscle relaxation and penile erection even in the absence of sexual stimulation. Intracavernosal injections of papaverine, a nonspecific PDE inhibitor (which inhibits the breakdown of both cGMP and cAMP), combined with phentolamine, an α_1- and α_2-adrenergic receptor antagonist vasodilator (bi-mix), or the two combined together with alprostadil (tri-mix), are also used to induce smooth muscle relaxation and erection.

Nonpharmacologic therapies include vacuum pumps that draw blood into the penis and induce tumescence. Vacuum pumps are often used with veno-occlusive elastic rings to maintain the erection. Some men are best treated with surgically implanted penile prostheses.

Studies in experimental animals and in vitro have found that androgen deficiency impairs penile nerve, trabecular smooth muscle, vascular endothelial, and tunica albuginea structure and function; reduces both endothelial and neuronal NO synthase synthesis and activity; and causes accumulation of adipocytes in the subtunical region of the corpora cavernosa.[153] These changes are reversed with androgen administration, suggesting a direct penile effect of androgens in addition to their central role in maintaining penile erections. In humans, ARs are expressed in the corpora cavernosa tissue. However, there is no conclusive evidence to support the notion that androgen treatment has a direct effect in the penis to enhance the response to PDE5 inhibitor therapy in androgen-deficient men with erectile dysfunction. In practice, symptomatic men with androgen deficiency and sexual dysfunction are usually treated with testosterone replacement, which can variably improve erectile dysfunction, particularly in younger hypogonadal men with severe androgen deficiency and no comorbid illness. In the placebo-controlled Testosterone Trials, 1 year of physiologic transdermal testosterone therapy improved erectile function in older men with hypogonadism, although the improvement was less than that observed with PDE5 inhibitors.[162] If erectile dysfunction does not improve with testosterone treatment alone, patients are given additional therapy for erectile dysfunction (e.g., addition of a PDE5 inhibitor). In some hypogonadal men, PDE5 inhibitor treatment alone may be sufficient to improve erectile dysfunction but is not adequate to treat reduced libido or other symptoms of androgen deficiency.[161]

In addition to the brain disorders that cause hypoactive sexual desire disorder and erectile dysfunction, spinal cord and peripheral disorders (e.g., peripheral nervous system disorders, peripheral vascular disease, medications that affect peripheral nerve and vascular function, penile abnormalities) may also cause erectile dysfunction that is usually not associated with hypoactive sexual desire (see Table 19.2). However, long-standing, severe erectile dysfunction may cause performance anxiety or depression, which may secondarily reduce libido. Furthermore, peripheral disorders that cause erectile dysfunction may also affect brain function and alter sexual interest and drive, contributing to erectile dysfunction. Tricyclic antidepressants may affect both peripheral nervous system and CNS function.

Spinal cord disorders, such as spinal cord injury due to trauma, vascular compromise, spinal stenosis, epidural abscess, tumor, transverse myelitis, multiple sclerosis, or other spinal cord lesions, usually cause erectile dysfunction. In general, the severity of erectile dysfunction associated with spinal cord injury and the response to treatment vary with the cord level involved, the severity of the lesion (i.e., complete vs. incomplete), and the time since the injury. *Peripheral nerve disorders*, particularly those that affect the autonomic nervous system, may disrupt the normal regulation of penile erectile tissue and cause erectile dysfunction. For example, erectile dysfunction may be caused by diabetes mellitus or other diseases that cause peripheral neuropathy (e.g., amyloidosis, vasculitis, heavy metal toxicity, renal failure, multiple system atrophy, acute intermittent porphyria) or by pelvic, prostate, or retroperitoneal surgery or damage (e.g., abdominoperineal resection of the rectum, pelvic lymph node dissection, prostatectomy, aortoiliac bypass, lumbar sympathectomy). Peripheral nervous system medications, including anticholinergic agents, antihistamines, antidepressants, sympathomimetic medications, α-adrenergic agonists, and β-adrenergic antagonists, often impair erectile function by affecting peripheral nervous system regulation of erectile tissue of the penis, and many also cause erectile dysfunction by altering neurotransmitter function in the nervous system and penis.

The blood supply of the penis is derived from the internal iliac (hypogastric) artery, a branch of the common iliac artery that bifurcates from the aorta.[150] The internal iliac artery gives rise to the internal pudendal artery, which branches into the dorsal penile, bulbourethral, and cavernosal arteries. The cavernosal arteries run through the middle of the corpora cavernosa and give off corkscrew-shape branches, the helicine arteries, that open directly into the lacunar spaces. Smooth muscle relaxation of lacunar spaces increases blood flow into the corpora cavernosa, resulting in penile tumescence. Blood from the lacunar spaces or cavernosal sinusoids collects in the subtunical plexus and is delivered via emissary veins to the deep dorsal vein, which ultimately drains into the internal and common internal iliac veins and then into the inferior vena cava. With filling of the lunar spaces of the corpora cavernosa and penile tumescence against the fibrous tunica albuginea, venous outflow from the subtunical venous plexus is impeded, and sustained tumescence or erection ensues. Disorders of arterial inflow or venous output may cause erectile dysfunction.

Peripheral vascular disease due to aortoiliac atherosclerosis is probably the most common cause of erectile dysfunction in aging men.[150,156] These men usually have absent or severely diminished femoral artery pulses, and some present clinically with Leriche syndrome (absent femoral pulses, buttock or leg claudication, and erectile dysfunction). Other men with iliac atherosclerosis may be able to achieve an erection, but with penetration and use of the hip muscles for thrusting during sexual intercourse, blood is diverted from the penis to the hips, resulting in premature detumescence and loss of erection; this is known as the *pelvic steal syndrome*. Atherosclerotic large- and small-vessel disease may contribute to erectile dysfunction in men with diabetes mellitus, hypertension, CKD, smoking, and other atherosclerotic risk factors. Erectile dysfunction occurs in about 50% of men with diabetes mellitus. Smoking, specifically nicotine, also causes direct vasoconstriction of the corpora cavernosum and erectile dysfunction. Other

conditions that compromise aortoiliac circulation, such as pelvic trauma, irradiation, and vasculitis, are less common causes of erectile dysfunction. Chronic pressure on the pudendal artery from bicycle riding, especially with some bicycle seats, may cause penile ischemia and erectile dysfunction; in addition, pressure on the pudendal nerve may cause penile numbness and contribute to sexual dysfunction. *Penile venous incompetence* (venous leakage) may cause premature loss of erections and inability to maintain erections sufficient to complete intercourse.

Many *antihypertensive medications*, including diuretics, α- and β-adrenergic antagonists, angiotensin-converting enzyme inhibitors, and calcium channel antagonists, have been implicated as causes of erectile dysfunction. *Penile abnormalities*, such as Peyronie disease or chordee (fibrosis or scarring of the tunica albuginea resulting in bending of the penis), micropenis or microphallus, penile trauma, phimosis (inability to retract the foreskin over the penis), and priapism (painful extended erections) may also cause erectile dysfunction.

Evaluation of Erectile Dysfunction. The cause of erectile dysfunction is usually strongly suspected based on a careful medical, psychiatric, and medication history and physical examination.[150,156] Erectile dysfunction of psychogenic origin usually occurs abruptly, is transient, is intermittent or associated with a stressful situation, occurs with only some partners but not with others, or does not occur with masturbation. Spontaneous evening and morning erections are usually maintained in psychogenic erectile dysfunction but lost with organic causes. Spontaneous erections may be detected by formal measurements of nocturnal penile tumescence in a sleep laboratory or by breakage of wires of different tensile strength in a snap gauge (RigiScan), but these assessments are not routinely performed in practice and usually are not necessary.

Patients with nonpsychogenic brain disorders, spinal cord or peripheral nervous system disorders, vascular disorders, or penile abnormalities that cause organic erectile dysfunction usually exhibit clinical manifestations of the underlying disorder, and offending drugs that impair erectile function are revealed with a careful review of medications. Androgen deficiency is a cause of reduced libido and erectile dysfunction and occurs in 15% to 20% of men who complain of sexual dysfunction in a general medical clinic.[165] Therefore, evaluation of men who present with sexual dysfunction should include inquiry regarding other symptoms of androgen deficiency, examination for signs such as small testis size and gynecomastia, and confirmation of androgen deficiency by measurement of serum testosterone concentrations (see later discussion).

Peripheral pulses, particularly the presence of femoral pulses, should be tested to assess for peripheral vascular disease. Diagnosis of penile vascular insufficiency may be suspected by Doppler ultrasound measurement of the ratio of penile to brachial systolic blood pressure (penile/brachial index). A penile/brachial index greater than 0.75 is normal, whereas an index of less than 0.60 is suggestive of vascular erectile dysfunction. If there is a clinical suspicion of spinal cord disease, perineal and penile sensation should be assessed. A cremasteric reflex (stroking of the inner thigh associated with contraction of the ipsilateral cremasteric muscle and pulling up of the scrotum and testis) and a bulbocavernosus reflex (squeezing of the glans penis associated with contraction of the anal sphincter) should be elicited to assess spinal cord levels L1-L2 and S2-S4, respectively. Finally, the penis should be examined for abnormalities, such as penile plaques, angulation, or tight and unretractable foreskin.

Ejaculatory Disorders and Orgasmic Dysfunction

After the plateau phase of erection is achieved, sympathetic nervous system stimulation from the thoracolumbar (T10-L2) spinal erection center travels via the hypogastric nerve and pelvic plexus, enters the penis via the cavernosal nerve, and causes α-adrenergic receptor–mediated contraction of the cauda epididymis, vas deferens, accessory sex glands (the bulbourethral or Cowper glands and the urethral glands or glands of Littre), prostate, seminal vesicles, and ejaculatory ducts that moves sperm and semen into the posterior urethra (*emission*). It also stimulates closure of the internal urethral sphincter to prevent retrograde ejaculation of sperm into the bladder.[150] After emission, continued sensory stimulation of the penis with sexual intercourse or masturbation stimulates reflex rhythmic contractions of the ischiocavernosus and bulbocavernosus muscles, resulting in expulsion of semen from the urethra (*ejaculation*).[150]

Like erection, ejaculation is under considerable control by higher brain centers, with both voluntary and involuntary regulation.[150] *Premature ejaculation* is ejaculation that occurs before or shortly after vaginal penetration during sexual intercourse and is followed by a rapid loss of erection.[166] The cause of premature ejaculation is usually a psychological disturbance such as performance anxiety; it is rarely the result of an organic cause. There is evidence that serotoninergic neurotransmission inhibits sexual function and ejaculation. Selective serotonin reuptake inhibitors retard ejaculation, an effect that is used therapeutically to treat premature ejaculation.[166,167] Other men with psychological disorders such as excessive anxiety may have *retarded ejaculation* (inability to ejaculate), either in isolation or in combination with impaired libido and erections. The ejaculate is composed of spermatozoa (10%) and seminal fluid (90%), the latter derived mostly from the seminal vesicles (65%) and the prostate gland (30%). Because secretions from these accessory sex glands are androgen dependent, severe androgen deficiency may result in *absent* or *reduced ejaculation*. Absent or reduced ejaculation may also be caused by urethral abnormalities. Autonomic neuropathy, such as that caused by diabetes mellitus, sympatholytic drugs, thoracolumbar sympathectomy, extensive retroperitoneal or pelvic surgery, or bladder neck surgery, may be associated with absent or reduced ejaculation by causing *retrograde ejaculation* into the bladder.

Orgasm, the pleasurable sensation associated with ejaculation, usually occurs simultaneously with ejaculation and is mediated by CNS activation via ascending pathways from the spinal cord erection centers to regions of the temporal lobe and limbic system.[150] Because of impaired libido and erectile dysfunction, men with androgen deficiency may also fail to achieve an orgasm. Isolated absence of orgasm in the presence of normal libido, erections, and ejaculation is relatively rare and is almost always caused by a psychological disorder.

Disorders of Detumescence. After ejaculation, the thoracolumbar sympathetic outflow acts via α-adrenergic receptor stimulation to cause contraction of trabecular smooth muscle, which results in collapse of lacunar spaces, vasoconstriction of arterioles of the corpora cavernosa (reducing blood flow into the penis), and decompression of subtunical venules, leading to an increase in venous outflow and a flaccid penis (*detumescence*).[150] Premature detumescence may contribute to erectile dysfunction, such as that caused by penile venous incompetence. Intracorporal injection of an α-adrenergic receptor antagonist, phentolamine, together with papaverine and PGE_1, causes sustained lacunar smooth muscle relaxation, arteriole vasodilatation, and penile tumescence and is used to treat erectile dysfunction caused by premature detumescence.

Priapism is failure of detumescence with persistence of erection lasting for longer than 4 hours that is unrelated to sexual stimulation and is usually painful.[150,168] An erection that persists for more than 4 hours is an emergency and may be complicated by ischemia, thrombosis, and vascular damage that contribute further to erectile dysfunction; if ischemia is severe, it can cause gangrene and eventual loss of the penis. Priapism may be idiopathic, or it may be caused by medications (e.g., intracavernosal injection therapy for erectile dysfunction, phenothiazines, trazodone, cocaine), by hematologic disorders such as sickle cell disease or chronic myelogenous leukemia, by neurologic disorders such as spinal cord injury, or by infiltrative diseases such as amyloidosis. The initial treatment is administration of the α-adrenergic receptor agonist pseudoephedrine; if this is unsuccessful, aspiration of blood from the corpora cavernosa is performed with local anesthesia.

Gynecomastia

Gynecomastia is benign enlargement of the male breast caused by proliferation of glandular breast tissue.[169-171] On inspection, it is difficult to distinguish gynecomastia from increased adipose tissue deposition within the breast in the absence of glandular proliferation (pseudogynecomastia), which is commonly present in obese men and boys. Detection of glandular breast tissue requires a careful and properly performed physical examination (see earlier discussion), feeling for a firm, rubbery, finely lobular, freely mobile disc of tissue that extends concentrically from under the nipple and areola. Initially, gynecomastia of relatively recent and rapid onset may be painful and associated with tenderness. With time, glandular tissue is replaced by fibrous tissue and tenderness resolves, although palpable tissue remains. In contrast, pseudogynecomastia is soft, nondiscrete, and irregularly lobular, similar to subcutaneous (SC) fat in the abdomen.

Gynecomastia is usually present bilaterally but may be asymmetric in size and variably symptomatic. If palpable breast tissue is present unilaterally, the major concern is male breast cancer. Breast cancer is usually rock hard and indurated, eccentrically located from the nipple and areola, and fixed to underlying tissue; it may be associated with skin dimpling with retraction of hair follicles (*peau d'orange*), nipple retraction, nipple bleeding or discharge, or axillary lymphadenopathy.[172] Other chest wall tumors may cause unilateral breast enlargement, including lipomas, sebaceous or dermoid cysts, hematomas, fat necrosis, lymphangiomas, neurofibromas, and lymphomas.

The primary hormones that regulate breast tissue development are estrogens, which stimulate the growth and differentiation of breast epithelium to form ducts (ductal hyperplasia), and progesterone, which controls acinar development and the formation of glandular buds (glandular formation).[169,171] GH, IGF1, insulin, thyroid hormone, and cortisol play permissive roles in breast development. Androgens inhibit the growth and differentiation of breast tissue. Prolactin stimulates differentiated breast acinar cells to produce milk, but high progesterone (and to a lesser extent high estradiol) concentrations inhibit lactogenesis. Therefore, milk production requires a reduction in high progesterone (and to a less extent reduction in high estradiol) concentrations in the presence of high prolactin concentrations, as occurs in the first few days after parturition. Milk production (galactorrhea) is rarely seen in men with hyperprolactinemia and gynecomastia, because progesterone concentrations are not usually high enough for breast acinar development to occur, and progesterone and estradiol concentrations do not decline from baseline in men in the presence of high prolactin concentrations to stimulate lactogenesis.

Gynecomastia develops in clinical situations in which the concentrations or activity of estrogens is relatively high in comparison with androgens (i.e., high estrogen to androgen ratio). This hormonal milieu may result from high estrogen or low androgen concentrations or activity. Androgen deficiency, because it decreases the inhibitory influence of androgens on breast development, is a major cause of gynecomastia. However, the differential diagnosis of other causes of gynecomastia should be considered in patients who present with breast enlargement with or without tenderness.

Causes of Gynecomastia

Physiologic gynecomastia occurs normally in neonatal and pubertal boys. Transient gynecomastia (neonatal gynecomastia) occurs in 60% to 90% of neonatal boys as a result of exposure in utero to high concentrations of maternal estrogens; it resolves within several weeks after delivery[169-171] (Table 19.3). At the time of puberty, breast enlargement greater than 0.5 cm in diameter, which is often tender, initially occurs in 60% to 70% of boys by 14 years of age and then regresses within 1 to 2 years. This pubertal gynecomastia is thought to be caused by a transient rise in serum concentrations of estrogen relative to testosterone during puberty.

Pathologic gynecomastia may result from excessive estrogen concentrations or action or from androgen deficiency or androgen resistance/insensitivity in isolation. In some conditions, both estrogen excess and androgen deficiency contribute to proliferation of glandular breast tissue.[169-171] For example, in most conditions that cause gynecomastia as a result of excessive estrogen exposure, high circulating estrogen concentrations inhibit endogenous gonadotropin and testosterone secretion and cause secondary hypogonadism, which also contributes to the growth of breast tissue. In addition, some disorders of the testes that cause androgen deficiency (i.e., primary hypogonadism), such as Klinefelter syndrome, result in high circulating LH concentrations that stimulate aromatase activity in Leydig cells, leading to higher concentrations of estradiol relative to testosterone and contributing to the pathogenesis of gynecomastia.

Estrogen excess disorders that cause gynecomastia include exposure to exogenous estrogens (e.g., diethylstilbestrol treatment of prostate cancer, contact with an estrogen-containing cream or cosmetic, accidental occupational exposure to estrogens, ingestion of estrogen-containing nutritional supplements or excessive amounts of phytoestrogens) and exposure to ER agonists such as marijuana smoke (unidentified phenolic components but not active cannabinoids[173]) or digitoxin. Ingestion of normal dietary amounts of phytoestrogens (e.g., soybean isoflavones) does not usually cause gynecomastia.[174] Uncommonly, administration of testosterone or other aromatizable androgens, usually to prepubertal boys or men with long-standing, severe androgen deficiency, induces or worsens gynecomastia by initially causing relatively higher estradiol than testosterone concentrations.

Increased peripheral aromatase activity with increased conversion of androgens to estrogens in excessive amounts of adipose tissue is thought to cause mild to moderate gynecomastia in men with obesity.[169-171] In addition, increased aromatization of androgens to estrogens with increasing amounts of adipose tissue (including that within the breast) probably contributes substantially to the increased prevalence of gynecomastia with aging, which occurs in up to 65% of men from 50 to 80 years of age.[169-171] Familial gynecomastia, an autosomal dominant or X-linked genetic disorder caused by constitutive activation of the *CYP19A1* (aromatase) gene that results in increased peripheral conversion of androgen to estrogen, is a very rare cause of gynecomastia that manifests as prepubertal gynecomastia persisting into adulthood.

TABLE 19.3 Causes of Gynecomastia

Cause	Examples
Physiologic Causes	
Maternal estrogen exposure	Neonatal gynecomastia
Transient increase in estrogen to androgen concentrations	Pubertal gynecomastia
Estrogen Excess	
Estrogens or estrogen receptor agonists	Estrogens, digitoxin, testosterone or other aromatizable androgens
Increased peripheral aromatase activity	Obesity, aging, familial
Estrogen-secreting tumors	Adrenal carcinoma, Leydig or Sertoli cell tumor
hCG-secreting tumors	Germ cell, lung, hepatic carcinoma
hCG treatment	
Androgen Deficiency or Resistance	
Androgen Deficiency	Primary or secondary hypogonadism
Hyperprolactinemia causing androgen deficiency	
Androgen Resistance Disorders	Congenital and acquired androgen resistance
Drugs that interfere with androgen action	Spironolactone, androgen receptor antagonists, 5α-reductase inhibitors, histamine 2 receptor antagonists
Systemic Disorders	
Organ failure	Hepatic cirrhosis, chronic kidney disease
Endocrine disorders	Untreated hyperthyroidism, acromegaly, growth hormone treatment, Cushing syndrome
Nutritional disorders	Refeeding, recovery from chronic illness (hemodialysis, insulin, isoniazid, antituberculous medications, efavirenz)
Idiopathic Causes	
Drugs	HAART, calcium channel antagonists, amiodarone, antidepressants (SSRIs, tricyclic antidepressants), alcohol, amphetamines, penicillamine, sulindac, phenytoin, omeprazole, theophylline
Adult-onset idiopathic gynecomastia	
Persistent prepubertal macromastia	

HAART, Highly active antiretroviral therapy; *hCG,* human chorionic gonadotropin; *SSRIs,* selective serotonin reuptake inhibitors.

Estrogen-secreting tumors of the adrenal gland or testis are uncommon causes of gynecomastia. Feminizing adrenal tumors are usually malignant and large, manifesting with a palpable abdominal mass. In contrast, estrogen-secreting Leydig or Sertoli tumors are usually small and benign. Feminizing Sertoli tumors (particularly the large cell calcifying variety) may occur in isolation or in association with autosomal dominant disorders such as Peutz-Jeghers syndrome (multiple intestinal polyps and mucocutaneous pigmented macules) or the Carney complex (cardiac or cutaneous myxomas, pigmented skin lesions, and endocrinopathy, including functioning endocrine tumors of the adrenal and testis). *hCG-secreting tumors* (e.g., germ cell, lung, gastric, renal cell, or hepatic carcinomas in adults; hepatoblastomas in boys) or *hCG treatment* of gonadotropin deficiency increases aromatase activity in Leydig cells and stimulates excessive secretion of estradiol relative to testosterone, causing relative rapid onset of symptomatic gynecomastia.

Disorders and drugs that cause *androgen deficiency*, such as conditions that cause either primary or secondary hypogonadism (including medications such as cytotoxic agents) or androgen resistance, are major causes of gynecomastia.[169-171] Although prolactin acts on the breast to facilitate milk production in developed glandular tissue, the major mechanism by which hyperprolactinemia causes gynecomastia is inhibition of endogenous gonadotropin and testosterone production (inducing androgen deficiency), which acts indirectly to stimulate breast development by reducing the inhibitory influence of androgens on the breast. Hyperprolactinemia is the main reason that many CNS-active medications, such as antipsychotics, antidepressants, and sedatives, are associated with gynecomastia. Drugs that interfere with androgen action, such as spironolactone (in contrast to eplerenone, a selective aldosterone receptor antagonist that does not cause gynecomastia), AR antagonists (e.g., flutamide, bicalutamide, nilutamide and enzalutamide), marijuana, and histamine 2 (H_2) receptor antagonists, may cause gynecomastia.

Androgen deficiency contributes to the pathogenesis of gynecomastia in *systemic disorders* such as major organ failure—and particularly in hepatic cirrhosis and CKD, which are commonly associated with combined primary and secondary hypogonadism—and in *endocrine disorders* such as acromegaly and Cushing syndrome, which may be associated with secondary hypogonadism.[169-171] In hepatic cirrhosis, there is reduced catabolism of Δ^4-androstenedione, resulting in increased peripheral conversion of Δ^4-androstenedione to estrone and increased circulating estrogen concentrations. In addition, in both hepatic cirrhosis and hyperthyroidism, increased serum concentrations of SHBG, which binds testosterone with greater affinity than estradiol, result in relatively higher free estradiol compared with free testosterone concentrations and thereby contribute to stimulation of breast tissue and development of gynecomastia. LH concentrations are often elevated in men with hyperthyroidism, which stimulates relatively more estradiol than testosterone secretion by Leydig cells of the testes. Excessive GH with acromegaly or GH treatment and excessive cortisol with Cushing syndrome directly stimulate breast tissue growth in addition to causing secondary hypogonadism, both of which contribute to the pathogenesis of gynecomastia.

Gynecomastia often accompanies *nutritional disorders*, particularly during nutritional repletion after a period of starvation and weight loss (refeeding gynecomastia) and, analogously, during recovery from chronic illness.[169-171] In both starvation and severe chronic illness that is commonly associated with anorexia and weight loss, central GnRH production and concomitant

gonadotropin and testosterone secretion are markedly suppressed. With refeeding or restitution of appetite and weight gain, there is activation of the hypothalamic-pituitary-testicular axis and restoration of gonadal function, similar to what occurs during puberty but occurring more rapidly (a "second puberty"), resulting in transiently higher concentrations of estrogen relative to androgen concentrations and inducing gynecomastia. Refeeding gynecomastia was described initially in World War II prisoners who developed painful gynecomastia after liberation and nutritional repletion. Analogously, refeeding-like gynecomastia may occur in stage 5 CKD with the initiation of hemodialysis, in type 1 diabetes mellitus (T1DM) with insulin therapy, in tuberculosis with antituberculosis medications, and in human immunodeficiency virus (HIV) infection or acquired immunodeficiency syndrome with highly active antiretroviral treatment (HAART). As mentioned, these chronic systemic disorders also cause androgen deficiency that may contribute to the pathogenesis of gynecomastia. HAART also may cause lipohypertrophy and fat accumulation in the breast (pseudogynecomastia); efavirenz, a component of some HAART regimens, has estrogenic activity that might cause true gynecomastia.

The mechanisms of gynecomastia's causal relationship with many *drugs* are not entirely clear, and these cases are usually classified as idiopathic. Such drugs include calcium channel blockers (e.g., nifedipine, verapamil), amiodarone, antidepressants (selective serotonin reuptake inhibitors, tricyclic antidepressants), alcohol, amphetamines, penicillamine, sulindac, phenytoin, omeprazole (much less commonly than H_2-receptor antagonists), and theophylline.[169-171,175,176]

In many cases of adult-onset gynecomastia, the cause remains *idiopathic*. Most of these cases are probably caused by increased aromatization of androgens to estrogens associated with increased peripheral adiposity, enhanced breast production of estrogens, enhanced sensitivity to estrogens, or some combination of these factors. Rarely, boys may develop severe pubertal gynecomastia (female size breast development, Tanner stages III through V) that persists to adulthood (*persistent pubertal macromastia*). This disorder is not associated with specific hormonal or receptor abnormalities.

Evaluation

Most gynecomastia is asymptomatic and of mild degree but can be appreciated on a properly performed, careful physical examination (as described earlier). Asymptomatic gynecomastia (<5 cm) found incidentally on examination does not warrant evaluation. However, breast enlargement that is recent and rapid in onset, large (≥5 cm), symptomatic (i.e., associated with breast pain, tenderness, or galactorrhea), asymmetric, or suspicious for malignancy (eccentrically located, rock hard, fixed to overlying or underlying tissues, or associated with bloody nipple discharge or lymphadenopathy) should evaluated.

A careful history, including medication history, and physical examination usually identify potential predisposing conditions or medications causing gynecomastia that in older men may be mulifactorial.[169-171] Clinical evaluation should focus on evidence of androgen deficiency; assessment of prescription and over-the-counter medications, substance abuse, herbal or nutritional supplement intake, cosmetic use, and usual dietary intake; symptoms and signs of systemic illness (e.g., hepatic or renal disease), malignancy, or endocrine disorders (e.g., thyroid, GH, cortisol excess); and history of recent recovery from malnutrition, severe weight loss, or chronic illness. At a minimum, the initial laboratory evaluation comprises serum testosterone (calculated free testosterone if SHBG perturbation is suspected), LH, FSH, TSH, and renal and liver function tests. Evaluation also usually includes measurements of estradiol, prolactin, and βhCG, although clinically important elevations of these hormones suppress serum gonadotropin concentrations. Breast enlargement suspicious for malignancy should be evaluated by mammography and biopsy.

Treatment

Pubertal gynecomastia usually regresses spontaneously without treatment in 1 to 2 years and by 18 years of age in about 90% of cases. In adults, spontaneous regression of symptoms (breast pain and tenderness, nipple sensitivity) associated with inflammatory glandular proliferation usually occurs within 6 months, after which progressive stromal fibrosis causes permanent palpable breast tissue and only partial regression of gynecomastia by 1 year.

Initial treatment of gynecomastia is directed at correction of the underlying cause of breast enlargement or discontinuation or replacement of a potentially offending medication.[177] No treatment is effective for gynecomastia of 6 months or more; absence of breast tenderness generally indicates the chronic fibrotic stage of gynecomastia that will not remit. Prophylactic low-dose breast irradiation (10–15 Gy over 1–3 days) may be used before androgen deprivation therapy in men with prostate cancer to prevent the development of gynecomastia, which is more common in surgical orchidectomy and in AR antagonist monotherapy than in combined therapy with a GnRH agonist or antagonist. Testosterone replacement therapy in androgen-deficient men may result in partial regression of gynecomastia if breast enlargement is of recent onset. For gynecomastia of recent onset (<6 months), selective ER antagonists (tamoxifen, 10–20 mg daily, or raloxifene, 60 mg daily) are effective in treating pubertal and adult gynecomastia and preventing gynecomastia induced by androgen deprivation therapy. For unclear reasons, aromatase inhibitors (e.g., anastrozole) generally are not effective. Although tamoxifen is not approved for treatment of gynecomastia, it has been shown to be effective in the treatment of idiopathic gynecomastia, resulting in partial regression in approximately 80% and complete regression in about 60% of cases. A gel formulation of DHT, a nonaromatizable androgen, is used to treat gynecomastia in some countries outside the United States.

Gynecomastia of recent onset, during the initial phase of ductal proliferation, periductal inflammation and edema, and subareolar fat accumulation, is usually responsive to medical therapy (e.g., androgen replacement in hypogonadal men, ER antagonist therapy). With long-standing gynecomastia (>6 months), there is progressive stromal fibrosis of the breast that is not responsive to medical treatment. In these cases, surgical reduction mammoplasty (i.e., removal of breast tissue [SC mastectomy] with or without periareolar adipose tissue [liposuction]) is necessary, especially if breast enlargement is severe, painful, socially embarrassing, or disfiguring.

Infertility

Infertility is defined as the inability of a sexually active couple to achieve conception despite 1 year of unprotected intercourse. The probability of conception in a sexually active young couple (both younger than 35 years) is approximately 85% by 1 year. Approximately 15% of couples in the reproductive age group are infertile, and a male factor contributes to the cause (either in isolation or in combination with a female factor) in about half of the cases. Therefore, male infertility is a common condition, affecting approximately 7% of men.[178]

Causes of Male Infertility

In about 80% to 90% of infertile men, infertility is caused by primary or secondary hypogonadism, manifested most commonly by an isolated impairment of sperm production or function; much less commonly by androgen deficiency and impaired spermatogenesis; and rarely by androgen resistance[179,180] (Table 19.4). The evaluation and specific causes of hypogonadism are discussed in detail in subsequent sections. Most men with isolated impairment in sperm production have a primary disorder of the testes that is idiopathic in 60% to 70% of cases (if one includes idiopathic oligozoospermia or azoospermia and varicocele, given that relationship of varicocele to the pathogenesis of infertility is unclear). If isolated impairment of spermatogenesis is severe in men with primary hypogonadism, serum FSH concentrations may be selectively elevated (FSH >8 IU/L) as a result of reduced negative feedback by inhibin B from Sertoli cells of the testis.

Disorders of spermatogenesis caused by primary hypogonadism may be associated with chromosomal or genetic disorders. There is an 8- to 10-fold increase in the prevalence of chromosomal abnormalities among infertile men with impaired spermatogenesis—specifically, sex chromosomal aneuploidy (e.g., Klinefelter syndrome) or Robertsonian translocations of two nonhomologous chromosomes, most commonly involving chromosomes 13 and 14 or chromosomes 14 and 21.[181] The long arm of the Y chromosome (Yq), specifically the azoospermia factor (*AZF*) region (Yq11), contains many genes that encode for proteins that have important roles in spermatogenesis. This region contains highly homologous palindromic DNA repeat sequences that are susceptible to rearrangement and deletions. Small deletions in the *AZF* region (*Y chromosome microdeletions*) are the most common genetic cause of impaired sperm production and male infertility; they are found in 5% to 10% of men with azoospermia or severe oligozoospermia (sperm concentration <5 million/mL).[181] Y chromosome microdeletions have been identified in three regions: in the *AZFa* region, microdeletions are uncommon but are usually associated with azoospermia and Sertoli cell–only histology; in the *AZFb* region, they are usually associated with severe oligozoospermia and germ cell arrest at the pachytene primary spermatocyte stage; and in the *AZFc* region, where the majority of Y chromosome microdeletions reside, they are usually associated with germ cell arrest at the spermatid stage or hypospermatogenesis with some mature spermatids present. Occasionally, microdeletions in the *AZFb* and *AZFc* regions are associated with azoospermia and Sertoli cell–only histology. Genes encoding a number of candidate proteins for male infertility include *DDX3Y* (DEAD box Y, an ATP-dependent RNA helicase), *RBMY* (RNA-binding motif Y-linked, an RNA-binding protein), and *DAZ* (deleted in azoospermia, another RNA-binding protein) in the *AZFa, AZFb,* and *AZFc* regions, respectively.[181,182]

Approximately 15% to 20% of male infertility is caused by *disorders of sperm transport* from the testes to the urethra, most commonly by genital tract obstruction. *Congenital bilateral absence of the vas deferens* (CBAVD) is present in 1% to 2% of men with infertility.[181,183,184] Seventy-five percent of men with CBAVD are heterozygous for the cystic fibrosis transmembrane conductance regulator gene (*CFTR*) that encodes for an epithelial chloride channel. They do not have obvious clinical manifestations of cystic fibrosis, although some manifest abnormalities on sweat chloride testing and sinopulmonary infections. Conversely, almost all men with clinical cystic fibrosis have CBAVD. CBAVD is also commonly associated with absence of the seminal vesicles, ejaculatory ducts, and epididymides due to fetal atrophy of these wolffian duct derivatives; in 10% of cases, there is also renal agenesis or hypoplasia.

Other causes of genital tract obstruction include other congenital defects of the epididymides and vas deferens (e.g., epididymal cysts associated with prenatal diethylstilbestrol exposure); vasectomy (surgical ligation of the vas deferens); postinfectious fibrosis (e.g., associated with gonorrhea, *Chlamydia* infection, other sexually transmitted diseases; tuberculosis; leprosy); and Young syndrome, a rare, congenital primary ciliary dyskinesia syndrome characterized by bronchiectasis, recurrent sinopulmonary infections, and obstructive azoospermia caused by thickened, inspissated mucous secretions obstructing the epididymides.

Although a causal link to infertility has not been clearly established, other genital tract abnormalities may contribute to impaired sperm transport and the pathogenesis of infertility in some men. *Accessory gland dysfunction*, such as reduced seminal vesicle and prostate secretions associated with disorders that cause severe androgen deficiency or resistance, may contribute to reduced fertility, although the main effects of these disorders are

TABLE 19.4 Causes of Male Infertility

Cause	Examples
Hypogonadism	
Isolated impairment of sperm production or function	
Androgen deficiency and impaired sperm production	
Androgen resistance	
Disorders of Sperm Transport	
Genital tract obstruction	Congenital bilateral absence of the vas deferens, cystic fibrosis, other congenital defects, vasectomy, postinfectious fibrosis, Young syndrome
Accessory gland dysfunction	Androgen deficiency or resistance, infection or inflammation, antisperm antibodies (immunologic)
SNS dysfunction	Autonomic neuropathy, sympatholytic drugs, sympathectomy, retroperitoneal or abdominopelvic surgery, spinal cord injury or disease, vasovasostomy
Ejaculatory Dysfunction	
Premature or retarded ejaculation	
Retrograde ejaculation	Prostatectomy, bladder neck surgery, autonomic neuropathy, SNS dysfunction
Reduced ejaculation	Androgen deficiency or resistance, SNS dysfunction, ureteral abnormalities
Coital Disorders	
Erectile dysfunction	
Defects in coital technique	Infrequent intercourse (< once weekly), poor timing in relation to ovulation, premature withdrawal of penis

SNS, Sympathetic nervous system.

to impair spermatogenesis and cause sexual dysfunction. *Infection or inflammation* of the epididymides, seminal vesicles, or prostate gland may affect fertility directly by impairing sperm maturation or function or secondarily by causing scarring of the genital tract or induction of *antisperm antibodies* in semen (resulting in sperm agglutination and impaired sperm function).[185,186] *Sympathetic nervous system dysfunction* (e.g., associated with autonomic neuropathy, sympatholytic drugs, sympathectomy, retroperitoneal or abdominopelvic surgery, spinal cord injury or disease, vasovasostomy) may contribute to impaired sperm transport and male infertility.

Ejaculatory dysfunction may cause or contribute to male infertility by preventing normal or efficient deposition of sperm into the vagina and female genital tract. Premature or delayed ejaculation may contribute to infertility if ejaculation occurs during arousal or foreplay before vaginal penetration or after withdrawal from the vagina. Retrograde ejaculation of semen into the bladder, rather than the urethra, occurs with neuromuscular failure of normal bladder sphincter contraction during ejaculation. Retrograde ejaculation may be associated with prostatectomy or bladder neck surgery (e.g., transurethral resection of the prostate), autonomic neuropathy (e.g., complicating diabetes mellitus), or sympathetic nervous system dysfunction, and particularly with sympatholytic drugs (e.g., α-adrenergic receptor antagonists like prazosin or terazosin), retroperitoneal or abdominopelvic surgery (e.g., retroperitoneal lymph node dissection), and spinal cord injury or disease. Reduced ejaculation caused sympathetic nervous system dysfunction or urethral abnormalities may contribute to reduced sperm delivery to the female genital tract.

Erectile dysfunction may contribute to male infertility by causing unsuccessful vaginal intercourse. Coital disorders are uncommon causes of male infertility, but they are potentially correctable with proper education. Infrequent vaginal intercourse (less than weekly), intercourse during menses rather than just before or around the time of ovulation, and premature withdrawal of the penis during intercourse may contribute to reduced fertility.

Evaluation

Because a coexisting female factor contributes to infertility in 30% of cases, it is important for the female partner to undergo evaluation for ovulation (menstrual periods, androgenization) and for cervical disorders (postcoital testing) and uterine and tubal disorders (hysterosalpingogram, pelvic ultrasound). In men, the history and physical examination are usually able to identify the potential cause of male infertility.[179-181]

In addition to an assessment of general health and medical comorbid conditions, the initial clinical evaluation should focus on the following:

- Symptoms and signs of androgen deficiency or resistance (as detailed elsewhere in this chapter)
- Scrotal examination for presence of a large varicocele, presence and size of the testes, and presence or absence of firm, fibrous cords of the vas deferens
- Family history or evidence of cystic fibrosis
- Previous vasectomy or vasovasostomy
- History or manifestations of genitourinary infections
- Medications, particularly ones that cause androgen deficiency or resistance and sympatholytic agents
- Ejaculatory problems, particularly absent or reduced ejaculate
- Autonomic neuropathy (e.g., complicating diabetes mellitus)
- Retroperitoneal or abdominopelvic surgery
- Spinal cord injury or disease
- Erectile dysfunction
- Coital practices and techniques.

The initial laboratory evaluation of male infertility should begin with at least two or three seminal fluid analyses performed over a period of a few months (see later discussion) to assess semen volume, sperm count and concentration, and sperm motility and morphologic appearance, with the aim of identifying men who have impaired sperm production or function—the major cause of male infertility. The presence of leukocytes in semen ($>10^6$/mL, termed *leukospermia* or *pyospermia*) may suggest genitourinary inflammation or infection, but routine cultures are not helpful in guiding treatment. Agglutination of spermatozoa in semen (i.e., sticking of motile sperm to each other) suggests the presence of *antisperm antibodies* that can be measured in semen and might indicate an immunologic cause of male infertility, but it is unclear whether antisperm antibodies affect fertility.[187]

Seminal fluid fructose is derived mostly from the seminal vesicles (60%) and to a lesser extent from the prostate gland (30%). Absent or low seminal fluid fructose and low semen volume suggest either congenital absence of the vas deferens and seminal vesicles or obstruction of the ejaculatory ducts. Transrectal or scrotal ultrasonography to detect dilated seminal vesicles should be done to confirm ejaculatory duct obstruction. In men who have little or no ejaculate, a postejaculatory urine specimen should be collected and examined for the presence of sperm, indicating retrograde ejaculation.

Serum testosterone concentrations should be measured on at least two occasions to confirm androgen deficiency, and measurements of LH and FSH should be performed to determine whether the patient has primary or secondary hypogonadism (see later discussion). Men with primary hypogonadism have low testosterone with elevated serum LH and FSH concentrations (FSH higher than LH concentrations). Identification of infertile men with secondary hypogonadism (low testosterone with low or inappropriately normal LH and FSH concentrations) potentially has important therapeutic implications. In men with impaired sperm production due to gonadotropin deficiency, spermatogenesis may be stimulated and fertility restored with the use of gonadotropin or GnRH therapy. Secondary hypogonadism is one of few treatable causes of male infertility. Elevated concentrations of testosterone, LH, and FSH suggest androgen resistance: LH is usually higher than FSH.

Measurements of FSH concentrations specifically as a marker of Sertoli cell and seminiferous tubule function are useful in identifying men with severe defects in spermatogenesis and impairment of seminiferous tubule and Sertoli cell function; such patients often demonstrate selective elevation in serum FSH concentrations with normal or high-normal LH concentrations due to loss of negative feedback inhibition of pituitary FSH secretion by inhibin B.[188] In young men with proven fertility, the upper limit of normal for serum FSH is 8 IU/L.[189] Many commercial laboratories have higher upper limits of normal because they have included men without proven fertility. However, men with less severe seminiferous tubule dysfunction and impairment of spermatogenesis and those with azoospermia due to genital tract obstruction (obstructive azoospermia) have normal serum FSH concentrations.

Genetic disorders make up a small but significant proportion of the causes of male infertility. Because ART, and specifically ICSI, which involves direct injection of spermatozoa into the cytoplasm of an ovum (discussed later), is commonly used to treat male

infertility, the potential exists for transmission of genetic defects to offspring. Therefore, genetic testing and counseling should be offered to men who are considering ICSI, particularly for those with severe oligozoospermia or azoospermia.[179-181]

Men in whom bilateral congenital absence of the vas or genital tract obstruction is confirmed by transrectal or scrotal ultrasound and those who have unexplained obstructive azoospermia should undergo genetic testing for *CFTR* mutations and genetic counseling before ICSI. In men with severe oligozoospermia (sperm concentration <5 million/mL) or azoospermia, testing for Y chromosome microdeletions in the *AZF* region should be performed routinely. There is a high prevalence of sex chromosome and autosomal chromosome defects, often in the absence of other phenotypic abnormalities, in men with moderately impaired spermatogenesis and infertility. Therefore, karyotyping is recommended before ICSI for infertile men with impaired sperm production, particularly for those with a sperm concentration of less than 10 million/mL.

In azoospermic men with normal semen volume, a normal fructose level, and a normal FSH level in whom it is unclear whether azoospermia is caused by germ cell failure, genital tract obstruction, or both, surgical exploration of the scrotum and testis biopsy are needed. Microsurgical biopsy is also used to harvest sperm for ICSI, even in men with known severe impairment in spermatogenesis, such as those with Klinefelter syndrome.[179,180,190,191]

Specialized tests of in vitro sperm function, such as detailed examination of sperm motility using computer-assisted semen analysis, cervical mucus penetration tests, acrosome reaction, and human zona pellucida binding tests, may be useful in some men who are considering intrauterine insemination (IUI) or in vitro fertilization (IVF). However, these tests should be performed only in highly specialized laboratories that have demonstrated excellent quality control. Even in such laboratories, there is a high rate of clinical false-positive and false-negative results, limiting the clinical utility of these tests.

Treatment

In men with infertility caused by primary hypogonadism (whether due to androgen deficiency and impairment of sperm production or to isolated impairment of sperm production or function), defects in sperm production are not effectively treated with drugs, although spontaneous recovery of spermatogenesis may occur at variable times after discontinuation of cytotoxic drugs or ionizing radiation. Because intratesticular testosterone concentrations are normally approximately 100-fold higher than serum concentrations, exogenous testosterone treatment of men with androgen deficiency cannot deliver sufficient amounts of testosterone to support sperm production in the testis.

In men with secondary hypogonadism, however, sperm production can be stimulated with gonadotropin or GnRH treatment, or spermatogenesis may recover sufficiently to restore fertility after discontinuation of drugs that suppress gonadotropins, such as androgenic anabolic steroids, progestins, glucocorticoids, opioids, and drugs causing hyperprolactinemia.

Most men with a varicocele and infertility have abnormal seminal fluid. However, varicocele repair has not been demonstrated to be effective in restoring fertility to these men. Therefore, unless a varicocele is very large or symptomatic, surgical repair is not recommended.[12,192] Although clinical trials have failed to demonstrate effectiveness,[193] infertile men with leukospermia or sperm agglutination are sometimes treated empirically with a 14-day course of antibiotics, such as doxycycline, trimethoprim-sulfamethoxazole, or a fluoroquinolone. Although high-dose prednisone (40–60 mg for several months) has been recommended to treat infertility in men with sperm in the ejaculate and serum antisperm antibodies, a recent systematic review concluded that antisperm antibodies do not cause male infertility. It is likely that the "response" to corticosteroid therapy is due to the fact that some of these men eventually conceive without any therapy.[187] Empiric high-dose corticosteroid therapy is not justified because of the high risk of toxicity.

Although ICSI is costly, it is used increasingly to treat male infertility, and it dramatically improves the prognosis for men with impaired sperm production regardless of the cause.[190,191] Spermatozoa that are ejaculated or obtained by testicular biopsy (TESE) or from the epididymis (*microsurgical epididymal sperm aspiration* [MESA]) are used for ICSI and other ARTs. With ICSI, fertilization rates of about 60% and pregnancy rates of approximately 20% are achieved, irrespective of the cause of male infertility or source of spermatozoa. ICSI after TESE using microsurgical testis biopsy or fine-needle aspiration to retrieve sperm has been successful in restoring fertility to men with primary hypogonadism who had severe impairments in spermatogenesis and azoospermia that were previously thought to be untreatable (e.g., Klinefelter syndrome, prolonged azoospermia after chemotherapy).[194] Because of the potential for chromosomal abnormalities and transmission of Y chromosome microdeletions and *CFTR* mutations that cause infertility in male offspring, genetic testing and counseling should be conducted if ICSI is being considered (see earlier discussion).[181]

Obstruction of the epididymides or the ejaculatory ducts can be corrected surgically, such as with end-to-end anastomosis of the epididymides or transurethral resection of the ejaculatory ducts. More commonly, MESA is used to obtain spermatozoa that can be incubated with ova in vitro (IVF) or directly injected into an ovum (ICSI), and this method is more successful in restoring fertility than surgical options. In contrast, microsurgical reanastomosis of the vas (vasovasostomy) to reverse vasectomy is less costly and more successful in restoring fertility than MESA followed by IVF or ICSI. Return of sperm in the ejaculate occurs in approximately 90% of men who undergo vasectomy reversal, but restoration of fertility occurs in only about 50%, probably because of stenosis or blockage of the previous vasovasostomy, epididymal blockage, or the development of antisperm antibodies in response to the vasectomy.[195]

In men with retrograde ejaculation, collection of spermatozoa in alkalinized postejaculation urine, followed by extensive washing and IUI or ICSI, has been used successfully to treat infertility. With proper education, coital disorders that contribute to infertility may be corrected. In addition, the timing of intercourse may be optimized to occur a few days before and after ovulation (the period of highest probability for conception) based on basal body temperature measurements or, more accurately, on commercially available rapid urinary LH kits to estimate the timing of ovulation in the female partner.

If the treatment options described previously are not available or affordable to infertile couples who desire children, artificial insemination with donor sperm or adoption may be considered.

Diagnosis of Male Hypogonadism

Clinical Manifestations of Androgen Deficiency

The diagnosis of male hypogonadism requires clinical manifestations consistent with androgen deficiency and unequivocally low serum testosterone concentrations. In community-dwelling middle-age and older men, the crude prevalence of symptomatic

androgen deficiency is 2% to 9%, depending on the constellation of symptoms and signs and the biochemical definition of androgen deficiency used (i.e., the threshold used for a single low testosterone concentration).[196-198] This prevalence increases with age and is much higher in a primary care setting.[199] In community populations, the prevalence of low testosterone concentrations alone, without consideration of symptoms and signs of androgen deficiency, is much higher than that of clinical androgen deficiency. This underscores the importance of making a diagnosis of hypogonadism only in men who have clinical manifestations and consistently low testosterone concentrations. Both the clinical and the biochemical diagnosis of androgen deficiency can be challenging, especially in older adults.

Although the manifestations of fetal androgen deficiency or resistance (ambiguous genitalia and 46,XY DSD) and those of androgen deficiency of prepubertal onset (eunuchoidism) are usually clinically obvious, the clinical diagnosis of androgen deficiency in adults is more difficult. As described previously, the symptoms and signs of androgen deficiency are nonspecific and have a broad differential diagnosis. Moreover, clinical manifestations may be modified by several factors, such as the severity and duration of androgen deficiency, age, comorbid illnesses, medications, previous testosterone treatment, and individual variations in androgen sensitivity, all of which contribute to variability in clinical presentation that may confound the diagnosis.[116] Because the manifestations of androgen deficiency in adults are nonspecific, other potential causes (e.g., depression, comorbid illness, or medications) should be considered in the differential diagnosis to explain clinical features in any individual patient.[200]

The degree and duration of androgen deficiency have impressive effects on clinical manifestations. The severe and relatively rapid suppression of testosterone concentrations in men with prostate cancer treated with a GnRH agonist or orchidectomy results in prominent clinical manifestations with notable reductions in erectile function, libido, energy, and mood; hot flushes and sleep disturbances; infertility; decreases in muscle mass and strength, BMD (associated with an increase in fracture risk), and body hair; gynecomastia; increases in body fat; anemia; and possibly increases in the risks for diabetes mellitus and cardiovascular events.[201,202] In contrast, men with mild androgen deficiency may have few or no referable manifestations; such patients have "subclinical" androgen deficiency that may or may not be associated with clinically significant outcomes. The latter situation is analogous to that observed in other endocrine disorders such as subclinical hypothyroidism or asymptomatic primary hyperparathyroidism.

Aging is associated with alterations in body functions, such as declines in sexual function, muscle mass and strength, and BMD, that result in clinical manifestations similar to those of androgen deficiency.[144] These alterations associated with aging may also be caused in part by age-related androgen deficiency. To add to the clinical complexity in older men, age-associated comorbid illnesses and medications used to treat these illnesses may modify the symptoms and signs of androgen deficiency, and in many instances, they may also contribute to the cause of androgen deficiency. Therefore, it is understandable why the diagnosis of clinical androgen deficiency is challenging in older men, particularly in frail elderly men who have multiple comorbid illnesses and are taking numerous medications.

Previous testosterone treatment that has been discontinued may affect the clinical manifestations of androgen deficiency, depending on the duration of therapy and the time since discontinuation. It is also likely that clinical manifestations of androgen deficiency are affected by individual variations in androgen action on specific target organs. Alterations in androgen sensitivity may result from individual or tissue-specific differences in the activity of the AR or the ER and associated coregulators, or from differences in active metabolism of testosterone to estradiol or DHT or inactivation of testosterone.

In men with clinical manifestations suggestive of androgen deficiency, the diagnosis of hypogonadism is confirmed biochemically by measurement of consistently low serum testosterone concentrations[116] (Fig. 19.19).

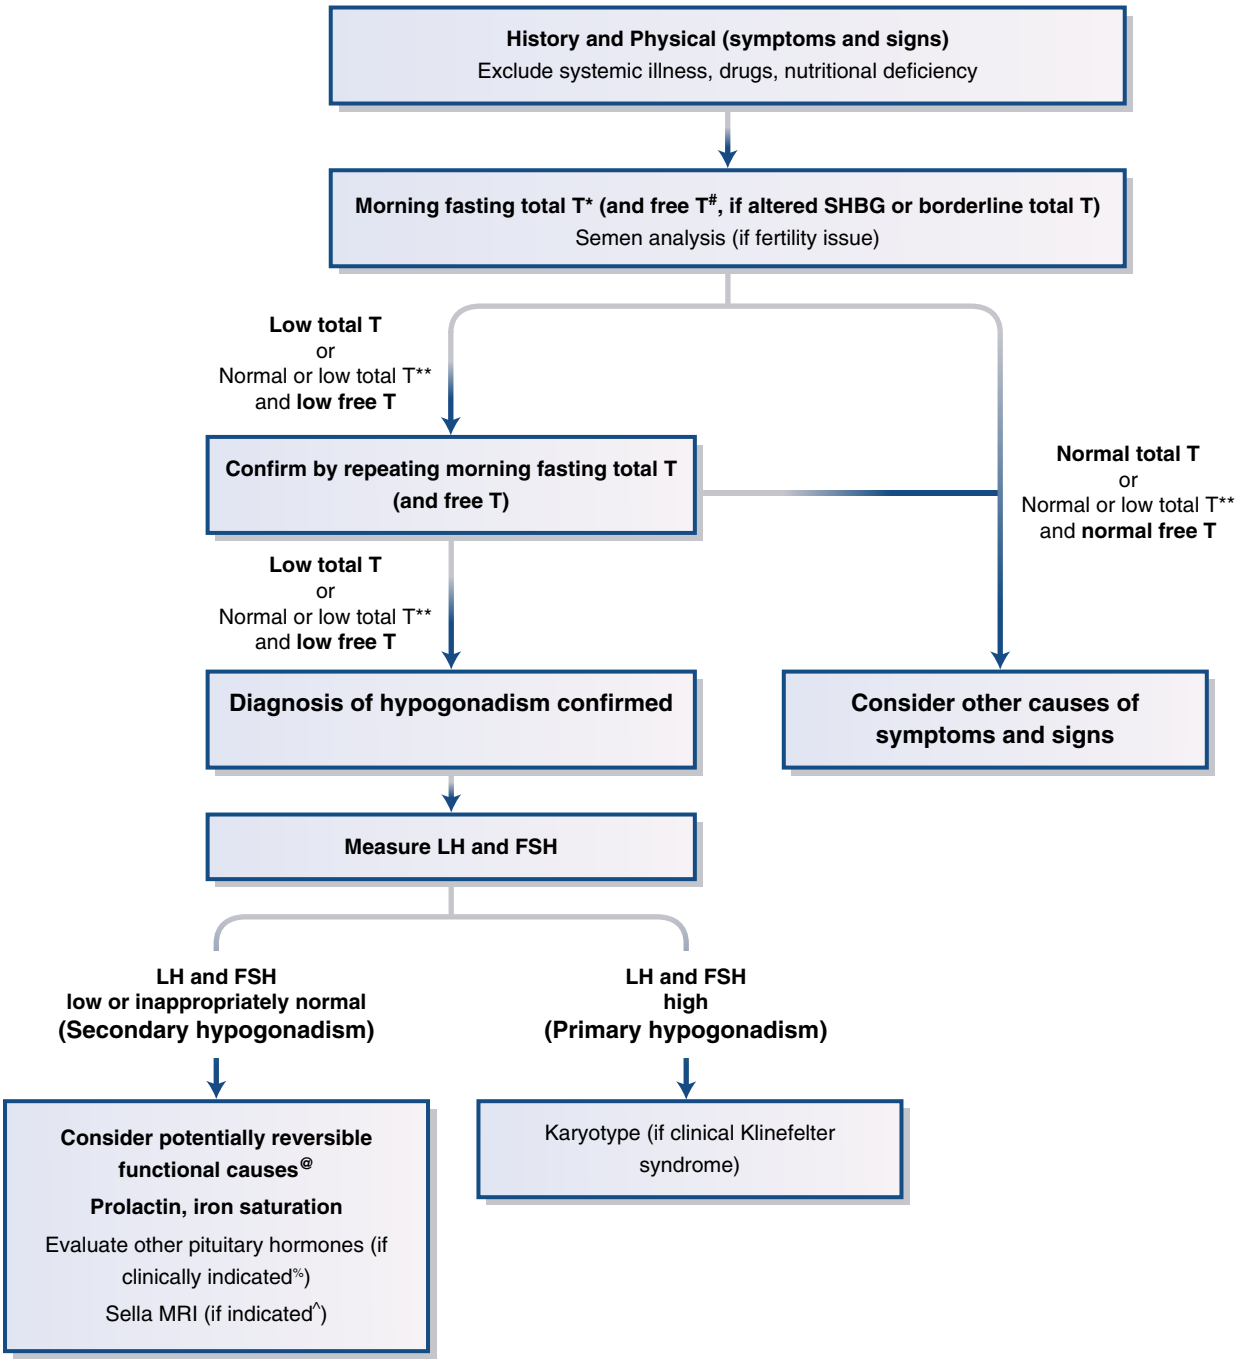
Testosterone Measurements

As with the clinical manifestations, the biochemical confirmation of androgen deficiency presents its own difficulties. Testosterone concentrations exhibit both biologic and assay variability. Total testosterone concentrations are affected by alterations in SHBG, and testosterone concentrations may be suppressed transiently with illness, certain medications, and some nutritional deficiencies.[116] Therefore, the biochemical diagnosis of androgen deficiency requires demonstration of consistently and unequivocally low serum testosterone concentrations in at least two blood samples obtained between 7 AM and 10 AM, preferably fasting. In men who have conditions that alter SHBG, accurate and reliable free or bioavailable testosterone measurements are needed to confirm the diagnosis of hypogonadism. Finally, the diagnosis of hypogonadism should not be made during acute or subacute illness.

The threshold level of circulating total or free testosterone below which symptoms and signs of androgen deficiency occur and for which testosterone treatment will improve clinical manifestations is not known. However, the concept of a single threshold testosterone level is probably not valid, nor is it clinically useful, because thresholds vary with the specific symptom and the androgen target organ or tissue. In general, symptoms and signs of androgen deficiency are more likely to occur with a total testosterone level that is below the lower limit of the normal range for young, nonobese, healthy men (approximately 265–280 ng/dL or 2.65–2.8 ng/mL [9.2–9.7 nmol/L], when using an accurate and reliable assay).[203] The likelihood and severity of clinical manifestations of androgen deficiency increase with a greater decline in testosterone level below normal.

Variability in Testosterone Concentrations

Because serum testosterone concentrations exhibit both biologic and assay variability, a single measurement is not a reliable indicator of an individual's average concentration. Serum testosterone concentrations exhibit both ultradian and circadian variation, providing physiologic sources of biologic variability. Ultradian fluctuations in serum testosterone concentrations, characterized by peaks of incremental amplitude that average approximately 240 ng/dL (40% fractional amplitude) with a 95-minute duration,[45] have been reported in a small number of young men; more chaotic peaks with lower amplitude have been reported in older men.[204] As described previously, the circadian variation in serum testosterone peaks at about 8 AM and has a maximum excursion averaging 140 ng/dL.[64] The circadian variation in testosterone is blunted but still present in older men, with a maximum excursion averaging 60 ng/dL. In young men, serum testosterone concentrations are 20% to 25% lower at 4 PM than at 8 AM (i.e., over the course of usual clinic hours).[205] This difference decreases with age: in 70-year-old men, testosterone concentrations are 10% lower at 4 PM than at 8 AM. Most importantly, many young and old men who have testosterone concentrations that are below normal



• **Fig. 19.19** Algorithm for the diagnosis and evaluation of suspected androgen deficiency. In men with clinical manifestations (symptoms and signs) consistent with androgen deficiency, a morning fasting total testosterone (T), and if a condition is present that causes an alteration in the level of sex hormone–binding globulin (SHBG; see Table 19.5) or if total T is borderline (e.g., between 200 and 400 ng/dL), an accurate measurement of free T level should be obtained initially. Acute systemic illnesses, drugs, or nutritional deficiency that could lower T concentrations should be excluded. If the initial total and/or free T level is low, they should be repeated to confirm a diagnosis of male hypogonadism. *The lower limit of the normal range for total T harmonized to Centers for Disease Control and Prevention (CDC) standards in healthy nonobese men age 19 to 39 years is 264 ng/dL (9.2 nmol/L); this limit could be used for total T assays that are CDC certified. Depending on the assay and reference population used, the lower limit of the normal range established in non–CDC-certified laboratories may not accurately identify men with hypogonadism. #Free T should be measured by an accurate method, such as the equilibrium dialysis method or estimated from total T, SHBG with or without albumin concentrations, using a formula that accurately reflects free T by equilibrium dialysis. The normal range for free T in healthy young men is usually between 5 and 6 ng/dL (0.17–0.31 nmol/L) in most laboratories. **Total T may also be high in some conditions in which SHBG concentrations are very high, such as human immunodeficiency virus disease or with use of some anticonvulsants. Concentrations of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) should be obtained (in same sample as T measurements) to determine whether T deficiency is caused by secondary hypogonadism (low T with low or normal LH and FSH) or primary hypogonadism (low T with high LH and FSH). @In men with secondary hypogonadism, potentially reversible or treatable functional causes of primary and secondary hypogonadism that might be managed without T treatment should be considered (denoted in Tables 19.7 and 19.8); serum prolactin and iron saturation should be assessed; and %if there is clinical indication of hypopituitarism or sella abnormality on imaging, evaluation of other pituitary hormones (e.g., free T4 and TSH) should be performed. ^Pituitary imaging (sella magnetic resonance imaging [MRI]) to exclude pituitary and/or hypothalamic tumor or infiltrative disease is indicated if there is severe secondary hypogonadism (e.g., serum total T < 150 ng/dL [5.2 nmol/L]), panhypopituitarism, persistent hyperprolactinemia, or symptoms or signs of tumor mass effect (e.g., new-onset headache, visual impairment, visual field defect, or cerebrospinal fluid rhinorrhea) are present. A sella computed tomography scan may be sufficient if macroadenoma is suspected or to assess parasellar bone involvement. (Redrawn from Bhasin S, Ponce JP, Cunningham GC, et al. Testosterone therapy in men with hypogonadism: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab.* 2018;103:1715–1744.)

in the afternoon have consistently normal concentrations in the morning. Testosterone concentrations are also lowered by glucose infusion or food intake,[206,207] and thus measurements should preferably be done in the fasting state. Given these findings and the fact that normal ranges of testosterone concentration are usually based on morning blood samples, testosterone measurements to confirm the diagnosis of hypogonadism should preferably be performed in the morning in the fasting state.

There is also substantial day-to-day variation in serum testosterone concentrations, underscoring the need to repeat the measurement to confirm low concentrations, particularly if the first result was only moderately below normal. Among men with serum testosterone concentrations of less than 300 ng/dL on an initial test, 30% to 35% were found to have a normal level on repeat testing.[208] Among community-dwelling middle-age and older men who had an initial serum testosterone concentration of less than 250 ng/dL, 20% were found to have an average testosterone level higher than 300 ng/dL (i.e., within the normal range) when six samples were drawn over the subsequent 6 months.[209] However, none of the subjects who had an initial average serum testosterone concentration of less than 250 ng/dL on two separate samples obtained 1 to 3 days apart had an average level higher than 300 ng/dL in six samples drawn over the next 6 months. These findings support the need to measure testosterone on at least two occasions to confirm the diagnosis of androgen deficiency.

Total Testosterone Assays

Total testosterone assays are performed in most local laboratories and are readily available to clinicians. Therefore, total testosterone is recommended as the initial measurement for the assessment of androgen deficiency. In local clinical laboratories, total testosterone is usually measured by automated platform-based direct immunoassays on unextracted serum or plasma. However, there is substantial variability in results from different assays, mostly because the accreditation of laboratories has been based on the reproducibility of results in comparison to other laboratories using the same method or kit, rather than on the accuracy of results. For example, when identical quality control samples were assayed by different methods or kits, the reported measured values ranged from 160 to 508 ng/dL. Moreover, the lower limit of the normal range in some assays was as low as 132 to 210 ng/dL (clearly in the hypogonadal range for most conventional assays).[210] In contrast, the lower limit of the normal range based on conventional radioimmunoassays after extraction is approximately 280 to 300 ng/dL. Most commercial reference laboratories now measure testosterone by liquid chromatography tandem mass spectrometry methods after solid phase extraction that are more accurate and precise than immunoassays.

To address the problems in the accuracy, quality control, and lack of standardization of total testosterone assays, the US Centers for Disease Control and Prevention (CDC) has developed a program to standardize and harmonize testosterone assays using accuracy-based quality control standards to which most commercial reference laboratories participate.[203,211] Recently, the College of American Pathologists also instituted an accuracy-based quality control program, but, unfortunately, neither of these programs is mandatory for certification. Recently, a harmonized reference range was established for total testosterone, cross-calibrated to the CDC reference method and standards, in more than 9000 community-dwelling men from four large cohorts in the United States and Europe.[203] The harmonized reference range in healthy, nonobese men 19.39 years of age was 264 to 916 ng/mL. This range could be used for laboratories that perform a CDC-certified total testosterone assay but not necessarily for total testosterone assays that are not CDC certified for accuracy.

The prevalence of low testosterone concentrations is high in several clinical conditions, namely in the presence of a pituitary or sellar mass; irradiation; disease; use of certain medications, such as opiates or high-dose glucocorticoids; HIV disease with weight loss; late-stage CKD; withdrawal from long-term androgenic anabolic steroid use; infertility; BMD concentrations that reveal osteoporosis or low-trauma fracture; and low libido or erectile dysfunction. If clinical manifestations consistent with androgen deficiency are present in men with these conditions, testosterone measurements should be performed.[116]

Total Testosterone Affected by Alterations in SHBG

Because a substantial proportion (30–40%) of circulating testosterone is bound tightly to SHBG, alterations in SHBG concentration may affect total testosterone concentrations without altering free or bioavailable testosterone. Conditions that suppress SHBG concentrations (even within the broad normal range) lower total testosterone (sometimes to below the normal range) without affecting circulating free or bioavailable testosterone concentrations[116] (Table 19.5). Common conditions that lower SHBG concentrations include moderate obesity, often associated with type 2 diabetes mellitus (T2DM); protein-losing states, such as nephrotic syndrome; administration of glucocorticoids, progestins, or androgens; untreated hypothyroidism; acromegaly; familial SHBG deficiency; and SHBG gene polymorphisms. SHBG concentrations are increased with increasing age, hepatic cirrhosis and inflammation (hepatitis of any cause), estrogens, hyperthyroidism, anticonvulsants, HIV disease, and SHBG gene polymorphisms.

If conditions that affect SHBG concentration are present in a patient or if total testosterone concentrations are close to the lower limit of the normal range (e.g., total testosterone concentration 200–400 ng/dL), serum free or bioavailable testosterone measurements should be obtained to confirm androgen deficiency. Unfortunately, accurate and reliable assays for free or bioavailable

testosterone are not performed routinely in most local clinical laboratories. Although direct free testosterone assays using analogue immunoassay methods (that may be automated) are widely available and inexpensive, these assays are inaccurate and are affected by alterations in SHBG, so they are not recommended.[212-214]

The gold standard method for measurement of free testosterone concentrations is equilibrium dialysis or centrifugal ultrafiltration. Free testosterone concentrations may be calculated accurately from measurements of total testosterone, SHBG, and albumin using affinity constants for binding of testosterone to its binding proteins and published formulas. Calculated free testosterone values are comparable to those measured by equilibrium dialysis.[213] However, calculated values depend on the specific testosterone and SHBG assays employed and the formula used to estimate free testosterone.[215] There are several formulas used for calculation of free testosterone that all demonstrate some bias relative to the equilibrium dialysis method, largely as a result of assuming a single or two identical, noninteracting binding sites on SHBG.[113] However, they all provide reasonable approximations of free testosterone in the normal to low range of values that are less prone to misinterpretation and overdiagnosis of hypogonadism than total testosterone measurements when alterations in SHBG concentrations are present.

Bioavailable testosterone is measured by ammonium sulfate precipitation of SHBG-bound testosterone and measurement of free and albumin-bound testosterone in the supernatant. Bioavailable testosterone concentrations may also be calculated from measurements of total testosterone, SHBG, and albumin. In general, fewer studies used bioavailable versus free testosterone measurements, so many clinicians use free rather than bioavailable testosterone measurements to diagnose hypogonadism. These accurate and reliable measurements of free and bioavailable testosterone are available in commercial laboratories and should be used to confirm androgen deficiency in men who have conditions that affect SHBG and in those with total testosterone concentrations near the lower limit of the normal range. In a recent report, 60% of more than 3600 men in a single health care system who had low total testosterone concentrations were found to have normal calculated free testosterone concentrations using the laboratory reference range that was utilized by practitioners to make clinical decisions. These findings highlight the potential clinical importance of using free testosterone to confirm a biochemical diagnosis of hypogonadism.[216]

Transient Suppression of Testosterone

In evaluating men for a diagnosis of male hypogonadism, it is important to recognize that serum testosterone concentrations may be suppressed transiently during acute (particularly critical) and subacute illness and recovery; with the short-term use of certain medications, such as opioids, high-dose glucocorticoids, and CNS-active medications or recreational drugs that suppress gonadotropin and testosterone production; and during transient malnutrition, such as that associated with illness, eating disorders, or excessive or prolonged strenuous exercise (resulting in low energy intake relative to energy expenditure). In such situations, measurement of serum testosterone should be delayed until the patient is completely recovered from the illness, the offending drugs are discontinued, the malnutrition is corrected, or the excessive exercise is stopped.[116]

Screening and Case Finding for Androgen Deficiency

In the absence of evidence for long-term clinically meaningful health benefits greater than risks for testosterone treatment of androgen deficiency, screening for androgen deficiency in the general population or in all elderly men is not indicated. In addition, existing screening instruments lack sufficient specificity and sensitivity to be clinically useful.[116] In certain clinical conditions, case finding is warranted because hypogonadism is common. These conditions include hypothalamic-pituitary disease, mass, surgery, or radiation therapy; medications that suppress testosterone production (e.g., opioids, glucocorticoids); withdrawal from long-term androgenic anabolic steroid use; HIV-associated weight loss and other wasting syndromes; infertility; osteoporosis or minimal-trauma fragility fracture, especially in young men; and low libido or erectile dysfunction.[116]

Seminal Fluid Analysis

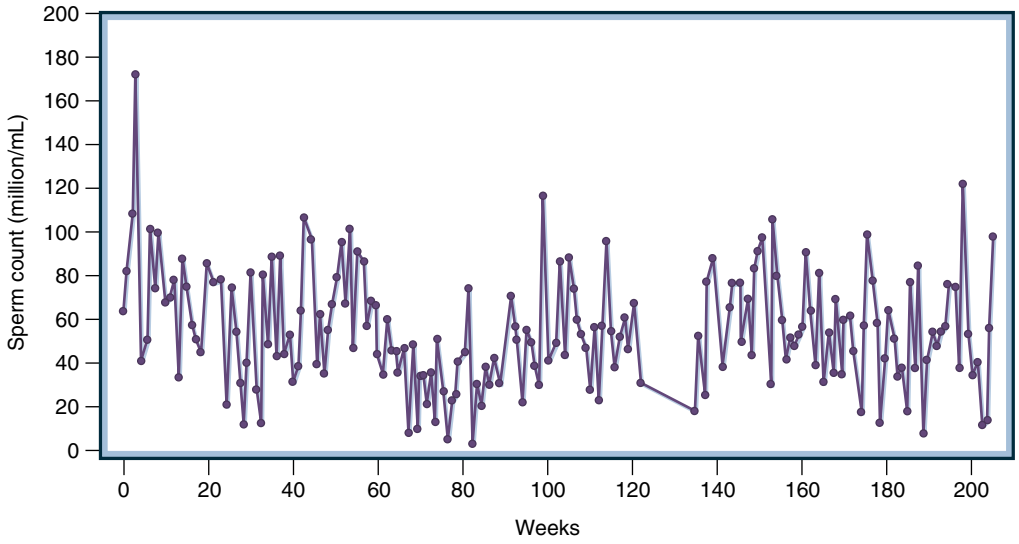
If infertility is a main complaint, whether or not androgen deficiency is also present, seminal fluid analysis should be performed to determine the presence and degree of impairment of sperm production. Seminal fluid analyses are performed on ejaculated semen samples obtained by masturbation after a standardized period (of at least 48 hours and not more than 7 days) of abstinence from ejaculation. Semen collection after withdrawal of the penis from the partner just before ejaculation during sexual intercourse (coitus interruptus) is usually incomplete and is not recommended, but it may be an option if masturbation is not possible or is not permitted for personal or religious reasons. Seminal fluid analyses should be performed in a specialized laboratory that employs standardized procedures, such as those outlined by the WHO, and is certified and qualified to carry out these procedures.[29]

According to recently revised WHO criteria based on approximately 1800 to 1900 men from 14 countries whose partners became pregnant in 12 months or less (Table 19.6), the lower limit of normal sperm concentration is 15 million/mL; semen volume is 1.5 mL; total sperm count is 39 million per ejaculate; total sperm motility (both progressive and nonprogressive) is 40% and progressive sperm motility is 32%; and the percentage of sperm with normal morphologic forms, using strict criteria to eliminate spermatozoa with even mild abnormalities, is at least 4%.[29] Values below these lower limits may be classified as falling into the subfertile range, and such values are found in independent (unscreened) populations. In another study, the subfertile ranges were defined as follows: sperm concentration, less than 13.5 million/mL; motility, less than 32%; and strict morphologic structure, less than 9%. The respective fertile ranges were greater than 48 million/mL for sperm concentration, 63% for motility, and 12% for strict morphologic structure. Values between these ranges indicated indeterminate fertility.[217]

TABLE 19.6 Normal Seminal Fluid Analysis

Parameter	Normal Value
Sperm concentration	≥15 million/mL
Semen volume	≥1.5 mL
Sperm count	≥39 million per ejaculate
Sperm motility	≥40% (progressive sperm motility >32%)
Sperm morphology	≥4% normal forms (by strict criteria excluding sperm with mild abnormalities)

From *WHO Laboratory Manual for the Examination and Processing of Human Semen*. 5th ed. Geneva, Switzerland: World Health Organization; 2010.



• **Fig. 19.20** Normal variation in sperm concentration (millions of spermatozoa per milliliter of ejaculate) in a healthy young man: results of frequent sampling over a period of 210 weeks. At several times during this period, sperm concentrations dropped below the normal range (15 million/mL). (From Matsumoto AM. The testis. In: Felig P, Frohman LA, eds. *Endocrinology and Metabolism,* 4th ed. New York, NY: McGraw-Hill; 2001:635–705.)

Sperm counts and concentrations exhibit extreme variability[9] (Fig. 19.20) for several reasons, including variations in sexual activity and abstinence, completeness of collection, recent illness (especially febrile illness) that may suppress spermatogenesis, and lifestyle factors such as frequent and prolonged hot tub use. Therefore, at least two or three seminal fluid analyses, separated by at least 1 to 2 weeks, should be performed to assess sperm production adequately. In addition, to assess motility, freshly collected semen (within 1 hour of ejaculation) should be used, necessitating collection at or near the laboratory in which the analysis is to be performed.

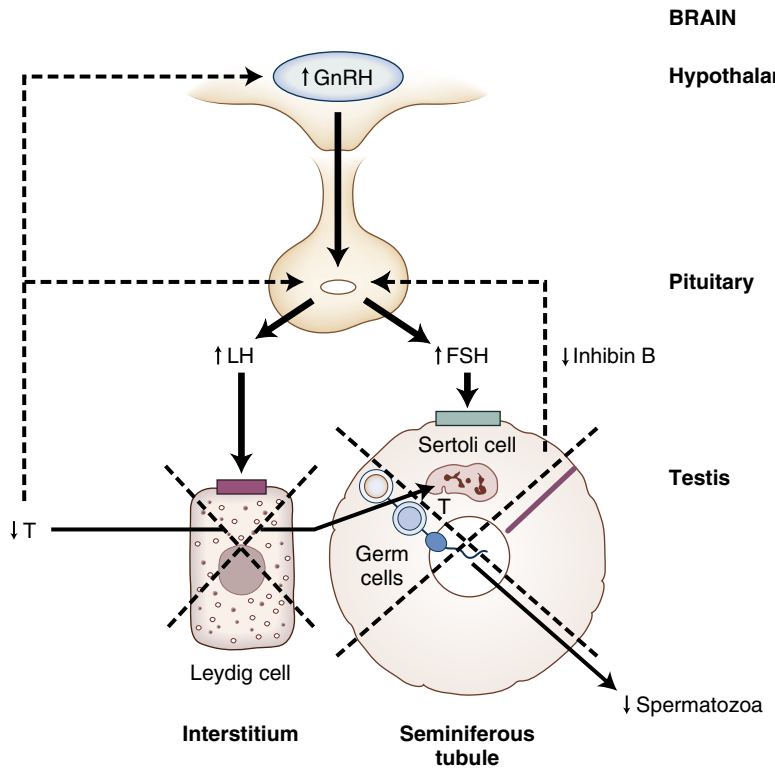
Gonadotropin Measurements

Androgen Deficiency and Impaired Sperm Production

The diagnosis of hypogonadism is confirmed in men with symptoms and signs consistent with androgen deficiency and in whom low testosterone concentrations are found on at least two occasions. Testosterone concentrations should not be measured shortly after an acute illness, medication use, or nutritional deficiency that could transiently lower testosterone. Furthermore, an accurate assay of free or bioavailable testosterone should be performed for men who have conditions that alter SHBG or a total testosterone level near the lower limit of normal. In men with confirmed hypogonadism, measurements of serum gonadotropins, LH, and FSH should be measured to distinguish primary from secondary hypogonadism[116] (see Fig. 19.19).

Men with primary hypogonadism caused by a disorder of the testis have low serum testosterone in association with elevated LH and FSH concentrations as a result of reduced negative feedback suppression of gonadotropin secretion by testosterone and inhibin B (FSH concentrations are higher than LH concentrations in men with primary hypogonadism) [9] (Fig. 19.21). In contrast, men with secondary hypogonadism caused by a disorder of the pituitary or the hypothalamus (or both) have low testosterone in association with low gonadotropin concentrations or inappropriately normal LH and FSH given the presence of low testosterone concentrations[9] (Fig. 19.22). In most local clinical laboratories, LH and FSH are measured by newer-generation nonradioactive immunoassays that have sufficient sensitivity to distinguish between normal and low concentrations. Although there are differences in reference ranges for LH and FSH among commercial gonadotropin assays, they are relatively minor, and a consensus reference range in healthy eugonadal young men for LH is 1.6 to 8.0 IU/L and FSH is 1.3 to 8.4 IU/L.[189] Reference ranges in which the upper limit is higher than these have included older men or men with unrecognized impairment of spermatogenesis.

Aging, some systemic illnesses (e.g., iron overload syndromes), and certain medications (e.g., glucocorticoids) may cause defects in both the testes and the hypothalamus or pituitary, resulting in combined primary and secondary hypogonadism. In most cases, a hormonal pattern consistent with either primary or secondary hypogonadism predominates. For example, men with hemochromatosis have defects in both the pituitary and the testes due to iron overload, but they usually have low testosterone and gonadotropin concentrations, a hormonal pattern consistent with secondary hypogonadism. Men with late-stage CKD have both testis and hypothalamic-pituitary dysfunction but usually have low testosterone and elevated LH and FSH concentrations, the latter mostly due to reduced clearance of gonadotropins by the kidney. However, in the presence of comorbid illness, nutritional deficiency, or certain medications, men with CKD may have suppression of gonadotropins and testosterone into the normal range and hormonal pattern consistent with secondary hypogonadism. Some men have more than one disorder influencing the gonadal axis, one affecting the testis and another affecting the hypothalamus or pituitary. This may result in a hormonal pattern that is predominantly consistent with either primary or secondary hypogonadism or in a combined pattern (e.g., very low testosterone concentrations with only slightly elevated or high-normal gonadotropin concentrations that are lower than expected given the presence of very low testosterone concentrations).



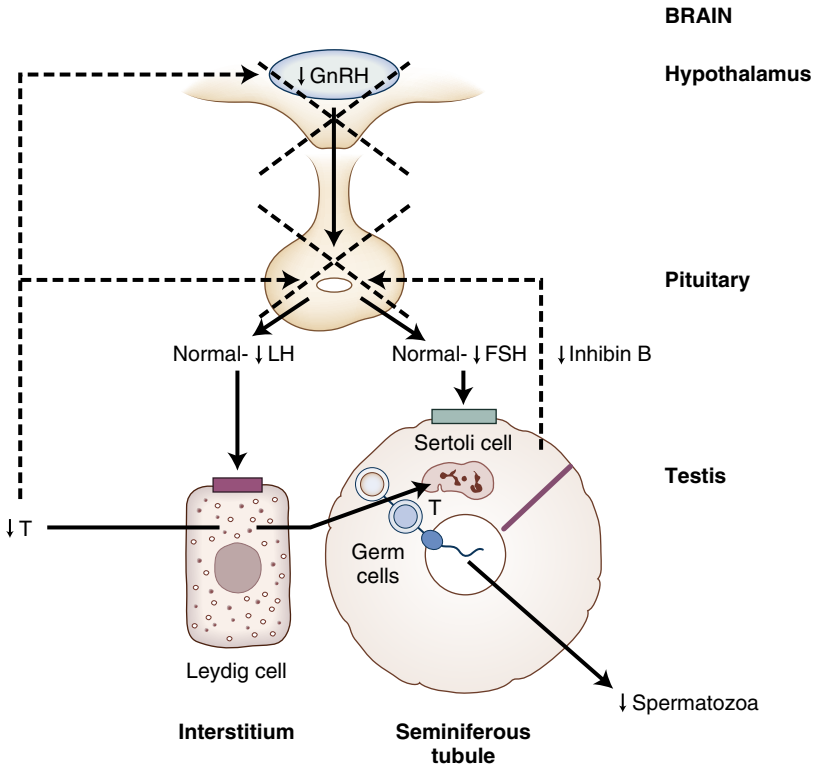
• **Fig. 19.21** Schematic diagram of alterations in the hypothalamic-pituitary-testicular axis with primary hypogonadism due to testicular disease, which results in both androgen deficiency and impairment of sperm production and elevated luteinizing hormone (LH) and follicle-stimulating hormone (FSH) concentrations (with FSH concentrations usually higher than LH concentrations) due to loss of negative feedback regulation of gonadotropins. *GnRH,* gonadotropin-releasing hormone; *T,* testosterone. (Modified from Matsumoto AM. The testis. In: Felig P, Frohman LA, eds. *Endocrinology and Metabolism.* 4th ed. New York, NY: McGraw-Hill; 2001:635–705.)

Distinguishing primary from secondary hypogonadism helps define the specific cause of hypogonadism and has important clinical and therapeutic implications.[9] Secondary hypogonadism may be caused by a destructive process in the pituitary or hypothalamus, such as a pituitary adenoma (i.e., organic causes). A large pituitary adenoma (macroadenoma) may cause space-occupying tumor mass effects such as headaches, visual field defects, hydrocephalus, or cerebrospinal fluid rhinorrhea, or it may result in impaired or excessive secretion of some anterior pituitary hormones, leading to clinical manifestations and therapeutic implications beyond the treatment of androgen deficiency alone. Secondary hypogonadism may be caused by disorders that are transient, such as an acute illness, certain medications (e.g., opioids, glucocorticoids), or malnutrition associated with illness (i.e., functional causes of gonadotropin suppression). In such cases, androgen deficiency may resolve with treatment of and recovery from the illness or malnutrition or discontinuation of the offending medication. Finally, in men with secondary hypogonadism who have gonadotropin deficiency but otherwise normal testes, gonadotropin or GnRH treatment may be used to stimulate spermatogenesis and androgen production and to restore fertility in men who wish to father children. In contrast, infertility in men with primary hypogonadism is not treatable with hormone therapy.

Isolated Impairment of Sperm Production or Function

Most men with isolated impairment of sperm production have low sperm counts or abnormalities in sperm motility or morphologic appearance (or both) but no clinical manifestations of androgen deficiency and normal concentrations of testosterone and gonadotropins. Most men with isolated impairment of sperm production or function are classified as having primary hypogonadism with an isolated defect in the seminiferous tubule compartment of the testes (Table 19.7); in such cases, there is no improvement in spermatogenesis with gonadotropin treatment like there is in secondary hypogonadism. Men with severe seminiferous tubule failure and azoospermia or severe oligozoospermia may demonstrate a selective elevation in FSH concentrations as a result in reduced negative feedback from inhibin B with normal LH concentrations[9] (Fig. 19.23). Occasionally, isolated impairment in sperm production is caused by gonadotropin deficiency (i.e., secondary hypogonadism) (Table 19.8); this may occur in men who are taking high doses of testosterone and in those who have androgen-secreting tumors; congenital adrenal hyperplasia; or, rarely, isolated FSH deficiency.

Men with nonfunctioning or gonadotropin-secreting pituitary macroadenomas often have secondary hypogonadism with clinical manifestations of androgen deficiency and low testosterone concentrations.[53] Many of these men secrete excessive amounts of



• **Fig. 19.22** Schematic diagram of alterations in the hypothalamic-pituitary-testicular axis with secondary hypogonadism due to hypothalamic or pituitary disease, which results in both androgen deficiency and impairment of sperm production and inappropriately normal or low luteinizing hormone (LH) and follicle-stimulating hormone (FSH) concentrations. *GnRH,* gonadotropin-releasing hormone; *T,* testosterone. (Modified from Matsumoto AM. The testis. In: Felig P, Frohman LA, eds. *Endocrinology and Metabolism,* 4th ed. New York, NY: McGraw-Hill; 2001:635–705.)

biologically inactive but immunoassay-detectable intact FSH, free α-, FSHβ-, and LHβ-subunits but rarely immunoassay-detectable intact LH. Therefore, a gonadotropin-secreting pituitary tumor should be suspected in a man who has clinical manifestations of androgen deficiency, low testosterone, and elevated FSH but normal or low LH (or, rarely, elevated LH but normal or low FSH), which is an atypical gonadotropin pattern for men with androgen deficiency.

Rarely, disorders of androgen action or androgen resistance manifest in adults (Table 19.9). These men usually present with clinical manifestations similar to those of men with mild androgen deficiency, usually with an almost normal male phenotype and frequently with varying degrees of hypospadias, cryptorchidism, scrotal abnormalities, or impairment in sperm production. Usually, both serum testosterone and gonadotropin concentrations are elevated (with LH concentrations higher than FSH concentrations) [9] (Fig. 19.24).

Further Evaluation

Testosterone measurements and assessment of sperm production, combined with measurement of gonadotropin concentrations, allow classification of the causes of male hypogonadism into primary or secondary hypogonadism and subclassification of the latter into disorders causing both androgen deficiency and impairment in sperm production and those causing isolated impairment of sperm production or function (see Tables 19.7 and 19.8).

Once hypogonadism has been classified as primary or secondary hypogonadism, further evaluation includes a history (including medication review), physical examination, and laboratory testing to identify a specific cause or causes of hypogonadism. In men with primary hypogonadism and suggestive clinical manifestations such as very small testes (e.g., <6 mL) and gynecomastia, low or low-normal testosterone, azoospermia, and markedly elevated gonadotropins, a karyotype may be obtained to confirm the diagnosis of Klinefelter syndrome.

In men with secondary hypogonadism, further evaluation may include measurements of serum prolactin (in almost all cases) to exclude hyperprolactinemia; iron saturation and ferritin to screen for hereditary hemochromatosis, especially in men with other manifestations of iron overload (e.g., liver failure, diabetes, and CHF) and in young men with unexplained selective gonadotropin deficiency; further testing to exclude excessive secretion or deficiency of anterior pituitary hormones; and magnetic resonance imaging (MRI) of the sella turcica to exclude a pituitary or hypothalamic tumor or infiltrative disease. Computed tomography (CT) of the sella turcica usually detects a pituitary macroadenoma but is less sensitive than sella MRI in detecting smaller tumors and infiltrative disease; CT is more sensitive in detecting parasellar bone destruction.[116]

It is not cost effective to perform sella MRI in all men with secondary hypogonadism. This modality should be reserved for men with secondary hypogonadism and the following: serum

TABLE 19.7 Causes of Primary Hypogonadism

CAH, Congenital adrenal hyperplasia; *FSH,* follicle-stimulating hormone; *LH,* luteinizing hormone; *TART,* testicular adrenal rest tumor.

testosterone less than 150 ng/dL and low gonadotropin concentrations[218-220]; discordant LH and FSH concentrations (i.e., one gonadotropin markedly elevated but the other not); hyperprolactinemia (even mild); clinical and biochemical evidence of excessive secretion of other pituitary hormones (e.g., free α-subunit secretion, Cushing syndrome, acromegaly), panhypopituitarism, or diabetes insipidus; tumor mass effects (e.g., severe headache, new onset of blurry vision or visual impairment, visual field defects, or cerebrospinal fluid rhinorrhea); and no obvious functional cause of secondary hypogonadism (e.g., morbid obesity, long-acting opioid, or chronic high-dose glucocorticoid therapy).

In evaluating the etiology of secondary hypogonadism, it is important to consider potentially reversible/treatable causes of gonadotropin suppression that are more common than organic congenital or destructive causes of gonadotropin deficiency and might be managed by discontinuation of an offending medication (e.g., opioid pain medication), treatment of the underlying condition (e.g., obesity), or organ transplantation (e.g., renal transplantation).

In men who have severe androgen deficiency caused by primary or secondary hypogonadism or who have sustained a low-trauma or fragility fracture, dual-energy x-ray absorptiometry scanning to assess BMD should be performed to exclude osteopenia or osteoporosis.[116]

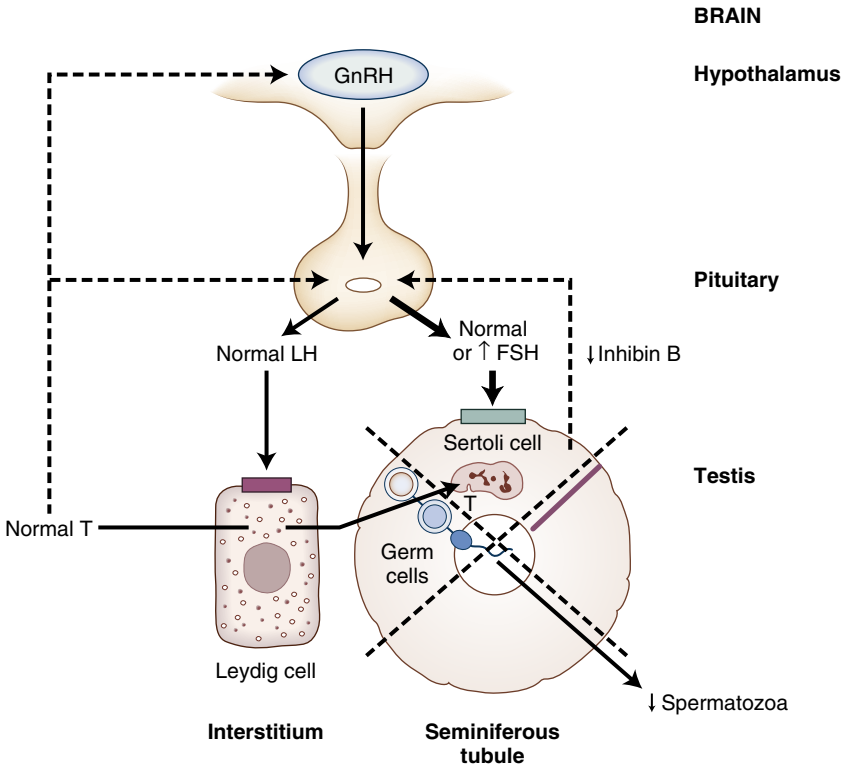
Causes of Primary Hypogonadism

Androgen Deficiency and Impairment in Sperm Production

Congenital or Developmental Disorders

Klinefelter Syndrome. Classically, Klinefelter syndrome is characterized by very small, firm testes; azoospermia and infertility; varying degrees of androgen deficiency and eunuchoidism; and uniformly elevated gonadotropin concentrations.[20,221,222] It is the most common sex chromosome abnormality and the most common cause of primary hypogonadism, resulting in androgen deficiency and impaired sperm production. It occurs prenatally and neonatally in 1 of every 500 to 700 males, and the prevalence in adults is 1 in 2500.[1,2] Because the syndrome does not cause premature death in boys, the low adult prevalence indicates that Klinefelter syndrome is often overlooked and underdiagnosed in men. Given the almost uniform finding of extremely small testes and other phenotypic abnormalities, it is surprising that about 75% of men with Klinefelter syndrome are never diagnosed. This might be due to failure to recognize mild phenotypes or failure to perform a testicular exam. The risk of having a child with Klinefelter syndrome increases with both maternal and paternal age.

The chromosomal abnormality in Klinefelter syndrome is the presence of one or more extra X chromosomes due to maternal meiotic nondisjunction (mostly in meiosis I) in approximately 50% of the cases or paternal meiotic nondisjunction in the remaining cases.[20,221,222] The principal karyotype in 90% of men with Klinefelter syndrome is 47,XXY. Most of the remaining 10% have mosaic Klinefelter syndrome (47,XXY/46,XY), in which there is a 47,XXY karyotype in some tissues or cells and a normal 46,XY karyotype in other tissues or cells. Mosaicism occurs as a result of postfertilization mitotic nondisjunction. Men with mosaic Klinefelter syndrome usually demonstrate a variable and less severe phenotype that depends on the specific tissues in which an extra X chromosome is present. Some men with mosaicism have a normal karyotype in the testis with intact spermatogenesis and fertility. Rarely, men with Klinefelter syndrome have more



• **Fig. 19.23** Schematic diagram of alterations in the hypothalamic-pituitary-testicular axis with an isolated seminiferous tubule defect that results in isolated impairment of sperm production or function. Follicle-stimulating hormone (FSH) concentrations may be normal or selectively elevated (if defect in spermatogenesis is severe) with normal testosterone and luteinizing hormone (LH) concentrations. *GnRH,* gonadotropin-releasing hormone; *T,* testosterone. (Modified from Matsumoto AM. The testis. In: Felig P, Frohman LA, eds. *Endocrinology and Metabolism.* 4th ed. New York, NY: McGraw-Hill; 2001:635–705.)

than one extra X chromosome (e.g., 48,XXXY, 49,XXXXY). Men with these variants manifest a more severe phenotype than is seen in classic Klinefelter syndrome.

Infants with Klinefelter syndrome may manifest micropenis, hypospadias, cryptorchidism, or developmental delay.[222,223] During childhood, boys with the syndrome commonly have small testes and reduced penile length relative to age-matched normal individuals and may manifest relatively tall stature, clinodactyly, hypertelorism, gynecomastia, elbow dysplasia, high-arched palate, hypotonia, language delay or learning and reading disabilities requiring therapy, and behavioral problems.[222,224] However, these manifestations may be mild and are often missed. Fewer than 10% of boys with Klinefelter syndrome (usually those with the most severe phenotype) are diagnosed before puberty. At puberty, the testes fail to increase in size and become firm due to a progressive loss of germ cells and seminiferous tubule hyalinization and fibrosis; Sertoli cell products, inhibin B, and AMH decline to very low or undetectable serum concentrations; circulating testosterone concentrations increase but to less than normal concentrations in some boys, resulting in varying degrees of eunuchoidism and gynecomastia; and FSH concentrations are disproportionately elevated relative to LH concentrations. Elevation of serum LH disproportionately to FSH is an indication of a disorder other than Klinefelter syndrome or any cause of primary hypogonadism that affects both Sertoli cell and Leydig cell dysfunction—for example, rare diseases such as disorders of testosterone biosynthesis or abnormalities of LH or its receptor should be considered.

In adults, the most prominent and consistent clinical feature of Klinefelter syndrome is very small testes, less than 4 mL in volume (<2.5 cm in length); this feature is easily detected on examination and should alert the clinician to the possibility of Klinefelter syndrome[8,225] (see Fig. 19.18). Men with this syndrome may present with a complaint of infertility and subsequently be found to have azoospermia and very small testes.[226] Other manifestations include varying degrees of androgen deficiency, eunuchoidism, and gynecomastia[221] (Fig. 19.25). In contrast to the classic long arms and legs of eunuchoidism seen in patients with androgen deficiency of prepubertal onset, Klinefelter syndrome results in a disproportionate increase in lower- compared with upper extremity long bone growth. Gynecomastia occurs in 50% to 80% of men with the syndrome and may be quite prominent and embarrassing. Learning and developmental disabilities occur in about 70% of men who are diagnosed with Klinefelter syndrome; the prevalence of cognitive impairment might be lower in men with undiagnosed Klinefelter syndrome. Character and personality disorders and behavioral problems occur commonly, possibly in part because of the psychosocial consequences of androgen deficiency and learning disabilities. Men with Klinefelter syndrome have intelligence quotient scores that are reduced by 10 to 15 points but not into the intellectual disability range. Taurodontism,

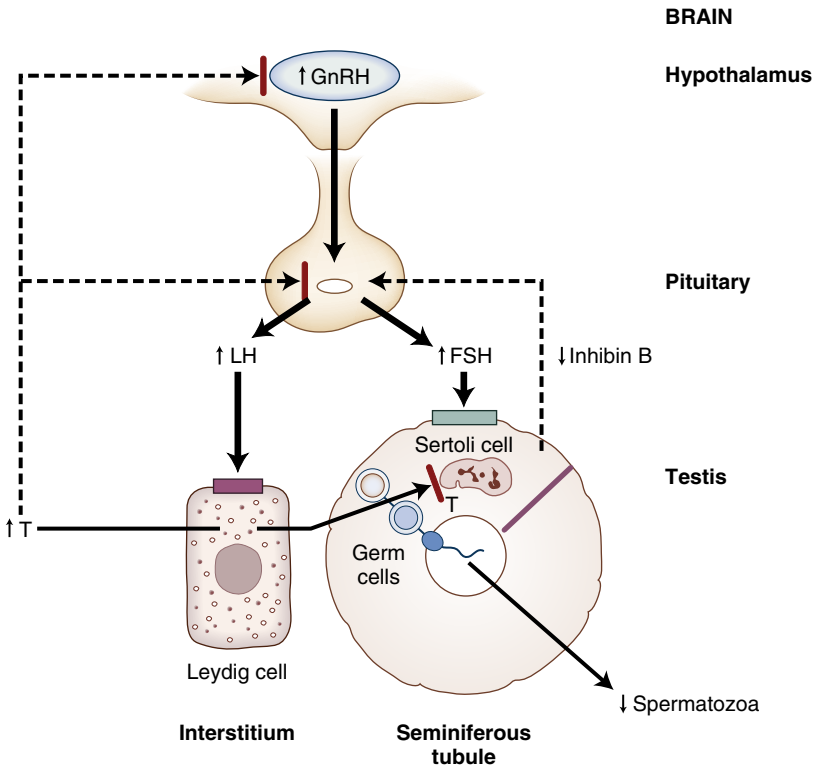
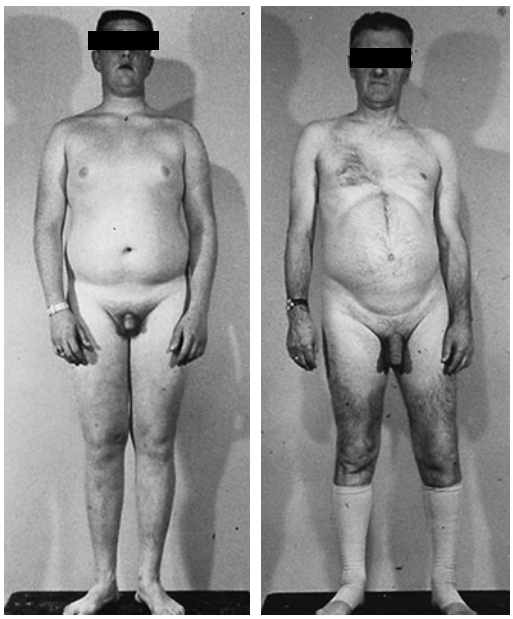
characterized by enlarged molar teeth resulting from enlargement and extension of the pulp chamber, is present in 40% of men with Klinefelter syndrome.

As described previously, the *AR* gene is located on the X chromosome, and the length of the highly polymorphic CAG repeat in exon 1 of the *AR* gene is inversely related to AR activity. In Klinefelter syndrome, the X chromosome carrying the *AR* gene with a short CAG repeat length (i.e., greater AR activity) undergoes inactivation preferentially.[139] Klinefelter syndrome patients with short CAG repeat lengths were found to have more stable relationships, higher educational concentrations, and greater responses to testosterone treatment. In contrast, men with long CAG repeat length (i.e., reduced AR activity) had longer arms and legs, smaller testes, a greater degree of gynecomastia, and lower BMD. Therefore, skewed inactivation of the X chromosome resulting in preferential activity of the long CAG repeat may contribute to phenotypic severity and variability of Klinefelter syndrome.

Most men with mosaic Klinefelter syndrome exhibit less severe clinical manifestations than those with the classic syndrome. Men with more than two extra X chromosomes have more severe manifestations and a higher incidence of intellectual disability and somatic abnormalities such as hypospadias, cryptorchidism, and radioulnar synostosis. Very rarely, some phenotypic males with a 46,XX karyotype exhibit typical clinical manifestations



• **Fig. 19.24** Schematic diagram of alterations in the hypothalamic-pituitary-testicular axis with androgen resistance due to impaired androgen action (e.g., androgen receptor mutation), which results in high testosterone (T) concentrations but reduced androgen action. This leads to manifestations of androgen deficiency, impaired sperm production, and elevated luteinizing hormone (LH) and follicle-stimulating hormone (FSH) concentrations (with LH concentrations that are higher than FSH concentrations) due to impaired androgen-mediated negative feedback regulation of gonadotropins. *GnRH,* gonadotropin-releasing hormone. (Modified from Matsumoto AM. The testis. In: Felig P, Frohman LA, eds. *Endocrinology and Metabolism.* 4th ed. New York, NY: McGraw-Hill; 2001:635–705.)

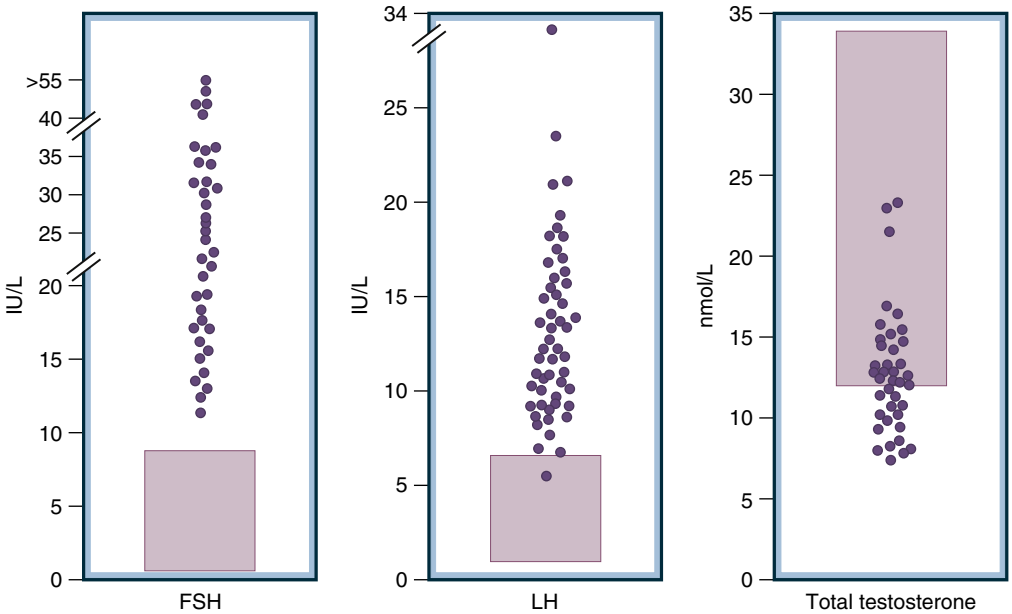


• **Fig. 19.25** Variability in the degree of androgen deficiency manifested in men with Klinefelter syndrome. The man on the left, who has classic 47,XXY Klinefelter syndrome, demonstrates androgen deficiency of prepubertal onset with eunuchoidal body proportions, small penis, sparse chest and pubic hair, poor muscle development, prepubertal fat distribution, and very small testes (2 mL bilaterally). The man on the right, who has mosaic 47,XXY/46,XY Klinefelter syndrome, demonstrates normal body proportions, penis size, and body hair but small testis size (8 mL bilaterally). (From Smyth CM, Bremner WJ. Klinefelter syndrome. *Arch Intern Med.* 1998;158:1309–1314.)

of Klinefelter syndrome but have shorter stature and a greater incidence of cryptorchidism, gynecomastia, and androgen deficiency.[227] In most of these cases, there has been a translocation of an SRY-containing segment of the Y chromosome onto an X chromosome.

In addition to infertility, variable androgen deficiency, and gynecomastia, patients with Klinefelter syndrome have an approximately 20- to 50-fold increased risk in breast cancer compared with normal men (although the absolute lifetime risk of <1% is low); such patients account for approximately 4% of all cases of male breast cancer.[228] Klinefelter syndrome is also associated with increased risk for mitral valve prolapse; lower extremity varicose veins, venous stasis ulcers, deep vein thrombosis, and pulmonary embolism; autoimmune diseases such as systemic lupus erythematosus, rheumatoid arthritis, and Sjögren syndrome; other cancers such as extragonadal germ cell cancer and non-Hodgkin lymphoma; T2DM and the metabolic syndrome; and psychiatric illnesses such as depression and schizophrenia. There is a small reduction in life expectancy of approximately 5 to 6 years in men with Klinefelter syndrome, associated with a higher rate of death due to a variety of common causes.[222,229,230]

Azoospermia is present in more than 95% of men with classic Klinefelter syndrome and infertility in more than 99%. Serum total testosterone concentrations are usually low but may fall in the low-normal to mid-normal range in 40% to 50% of cases[20,221,231] (Fig. 19.26). Relative to normal men, some men with Klinefelter syndrome have relatively high serum estradiol concentrations, which probably contributes to the development of gynecomastia, and increased SHBG concentrations. Increased SHBG concentrations provide a partial explanation for normal total testosterone concentrations in the presence of low concentrations of free testosterone. Serum FSH concentrations are almost always elevated, and LH concentrations are usually elevated but may fall into the high-normal range in some men, consistent



• **Fig. 19.26** Serum concentrations of follicle-stimulating hormone (FSH, *left*), luteinizing hormone (LH, *middle*), and total testosterone (T, *right*) in men with Klinefelter syndrome (*dots*) compared with normal men (normal range depicted by *shaded boxes*). A substantial proportion of men with Klinefelter syndrome have total T concentrations within the normal range, but almost all have elevated LH and FSH concentrations. (From Smyth CM, Bremner WJ. Klinefelter syndrome. *Arch Intern Med.* 1998;158:1309–1314.)

with primary hypogonadism[20,221,231] (see Fig. 19.26). Symptoms of androgen deficiency in the presence of normal total and free testosterone and elevated gonadotropin concentrations occur in some men with Klinefelter syndrome, suggesting relative androgen deficiency or resistance.

The diagnosis of Klinefelter syndrome is confirmed by *karyotype analysis*, which is usually performed on cultured peripheral blood lymphocytes. Occasionally, karyotype analysis is performed on cultured skin fibroblasts and testis tissue if mosaicism is suspected. If a fetus is diagnosed on prenatal testing with 47,XXY Klinefelter syndrome, genetic counseling should be provided. Klinefelter syndrome has a generally good prognosis, but a minority of couples choose termination of a fetus with a prenatal diagnosis of Klinefelter syndrome.

Treatment of Klinefelter syndrome is directed at correction of androgen deficiency. Infants with micropenis may benefit from (systemic or penile topical) testosterone treatment. For boys with Klinefelter syndrome, early intervention with speech and reading therapy is important if speech delay and dyslexia are present. At puberty, testosterone treatment may be needed for adequate development of secondary sexual characteristics; peak bone mass and BMD; muscle mass and strength; and energy, motivation, mood, and behavior. Adults with Klinefelter syndrome who have clinical manifestations of androgen deficiency and consistently low concentrations of serum total or free testosterone (or both) should receive testosterone replacement therapy. In addition, men who have symptoms and signs of androgen deficiency but normal total and free testosterone concentrations should be offered a trial of testosterone treatment.

Although azoospermia and infertility are not generally reversible with medical therapy, TESE permits identification of the relatively few seminiferous tubules that contain active spermatogenesis and harvesting of sperm from 50% to 70% of men with Klinefelter syndrome for use in ICSI; this approach results in live birth rates of approximately 45% in specialized centers.[232] Because there is an increased risk of sex chromosome and autosomal aneuploidy, genetic counseling and prenatal or preimplantation testing should be provided to couples who undergo ICSI.

Chronic, nontender gynecomastia does not resolve with testosterone treatment and requires reduction mammoplasty. Psychological counseling for patients and spouses and participation in support groups may be extremely helpful for men with Klinefelter syndrome.

Myotonic Dystrophy. Myotonic dystrophy is an autosomal dominant, multisystem disorder that is characterized by progressive muscle weakness and wasting (particularly in the lower legs, hands, neck, and face) and results in physical disability; myotonia (involuntary sustained contraction of muscles); cataracts; cardiac conduction defects; respiratory insufficiency; dysphagia; testicular atrophy, impaired spermatogenesis, infertility, and androgen deficiency; premature frontal balding; and intellectual disability.[233] Features of the disease usually develop in young adults but can occur at any age, and their severity varies widely among affected individuals. Two types of myotonic dystrophies are caused by expansion of CTG trinucleotide repeats in two different genes. Myotonic dystrophy type 1 has more severe clinical features and is caused by CTG repeat expansion in the dystrophia myotonica protein kinase (*DMPK*) gene; it accounts for 98% of cases. Myotonic dystrophy type 2 is less severe and is caused by CTG repeat expansion in the CCHC-type zinc finger, nucleic acid–binding protein (*CNBP*) gene.

Primary hypogonadism occurs in approximately 80% of young to middle-age men with myotonic dystrophy.[234,235] Most of these men have isolated impairment of sperm production or function with testicular atrophy, oligozoospermia or azoospermia, moderate to severe testicular damage on testis biopsy, infertility, and disproportionately elevated FSH compared with LH concentrations. Approximately 20% to 40% of men with myotonic dystrophy have variable degrees of androgen deficiency with low testosterone concentrations and elevated LH and FSH; testosterone replacement therapy is appropriate for these men. High-dose testosterone therapy has been demonstrated to improve muscle mass but has not been shown to affect muscle strength.[236] Infertility due to myotonic dystrophy is not reversible with medical therapy, and patients who desire children need to pursue ART or other options; genetic counseling and preimplantation or prenatal testing should be provided, given the autosomal dominant nature of the disease.

Cryptorchidism. Cryptorchidism is the failure of one or both testes to descend normally from within the abdomen through the inguinal canal into the scrotum. It is the most common congenital disorder of the male genital tract in children, affecting 2% to 4% of full-term male infants.[237-239] It is more common in premature, low-birth-weight, and small-for-gestational-age infants. Spontaneous descent of the testis occurs during the first year in most infants (probably induced by the neonatal surge of gonadotropins and testosterone), so the prevalence of cryptorchidism in boys and adults is lower, approximately 0.3% to 1.0%. Because a patent processus vaginalis is usually also present, inguinal hernia is found in conjunction with cryptorchidism in 50% to 80% of cases. Both unilateral and bilateral cryptorchidism are associated with impaired sperm production, infertility, and an increased risk of testicular cancer.

In contrast to cryptorchidism, *ectopic testes* are located outside the normal path of testicular descent.[240] Ectopic testes may be located anywhere in the perineum or in the femoral or superficial inguinal regions. It is also important to distinguish cryptorchidism from *retractile testes* (pseudocryptorchidism). Retractile testes are located in the scrotum but withdraw into the inguinal canal or abdomen with minimal stimulation due to a hyperactive cremasteric reflex; retractile testes are not usually associated with impaired sperm production, infertility, or increased risk of testicular cancer. However, impaired spermatogenesis and fertility have been reported in men with bilateral retractile testes that are located high in the inguinal canal or, sometimes, in the abdomen.

Bilateral cryptorchidism may be associated with several disorders causing primary hypogonadism (including Klinefelter syndrome variants and Noonan syndrome), secondary hypogonadism (including CHH, Kallmann syndrome, and complex genetic disorders associated with multiple congenital anomalies or defects, e.g., Prader-Labhart-Willi syndrome or Laurence-Moon-Biedl syndrome), and androgen resistance syndromes (e.g., Reifenstein syndrome).[241] Cryptorchidism may also be caused by mutations of the Leydig cell product, INSL3, which controls growth of the gubernaculum or of its receptor (RXFP2) in up to 5% of cases.

Unilateral or bilateral cryptorchidism that is not related to known causes of hypogonadism or androgen resistance usually results in isolated impairment of sperm production associated with low sperm counts; normal testosterone concentrations; a selective elevation in FSH concentrations; and, occasionally, high LH concentrations.[237,242] Rarely, cryptorchidism causes Leydig cell failure and androgen deficiency (e.g., in adults with uncorrected bilateral cryptorchidism), producing low serum testosterone with high LH and FSH concentrations.[243,244] Azoospermia occurs in 50% to 60% and oligozoospermia in 75% to 100% of men with bilateral cryptorchidism; among men with unilateral cryptorchidism, these

figures respectively are 15% to 20% and 20% to 40%. This suggests that the function of both testes is compromised in unilateral cryptorchidism. An underlying developmental or environmental disorder affecting both testes (*testicular dysgenesis*) may contribute to impaired spermatogenesis in these individuals.[237,242] The formation of A_d spermatogonia from neonatal gonocytes is inhibited in undescended testes.[245] Uncommonly, normal testicular descent is impeded by an anatomic abnormality, such as a large external inguinal hernia. In this instance, both testes function normally, and orchiopexy before puberty is generally recommended to preserve spermatogenesis and fertility.

The risk of testicular cancer in an undescended testis is 2.5- to 8-fold greater than in a scrotal testis, and the risk remains higher even after the testis is surgically relocated into the scrotum, supporting the notion that cryptorchidism is a manifestation of a underlying testicular disorder (i.e., testicular dysgenesis).[237,241,242,246] Even though the incidence of testicular cancer is only 1 or 2 per 100,000 males, the lifetime risk of malignancy in a cryptorchid testis is substantial. The prevalence of testicular carcinoma in situ, which is thought to precede testicular cancer, is about 3% in the cryptorchid testis. Testicular cancer usually occurs in men from 20 to 40 years of age.

A careful physical examination should be performed to assess the location of testes within the scrotum or inguinal canal; the presence of an inguinal hernia, hydrocele, or other scrotal mass; the cremasteric reflex induced by stroking of the upper medial thigh; and penile size and the position of the urethral meatus. The examination should be performed with the patient standing, squatting, or supine with legs abducted. Scrotal examination may be difficult in a morbidly obese man with a large abdominal panniculus. Techniques that may be helpful in the detection of retractile testes include examination during a Valsalva maneuver, with pressure applied to the lower abdomen, or after scrotal warming with a warm towel to facilitate testicular descent. In addition, elicitation of the cremasteric reflex may cause a localized puckering of the scrotal skin if a retractile testis is present in the scrotum. Often, a low undescended testis may be confirmed by pushing with one hand on the lower abdomen, with firm strokes from the anterior superior iliac spine through the groin and to the pubis, toward and into the scrotum, and then grasping the testis with the other hand. After the testis has been held in the scrotum until the cremasteric muscle fatigues, it is released. If the testis then retracts, it is considered a retractile testis; a low cryptorchid testis returns to its undescended position after release. Absence of a palpable testis in the scrotum after repeated examinations may be a result of cryptorchidism, an extremely atrophic testis, or anorchia (absent testis). Up to 50% of men with a unilateral, nonpalpable testis in the scrotum have a severely atrophic or absent testis instead of cryptorchidism; in these instances, the contralateral testis may be relatively large (by about 2 mL). High-resolution ultrasonography (or MRI) usually localizes testes that are not palpable.

Treatment for persistent cryptorchidism should be started before puberty, when greater germ cell degeneration occurs.[237,242] The exact timing of treatment is controversial, but recent recommendations suggest that treatment should be instituted between 6 and 12 months or up to 24 months of age. Hormonal treatment with hCG in prepubertal boys is effective in stimulating descent of a cryptorchid testis in approximately 10% to 20% of cases. A trial of hCG therapy may be attempted in the hope of avoiding surgery. If hormonal treatment is unsuccessful or not attempted, an orchiopexy (surgical relocation and fixation of the testis into the scrotum with ligation of the hernia sac at the external or internal inguinal ring) should be performed to allow examination of the testes (e.g., as in monitoring for malignancy) and preservation of remaining testis function. Despite orchiopexy, spermatogenesis remains impaired and fertility rates are reduced, particularly with bilateral cryptorchidism (65% paternity rate after orchiopexy). If orchiopexy is performed before puberty, the risk of testicular cancer is reduced but is still increased two- to threefold. In patients with a history of unilateral cryptorchidism, the risk of malignancy in the contralateral testis is also increased. Because the risk of malignancy is two to six times higher in men who underwent orchiopexy after puberty and the fertility potential is poor, some clinicians recommend orchidectomy for men with cryptorchidism discovered after puberty. The majority of testis cancers found in persistently cryptorchid testes are seminomas, whereas those in cryptorchid testes after orchiopexy are mostly nonseminoma testicular cancers.

Noonan Syndrome. Noonan syndrome is an autosomal dominant or occasional sporadic genetic disorder that is characterized by short stature; unusual facial features (hypertelorism, downward-slanting eyes, ptosis, strabismus, low-set ears with thickened helices, high nasal bridge, micrognathia and triangular-shaped face, high-arched palate, low hairline, dental malocclusion); short, webbed neck; shield-like chest, pectus excavatum or carinatum, scoliosis, cubitus valgus, and joint laxity; intellectual disability; cardiac disease (pulmonary stenosis, hypertrophic cardiomyopathy); hepatosplenomegaly; lymphedema; and cryptorchidism.[247,248]

Because several these clinical features resemble those of females with Turner syndrome, Noonan syndrome was previously called *male Turner syndrome*. However, the karyotype in these men is normal. Noonan syndrome affects approximately 1 in 1000 to 2500 live births and is caused by mutations in genes in the Ras-MAPK signaling pathway.[247,248] Approximately 50% of men with Noonan syndrome have mutations in the protein tyrosine phosphatase nonreceptor type 11 (*PTPN11*) gene, and the remainder have mutations in the son of sevenless homolog 1 (*SOS1*), *RAF1*, or *KRAS* genes.

Men with Noonan syndrome may demonstrate primary hypogonadism characterized by androgen deficiency and impaired sperm production with elevated gonadotropin concentrations; they usually present with delayed puberty.[249] Cryptorchidism is present in more than 50% of men with the syndrome and contributes to the cause of hypogonadism.

Bilateral Congenital Anorchia. Congenital anorchia (also known as functional prepubertal castrate or vanishing testis syndrome) is a rare condition in which there is absence of one or both testes in a phenotypically and genotypically normal male.[250,251] Normal fetal testis function is needed for normal male internal and external genital differentiation and development during early gestation. The presence of otherwise normal male internal and external genitalia without müllerian duct–derived structures or descent of the spermatic cord structures (e.g., vas deferens, blood vessels) into the scrotum implies that normally functioning testes must have been present during the first 16 weeks of gestation and subsequently lost during fetal or neonatal life. The prevalence of bilateral congenital anorchia is 1 in 20,000, and that of unilateral congenital anorchia is 1 in 5000 males. The cause is not known but is probably heterogeneous. It is hypothesized that congenital anorchia may be caused by spermatic vascular compromise due to torsion or trauma during or after testicular descent.

Infants with bilateral anorchia present with micropenis in almost 50% of cases, supporting a prenatal origin of the

disorder.[250,251] Males with congenital anorchia usually present with prepubertal primary hypogonadism with delayed puberty and eunuchoidism (see Fig. 19.14), very low testosterone concentrations in the castrate range, and elevated gonadotropin concentrations. On examination, palpable testes are absent, but spermatic cords and epididymides are usually present. Normal testosterone and gonadotropin concentrations in pubertal or adult patients with absent testes exclude the diagnosis of congenital anorchia and should raise the possibility of bilateral cryptorchidism, which carries an increased risk for testicular malignancy.

An hCG stimulation test may be performed to distinguish congenital anorchia from bilateral cryptorchidism. In patients with congenital anorchia, serum testosterone concentrations do not increase in response to prolonged hCG administration (e.g., 1000–2000 IU three times weekly for 2 weeks), whereas most patients with bilateral cryptorchidism respond to hCG. However, lack of testosterone response to hCG administration for 6 weeks has been reported in men with bilateral cryptorchidism.[252] Serum AMH concentrations are usually undetectable in patients with congenital anorchia.[253] Measurements of AMH concentrations are more sensitive than those of testosterone concentrations but equally specific. If clinical examination and endocrine biochemical tests do not distinguish bilateral anorchia from cryptorchidism, then imaging studies (e.g., MRI) and laparoscopy or surgical abdominal exploration may be necessary to confirm the diagnosis.

Treatment of bilateral congenital anorchia consists of testosterone replacement to stimulate penile length in patients with micropenis and to induce and maintain sexual development in boys with delayed puberty and eunuchoidism. Implantation of testicular prostheses in the scrotum may be of psychological and cosmetic value.

Autoimmune Polyglandular Syndrome. Autoimmune polyglandular syndromes are characterized by a clustering of organ-specific autoimmune disorders that involve many endocrine and nonendocrine tissues and are associated with circulating autoantibodies to components of these tissues. Autoimmune polyglandular syndrome type 1, also called *autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy*, is a rare autosomal recessive disorder that is caused by a mutation in the autoimmune regulator (*AIRE*) gene.[254,255] Its main features are mucocutaneous candidiasis, hypoparathyroidism, primary adrenal insufficiency, and the presence of autoimmune disorders including primary hypogonadism. The prevalence of primary hypogonadism is much more common in females than in males. In females, hypogonadism is manifested as premature ovarian failure and is present in 35% to 70% of cases, whereas in males, it is present in 8% to 28% of cases and is manifested either by androgen deficiency and impairment in sperm production with elevated serum gonadotropin concentrations or isolated impairment in sperm production (azoospermia) and isolated elevation of FSH concentrations.

Autoimmune polyglandular syndrome type 2 is a common polygenic disorder associated with the genes for human leukocyte antigens DR3 and DR4.[254,255] It is characterized by autoimmune primary adrenal insufficiency, thyroid disease (Hashimoto or Graves disease), and T1DM in addition to other autoimmune disorders including primary hypogonadism (again, more common in females than in males). In autoimmune polyglandular syndrome type 2, primary hypogonadism is associated with circulating steroid-producing cell autoantibodies and with specific autoantibodies to P450 11A1 and P450 17A1 (cholesterol side-chain cleavage enzyme and 17α-hydroxylase/17,20-lyase, respectively).

Defects in Testosterone Biosynthetic Enzymes. Males with uncommon defects in 17,20-lyase/17α-hydroxylase, 17β-HSD/17-ketoreductase type 3, or 3β-HSD type 2, resulting from mutations in the *CYP17A1*, *HSD17B3*, and *HSD3B2* genes, respectively, usually present at birth as phenotypic females with partial virilization or with ambiguous genitalia. However, patients with incomplete defects in these enzymes occasionally present as phenotypic males with hypospadias, gynecomastia, and primary hypogonadism with androgen deficiency manifested by delayed puberty.

Because 17,20-lyase and 17α-hydroxylase activities reside in the same enzyme, mutations in *CYP17A1* usually cause deficiencies in both activities, leading to elevated concentrations of progesterone, corticosterone, and the aldosterone precursor 11-deoxycorticosterone.[256] Rarely, males exhibiting isolated 17,20-lyase deficiency with elevated 17-hydroxyprogesterone concentrations have been reported.[257] XY males with 17α-hydroxylase deficiency may have hypertension and hypokalemia due to excessive production of 11-deoxycorticosterone that has potent mineralocorticoid activity, as well as variable degrees of sex steroid hormone deficiency; more severe 17α-hydroxylase deficiency is characterized by a female phenotype due to lack of testosterone effects on the wolffian ducts. Patients with 17α-hydroxylase deficiency usually do not manifest adrenal insufficiency because of increased production of the cortisol precursor corticosterone that has glucocorticoid activity. Males with either partial, combined 17,20-lyase/17α-hydroxylase deficiency, or isolated 17,20-lyase deficiency have primary hypogonadism with low testosterone and elevated LH and FSH concentrations (LH > FSH); they require testosterone treatment at the time of puberty.

Patients with 17β-HSD/17-ketoreductase type 3 deficiency may have ambiguous genitalia and be raised as females; however, at puberty, their testosterone concentrations increase sufficiently to induce virilization, resulting in gender reassignment (similar to individuals with low serum DHT concentrations due to 5α-reductase deficiency).[258] Serum testosterone concentrations are low to normal, but androstenedione and gonadotropin concentrations are increased.

Incomplete deficiency of 3β-HSD type 2 is a rare disorder that may manifest in adolescents with mild ambiguous genitalia, delayed virilization, gynecomastia, low testosterone concentrations, and elevated LH and FSH concentrations.[259] Concentrations of pregnenolone, 17-hydroxypregnenolone, and DHEA are elevated. Spontaneous virilization and puberty due to direct effects of high concentrations of the weak androgen DHEA or conversion of DHEA to testosterone via 3β-HSD type 1 (or both) has been reported. A eugonadal male with partial 3β-HSD deficiency who presented with gynecomastia has also been reported.[260]

LH Receptor Mutations. Inactivating mutations of the LH receptor in XY males usually cause Leydig cell aplasia or hypoplasia. These patients usually present with DSD characterized by a female phenotype without breast development at puberty (Leydig cell aplasia) or genital ambiguity (hypoplasia) and cryptorchidism.[58] Rarely, partially inactivating LH receptor mutations result in a male phenotype with micropenis, hypospadias, delayed sexual development, undervirilization, low testosterone concentrations, impaired sperm production, and high serum LH concentrations. However, they usually have normal FSH concentrations. An individual with an LH receptor mutation was reported to exhibit normal concentrations of testosterone and spermatogenesis after hCG stimulation, suggesting that hCG action via the LH receptor may be dissociated from that of LH.[261]

Congenital Adrenal Hyperplasia. Adolescent and adult male patients with congenital adrenal hyperplasia due to 21-hydroxylase deficiency may develop *testicular adrenal rest tumors* (TARTs) that resemble Leydig cell tumors but do not contain intracytoplasmic Reinke crystalloids that are commonly found (approximately 40–50%) on histologic analysis in the latter.[262-264] TARTs may be large and easily palpable, or they may be detectable only on testicular ultrasonography. These tumors are thought to originate embryologically from aberrant adrenal tissue, and they are responsive to adrenocorticotropic hormone (ACTH). TARTs regress with supraphysiologic glucocorticoid therapy at a dosage that suppresses circulating ACTH concentrations, and they may grow with physiologic dosages of glucocorticoids.

21-Hydroxylase deficiency is an autosomal recessive condition caused by a mutation in the *CYP21A2* gene. It is the most common enzymatic defect causing congenital adrenal hyperplasia. 21-Hydroxylase deficiency produces an accumulation of steroid substrates (17-hydroxyprogesterone and progesterone) that results in excessive production of adrenal androgens (androstenedione, DHEA, and 11-hydroxyandrostenedione) that are subsequently converted to testosterone and 11-ketotestosterone. In addition, classic (severe) 21-hydroxylase deficiency causes reduced production of cortisol and aldosterone, resulting in deficiency of glucocorticoid and mineralocorticoid, respectively, and increased ACTH secretion (due to reduced cortisol negative feedback). Elevated ACTH secretion stimulates adrenal gland growth, resulting in adrenal hyperplasia. Glucocorticoid treatment lowers ACTH secretion, reduces excessive adrenal androgen production, treats clinical adrenal insufficiency, and prevents excessive adrenal hyperplasia.

Excessive adrenal androgen production due to untreated or inadequate glucocorticoid therapy for 21-hydroxylase deficiency suppresses gonadotropin secretion by sex steroid negative feedback regulation and causes secondary hypogonadism.[265] Because androgen concentrations are maintained by excessive adrenal production, men with 21-hydroxylase deficiency may not have clinical androgen deficiency. However, they usually have isolated impairment of sperm production due to suppression of circulating gonadotropin concentrations (due to the increased production of adrenal sex steroids and exogenous corticosteroid therapy). Glucocorticoid therapy reduces excessive adrenal androgen production and usually restores gonadotropin secretion and normalizes testis function, but supraphysiologic dosages of glucocorticoids may be required for these effects. Early glucocorticoid treatment may prevent or induce regression of adrenal rest tumors that may affect testicular function directly or cause mechanical obstruction of seminiferous tubules.[262-265]

If TARTs are present, lack of suppression of circulating ACTH stimulates their growth, often resulting in very large tumors that can cause irreversible testicular damage.[262-265] When testicular damage occurs, the patient will have irreversibly impaired sperm production due to loss of seminiferous tubules and may also have androgen deficiency due to loss of Leydig cells. With suppression of circulating ACTH with glucocorticoid treatment, TARTs may regress completely, but the damaged testes remain small and serum testosterone concentrations and sperm counts low. Although excessive amounts of glucocorticoid therapy will suppress ACTH production and TART growth, they also suppress serum gonadotropins, serum testosterone, and sperm production.

Down Syndrome. Down syndrome, or trisomy 21, is a chromosomal disorder in which all or part of an extra chromosome 21 is present.[266] It affects 1 of every 700 to 800 infants and is the most common cause of intellectual disability in children. Down syndrome is characterized by moderate to severe intellectual disability; spontaneous, warm, and cheerful personality; short stature; characteristic facial features (most notably round facies with microgenia, upward-slanting and almond-shaped eyes resulting from bilateral epicanthal folds, macroglossia, and flat nasal bridge); congenital heart defects; primary hypothyroidism; and defects affecting most other body systems. Males with Down syndrome usually manifest primary hypogonadism, most commonly characterized by isolated impairment in sperm production with normal or selective elevation of FSH concentrations. Histologically, they may manifest hypospermatogenesis (moderate to severe reduction in all germ cell types), maturation arrest, or Sertoli cell–only syndrome with loss of all germ cells. Less commonly, they demonstrate mild to moderate androgen deficiency with low or low-normal testosterone and elevated LH and FSH concentrations.

Complex Genetic Syndromes. Primary hypogonadism resulting in androgen deficiency and impaired sperm production or in isolated impairment in sperm production or function may occur as a manifestation of complex genetic syndromes, usually in association with several congenital anomalies or defects and distinct morphologic developmental manifestations.[267] Examples include the Alström, ataxia telangiectasia, Marinesco-Sjögren, Robinow, Rothmund-Thomson, Sohval-Soffer, Weinstein, Werner, and Wolfram syndromes.[268-277] Prader-Labhart-Willi syndrome (associated with cryptorchidism), Laurence-Moon-Bardet-Biedl syndrome, and Alström syndrome are disorders that are commonly associated with secondary hypogonadism, but primary hypogonadism may also occur in these disorders.[278-281]

Acquired Disorders

Bilateral Surgical Castration and Trauma. Bilateral surgical castration causes a rapid and profound decline in testosterone concentrations within hours, resulting in severe clinical manifestations of androgen deficiency, including hot flushes. Severe blunt trauma to the testes and associated vascular compromise may result in testicular atrophy and loss of testis function, including androgen deficiency and impaired spermatogenesis or isolated impairment in sperm production or function.

Drugs and Ionizing Radiation. Certain drugs that affect androgen production may cause androgen deficiency. Ketoconazole and abiraterone inhibit 17,20-lyase and 17α-hydroxylase activity at high doses (>400 mg daily and 1000 mg daily, respectively) and have been used, in conjunction with other agents, to lower both adrenal and testicular androgen production in the treatment of prostate cancer.[282-284] Spironolactone, a nonspecific aldosterone antagonist, acts mainly as a competitive AR antagonist and inhibits androgen action.[285] However, it also inhibits 17,20-lyase and 17α-hydroxylase activity and testosterone biosynthesis at high doses.[286,287] Enzalutamide is a competitive AR antagonist that also inhibits postreceptor AR action (translocation of AR into the nucleus, binding of AR cofactors, and DNA binding) that is used to treat castration-resistant prostate cancer.[288] Chronic excessive intake of alcohol may directly inhibit testosterone production, but it may also suppress gonadotropins; it may be associated with nutritional deficiency or chronic liver disease that may contribute to androgen deficiency and impairment in sperm production.[289,290]

In general, because spermatogenesis involves active cell replication, the germ cell compartment is much more sensitive to external or environmental influences (e.g., chemotherapy agents,

ionizing radiation) than are Leydig cells. Exposure to such agents often results in primary hypogonadism characterized by an isolated impairment in sperm production or function and elevated FSH concentrations. However, severe testis damage induced by these agents may cause Leydig cell dysfunction or damage, resulting in both androgen deficiency and impairment of sperm production, and elevated LH and FSH (FSH > LH) concentrations.

Combination chemotherapy regimens that include alkylating agents (e.g., cyclophosphamide, ifosfamide, procarbazine, busulfan, chlorambucil), such as those used for the treatment of Hodgkin and non-Hodgkin lymphoma and leukemia, or use of alkylating agents, such as cyclophosphamide, in the treatment of systemic rheumatic disorders are particularly toxic to the testes and may result in androgen deficiency in up to 20% of patients.[291,292] High-dose chemotherapy and total-body irradiation before bone marrow transplantation may also cause androgen deficiency in a substantial proportion of men. In contrast, men with testicular cancer who undergo combination chemotherapy that includes platinum drugs (together with unilateral orchidectomy and, often, radiation therapy) have a relatively low prevalence of usually mild androgen deficiency with slightly low to low-normal testosterone concentrations and elevated LH concentrations.[292]

Exposure of testes to ionizing irradiation commonly suppresses spermatogenesis in a dose-dependent manner, and doses greater than 600 to 800 cGy may compromise Leydig cell function and reduce testosterone production.[16,293,294]

Clinical practice guidelines for ongoing surveillance for testicular toxicity in childhood and young adult cancer survivors have been established by several groups.[295,296]

Orchitis. Viral infection of the testes may result in testicular atrophy; impaired sperm production; and, in severe cases, androgen deficiency. *Mumps orchitis* was common before the introduction of the measles/mumps/rubella vaccine in 1968, after which rates of mumps infection decreased profoundly.[297,298] Because some people are fearful about potential side effects of vaccinations, there has been a resurgence of mumps infections and orchitis in adolescents and young adults. Prepubertal mumps orchitis is very uncommon and is not associated with subsequent testicular dysfunction. Orchitis is the most common complication of mumps infection in pubertal boys and adults. It usually causes permanent seminiferous tubule damage; impaired spermatogenesis; and, in severe cases, Leydig cell failure and androgen deficiency.

Mumps infection usually manifests with headache, fever, and malaise followed by unilateral or bilateral parotid swelling due to parotiditis.[297,298] Testis pain and swelling due to orchitis occurs in about 10 days or up to 6 weeks after the onset of parotiditis and may be subclinical in up to 50% of cases. Epididymitis accompanies orchitis in 85% of cases. Mumps orchitis is usually unilateral but may be bilateral in 15% of cases in adolescents and in 30% of cases in young adults. Even if orchitis is clinically unilateral, degenerative changes may occur in the apparently unaffected testis. Germ cell sloughing occurs as a result of acute infection, inflammation, and ischemia resulting from pressure induced by swelling of the testes within the tunica albuginea. The acute phase is followed by seminiferous tubule fibrosis and then testicular atrophy (30–50% of cases) during the next several months, resulting in impaired spermatogenesis in 25% to 40% of cases. In severe cases, prednisone may be used to reduce inflammation and swelling associated with mumps orchitis, but it does not prevent testicular damage.

Untreated or undertreated HIV infection may cause gonadotropin suppression and secondary hypogonadism, particularly when associated with wasting and systemic illness. However, in 20% to 30% of cases, HIV infection causes primary hypogonadism characterized by low testosterone and elevated gonadotropin concentrations. The cause of primary hypogonadism is orchitis that is caused by HIV infection of the testis or occurs secondary to opportunistic infection (e.g., by cytomegalovirus [CMV], *Mycobacterium avium intracellulare*, *Toxoplasma gondii*) associated with the patient's immunocompromised state.[299,300]

Other causes of infectious orchitis usually associated with epididymitis include echovirus, arbovirus, or lymphocytic choriomeningitis infection; gonorrhea or *Chlamydia* infection in young adults and urinary pathogens such as *Escherichia coli* in older men; leprosy and tuberculosis; brucellosis, glanders, and syphilis; and parasitic infections such as filariasis and bilharziasis.[299,301]

Systemic Disorders

Low serum testosterone concentrations associated with symptoms and signs consistent with androgen deficiency are commonly associated with chronic diseases affecting the liver, kidney, heart, and lungs.[4,5] The underlying cause of both clinical and biochemical hypogonadism in these conditions is complex and multifactorial. The illness itself, associated complications, nutritional compromise, and medications used to treat the illness may contribute to or confound the clinical manifestations of androgen deficiency and also may suppress gonadotropin and testosterone production, thereby playing an etiologic role. Chronic systemic diseases usually affect both testicular and hypothalamic-pituitary function and cause combined primary and secondary hypogonadism. Clinically, however, measurements of gonadotropin concentrations usually suggest predominantly primary hypogonadism (i.e., elevated gonadotropins) or secondary hypogonadism (i.e., normal or low gonadotropins). The benefits and risks of testosterone therapy in patients with these systemic disorders have not been evaluated in long-term randomized, controlled outcome studies.

Chronic Liver Disease. In men with chronic liver disease of any cause (and particularly in those with hepatic cirrhosis or liver failure), sexual dysfunction, gynecomastia, and testicular atrophy resulting in impaired androgen and sperm production occur commonly, affecting 50% to 75% of these patients.[4,5,302-304] Total testosterone concentrations may be low but are often normal or high normal, because SHBG concentrations are increased substantially with cirrhosis and chronic active hepatitis. Therefore, measurements of free or bioavailable testosterone using accurate assay methods should be used to assess androgen deficiency. Free and bioavailable testosterone concentrations are usually low, and LH concentrations are usually elevated or in the high-normal range in patients with mild to moderate hepatic cirrhosis (Child-Pugh class A or B).

Estrogen (estrone and estradiol) concentrations are usually high due to increased production (e.g., induced by alcohol excess) and reduced clearance of adrenal androgens (e.g., androstenedione), which provide increased substrates for aromatization of androgens to estrogens. High estrogen concentrations contribute to the development of gynecomastia (high estrogen-to-androgen ratio), palmar erythema and spider angiomas, and increased prolactin concentrations. Treatment of ascites and edema with spironolactone may further lower testosterone concentrations and block androgen action, contributing to gynecomastia and other manifestations of androgen deficiency. Serum FSH and LH concentrations may be suppressed by high estrogen and prolactin concentrations and by the malnutrition that occurs commonly in men with hepatic cirrhosis and liver failure; these factors may

contribute a hormonal pattern more consistent with secondary hypogonadism in some men. Oligozoospermia or azoospermia associated with abnormalities in sperm motility and morphologic appearance occurs in approximately 30% to 50% of men with chronic liver disease.

Testosterone treatment of androgen deficiency is usually well tolerated but occasionally may worsen gynecomastia and rarely may increase edema and ascites by causing fluid retention. A preliminary double-blind, randomized, placebo-controlled 12-month trial in men with hepatic cirrhosis found that testosterone improved lean body and bone mass, reduced fat mass, and improved hemoglobin and hemoglobin A_{1c} concentrations.[305] Because immunosuppressive medications such as prednisone and cyclosporine are used to prevent rejection, liver transplantation only partially reverses hypogonadism associated with chronic liver disease.[302,306]

Chronic Kidney Disease. Late-stage CKD commonly causes combined primary and secondary hypogonadism, resulting in androgen deficiency and impairment in sperm production in 50% to 60% of these patients.[4,5,307] Serum testosterone concentrations are low, and LH and FSH concentrations are high, in large part because of markedly reduced renal clearance of gonadotropins and increased secretion resulting from reduced negative feedback. SHBG concentrations are usually not affected by CKD unless nephrotic syndrome is present, in which case concentrations of SHBG and, consequently, total testosterone may be low. In the latter situation, free or bioavailable testosterone measurements should be performed to assess androgen deficiency. Sperm production is impaired, and sperm motility and the percentage of sperm with normal morphologic appearance are reduced. The Leydig cell response to hCG administration is reduced, consistent with primary testicular dysfunction. The frequency and amplitude of pulsatile LH secretion are altered, suggesting an alteration in hypothalamic-pituitary function as well. Hyperprolactinemia, relative nutritional deficiency, uremia, the proinflammatory state, comorbid conditions that secondarily suppress gonadotropins, and zinc deficiency that affects testicular function may contribute to testicular dysfunction in men with CKD.

Randomized controlled trials that assess the long-term clinical benefits and risks of testosterone treatment have not been conducted.[308] Hemodialysis and peritoneal dialysis do not improve testosterone or sperm production.[307,309] Successful renal transplantation usually brings testosterone and sperm production to almost normal concentrations, although immunosuppression by rapamycin inhibitors (e.g., sirolimus) may impair testis function slightly.[307,310,311]

Aging. After age 40 years, there is a gradual and progressive decline in total testosterone concentrations (by approximately 1% per year) such that an increasing proportion of older men have low serum testosterone concentrations in the hypogonadal range.[312-314] Because SHBG concentrations increase with age, free and bioavailable testosterone concentrations decline even more rapidly (2–3% per year). Daily sperm production, sperm motility, percentage of sperm with normal morphologic forms, Sertoli cell number, and inhibin B concentrations also decline with aging.[144] Leydig cell number and testosterone production in response to stimulation by hCG are reduced, consistent with primary testicular dysfunction.[144] In older men, circadian variation in testosterone concentration is present but blunted.[64] Furthermore, pulsatile LH secretion is more irregular and disorderly and LH pulse amplitude is reduced in older men compared with those who are younger. Pulsatile GnRH administration normalizes pulsatile LH but not testosterone secretion, consistent with an impairment of hypothalamic GnRH secretion occurring in combination with a primary defect in testosterone production by the testis.[315,316]

Serum LH and FSH concentrations increase (by about 1–2% per year) with aging but do not usually rise above the normal range until very old age (>70 years).[312-314,317] Therefore, the most common hormonal profile associated with aging observed in middle-age to older men is low testosterone with normal LH and FSH concentrations, consistent with secondary hypogonadism; gonadotropin suppression is thought to be largely related to age-related comorbidities (e.g., obesity, illness, and medications). As men get older, gonadotropins continue to rise. A hormonal pattern of low testosterone and elevated LH and FSH concentrations, consistent with primary hypogonadism, is more prevalent in very old men, particularly after 70 years of age.

As men age, they may develop chronic organ failure or systemic illnesses, take an increasing number of medications, and develop nutritional deficiency or wasting syndromes that are associated with low testosterone concentrations.[318] It is likely that these comorbid conditions contribute to low testosterone and clinical hypogonadism associated with aging in men. Conversely, the age-related decline in testosterone concentrations may contribute to the susceptibility to or severity of clinical hypogonadism observed in these conditions.

In community-dwelling middle-age to older men, the prevalence of low testosterone increased from 12% among men in their 50s to 48% among men older than 80 years.[313] However, the prevalence of *clinical androgen deficiency* (i.e., symptoms and signs consistent with androgen deficiency and low testosterone concentrations) was 6% to 9% and increased with age, reaching 18% to 23% among men in their 70s.[196,197] When more stringent criteria for the diagnosis of androgen deficiency associated with aging were used (i.e., three sexual symptoms and a low testosterone level defined as late-onset hypogonadism), the prevalence was 2% and also increased with age, reaching 5% among men in their 70s.[198]

The decline in testosterone concentrations with aging is associated with alterations in body function that could be attributable to androgen deficiency.[144] These include a decline in muscle mass and strength associated with reduced physical function and performance; decreased BMD and increased risk of osteoporosis and fractures; increased body fat; reduction in sexual function and activity, including reduced libido and erectile dysfunction; decline in vitality, energy, mood, and cognitive function; and alterations in sleep quality. Similar changes occur in younger hypogonadal men and improve with testosterone treatment, raising the possibility that the decline in testosterone concentrations that occurs with aging may contribute to these age-associated changes in body function.

Previous relatively small, short-term (up to 3 years) studies of testosterone treatment in heterogeneous groups of older men with low or low-normal testosterone concentrations without regard to the presence of symptoms or signs of androgen deficiency have produced conflicting results. Most demonstrated beneficial effects of testosterone treatment on body composition, with increasing lean or muscle mass and decreasing fat mass, but less consistent effects on muscle strength and performance, BMD, sexual function, vitality, and cognitive function. The only adverse effect found in these studies was excessive erythrocytosis in some men.

The Testosterone Trials were seven coordinated, double-blind, placebo-controlled studies with allocation by minimization that evaluated the short-term effects of testosterone treatment for 1 year on sexual function, physical function, vitality, cognitive

function, bone density, anemia, and coronary artery plaque volume in a large number (788) of older men (average age of 72 years) with unequivocal hypogonadism (symptoms and signs of low libido, difficulty walking and slow walking speed, and/or low energy, as well as two morning testosterone concentrations of <275 ng/dL) for no apparent reason other than age. Compared with placebo, testosterone treatment for 1 year that raised testosterone concentrations to the mid-normal range for young men improved sexual function (sexual activity, libido, and erectile dysfunction), anemia and hemoglobin, volumetric BMD, and estimated bone strength; slightly improved walking distance, mood, and depressive symptoms; and did not improve multiple domains of cognitive function and vitality. In addition, testosterone treatment caused erythrocytosis (hemoglobin concentration >17.5 g/dL) and an increase in PSA concentration of more than 1.0 ng/mL in a small number of men and increased noncalcified coronary artery plaque volume on CT angiography. There was no difference in LUTS or cardiovascular or prostate adverse events in testosterone- and placebo-treated men (although the Testosterone Trials were underpowered for the latter outcomes).[162,319-323]

Previous studies of testosterone treatment in frail older men with low testosterone concentrations found beneficial effects on muscle strength and physical performance; there was an increase in self-reported cardiovascular adverse events in one small study but not in another similar study.[324,325] Meta-analyses of testosterone treatment trials[326-328] and pharmacoepidemiologic studies evaluating cardiovascular events associated with testosterone treatment[329-337] have also been conflicting. Meta-analyses of testosterone treatment trials, although underpowered, found no increased risk of prostate cancer,[338] and pharmacoepidemiology studies have been inconsistent, showing no or possibly increased risk of low-grade and reduced risk of high-grade, aggressive prostate cancer with testosterone treatment.[337,339-342]

Larger, long-term, randomized trials are needed to determine the balance of clinical benefits (e.g., related to frailty and fractures) and risks (particularly as related to prostate cancer and cardiovascular disease [CVD]) of testosterone treatment in elderly men. Until results from these outcome studies are available, testosterone treatment should be considered only for older men who have clinically significant manifestations of androgen deficiency (e.g., low libido and anemia) and unequivocally low serum testosterone concentrations, and only after a careful discussion of the uncertainty concerning the long-term benefits and risks of treatment.[116]

Other Systemic Disorders. Primary hypogonadism with low testosterone concentrations or elevated LH concentrations (or both) occurs in up to 20% of men with *malignancy* such as advanced Hodgkin disease or testicular cancer before gonadotoxic chemotherapy and radiation therapy.[343-345] Impairment of sperm production is found more frequently in about 30% to 50% of men with Hodgkin disease or testicular cancer before therapy. The mechanism of gonadal dysfunction before treatment is not clear.

Sickle cell disease is an autosomal recessive disorder caused by a point mutation in the β-globulin chain. It results in an abnormal hemoglobin (hemoglobin S) that polymerizes, leading to sickle-shape, rigid, and fragile red blood cells. The disease is characterized by recurrent episodes of painful, vaso-occlusive events in a variety of organs due to thrombosis, ischemia and infarction, and hemolysis. Sickle cell disease is a common disorder, affecting approximately 1 in 700 African-American infants. Sickle cell disease may cause primary hypogonadism characterized by low to low-normal testosterone concentrations, clinical manifestations consistent with androgen deficiency, testicular atrophy and impaired spermatogenesis, and elevated gonadotropin concentrations, possibly due to repeated testicular vaso-occlusive events and infarction.[346-348] Hydroxyurea therapy and possibly zinc deficiency may contribute to impaired spermatogenesis. Men with sickle cell disease may experience priapism due to penile vaso-occlusion, and this may be precipitated by restoration of libido with testosterone treatment of hypogonadism.

Within the first few months to 1 year after a *spinal cord injury*, testosterone concentrations and sperm production are suppressed, and gonadotropins are usually normal. However, in some men, LH or FSH concentrations or both may be elevated in the presence of low to low-normal testosterone, consistent with primary hypogonadism.[349] Some men demonstrate low testosterone and elevated gonadotropin concentrations chronically after spinal cord injury.[350-352] The latter condition may be caused by hyperprolactinemia associated with medications, as well as nutritional deficiency, obstructive sleep apnea, or comorbidities associated with chronic spinal cord injury. Testis biopsy has revealed impaired spermatogenesis in approximately 40% of men with spinal cord injury, but mature sperm that could be used for TESE and ICSI were present in almost 90%.[353]

Vasculitis (e.g., polyarteritis nodosa, granulomatosis with polyangiitis, Henoch-Schönlein purpura, Behçet disease) or *infiltrative disease* (e.g., systemic amyloidosis) involving both testes may cause testicular damage and may necessitate orchidectomy, resulting in both androgen deficiency and impaired sperm production.[354-356]

Isolated Impairment of Sperm Production or Function

Congenital or Developmental Disorders

As described previously, cryptorchidism, myotonic dystrophy, and Down syndrome most commonly manifest with primary hypogonadism characterized by isolated impairment in sperm production without androgen deficiency and selectively elevated FSH concentrations. In men with less severely impaired spermatogenesis, serum gonadotropin concentrations are normal, but it is most appropriate to classify these men as having primary hypogonadism with isolated impairment in sperm production, because gonadotropin treatment has not been demonstrated to improve fertility.

Varicocele

Varicocele is a dilatation of the pampiniform venous plexus surrounding the spermatic cord in the scrotum. It is caused by retrograde blood flow into the internal spermatic vein, which is usually caused by defective or absent valves in spermatic veins or, rarely, by obstruction of normal venous drainage by extrinsic or intrinsic venous compression (e.g., from a tumor). It usually occurs on the left side, and most cases are asymptomatic. A varicocele is present in 10% to 15% of men in the general population and more frequently in infertile men (up to 30–40%).[192,357]

The relationship of varicocele to impaired sperm production and infertility is unclear.[192,357] Approximately 50% of men who have a varicocele demonstrate normal semen analyses, and most with varicoceles are fertile. Men with a large varicocele and infertility usually exhibit low sperm counts with reduced motility and increased numbers of sperm with abnormal morphologic appearance (e.g., tapered or amorphous sperm heads), but these abnormalities are not specific for varicocele. Varicocele is painful in 2% to 10% of men with infertility. Testis size and serum concentrations of testosterone, LH, and FSH are usually normal, although

there may be an isolated elevation of serum FSH in men with decreased spermatogenesis. Testis biopsy in men with a varicocele and abnormal semen parameters reveals a spectrum of histopathologic findings, including hypospermatogenesis, maturation arrest, and Sertoli cell–only histology.

It is unclear whether varicocele ligation improves fertility in men who present with infertility. Controlled trials to investigate the efficacy of varicocele ligation have not demonstrated improved fertility. However, these trials were generally small, heterogeneous, and of poor quality. A small number of controlled trials of infertile men with palpable varicocele and at least one abnormal semen parameter suggested improvement in the spontaneous pregnancy rate with varicocele ligation. Some organizations have recommended surgical ligation for infertile men who have a large, palpable varicocele with an abnormal seminal fluid analysis.[192,357]

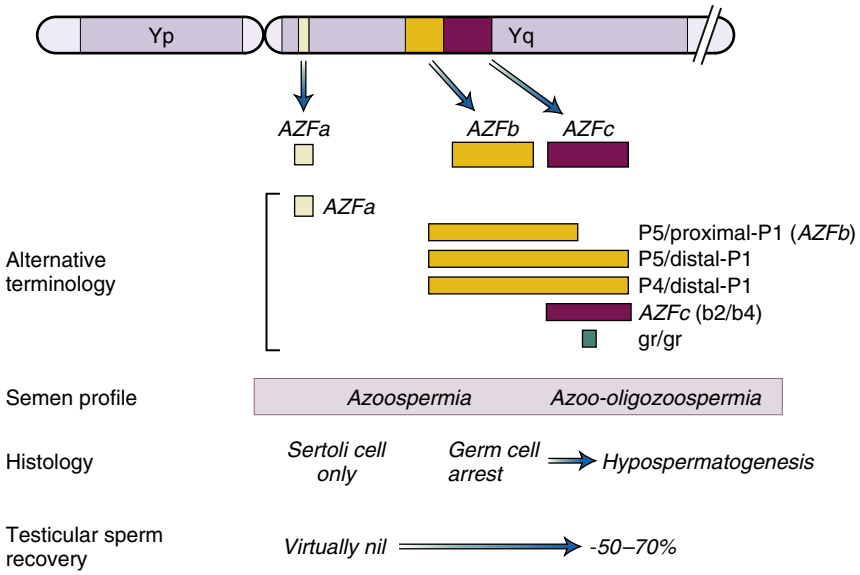
Y Chromosome Microdeletion. Yq chromosome (long arm of the Y chromosome) microdeletions are the most common genetic cause of impaired sperm production and male infertility. They are found in 5% to 10% of men with severe oligozoospermia and in 10% to 15% of men with azoospermia.[181] As mentioned earlier, microdeletions have been identified in three regions of the long arm of the Y chromosome[181,182,358] (Fig. 19.27).

Microdeletions in the *AZFa* region, which contains the *DDX3Y* and *USP9Y* (ubiquitin specific peptidase 9, Y-linked) genes, are usually associated with azoospermia and Sertoli cell–only histology. Microdeletions in the *AZFb* region, which contains multiple copies of the *RBMY* and *PRY* (PTPM13-like, Y-linked) genes, are usually associated with severe oligozoospermia and germ cell arrest at the pachytene primary spermatocyte stage and occasionally with hypospermatogenesis. Microdeletions in the *AZFc* region, which contains the *DAZ* (deleted in azoospermia) gene and is where the majority of Y chromosome microdeletions reside, are usually associated with germ cell arrest at the spermatid stage or with hypospermatogenesis with some mature spermatids present. *AZFc* microdeletions are found in approximately 12% of men with nonobstructive azoospermia and in 6% of men with severe oligozoospermia. Microdeletions in both the *AZFb* and the *AZFc* region are usually associated with azoospermia and Sertoli cell–only histology.

Yq microdeletion analysis should be considered for couples who are contemplating ICSI, because these microdeletions have been shown to be transmitted to male offspring with the ICSI procedure.[181] If ICSI is performed in men with Y chromosome microdeletions, genetic counseling and preimplantation or prenatal testing should be considered.

Sertoli Cell–Only Syndrome (Germ Cell Aplasia). Sertoli cell–only syndrome, or germ cell aplasia, is an uncommon histologic diagnosis in which the seminiferous tubules are completely devoid of germ cells and are lined only with Sertoli cells with little to no fibrosis or hyalinization.[359] Men with this disorder present with infertility, normal androgenization, moderately small testes (10 to 20 mL in volume), azoospermia, normal testosterone and LH concentrations, and selectively elevated FSH concentrations (indicating severe seminiferous tubule dysfunction).[360] Occasionally, LH concentrations are slightly high, and the testosterone response to hCG stimulation is reduced, suggesting mild Leydig cell dysfunction.

The cause of Sertoli cell–only syndrome is not known, but it is thought to result from congenital absence of germ cells due to a failure of gonocyte migration. In some families, however, germ cells were present before puberty but were subsequently lost during or after puberty. As described previously, a Sertoli cell–only histology may be associated with microdeletions in the long arm of the Y chromosome in the *AZF* regions.[361] Severe germ cell



• **Fig. 19.27** Schematic diagram of the short (Yp) and long (Yq) arms of the human Y chromosome. Deletions in regions of Yq, specifically in azoospermia factor (AZF) regions, are associated with severe defects in sperm production. Microdeletions in the *AZFa* region are usually associated with azoospermia and Sertoli cell–only histology. Microdeletions most commonly affect the *AZFc* region and may be associated with severe oligozoospermia or azoospermia. However, even if oligozoospermia or azoospermia is present, sperm for use in intracytoplasmic sperm injection are recoverable from half of the patients by testicular sperm extraction at biopsy. (From McLachlan RI, O'Bryan MK. Clinical review: state of the art for genetic testing of infertile men. *J Clin Endocrinol Metab.* 2010;95:1013–1024.)

damage and loss occurring with Klinefelter syndrome, mumps orchitis, cryptorchidism, ionizing radiation, or alkylating agents may result in seminiferous tubules lined only with Sertoli cells. However, in these cases of acquired Sertoli cell–only syndrome, there is usually extensive seminiferous tubule sclerosis or hyalinization, and the testes are usually smaller. Infertility is irreversible in congenital Sertoli cell–only syndrome, but it may be reversible with time in some cases of acquired Sertoli cell–only syndrome.

Primary Ciliary Dyskinesia (Immotile Cilia Syndrome). Primary ciliary dyskinesia, or immotile cilia syndrome, is a rare, heterogeneous, autosomal recessive genetic disorder of cilia. It is characterized primarily by recurrent respiratory infections (sinusitis and bronchitis) that lead to the development of bronchiectasis, caused by impaired mucociliary clearance due to dyskinesia of respiratory tract cilia, and to infertility caused by asthenozoospermia (nonmotile or poorly motile sperm) due to impaired sperm tail movement.[28,362] In half of the cases, primary ciliary dyskinesia is associated with situs inversus and is known as *Kartagener syndrome*. Some men exhibit abnormalities of sperm motility in the absence of respiratory tract involvement.

Patients with primary ciliary dyskinesia and impaired sperm motility demonstrate ultrastructural abnormalities of the axoneme, the microtubule cytoskeleton of the sperm flagellum, especially in the dynein arms (motor protein complexes). Almost all men with primary ciliary dyskinesia have mutations of the genes encoding the dynein axonemal heavy chain 5 (*DNAH5*), dynein intermediate chain 1 (*DNAI1*), or dynein axonemal heavy chain 11 (*DNAH11*). These men present with infertility and an isolated impairment in sperm motility with normal sperm counts and morphologic structure and normal testosterone and gonadotropin concentrations.

FSH Receptor Mutations. Rare inactivating FSH receptor mutations have been described in males.[58,86] In contrast to females with FSH receptor mutations, who have primary amenorrhea and infertility, men have a more variable presentation. Some demonstrate severe oligozoospermia, whereas others have moderate oligozoospermia or normal sperm concentrations with abnormal sperm morphologic appearance, and some have normal fertility. Serum testosterone concentrations are normal, FSH concentrations are elevated, and LH concentrations are slightly high to normal. It is possible that normal testosterone production within the testes contributes to the persistence of spermatogenesis and fertility in the absence of FSH action.

Acquired Disorders

Because seminiferous tubule function is more susceptible to damage than Leydig cell function, most men with primary hypogonadism due to chemotherapy agents, ionizing radiation, or orchitis caused by mumps or other infections manifest isolated impairment of sperm production without androgen deficiency.

Alkylating agents (e.g., cyclophosphamide, ifosfamide, procarbazine, busulfan, chlorambucil) used in combination chemotherapy regimens to treat lymphoma and leukemia almost uniformly cause azoospermia that recovers after 5 years in up to two thirds of men.[291,363-365] The effect of cyclophosphamide is dose dependent, and cumulative doses of cyclophosphamide of 10 g/m^2 for malignancy are likely to result in severe oligozoospermia or azoospermia that may be irreversible.[365] High-dose chemotherapy and total-body irradiation before bone marrow transplantation commonly cause irreversible germ cell damage associated with azoospermia or severe oligozoospermia and elevated FSH concentrations. Sperm production is suppressed initially in men with testicular cancer who undergo combination chemotherapy that includes platinum drugs, unilateral orchidectomy, and often radiation therapy.[292] However, sperm production recovers in 80% of men by 5 years. Before chemotherapy begins, cryopreservation of sperm for subsequent use in IUI, IVF, or ICSI should be offered to men who desire future fertility. Approaches aimed at suppressing gonadotropins with GnRH agonists or exogenous testosterone administration have not been uniformly effective in preventing germ cell damage by chemotherapy.

Methotrexate and sulfasalazine may cause oligozoospermia and low sperm motility and contribute to infertility.[366,367] The processes of human spermatogenesis, and particularly the spermatogonia, are very sensitive to the effects of exposure to ionizing radiation.[16,293,294] X-radiation doses as low as 15 cGy may suppress sperm production temporarily. The time required to recover spermatogenesis after x-irradiation is dose dependent. Recovery of sperm counts to baseline takes 9 to 18 months after exposure to 100 cGy or less and up to 5 years after 400 to 600 cGy. Although Leydig cell function is more resistant to ionizing radiation, x-irradiation of greater than 800 cGy may cause Leydig cell damage and androgen deficiency. As with chemotherapy, sperm banking before radiation therapy for later use in ART offers hope for subsequent fertility.

Prolonged and repeated *thermal trauma* (e.g., with excessive hot tub use) to the testes may transiently suppress sperm production.[368,369] In addition, many chemical agents used in industry and laboratories have been implicated as direct toxins to the testes. Examples of *environmental toxins* include carbon disulfide, a solvent used in rayon production; dibromochloropropane, an insecticide; lead; deuterium oxide; ethyl glycol; cadmium; fluoroacetamide; nitrofurans; dinitropyroles; diamines; and α-chlorohydrin.[370] Furthermore, it is postulated that environmental or xenobiotic agents such as phthalates act as antiandrogens or estrogens to alter reproductive function; these agents have been termed *endocrine disruptors*.[371] Such environmental agents have been implicated in causing the increased incidence of testicular dysgenesis syndrome (i.e., hypospadias, cryptorchidism, declining sperm counts, and testicular cancer).[372]

Systemic Disorders

An acute *febrile illness* may cause a temporary suppression of spermatogenesis.[373] In men with spinal cord injury resulting in tetraplegia or paraplegia, impaired sperm production may be caused in part by increased scrotal temperature due to loss of lumbar sympathetic innervations.[349-351,353] Men with malignancy, particularly Hodgkin lymphoma or testicular cancer, may have impaired spermatogenesis with azoospermia or oligozoospermia in 30% to 80% of cases before treatment (the former possibly related to B symptoms of fever, night sweats, and weight loss).[331,343,345,364]

In most men who present with infertility and an isolated impairment of sperm production, a cause cannot be identified. *Idiopathic oligozoospermia or azoospermia* occurs in 60% to 80% of cases (including men with varicocele).[178-180] If isolated impairment of spermatogenesis is severe in men with primary hypogonadism, serum FSH concentrations may be selectively elevated. As mentioned earlier, men with less severely impaired spermatogenesis and normal serum gonadotropin concentrations are still classified as having a disorder of primary hypogonadism, because gonadotropin treatment has not been demonstrated to improve fertility in such cases.

Causes of Secondary Hypogonadism

Androgen Deficiency and Impairment in Sperm Production

Congenital or Developmental Disorders

Constitutional Delay of Growth and Puberty. It is important to consider *constitutional delay of growth and puberty* (CDGP) in the differential diagnosis of secondary hypogonadism because it is a transient cause of secondary hypogonadism and is the most common cause of pubertal delay, usually associated with growth delay and short stature in boys.[146,147,374,375]

The initial endocrine event that precedes the phenotypic changes of puberty is activation of the CNS mechanisms that regulate GnRH production, which results in pulsatile LH followed by testosterone secretion, initially at night (see Fig. 19.5) and then throughout the day.[42] Under the influence of increasing testosterone concentrations, secondary sexual characteristics appear between 9 and 13 years of age.

The first physical sign of pubertal development is an increase of testis size to greater than 3 mL in volume and thinning of the scrotal skin that is followed by development of rugal folds and increased pigmentation.[146,147,149,374,375] Subsequently, penile length increases, and pubic hair develops over the next 1 to 2 years, followed by long bone growth (with peak height velocity occurring approximately 3 years later) and development of other secondary sexual characteristics, such as laryngeal enlargement and deepening of the voice. In boys, peak bone mass usually is not reached until the third decade. There is considerable variability in the onset and progression of puberty and the degree of virilization, and these variations are attributable in large part to an individual's genetic and ethnic background.

The absence of sexual maturation and testis size less than 3 mL at 14 years of age is diagnostic of delayed puberty.[146,147,149,374,375] Boys with delayed puberty often experience considerable psychosocial distress due to the lack of sexual and physical development that results in their being considered younger than their peer group and having difficulty competing in athletics. In addition to the lack of sexual development, both boys and their parents are usually also concerned about the boy's failure to undergo a growth spurt and his short stature.

CDGP, or transient secondary hypogonadism, is the cause of delayed puberty in approximately 65% of cases.[146,147,149,374,375] CDGP is usually clinically indistinguishable from permanent organic causes of secondary hypogonadism (e.g., due either to known genetic mutations or IHH) or acquired hypogonadotropic hypogonadism due to an identifiable cause (e.g., pituitary or hypothalamic disease). However, permanent causes of delay puberty occur in less than 10% of cases. Other causes of delayed sexual development and growth account for about 25% of cases, and they are usually clinically apparent on presentation. These causes include functional secondary hypogonadism (e.g., due to chronic systemic illness, hypothyroidism, medications) and primary hypogonadism (e.g., due to Klinefelter syndrome, mumps, chemotherapy, radiation therapy) or androgen resistance.

CDGP is a physiologic variant of normal puberty that is characterized by a slowing of the growth rate and of the timing and tempo of pubertal development.[146,147,149,374,375] Because there is an increased prevalence of CDGP in families with GnRH deficiency (CHH), CDGP could represent a mild variant of CHH in some cases.[376] However, a recent study found distinct genetic profiles in boys with CDGP and CHH.[377] No genes or genetic polymorphisms have been identified that determine the variations in the timing of normal puberty; however, a family history of delayed puberty or being a "late bloomer" is found in 80% of boys with CDGP.

Clinically, a boy with CGDP has congruent delays in growth, sexual development, and bone development. The height age (i.e., the age that corresponds to the child's height when plotted at the 50th percentile on a growth chart), stage of sexual development, and bone age are concordant and delayed compared with chronologic age.[146,147,149,374,375] Height velocity in boys with CGDP is slower than peers of the same chronologic age because puberty accelerates growth velocity.

In the absence of anosmia, hyposmia, or other morphologic abnormalities, CDGP cannot be distinguished clinically or biochemically from permanent CHH (see later discussion). If spontaneous puberty does not develop by 18 years of age in a normosmic patient, the diagnosis is usually CHH. It should be noted that reversal and relapse of hypogonadism after age 18 has been reported in a few older men with anosmic (Kallmann syndrome) or normosmic CHH.[378-380]

Eventually, boys with CDGP undergo normal growth and sexual development, although they do so several years after their peers.[146,147,149,374,375] Normal height is usually attained, but target mid-parental height may not be achieved. In addition, acquisition of peak bone mass may be compromised in some men. Boys with CDGP may experience severe emotional distress and social exclusion or isolation resulting from immature sexual development and short stature. Therefore, after exclusion of organic causes of delayed puberty, low-dose testosterone treatment is usually initiated in boys with CDGP at age 14 years, or sometimes sooner, to induce sexual maturation and growth that is more consistent with that of their peers. Testosterone is usually started at a low dose and gradually increased over several years; it is stopped intermittently to assess whether spontaneous puberty occurs (see later discussion).

Hereditary Hemochromatosis. Hereditary hemochromatosis is a common autosomal recessive disorder that is characterized by inappropriately high gastrointestinal iron absorption resulting in excessive iron storage in a number of tissues, most prominently those of the liver, pancreas, heart, joints, skin, testes, and pituitary gland.[381,382] In most cases, hereditary hemochromatosis is caused by mutations in the hemochromatosis gene (*HFE*), most commonly homozygous C282Y/C282Y mutations (70–85%) or compound heterozygote C282Y/H63D mutations (5–10%), or rarely, by other mutations in iron-regulating genes such as transferrin receptor 2 (*TFR2*), hepcidin antimicrobial peptide (*HAMP*), hemojuvelin (*HJV*), and solute carrier family 40A1 (*SLC40A1*). Homozygous C282Y mutations occur in approximately 1 of every 200 to 400 Caucasians of Northern European descent.

Regardless of the specific mutation causing hereditary hemochromatosis, iron overload results from insufficient hepatic production of hepcidin, a peptide hormone that degrades the iron-exporter protein, ferroportin; this causes unregulated iron absorption in the duodenum and iron overload in tissues.[381,382] Initially, iron overload causes an increase in transferrin iron saturation, followed by an increase in ferritin concentrations in most men with hemochromatosis. Therefore, the biochemical penetrance is high. Evaluation for hemochromatosis should be considered if iron saturation is greater than 45% in men. In the absence of inflammation or cancer, a serum ferritin level higher than 1000 µg/L is associated with greater risk of hepatic cirrhosis in patients with hemochromatosis, and a liver biopsy or MRI for hepatic iron content should be considered.

In contrast to biochemical abnormalities consistent with iron overload, the clinical penetrance of hereditary hemochromatosis is quite low (0.5–2.0%), and manifestations of iron overload (hepatic cirrhosis or carcinoma, diabetes mellitus, heart failure or arrhythmias, arthralgias or polychondritis, bronzing of skin, hypogonadism) are far less common.[381,382] This may be related to the importance of secondary insults to end organs (e.g., alcoholic liver damage) that contribute to clinical manifestations or to earlier diagnosis with increased awareness and screening. Clinical manifestations, when present, usually appear at between 40 and 60 years of age. Hypogonadism, changes in skin color, and arthralgias of the hands are usually the earliest clinical manifestations of iron overload.

Men with end-organ effects from hereditary hemochromatosis almost always have secondary hypogonadism resulting in androgen deficiency and impairment in sperm production due to iron overload in the pituitary gland that causes selective gonadotropin deficiency.[383] Serum testosterone concentrations and sperm counts are low, LH and FSH concentrations are usually low, and gonadotropin response to GnRH stimulation is absent or markedly attenuated. In the presence of cirrhosis caused by hemochromatosis, SHBG concentrations may be elevated; as a result, serum free testosterone concentrations may be low in the presence of normal total testosterone concentrations. Therefore, accurate and reliable assessment of free testosterone are needed to confirm biochemical androgen deficiency in men with hepatic cirrhosis due to hemochromatosis. Iron deposition in the pituitary may be detected by MRI. Iron overload also occurs in the testes and may occasionally cause a modest reduction in testosterone response to gonadotropin stimulation, resulting in combined primary and secondary hypogonadism. However, in most cases, gonadotropin treatment can stimulate normal testicular function, including spermatogenesis and fertility.

The prevalence of hypogonadism in iron overload has declined from between 10% and 100% in older reports to approximately 6% more recently due to earlier diagnosis and less severe iron overload. Hypogonadism is preventable and may be reversed with therapeutic phlebotomy early in the course of iron overload.

Congenital Hypogonadotropic Hypogonadism. CHH, either due to known mutations (see the following discussion) or idiopathic (referred to as IHH, previously known as hypogonadotropic eunuchoidism), is an uncommon, clinically heterogeneous group of disorders characterized by isolated gonadotropin deficiency of varying degree with otherwise normal pituitary function.[384,385] Most cases of CHH are likely due to genetic mutations, many of which remain to be identified. Males with CHH fail to undergo normal puberty, resulting in incomplete sexual maturation or eunuchoidism, androgen deficiency with very low testosterone (usually in the prepubertal range), low to low-normal LH and FSH concentrations, and impaired sperm production. Gonadotropin deficiency is caused by a defect in normal GnRH production or action, as evidenced by absent or abnormal patterns of pulsatile LH secretion[47] (see Fig. 19.7) and the ability of exogenous pulsatile GnRH treatment to restore normal gonadotropin secretion and testis function. Infants with CHH may have micropenis or cryptorchidism. Rarely, a man with normal virilization may develop CHH as an adult.[386]

In approximately 60% of cases, CHH is associated with anosmia or hyposmia and is known as Kallmann syndrome.[384] Developmental failure of olfactory bulbs (detectable on brain MRI) is responsible for the anosmia or hyposmia. The remaining 40% of men have normosmic CHH. In addition, some men with CHH exhibit other developmental defects, including synkinesia (mirror movements), unilateral renal agenesis, cleft lip/palate or high-arched palate, sensorineural hearing loss, digital skeletal abnormalities such as syndactyly or brachydactyly (fourth metacarpal), dental agenesis, eye movement abnormalities or color blindness (deuteranopia), and agenesis of the corpus callosum.

The prevalence of Kallmann syndrome is approximately 1 in 8000 to 10,000 men, and there is a marked male predominance (male-to-female ratio, 4:1–5:1).[387] X-linked recessive, autosomal dominant, and autosomal recessive modes of inheritance are observed, but many cases are sporadic. Family members of a man with Kallmann syndrome may have variable clinical expressions, such as normosmic CHH, isolated anosmia, or CDGP.[50,385,388] In approximately 30% to 40% of cases, Kallmann syndrome is caused by a known mutation of genes that play important roles in the migration of GnRH neurons from the olfactory placode to the hypothalamus and in normal development of the olfactory bulbs during fetal development. These include mutations of *ANOS1* (10–20%), *FGFR1/KAL2* (10%), *PROK2* (5%), and *PROKR2* (5%).[50,385,388] (*ANOS1* and *ANOS2* were formerly known as *KAL1* and *KAL2*). CHH without known gene mutation is sometimes called *idiopathic hypogonadotropic hypogonadism* (IHH).

The *ANOS1* gene is located on the X chromosome and encodes an extracellular adhesion glycoprotein known as anosmin 1.[50,385,388] Mutation or deletion of *ANOS1* results in failure of the normal migration of GnRH neurons from the olfactory placode to the hypothalamus, resulting in severe GnRH deficiency; it is the main cause of X-linked recessive Kallmann syndrome (type 1). The phenotype of Kallmann syndrome caused by *ANOS1* mutations is more severe and less variable than that of other known genetic defects. Synkinesia or dysdiadokinesia is present in 80% and unilateral renal agenesis in 30% of cases. The *FGFR1* gene encodes for a fibroblast growth factor receptor that also plays an important role in the migration of GnRH neurons during development.[50,385,388] Mutations in this gene cause a spectrum of phenotypes, from severe autosomal dominant Kallmann syndrome (type 2) and normosmic CHH to CDGP associated with cleft lip/palate (in 30% of cases), dental agenesis, and skeletal abnormalities such as brachydactyly and syndactyly. *PROK2* and *PROKR2* encode for a peptide and its G protein–coupled receptor that play important roles in normal GnRH neuronal migration and olfactory bulb development.[50,385,388] The clinical phenotypes in men with *PROK2* or *PROKR2* mutations are quite variable, ranging from severe Kallmann syndrome (type 4 or type 3, respectively) to normosmic CHH.

In approximately 30% of cases, normosmic CHH is caused by mutations in genes involved in hypothalamic-pituitary function (particularly during puberty). These include mutations in *GNRHR*, the GnRH receptor (10–20%); *KISS1R*, which encodes the receptor for kisspeptin 1/metastin, an important GnRH stimulatory neuropeptide particularly at the time of puberty (2–5%); *TAC3*, which encodes neurokinin B, another important GnRH stimulatory neuropeptide, and the gene for its receptor, *TAC3R*; *FGFR1/KAL2* (2–5%); *PROK2*; the genes for leptin (*LEP*) and its receptor (*LEPR*), which are associated with massive obesity; and, rarely, the GnRH gene, *GNRH1*.[50,385,388]

Hypogonadotropic hypogonadism is a component of complex genetic syndromes associated with specific dysmorphic features or combined hormonal defects. For example, the *CHARGE syndrome*, characterized by *C*oloboma of the eye or CNS anomalies, *H*eart anomalies, nasal choanal *A*tresia, growth *R*etardation, *G*enital defect (hypogonadism), and *E*ar anomalies (deafness, dysmorphic

ears, and hypoplasia of the semicircular canals), may be associated with Kallmann syndrome or normosmic CHH.[385,388-390] In approximately 60% of cases, CHARGE syndrome is caused by a mutation in the chromodomain helicase DNA-binding protein 7 gene (*CHD7*), which encodes for a chromatin remodeling protein. *CHD7* mutations have been found in approximately 3% to 4% of men with Kallmann syndrome or normosmic CHH, and it is hypothesized that CHH may be a mild variant of the CHARGE syndrome.

X-linked congenital adrenal hypoplasia, characterized by adrenal insufficiency due to adrenal hypoplasia and normosmic CHH, is caused by a mutation in the dose-sensitive sex reversal–adrenal hypoplasia critical region on the X chromosome protein 1 gene (*DAX1*), now known as *NR0B1* (nuclear receptor subfamily 0, group B, member 1), which encodes for an orphan nuclear receptor. Mutations of the SF-1 gene (*NR5A1*), which encodes another orphan nuclear receptor, the prohormone convertase 1 gene (*PC1*), which encodes an enzyme involved in post-translational processing of pituitary prohormones and neuropeptides, and genes for many pituitary transcription factors such as *HESX1* (septo-optic dysplasia or de Morsier syndrome), *LHX3*, *LHX4*, *POUF1*, and *PROP1* cause deficiencies in multiple anterior pituitary and other hormones in addition to gonadotropin deficiency. Mutations in the latter transcription factors may also be associated with specific dysmorphic features. Unlike men with CHH, those with multiple hormone defects usually fail to normalize gonadotropin and testicular function in response to chronic pulsatile GnRH administration.[50,385,388,391]

In the absence of anosmia, hyposmia, or features of Kallmann syndrome (e.g., synkinesia), it is not possible to confidently distinguish an individual who has normosmic CHH not associated with a complex genetic syndrome from someone who has CDGP.[146,147,374,375] In both conditions, there may be a family history of delayed puberty, CHH, or Kallmann syndrome; a history of cryptorchidism; clinical manifestations of delayed sexual maturation or eunuchoidism; and low serum testosterone and low to low-normal gonadotropin concentrations. In contrast to boys with CHH, who have normal height for their chronologic age, those with CDGP usually manifest some growth delay and short stature. Boys with CHH may have a history of micropenis and usually demonstrate pubertal delay beyond 19 years of age, although some individuals undergo spontaneous puberty after 20 years of age or reversal of CHH in adulthood; a subset of the latter may also subsequently relapse with CHH.[378-380] Currently, there is no diagnostic test that completely and reliably distinguishes isolated normosmic CHH from CDGP.

As discussed previously, after organic causes of delayed puberty (e.g., craniopharyngioma) have been excluded, low-dose testosterone therapy is usually initiated in boys with delayed puberty at about 14 years of age to induce sexual maturation and growth.[146,147,374,375] Testosterone is usually discontinued intermittently to assess whether spontaneous puberty occurs, as determined by an increase in testis size. Boys with CHH usually require continued testosterone treatment to achieve and maintain sexual maturation, whereas those with CDGP do not require further treatment after spontaneous secretion of gonadotropin and testosterone commences. Sustained reversal occurs after discontinuation of therapy in up to 10% of men with Kallmann syndrome or normosmic CHH who present initially with absent or partial sexual maturation.[378-380] Therefore, it is reasonable to discontinue treatment briefly to assess the reversibility of hypogonadotropic hypogonadism in all patients.

If fertility is desired, testosterone therapy is stopped and gonadotropin replacement therapy (or in some specialized centers, pulsatile GnRH) is initiated to stimulate sperm production. Previous treatment with testosterone might be expected to suppress endogenous gonadotropin production further; however, previous androgen therapy does not alter the subsequent overall response of spermatogenesis to gonadotropin therapy, although the response to gonadotropins might be slower.[392-394] Gonadotropin therapy is much more likely to stimulate spermatogenesis if there is some evidence of sexual maturation and larger testes at baseline and no history of cryptorchidism or another primary testicular disorder.[386,395] Even in the absence of clinical evidence of hypothalamic-pituitary-testicular disorder, 10% to 20% of men with CHH do not have an adequate gonadotropin or testicular response to chronic pulsatile GnRH therapy, suggesting underlying pituitary or testicular defects.[396]

Men with CHH have varying degrees of gonadotropin deficiency, as evidenced by a persistent but abnormal pattern of pulsatile LH secretion[47] (see Fig. 19.7). In some men with CHH, FSH secretion predominates relative to LH secretion, resulting in some germ cell maturation and spermatogenesis and a rare variant form of CHH known as *isolated LH deficiency*, or the "fertile eunuch syndrome."[397-399] This syndrome is characterized by androgen deficiency of prepubertal onset or eunuchoidism caused by LH deficiency but pubertal or almost adult-size testes in which advanced-stage spermatogenesis is present because of relatively preserved FSH secretion. However, spermatogenesis is usually not completely normal in these men, and they are not fertile, as the name of the syndrome might imply. Because there is only relative gonadotropin deficiency and some spermatogenesis is present, treatment with LH-like activity (hCG) stimulates Leydig cell testosterone production and ameliorates androgen deficiency, stimulating spermatogenesis sufficient for induction of fertility. Men with *isolated FSH deficiency* in the absence of an FSHβ mutation have been reported, but the degree and nature of the defect in pulsatile gonadotropin secretion have not been well documented.[400-402]

Men with inactivating *LHβ mutations* usually demonstrate a lack of pubertal development, impaired spermatogenesis or azoospermia, and infertility.[59,403,404] Recently, however, a man with an LHβ mutation resulting in a partially active LH molecule (as indicated by expression of steroidogenic enzymes in a few mature Leydig cells and low intratesticular testosterone concentrations) was reported to have complete and quantitatively normal spermatogenesis.[80] Complete spermatogenesis was achieved in the presence of very low LH and intratesticular testosterone concentrations and high serum FSH concentrations in this man. Men with inactivating *FSHβ mutations* generally have been found to have azoospermia with undetectable FSH, low or low-normal testosterone, and high LH concentrations.[80,82-85,405,406]

Secondary hypogonadism may be present in several *complex genetic syndromes*, such as Prader-Labhart-Willi, Laurence-Moon-Bardet-Biedl, Alström, Bjornstad, Börjeson-Forssman-Lehmann, Bosma, Chudley, Costello, Gordon-Holmes, Johnson-McMillin, Juberg-Marsidi, LEOPARD (multiple *L*entigines, *E*lectrocardiographic conduction abnormalities, *O*cular hypertelorism, *P*ulmonary stenosis, *A*bnormal genitalia, growth *R*etardation, and sensorineural *D*eafness), Martsof, Moebius-Poland, Roifman, Rud, and Woodhouse-Sakati syndromes.[267,280,407-422] Most of these syndromes are diagnosed by pediatricians and pediatric endocrinologists based on the clustering of specific dysmorphic features and congenital anomalies that are characteristic of the

syndrome.[267] Secondary hypogonadism in these disorders usually causes androgen deficiency of prepubertal onset. Many but not all of these syndromes are associated with CNS abnormalities or intellectual disability. Obesity may contribute to the cause of hypogonadism and may alert clinicians to the potential presence of a complex genetic syndrome. Some, such as the Prader-Labhart-Willi, Laurence-Moon-Bardet-Biedl, and Alström syndromes, have been reported to be associated with both primary and secondary hypogonadism.[270,278,279,281]

Acquired Disorders

Hyperprolactinemia. Hyperprolactinemia is a common cause of secondary hypogonadism. These patients have low testosterone concentrations and low to low-normal gonadotropin concentrations and present with sexual dysfunction (reduced libido and erectile dysfunction), infertility, and gynecomastia.[423,424] Because the male breast usually is not exposed to a relatively high estrogen and progestin milieu needed to induce ductal hyperplasia and glandular formation in women, high prolactin concentrations in men rarely result in galactorrhea. Hyperprolactinemia causes gonadotropin deficiency primarily by suppressing pulsatile hypothalamic GnRH secretion, as evidenced by reduced spontaneous LH pulse frequency and amplitude and by restoration of normal LH pulsatility and testosterone concentrations with dopamine agonist treatment or pulsatile GnRH administration.[425]

Common causes of hyperprolactinemia resulting in clinical secondary hypogonadism are a prolactin-secreting adenoma, pituitary stalk disease (e.g., stalk compression from a non–prolactin-secreting adenoma, traumatic stalk section); hypothalamic disease (e.g., hypothalamic tumors, granulomatous disease); and medications.[423,424]

In contrast to women who usually present with microadenomas, men with prolactin-secreting adenomas usually present with large macroadenomas because of a lack of overt symptoms or possibly a gender-specific difference in the biologic behavior of the tumor.[426,427] In approximately 10% of cases, there is excessive co-secretion of prolactin and GH. In men with prolactin-secreting macroadenomas, serum prolactin concentrations are usually higher than 250 ng/mL, and they can be higher than 1000 ng/mL with tumors larger than 2 cm in diameter. Some patients with very large prolactin-secreting macroadenomas have only modestly elevated serum prolactin concentrations, which is caused by an assay artifact from saturation of both the capture and detection antibodies used in two-site sandwich immunoassays.[428] This phenomenon is known as the pro-zone or "hook" effect and necessitates dilution of serum samples prior to assay. Measurement of prolactin after serial dilution should be considered for all patients with large pituitary tumors and modest hyperprolactinemia.

Diseases affecting the pituitary stalk and hypothalamic diseases may cause hyperprolactinemia because of disruption of the hypothalamic hypophyseal portal tract and transport of dopamine from the hypothalamus to the pituitary in the former condition or loss of hypothalamic dopamine-containing neurons in the latter. Suprasellar extension of a large, non–prolactin-secreting pituitary macroadenoma that compresses the pituitary stalk usually causes hyperprolactinemia with serum prolactin concentrations in the 20- to 250-ng/mL range, although higher concentrations are occasionally seen.[423,424]

Medications that cause hyperprolactinemia (prolactin concentration usually <100 ng/mL) interfere with hypothalamic dopamine production or action or affect the regulation of dopamine secretion by CNS neurotransmitters (e.g., serotonin).[429,430] The medications that most commonly cause hyperprolactinemia are dopamine D_2 receptor antagonists, such as typical antipsychotic drugs (phenothiazines, thioxanthenes, and butyrophenones), some atypical antipsychotic agents (e.g., risperidone, molindone), and gastrointestinal promotility agents (e.g., metoclopramide, domperidone). In contrast, newer atypical antipsychotic medications such as clozapine, olanzapine, quetiapine, ziprasidone, and aripiprazole much less commonly increase prolactin. Other medications that cause hyperprolactinemia less commonly include some tricyclic antidepressants (e.g., clomipramine), monoamine oxidase inhibitors (e.g., pargyline; clorgiline, which is rarely used), and antihypertensive agents (verapamil; α-methyldopa and reserpine, which are rarely used). Selective serotonin and serotonin/norepinephrine reuptake inhibitors in general have minimal to no effect on prolactin concentrations.

Serum prolactin concentrations may be elevated in patients with CKD, in proportion to the degree of renal impairment, because of both increased secretion and decreased clearance, and this may contribute to the hypogonadism associated with chronic renal failure. The mild hyperprolactinemia associated with primary hypothyroidism does not usually suppress gonadotropin secretion significantly or cause clinical secondary hypogonadism in men. However, if primary hypothyroidism is severe and long standing, it may cause slight enlargement of the pituitary gland, which may be confused with a pituitary adenoma.

Treatment is aimed initially at the underlying cause of hyperprolactinemia. In men with prolactin-secreting macroadenomas, treatment is initiated with a dopamine agonist medication such as bromocriptine or carbergoline.[423,424,426,431] Dopamine agonist therapy usually results in a reduction of serum prolactin, decreased tumor size, and improvement in visual field defects. Treatment with these agents may also improve sexual dysfunction, normalize testosterone concentrations, and improve semen quality. In men who remain persistently hypogonadal despite adequate dopamine agonist treatment, testosterone therapy may be initiated to treat manifestations of androgen deficiency. Testosterone is aromatized to estradiol, and this estrogen theoretically might increase prolactin concentrations and tumor growth by direct action on pituitary lactotrophs; this effect may also cause resistance to dopamine agonist therapy.[432] Therefore, monitoring of tumor size is required during testosterone replacement therapy.

In some men who do not respond to dopamine agonist treatment alone, gonadotropin or pulsatile GnRH therapy may be necessary to stimulate spermatogenesis sufficient to induce fertility. Surgery or radiation therapy may be needed for tumors that are resistant to dopamine agonists, and urgent surgery may be needed for pituitary apoplexy or rapidly progressive tumor mass effects such as visual loss. Medications that cause hyperprolactinemia may be stopped or switched to ones that do not elevate prolactin. For antipsychotic and antidepressant medications, such changes should be made in consultation with the patient's psychiatrist.[429] If discontinuing or switching drugs is not an option, testosterone treatment may be needed to treat androgen deficiency. Addition of a dopamine agonist while administration of an offending antipsychotic medication is continued should be done with extreme caution, because there is a risk of exacerbating psychosis.

Opioids. Use of opiates or opioid medications, particularly potent, long-acting narcotic analgesics such as methadone (>30 mg daily), controlled-release or intrathecal morphine sulfate or the transdermal fentanyl patch, and drugs of abuse such as heroin (diacetylmorphine) or time-released oxycodone (OxyContin), profoundly suppress gonadotropin secretion, resulting in severe androgen deficiency.[433-437]

Prolonged use of opioids causes symptomatic androgen deficiency, resulting in sexual dysfunction and long-term consequences such as loss of BMD and increased risk of osteoporosis; this is a common cause of secondary hypogonadism associated with androgen deficiency and impairment in sperm production. Although the benefits and risks of testosterone treatment have not been evaluated in randomized controlled studies,[438] testosterone treatment should be considered in cases of secondary hypogonadism due to chronic use of opioids. In contrast, short-term use of opioids or use of short-acting opioids (e.g., postoperatively) may cause only a transient suppression of gonadotropins and testosterone that does not require treatment.

Administration of opioid antagonists such as naloxone or naltrexone results in an increase in LH pulse frequency in normal men, suggesting that endogenous opioid neuronal systems within the hypothalamus exert a negative regulation on pulsatile GnRH secretion.[439] Therefore, exogenous administration of opioids most likely causes reduced gonadotropin secretion by suppressing hypothalamic GnRH secretion. The action of exogenous opioids on GnRH secretion is probably mediated by μ-opioid receptors. In this regard, the pure μ-opioid receptor agonist methadone more commonly and severely suppresses gonadotropins and testosterone than does buprenorphine, which is a partial μ-receptor, δ-receptor, and opioid receptor–like 1/nociceptin receptor agonist and κ-opioid receptor antagonist.[434,440] Both methadone and buprenorphine are used clinically for detoxification and maintenance treatment of opioid addiction.

In men taking chronic high-dose, long-acting opioids, serum testosterone, LH, and FSH are usually severely suppressed, and sperm production is impaired.[436,441] The most prominent abnormality demonstrated on seminal fluid analysis in men taking methadone is reduced sperm motility (asthenospermia), but abnormalities in sperm morphologic structure (teratospermia) and oligozoospermia are also seen.[367] Functional δ-, κ-, and μ-opioid receptors have been reported to be present on human spermatozoa.[442] Therefore, exogenous opioids may have a direct effect by slowing sperm motility, independent of their effects on the hypothalamic-pituitary-testicular axis.

Sex Steroids. Administration of sex steroids—androgens, progestins, or estrogens—suppresses gonadotropin secretion by negative feedback mechanisms at the hypothalamus or the pituitary gland or both; chronic administration may cause secondary hypogonadism, resulting in androgen deficiency and impaired sperm production.

Synthetic androgens (androgenic anabolic steroids) and testosterone are used by a significant number of teenage boys and men to increase muscle bulk and strength and enhance athletic performance or physical appearance. For these purposes, these androgens are used in extremely high doses in a variety of combinations and patterns for prolonged periods. The prevalence of anabolic steroid abuse ranges from approximately 1% to 6% in various populations, including high school and college students, weightlifters, body builders (who often have muscle dysphoria, an obsessive preoccupation with a muscular appearance), young recreational athletes, and competitive athletes.[131,443,444]

During chronic administration of high-dose androgenic anabolic steroids, serum concentrations of testosterone, LH, and FSH are very low, and sperm counts are usually suppressed to severe oligozoospermia or azoospermia.[131,443-445] Unless testosterone is being administered, serum testosterone concentrations are low because synthetic androgenic anabolic steroids do not cross-react in testosterone assays. Because of the androgenic effects of these anabolic steroids, individuals taking these agents may not complain of androgen deficiency symptoms.

After discontinuation of even prolonged anabolic steroid use, recovery of the hypothalamic-pituitary-testicular axis usually occurs within weeks to months. However, for unclear reasons, some men experience a protracted period of symptomatic hypogonadism that may last for several months to several years, particularly in older men.[131,443-446] It usually is not possible to know whether these men had underlying hypogonadism before taking anabolic steroids; therefore, if secondary hypogonadism is severe, an appropriate workup, which might include sellar imaging (if hypogonadism is severe), is usually needed. Prolonged secondary hypogonadism after androgenic anabolic steroid use often causes sexual dysfunction and depressed mood. Severe symptoms may lead to continued use of these agents and anabolic steroid dependence. Treatment with testosterone to relieve symptoms of androgen deficiency or with gonadotropins (hCG) to stimulate sperm production and induce fertility may be needed. Although poorly studied, off-label treatment with clomiphene citrate and aromatase inhibitors have also been reported to stimulate gonadotropin and testosterone secretion in these men.[447]

Chronic administration of high doses of progestins, such as megestrol acetate or depo-medroxyprogesterone acetate, or estrogens, such as diethylstilbestrol, also suppresses gonadotropins and testicular function, resulting in secondary hypogonadism. Megestrol acetate is used to stimulate appetite in wasting conditions such as cancer and HIV disease. At the doses used for this purpose, it causes severe symptomatic androgen deficiency and suppression of sperm production.[448] Weight gain induced by megestrol acetate is mostly fat rather than lean mass, in part because of the androgen deficiency that it causes.[449] Most importantly, megestrol acetate may cause symptomatic and potentially life-threatening secondary adrenal insufficiency from simultaneous suppression of cortisol production.[448] Both megestrol and depo-medroxyprogesterone acetate have been used to induce medical castration in patients with prostate cancer.[450] Medroxyprogesterone acetate has also been used to reduce libido in psychiatric conditions manifested by deviant sexual behavior (paraphilia), and it is used in combination with testosterone (to prevent androgen deficiency) for suppression of spermatogenesis in male contraceptive development trials.[105,451] Administration of estrogens (e.g., low-dose diethylstilbestrol for prostate cancer), exposure to estrogen-containing substances, or excessive estradiol production by estrogen-secreting tumors (e.g., Sertoli or Leydig cell tumors) suppresses gonadotropin and testosterone production and causes secondary hypogonadism, usually with prominent gynecomastia.[452-455]

GnRH Analogues. GnRH analogues, both agonists and antagonists, severely suppress endogenous gonadotropin and testosterone production (i.e., medical castration); they are used to treat androgen-dependent pathologic states such as locally advanced or metastatic prostate cancer and central precocious puberty.[202,456,457] Administration of GnRH agonists (e.g., leuprolide, goserelin) produces an initial stimulation of gonadotropin and testosterone secretion (known as a flare), which is followed in 1 to 2 weeks by GnRH receptor downregulation and marked suppression of gonadotropins and testosterone to castration concentrations.[202] The initial surge in testosterone concentrations has been associated with clinical flares in metastatic prostate cancer, and there have been reports of increased bladder outlet obstruction, bone pain, pathologic fracture, spinal cord compression, and death. However, these complications are very uncommon, and it is not clear that they are directly related to the initial increase in

testosterone concentrations. To prevent the potential complications associated with the testosterone flare, AR antagonists (e.g., bicalutamide) are usually coadministered with a GnRH agonist for men with metastatic prostate cancer.[458] In contrast to agonists, GnRH antagonists (e.g., degarelix) cause an immediate suppression of gonadotropin and testosterone secretion without a flare; whether clinically relevant outcomes differ between GnRH agonists and antagonists is not clear.[456,457]

Continuous administration of GnRH agonists in men with locally advanced or metastatic prostate cancer induces castration or near-castration testosterone concentrations and causes symptoms of severe androgen deficiency, including sexual dysfunction with reduced libido and reduced spontaneous erections, diminished energy and motivation, depressed mood and irritability, hot flushes and sleep disturbance, decreased memory and concentration, reduced in muscle mass and strength, increased fat mass and insulin resistance, decreased BMD resulting in osteopenia or osteoporosis, gynecomastia and loss of male hair pattern, and decreased hemoglobin and hematocrit, resulting in significant decline in quality of life.[201,202] As a result, increasingly, GnRH agonist therapy is administered intermittently in the treatment of advanced prostate cancer. However, in a substantial number of men who stop GnRH agonist therapy, testicular function remains suppressed, and testosterone concentrations persist within the castrate or hypogonadal range for prolonged periods (up to 1–3 years).[459-461] Risk factors for prolonged testicular suppression are longer duration of GnRH agonist therapy, older age (>70 years), and possibly low testosterone concentrations and hypogonadism that was present before treatment.

Some, but not all, large observational population-based studies have found that prolonged GnRH agonist therapy increases the risk of diabetes mellitus, coronary heart disease, myocardial infarction, sudden cardiac death, stroke, and fractures. Consequently, the US Food and Drug Administration (FDA) has recommended that the risk factors for these diseases should be assessed and the benefits and risks of GnRH agonist therapy weighed before it is used and that monitoring for these conditions should be continued during treatment.[202,462-465] A 2011 meta-analysis of randomized trials reported that androgen deprivation therapy of men with unfavorable-prognosis prostate cancer was not associated with an increased risk of cardiovascular mortality but was associated with an improved prostate cancer–specific mortality rate.[466] However, another meta-analysis of cohort and randomized trials found that androgen deprivation therapy was associated with an increase in nonfatal cardiovascular events and acute myocardial infarction.[467]

Hypopituitarism. A destructive or infiltrative lesion of the pituitary gland or hypothalamus commonly causes impaired pituitary hormone production (hypopituitarism) and gonadotropin deficiency, resulting in androgen deficiency and impairment in sperm production. The prevalence of hypopituitarism has been estimated to be approximately 1 in 2200.[468,469]

Hypopituitarism is most commonly caused by *pituitary adenomas* and their treatment (hypophysectomy or radiation therapy) or by *hypothalamic* or *parasellar tumors* such as craniopharyngioma, meningioma, optic glioma or astrocytoma, metastatic carcinoma (from the breast, lung, colon, or prostate), pinealoma, germinoma, chordoma, and ependymoma; together, these tumors account for approximately 90% of cases.[468,469]

Other conditions of the pituitary or hypothalamus (or both) that cause hypopituitarism include cranial radiation therapy (intracranial tumors, acute lymphoblastic leukemia prophylaxis, nasopharyngeal carcinoma, total-body irradiation), vascular compromise (traumatic brain injury,[470-472] infarction or pituitary apoplexy, subarachnoid hemorrhage, ischemic stroke, vascular malformation), granulomatous or infiltrative disease (sarcoidosis, histiocytosis X, granulomatosis with polyangiitis, hemochromatosis, transfusion-induced iron overload), infection (tuberculosis, fungal infections like aspergillosis or coccidioidomycosis, basilar meningitis, encephalitis, syphilis, Whipple disease), pituitary stalk disease (traumatic injury, e.g., basilar skull fracture or surgical pituitary stalk section, granulomatous disease, lymphocytic infundibuloneurohypophysitis, infection, tumor), lymphocytic hypophysitis (particularly lymphocytic infundibuloneurohypophysitis, which is more common in men, rather than lymphocytic adenohypophysitis, which is more common in women), and autoimmune hypophysitis (e.g., with cytotoxic T-lymphocyte–associated protein 4 inhibitors, e.g., ipilimumab therapy).[470-475] These conditions are discussed in Chapter 9.

Destructive or infiltrative lesions of the pituitary gland (e.g., nonfunctioning pituitary adenoma) usually result in a gradual, progressive loss of anterior pituitary function. In these instances, GH and gonadotropin (LH and FSH) deficiency (i.e., secondary hypogonadism) usually occur initially, followed by deficiencies of TSH (secondary hypothyroidism) and, eventually, ACTH (secondary adrenal insufficiency), resulting in *panhypopituitarism*.[468,469] However, there are many exceptions to this order of loss, depending on the specific location of the pituitary lesion and the nature of the underlying disease process. For example, lymphocytic hypophysitis usually causes ACTH and TSH deficiency without impairment of gonadotropin production, and ACTH deficiency is more common than TSH deficiency after radiation therapy involving the hypothalamic-pituitary axis. Anterior pituitary hormone loss is even less predictable in disease processes involving the hypothalamus, in part because of the more disperse anatomic arrangement in the hypothalamus of nuclei that produce releasing factors for pituitary hormones. Acute destructive processes such as pituitary apoplexy usually cause panhypopituitarism.

Diseases of the hypothalamus or high in the pituitary stalk may be associated with *diabetes insipidus*, which is caused by destruction or retrograde degeneration of neurons producing arginine vasopressin in the supraoptic or the paraventricular nuclei, respectively.[476-479] Processes involving only the pituitary gland do not cause diabetes insipidus.

Hypothalamic and pituitary stalk diseases may cause hyperprolactinemia due to loss of dopamine-containing neurons or interruption of the hypothalamic hypophyseal portal tract and transport of dopamine from the hypothalamus to the pituitary. Pituitary microadenomas or macroadenomas may produce prolactin, and suprasellar extension of nonsecretory pituitary macroadenomas or those secreting other hormones (e.g., GH) may cause hyperprolactinemia by interrupting the hypothalamic-hypophyseal portal system.

Prepubertal boys who have hypopituitarism resulting in gonadotropin deficiency present with delayed puberty and eunuchoidism, and men present with adult androgen deficiency and complaints of reduced libido and erectile dysfunction. However, in patients with secondary hypogonadism, clinicians must be alert to the possibility and clinical manifestations of *deficiencies of other pituitary hormones* (ACTH, TSH, GH, and arginine vasopressin); *excessive pituitary hormone production* by pituitary adenomas and resulting clinical syndromes, such as excessive prolactin production resulting in hyperprolactinemia, ACTH resulting in Cushing syndrome, GH resulting in acromegaly, gonadotropin and free α- and β-subunits (which usually do not result in a hormone excess

syndrome but rarely cause precocious puberty), or, rarely, TSH resulting in hyperthyroidism; and *tumor mass effects* such as headache, visual disturbance, and visual field defects (typically bilateral superior quadrantanopia or bitemporal hemianopia, but a unilateral effect and a variety of visual field defects may be present) and, uncommonly, cerebrospinal fluid rhinorrhea, cranial nerve palsies, temporal lobe epilepsy, and personality changes.[468,469,480,481] It is important to have a high index of suspicion for the presence of secondary adrenal insufficiency in patients with hypothalamic or pituitary disease, because it is a life-threatening and treatable condition that manifests with nonspecific symptoms and signs. In boys with hypopituitarism who present with a clinical picture of CDGP, GH deficiency may occur in conjunction with gonadotropin deficiency and may contribute to short stature and growth delay.

Usually in men with secondary hypogonadism due to hypopituitarism, the serum testosterone level and sperm count are very low, and LH and FSH concentrations are distinctly low or, less commonly, in the low-normal to slightly low range. Men with panhypopituitarism may have more severe testosterone deficiency than those with CHH.[482] The gonadotropin response to acute or chronic GnRH stimulation is not a clinically useful differential diagnostic test, because it does not reliably distinguish between pituitary and hypothalamic disease that cause gonadotropin deficiency in hypopituitarism. If hypopituitarism is suspected on the basis of the initial clinical and laboratory evaluation, further evaluation should include hypothalamic-pituitary imaging, preferably an MRI with gadolinium contrast enhancement, which can better define the presence and extent of hypothalamic and pituitary disease compared with a CT scan (although CT is less expensive and equally sensitive for identifying a pituitary macroadenoma or microcalcifications found frequently in craniopharyngioma, and it more accurately assesses parasellar bone destruction); formal visual field examination; and investigation of anterior pituitary hormone deficiency or excess.[468,469]

Treatment is aimed at the underlying cause of the hypopituitarism and treatment of pituitary hormone deficiency, including treatment of androgen deficiency secondary to gonadotropin deficiency with testosterone replacement therapy.[468,469] With transsphenoidal surgical treatment of pituitary adenomas, pituitary function is improved in approximately 50% of cases. Dopamine agonist treatment of prolactin-secreting pituitary adenomas improves pituitary function in 60% to 75% of cases. If fertility is desired, testosterone treatment is stopped and gonadotropin therapy is initiated, initially with hCG alone. In men with acquired gonadotropin deficiency, normal testicular volumes and no coexisting testicular disease, hCG treatment alone (without addition of FSH therapy) often stimulates spermatogenesis to concentrations sufficient to restore fertility.[79]

Systemic Disorders

Glucocorticoid Excess (Cushing Syndrome). Excessive concentrations of either exogenous or endogenous glucocorticoids (the latter due to pituitary Cushing disease, ectopic ACTH syndrome, or adrenal adenoma) is a common acquired cause of secondary hypogonadism, resulting in symptomatic androgen deficiency and impaired sperm production.[483-486] In contrast to those patients with adrenal adenoma, some men with glucocorticoid excess due to adrenal carcinoma secrete excessive amounts of androgens (and mineralocorticoids) and do not demonstrate manifestations of androgen deficiency.

Glucocorticoids act primarily to suppress gonadotropins via inhibition of hypothalamic GnRH secretion, but they may also have direct suppressive effects on testis function and therefore produce combined primary and secondary hypogonadism. However, high-dose immunosuppressive glucocorticoid therapy is most commonly associated with a hormone pattern characterized by low testosterone and low-normal gonadotropin concentrations, consistent with secondary hypogonadism. Occasionally, in men receiving glucocorticoid treatment, gonadotropins are high normal or slightly elevated, suggesting primary hypogonadism.

Although most commonly observed with high-dose glucocorticoid treatment, daily doses as low as 5.0 to 7.5 mg of prednisone may cause hypogonadism, particularly in older men. Because high doses of glucocorticoids may suppress SHBG concentrations, it is important to confirm the biochemical diagnosis of hypogonadism using an accurate measurement of free testosterone (i.e., calculated free testosterone or free testosterone by equilibrium dialysis). In preliminary studies of men receiving chronic glucocorticoid therapy, testosterone treatment was found to improve muscle mass, BMD, and quality of life.[487]

Chronic Organ Failure. Chronic organ failure, such as in hepatic cirrhosis, CKD, chronic lung disease, or CHF, is a common cause of symptomatic secondary hypogonadism.[4,5] As discussed previously, chronic systemic illness commonly affects the hypothalamic-pituitary-testicular axis at multiple sites and usually causes combined primary and secondary hypogonadism, but many disorders are associated with a hormone pattern characterized by low serum testosterone and low to low-normal gonadotropin concentrations, indicative of secondary hypogonadism.

The cause of clinical and biochemical hypogonadism in these cases is multifactorial and encompasses both the chronic disease itself and its associated conditions of malnutrition, wasting, a proinflammatory state (with elevated proinflammatory cytokines like IL2, IL6, and tumor necrosis factor α [TNFα]),[488] medication use (e.g., alcohol, opiates, glucocorticoids), chronic stress, and other comorbid illnesses. These associated factors play a large role in suppressing gonadotropin concentrations and contribute to the hormonal pattern of secondary hypogonadism associated with chronic organ failure. The degree to which these factors contribute to the clinical and biochemical manifestations of hypogonadism varies considerably among individuals. Furthermore, biochemical confirmation of low testosterone in patients with chronic organ failure or systemic illness may be confounded by alterations in SHBG. Therefore, accurate and reliable measurements of free testosterone are needed to establish biochemical androgen deficiency in the presence of chronic systemic illness.

Hepatic cirrhosis from any cause (e.g., alcoholic or nonalcoholic liver disease) is commonly associated with a hormone pattern that is consistent with primary hypogonadism (i.e., low free testosterone, high LH, and normal to high-normal FSH concentrations) in mild to moderate disease (Child-Pugh class A or B) and with secondary hypogonadism (i.e., low free testosterone and low-normal LH and FSH concentrations) in severe to end-stage liver disease (Child-Pugh class C).[303,304] SHBG concentrations increase progressively with the severity of cirrhosis, resulting in normal or high serum total testosterone concentrations despite low free testosterone concentrations and clinical manifestations of androgen deficiency. In men with cirrhosis, sperm production is commonly impaired, and sperm motility is reduced.

In alcoholic cirrhosis, serum estrone and estradiol concentrations are relatively high as a result of increased production of adrenal androgens (e.g., androstenedione) induced by alcohol and its metabolite, acetaldehyde; reduced clearance of these androgens by the liver; and subsequent aromatization of androstenedione to

estrone and its conversion to estradiol.[4,5] Relative hyperestrogenism is responsible for several of the clinical manifestations commonly observed in men with alcoholic cirrhosis compared with nonalcoholic cirrhosis, including gynecomastia, palmar erythema, plethora, spider angiomas, and loss of male body hair (reduced axillary and pubic hair and a female escutcheon). Men with severe alcoholic cirrhosis usually have atrophic testes (usually soft in consistency) due to direct toxic effects of alcohol.

In men with severe hepatic cirrhosis, pulsatile GnRH secretion and the pituitary response to GnRH are diminished, contributing to secondary gonadal failure.[489] Spironolactone, which is used to treat edema and ascites associated with portal hypertension, is an AR antagonist and an androgen biosynthesis inhibitor. Its use may contribute to symptoms of androgen deficiency, gynecomastia, and hypogonadism. Protein-calorie malnutrition, complications of cirrhosis such as infection, and continued alcohol abuse contribute to the clinical manifestations and cause of low testosterone in these chronically ill men. A preliminary 12-month double-blind, placebo-controlled study in men with cirrhosis and low testosterone concentrations found that testosterone treatment was safe and increased lean body and bone mass and hemoglobin concentrations and reduced fat mass.[305] Successful liver transplantation improves but does not normalize gonadal function, probably because of chronic immunosuppressive treatment with glucocorticoids and other agents.[490]

As described earlier, *CKD* is commonly associated with a hormone pattern of low serum testosterone and elevated gonadotropin concentrations resulting from reduced renal clearance, consistent with primary hypogonadism.[4,5,307,309,311] With increasing stage of CKD, there is progressive reduction in sperm concentration and motility and alterations in sperm morphology.[491] However, the amplitude of pulsatile LH secretion is reduced, suggesting impaired hypothalamic-pituitary function in men with CKD.[492] Gonadotropin secretion may also be suppressed by coexisting uremia, hyperprolactinemia, malnutrition, a proinflammatory state, comorbid conditions (e.g., diabetes), and obesity, and some men demonstrate a hormone pattern that is more consistent with secondary hypogonadism (i.e., with low testosterone and normal to high-normal gonadotropin concentrations). Randomized controlled trials to assess the long-term clinical benefits and risks of testosterone treatment in CKD patients who are high risk of cardiovascular events and mortality have not been performed.[308] Successful renal transplantation usually normalizes concentrations of testosterone and gonadotropins and sperm production, although spermatogenesis and Sertoli cell function recover more slowly and to a lesser extent.[307,309,493]

Men with *chronic lung disease*, especially chronic obstructive pulmonary disease (COPD), commonly have low serum testosterone concentrations.[494-496] The prevalence of biochemical hypogonadism depends on the population studied and varies from 12% in a community-based population to 38% in male veterans, the latter being a population with numerous comorbid conditions that lower testosterone concentrations. In the population of veterans, approximately 75% of men with COPD with low serum testosterone have low or low-normal gonadotropin concentrations, consistent with secondary hypogonadism, and the remainder have elevated gonadotropins, indicative of primary hypogonadism.[495] Coexisting factors that contribute to the clinical symptoms and biochemical diagnosis of hypogonadism in men with severe COPD include muscle wasting, inactivity, and deconditioning; malnutrition and cachexia; chronic stress and inflammation; medications (e.g., glucocorticoids); and hypoxia. Hypoxia suppresses gonadotropin and testosterone secretion independent of glucocorticoid therapy in men with COPD or idiopathic pulmonary fibrosis.[494-497] Preliminary studies have demonstrated an increase in lean mass with testosterone treatment in men with COPD and low testosterone concentrations but inconsistent improvements in muscle strength, including respiratory muscle function, and no effects on endurance or quality of life.

CHF is associated with biochemical androgen deficiency in approximately 25% to 30% of cases.[498-500] Men with CHF who have low serum testosterone usually have normal to low-normal gonadotropin concentrations, suggesting secondary hypogonadism. However, it is unclear whether men with CHF and low testosterone differ from those with normal testosterone in regard to symptoms and signs or response to testosterone therapy.[499] In limited initial clinical trials in men with CHF, testosterone treatment improved exercise tolerance, muscle strength, and oxygen capacity in men with either low or normal testosterone concentrations, suggesting a pharmacologic effect of testosterone independent of the presence of androgen deficiency. In a preliminary randomized controlled pilot study in men with CHF with reduced ejection fraction and low testosterone concentrations, testosterone treatment was safe but did not improve functional capacity, walking distance, left ventricular ejection fraction, brain natriuretic peptide concentrations, or quality of life.[501]

Chronic Systemic Illness. Several chronic systemic illnesses, such as T2DM, malignancy, rheumatic disease, and HIV disease, may also cause secondary hypogonadism characterized by low serum testosterone concentrations and low or low-normal gonadotropin concentrations.[4,5] As in men with chronic organ failure, the cause of clinical and biochemical hypogonadism is multifactorial due to the chronic illness itself and associated obesity (e.g., with diabetes mellitus) or malnutrition (e.g., with malignancy), wasting, proinflammatory state, medication use (e.g., opiates, glucocorticoids), chronic stress, or other comorbid illnesses. These factors suppress gonadotropin concentrations and contribute variably to the clinical and biochemical androgen deficiency seen in individuals with systemic illness. Because systemic illnesses and associated comorbid conditions and medications may alter SHBG concentrations, accurate measurements of free testosterone (i.e., calculated free testosterone or free testosterone by equilibrium dialysis) are needed to confirm biochemical androgen deficiency.

Low serum free testosterone and low or low-normal gonadotropin concentrations, consistent with secondary hypogonadism, occur in 30% to 50% of men with *T2DM*.[502,503] Low testosterone concentrations are associated with nonspecific clinical manifestations that may be caused by androgen deficiency, such as sexual dysfunction and reduced vitality. Insulin resistance and moderate obesity are commonly associated with T2DM. In patients with T2DM and moderate obesity, low total testosterone concentrations commonly result from reduced SHBG concentrations caused by insulin resistance and action on the liver. Therefore, it is important to confirm biochemical androgen deficiency in these men by using calculated free testosterone values or measurements of free testosterone by equilibrium dialysis.

Secondary hypogonadism and clinical manifestations of androgen deficiency may also be caused by comorbid conditions and complications associated with diabetes, such as obesity, atherosclerotic vascular disease, the proinflammatory state of diabetes, diabetic neuropathy, and CKD. A meta-analysis of seven placebo-controlled randomized trials of testosterone treatment in men with T2DM failed to improve glycemic control as assessed by hemoglobin A_{1c} and insulin resistance by homeostatic model assessment of

insulin resistance 2.[504] Therefore, testosterone treatment should only be considered only in those diabetic men with symptomatic androgen deficiency that has been confirmed by accurate free testosterone measurements. If symptoms do not improve with an adequate trial of testosterone therapy (e.g., 6 months), discontinuation of treatment should be considered, particularly in men who had borderline or slightly low testosterone concentrations before therapy.

Men with poorly controlled T1DM may have reduced serum testosterone and gonadotropin concentrations and reduced LH pulse amplitude and frequency, which are not present in those with well-controlled disease and in the absence of obesity.[505,506]

Men with *malignancy* commonly have secondary hypogonadism characterized by low serum testosterone concentrations and low or low-normal gonadotropin concentrations.[364,507,508] As mentioned previously, some men with malignancy present with low testosterone and elevated gonadotropin concentrations, consistent with primary hypogonadism. Malnutrition, wasting (cancer cachexia), systemic inflammation, medication use (e.g., opioid pain medications, glucocorticoids), chronic stress, and concomitant comorbid illnesses contribute to clinical and biochemical hypogonadism in men with cancer. Because SHBG may be reduced as a result of these associated conditions, accurate free testosterone measurements are needed to confirm androgen deficiency.

Primary or secondary hypogonadism may be present before systemic chemotherapy or radiation therapy, as well as after treatment. A low free testosterone concentration with normal or elevated gonadotropin concentrations was found in 40% to 60% of men with advanced malignancy (i.e., metastatic cancer) presenting with malnutrition and men with various stages of Hodgkin disease before chemotherapy.[344,345,364] Low concentrations of free testosterone and bioavailable testosterone were present, respectively, in approximately 78% and 66% of men with a variety of cancers, excluding those with androgen-dependent cancer (prostate, breast) or testicular cancer, most of whom received chemotherapy or radiation therapy or both.[364,507] Low testosterone was associated with reduced quality of life and sexual function.[508]

Men with *rheumatic diseases*, particularly the systemic autoimmune disorder rheumatoid arthritis, may manifest symptoms of sexual dysfunction (reduced libido and erectile dysfunction) and low serum free or bioavailable testosterone and gonadotropin concentrations in approximately 30% of cases.[509,510] Secondary hypogonadism in rheumatoid arthritis may be due in part to systemic inflammation (with elevated proinflammatory cytokines like IL2, IL6, and TNFα), complications such as rheumatoid lung, and treatment with glucocorticoids, but it may also occur early in the course of rheumatoid arthritis in the absence of complications and before glucocorticoid therapy.[509,510] In men with long-standing rheumatoid arthritis, low free testosterone concentrations do not normalize after marked suppression of inflammation induced by anti-TNF therapy.[511] Testosterone treatment may improve symptoms of androgen deficiency, but it does not reduce disease activity.[512]

Men with systemic lupus erythematosus may also demonstrate low free testosterone concentrations in conjunction with normal or low-normal gonadotropin concentrations, indicative of secondary hypogonadism or elevated gonadotropins, consistent with primary hypogonadism.[513-516] Factors that contribute to gonadotropin suppression and secondary hypogonadism include chronic systemic illness and inflammation, major organ involvement or organ failure (heart, lung, brain, kidney), and glucocorticoid therapy.[516] Factors that contribute to primary testicular dysfunction include systemic and local inflammation or vasculitis, organ failure, and treatment with cytotoxic agents such as cyclophosphamide.

In observational cohort studies, low testosterone concentrations are associated with rheumatic autoimmune disease, including rheumatoid arthritis and systemic lupus erythematosus.[517,518] It is possible that the hypogonadism contributes to the immunologic pathophysiology of rheumatic disorders.[519,520] Autoimmune diseases, particularly autoimmune rheumatic diseases (e.g., Sjögren syndrome, systemic lupus erythematosus, rheumatoid arthritis), thyroid disease (Hashimoto disease, Graves disease), and autoimmune neurologic diseases (e.g., myasthenia gravis, multiple sclerosis), occur more commonly in women than in men. Sex steroid hormones, primarily estrogens and androgens, modulate immune function by direct actions on immune cell function and may play a role in sex differences in autoimmunity and in the pathophysiology of autoimmune disorders.

Men with *HIV disease* commonly have hypogonadism characterized by symptomatic androgen deficiency and impaired sperm production with low free testosterone concentrations due to combined primary and secondary hypogonadism.[300,521] Hypogonadism occurred in up to 50% of men with HIV wasting before the advent of HAART. Although androgen deficiency is less common since the advent of HAART, it occurs in approximately 20% of HIV-infected men. In 75% to 90% of cases, low free testosterone is associated with low or low-normal gonadotropin concentrations, consistent with secondary hypogonadism.[522,523] In the remaining 10% to 25% of cases, gonadotropin concentrations are elevated, indicating primary hypogonadism.

As in other chronic systemic illnesses, the cause of hypogonadism in men with HIV disease is multifactorial.[4,5] In addition to HIV infection itself, gonadotropin suppression and secondary hypogonadism may be caused by malnutrition, wasting, and cachexia; opportunistic infections affecting hypothalamic-pituitary function (e.g., CMV, *T. gondii*); systemic inflammation (with elevated concentrations of cytokines like IL2, IL6, and TNFα); medications (e.g., opiates, glucocorticoids, megestrol acetate); ongoing substance abuse (e.g., alcohol); and acute and chronic illnesses. Conditions that may play a role in causing primary hypogonadism include opportunistic infections affecting the testes (CMV, *M. avium intracellulare, T. gondii*), malignancies involving the testes (Kaposi sarcoma, lymphoma), systemic inflammation, and medications (chemotherapy for secondary neoplasms, ketoconazole).[300,521,522,524]

Protein-calorie malnutrition may suppress SHBG concentrations, and advancing HIV infection is associated with elevated SHBG concentrations. Therefore, accurate measurements of free testosterone concentrations should be used to evaluate men with HIV disease for androgen deficiency.[523,525] Sperm production associated with abnormalities in sperm motility and morphologic structure and testicular atrophy may be present. It is important to recognize that HIV may be present in semen even when it is undetectable in plasma.[300]

In small clinical trials, treatment with testosterone or an androgenic anabolic steroid has been demonstrated to improve libido and sexual function, increase muscle mass and strength and BMD, decrease fat mass, improve mood, well-being, and quality of life, and increase hematocrit in HIV-infected men with low serum testosterone concentrations.[116]

Men with chronic *spinal cord injury* at any level resulting in tetraplegia or paraplegia may have secondary hypogonadism with low serum testosterone and low or normal gonadotropin

concentrations.[350,351] Less commonly, some men with chronic spinal cord injury demonstrate low testosterone and elevated gonadotropins concentrations (consistent with primary hypogonadism) or combined primary and secondary hypogonadism. In men with lower spinal cord injury causing paraplegia, there may be a transient suppression of testosterone concentrations within 4 months after the injury that resolves in most cases.[352,526] Gonadotropin suppression is caused in part by several conditions associated with spinal cord injury, such as acute and chronic trauma and stress associated with the injury and attendant complications; obstructive sleep apnea; obesity or nutritional compromise; hyperprolactinemia (usually associated with medications); and medication use (e.g., glucocorticoids, opioids, CNS-active drugs). The benefits and risks of testosterone treatment in patients with spinal cord injury are not clear.

Thalassemia major, or β-thalassemia, is an autosomal recessive disorder characterized by absent or severely deficient synthesis of β-globulin chains of hemoglobin resulting in severe anemia that requires lifelong blood transfusions. It is common in the Mediterranean region, in India, and in Southeast Asia. Chronic blood transfusions in patients with β-thalassemia cause *transfusion-related iron overload* in tissues and produce clinical manifestations similar to those that occur in patients with hereditary hemochromatosis. Transfusion-related iron overload may also occur in patients with sickle cell anemia, refractory aplastic anemia, or myelodysplastic syndrome.

Iron deposition in the testes and pituitary gland usually causes combined primary and secondary hypogonadism.[527-529] However, males with transfusion-related iron overload usually exhibit a hormonal pattern indicative of secondary hypogonadism, with low serum free testosterone and low to low-normal gonadotropin concentrations in most cases. Hypogonadism due to transfusion-related iron overload may manifest with androgen deficiency and impaired sperm production; affected boys usually have short stature and pubertal and growth delay.[530] Early iron chelation therapy with agents such as deferoxamine, deferasirox, or deferiprone may reverse hypogonadism and improve survival.[531] In men with long-standing β-thalassemia, chelation therapy does not reverse hypogonadism.[532]

Sickle cell disease may be associated with low serum testosterone and low to low-normal gonadotropin concentrations, indicative of secondary hypogonadism.[533-535] Gonadotropin suppression may be caused by transfusion-induced iron overload (although much less commonly than in men with β-thalassemia[348,536]), hypothalamic-pituitary microinfarctions, medications (e.g., opioids for chronic pain), systemic inflammation, nutritional deficiencies, and chronic systemic illness and stress secondary to repeated painful vaso-occlusive events. As discussed earlier, men with sickle cell disease may present with primary hypogonadism due to testicular microinfarctions caused by vaso-occlusive events or iron overload affecting the testes. Priapism, which may occur with vaso-occlusive events, has been reported in patients receiving testosterone therapy.[531,537] As in β-thalassemia, early iron chelation therapy may reverse hypogonadism.

Uncommonly, boys or men with *cystic fibrosis* have low serum testosterone and low to low-normal gonadotropin concentrations, a hormonal pattern consistent with secondary hypogonadism.[538] Chronic systemic illness and inflammation, malnutrition, and glucocorticoid use may contribute to gonadotropin suppression.

Nutritional Disorders or Endurance Exercise. Starvation, malnutrition, and eating disorders (anorexia nervosa) suppress gonadotropin and testosterone secretion, resulting in symptomatic secondary hypogonadism with androgen deficiency (usually manifested by reduced libido, sexual activity, and performance) and impaired sperm production; these effects are reversed with restoration of food/calorie intake and weight gain. Fasting for periods of 3 to 5 days suppresses gonadotropin and testosterone secretion and decreases LH pulse amplitude and frequency.[539-541] These changes are reversed completely by pulsatile GnRH administration or low-dose recombinant human methionyl leptin replacement, suggesting that short-term starvation suppresses leptin production, which in turn suppresses the hypothalamic GnRH pulse generator.[542-544] Severe protein-calorie malnutrition, often associated with other nutritional deficiencies, may cause severe suppression of testosterone and elevation of gonadotropin concentrations, indicative of primary hypogonadism.[540,545]

Chronic *endurance exercise* results in low serum testosterone, low to low-normal gonadotropin concentrations, and impaired sperm production and motility, consistent with secondary hypogonadism.[546-548] High-intensity endurance training and exercise, such as occurs in the military and with overtraining in athletes, is associated with relative calorie deprivation (resulting in energy expenditure that is greater than energy intake, i.e., a relative energy deficit) and intense stress that causes more severe suppression of gonadotropin and testosterone concentrations and symptoms of androgen deficiency than is seen with chronic lower-intensity endurance exercise. This condition has been referred to as relative energy deficit in sport by the International Olympic Committee.[539,546-549] Suppression of the hypothalamic-pituitary-testicular axis resolves with cessation of training and increased calorie intake.[546,547] Other than reduced spermatogenesis, the clinical consequences of androgen deficiency induced by endurance exercise are not clear.[550] In contrast to chronic endurance exercise, short-term endurance or resistance exercise in some men results in an acute and transient increase in testosterone concentrations that is modified by the intensity of exercise and prior training and is possibly related to hemoconcentration, reduced metabolic clearance, or transient increases in serum LH concentrations.[551]

Mild to moderate obesity results in reduced SHBG and total testosterone concentrations. Free testosterone is usually normal but may be reduced in association with low or low-normal gonadotropin concentrations in some men, particularly in those with comorbid conditions such as T2DM or obstructive sleep apnea.[552-555] In men with *morbid obesity* (body mass index [BMI] >40 kg/m^2) or massive obesity (BMI >45 kg/m^2), serum free testosterone is low, gonadotropin concentrations are low or low normal, and LH pulse amplitude (but not frequency) is reduced, indicative of secondary hypogonadism.[556] Morbidly and massively obese men often complain of reduced libido and sexual dysfunction, but these symptoms are confounded by obesity and comorbid conditions associated with morbid obesity, such as depression, diabetes, and obstructive sleep apnea. Gonadotropin suppression and androgen deficiency is likely due to proinflammatory cytokines and dysregulated leptin signaling, as well as obesity-related comorbidities.[555,557] Bariatric surgery and substantial weight loss increase serum gonadotropin and testosterone concentrations, but modest weight loss achieved by dieting is less effective in reversing obesity-related hypogonadism.[555,558-561] In a small, 56-week, randomized, double-blind, placebo-controlled trial in men with mild to moderate symptoms of androgen deficiency and low testosterone concentrations, testosterone treatment plus a very low energy diet improved symptoms and reduced fat mass while maintaining lean mass versus diet alone that resulted in reductions in both fat and lean body mass.[562,563]

Morbid obesity may be complicated by *obstructive sleep apnea* syndrome. Men with untreated or inadequately treated obstructive sleep apnea have low gonadotropin and testosterone concentrations in part related to but also independent of obesity and age.[553,564,565] Adequate treatment with continuous positive airway pressure (CPAP) may improve symptoms (e.g., erectile function) and reverse biochemical secondary hypogonadism in some but not all men. Treatment of hypogonadism with relatively high doses of testosterone (e.g., doses associated with the use of parenteral testosterone esters) may induce or worsen obstructive sleep apnea in men with predisposing conditions such as obesity and in older men.[553,566-570] Testosterone replacement therapy of obese men with obstructive sleep apnea that produce more physiologic testosterone concentrations has been demonstrated to improve sexual desire without inducing or worsening obstructive sleep apnea.[571]

Acute and Critical Illness. Acute and critical illnesses, including medical and surgical illnesses requiring hospital or intensive care unit admission (e.g., myocardial infarction, respiratory illness, sepsis, burns, surgery, polytrauma, stroke, traumatic brain injury, liver disease, fractures), suppress gonadotropin and testosterone secretion as a result of combined primary and secondary testicular dysfunction.[572-575] However, the predominant hormone pattern during acute or critical illness is low serum testosterone with low or low-normal gonadotropin concentrations, suggesting secondary hypogonadism. Spontaneous LH pulse amplitude is reduced, but pulse frequency is maintained, and pulsatile GnRH administration only partially corrects secondary hypogonadism, underscoring the presence of concomitant pituitary and testicular defects.[576] For unclear reasons, aromatization of testosterone to estradiol and serum concentrations of estradiol may be increased, sometimes markedly, in patients with acute or critical illness despite low testosterone concentrations.[577] Elevated estradiol concentrations are associated with fatality in critically ill and injured patients.[578-581] A caveat regarding these studies is that estradiol was measured by immunoassay, not by state-of-the-art mass spectrometry-based assays that are more accurate, sensitive, and specific than immunoassays for estradiol measurements in men.[582]

The severity and duration of testosterone suppression are related to the severity of the acute or critical illness, the presence of underlying chronic systemic illnesses, age, and the medications used (e.g., glucocorticoids, opioids).[572,573] Recovery of testosterone and gonadotropin concentrations may take several weeks to months, depending on the severity and duration of the acute illness, duration of subacute recovery and rehabilitation, complications including malnutrition, medications, and underlying chronic systemic illnesses or organ failure. In the presence of underlying chronic disease or organ failure, hypogonadism may persist long after recovery from the acute illness. For these reasons, evaluation for underlying hypogonadism should not be performed during acute or subacute illness and recovery. Assessment should be delayed for several months until recovery to the individual's baseline or near-baseline clinical condition has occurred.

Aging. As discussed earlier, aging is associated with a gradual and progressive decline in total and free testosterone concentrations; as a result, an increasing proportion of older men have low serum testosterone concentrations in the hypogonadal range.[312-314] The prevalence of clinical androgen deficiency is 6% to 9% and increases with age, reaching 18% to 23% among men in their 70s.[196,197] Serum gonadotropin concentrations increase with aging but do not usually rise above the normal range until very old age, usually beyond 70 years of age.[314] Therefore, the most common hormonal profile observed in clinically hypogonadal middle-aged to older men is low testosterone with normal LH and FSH concentrations, indicative of secondary hypogonadism. Pulsatile LH secretion is abnormal and is characterized by disorderly LH pulses of reduced amplitude; it is normalized by exogenous pulsatile GnRH administration, suggesting a defect in hypothalamic GnRH secretion.[316]

The presence of obesity, chronic systemic illness or organ failure, medications, or malnutrition or wasting syndromes that occur more frequently with increasing age may contribute to suppression of gonadotropin and testosterone production in middle-aged to older men. Conversely, the age-related decline in testosterone may also contribute to the susceptibility and severity of clinical hypogonadism that occur in these conditions.[200,318] Many of the comorbidities that contribute to low testosterone concentrations in older men are potentially reversible or treatable (functional hypogonadism, see later discussion). Therefore, management of underlying causes of functional causes of hypogonadism and symptoms androgen deficiency in older men should be utilized as an initial or adjunctive approach to testosterone replacement therapy.[583]

Previous relatively small, short-term studies of testosterone treatment in heterogeneous populations of older men have produced conflicting results, with most finding beneficial effects of testosterone treatment on body composition (increasing lean mass and decreasing fat mass) but less consistent effects on muscle strength and performance, BMD, sexual function, vitality, and cognitive function.

Recently, results of the Testosterone Trials, a coordinated set of seven double-blind, placebo-controlled studies that evaluated the short-term effects of testosterone treatment in 788 older men (average age of 72 years old) with unequivocal hypogonadism (symptoms and signs of low libido; difficulty walking and slow walking speed; and/or low energy; and average of two morning serum total testosterone concentrations <275 ng/dL) with no apparent cause of hypothalamic-pituitary-gonadal disease. Compared to placebo, testosterone treatment for one year that increased and maintained testosterone concentrations to the mid-normal range for young men significantly improved sexual function (sexual activity, libido and erectile dysfunction), anemia and hemoglobin, volumetric BMD and estimated bone strength; slightly improved walking distance, mood and depressive symptoms; and did not improve multiple domains of cognitive function and vitality. There has been controversy about the clinical importance of these findings. In addition, testosterone treatment caused erythrocytosis (hemoglobin concentration >17.5 g/dL) and an increase in PSA concentration >1.0 ng/mL in small number of men; and increased noncalcified coronary artery plaque volume on CT angiography. There was no difference in LUTS or cardiovascular or prostate adverse events in testosterone- and placebo-treated men (although the Testosterone Trials were underpowered for the latter outcomes).[162,319-323]

Larger, long-term, randomized trials are needed to determine the balance of clinical benefits and risks (particularly prostate cancer and cardiovascular risks) associated with testosterone treatment in older men. For now, testosterone treatment should be considered on an individual basis only for older men who have clinically significant symptoms and signs of androgen deficiency and unequivocally low serum testosterone concentrations, and only after a careful discussion of the uncertainty regarding the benefits and risks of treatment.[116] In addition, in older men, there should be consideration of treatment of underlying comorbidities and discontinuing medications that may cause functional hypogonadism.

Isolated Impairment of Sperm Production or Function

Congenital or Developmental Disorders

Congenital Adrenal Hyperplasia. If untreated or inadequately treated with glucocorticoids, congenital adrenal hyperplasia caused by deficiency of 21-hydroxlase or 11β-hydroxylase results in excessive secretion of adrenal androgen precursors (including androstenedione, DHEA, and 11-hydroxyandrostenedione) that are converted to testosterone and other androgens (e.g., 11-ketotestosterone). Elevated circulating androgen concentrations suppress gonadotropin secretion by negative feedback regulation, which in turn decreases endogenous testosterone secretion and sperm production, resulting in secondary hypogonadism. Excessive adrenal androgen production may offset testicular androgen deficiency, so secondary hypogonadism may be manifested by an isolated impairment of sperm production and function.[584]

Glucocorticoid therapy at dosages that suppresses serum ACTH concentrations to normal or low levels reduces excessive adrenal androgen production and may restore gonadotropin secretion and may normalize testis function, including spermatogenesis. As discussed previously, supraphysiologic glucocorticoid treatment is usually required to reduce adrenal androgen concentrations to normal, and the high dosages of glucocorticoids suppress the hypothalamic-pituitary-testicular axis and result in low gonadotropin, testosterone, and sperm concentrations in many men with congenital adrenal hyperplasia. In addition, some men with congenital adrenal hyperplasia continue to manifest impaired sperm production and function due to irreversible testicular damage caused by large TARTs.

Isolated FSH Deficiency and *FSHβ* Mutations. Rare cases of men with isolated FSH deficiency in the absence of *FSHβ* gene mutations have been reported; these patients had isolated impairment in sperm production characterized by azoospermia or severe oligozoospermia, and hypospermatogenesis or maturation arrest was found in the few who underwent testis biopsy.[400-402] These men had normal virilization, normal concentrations of testosterone and LH, low to undetectable serum FSH concentrations with poor or no response to GnRH administration, normal LH, and normal inhibin B and activin A concentrations when tested. In one man, administration of recombinant human FSH (rhFSH) alone resulted in a robust increase in sperm counts and induced fertility on two occasions.

Men with inactivating mutations of *FSHβ* have been found generally to have azoospermia with undetectable FSH, low or low-normal testosterone, and high LH concentrations.[82-85,405,406] In one man, rhFSH administration was demonstrated to increase testosterone concentrations, suggesting that FSH-stimulated Sertoli cells may enhance LH-induced Leydig cell production of testosterone via a paracrine mechanism.[585]

Acquired Disorders

Androgen Administration or Excess. Exogenous testosterone administration (in normal men or in men with partial hypogonadism)[586] or stimulation of endogenous testosterone production by hCG administration[587] or ectopic hCG-secreting tumors (e.g., testis cancer, lung cancer)[588] suppresses pituitary gonadotropin secretion by negative feedback regulation; this in turn suppresses spermatogenesis by the testes in the presence of normal or high serum testosterone concentrations (i.e., secondary hypogonadism with isolated impairment of sperm production).[589,590] Use of some androgenic anabolic steroids (e.g., nandrolone) may also produce low gonadotropin concentrations and isolated reduction in spermatogenesis while providing sufficient androgen activity to avoid clinical androgen deficiency; however, endogenous testosterone production is usually also suppressed by androgenic anabolic steroid use, resulting in low serum testosterone concentrations.

Discontinuation of androgen or hCG administration results in restoration of normal gonadotropin secretion and recovery of normal sperm production and testosterone production by the testis. Long-term anabolic steroid abuse in athletes has been reported to be associated with testicular atrophy and severe oligozoospermia or azoospermia that persists for several months to years after discontinuation of the performance-enhancing agents.[445] Suppressed sperm production induced by anabolic steroids may respond to treatment with hCG or with clomiphene citrate (off-label use).[447,591] Administration of testosterone in combination with progestins in normal men has been the main strategy used to suppress sperm production in recent hormonal male contraceptive development trials.[105]

Malignancy. Malignancies that occur commonly in men of reproductive age (e.g., testicular cancer, Hodgkin disease) manifest with impaired sperm production and function before chemotherapy or radiation therapy in 30% to 80% of cases.[343-345,364] Among men with cancer who provided semen samples for cryopreservation before treatment, approximately 64% had abnormal semen parameters, and 12% had no viable sperm.[592]

In population studies, testicular cancer is associated with infertility. This association may reflect abnormal testicular development, termed *testicular dysgenesis syndrome*, caused by exposure to environmental gonadotoxins or endocrine disruptors (e.g., estrogens) or by an underlying genetic predisposition.[343,364,593] Testicular dysgenesis syndrome is also associated with cryptorchidism and hypospadias, and the former is associated with an increased risk of testicular cancer and abnormal spermatogenesis. Ectopic hCG secretion and possibly increased scrotal temperature associated with cancer within the testis may also contribute to impaired spermatogenesis in men with testicular cancer.[593] Hodgkin disease and other lymphomas and leukemias may be associated with fever, weight loss, and systemic inflammation.[593] These cancers may also involve the testis. All of these factors may play a role in impairing sperm production. Men with these cancers who have systemic disease, symptoms, or inflammation may present with low-normal testosterone, suppressed gonadotropin concentrations, and abnormal semen analysis, consistent with secondary hypogonadism causing isolated impairment of sperm production or function.

Hyperprolactinemia. Men with severe hyperprolactinemia (e.g., prolactin concentrations >200 ng/mL) develop secondary hypogonadism causing androgen deficiency and impaired sperm production. Mild hyperprolactinemia may be associated with isolated impairment of sperm production.[594] In most of these cases, gonadotropin and testosterone concentrations are normal, and spermatogenesis is not improved with dopamine agonist treatment.[595] Therefore, hyperprolactinemia does not contribute to impairment in sperm production and probably is not clinically significant in most cases. In most instances, abnormal sperm production and function are caused by a primary testicular disorder, such as idiopathic oligozoospermia or azoospermia. Rarely, some men with moderate hyperprolactinemia (e.g., prolactin concentrations of 100–200 ng/mL) have low-normal testosterone and gonadotropin concentrations and isolated impairment of sperm production that respond to dopamine agonist treatment.[594]

Androgen Resistance Syndromes

Congenital Disorders

Congenital androgen resistance and insensitivity syndromes are usually caused by defects in androgen action due to mutations

in the *AR* gene or in the steroid 5α-reductase type 2 gene, *SRD5A2*.[125,136,596,597] Males with severe defects in androgen action present at birth either as phenotypic females, as occurs with *complete androgen insensitivity syndrome* (CAIS, previously known as testicular feminization syndrome), or as males with ambiguous genitalia and *46,XY DSD* (previously termed *male pseudohermaphroditism*).[597] Individuals with *partial androgen insensitivity syndrome* (PAIS) present with varying degrees of impaired androgen action and mildly to severely disordered male sexual development.

CAIS usually presents as a 46,XY phenotypic female with normal breast development, primary amenorrhea, and absence of body hair.[597] Severe androgen insensitivity results in absence of facial, axillary, and pubic hair; normal-appearing female external genitalia and distal two thirds of the vagina; and poorly developed or absent male internal genitalia (prostate, epididymides, seminal vesicles, and vasa deferentia) as a result of fetal androgen resistance. In adults with CAIS, female breast development is present due to conversion of normal to high concentrations of testosterone (which are secreted by the testes at puberty) to estradiol, which stimulates breast development. Because testes that are intra-abdominal or inguinal in location at birth secrete AMH normally during fetal development, female internal genitalia (proximal vagina, uterus, and fallopian tubes) are absent.

There is considerable variation in the presentation of individuals with PAIS.[597] Some of these males present at birth with ambiguous genitalia, whereas others present at puberty or in adulthood with mild genital abnormalities or relatively normal genital development. Clinical manifestations of androgen deficiency and disordered male sexual development range from severe undervirilization to near-normal virilization with infertility. In men with PAIS, manifestations that are indicative of disordered sexual development, such as microphallus, hypospadias, scrotal abnormalities (e.g., bifid scrotum), cryptorchidism, and gynecomastia, are common. Gynecomastia is present in almost all of these individuals.

As a result of the variability in clinical manifestations, PAIS encompasses many disorders, previously referred to as Reifenstein, Lubs, Rosewater, and Gilbert-Dreyfus syndromes. For example, Reifenstein syndrome is characterized by hypospadias, gynecomastia, undervirilization, a small prostate gland, cryptorchidism, and impaired spermatogenesis. However, even in the same family, different members may have different clinical manifestations. Some family members may not have hypospadias, and others may be normally virilized. Given this degree of variability in manifestations, the older eponyms are not clinically useful.[597]

Some men with PAIS have no evidence of disordered male sexual development and present with isolated impairment of sperm (idiopathic oligozoospermia or azoospermia), occasionally in association with gynecomastia, high to high-normal testosterone concentrations, and elevated LH concentrations. This disorder is referred to as minimal AIS.[136,596]

In CAIS and PAIS, serum testosterone concentrations are high or high normal with high serum LH concentrations, but FSH concentrations are usually normal. Most 46,XY individuals with CAIS have autosomal recessive mutations of the *AR* gene on the X chromosome that alter its primary sequence and structure (almost always resulting in CAIS) or its function, resulting in impaired androgen binding to AR, AR binding to DNA, or AR transactivation.[136,596] In men with PAIS, the correlation of *AR* genotype and clinical phenotype is relatively poor. In many men with PAIS or minimal AIS, no mutations in *AR* are identifiable. These men may have high CAG repeat length in the *AR* gene, misdiagnosis with unrecognized mutations of other genes such as *SRD5A2*, or mutations of coactivators or corepressors that regulate AR function.

An increase in the number of trinucleotide CAG repeats in the first exon of the *AR* gene results in expansion of the polyglutamine tract in the N-terminal domain of the AR.[139] The CAG repeat length is inversely correlated with AR function and action. Pathologic increase to more than 40 to 62 CAG repeats (normal range, 11–35) causes Kennedy disease (spinal and bulbar muscular atrophy), a rare neurodegenerative disease that is thought to be caused by neurotoxicity from intracellular aggregation of the abnormal AR and associated coregulator proteins (see earlier discussion).[137,138] Men with Kennedy disease have clinical manifestations of partial androgen resistance, including gynecomastia, sexual dysfunction, oligozoospermia or azoospermia, and infertility associated with high testosterone and high or normal gonadotropin concentrations. Higher CAG repeat numbers within the normal range have been reported to be associated with decreased virilization, impaired spermatogenesis and infertility, and gynecomastia in some studies but not others.[139]

5α-Reductase deficiency, caused by an autosomal recessive mutation in *SRD5A2*, is a rare condition similar to PAIS.[598] Affected individuals typically present with markedly ambiguous genitalia, usually characterized by a clitoris-like phallus, a severely bifid scrotum, an apparent vaginal opening with perineal and scrotal hypospadias (termed *pseudovaginal perineoscrotal hypospadias*), an atrophic prostate, and testes located in the inguinal canal or scrotum or sometimes intra-abdominally (cryptorchidism). In contrast to men with AISs, wolffian duct differentiation is unaffected, and patients with 5α-reductase deficiency have normal male internal genitalia (epididymides, seminal vesicles, ejaculatory ducts, and vasa deferentia). AMH secretion by the fetal testes causes regression of müllerian duct structures, so no female internal genitalia develop.

Because ambiguous genitalia resemble female more than male external genitalia, individuals with 5α-reductase deficiency are usually raised as females.[125] However, with the marked increase in testosterone production by the testes at puberty, partial virilization occurs (i.e., penile growth, rugation and pigmentation of the scrotum, increased muscle mass and height, deepening of the voice, increase in libido, and spontaneous erections), and some of these individuals take on a male gender role at puberty, depending on complex psychosocial factors and cultural background. Sebum production is normal in these men. Because normal androgen action in the skin and prostate requires conversion of testosterone to DHT by 5α-reductase, men with 5α-reductase deficiency do not develop a male body hair pattern, and the prostate gland remains nonpalpable. Prostate cancer and BPH have not been reported in these men.

Men with 5α-reductase deficiency have high-normal to high serum testosterone and normal to slightly elevated LH and FSH concentrations (LH > FSH). Serum DHT concentrations are low, and the serum testosterone/DHT ratio is variably elevated. Spermatogenesis is impaired (oligozoospermia or azoospermia) as a result of cryptorchidism, but normal sperm production has been reported in some men with descended testes.[599]

Individuals with CAIS are usually raised as females and undergo orchidectomy (particularly if the testes are intra-abdominal) and treatment with estrogen replacement; more recently, testosterone therapy for reduced sexual functioning has been shown to be more effective than estrogen.[597,600] In men with PAIS or 5α-reductase deficiency, virilization has been induced with high-dose testosterone treatment, which increases serum

testosterone concentrations to above the normal range and normalizes DHT concentrations.[597]

Acquired Disorders

AR antagonists (flutamide, bicalutamide, and nilutamide) induce androgen resistance and are used to treat androgen-dependent prostate cancer.[601] Drugs such as spironolactone, cyproterone acetate, marijuana, and H_2 receptor antagonists (specifically cimetidine) have AR antagonist activity.[602-606]

Men with *celiac disease* or gluten-sensitive enteropathy may experience manifestations of androgen deficiency, including reduced virilization, sexual dysfunction, impaired sperm production and function, and infertility. They may also demonstrate high to high-normal concentrations of serum total and free testosterone and high LH concentrations, indicative of androgen resistance.[607-610] Manifestations of androgen deficiency and biochemical androgen resistance may improve with dietary gluten restriction and improvement in small bowel atrophy in some men.[609] Malnutrition, nutritional deficiencies, chronic systemic illness, and hyperprolactinemia may occur in men with celiac disease and may contribute to their clinical manifestations. Serum DHT concentrations may be low despite high testosterone concentrations in men with celiac disease, suggesting that partial acquired 5α-reductase deficiency may also be present and may play a role in androgen resistance. The main source of circulating DHT is from conversion of testosterone to DHT by 5α-reductase type 1 in the skin and liver.[608] However, 5α-reductase is also present in the gastrointestinal tract, so it is possible that loss of enzyme activity in the small bowel with active celiac sprue contributes to low DHT concentrations.

Treatment of Androgen Deficiency

Functional Versus Organic Causes of Hypogonadism

Prior to initiating testosterone replacement therapy, it is important to consider whether the cause of hypogonadism is functional or organic.[200] *Organic hypogonadism* is caused by congenital/developmental, destructive, or infiltrative disorders of the hypothalamus, pituitary gland, or testes that result in *permanent* hypogonadism. Generally, organic hypogonadism presents with clinically unequivocal severe androgen deficiency (also referred to as classical hypogonadism). Most causes of primary hypogonadism and some causes of secondary hypogonadism are organic (see Tables 19.7 and 19.8). *Functional hypogonadism* is caused by nondestructive suppression of hypothalamic, pituitary, or, uncommonly, testis function that is *potentially reversible without medical or surgical therapy*. Drug-induced primary hypogonadism is a functional cause. Many causes of secondary and combined primary and secondary hypogonadism are due to functional gonadotropin suppression.

Management or treatment of functional causes of hypogonadism might improve or resolve clinical and biochemical androgen deficiency and should be considered before initiating testosterone replacement therapy. For example, functional hypogonadism caused by hyperprolactinemia may be treated by discontinuation of medications that cause hyperprolactinemia or dopamine agonist therapy; opioids, glucocorticoids, CNS-active medications, or progestins may be reversed by discontinuation of the offending drug; nutritional deficiency may be corrected by nutritional supplementation and weight gain; morbid obesity may be improved with diet-induced weight reduction or bariatric surgery; obstructive sleep apnea may be improved by CPAP therapy; T2DM may be improved by weight loss and reduction in insulin resistance; and alcohol abuse may be improved with treatment of alcohol dependence and abstinence. In many instances, however, functional causes of hypogonadism cannot be treated or managed in a reasonable time frame (e.g., opioid or glucocorticoid therapy for chronic comorbid illnesses), so testosterone treatment should be considered.

Testosterone Replacement Therapy

Therapeutic Goals and Management

The overall goal of testosterone replacement therapy is to correct or improve the clinical manifestations of androgen deficiency in men with primary or secondary hypogonadism. Because specific manifestations vary with the stage of sexual development, the specific goals of testosterone treatment vary depending on whether the patient is an adolescent or an adult.[6,116]

In boys with *androgen deficiency of prepubertal onset* and delayed puberty, the goals of testosterone treatment are the following[146,147,374,375]:

- To induce and maintain secondary sexual characteristics, including growth of the penis and scrotum, and a male body hair pattern
- To increase muscle mass and strength
- To stimulate BMD, acquisition of peak bone mass, and long bone growth without compromising adult height by inducing premature closure of epiphyses
- To stimulate libido and spontaneous erections
- To improve energy, mood, and motivation
- To induce laryngeal enlargement and deepening of the voice
- To increase red blood cell production into the normal adult male range.

Testosterone treatment also stimulates the growth of accessory sex glands (seminal vesicles and prostate), resulting in seminal fluid production and an increase in ejaculate volume, but it does not stimulate sperm production to a degree sufficient for induction of fertility. The most common cause of delayed puberty is not a pathologic condition but rather CDGP. Testosterone therapy in boys who present with delayed puberty utilizes low-dose testosterone to avoid premature epiphyseal closure and compromise of adult height, and treatment is given intermittently until spontaneous puberty occurs (see later discussion). If spontaneous puberty does not occur, the testosterone dose is increased gradually to adult concentrations.[146,147,374,375]

The goals of testosterone therapy in *adult hypogonadism* are the following[6,116]:

- To improve sexual function and activity by restoring libido and improving erectile function
- To increase muscle mass and strength, potentially improving physical function and performance
- To increase BMD, potentially reducing the risk of fractures
- To improve energy, vitality, mood, and motivation
- To increase hematocrit into the normal adult male range
- To restore male hair growth.

Recent-onset gynecomastia that is usually symptomatic may respond to testosterone treatment, but severe or long-standing gynecomastia requires surgical excision. Spermatogenesis requires relatively high intratesticular concentrations of testosterone that cannot be achieved by exogenous androgen administration. Therefore, testosterone replacement therapy does not stimulate sperm production or increase testis size, nor does it restore fertility. Treatment of infertility in hypogonadal men is usually possible only in those men with secondary hypogonadism and gonadotropin

deficiency; gonadotropin or GnRH therapy is used to induce spermatogenesis and fertility.[611]

The normal adult range of serum testosterone concentrations is broad and is usually based on results in healthy young men using blood samples drawn in the morning. In young men with androgen deficiency, testosterone replacement therapy produces beneficial clinical effects as serum testosterone concentrations are increased into this normal range. Serum testosterone concentrations decline gradually and progressively with age, but the physiologic significance of this age-related decline is unclear. Initial studies in older men with low serum testosterone concentrations demonstrated some clinical beneficial effects with testosterone treatment that increased testosterone concentrations into the normal young adult range.[322,612] Therefore, the goal of testosterone treatment of hypogonadism is to restore serum testosterone concentrations to within the normal adult range, irrespective of age.[116]

The dose-response effects of testosterone vary in different target organs and for different clinical outcomes.[613] For example, the action of testosterone on muscle mass demonstrates a continuous dose-response relationship. With testosterone administration, muscle mass increases when testosterone concentrations are increased from below normal to within the normal range, and it continues to increase as concentrations are raised from within to above the normal range. In contrast, the actions of testosterone on libido exhibit threshold dose-response characteristics: testosterone administration increases libido when serum testosterone concentrations are increased from low to low-normal concentrations but does not continue to stimulate libido further as serum testosterone is increased to normal or supraphysiologic concentrations.

In men with severe, long-standing androgen deficiency, testosterone replacement therapy induces profound alterations in sexuality, behavior, and physical appearance that may be upsetting to patients and their partners and may result in serious adjustment problems. To reduce the likelihood of problems, it is important to inform and counsel hypogonadal men and their partners regarding changes in body characteristics and behavior that are expected during testosterone replacement therapy. In some men with severe, long-standing hypogonadism, initiation of testosterone replacement with a low-dose regimen (e.g., testosterone enanthate or cypionate 100 mg every 2 weeks, testosterone patch 2 mg daily, or 1.62% testosterone gel 20.25 mg daily) for several months, followed by an increase to full testosterone replacement, may produce a more gradual symptomatic transition from hypogonadism to eugonadism and may result in fewer adjustment difficulties.[614]

Because the metabolic clearance rate of testosterone is reduced in older men with hypogonadism, therapeutic testosterone concentrations may be achieved with lower dosages of testosterone.[615] In some clinical situations, such as severe symptomatic BPH or the presence of numerous comorbid illnesses, full testosterone replacement may be ill advised. In these instances, low-dose testosterone supplementation may also be more prudent than full testosterone replacement therapy. Low dosages of testosterone may be sufficient to induce some beneficial effects while minimizing the potential worsening of LUTS (although this has not been demonstrated as an adverse effect of testosterone therapy).

The potential effectiveness of low-dose testosterone supplementation is suggested by studies of short-acting testosterone formulations (e.g., oral testosterone undecanoate and sublingual testosterone cyclodextrin) that produced anabolic effects despite serum testosterone concentrations that were not sustained within the normal range.[616,617] An analogy may be made to the use of hydrocortisone for glucocorticoid replacement therapy, in which the duration of biologic action of hydrocortisone on tissues is not reflected by its serum concentrations. Short-term administration of low-dose testosterone enanthate (50 mg/week IM) was found to increase muscle strength and power in some young men in whom hypogonadism was induced by concomitant GnRH agonist treatment.[618]

Hypogonadism due to gonadotropin deficiency may be caused by hypothalamic-pituitary disease that requires specific management in addition to testosterone replacement. Therefore, careful evaluation to determine the cause of secondary hypogonadism should be performed before testosterone treatment is started. For example, pituitary or hypothalamic tumors may cause mass effects such as visual field defects, or they may be associated with deficiency or excessive secretion of other pituitary hormones. These tumors may require surgery or radiation therapy, additional hormonal replacement, medical therapy, or some combination of these treatments to reduce excessive pituitary hormone secretion. In some cases, treatment of the underlying cause of secondary hypogonadism corrects the androgen deficiency (e.g., stopping a medication that causes hyperprolactinemia or gonadotropin deficiency). In men with gonadotropin deficiency and otherwise normal testes who are interested in fathering children, gonadotropin therapy may be used instead of testosterone replacement to stimulate sperm production, restore fertility, and correct androgen deficiency. Similarly, men with secondary hypogonadism due to hypothalamic disease may be treated with pulsatile GnRH to stimulate testosterone and sperm production and restore fertility.

A comprehensive clinical approach is important for optimal management of hypogonadism. It is important to consider causes other than androgen deficiency that might contribute to symptoms and signs, and to manage them appropriately. In hypogonadal men who complain primarily of sexual dysfunction, an underlying neurovascular disease or use of certain medications is usually the major cause of erectile dysfunction. In these men, testosterone treatment alone is insufficient to completely restore erections and permit satisfactory sexual intercourse. Additional treatment with a PDE5 inhibitor (sildenafil, vardenafil, or tadalafil),[161,619] intracavernosal or intraurethral alprostadil (MUSE), intracavernosal alprostadil/papaverine/phentolamine (tri-mix), penile vacuum device, or penile prosthesis might be needed for a satisfactory clinical outcome. In hypogonadal men who present with osteoporosis, it is critical to perform a thorough evaluation for other common causes of bone loss (e.g., vitamin D deficiency, alcohol abuse, smoking, medications, inactivity, primary hyperparathyroidism) and to treat them as well. It is also important to institute measures to prevent falls to reduce the risk of fractures.

Testosterone Formulations

Testosterone formulations that are used to treat male hypogonadism are summarized in Table 19.10.[6,116] In the United States, approved formulations include parenteral testosterone esters that are administered by long- and short-acting IM injection, transdermal testosterone patch and testosterone gels or solutions, a transbuccal testosterone tablet, and an intranasal testosterone gel.

Oral 17α-alkylated testosterone derivatives, such as methyltestosterone and fluoxymesterone, should not be used for testosterone replacement therapy.[6] It is difficult to achieve full androgen replacement with these oral formulations because they are weak androgens that have low bioavailability. They also have the potential for serious hepatotoxicity.[620] 17α-Alkylated androgens most commonly cause cholestasis that is reversible with discontinuation. More concerning is the potential for these agents to cause

TABLE 19.10 Treatment of Adult Male Hypogonadism

Formulation	Dosage	Advantages	Disadvantages
Treatment of Androgen Deficiency			
Formulations Available in the United States			
Parenteral Testosterone Esters			
Testosterone enanthate or cypionate, IM injections	*Adults:* 150–200 mg IM every 2 wk or 75–100 mg IM every wk 50 mg, 75 mg, or 100 mg SC by autoinjector *Prepubertal boys:* 50–100 mg monthly or 25–50 mg every 2 wk, increasing to 50–100 mg every 2 wk and then to adult replacement dosage over 2–4 yr or until spontaneous pubertal development occurs	Extensive clinical use Inexpensive with self-injection Some dose flexibility	IM injections, discomfort Symptomatic fluctuation of T concentrations (supraphysiologic after injection to low normal or low before next injection) Frequent IM injections to reduce fluctuations of T concentrations More erythrocytosis than with transdermal T
Testosterone undecanoate, IM injections	750 mg at 0 and 4 wk, then every 10 wk	Less frequent IM injections Maintenance of normal T concentrations for a longer duration No apparent fluctuations in symptoms	REMS: Slow, deep IM injection in clinic (no self-injection); 30-min observation for potential POME and anaphylaxis IM injections, discomfort Large-volume injection (3 mL) Self-injection not possible Rarely, cough immediately after injection Prolonged maintenance of T level after discontinuation if adverse effects develop
Transdermal Testosterone			
Testosterone patch (nonscrotal)	2 or 4 mg (one patch) or 6 mg (one 2-mg plus one 4-mg patch) applied daily over nonpressure areas	Low- to mid-normal physiologic T concentrations Mimics normal circadian variation when applied nightly No injections Less erythrocytosis than with parenteral T Rapid withdrawal of T replacement if adverse effects occur	Frequent skin irritation Low-normal T concentrations: two patches may be needed Skin adhesion poor with excessive sweating Daily application More expensive than parenteral T
Testosterone gels and solution	*1% T gel:* 5–10 g of gel (containing 50–100 mg of T) applied daily over shoulders or upper arms; available in foil sachets of 2.5 or 5.0 g (containing 25 or 50 mg of T, respectively), or a tube of 5 g (containing 50 mg of T) *1.62% T gel:* 20.25–81.00 mg (containing 20.25–81.00 mg of T) applied daily to shoulders or upper arms; available in 20.25- and 40.50-mg packets (containing 20.25 and 40.50 mg of T, respectively) or metered-dose pump delivering 12.5 mg per pump depression *2% gel:* 40–70 mg (containing 40–70 mg of T) applied daily to inner thighs; available in a metered-dose pump delivering 10 mg per pump depression *2% solution:* 30–120 mg applied to underarms; available in a metered-dose pump applicator delivering 30 mg per pump depression	Low- to high-normal steady-state physiologic T concentrations No injections Little skin irritation Dose flexibility Rapid withdrawal of T replacement if adverse effects occur For 1.62% or 2% gel: less gel amount in more concentrated formulations Less gel amount in more concentrated formulations For 2 % solution: absorption of solution not affected by deodorant or antiperspirant Absorption of solution not affected by deodorant or antiperspirant	Potential for contact transfer of T to women or children Daily application More expensive than parenteral T, especially with higher doses Moderately high DHT concentrations One formulation has a musk odor and another is associated with stickiness or skin dryness Slight skin irritation in some men Solution may drip under arms
Transbuccal testosterone	30-mg tablet applied between cheek and gum two times daily	Mid-normal steady-state physiologic T concentrations No injections, patch or gel application, or their associated disadvantages Rapid withdrawal of T replacement if adverse effects occur	Twice-daily application Gum irritation or inflammation Altered or bitter taste High learning curve for proper application; requires careful instruction or poor acceptability occurs Tablets may be difficult to remove or may fall off prematurely No dose flexibility Moderately high DHT concentrations More expensive than parenteral T

TABLE 19.10 Treatment of Adult Male Hypogonadism—cont'd

Formulation	Dosage	Advantages	Disadvantages
Treatment of Androgen Deficiency			
Testosterone nasal gel	11 mg (delivering 1.1 mg of T) three times daily (every 6–8 hours) for a total daily dose of 33 mg (delivering 3.3 mg of T) daily Available in a metered-dose pump that delivers 5.5 mg (delivering 0.55 mg of T) per pump depression	No injections No interaction with sympathomimetic nasal decongestants	Thrice-daily administration Learning curve for proper administration Fluctuation in T concentrations from lower- to upper-normal range after administration No nose blowing or sniffing for 1 hour after administration Discontinue with severe rhinitis Nasal irritation Not recommended with other intranasal drugs or chronic nasal conditions
Testosterone pellets	2–6 pellets (each 3.2 mm diameter × 9 mm in length pellet containing 75 mg of T, for a total of 150–450 mg of T delivered) implanted SC every 3–6 mo (usually 3–4 mo)	Maintenance of normal T concentrations for a longer duration	Requires surgical incision Extrusion, bleeding, and infection can occur uncommonly Large number of pellets Not easily removed; fibrosis may occur Lack of ability for rapid withdrawal of T replacement if adverse effects occur Infrequent use
Testosterone Formulations Available Outside the United States			
Oral testosterone undecanoate	40–80 mg PO with meals twice a day to three times daily	Oral administration is convenient for many	Twice- or thrice-daily administration Variable T concentrations and clinical responses Requires administration with meal High DHT concentrations
Testosterone-in-adhesive matrix patch	Two patches (delivering 4.8 mg of T per day) applied every 2 days	Low- to mid-normal physiologic T concentrations Duration 2 days No injections	Some skin irritation Two patches needed
Treatment to Initiate and Maintain Sperm Production in Men With Hypogonadotropic Hypogonadism			
Initially to Stimulate Testosterone and Potentially Sperm Production			
hCG	500–2000 IU given SC two to three times weekly to maintain serum T concentrations within the normal range for 6–12 mo	Effective in stimulating endogenous T production In men with acquired and some men with partial congenital hypogonadotropic hypogonadism, sperm production may be stimulated with hCG treatment alone SC injections easier than IM injections (smaller needle, injection not as deep) Less fluctuation in T concentrations compared with IM T ester injections No injection, patch, or buccal tablet	Injections two to three times weekly Expensive Higher doses needed in men with concomitant primary testicular disease (e.g., cryptorchidism) Breast tenderness or gynecomastia secondary to high estradiol production by testes May require dilution Occasional burning sensation with injection Ineffective in primary hypogonadism
Added to hCG to Stimulate Sperm Production			
FSH Human menopausal gonadotropin, human FSH, or recombinant human FSH	After 6–12 mo of hCG treatment alone resulting in normal T concentrations, add FSH 75–300 IU given SC three times weekly for an additional 6–12 mo or longer	Effective in stimulating sperm production in men with hypogonadotropic hypogonadism	Injections three times weekly Extremely expensive, prohibitive cost for most Breast tenderness or gynecomastia secondary to high estradiol production by testes May require dilution Occasional burning sensation with injection In men with concomitant primary testicular disease (e.g., cryptorchidism), stimulation of spermatogenesis is not likely
To Stimulate Testosterone and Sperm Production			
GnRH	5–25 ng/kg SC every 2 hr by programmable infusion pump for 6–12 mo	Effective in stimulating both endogenous T and sperm production	GnRH not readily available Requires pump use and management, usually in a specialized center Expensive Infrequently used except at certain sites Rarely, local irritation, infection

DHT, Dihydrotestosterone; FSH, follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *hCG,* human chorionic gonadotropin; *IM,* intramuscular; *PO,* orally; *POME,* potential pulmonary oil microembolism; *REMS,* Risk Evaluation and Mitigation Strategy; *SC,* subcutaneous; *T,* testosterone.

peliosis hepatis (blood-filled cysts in the liver) or benign or malignant hepatic tumors. 17α-Alkylated androgens also lower HDL cholesterol and raise LDL cholesterol, causing a proatherogenic lipid profile, and they are relatively expensive. Therefore, these oral androgens carry greater potential risks with few therapeutic benefits compared with other testosterone formulations, and they should not be used to treat male hypogonadism.

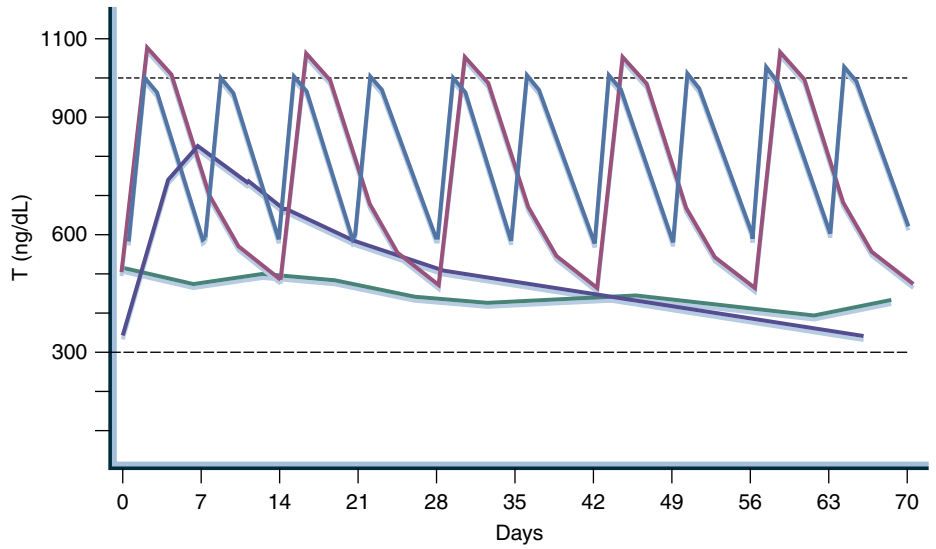
Parenteral Testosterone Esters. Relatively long-acting parenteral 17β-hydroxyl esters of testosterone, *testosterone enanthate* and *testosterone cypionate*, are administered by IM injection. These are effective, safe, and relatively practical and inexpensive preparations that have been used for testosterone replacement in hypogonadal men for decades. Transdermal testosterone gel formulations provide more physiologic testosterone concentrations and are now used more commonly than testosterone ester injections. However, testosterone esters are preferred over transdermal formulations by some hypogonadal men because they are the least expensive formulation available, require less frequent administration, and usually produce more consistent but higher average serum testosterone concentrations. Given proper instruction, most hypogonadal men (or a family member) can self-administer IM testosterone ester injections. Otherwise, testosterone injections need to be administered in a clinic setting.

Esterification of testosterone at the 17β-hydroxyl group increases its hydrophobicity and solubility within an oil vehicle (sesame oil for testosterone enanthate, cottonseed oil for testosterone cypionate). After IM injection, testosterone esters are released slowly from the oil vehicle within muscle and hydrolyzed rapidly to testosterone, which is released into the circulation, resulting in relatively high peak serum testosterone concentrations but an extended duration of release. Testosterone enanthate and testosterone cypionate have similar pharmacokinetic profiles, duration of action, and therapeutic efficacy, so they are considered therapeutically equivalent.[621,622]

In adults with hypogonadism, the usual starting dose of testosterone enanthate or cypionate is 150 mg to 200 mg via IM injection every 2 weeks. After IM administration of 200 mg of testosterone enanthate, serum testosterone concentrations usually rise above the normal range for 1 to 3 days and then decline gradually over 2 weeks to the lower end of the normal range, or sometimes to below-normal concentrations, before the next injection[623] (Fig. 19.28). The extreme rise and fall of serum testosterone concentrations may cause fluctuations in energy, mood, and libido that are disturbing to some men. Shortening the dosing interval to every 10 days and reducing the dose to 150 mg (i.e., 150-mg IM injection every 10 days) may alleviate symptoms associated with nadir testosterone concentrations occurring before the next injection. Alternatively, some patients prefer changing the dose of testosterone enanthate or cypionate to 75 to 100 mg IM every week to reduce swings in testosterone concentrations and associated symptoms (see Fig. 19.28). Administration of testosterone enanthate at doses of 300 mg IM every 3 weeks or 400 mg IM every 4 weeks produces extremely wide fluctuations in serum testosterone concentrations with markedly supraphysiologic concentrations for several days after an injection and concentrations below normal 3 weeks after an injection); these regimens are not recommended[623].

Because CDGP in which puberty eventually occurs spontaneously is clinically indistinguishable from delayed puberty caused by permanent hypogonadotropic hypogonadism (e.g., CHH),[146,147,374,375] testosterone treatment usually is not initiated in boys with androgen deficiency due to a cause of prepubertal onset until they are about 14 years of age (with a bone age of at least 10.5 years). Testosterone therapy is administered intermittently to allow determination of spontaneous puberty, if it occurs. Occasionally, testosterone therapy is started at a younger age if delayed genital development and growth are causing severe psychological distress in affected boys and their families.

In boys with androgen deficiency due to a cause of prepubertal onset, treatment is initiated with a very low dose of testosterone enanthate or cypionate (e.g., monthly IM injection of 50–100 mg or 25–50 mg every 2 weeks) to prevent premature closure of long bone epiphyses that would compromise adult height.[146,147,374,375] These low dosages of testosterone are sufficient to induce some



• **Fig. 19.28** Schematic diagram of serum testosterone (T) concentrations after chronic administration of T enanthate 200 mg intramuscularly every 2 weeks (red) or 100 mg every week (blue), T undecanoate 750 mg intramuscularly every 10 weeks (black), and T gel 1.62% transdermally daily (green). Dashed line denotes the reference range of serum T concentrations in adult men (300–1000 ng/dL).

virilization and long bone growth without interfering with the spontaneous puberty that occurs eventually in boys with CDGP. Testosterone treatment is continued for 3 to 6 months and then stopped for 3 to 6 months to assess whether spontaneous pubertal onset occurs. If there is indication that spontaneous puberty is occurring (e.g., testis size >8 mL), testosterone therapy is discontinued. If there is no evidence of spontaneous puberty, intermittent testosterone treatment is continued. The dose of testosterone enanthate or cypionate is increased gradually to 50 to 100 mg IM every 2 weeks and then to full adult replacement doses over the next several years to mimic the gradual increase in testosterone concentrations that occurs during spontaneous puberty.

At present, transdermal testosterone formulations are not approved for use in boys with delayed puberty. However, because they circumvent the need for IM injections, low-dose transdermal testosterone patches and gels would provide very useful alternatives for the treatment of androgen deficiency due to a cause of prepubertal onset in boys, but they are currently not approved for this indication.

A formulation of *testosterone undecanoate* in castor oil (*Aveed*, Endo Pharmaceuticals, Malvern, PA) was approved in 2014 for use in the United States for treatment of male hypogonadism. This formulation is administered by slow IM injection into the gluteus muscle at a dose of 750 mg in 3 mL of castor oil initially, followed by another injection of the same dose 4 weeks later and then every 10 weeks to produce and maintain serum testosterone concentrations within the normal range in most hypogonadal men.[624] Steady state is achieved after the third injection, and mean testosterone concentrations peak in the high-normal range at 7 days after injection and gradually decline over the next 10 weeks to mean nadir concentrations just above the lower limit of the normal range (see Fig. 19.28). Despite this decline in testosterone concentrations, fluctuations in or recurrence of symptoms of androgen deficiency have not been reported. Although some men experience discomfort with large-volume injections, they are generally tolerated well and have the advantage of fewer injections than shorter-acting testosterone ester formulations.

A different formulation of testosterone undecanoate in a castor oil vehicle (*Nebido*, Bayer Schering Pharma AG, Berlin, Germany) has been approved and is used in Europe and other countries for testosterone replacement therapy in hypogonadal men.[625] It is administered at a dose of 1000 mg in 4 mL IM, followed by another injection of the same dose 6 weeks later and then every 10 to 14 weeks.

Because of the large volume of drug administered and the need for proper injection technique, self-administration of IM testosterone undecanoate is not possible. Coughing may occur in a small number of men immediately after injection of testosterone undecanoate (this also occurs with shorter-acting testosterone ester injections). Although there is no direct evidence for the cause of coughing, it is conjectured to be related to pulmonary oil microembolism (POME) emanating from the large volume of castor oil vehicle that is injected into the muscle with this formulation. For these reasons, the FDA has required a risk evaluation and mitigation strategy for use of testosterone undecanoate (Aveed) in the United States that requires training of personnel and certification of the health care facility to ensure proper injection technique (slow IM injection) and adequate monitoring (for 30 minutes) and treatment capability for potential POME or anaphylaxis following injection.

In 2018, a testosterone enanthate formulation of 50 mg, 75 mg, or 100 mg (0.5-mL solution) in a prefilled, single-use, small-needle autoinjector for weekly SC injection was approved for use in testosterone replacement therapy of hypogonadal men (*Xyosted*, Antares Pharma, Ewing, NJ).[626,627]

Transdermal Testosterone. Transdermal testosterone formulations available for testosterone replacement therapy for male hypogonadism include an adhesive testosterone patch, two 1% testosterone gels, a 1.62% testosterone gel, a 2% testosterone gel, and a 2% testosterone solution (see Table 19.10). Transdermal delivery of testosterone is used in hypogonadal men who prefer this method or are unable to tolerate or self-administer IM injections of testosterone ester. Currently, testosterone gel is the most frequently used formulation for treatment of male hypogonadism in the United States.

In contrast to testosterone ester injections, which produce transient supraphysiologic testosterone concentrations, patch, gel, and solution formulations produce a more physiologic range of testosterone concentrations; use of the patch results in a circadian variation in testosterone concentrations, and the gel formulations usually produce relatively constant steady-state serum testosterone concentrations.

Testosterone stimulates red blood cell production, and testosterone replacement therapy may result in excessive erythrocytosis. In men with hypogonadism, excessive erythrocytosis occurs less commonly with testosterone patch therapy than with testosterone enanthate injections, suggesting that physiologic testosterone concentrations produced by transdermal testosterone therapy may be associated with fewer androgenic adverse effects.[628] Compared with testosterone ester injections, transdermal formulations have a short half-life in SC tissue and in the circulation; consequently, their discontinuation results in a rapid fall in serum testosterone concentrations and a shorter duration of action. Therefore, an advantage of transdermal testosterone is the ability to withdraw androgen replacement relatively rapidly if excessive erythrocytosis develops or if prostate cancer is detected.

Disadvantages of transdermal formulations include the requirement for daily application, greater expense compared with testosterone ester injections, skin irritation or rash with testosterone patches[629] (less common with testosterone gels and solution), and the potential with gel and solution formulations for transfer of testosterone to others through skin contact at the application site.

The first transdermal testosterone delivery system for treatment of male hypogonadism was a scrotal testosterone patch.[630] Treatment required daily application of a relatively large, nonadhesive patch to clean, dry, and preferably shaven scrotal skin and the use of brief-style underwear to hold them in place. These requirements were not acceptable to some hypogonadal men. In addition, in some men with congenital androgen deficiency, the scrotum was too small to accommodate even the smaller-size testosterone patch. Because of poor adherence to scrotal skin, thin adhesive strips were added as an option to this patch. Some men using this testosterone patch experienced skin irritation and itching. The scrotal testosterone patch produced serum DHT concentrations in the upper-normal range or above the normal range as a result of high 5α-reductase activity within scrotal skin. The nonscrotal testosterone patch and testosterone gels have supplanted the scrotal testosterone patch for testosterone replacement therapy, and the latter is no longer available in the United States.

A nonscrotal testosterone patch, *Androderm* (Allergan USA, Madison, NJ), is available for testosterone replacement therapy in male patients with hypogonadism.[631] This patch is composed of a central reservoir containing testosterone and permeation enhancers in an alcohol-based gel surrounded by an adhesive patch that is

applied to the skin of the back, abdomen, upper arms, or thighs, avoiding areas over a bony prominence. When applied at night, the testosterone patch produces serum testosterone concentrations that peak in the morning, mimicking the circadian variation of endogenous testosterone concentrations in normal men. Androderm patches are available in two sizes delivering 2 mg (32 cm^2) or 4 mg (39 cm^2) of testosterone daily. Long-term use of the testosterone patch usually maintains serum testosterone concentrations within the mid- to low-normal range and improves the clinical manifestations of androgen deficiency. Usually, to achieve consistent mid- to high-normal testosterone concentrations, application of two patches may necessary—one 2-mg patch plus one 4-mg patch or two 4-mg patches.[632]

The major limitation of Androderm is skin irritation or rash of varying severity; this side effect occurs in at least 30% to 60% of patients.[629] Mild to moderate erythema and irritation are almost always present, probably because of a skin reaction to the permeation-enhancing agent or adhesive. Uncommonly, severe contact dermatitis or burn-like skin reactions occur. Pretreatment of the skin under the reservoir of the patch with a topical corticosteroid such as triamcinolone acetonide 0.1% cream reduce the incidence and severity of skin irritation produced by testosterone patches.[633]

There are several testosterone gels on the market, and they are the most frequently used testosterone formulations for the treatment of male hypogonadism in the United States. The gels are dispensed into the palm of the hand and applied daily in the morning to clean, dry skin. The specified site of application varies by gel product, but none of them are applied on the face or scrotum. The alcohol-based gel dries rapidly after application, and testosterone is absorbed into the SC space, where it is released steadily over the remainder of the day, producing relatively steady-state testosterone concentrations. Residual testosterone remains on the surface of the skin of the hands and at the sites of application. Therefore, the hands should be washed with soap and water after application, the sites of gel application should be covered with clothing, and skin contact with the application sites by others (especially women and children) should be avoided for several hours or the site has been washed to prevent transfer of testosterone.[634] Because of reports of contact transfer of testosterone to children, these instructions and caution to avoid contact transfer are now in an FDA black box warning in the prescribing information for all transdermal testosterone formulations. Residual testosterone on the skin at application sites may be washed off (e.g., by showering or bathing), but washing the sites should be avoided for a minimum of 1 hour and ideally for 6 hours or more after application (to maximize testosterone absorption).

In contrast to testosterone patches, local skin irritation with testosterone gel formulations is relatively uncommon, occurring in fewer than 5% of men, and is probably related mostly to drying of the skin by the alcohol. Some men complain of stickiness of the skin after the alcohol-based gel dries. Testosterone gels produce serum DHT concentrations at the upper end or above the normal range as a consequence of 5α-reductase activity in the relatively large surface area of skin over which the gel is applied. A major limitation of the use of testosterone gel for testosterone replacement therapy is the high cost. Generic testosterone gel products have been approved and are less costly than brand products, but their availability has been variable, and they are not inexpensive.

The first gel developed, AndroGel 1% (Abbott, Abbott Park, IL) was available initially in foil sachets at two different doses: 2.5 g of gel (containing 25 mg of testosterone) or 5 g of gel (containing 50 mg of testosterone). (Because only about 10% of the medication is absorbed, these sachets deliver 2.5 or 5.0 mg of testosterone, respectively.) The starting dose of AndroGel is 5 g daily. Based on testosterone concentrations or clinical response, approximately 2 weeks after initiation of therapy, the dose may be increased to 7.5 g (i.e., one 2.5-g packet plus one 5.0-g packet) or to 10.0 g (two 5.0-g packets) daily or decreased to 2.5 g daily. AndroGel is now available in a more concentrated reformulation of 1.62% that is delivered by a metered-dose pump that delivers 12.5 mg of testosterone per actuation, or foil packets of 20.25 or 40.5 mg of testosterone. With titration, the dosage of AndroGel 1.62% ranges from 20.25 to 81 mg of testosterone.

Testim (Auxilium Pharmaceuticals, Chesterbrook, PA) is the other 1% hydroalcoholic testosterone gel that is available for treatment of male hypogonadism.[635] Like AndroGel, Testim is applied daily in the morning to intact, clean, dry skin over the shoulders and arms. In short-term, placebo-controlled trials, Testim maintained steady-state physiologic serum testosterone concentrations in hypogonadal men and improved the clinical manifestations of androgen deficiency.[636] After the initial application of Testim, serum testosterone concentrations are approximately 30% higher than those achieved after application of AndroGel. However, no direct comparison of steady-state testosterone concentrations with long-term use of the two testosterone gels is available.

Testim is packaged in a 5-g tube containing 50 mg of testosterone and delivering approximately 5 mg of testosterone (i.e., 10% absorption). The starting dose of Testim is 5 g daily. Based on testosterone concentrations or clinical response approximately 2 weeks after initiation of therapy, the dose may be increased to 10 g (two tubes) daily. In contrast to AndroGel, Testim is not available in a dose of 2.5 g or in a metered-dose dispenser, limiting dose adjustments with this formulation. Whereas AndroGel is odorless, Testim has a musk-like scent. Depending on the individual patient and his partners, this aroma might be pleasant or objectionable. Testim contains a skin emollient and is less drying to the skin than AndroGel.

Two additional transdermal formulations for the treatment of male hypogonadism have been approved in the United States. *Fortesta* (Endo Pharmaceuticals, Malvern, PA) is a 2% testosterone gel that is applied to the inner thighs at a daily dosage of 40 to 70 mg (delivering 4–7 mg of testosterone) daily by a metered-dose pump that delivers 10 mg of testosterone per pump depression (delivering 1 mg of testosterone).[637] *Axiron* (Eli Lilly, Indianapolis, IN) is a 2% testosterone solution that is applied to axillary skin at a dosage of 30 to 120 mg (delivering 3-12 mg of testosterone) daily using a metered-dose pump applicator that delivers 30 mg (delivering 3 mg of testosterone) per pump depression.[638] Both of these transdermal testosterone formulations are able to achieve and maintain relatively steady-state serum testosterone concentrations within the normal range in hypogonadal men. The advantages and disadvantages of these formulations are similar to those of AndroGel and Testim gels. There might be a higher risk of clinically important secondary transfer of testosterone to sexual partners with the use of Fortesta, and some men complain of dripping of the 2% Axiron testosterone solution from the axilla. In addition, some men might need to shave their axilla to apply Axiron; secondary transfer might be less likely to occur with axillary application, however.

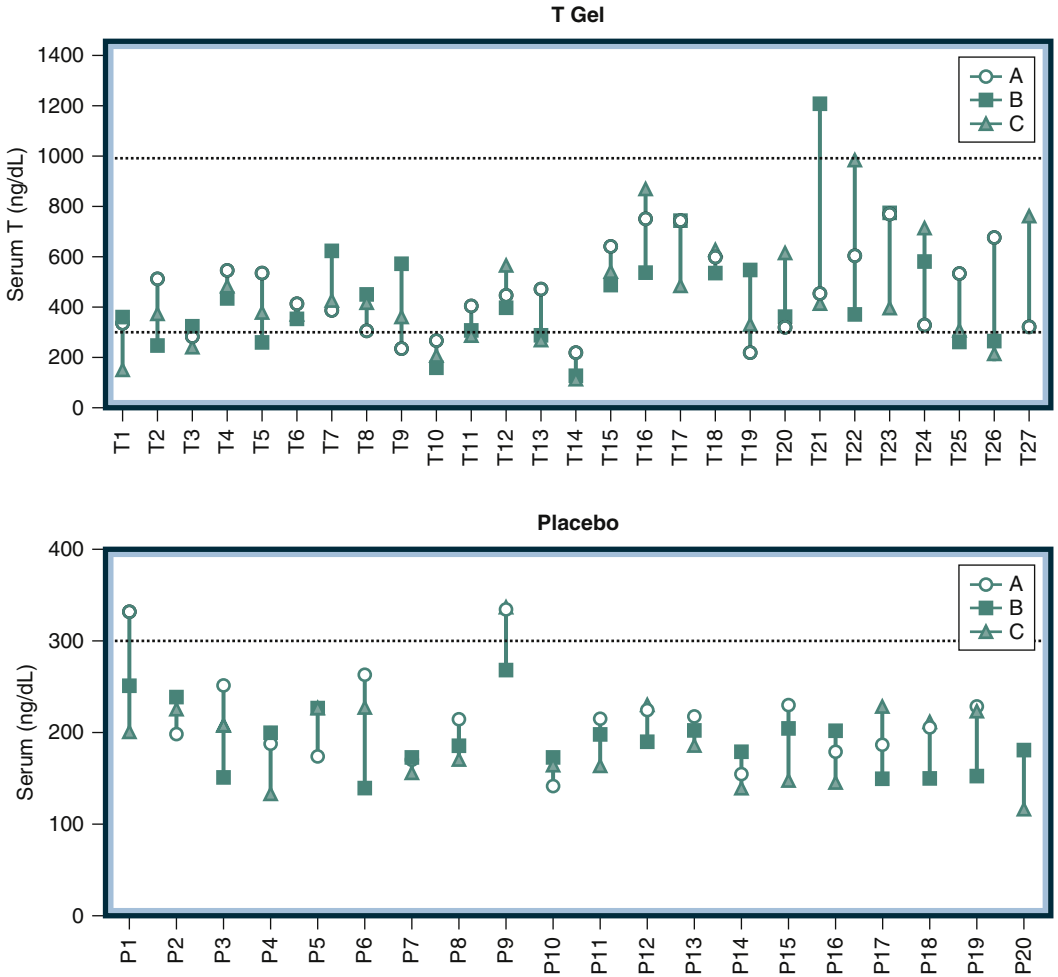
Long-term use of testosterone gel in hypogonadal men usually maintains steady-state physiologic serum testosterone concentrations and improves the clinical manifestations of androgen deficiency[208,639,640] (see Fig. 19.28). With all transdermal testosterone

formulations, serum testosterone concentrations may vary considerably both within and between individuals and from day to day, and therefore it is difficult to judge the adequacy of a particular dose in maintaining testosterone concentrations using single measurements of testosterone[641] (Fig. 19.29).

In contrast to FDA-approved transdermal testosterone formulations, testosterone concentrations contained in compounded testosterone gels and creams vary considerably and are inaccurate. In one study, AndroGel contained testosterone amounts that were consistent and accurate; there was little variation within and between batches of AndroGel. However, in this same study, only 30% to 50% of batches of compounded testosterone formulations from 10 different pharmacies contained testosterone amounts within 20% of the stated dose; one compounded formulation had virtually no testosterone.[642]

Transbuccal Testosterone. A transbuccal testosterone tablet, *Striant* (Columbia Laboratories, Livingston, NJ), is available for testosterone replacement therapy in hypogonadal men[643,644] (see Table 19.10). This formulation is a small mucoadhesive tablet that contains 30 mg of testosterone in an oil-water emulsion carrier vehicle. The tablet contains polycarbophil, which, after application, remains attached to buccal mucosa until epithelial cells turn over (approximately every 12–15 hours). The tablet is placed in the mouth between the inner cheek and gum, above the incisors, with the monoconvex side toward the gum and the flat side toward the cheek. After placement, the tablet softens and swells with hydration and becomes gelatinous and sticky, causing it to adhere to the gum. Testosterone is released at a controlled and sustained constant rate from the tablet through the buccal mucosa into the systemic circulation, circumventing first-pass hepatic metabolism.

Striant tablets are placed on the buccal mucosa twice daily, with one tablet applied in the morning and removed after 12 hours and another applied in the evening on the opposite side.[643,644] Use of Striant requires careful instruction to orient the tablet with the rounded side against the gum and to hold it firmly in place with a finger over the lip for approximately 30 seconds. If the tablet falls off or is dislodged, a new tablet should be applied and left in place until the next regularly scheduled dose. Swallowing of the tablet is not harmful. The buccal tablet is removed by gently sliding it downward toward the incisor to avoid scratching the gum.



• **Fig. 19.29** Large variability of serum testosterone (T) concentrations 2 hours after 16 ± 2 weeks of transdermal application of daily gel application at ambulatory clinic visits (*A*, open circles; *B*, closed squares) and an inpatient visit (*C*, shaded triangles) in participants in the Testosterone Trials who received T gel 1% (upper, participants T1–T27) and placebo gel (bottom panel, participants P1–P20). Within-subject variation is shown by a *shaded vertical line* between the highest and lowest T concentration for each man. The *dashed line* denotes the reference range of serum T concentrations in adult men (300–1000 ng/dL).

Application of a Striant tablet containing 30 mg of testosterone every 12 hours produces, on average, steady-state testosterone concentrations in the mid-normal range throughout the day.[643,644] Although a formal study has not been conducted, unrestricted intake of food and beverage (including alcohol), tooth brushing, mouth washing, and gum chewing did not appear to affect the absorption of testosterone in pharmacokinetic studies. Contact transfer of testosterone in saliva to others has not been reported to occur. Like the transdermal testosterone gels, Striant produces high-normal to high serum DHT concentrations, probably because of 5α-reductase activity in the buccal mucosa. In general, transbuccal testosterone tablets are tolerated well. In one study, approximately 10% to 15% of men developed gum or mouth irritation or inflammation, and 5% experienced an altered or bitter taste in the mouth.[643]

Like the transdermal testosterone formulations, Striant is relatively expensive compared with testosterone ester injections. Initially, patients are aware and bothered by the tablet between their cheek and gum, resulting in premature discontinuation of the formulation. However, with continued use, the unusual sensation and awareness of the buccal tablet diminish and become less bothersome. Twice-daily application of Striant is required to sustain physiologic testosterone concentrations, and this makes compliance challenging. Informing patients that awareness of the buccal tablet diminishes over time and linking application of the transbuccal tablet to a routine daily activity such as morning and evening tooth brushing may help improve and maintain compliance.

Testosterone Nasal Gel. A 1% testosterone nasal gel formulation, *Natesto* (Aytu Bioscience, Englewood, CO), has been approved by the FDA to treat men with hypogonadism.[645] This formulation is administered intranasally at a dosage of 11 mg testosterone in 1.1 g gel (delivering 1.1 mg of testosterone in each nostril) three times daily (every 6–8 hours) by a metered-dose pump that delivers 5.5 mg (delivering 0.55 mg of testosterone) per pump depression; the total daily dose is therefore 33 mg (delivering 3.3 mg of testosterone). It is advised that there should be no nose blowing or sniffing for 1 hour after administration, and treatment should be discontinued temporarily during episodes of severe rhinitis. Although there is no interaction with symphathomimetic nasal decongestants, potential interaction with other intranasally administered medications is not known, so use with other nasal drugs is not recommended. It is also not recommended for patients with chronic nasal conditions. When administered to hypogonadal men, mean serum testosterone concentrations peak in the high-normal range approximately 1 hour after administration and decline over 6 to 8 hours to concentrations at or slightly below normal.

Testosterone Pellets. SC testosterone pellets are used infrequently in the United States but more commonly in Australia and some European countries for testosterone replacement therapy in men with hypogonadism.[646,647] In the United States, *Testopel Pellets* (Auxilium Pharmaceuticals, Chesterbrook, PA) are available for testosterone replacement (see Table 19.10). These are cylindrical pellets, 3.2 mm in diameter by 8 to 9 mm in length, that contain 75 mg of testosterone. Testopel Pellets are recommended at doses that range from 150 to 450 mg testosterone (i.e., two to six 75-mg pellets) and are implanted every 3 to 4 months.[646] However, a recent report of implantation of 6 to 12 pellets (450–900 mg of testosterone) found that decline in serum testosterone concentrations to below normal occurred by 3 to 4 months after implantation regardless of BMI or the number of pellets implanted (from 6–9 or 10–12).[648]

Pharmacokinetic profiles for testosterone pellets depend on the specific pellet formulation.[647,649,650] In European studies using a different formulation, SC implantation of three to six 200-mg pellets (for a total of 600–1200 mg of testosterone) produced the almost zero-order, sustained release of testosterone and maintained steady-state physiologic serum testosterone concentrations for 4 to 6 months in hypogonadal men.[649] Testosterone pellets are implanted subcutaneously with the use of a trocar that is introduced through a small skin incision. This minor surgical procedure is repeated three to four times yearly to maintain normal serum testosterone concentrations.

Although spontaneous extrusion of pellets and local bleeding or infection may occur occasionally, these problems are uncommon in experienced hands. If adverse effects develop after implantation, a major concern is that removal of the testosterone pellets will be difficult, if not impossible. Therefore, the use of testosterone pellets is inappropriate for testosterone replacement in older patients who are predisposed to erythrocytosis and prostate disease during treatment.

Testosterone Formulations Available Outside the United States

Oral Testosterone Undecanoate. In many countries outside the United States, an oral 17β-hydroxyl ester of testosterone, testosterone undecanoate (*Andriol Testocaps*, Organon, Oss, Netherlands), is available for testosterone replacement therapy in hypogonadal men.[651,652] Testosterone undecanoate, which is formulated in a castor oil vehicle, is absorbed directly from the gastrointestinal tract into the lymphatic system and then into the systemic circulation, thereby avoiding first-pass hepatic accumulation and inactivation. Serum testosterone concentrations peak approximately 5 hours after administration of testosterone undecanoate and fall to pretreatment concentrations within 8 to 12 hours. For testosterone replacement therapy, it is administered at relatively high doses, 40 to 80 mg two to three times daily (total dose, 80–240 mg daily). The frequency of administration makes compliance difficult for many men. Absorption of testosterone undecanoate requires concomitant food ingestion, and serum testosterone concentrations and clinical responses are highly variable. Because of 5α-reductase activity in the gastrointestinal tract, serum DHT concentrations are often very high.

The use of castor oil and propylene glycol laurate instead of oleic acid, the vehicle used in the original formulation, permits storage at room temperature and extends the shelf life of Andriol Testocaps for up to 3 years while maintaining pharmacokinetic and pharmacodynamic characteristics similar to those of the original formulation. Testosterone concentrations fall quickly after discontinuation of testosterone undecanoate. Therefore, it may be particularly useful for testosterone replacement therapy in older men with clinically significant prostate disease and comorbid conditions, in whom rapid withdrawal of androgen action is desirable if adverse effects develop, and in those for whom only low-dose testosterone supplementation is needed.

Transdermal Testosterone Formulations. A *testosterone-in-adhesive matrix patch* (*Testopatch*, Pierre Fabre, Castres, France) is available in many countries in Europe for testosterone replacement therapy in patients with male hypogonadism.[654,655] This patch is composed of an adhesive matrix that contains testosterone (0.5 mg/cm^2) and excipients that comes in three sizes—30, 45, and

60 cm^2. Two 60-cm^2 patches (delivering approximately 4.8 mg of testosterone daily) are applied to the skin of the arms, trunk, or thighs every 2 days to maintain serum testosterone concentrations in the normal range in hypogonadal men. Skin irritation has been reported to occur in about 20% of patients using this patch.

Nontestosterone Therapies for Male Hypogonadism

Clomiphene and Aromatase Inhibitors. As noted previously, clomiphene and aromatase inhibitors (e.g., anastrozole) have been used off label to increase serum testosterone concentrations to enhance athletic performance or develop a muscular appearance. These drugs are not approved for use in male hypogonadism. Because their mechanism of action is to increase pituitary secretion of gonadotropins (thereby stimulating testicular production of testosterone), they will not be effective in men with primary hypogonadism (who already have high gonadotropin concentrations) and men with severe secondary hypogonadism who cannot produce more gonadotropins. In addition, safety and efficacy of these drugs have not established for the treatment of male hypogonadism.[116] Aromatase inhibitor therapy is associated with increased fat mass and decreased sexual function and is likely to decrease bone mass.[120-122]

Selective AR Modulators. There is considerable interest in the development of selective AR modulators (SARMs), which are nonsteroidal molecules that interact with AR and have differential effects on various androgen target organs.[656,657] The goal is to develop an orally active, nonsteroidal SARM that will maintain the beneficial anabolic and androgenic actions of testosterone on muscle, bone, sexual function, and mood but have reduced potential for adverse effects (e.g., on the prostate gland). These novel drugs are being developed primarily for use in muscle-wasting conditions such as age-related sarcopenia and cancer cachexia but not at present for treatment of male hypogonadism. The mechanisms by which SARMs act in a tissue-specific manner are unclear. It is possible that SARMs have less stimulatory effect on the prostate because they are not actively metabolized by 5α-reductase, or they may act by unique interactions with tissue-specific AR coactivator and corepressor molecules.

Nonsteroidal SARMs have been developed that have anabolic actions in muscle and bone but reduced stimulatory effects on the prostate gland in animals.[656,657] SARMs do not have intrinsic ER activity, and if they suppress endogenous gonadotropin, testosterone, and estradiol secretion, they will produce a state of relative estrogen deficiency. Therefore, studies evaluating the clinical benefits and risks of an SARM must consider potential adverse effects on target actions that are regulated by estradiol in men, such as effects on BMD, fat mass, sexual function, and possibly lipids (HDL cholesterol), cardiovascular function, and brain function. The importance of estrogens on bone, for example, was underscored by a recent long-term study of the potent, nonaromatizable androgen—DHT gel—administered to older men. Compared with placebo, DHT gel stimulated lean body mass and reduced fat mass but reduced BMD.[99]

Monitoring Clinical Response and Testosterone Concentrations

The clinical responses to testosterone replacement and serum testosterone concentrations are used to monitor the adequacy of testosterone therapy in androgen-deficient men[116] (Table 19.11). Symptoms and signs of androgen deficiency should be assessed before the initiation of testosterone treatment, 3 to 12 months after starting testosterone, and then yearly. By 3 to 6 months, most hypogonadal men experience improvements in libido, sexual function and activity, energy, vitality, motivation, and mood.[658] Increases in body hair growth, muscle mass and strength, and BMD occur over the subsequent months to years of testosterone therapy.

Serum testosterone concentrations are monitored to determine the adequacy of therapy and to avoid overreplacement or underreplacement. This is particularly important in men treated with the transdermal testosterone patch, gels, and solution, as the bioavailability of these formulations is highly variable among individuals; because of this variability, decisions regarding the adequacy of a given dosage of transdermal testosterone should not be made on a single testosterone measurement.[641] The goal of testosterone replacement therapy is to achieve average serum testosterone concentrations within the normal range.[116]

For testosterone ester injections, testosterone concentrations should be measured at 3 to 6 months of treatment, midway between two injections (e.g., 1 week after an injection if the injections are given every 2 weeks). Serum testosterone concentrations measured at the nadir of the injection interval (i.e., just before the next injection) may help to document an inadequate dosing interval. For the testosterone patch, testosterone concentrations should be measured after approximately 3 to 4 weeks of daily use, 8 to 10 hours after application of a patch on the previous evening. For testosterone gels and solution, testosterone concentrations should be measured after about 2 weeks of daily use, at any time after application of the gel. For buccal testosterone, serum testosterone should be measured 4 to 6 weeks after initiation of therapy, at any time after application of the buccal tablet, preferably in the morning.

Risks and Adverse Effects

Contraindications and Precautions. Testosterone treatment is contraindicated in men with metastatic prostate cancer or breast cancer.[116] The primary concern is that testosterone administration could stimulate the growth of these androgen- or estrogen-dependent malignancies. Testosterone therapy is particularly risky in men with metastatic prostate cancer, in whom rapid growth of metastatic tumors may worsen bone pain or cause spinal cord compression. In fact, the mainstay of treatment for metastatic prostate cancer is androgen-deprivation therapy to reduce endogenous testosterone production and action; this is achieved by GnRH agonist and AR antagonist treatment or by surgical orchidectomy.[659] The effect of testosterone replacement in hypogonadal men with localized prostate cancer is not known. However, in the absence of evidence, testosterone treatment in men with clinical evidence of active prostate cancer should be avoided.

The safety of testosterone therapy in hypogonadal men who have been surgically cured of organ-confined, low-grade prostate cancer (Gleason score <7 or 3+4, PSA <10 or 20 ng/mL, and clinical stage 1 or 2a) and have had clinically undetectable disease and an undetectable PSA level for several years also is not clear. Because these men would not have been treated with androgen-deprivation therapy, testosterone replacement to restore eugonadal concentrations of testosterone seems reasonable. In these patients, a careful discussion of the potential benefits and risks of testosterone replacement should be undertaken, and therapy should be initiated only after informed consent and with careful monitoring by DRE and measurement of PSA concentrations. It is prudent to avoid testosterone treatment in men with organ-confined, high-risk prostate cancer (e.g., Gleason score 8–10, PSA >20 ng/mL, and clinical stage ≥T3) despite undetectable PSA concentrations

TABLE 19.11 Monitoring During Testosterone Treatment

Parameter	Timing	Further Management
Measures of Efficacy		
Symptoms and signs of androgen deficiency	At baseline, after 3–12 mo, and then yearly	Continue testosterone treatment in men with clinical improvement and no adverse effects. Consider discontinuing testosterone treatment in men if no clinical improvement.
BMD	For men at high risk for fracture, BMD before treatment; for men with osteoporosis or minimal-trauma fracture, BMD after 1–2 yr	Institute appropriate treatment for men with osteoporosis, including calcium and vitamin D.
Serum testosterone	*Testosterone ester injection:* After 3–6 mo, measured midway between injections or at end of dosing interval (if androgen deficiency symptoms are present at that time) *Testosterone patch:* After 3–4 wk, at 8–10 hr after application *Testosterone gel:* After 2 wk, at any time after application *Buccal testosterone:* After 4–6 wk, at any time after application (preferably in the morning) *Testosterone pellets:* At end of dosing interval *Oral testosterone undecanoate:* After 1 wk, at 3–5 hr after oral dose *Testosterone undecanoate injection:* At end of dosing interval	Adjust dose or dosing interval to achieve serum testosterone concentrations in the mid-normal range.
Adverse Effects		
Hematocrit	At baseline, after 3–6 mo, and then yearly	If hematocrit is >54%, stop or reduce dosage of testosterone until hematocrit declines to normal and reinitiate testosterone at a lower dosage. Investigate for a hypoxic condition such as obstructive sleep apnea or chronic lung disease.
PSA level, with or without DRE (using shared decision making, i.e., if a patient desires prostate cancer screening after discussion of risks and benefits of PSA screening and monitoring), in men >50 yr (>40 if risk factors for prostate cancer)	At baseline, after 3–6 mo, and then according to accepted guidelines	Urologic evaluation with any of the following: • Confirmed PSA >4 ng/mL any time during testosterone treatment • PSA increase >1.4 ng/mL within 12 mo of testosterone treatment • Palpable abnormality (nodule or induration) on DRE • Worsening of lower urinary tract symptoms (e.g., IPSS score >19)
Obstructive sleep apnea (snoring, witnessed apnea, daytime somnolence, unexplained erythrocytosis, worsening hypertension or edema)	At baseline, after 3–12 mo, and then yearly	Evaluate for obstructive sleep apnea or adjustment of CPAP settings. Evaluate for other causes of hypoxia.
Formulation-specific adverse effects	At baseline, after 3–6 mo, and then yearly	Discontinue and switch to another formulation.
Testosterone ester injections	Discomfort, bleeding, or hematoma with IM injections Fluctuations in energy, mood, libido Allergy to oil vehicle (rare)	Reinstruct on the self-injection site technique. Consider shortening the injection interval if the nadir testosterone level is low.
Testosterone patch	Skin irritation Adhesion to skin	Coadministration of corticosteroid cream may reduce skin irritation.
Testosterone gel	Contact transfer to others Skin dryness at site of application	Reinstruct on washing hands and covering application area after gel dries or showering 4–6 hr after application, avoiding prolonged skin-to-skin contact of application site with women and children.
Buccal testosterone tablets	Gum irritation or inflammation Poor adhesion to gums Altered or bitter taste	Reinstruct on proper application and reassure to complete an adequate trial with the correct technique.
SC testosterone pellets	Pellet extrusion Implantation-site infection, bleeding, fibrosis	Reimplant pellets. Treat infection with appropriate drainage and antibiotics.

BMD, Bone mineral density; *CPAP,* continuous positive airway pressure; *DRE,* digital rectal examination; *IM,* intramuscular; *IPSS,* International Prostate Symptom Score; *PSA,* prostate-specific antigen.

after surgical or brachytherapy, as these individuals have high likelihood of recurrence and poor outcomes independent of testosterone therapy.

Before testosterone replacement therapy is started in men older than 50 years (>40 years if the man has risk factors for prostate cancer), prostate cancer screening should be offered after a shared decision-making discussion of the potential risks and benefits of prostate cancer screening (including detection and treatment of low-grade prostate cancer that might not benefit from treatment).[116] Minimal prostate cancer screening consists of measurement of serum PSA; there is controversy about the added value of a DRE as an initial screening test. Hypogonadal men with an abnormal DRE or a consistently elevated PSA value (e.g., >4 ng/mL in Caucasian men, >3 ng/mL in African-American men and men at high risk for prostate cancer) should have a urologic evaluation that may include a transrectal ultrasound study and biopsy of the prostate before starting testosterone. Older men, African-American men, men with an abnormal DRE, and men with a history of a first-degree relative with prostate cancer have an increased risk of prostate cancer; men with a previous negative prostate biopsy and men who are taking a 5α-reductase inhibitor have a reduced risk. A prostate cancer risk calculator, based on data from placebo-treated men in the Prostate Cancer Prevention Trial, is available to assess the risk of clinical (biopsy-detectable) and high-grade (Gleason score ≥7) prostate cancer according to ethnicity, age, PSA level, family history of prostate cancer, normal or abnormal DRE, results of prior prostate biopsy, and use of a 5α-reductase inhibitor. This calculator is available at http://myprostatecancerrisk.com/.[660,661] Although this tool has not been validated for men with untreated androgen deficiency (who usually have lower PSA concentrations than eugonadal men), the prostate cancer risk calculator may be helpful in assessing the risk of clinical or high-grade prostate cancer that may be present in a hypogonadal man before testosterone replacement is instituted.

Although breast cancer in men is rare, some disorders that cause androgen deficiency, such as Klinefelter syndrome, are associated with an increased risk of breast cancer.[662] Therefore, a careful breast examination for suspicious masses should be performed in hypogonadal men before starting testosterone treatment. The conversion of testosterone to estradiol may stimulate growth of ER-positive breast cancer.

Relative contraindications to testosterone replacement therapy include the following[116]:

- Presence of a PSA level greater than 4 ng/mL (or >3 ng/mL in individuals at high risk for prostate cancer, e.g., African-American men or those with a family history of prostate cancer), or prostate nodule or induration that has not been evaluated
- Baseline hematocrit in the high-normal range (e.g., hematocrit >48 at or near sea level or >50% at high altitudes), because further stimulation of erythropoiesis induced by testosterone therapy may result in erythrocytosis and, potentially, hyperviscosity and vascular complications, particularly in elderly men with underlying vascular disease
- Untreated obstructive sleep apnea, because higher-dose testosterone treatment may rarely worsen sleep-disordered breathing and its complications
- Severe edematous conditions (e.g., uncontrolled or poorly controlled CHF), because the fluid retention associated with testosterone therapy may worsen preexisting edema
- Severe LUTS due to BPH, such as in men with an IPSS greater than 19
- Desire for fertility in the near future
- Myocardial infarction or stroke within the past 6 months, because of an increased risk of a cardiovascular event independent of testosterone treatment, or thrombophilia or hypercoagulability, although rare, that predisposes men to venous thromboembolism (VTE) events.

Potential Adverse Effects and Monitoring. Monitoring for potential adverse effects of testosterone therapy is summarized in Table 19.11.[116]

Hematocrit. Testosterone replacement stimulates erythropoiesis in hypogonadal men, increasing the hemoglobin concentration and hematocrit from the female range into the normal adult male range.[663] Occasionally, testosterone treatment causes excessive erythrocytosis (e.g., hematocrit >54%) that may require temporary discontinuation of therapy or lowering of the testosterone dose until the hematocrit declines to normal; reinitiation of testosterone at a lower dose; or, uncommonly, therapeutic phlebotomy.[326] Excessive erythrocytosis occurs more commonly in older men[612] and in those treated with parenteral testosterone esters rather than transdermal testosterone patches, probably related to the supraphysiologic testosterone concentrations that are present for a few days after administration and the higher average testosterone concentrations produced by IM testosterone.[628] A greater erythropoietic response to testosterone is associated with stimulation of erythropoietin and suppression of ferritin and hepcidin (a liver-derived peptide that is the main negative regulator of iron bioavailability), possibly resetting the relationship between erythropoietin and hemoglobin and increasing the availability and use of iron for red blood cell production.[664,665]

Adverse effects of erythrocytosis induced by testosterone are poorly documented. However, there is concern that an excessive increase in red blood cell volume and blood viscosity could cause vascular complications such as thrombosis, especially in older men with underlying atherosclerotic CVD, resulting in stroke or myocardial infarction. Therefore hematocrit should be measured before testosterone therapy is initiated, 3 to 6 months after starting treatment, and then yearly.[116] If erythrocytosis develops during testosterone replacement therapy, testosterone should be stopped, and an evaluation should be performed to determine whether an underlying predisposing condition, such as hypoxia due to obstructive sleep apnea syndrome or chronic lung disease, is stimulating or contributing to erythrocytosis. Subsequently, testosterone may be restarted at a lower dosage.

CVD and VTE. The effects of testosterone replacement therapy in men with androgen deficiency on the risk of major cardiovascular events (MACE: myocardial infarction, stroke, and cardiovascular mortality) is not known. There are no adequately powered, large, long-term randomized controlled trials that have assessed the risk of MACE in hypogonadal men treated with testosterone. Pharmacoepidemiologic studies evaluating cardiovascular events associated with testosterone treatment[329-337] have been conflicting, with studies showing increased, no, or decreased risk of cardiovascular events associated with testosterone treatment. Meta-analyses of testosterone treatment trials[326-328,666-670] have largely (except for one study[327]) shown no increase in cardiovascular events associated with testosterone treatment; however, meta-analyses have been limited by heterogeneity of the study populations and testosterone treatment regimens; variability of study durations and reported outcomes including adverse events; and lack of sufficient sample size or prespecified, independent adjudication of MACE. Despite the lack of evidence, the FDA (but not the European Medicines Agency) required the addition of a warning regarding the potential

increased risk of cardiovascular events to the prescribing information for all testosterone formulations. A large, long-term, multicenter, randomized, placebo-controlled trial is currently being initiated to assess the risk of MACE in hypogonadal men with preexisting CVD or risk factors for CVD treated with testosterone.

A pharmacoepidemiologic and case-control study and a recent meta-analysis of testosterone treatment trials did not find an increased risk of VTE associated with testosterone treatment.[671-673] However, there were too few VTE events in randomized controlled trials of testosterone treatment to adequately assess risk. Case series have suggested that there is an increased risk of VTE events in men with a history of unprovoked VTE and thrombophilia who are treated with testosterone, even in the absence of erythrocytosis.[674] The FDA also required the addition of a warning regarding the possible risk of VTE to prescribing information for all testosterone formulations.

Prostate. Prostate size is reduced in men with androgen deficiency, and testosterone replacement therapy increases prostate volume to that of age-matched eugonadal men.[675] Testosterone therapy does not cause excessive prostate enlargement, and there is no evidence that it worsens LUTS, reduces urinary flow rate, causes urinary retention, or increases the need for invasive intervention for BPH (e.g., transurethral resection of the prostate). In the Testosterone Trials, testosterone versus placebo treatment for 1 year was not associated with an increase in IPSS score greater than 19 (severe LUTS).[162] However, long-term, controlled studies have not been performed to evaluate these outcomes in middle-age to older hypogonadal men, who are most at risk for development of clinically significant, symptomatic BPH. In hypogonadal men older than 40 years, LUTS may be monitored with the use of the IPSS or the AUA symptom score during testosterone treatment in accordance with accepted guidelines.[116] Concomitant therapy for LUTS (e.g., α-adrenergic receptor antagonists, 5α-reductase inhibitors, surgical bladder outlet procedures) should be considered in hypogonadal men with bothersome severe LUTS that affects quality of life.

There is no evidence that testosterone treatment causes prostate cancer. In middle-age to older men with androgen deficiency, there is concern that long-term testosterone therapy might stimulate previously unrecognized or clinically undetectable localized or metastatic prostate cancer or accelerate the growth of preexisting subclinical disease into clinically apparent prostate cancer. There is evidence that testosterone treatment initially stimulates the growth of metastatic prostate cancer, but its effect on progression of subclinical prostate cancer is not known. Meta-analyses of small, short-term, controlled studies (up to 3 years in duration) have not found an increased incidence of prostate cancer in older men treated with testosterone; however, these trials were underpowered to assess the risk of prostate cancer, particularly high-grade prostate cancer.[326,338] Pharmacoepidemiology studies have been inconsistent, showing no or possibly increased risk of low-grade prostate cancer (although this effect was confounded by ascertainment bias and greater prostate cancer screening in testosterone-treated men) and reduced risk of high-grade, aggressive prostate cancer with testosterone treatment.[337,339-342] Larger, longer-term, prospective randomized controlled trials are needed to determine whether testosterone therapy stimulates the growth and progression of subclinical prostate cancer into clinically evident and significant high-grade, aggressive disease.

Along with reduced prostate size, serum PSA concentrations in androgen-deficient men are decreased, and testosterone replacement increases PSA to concentrations observed in age-matched eugonadal men.[675] Because testosterone replacement is a potentially disease-modifying intervention that may alter the natural history of prostate cancer, prostate cancer screening and monitoring of PSA concentrations should be offered to patients older than 50 years (>40 years if the man has risk factors for prostate cancer) initiating testosterone treatment, after a discussion of risks and benefits of prostate cancer screening (i.e., shared decision making),[116] as PSA screening for prostate cancer has no effect or only modest effect on the mortality rate in the general population of men.[676-678]

In men older than 40 years who desire prostate cancer screening, PSA measurement (and DRE, depending on the skill of the practitioner and patient preference) should be performed before testosterone therapy is initiated, 3 to 12 months after starting treatment, and then in accordance with accepted guidelines. More intensive PSA monitoring should not be performed, because abnormal concentrations that would trigger a prostate biopsy are more likely to occur in older hypogonadal men on testosterone therapy, resulting in an increased likelihood of detecting localized, low-grade prostate cancer, for which the management is unclear.[679] The diagnosis of subclinical or localized low-grade prostate cancer does not affect overall mortality; however, the potential medical and surgical treatment, psychological, and socioeconomic consequences and morbidity of this diagnosis may be considerable.

Hypogonadal men receiving testosterone therapy who demonstrate a verified PSA level greater than 4 ng/mL or increase in PSA greater than 1.4 ng/mL within 12 months after starting therapy, an abnormal finding on DRE (nodule or induration), or an AUA symptom score or IPSS greater than 19 should undergo urologic evaluation.[116] Elevated PSA concentrations should be confirmed with a repeat measurement. If prostatitis or urinary tract infection that can markedly elevate PSA concentrations is suspected, PSA measurements should be repeated after appropriate antibiotic treatment.

Sleep Apnea. Testosterone treatment has been reported to induce or worsen obstructive sleep apnea, but the prevalence of clinically significant obstructive sleep apnea during testosterone replacement therapy is probably very low and may be dose related.[553,567,568] Short-term, high-dose testosterone treatment in older hypogonadal men significantly worsened obstructive sleep apnea, increased the duration of hypoxemia, and shortened total sleep time as assessed by polysomnography. In contrast, older men treated with a scrotal testosterone patch for 3 years did not demonstrate a significant worsening of sleep apnea as assessed by a portable device.[680] As discussed earlier, sleep apnea may conversely cause gonadotropin and testosterone suppression and secondary hypogonadism, probably because of the stress of oxygen desaturation and sleep disturbance.

Sleep apnea is associated with significant morbidity and mortality risks. Therefore, hypogonadal men, especially those at increased risk (e.g., obese men), should be monitored for symptoms of obstructive sleep apnea syndrome (e.g., loud snoring, apnea witnessed by a bed partner, daytime somnolence, unexplained erythrocytosis, worsening or recent onset of hypertension or edema) before starting testosterone therapy, after 3 to 12 months, and then yearly.[116] If symptoms suggest sleep apnea, a formal sleep study (polysomnography) should be performed. If obstructive sleep apnea is confirmed, appropriate treatment (e.g., CPAP) should be instituted before testosterone treatment is started or continued.

Reduced Sperm Production and Fertility. In men who have androgen deficiency and persistence of some sperm production

with either partial primary or secondary hypogonadism, testosterone treatment suppresses gonadotropin production by negative feedback regulation, which in turn suppresses spermatogenesis and may further impair fertility.[587] Suppression of sperm production is most important in men with secondary hypogonadism and normal testes who wish to father children. In these men, testosterone therapy should be discontinued, and gonadotropin therapy should be started, initially with hCG alone and then, if necessary, with combined hCG and FSH treatment to stimulate spermatogenesis.[79] In the absence of coexisting testicular disease (e.g., cryptorchidism), prior testosterone therapy does not impair—but might delay—the subsequent induction of sperm production with gonadotropins.[392-394]

Acne and Oily Skin. Boys with pubertal androgen deficiency who are receiving testosterone therapy to induce puberty and men with severe hypogonadism who are treated with full replacement doses of testosterone may develop acne and increased oiliness of the skin due to increased sebum production.[146,147,374,375] These conditions usually respond to local skin measures (e.g., benzoyl peroxide, retinoids) and antibiotics, reduction in testosterone dose, or both.

Gynecomastia. Occasionally, breast tenderness or gynecomastia develops or worsens during testosterone replacement therapy, particularly in boys who are receiving testosterone for induction of puberty, men with severe androgen deficiency who are treated with full replacement or high-dose testosterone, and hypogonadal men with predisposing conditions such as hepatic cirrhosis. Gynecomastia is commonly found in boys and men with androgen deficiency before the initiation of testosterone therapy. A careful breast examination should be performed before and again during testosterone replacement therapy to detect the presence or worsening of gynecomastia (breast tenderness or enlargement), or the rare occurrence of breast cancer.

Lipids. In hypogonadal men, testosterone replacement results in no change or only a slight decrease in HDL cholesterol and no change in total cholesterol or LDL cholesterol concentrations.[326,681] The reduction in HDL cholesterol is greater in men with more severe androgen deficiency and in those treated with supraphysiologic testosterone doses or with nonaromatizable, oral 17α-alkylated androgens.[620]

The clinical significance of HDL cholesterol reduction induced by testosterone in terms of cardiovascular risk is not known. Understanding of the effects of testosterone therapy on major cardiovascular outcomes (including myocardial infarction, stroke, cardiovascular mortality risk) will require larger, longer-term randomized controlled studies. Cardiovascular risk and lipid measurements should be evaluated as recommended by available practice guidelines; at present, more intensive monitoring in hypogonadal men receiving therapy is not justified.

Other Potential Adverse Effects. Frontal balding or androgenic alopecia may develop or worsen in genetically predisposed hypogonadal men during testosterone replacement therapy. Mild to moderate *weight gain* usually occurs during testosterone treatment because of the anabolic actions of testosterone on muscle mass and mild fluid retention. Testosterone therapy usually does not cause clinically significant edema, except occasionally in hypogonadal men with underlying edematous states such as CHF or hepatic cirrhosis.

Stimulation of excessive libido and erections by testosterone is rare and usually occurs in boys or young men with severe, long-standing androgen deficiency who are treated with full replacement or high-dose testosterone therapy. These symptoms usually resolve spontaneously or with a reduction in testosterone dose. Contrary to popular opinion, testosterone treatment does not cause pathologic aggressiveness, anger, or rage.[682,683] Instead, testosterone replacement therapy increases social aggressiveness, motivation, and initiative and reduces irritability and anger.

Profound behavioral and physical changes induced by testosterone treatment in men with severe, long-standing androgen deficiency may be upsetting to both patients and their partners. Therefore, changes that are expected to occur with testosterone replacement should be discussed with patients and their partners before and during treatment. Oral 17α-alkylated androgens may cause cholestasis or potentially serious hepatotoxicity.[620] However, liver toxicity does not occur with testosterone replacement therapy, and routine monitoring of liver enzymes is not necessary in hypogonadal men. IM injection of testosterone esters, particularly with large volume injections of testosterone undecanoate or rarely with testosterone enanthate and cypionate, has been reported to cause coughing that has been hypothesized to be due to POME, the significance of which is not known (see earlier discussion).

Formulation-Specific Adverse Effects. *Testosterone ester injections* may cause local discomfort, bleeding, or hematoma at the site of IM injections.[116] Instruction on proper injection technique minimizes the likelihood of these adverse effects. Fluctuations in energy, mood, and libido associated with the peak and nadir swings of testosterone concentrations after testosterone ester injections may be disturbing to some hypogonadal men and may require reduction of the dose injected and shortening of the injection interval or switching to transdermal testosterone. Rarely, an allergy may occur to the sesame oil (enanthate) or cottonseed oil (cypionate) vehicle used.

Testosterone patches frequently cause local skin erythema, irritation, itching, and contact dermatitis and occasionally lead to more severe reactions.[116] Use of a topical corticosteroid cream under the reservoir of the patch may reduce skin irritation and reactions, but often men prefer to switch to another testosterone formulation. Testosterone patches may adhere poorly to skin, particularly with excessive perspiration.

In contrast to testosterone patches, *testosterone gels* and *solution* cause little to no skin irritation. However, residual testosterone remains on the skin surface at the application sites, and there is a potential for transfer of testosterone to women and children who have prolonged intimate contact with these sites.[116] Precautions to avoid contact transfer of testosterone include washing the hands immediately after application of testosterone gel, covering the application site with clothing, washing off residual testosterone on skin by showering or bathing (4–6 hours after application), and avoiding prolonged skin-to-skin contact of the application site with women or children.

Buccal testosterone tablets may cause gum irritation, inflammation or recession, or an altered or bitter taste sensation, and they may adhere poorly to gums if not they are not properly applied.[116]

Nasal testosterone gel may cause nasal irritation, nasopharyngitis, rhinorrhea, epistaxis, and nasal scabbing.

SC testosterone pellets may uncommonly extrude spontaneously; rarely, there may be bleeding or infection at the site of implantation.[116]

Gonadotropin Therapy

Secondary hypogonadism manifests as prepubertal or adult androgen deficiency and impairment of sperm production due to gonadotropin deficiency. The primary goal of gonadotropin therapy in men with secondary hypogonadism is to initiate and

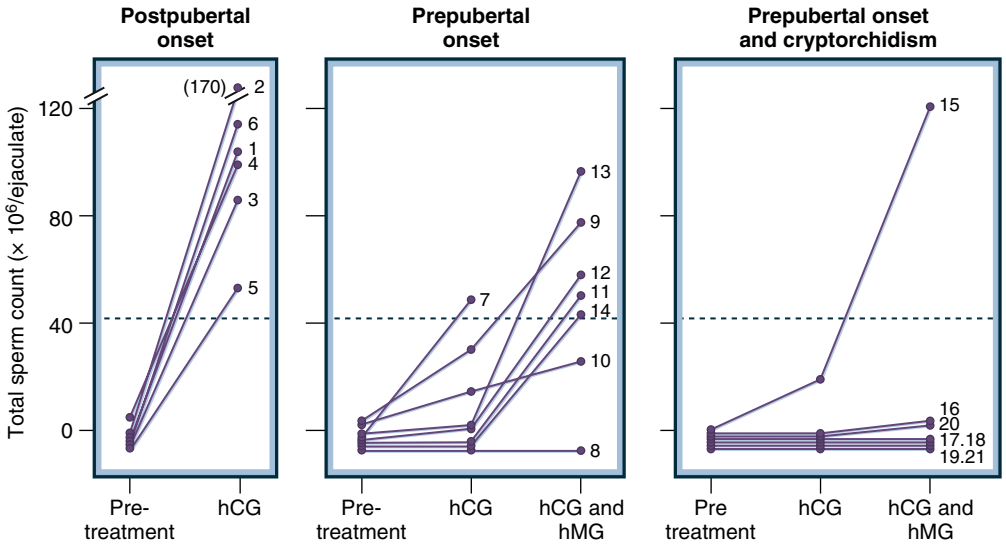
maintain spermatogenesis to establish and restore fertility.[614] Because gonadotropin therapy is more complex (requiring multiple injections weekly) and more expensive than testosterone replacement therapy, symptomatic androgen deficiency is usually treated with the latter. In patients with partial gonadotropin deficiency, testosterone treatment may suppress remaining gonadotropin secretion by negative feedback regulation. When fertility is desired and stimulation of sperm production is needed in a man with secondary hypogonadism, testosterone is discontinued and gonadotropin therapy is initiated. Previous testosterone treatment does not compromise subsequent stimulation of spermatogenesis by gonadotropins, although sperm production may be slower.[392-394]

The gonadotropin preparations most commonly used to treat secondary hypogonadism are purified urinary gonadotropins. Human recombinant gonadotropin preparations are now available and have much higher purity than urinary preparations, but they are more expensive. Because urinary gonadotropins are highly effective in treating gonadotropin deficiency, they remain the most commonly used preparations for treatment of infertility from secondary hypogonadism.

hCG is used to provide LH-like activity because its half-life is longer than that of LH. In contrast to LH, which would require pulsatile administration approximately every 2 hours, hCG is administered two to three times per week. Purified urinary preparations of hCG (derived from urine of pregnant women) that contain LH-like activity are used almost exclusively in gonadotropin therapy. FSH activity is usually provided by purified urinary *human menopausal gonadotropin* (hMG), which is derived from urine of menopausal women and contains both LH and FSH; by highly purified urinary *human FSH*; or by *rhFSH*. FSH preparations are administered three times weekly. hCG and FSH preparations may be administered either intramuscularly or subcutaneously.[684,685] Both are equally effective, but the latter is better tolerated and more easily self-administered.

In patients with prepubertal gonadotropin deficiency, initiation of sperm production requires treatment with both hCG and FSH[79] (Fig. 19.30). Gonadotropin therapy is initiated with administration of hCG alone at a dose of 500 to 2000 IU SC two to three times weekly to stimulate sufficient endogenous testosterone production to increase and maintain circulating testosterone concentrations in the normal range and to correct manifestations of androgen deficiency.[6] The dose of hCG is increased until serum testosterone concentrations are within the eugonadal range. Despite the more frequent injections, some men with secondary hypogonadism prefer hCG over testosterone treatment because costs are comparable (purified urinary hCG preparations compared with testosterone gels), SC injections are better tolerated than IM injections, testis size is generally larger, and spermatogenesis is increased. In addition, there is no risk of secondary transfer to intimate contacts, and some men prefer twice weekly SC injections to daily gel application.

Men with gonadotropin deficiency who also have primary testicular disease (e.g., cryptorchidism) or CHH may require larger doses of hCG (e.g., up to 3000–5000 IU two to three times weekly or occasionally much more). Men with secondary hypogonadism who have coexisting severe testicular damage may be completely unresponsive to hCG treatment (see Fig. 19.30). Because hCG stimulates Leydig cell aromatase activity within the testes, serum estradiol concentrations may increase disproportionately relative to testosterone concentrations, resulting in breast tenderness or gynecomastia more frequently than with testosterone replacement



• **Fig. 19.30** Total sperm count response to gonadotropin therapy with human chorionic gonadotropin (hCG) alone or in combination with human menopausal gonadotropin (hMG) in males with hypogonadotropic hypogonadism of postpubertal onset (*left*), prepubertal onset without cryptorchidism (*middle*), or prepubertal onset with cryptorchidism (*right*). Sperm production was induced by hCG alone in all men with postpubertal hypogonadotropic hypogonadism and in some with prepubertal onset who did not have cryptorchidism. Both hCG and hMG treatment was required to increase sperm production above the lower limit of normal (*dashed line*) in patients with prepubertal hypogonadotropic hypogonadism who did not have cryptorchidism. With one exception, men with prepubertal hypogonadotropic hypogonadism who also had cryptorchidism failed to respond to hCG alone or to combined hCG and hMG therapy. (From Finkel DM, Phillips JL, Snyder PJ. Stimulation of spermatogenesis by gonadotropins in men with hypogonadotropic hypogonadism. *N Engl J Med.* 1985;313:651–655.)

therapy. Some men may complain of burning at the site of SC injections of hCG.

hCG stimulates Leydig cell testosterone production, resulting in relatively high intratesticular testosterone concentrations that cause Sertoli cells to mature and sperm production to be initiated to varying degrees. In a small proportion of patients with partial gonadotropin deficiency of prepubertal onset and in almost all men with acquired postpubertal gonadotropin deficiency, treatment with hCG alone may stimulate sperm production[79] (see Fig. 19.30). Evidence for partial gonadotropin deficiency includes bilateral testicular volume larger than 8 mL, physical examination evidence of partial androgenization, low-normal serum gonadotropin concentrations, and low-normal serum inhibin B concentrations.[686-690] Most patients with severe CHH require FSH treatment in addition to hCG to stimulate complete spermatogenesis and induce fertility.[691-693]

If no sperm is present in the ejaculate after 6 to 12 months of treatment with hCG and serum testosterone concentrations in the eugonadal range, hMG or FSH at a dose of 75 IU three times weekly (increasing up to as much as 300 IU given subcutaneously three times weekly) is added, in combination with the same dose of hCG, for an additional 6 to 12 months or longer, until spermatogenesis is induced.

The induction of sperm production by gonadotropin therapy may take 12 to 24 months. Factors that limit the duration of gonadotropin treatment are impatience by patients and their partners and the expense of gonadotropins, particularly hMG or FSH preparations, which are very costly. Some couples may opt for alternative means to have children (e.g., adoption). In patients with CHH, sperm output is often low, possibly because of inadequate gonadotropin stimulation of Sertoli cell number and maturation during development.[694] Despite quantitatively low sperm production during gonadotropin therapy, fertility may be possible, sometimes at very low sperm counts (e.g., <1 million/mL).[686] Some patients who have very low sperm counts and remain infertile on gonadotropin treatment may elect to use ejaculated sperm for ICSI.

Once spermatogenesis has been initiated with combined hCG and FSH treatment in patients with prepubertal gonadotropin deficiency, sperm production may be maintained with hCG treatment alone.[611] In men with acquired postpubertal gonadotropin deficiency, reinitiation of spermatogenesis can usually be accomplished with hCG therapy alone.[79]

In men with secondary hypogonadism due to hypothalamic GnRH deficiency (e.g., CHH, Kallmann syndrome), pulsatile GnRH therapy may be used to stimulate production of endogenous gonadotropins (both LH and FSH) and testosterone and to initiate and maintain sperm production sufficient for fertility.[47] GnRH is administered subcutaneously with the use of a portable infusion pump that delivers small doses (pulses) of GnRH (e.g., GnRH 5–25 ng/kg SC every 1.5–2.0 hours, increasing to higher doses if needed); this treatment mimics a near-normal physiologic stimulus to the pituitary gland. In men with CHH, pulsatile GnRH treatment is successful in stimulating gonadotropin, testosterone, and sperm production in approximately 75% of cases; in the other 25% of cases, men fail to respond due to concomitant pituitary or testicular defects.[396] The effectiveness of pulsatile GnRH replacement in stimulating sperm production is comparable to that of gonadotropin therapy. Practically, however, the use of pulsatile GnRH therapy is limited to specialized centers because GnRH is not readily available, the infusion pump requires additional expertise and management, and therapy is expensive.

Sexual Dysfunction in Men and Women

SHALENDER BHASIN AND ROSEMARY BASSON

CHAPTER OUTLINE

KEY POINTS

- In contrast to the earlier sexual response model depicting a linear progression of discrete phases, current research conceptualizes sexual response as a motivation/incentive-based cycle comprising phases of physiologic response. These phases of the cycle overlap, and their order is variable.
- In middle-age and older men, sexual dysfunction is often related to comorbid conditions, such as diabetes, coronary artery disease, or a hormonal problem.
- Penile erection results from biochemical and hemodynamic events that are associated with activation of central nervous system sites, cavernosal smooth muscle relaxation, increased blood flow into cavernosal sinuses, and venous occlusion.
- Corporal smooth muscle tone is regulated by transmembrane and intracellular calcium flux, which in turn is regulated by potassium channels; connexin43-derived gap junctions; and cholinergic, adrenergic, and nonadrenergic, noncholinergic mediators, including nitric oxide.
- Testosterone regulates sexual thoughts and desire, sexual arousal, attentiveness to erotic stimuli, and sleep-entrained erections. Testosterone deficiency is a treatable cause of hypoactive sexual desire in men. In randomized trials, testosterone replacement therapy has been shown to improve erectile function and satisfaction with intercourse.
- Selective phosphodiesterase 5 inhibitors are safe and effective and have emerged as first-line therapy for men with erectile dysfunction.
- Sexual response is understood to be incentive based; multiple reasons for sex motivate receptivity to sexual stimuli that can be appraised as sexually arousing.
- Physical and subjective arousal may diverge. Women complaining of low sexual arousal usually physically respond to sexual stimuli in a laboratory setting. In contrast, men with erectile dysfunction from endothelial or neurologic deficit—the most common cause of men's arousal complaints—typically still experience mental sexual arousal/excitement.
- Women's sexual dysfunctions do not link to androgen deficit.
- Psychological therapies predominate in the treatment of women's sexual dysfunctions with emerging evidence of benefit from mindfulness-based cognitive therapy.
- About 10% to 15% of women have dyspareunia from provoked vestibulodynia—a chronic pain disorder associated with central sensitization of the nervous system and occasionally precipitated by low-dose combined contraceptives.

Men and women rate sexual health as highly important to their quality of life.[1] Recognizing the importance of sexual function as a determinant of quality of life, the World Health Organization declared sexual health a fundamental right of men and women. Yet disorders of sexual function are highly prevalent in men and women.[2] Epidemiologic surveys, such as the National Survey of Sexual Attitudes and Lifestyle (Natsal-3), indicate that 42% of men and 51% of women experienced some problem with sexual response in the previous year, causing distress in the lives of 10% to 11%.[2] The 2015 systematic review by the International Consensus Committee on Sexual Medicine found that low sexual interest was the most prevalent sexual concern for

women and erectile dysfunction (ED) the most common form of sexual dysfunction in men.[3] Among women, the loss of pleasure and the loss of interest were the most commonly reported problems during the previous year, and their incidence was similar among younger and older women.[3] In contrast, middle-age and older men reported higher prevalence of sexual dysfunction than younger men; the prevalence of ED ranged from less than 20% among men younger than 50 years of age to 25% to 76% among men older than 70 years.[3]

Sexual response exemplifies the intricate blending of mind and body so that dysfunction is neither purely psychological nor entirely biologic, but psychological and biologic factors both contribute to sexual dysfunction to varying degrees. Recent advances in our understanding of the physiologic and biochemical mechanisms of penile erection and the development of mechanism-specific therapies for ED have greatly clarified the importance of vascular health in maintaining erectile function. The 1980s and 1990s witnessed remarkable progress in our understanding of the physicochemical mechanisms that lead to penile tumescence and rigidity. It was recognized that penile erections are the result of cavernosal smooth muscle relaxation and increased penile blood flow.[4–6] The appreciation of nitric oxide as a key vasodilator in the vascular smooth muscle was a pivotal discovery, recognized later by awarding of the Nobel Prize in Physiology or Medicine to Robert F. Furchgott, Louis J. Ignarro, and Ferid Murad. The recognition that nitric oxide caused cavernosal smooth muscle relaxation by simulating guanylyl cyclase provided the foundation for the discovery of highly effective oral therapies for the treatment of ED.

The growing recognition that ED is commonly a manifestation of systemic disease[4,7–12] and the availability of easy-to-use therapeutic options, including oral and intraurethral drugs, have duly placed sexual disorders in men within the purview of the endocrinologist and the primary care provider. In middle-age and older men, but less so for women, sexual dysfunction is often related to comorbid medical conditions.[4,7–12] ED may signal asymptomatic coronary artery disease,[13,14] diabetes, or depression.[2] In women, sexual dysfunction is very strongly linked to mental health.[2,14–17] A similarly strong association was found between sexual dysfunction and relationship unhappiness in both men and women. The American Psychiatric Association's clinical definitions of sexual disorders published in the fifth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) in 2013[18] attempted to quantify symptom duration and severity more precisely, address the overlap between sexual desire and arousal in women, and include the important entity of sexual motivation/interest. Also included in DSM-5 are previously ignored aspects of women's sexual response, such as mental sexual arousal/excitement, pleasure, ability to trigger arousal and desire from sexual stimuli, and physical genital and nongenital sexual sensations (Table 20.1).

This chapter describes the current conceptualization of sexual response in men and women, the underlying pathophysiologic mechanisms of sexual dysfunction, the sexual sequelae of various endocrine disorders, and clinical assessment and diagnosis of sexual dysfunction and its management. Management strategies for sexual dysfunction stemming from hormonal and nonhormonal factors are also outlined.

TABLE 20.1 Current Definitions of Female Sexual Disorders

Female Sexual Interest/Arousal Disorder

Lack of sexual interest/arousal for a minimum duration of 6 months as manifested by at least three of the following indicators:

1. Absent/reduced frequency or intensity of interest in sexual activity
2. Absent/reduced frequency or intensity of sexual/erotic thoughts or fantasies
3. Absence or reduced frequency of initiation of sexual activity and typically unreceptive to a partner's attempts to initiate
4. Absent/reduced frequency or intensity of sexual excitement/pleasure during sexual activity on all or almost all (approximately 75%) sexual encounters
5. Sexual interest/arousal is absent or infrequently elicited by any internal or external sexual/erotic cues (e.g., written, verbal, visual)
6. Absent/reduced frequency or intensity of genital or nongenital sensations during sexual activity on all or almost all (approximately 75%) sexual encounters

Female Orgasmic Disorder

At least one of the two following symptoms, which must have been present for a minimum duration of approximately 6 months and be experienced on all or almost all (approximately 75%) occasions of sexual activity:

1. Marked delay in, marked infrequency of, or absence of orgasm
2. Markedly reduced intensity of orgasmic sensation

Genitopelvic Pain/Penetration Disorder

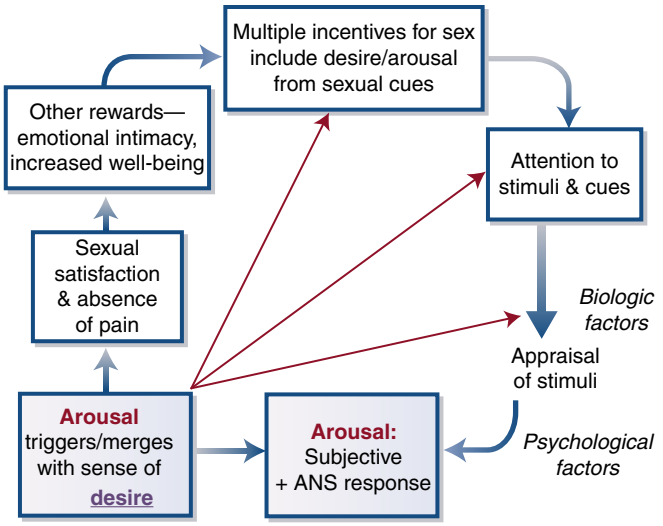
Persistent or recurrent difficulties for a minimum duration of approximately 6 months with one or more of the following:

1. Marked difficulty having vaginal intercourse/penetration
2. Marked vulvovaginal or pelvic pain during vaginal intercourse/penetration attempts
3. Marked fear or anxiety either about vulvovaginal or pelvic pain on vaginal penetration
4. Marked tensing or tightening of the pelvic floor muscles during attempted vaginal penetration

Human Sexual Response Cycle

The sexual response can be conceptualized as a motivation/incentive-based cycle comprising phases of physiologic response and subjective experience.[19–22] The phases of the cycle overlap, and their order is variable (Fig. 20.1). The motivations and incentives for sex are multiple and varied. A wish to both demonstrate and enhance emotional intimacy between partners is important for both men and women.[23] Depression is a major cause of reduced sexual motivation in otherwise healthy persons and in those with endocrine disease: comorbid depression has been identified as a major factor underlying sexual dysfunction in women with diabetes.[24–26] Endocrine disorders can markedly lessen sexual self-image, especially when associated with altered appearances, infertility, or the ability to be gainfully employed.[24,25,27,28]

Sexual desire—as in lust or drive triggered deliberately, accidently, even subliminally,[29] by sexual stimuli—is only one of many reasons people engage in sex and may or may not be sensed initially: desire can be triggered by the sexual excitement (i.e., the subjective sexual arousal) in response to sexual stimuli.[19,24,30,31] In both men and women, the relationship between desire and arousal is variable, complex, and often inseparable.[32–34] This overlap of phases is consistent with the neuroimaging data of sexual arousal, which have led to the concept that motivation is one facet of sexual arousal and desire is one component of motivation.[35] Many psychological and biologic factors influence the brain's appraisal and processing of sexual stimuli to enable or disable subsequent



• **Fig. 20.1** Circular human response cycle of vverlapping phases. Human sexual response is depicted as a motivation/incentive-based cycle of overlapping phases of variable order. A sense of desire may or may not be present initially: it can be triggered alongside the sexual arousal resulting from attending to sexual stimuli. Psychological and biologic factors influence the brain's appraisal of the sexual stimuli. Sexual arousal comprises subjective (pleasure/excitement/wanting more of the same) and physical (genital and nongenital) responses. The merged desire and arousal influence the ongoing attention to and appraisal of further sexual stimulation. The sexual and nonsexual outcomes influence present and future sexual motivation. ANS, autonomic nervous system. (Modified from Basson R. Human sexual response. *Handb Clin Neurol.* 2015;130:11–18.)

arousal.[16,23,24,26,30-32,34–42] The sexual and nonsexual outcomes influence future sexual motivation. The circle depicted in Fig. 20.1 may be partially or completely repeated several times during any given sexual encounter.[19] The sexual response cycle varies substantially among individuals and even within a person's own sexual life, and is influenced by multiple factors, including the stage of life cycle, age, relationship duration and happiness, and mental health[34] (see Fig. 20.1).

Even with sufficient sexual motivation and the presence of adequate stimuli, the arousal and pleasure may not occur if attention is not focused.[38] The attentional processes play a central role in facilitating the subjective and also the physiologic components of sexual arousal.[38] Sexual information is processed in the mind both automatically and consciously.[39] The sexual nature of the stimuli is processed by the limbic system, allowing genital congestion (observed to be rapid and involuntary in women and slower but still involuntary in men).[39] Conscious appraisal of sexual stimuli and contextual cues can lead to subjective arousal.[39-42] The latter may be further increased by awareness of the genital congestion of arousal, which is typically accurately registered and very relevant to men's experience.[19] For women, an important component of arousal is the change in perception of genital sensitivity such that touch is no longer neutral or even unpleasant but rather sexual and pleasurable. Subjective arousal is also cognitively appraised to evaluate whether sex is pleasurable and safe or whether it is shameful or likely to have a negative consequence.[39-42] These cognitive appraisals continually modify both the physiologic and subjective responses.[39,40]

Undue focus on nonerotic thoughts during sexual stimulation, generated possibly by anxiety, can be associated with sexual problems.[40] A study of men and women in long-term relationships found that women tended to report nonerotic thoughts about their body image and the consequences of sexual activity, whereas men were more likely to report nonerotic thoughts about problematic sexual performance.[41] A high frequency of nonerotic thoughts can be associated with increased likelihood of sexual dysfunction. Importantly, the more difficult it was to refocus back on an erotic thought, the more this predicted sexual difficulty occurred. This research is clearly relevant to patients with endocrine disease, which frequently has negative impact on sexual self-image and sexual function.[24,25]

The dual control theory for sexual appraisal by Bancroft and associates[43] envisions a balance between sexual activation and sexual inhibition in an individual's brain that determines whether sexual stimulation leads to arousal. In men, the inhibitions include the threat of performance failure and the threat of performance consequences; in women, relationship importance (reflecting the need for sex to be within a specific type of relationship), concerns about sexual function (worries and distractions about sexual function), and arousal contingency (the potential for arousal to be inhibited by contextual/situational factors) were inhibiting factors.[43]

Thus, the current conceptualization of men's and women's sexual responses is in marked contrast to an earlier model depicting a linear invariable progression of discrete phases—from desire to arousal to a plateau of high arousal, followed by orgasm/ejaculation and finally a phase of resolution.[44] Women's sexual dysfunction typically involves lessened arousal and desire and lessened frequency of orgasm, which is now embodied in DSM-5 as *sexual interest/arousal disorder* (SIAD)[45,46] (see Table 20.1). Although the focus in men has typically been on ED or premature ejaculation, they too may experience a more generalized sexual distress disorder affecting desire, erectile function, and ease of orgasm.[10,42]

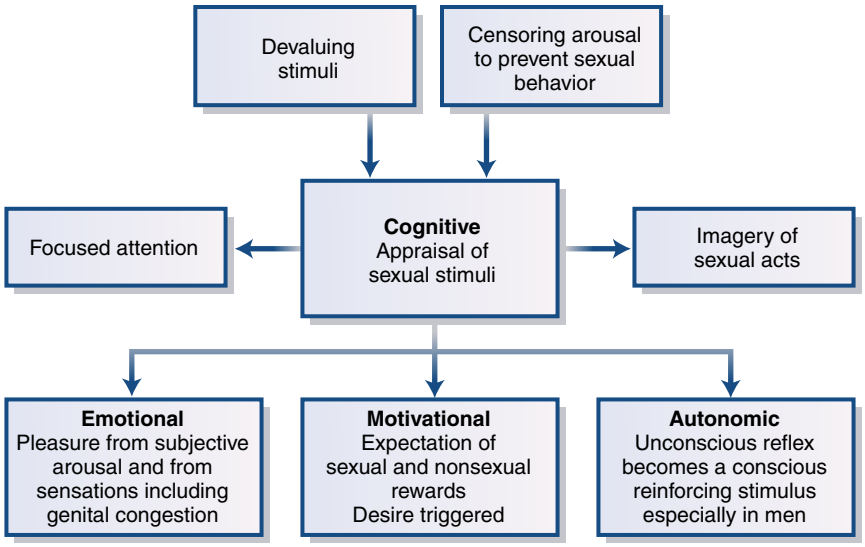
Physiologic Mechanisms of Human Sexual Response

Physiology of Desire and Arousal

Functional Brain Imaging of Sexual Arousal in Men and Women

Functional neuroimaging studies have clarified some of the neural correlates of sexual response.[47–53] These brain imaging studies during sexual stimulation—most of which were performed in healthy male heterosexual volunteers—has revealed engagement of a complex brain circuitry that involves activation of brain regions related to the different aspects of arousal and deactivation of other brain regions related to the inhibition of sexual arousal.[47–53]

In keeping with the current circular model of sexual response (depicting sexual incentives/motivations, information processing, overlap of arousal and desire, emphasis on both subjective and physiologic arousal, plus importance of reward), the model of sexual arousal emanating from the neuroimaging data comprises cognitive, motivational, emotional, and autonomic components[35] (Fig. 20.2). The cognitive component includes appraisal of potentially sexual stimuli, focused attention on those stimuli appraised as erotic, and imagery of actual sexual activity. The activations of the right lateral orbitofrontal cortex (OFC), of the right and the left inferior temporal cortices, of the superior parietal lobules, and of areas belonging to the neural network mediating motor imagery (inferior parietal lobules, left ventral premotor area, right and



• **Fig. 20.2** Brain areas activated during sexual arousal. Brain areas activated during sexual arousal allow (1) continued focus on sexual stimuli, imaging of sexual behavior, evaluation/censorship and limitation or prevention of actual behavior despite arousal (all constituting a cognitive component of arousal); (2) sexual feelings (an emotional component); (3) anticipation of reward (a motivational component); and (4) an autonomic/neuroendocrine response of physical sexual arousal. (Modified from Basson R, Weijmar Schultz W. Sexual sequelae of general medical disorders. *Lancet*. 2007;369[9559]:409–424.)

left supplementary motor areas, cerebellum) are considered to be the neural correlates of this cognitive component. The motivational component comprises the processes that direct behavior to a sexual goal, including the perceived urge to express overt sexual behavior. Thus, the motivational component is conceptualized as including the experience of sexual desire. Neural correlates are thought to involve the anterior cingulate cortex (ACC), claustrum, posterior parietal cortex, hypothalamus, substantia nigra, and ventral striatum. The emotional component is the brain activity underlying the pleasure from the mental excitement and the perception of genital and other physical responses. This pleasure comprises *liking* and *wanting*.[54] The left primary and secondary somatosensory cortices, the amygdalae, and the right posterior insula are conceived as neural correlates of this emotional component. The autonomic and neuroendocrine component includes the various responses (e.g., genital, cardiovascular, respiratory, changes in hormonal plasma levels) that allow preparedness for sexual activity: activations of the ACC, anterior insulae, putamens, and hypothalamus may contribute to this component.

The brain imaging studies during sexual arousal have highlighted three inhibitory components[35]:

1. Inhibition mediated by regions in the temporal lobes and the gyrus rectus of the OFC in the resting state. Patients with lesions in the gyrus rectus are noted to have excessive appetite for sexual and other pleasurable activities.[55] The Klüver-Bucy syndrome, a rare neurologic disorder associated with damage to both temporal lobes, is characterized by hypersexuality.[56] The inhibitory regions of the temporal lobes are distinct from those activated in response to visual sexual stimuli.
2. Inhibition of arousal once it has begun, to limit its expression because the circumstances are inappropriate, is mediated in the caudate nucleus and putamen. This is consistent with the case reports of hypersexuality associated with lesions in the head of the caudate nuclei.[57]
3. Activation of the left OFC is thought to block the ability of sexual stimuli to arouse. The brain regions that mediate inhibition of sexual arousal have been found to be activated during tasks that involve moral judgment, guilt, and shame.

In general, men typically show greater responsiveness to visual sexually arousing stimuli than do women.[58] Brain imaging in hypogonadal men before and after testosterone replacement therapy suggests that the left OFC might exert a testosterone-dependent inhibitory tonic control on sexual arousal and that this inhibitory control decreases on visual sexual stimulation.[53] In addition, the response of the right anterior insula to visual sexual stimulation appears to be related to circulating testosterone levels.[53]

Functional imaging during penile or clitoral stimulation to orgasm indicates that women show more activation in left frontoparietal regions, notably in the posterior parietal cortex and the supplementary motor area—regions associated with making a mental representation of another person's actions.[49] These findings may reflect gender differences in perspective and empathy. The brain responses during the orgasm(s) are similar in men and women, but men and women use different cerebral strategies to reach orgasm.[49]

The complexity and variability of these systems was reflected in a study of surgically menopausal women who were sexually active but were not receiving hormonal therapy.[48] When these surgically menopausal women viewed erotica during functional magnetic resonance imaging (fMRI), they failed to display the brain activation observed in premenopausal women or when they were treated with testosterone and estrogen. However, these women reported sexual arousal from the erotic videos regardless of the hormonal supplementation.[48]

Functional imaging studies in women with DSM-IV hypoactive sexual desire disorder (HSDD) show, unsurprisingly, reduced activity in sexual desire networks and increased activity in self-referential brain networks, areas involved in moral judgments, shyness, and visual analyses.[59] It is encouraging to note that even

structural changes associated with chronic pain can reverse with treatment, as these data suggest that both anatomic and functional changes associated with HSDD may be reversible with appropriate treatment.[52]

Neurotransmitters and Hormones Involved in Sexual Desire and Subjective Arousal

A variety of hormones and peptides are involved in the sexual response. The interplay among androgens and neurotransmitters is complex[60–70]: androgens influence neurotransmitter release, and neurotransmitters may modulate androgen receptor signaling.[58,62,64] The role of testosterone in desire and arousal is well documented in men but far less so in women.[63,64] Circulating levels of testosterone or androgen metabolites do not correlate with women's sexual function in large epidemiologic studies.[65–67,71] The radioimmunoassays used to measure testosterone concentrations in many epidemiologic studies were designed to measure the substantially higher levels of testosterone in men and lacked the sensitivity, precision, and accuracy in the low range prevalent in women. In studies that have used sensitive mass spectrometry–based assays to measure testosterone levels, no significant differences have been found in serum testosterone levels between women with low desire and low subjective arousal and healthy controls.[67,71,72] Additionally, Labrie and associates[68] proposed circulating levels of androgen metabolites—most notably androsterone glucuronide (ADT-G)—as markers of ovarian plus intracrine androgen activity. Circulating ADT-G levels decrease with age in women.[68] However, serum ADT-G levels have not been found to differ significantly between women with low desire and women without low desire[67,71] or to be associated with sexual dysfunction.[72]

ADT-G is viewed by many as a good marker of total androgenic activity. The C19 steroids 11β-hydroxyandrostenedione and testosterone can be converted to the androgenic steroid 11-ketotestosterone (11-KT) that can induce androgen receptor–mediated transactivation. 11-KT can be converted to 11-ketodihydrotestosterone, which can also activate androgen receptor signaling. The enzymes required for the production of 11-KT—P450 11B1 and HSD11B2—are expressed in the adrenal, peripheral tissues, and weakly in testes and the ovaries.[73] The circulating concentrations of 11-KT are similar to those of testosterone[73] in healthy women and have been reported to be increased in women with polycystic ovary syndrome and 21-hydroxylase deficiency.[74] Although 11-KT is known to serve as a major androgen in teleosts,[75] its precise role in androgenic disorders in women is incompletely understood.

Animal Models

In animal models, sex steroid hormones modulate sexual arousal by directing the synthesis of the enzymes and the receptors for neurotransmitters, such as dopamine, noradrenaline, melanocortins, and oxytocin.[60,61,69,70,76,77] Systems that act within the hypothalamus and limbic regions of the brain are involved in arousal, attention, and sexual behavior. It is thought that dopamine transmission in the medial preoptic area (MPOA) and the nucleus accumbens focuses the person's attention on sexual stimuli (the incentives or motivations for sexual activity). It is postulated that the behavioral pattern stimulated by these systems and the subjective feelings that accompany them constitute the phenomenon commonly referred to as *sexual desire* or *arousal*. The main part of this neural pathway includes the MPOA and its outputs to the ventral tegmental area. The latter contains dopaminergic cell bodies that project to various limbic and cortical regions, including the prefrontal cortex, the nucleus accumbens, the ACC, and the amygdala.

Brain pathways for sexual *inhibition* include opioid, endocannabinoid, and serotonin neural transmissions feeding back to various levels of the excitatory pathways.[61,62] It is thought that the behavioral pattern stimulated by the inhibitory pathways includes both refractoriness to sexual reward and satiety.

Exogenous opiates are sexually inhibiting independent of their inhibitory effect on luteinizing hormone (LH), gonadotropin-releasing hormone (GnRH), and testosterone.[76] Endogenous opioids modulate the feedback effects of sex steroids on the hypothalamus and pituitary.[76] β-Endorphin is synthesized in the anterior pituitary, the hypothalamus, and the nucleus of the tractus solitarius in the brainstem. The sexual inhibiting effects of opioids occur mainly through their action in the MPOA and the amygdala.[76] Low doses of opiates can have facilitating effects, possibly through actions in the ventral tegmental area to activate the mesolimbic dopamine system. Exogenous opiates can induce an intense feeling of pleasure, which has been likened to orgasm, followed by a state of relaxation and calm.[77]

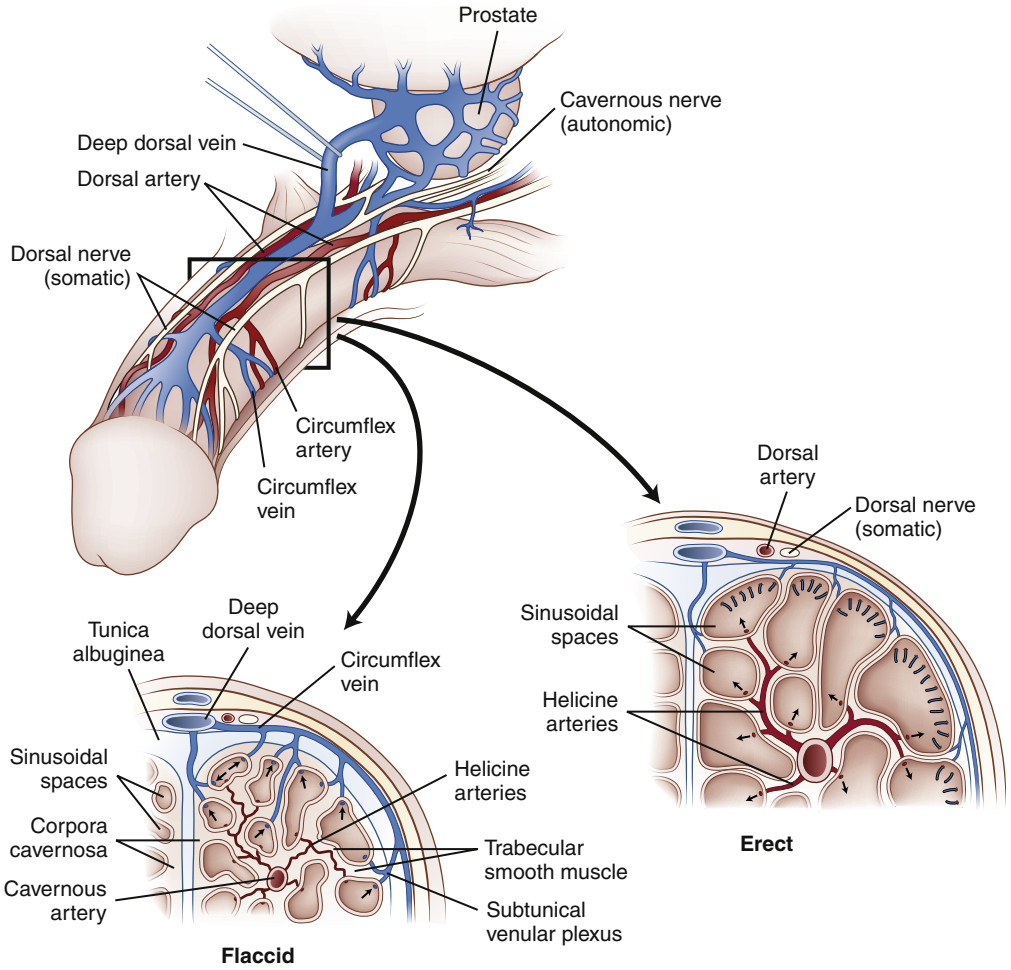
Melanocortins, derived from pro-opiomelanocortin, modulate sexual response through a specific receptor subtype, the melanocortin-4 receptor. Administration of melanocortin receptor agonists has been associated with an increase in spontaneous erections in healthy men and in men with ED, and with increased desire, but not genital responses, in women.[78,79]

Oxytocin levels increase close to orgasm. This hormone is known to be involved in pair bonding in some animal species, but its relevance in humans is less clear. The physiologic role of prolactin in the human sexual response remains uncertain.[80–82] Because a generalized reduction of dopamine activity in the hypothalamus results in increased prolactin secretion, it has been difficult to distinguish between the effects of raised prolactin itself and the possible effects of the reduced dopamine transmission. High levels of prolactin are associated with impaired sexual function in men and less clearly in women.[76,82]

The effects of the biologic factors are intertwined with those of the environmental and social factors. For instance, dopamine and progesterone, acting on their cognate receptors in the hypothalamus, can increase sexual behavior in oophorectomized, estrogenized female rats, and the presence of a male animal alongside the cage can cause an identical stimulation of the sexual behavior without the administration of either progesterone or dopamine.[83] In rodents, birds, and fish, complex neural networks enable the animal to assess the context of potential sexual activity and relate it to past experience and to the expectation of reward.[84]

Genital Sexual Congestion and Arousal

Men and women differ substantially with respect to the correlation between genital congestion and subjective sexual arousal (excitement). Whereas subjective arousal is typically concordant with genital congestion in men, there is highly variable but often poor correlation between subjective arousal and measures of genital congestion in women.[85,86] There are some exceptions in men: sleep-related erections are mostly dissociated from erotic dreams or from subjective sexual arousal.[87] In addition, psychophysiologic studies have found that men can get erections in response to films of assault or rape while experiencing no subjective arousal.[88] In contrast, a psychophysiologic study identified some 25% of men in a community sample with minimal penile response to an erotic video while their *subjective* arousal was similar to the remaining 75% of men with recorded penile congestion. There is preliminary evidence that mindfulness practice may increase concordance in association with improved sexual function.[89]



• **Fig. 20.3** Anatomy and mechanism of penile erection. Corpora cavernosa are made up of trabecular spaces that are surrounded by cavernosal smooth muscle. Helicine arteries provide the arterial supply to the cavernosal spaces. The dorsal nerve provides the sensory innervation to the penis. During erection, the relaxation of the trabecular smooth muscle and increased blood flow result in engorgement of the sinusoidal spaces in the corpora cavernosa. The expansion of the sinusoids compresses the venous return against the tunica albuginea resulting in entrapment of blood. This imparts rigidity to the tumescent penis. (Adapted from Lue TF. Erectile dysfunction. *N Engl J Med*. 2000;342[24]:1802–1813.)

In contrast to men's typically accurate assessment of their erections, women's assessment of their degree of genital congestion is less accurate. It is thought that genital congestion in women is a prompt, automatic reflex that occurs within seconds of an erotic stimulus; it may not be deemed at all sexually arousing by the woman, or it may even be deemed emotionally negative.[90] Viewing primates engaging in sexual activity subjectively arouses neither young men nor young women.[85] However, the young women viewing primate sex display marked genital congestion, as measured by vaginal photoplethysmography, whereas no genital response occurs in the men. Similarly, heterosexual women viewing lesbian women engaged in sexual activity report mostly low subjective arousal but show a prompt vasocongestive response; in contrast, heterosexual men viewing male same-sex activity show minimal genital or subjective response.[85]

Physiologic Mechanisms of Penile Erection

Penile Anatomy and Blood Flow

The erectile tissue of the penis consists of two dorsally positioned corpora cavernosa and a ventrally placed corpus spongiosum.[5,6,91,92] The erectile tissue of both the corpora cavernosa and corpus spongiosum is composed of numerous cavernous spaces separated by trabeculae.[5,6,91,92] These trabeculae are composed mainly of smooth muscle cells that are arranged in a syncytium. Endothelial cells cover the surfaces of the trabeculae.

The penile arterial blood supply is derived from pudendal arteries, which are branches of the internal iliac arteries (Fig. 20.3). The pudendal artery divides into cavernosal, dorsal penile, and bulbourethral arteries. The cavernosal arteries and their branches, the helicine arteries, provide blood flow to the corpora cavernosa.[5,6] Dilatation of the helicine arteries increases blood flow and pressure in the cavernosal sinuses.[5,6,91,92]

Penile Innveration

The neural input to the penis consists of sympathetic (T11-L2), parasympathetic (S2-S4), and somatic nerves[92] (Table 20.2). Sympathetic and parasympathetic fibers converge in the inferior hypogastric plexus, where the autonomic input to the penis is integrated and communicated to the penis through cavernosal nerves. In men the inferior hypogastric ganglionic plexus is located retroperitoneally near the rectum.[6,92]

TABLE 20.2 Innervation of the Penis

Types of Fibers	Location of Neurons in the Spinal Cord	Nerves Carrying the Fibers	General Function
Sympathetic	T10-L2	Prevertebral outflow through the hypogastric and cavernous nerves; additionally, paravertebral outflow through the parasympathetic ganglia, and pudendal or pelvic and cavernous nerves	Generally antierectile; sympathetic innervation plays an important role in regulating seminal emission
Parasympathetic	S2-S4	Cavernosal and pelvic nerves	Proerectile
Somatic	S2-S4	Pudendal nerve	Penile sensation, contraction of the striated muscles during ejaculation

Several brain regions, including the amygdala, MPOA, paraventricular nucleus of the hypothalamus, and periaqueductal gray matter, act coordinately to affect penile erections.[92] The MPOA of the hypothalamus serves as the integration site for the central nervous system control of erections; it receives sensory input from the amygdala and sends impulses to the paraventricular nuclei of the hypothalamus and the periaqueductal gray matter. Neurons in paraventricular nuclei project onto the thoracolumbar and sacral nuclei associated with erections.

The parasympathetic input to the penis is proerectile, and sympathetic input is mainly inhibitory.[92] The stimuli from the perineum and lower urinary tract are carried to the penis through the sacral reflex arc.[92]

Hemodynamic Changes During Penile Erection

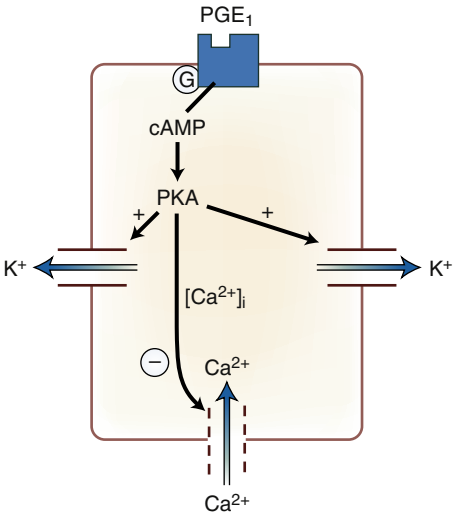
Penile erection results from a series of biochemical and hemodynamic events that are associated with activation of central nervous system sites involved in regulation of erections, relaxation of cavernosal smooth muscle, increased blood flow into the cavernosal sinuses, and venous occlusion resulting in penile engorgement and rigidity.[5,91] Normal penile erection requires coordinated involvement of intact central and peripheral nervous systems, corpora cavernosa and spongiosa, and normal arterial blood supply and venous drainage.[5,91]

As cavernosal smooth muscle relaxes and the blood flow to the penis increases, the increased pooling of blood in the cavernosal spaces results in penile engorgement[5,91] (see Fig. 20.3). The expanding corpora cavernosa compress the venules against the rigid tunica albuginea, restricting the venous outflow from the cavernosal spaces.[5,91] This facilitates entrapment of blood in the cavernosal sinuses, imparting rigidity to the erect penis.

Biochemical Regulation of Cavernosal Smooth Muscle Tone

The tone of the corporal smooth muscle cells determines the erectile state of the penis.[5,6,91] When the cavernosal smooth muscle cells are relaxed, the penis is engorged with blood and erect. When the cavernosal smooth muscle cells are contracted, there is predominance of sympathetic neural activity, and the penis is flaccid.[92]

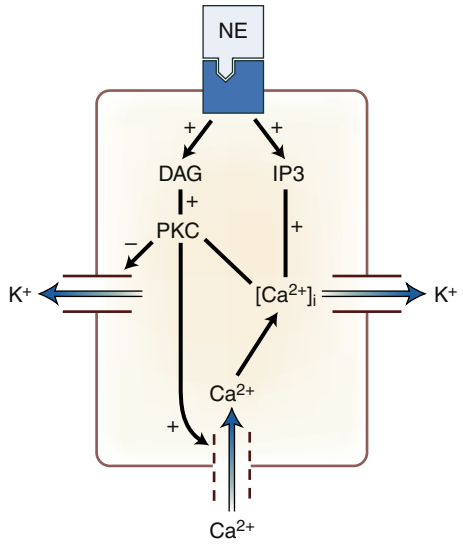
The smooth muscle tone in the corpora cavernosa is maintained by the release of stored intracellular calcium into the cytoplasm and influx of calcium through membrane channels.[93–96] The transmembrane influx of calcium in the cavernosal smooth muscle cells is mediated mostly by L-type voltage-dependent calcium channels, although T-type calcium channels are also expressed in cavernosal smooth muscle cells.[93–96] An increase in intracellular calcium activates myosin light chain kinase, resulting in phosphorylation of myosin light chain, actin-myosin interactions, and smooth muscle contraction.[96]



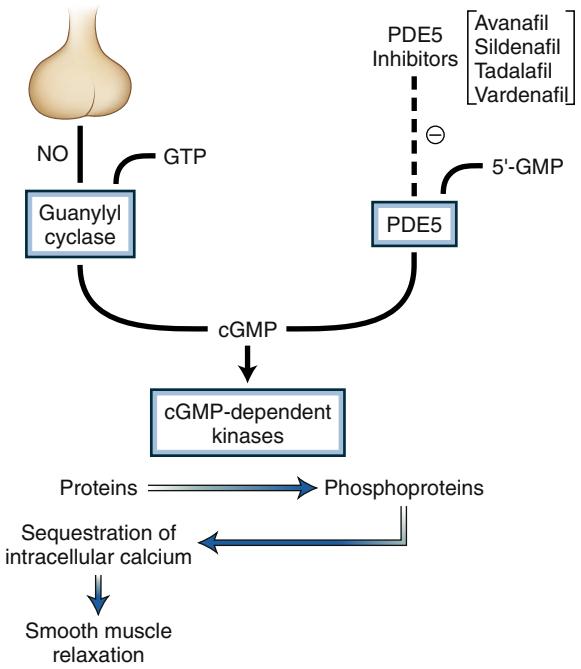
• **Fig. 20.4** Regulation of cavernosal smooth muscle contractility by PGE_1. The relaxation of the cavernosal smooth muscle is regulated by intracellular cAMP and cGMP. These intracellular second messengers by activation of specific protein kinases cause sequestration of intracellular calcium and closure of calcium channels, and opening of K^+ channels. This results in a net decrease in intracellular calcium causing smooth muscle relaxation. PGE_1 by binding to PGE_1 receptor increases the intracellular concentrations of cAMP, which activates PKA. PKA promotes the sequestration of intracellular calcium and inhibits calcium influx and stimulates K^+ channels. The nest result is a decrease in intracytoplasmic calcium and smooth muscle relaxation. Prostaglandin E_1 stimulates cAMP generation. cAMP, 3′,5′-cyclic adenosine monophosphate; *cGMP,* cyclic guanosine monophosphate; *PGE_1,* prostaglandin E_1; *PKA,* protein kinase A. (Adapted from Bhasin S, Benson GS. Male sexual function. In: De Kretser D, ed. *Knobil and Neill's Physiology of Reproduction*, 3rd ed. Boston, MA: Academic Press; 2006:1173–1194 and Lue TF. Erectile dysfunction. *N Engl J Med.* 2000;342[24]:1802–1813.)

The transmembrane and intracellular calcium flux in the cavernosal smooth muscle cells is regulated by several cellular processes that involve K^+ flux through potassium channels; connexin43-derived gap junctions; and several cholinergic, adrenergic, and nonadrenergic, noncholinergic mediators[93–101] (Figs. 20.4–20.6). The nonadrenergic, noncholinergic mediators include vasoactive intestinal peptide (VIP), calcitonin gene–related peptide (CGRP), and nitric oxide.[101]

Prostaglandin E_1 (PGE_1) binding to its cognate receptor results in generation of cyclic adenosine monophosphate



• **Fig. 20.5** Regulation of cavernosal smooth muscle contractility by norepinephrine. Norepinephrine (NE) that mediates adrenergic signals binds to adrenergic receptors and stimulates diacyl glycerol (DAG) and inositol-1,4,5-trisphosphate (IP_3). DAG stimulates protein kinase C (PKC), which along with IP_3 causes an increase in intracytoplasmic calcium and inhibition of K^+ channels. Increased intracellular calcium causes cavernosal smooth muscle contraction and loss of penile erection. (Adapted from Bhasin S, Benson GS. Male sexual function. In: De Kretser D, ed. *Knobil and Neill's Physiology of Reproduction*, 3rd ed. Boston, MA: Academic Press; 2006:1173–1194 and Lue TF. Erectile dysfunction. *N Engl J Med.* 2000;342[24]:1802–1813.)



• **Fig. 20.6** Regulation of cavernosal smooth muscle relaxation by nitric oxide (NO). cGMP regulates cavernosal smooth muscle relaxation by promoting sequestration of cytoplasmic calcium. NO is released from nonadrenergic, noncholinergic nerve endings and possibly from the endothelium. NO activates guanylyl cyclase that generates cGMP, which in turn activates cGMP-dependent kinases resulting in sequestration of intracellular calcium and smooth muscle relaxation. cGMP is degraded by cyclic nucleotide phosphodiesterases. Sildenafil, vardenafil, and tadalafil are selective inhibitors of PDE isoform 5 that is present in cavernosal smooth muscles. *cGMP,* cyclic guanosine monophosphate; *GTP,* guanosine triphosphate; *PDE5,* phosphodiesterase 5. (Adapted from Bhasin S, Benson GS. Male sexual function. In: De Kretser D, ed. *Knobil and Neill's Physiology of Reproduction*. 3rd ed. Boston, MA: Academic Press; 2006:1173–1194 and Lue TF. Erectile dysfunction. *N Engl J Med.* 2000;342[24]:1802–1813.)

(cAMP), which activates protein kinase A. Activated protein kinase A gates K^+ channels, resulting in K^+ efflux from the cell (see Fig. 20.4). The protein kinase A–mediated processes also result in a net decrease in intracellular calcium, favoring smooth muscle cell relaxation.

Adrenergic pathways, acting through norepinephrine and α_1-adrenergic receptors, activate phospholipase C, which generates diacyl glycerol and inositol trisphosphate (IP_3).[96] Diacyl glycerol activates protein kinase C, which inhibits K^+ channels and activates transmembrane calcium influx by activating L-type calcium channels[97,98] (see Fig. 20.5). IP_3 increases intracellular calcium by promoting the release of calcium from intracellular calcium stores.[97,98] The net increase in intracellular calcium promotes actin-myosin interactions, resulting in smooth muscle contraction and a flaccid penis.

Potassium Channels

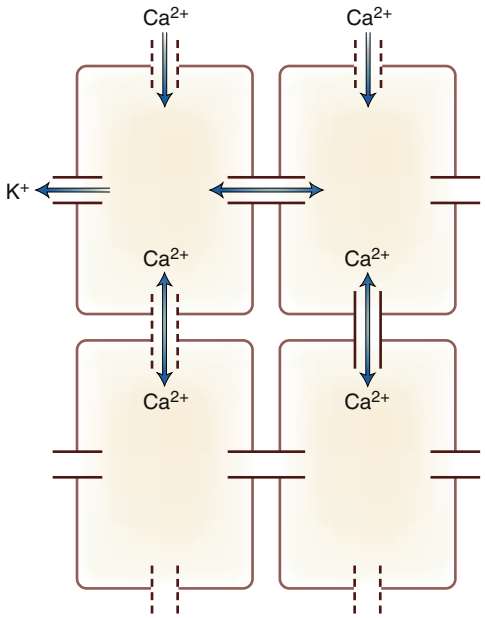
At least three types of potassium channels—adenosine triphosphate (ATP)-sensitive (K_{ATP}), voltage-gated (Kv), and calcium-sensitive K^+ channels (referred to as BK_{Ca} or maxi-K channels)—are expressed in the cavernosal smooth muscle cells.[99,100] Of these, the BK_{Ca} channels are the most important, as they account for 90% of K^+ efflux from the cavernosal smooth muscle cells. Agents that open BK_{Ca} channels have been shown to relax cavernosal smooth muscle cells in vitro.[100] Thus, the strategies that increase BK_{Ca} channel expression in vivo improve erectile capacity in diabetic and older rodents[100–102] and are being explored as therapy for ED. A phase I human gene therapy trial using this approach reported the feasibility of this approach, but there has not been a follow-up trial since then.[102] A phase 2a trial using a single intracavernosal injection of hMaxi K channel was initiated in 2016, but no data have been reported (NCT02713789).

Connexin43 Gap Junctions

The smooth muscle cells in the corpora cavernosa are connected by connexin43 gap junctions that allow the ions and some signaling molecules such as IP_3 to diffuse freely across smooth muscle cells[103] (Fig. 20.7). The ionic changes induced by a stimulus in one smooth muscle cell are communicated rapidly across other smooth muscle cells, resulting in coordinate regulation of the entire corpora cavernosa.[103] Thus, the corpora cavernosa can be viewed functionally as a syncytium of interconnected smooth muscle cells[103] (see Fig. 20.7).

Nitric Oxide

Nitric oxide, derived from the nerve terminals innervating the corpora cavernosa, the endothelial lining of penile arteries, and the cavernosal sinuses, is an important biochemical regulator of cavernosal smooth muscle relaxation. Nitric oxide also induces arterial dilatation.[104] The actions of nitric oxide on the cavernosal smooth muscle and the arterial blood flow are mediated through the activation of guanylyl cyclase, the production of cyclic guanosine monophosphate (cGMP), and the activation of cGMP-dependent protein kinase (also called *protein kinase G* [PKG]) (see Fig. 20.6). cGMP causes smooth muscle relaxation by lowering intracellular calcium. There is some evidence that nitric oxide inhibits Rho kinase–induced cavernosal smooth muscle sensitivity to calcium.[105]



• **Fig. 20.7** Interconnection of cavernosal smooth muscle cells in the penis. Connexin43-derived gap junctions connect adjacent corporal smooth muscle cells and allow flow of ions among interconnected smooth muscle cells. Therefore, alterations in action potential and K-channel activity in any myocyte affect the adjacent myocytes. (Modified from Melman A, Christ GJ. Integrative erectile biology: the effects of age and disease on gap junctions and ion channels and their potential value to the treatment of erectile dysfunction. *Urol Clin North Am*. 2001;28[2]:217–231, vii.)

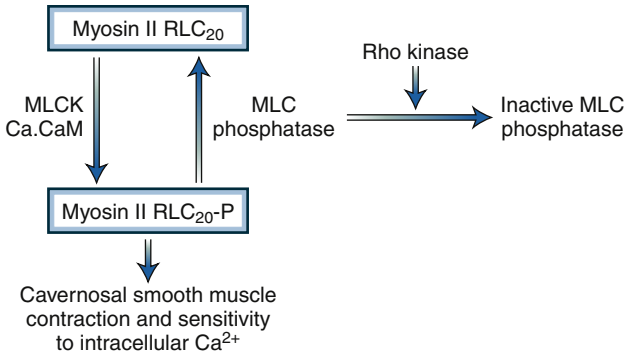
Cyclic Nucleotide Phosphodiesterases

Cyclic nucleotide phosphodiesterases hydrolyze cAMP and cGMP, thus reducing their concentrations within the cavernosal smooth muscle. Of the 13 or more isoforms of cyclic nucleotide phosphodiesterases that have been identified, isoforms 2, 3, 4, and 5 are expressed in the penis.[106–113] Only phosphodiesterase 5 (PDE5) is specific to the nitric oxide/cGMP pathway in the corpora cavernosa.[106–113] Hydrolysis of cGMP by this enzyme results in reversal of the smooth muscle relaxation and reversal of penile erection (see Fig. 20.6). Sildenafil, vardenafil, and tadalafil are potent and selective inhibitors of the activity of PDE5 that prevent breakdown of cGMP and thereby enhance penile erection[4,5] (see Fig. 20.6).

Regulation of Sensitivity to Intracellular Calcium by Rho A/Rho Kinase Signaling

Recently, considerable attention has focused on the role of Rho kinase in modulating the sensitivity of cavernosal smooth muscle to intracellular calcium.[114] A growing body of evidence suggests that sensitization to intracellular calcium is regulated by the balance between phosphorylation of the regulatory light chain of myosin II by a myosin light chain kinase and its dephosphorylation by a myosin light chain phosphatase[114–119] (Fig. 20.8). Phosphorylation of regulatory light chain of myosin II is necessary for activation of myosin II adenosine triphosphatases by actin, and its dephosphorylation prevents activation of myosin II adenosine triphosphatases.[114–119] The ratio of the activities of the kinase and the phosphatase is an important determinant of the contractile sensitivity of the cavernosal smooth muscle cell to intracellular calcium.[116]

Rho A is a guanosine triphosphatase (GTPase) of approximately 20 kDa that modulates Rho kinase activity, myosin light chain phosphorylation, and calcium sensitivity in smooth muscle cells.[114] The Rho A–GDP (guanosine diphosphate) complex is associated with a GDP dissociation inhibitor (RhoGDI) in its inactive state. Several



• **Fig. 20.8** The role of Rho A–Rho kinase in regulation of cavernosal smooth muscle sensitivity to intracellular Ca^{2+} is depicted. Sensitivity to calcium and smooth muscle contractility is regulated by the Rho A–Rho kinase system. The balance between phosphorylation of myosin regulatory light chain (Myosin II RLC_{20}) kinase and its dephosphorylation by a myosin light chain phosphatase is a major determinant of the smooth muscle sensitization to Ca^{2+}. By inhibiting the activity of myosin light chain (MLC) phosphatase, Rho kinase, the downstream effector of Rho A can regulate smooth muscle responsiveness to calcium. *Ca.CaM,* calcium-calmodulin; *MLCK,* myosin light-chain kinase. (Modified from Somlyo AP, Somlyo AV. Ca^{2+} sensitivity of smooth muscle and nonmuscle myosin II: modulated by G proteins, kinases, and myosin phosphatase. *Physiol Rev.* 2003;83[4]:1325–1358.)

intracellular signals can promote an exchange of GDP for GTP on Rho A through the mediation of guanine nucleotide exchange factors.[114–119] Rho A–GTP interacts with its downstream effector Rho kinase,[114–119] increasing the sensitivity of vascular smooth muscle to intracellular calcium by inhibiting the myosin light chain phosphatases. Although the Rho A/Rho kinase expression is not significantly different between young and older rats, the activity of Rho kinase is higher in older rats than in young rats[118]; the age-related increase in Rho kinase activity has been proposed as one possible mechanism to explain the age-related decrease in erectile capacity.[118] Inhibition of Rho kinase activity in experimental animals increases cavernosal smooth muscle relaxation and improves intracavernosal pressures and penile erections. Therefore, inhibitors of Rho A/Rho kinase signaling promise to provide attractive targets for the development of therapies for ED.[118,119]

Mechanisms of Ejaculation

The ejaculatory mechanisms consist of three processes: emission, ejection, and orgasm.[120–123] Although orgasm and seminal fluid ejection often occur contemporaneously, these two processes are regulated by separate mechanisms. Emission, the deposition of seminal fluid into the posterior urethra, is dependent on the integrity of the vasa deferentia, seminal vesicles, prostate gland, and the bladder neck.[122,123] Ejaculation refers to the ejection of seminal fluid containing sperm, and the secretions of seminal vesicles, prostate, and bulbourethral glands from the posterior urethra out through the urethral meatus, and is regulated primarily by the central nervous system activation of the sympathetic nervous system.[122] This emission is ejaculated out of the urethra by the contractions of the bulbospongiosus and levator ani muscles, the closure of the bladder sphincter due to sympathetic activation, and synchronized opening of the external urinary sphincter.[118] The sensation associated with the rhythmic contractions of these pelvic floor muscles is referred to as the *orgasm*.

The stria terminalis, the posteromedial amygdala, the subparafascicular thalamus, the MPOA of the hypothalamus, the periaqueductal gray matter in the midbrain region, and the

paragigantocellular nucleus in the pons integrate seminal fluid emission and ejection during copulatory behavior in animals[124,125] (see Table 20.2). The paragigantocellular nucleus in the pons through serotonergic pathways inhibits the lumbosacral motor nuclei that are involved in ejaculation[125,126]; the input from the MPOA to the paragigantocellular nucleus causes loss of this inhibition, resulting in ejaculation.[125,126] An ejaculation generator in the spinal cord integrates the central and peripheral sympathetic and parasympathetic signals to control ejaculation.[120,125] The parasympathetic fibers from the spinal ejaculation generator feed into the sacral parasympathetic nucleus and are carried from there through the pelvic nerve and the major parasympathetic ganglion into the seminal tract.[125] Sympathetic fibers are carried from the spinal ejaculation generator into the dorsal gray commissure and intermediolateral cell column and then through the lumbar sympathetic chain, pelvic nerve, superior hypogastric plexus, and major pelvic ganglion onto the seminal tract.[125]

Neural pathways that utilize serotonin (5-hydroxytryptamine [5HT]) and dopamine as neurotransmitters play an important role in regulating ejaculation.[122] Thus, administration of selective serotonin reuptake inhibitors (SSRIs) is being explored for the treatment of premature ejaculation.[124–127] At least 14 different serotonin receptor subtypes have been identified in different brain regions; 5HT1A somatodendritic receptors in the mesencephalic and medullary raphe nuclei reduce ejaculatory latency.[120] An improved understanding of the neurochemical mechanisms that regulate ejaculation may provide mechanism-specific targets for treatment of ejaculatory disorders.

TABLE 20.3 Domains of Sexual Function Regulated by Testosterone[a]

Domains of Sexual Function That Have Been Shown to Improve in Response to Testosterone Therapy of Androgen-Deficient Men

1. Sexual desire
2. Spontaneous sexual thoughts
3. Attentiveness to erotic stimuli
4. Frequency of nighttime and daytime erections
5. Duration, magnitude, and frequency of nocturnal penile erections
6. Overall sexual activity scores
7. Erectile function
8. Sexual satisfaction
9. Volume of ejaculate

Domains of Sexual Function That Have Not Been Shown to Improve in Response to Testosterone Therapy or for Which There Is Insufficient or Inconclusive Evidence

1. Erectile response to visual erotic stimulus
2. Erectile function in men who have normal or low-normal testosterone levels
3. Therapeutic response to selective phosphodiesterase inhibitors
4. Ejaculatory dysfunction
5. Orgasms

[a]Testosterone administration in androgen-deficient men improves overall sexual activity scores through its effects on specific domains of sexuality.

Modified from Bhasin S, Enzlin P, Coviello A, Basson R. Sexual dysfunction in men and women with endocrine disorders. *Lancet.* 2007;369(9561):597–611.

Role of Testosterone in Regulating Sexual Function in Men

Testosterone regulates many domains of sexual function in men and women.[27] Although androgen-deficient men can achieve penile erections in response to visual erotic stimuli, their overall sexual activity is decreased.[128] Spontaneous but not stimulus-bound erections are testosterone responsive[128] (Table 20.3). Testosterone promotes sexual thoughts and desire[53,128–134] and increases sexual arousal and attentiveness to erotic auditory and other stimuli.[129,130] Nocturnal erections, temporally related to peaks of nighttime testosterone secretion, are of lower amplitude and duration in androgen-deficient men, and testosterone therapy increases the frequency, fullness, and duration of nocturnal penile tumescence.[134,135] Maximum rigidity may require a threshold level of androgen activity.[136–140] Testosterone regulates nitric oxide synthase (NOS) in the cavernosal smooth muscle,[137,138] exerts trophic effects on cavernosal smooth muscle[139] and ischiocavernosus and bulbospongiosus muscles, and is necessary for the veno-occlusive response.[136–139] Androgen-deficient men show delayed orgasm and low ejaculatory volume.[27]

Testosterone therapy in androgen-deficient men improves overall sexual activity, sexual desire, erectile function,[141,142] spontaneous sexual thoughts, and attentiveness to erotic auditory stimuli; frequency of nighttime and daytime erections; duration, magnitude, and frequency of nocturnal penile erections; and the volume of ejaculate.[27,53,128–131,134-136,140,143–145] However, testosterone does not improve erectile response to visual erotic stimulus[128] or erectile function in men with ED who have normal testosterone levels.[140,143–147] Testosterone does not improve ejaculatory function in men with ejaculatory dysfunction and low testosterone levels.[148] In male rats, in whom endogenous testosterone production has been suppressed by administration of a GnRH antagonist, testosterone restores all measures of mating behavior at doses that are insufficient to restore prostate and seminal vesicle weights.[149,150] Similarly, in dose-response studies in humans rendered testosterone deficient by the administration of a GnRH agonist, sexual function is restored by testosterone doses that raise serum testosterone levels just above the lower limit of the normal male range[151]; further increase in serum testosterone levels does not further improve measures of sexual function.

Brain imaging studies suggest that processing of sexual stimuli may be altered in androgen-deficient men with decreased activation in those brain areas that are typically activated in eugonadal men and in androgen-deficient men after testosterone replacement in response to erotic stimuli.[53]

Acting on dopaminergic receptors in the MPOA of the hypothalamus, testosterone elicits reward-seeking behavior in male mammals.[61] This may be the basis for testosterone's motivational effects on mammalian sexual behavior.[61] The roles of cytochrome P450 19A1 (aromatase) and steroid 5α-reductase systems in mediating androgen effects on sexual function remain incompletely understood.[63] Studies suggest that 5α-reduction of testosterone to 5α-dihydrotestosterone is not essential for mediating testosterone's effects on desire or erectile function in eugonadal men.[152] Additional investigations, including those in men with mutations of the *CYP19A1* gene, suggest that aromatization to estradiol is important in mediating testosterone's effects on sexual desire.[153–155] Both testosterone and estradiol are required to maintain sexual function.

In surveys of community-dwelling middle-age and older men, low libido, poor morning erections, and ED are associated with low total and free testosterone levels.[156–158] However, androgen deficiency and ED are two independently distributed disorders that may coexist in middle-age and older men.[159–161] Selective

PDE5 inhibitors are highly effective first-line therapies for ED. However, one third of men with ED do not respond to PDE5 inhibitors; some of the men with ED who are PDE5 inhibitor nonresponders have low testosterone levels. Observations that testosterone stimulates penile NOS, increases penile blood flow, and has trophic effects on cavernosal smooth muscle and bulbospongiosus and ischiocavernosus muscles have led to speculation that testosterone therapy might improve erectile response to PDE5 inhibitors.[162–165] Spitzer and associates[166] evaluated whether the addition of testosterone to sildenafil improves erectile response in men with ED and low testosterone. In this randomized controlled trial (RCT), after optimization of sildenafil dose during an initial run-in period, subjects were assigned randomly to 14 weeks of daily testosterone or placebo gel. Sildenafil plus testosterone was not superior to sildenafil plus placebo in improving erectile function in men with ED and low testosterone.[166] In another placebo-controlled trial (TADTEST) of men with ED who were deemed tadalafil (Cialis) failures,[167] the primary analysis of all randomized subjects also did not show a significantly greater improvement in erectile function in the testosterone arm than in the placebo arm. However, in post hoc analysis, erectile function improved with the addition of testosterone in a subset of men with baseline testosterone of 10 nmol/L or less (300 ng/dL).[167] Thus, randomized trials have failed to support the hypothesis that addition of testosterone to PDE5 inhibitor improves erectile function in men with ED. Sildenafil alone raises testosterone levels, presumably because of its direct effects on Leydig cell steroidogenesis.[168] It is possible that testosterone may improve penile rigidity and overall satisfaction with sexual experience in men who are unequivocally hypogonadal.

Physiology of Physical Sexual Arousal in Women: Genital Congestion

Several physical changes occur in response to sexual stimuli with varying degrees of women's sexual excitement (i.e., their subjective sexual arousal), including genital swelling, increased vaginal lubrication, breast engorgement, and nipple erection; increased skin sensitivity to sexual stimulation; changes in heart rate, blood pressure, muscle tone, breathing, and temperature; and mottling of the skin with a sexual flush of vasodilatation over the chest and face.[169] These changes are reflexive, mediated by the autonomic nervous system. Within seconds, there is increased blood flow to the vagina; vasodilatation of the arterioles in the submucosal plexus increases transudation of interstitial fluid from the capillaries across the epithelium and into the vaginal lumen.[169] Simultaneously, there is relaxation of smooth muscle cells around the clitoral sinusoids, which promotes congestion.

The clitoris comprises the head, the shaft, the rami that extend along the pubic arch, and the periurethral tissue in front of the anterior vaginal wall, as well as the bulbar tissue that surrounds the anterior distal vagina and is contiguous with the periurethral tissue.[170] MRI studies have confirmed the presence of extensive clitoral tissue far beyond the visible portion of the clitoris.[170] As the clitoris becomes more swollen, it elevates to lie nearer the symphysis pubis. The vagina lengthens and dilates during arousal, elevating the uterus. The labia become swollen and darker red, and the lower third of the vagina swells.[170]

The autonomic nerves subserving the widespread genital congestion are at risk from gynecologic surgeries that sever the cardinal ligaments and the uterosacral ligaments to potentially injure Frankenhauser's nerve plexus and the uterovaginal nerve plexus.[171,172] Surgical procedures for hysterectomy that do not involve cutting or clamping the cardinal ligament, uterosacral ligament, or fascia and spare the pelvic nerve plexuses are less likely to impair sexual function.[171] Transvaginal tapes for urinary incontinence, especially transobturator tapes, may also compromise the autonomic nerves between the anterior vaginal wall and bladder.[172,173]

The correlation between genital congestion and subjective arousal in response to visual erotic stimuli is highly variable[49,82,83]; this is true in sexually healthy women and in women reporting a lack of desire or arousal or sexual pain. Women reporting chronic lack of arousal show prompt increases in vaginal congestion that are comparable to those in control women, but they report no subjective sexual excitement in response to the erotic stimulation. fMRI studies show that, unlike in men, activation of the areas organizing genital vasocongestion in women does not correlate with subjective excitement.[49,174]

The neurobiology of the genital vasocongestive response in women is complex and incompletely understood. Genital vasocongestion involves the release of nitric oxide and VIP from the sacral autonomic nerves.[175] Acetylcholine, which blocks noradrenergic vasoconstricting mechanisms and promotes nitric oxide release from the endothelium, is also released. There is communication between the nitric oxide–containing cavernosal nerve to the clitoris and the distal portion of the somatic dorsal nerve of the clitoris from the pudendal nerve. Pelvic sympathetic nerves release primarily vasoconstrictive norepinephrine and epinephrine, but some release acetylcholine, nitric oxide, and VIP. The provoked anxiety in the laboratory situation can *increase* the vasocongestive response of the genitalia to erotic stimulation in sexually healthy women.[87] The localization of NOS, cAMP, and cGMP-degrading PDE isoenzymes in human vaginal tissue is established, along with identification of cAMP and cGMP-binding proteins. The latter are co-localized with endothelial NOS (eNOS). Close proximity to VIP-positive nerves suggests that cAMP and cGMP work synergistically to control vaginal blood flow.[175] Neuropeptide Y (a vasoconstrictor), CGRP (possibly influencing capillary permeability and sensation), and substance P (a sensory transmitter) also innervate the vaginal microcirculation. The melanocortin-4 receptors and oxytocin also may be involved in clitoral and vaginal efferent pathways.[175]

Intermittency of the vaginal microcirculation due to contraction and relaxation of precapillary sphincters in response to hypoxia and the release of metabolites (CO_2, lactic acid, ATP) has been termed *vasomotion*. Vasomotion is present in the nonaroused state but decreases within seconds of a sexual stimulus, which increases arterial supply to recruit more capillaries and diminish vasomotion: vaginal vasocongestion follows. Slow oscillations in vaginal blood flow, independent of vaginal vasocongestion, have been shown to correlate with subjective arousal in healthy women and to be less marked in women with arousal disorder.[174]

Increased blood flow to the submucosal vaginal capillaries results in increased interstitial fluid production, which diffuses more quickly across the vaginal epithelial cells and onto the lumen: the lubrication fluid in the aroused state thereby contains less potassium and more sodium than in the nonaroused state. How important the contribution of permeability of the epithelial cells is to the process of lubrication is currently unclear. Relaxation of the vaginal wall smooth muscle that enables the vagina to move up into the pelvis is likely mediated by VIP.[174]

The clitoris is the most sexually sensitive area of the body. Immunohistologic studies have identified neurotransmitters

thought to be associated with sensation (substance P and CGRP) that are concentrated immediately under the epithelium of the glans clitoris. Nerve terminals in the glans clitoris known as *corpuscular receptors* are thought to be involved. They are mechanoreceptors, and their density is variable but can be up to 14 times greater than the density of similar receptors on the glans penis.[176] The physiology of nongenital physical changes and their correlation with subjective excitement remain poorly understood.

Physiology of Orgasm

Orgasm is largely a brain event typically triggered by genital stimulation; however, it can also be induced by stimulation of other parts of the body, including the breast and nipple; fantasy; sleep; certain medications; and, in women with spinal cord injury, by vibratory stimulation of the cervix. Vaginal stimulation involves all of the clitoral-urethral complex, including the clitoral rami, whereas direct stimulation of the clitoral shaft and glans does not involve the clitoral rami.[169] During vaginal intercourse, the penis distends the vagina and stretches the root of the clitoris. During penile thrusting, the anterior wall of the vagina is apposed against the root of the clitoris, perhaps explaining why some women can achieve orgasm by vaginal intercourse without simultaneous nonvaginal stimulation.[177] The root of the clitoris and the anterior wall of the vagina thus appear to be anatomically and functionally related.[178]

Orgasm is a subjective experience that is associated with ejaculation in healthy men and, in both men and women, with involuntary (reflexive) muscular contractions of the striated perineal muscles.[179] The characteristic fluctuations in the rectal pressure that occur during orgasm due to involuntary contractions of perineal muscles have been proposed as an objective measure that has a strong correspondence with the subjective experience of orgasm.[179]

Positron emission tomography (PET) studies during orgasm have shown largely similar brain activations and deactivations in men and women: activations mainly in the anterior lobe of the cerebellar vermis and deep cerebellar nuclei and deactivations in the left ventromedial cortex and OFC. The only gender difference in the PET findings during orgasm was the activation in the periaqueductal gray matter in men but not in women.[180,181] The lateral OFC is involved in urge suppression and behavioral release, whereas the medial parts encode hedonic experiences and become activated with increasing pleasure and deactivated with feelings of satiety. The medial OFC is part of the neuronal network that includes the amygdala, whose deactivation during orgasm is associated with a more carefree state of mind.[180] The variations in rectal pressure indicative of orgasm recorded using a rectal probe correlate with widespread blood flow changes in the prefrontal cortex measured using PET scanning.[181,182] The specific orgasm-related changes in the mid/anterior OFC during PET scanning suggest a role of the mid/anterior OFC in the experience of pleasure. Failed orgasm due to excessive behavioral suppression is associated with enhanced left lateral OFC activity. Researchers have speculated that the orgasm-related OFC dynamics may be related to the sense of loss of control during orgasm. Prefrontal, but not temporal, perfusion is negatively coupled to rectal pressure fluctuations associated with orgasm. Overall, the findings of reduced prefrontal metabolism during orgasm are in keeping with the critical role of the prefrontal cortex in behavioral and emotional control and with the experimental data relating exaggerated prefrontal activity with sexual dysfunction.

The role of oxytocin and prolactin in orgasm is unclear. Both hormone levels increase at the time of orgasm. PET scanning has confirmed increased pituitary blood flow in women, but not in men, at the moment of orgasm.[183] Both hormones can cause uterine and vaginal smooth muscle contraction, which may contribute to the sensations of orgasm.

Revised Definitions of Sexual Dysfunction in Men

In May 2013, DSM-5 provided an updated classification and definitions of male sexual disorders.[45] The salient differences of the new DSM-5 classification and definitions from DSM-IV are the following[46]:

1. DSM-5 includes only four male sexual disorders, as opposed to six in DSM-IV.[46] The four sexual disorders are the following:
   a. Male HSDD
   b. ED
   c. Premature ejaculation
   d. Delayed ejaculation
2. DSM-5 lists male HSDD as a separate entry.[45,46] Male orgasmic disorder has been renamed *delayed ejaculation*, and male ED has been changed to *ED.* Premature ejaculation remains unchanged.
3. Male dyspareunia, male sexual pain, sexual aversion disorder, and sexual dysfunction have been removed in DSM-5.[45,46]
4. Unlike DSM-IV, DSM-5 includes the requirement of experiencing the disorder 75% to 100% of the time to make a diagnosis of sexual disorder. DSM-5 also requires a minimum duration of approximately 6 months.[45,46]
5. DSM-5 requires that the sexual disorder must have caused significant distress. The DSM-IV requirement of "interpersonal difficulty" has been removed.[45,46]
6. DSM-5 added one new exclusion criterion: the disorder should not be better explained by a "nonsexual mental disorder or a consequence of severe relationship distress or other significant stressors."[45,46]

Male Hypoactive Sexual Desire Disorder

HSDD is the persistent or recurrent deficiency (or absence) of sexual fantasies and desire for sexual activity that causes marked distress and that is not better explained by another disorder, direct physiologic effects of a substance (medication), or general medical condition.[184–187] A diagnosis of HSDD is appropriate *only* if the person reports distress due to low sexual desire.[184-187] Low sexual desire is not necessarily pathologic, as low sexual desire may be an appropriate adaptation to relationship and health-related issues.[184–187]

Although DSM-5 limits a diagnosis of HSDD to causes other than medication, illness including androgen deficiency and depression, and relationship and addiction problems, in clinical practice the term *hypoactive sexual desire disorder* is often used for situations involving multiple factors, including androgen deficiency, prolactin excess, the use of medications (SSRIs, antiandrogens, GnRH analogues, antihypertensives, cancer chemotherapeutic agents, anticonvulsants), systemic illness, depression and other psychological problems such as low self-esteem, fear of emotional intimacy, fear of loss, long-term habit of sex alone with or without pornography, other causes of sexual dysfunction, or relationship problems. Thus, in practice, androgen deficiency is an important,

treatable cause of low desire in men and should be excluded by measuring serum total and free testosterone levels.[184–187]

The incidence and prevalence of HSDD in the general population are unknown. In studies of referred patient populations, the prevalence has been estimated to be 5% in men.[7,186–189] Prevalence increases with age.[186,187,189] HSDD often coexists with other sexual disorders, such as ED, and may develop as a consequence of other sexual disorders.[186,187,189]

Appropriate evaluation and treatment of HSDD are important because evaluation may lead to detection of treatable disease, including androgen deficiency, prolactin excess, or depression. Furthermore, low sexual desire may impede or reduce the effectiveness of treatments for other sexual dysfunctions.

Erectile Dysfunction

ED, previously referred to as *impotence* or *male ED*, is the inability to attain or maintain an erection or to achieve penile rigidity sufficient for satisfactory sexual intercourse.[5,6,45,46] DSM-5 requires that the inability to attain or maintain an erection should occur in 75% to 100% of encounters over a period of at least 6 months.[45,46] *Sexual dysfunction* is a more general term that also includes libidinal, orgasmic, and ejaculatory dysfunction, in addition to the inability to attain or maintain penile erection. Epidemiologic surveys,[188–198] including the Massachusetts Male Aging Study (MMAS)[190] and the National Health and Social Life Survey (NHSLS),[188] revealed a surprisingly high prevalence of ED. ED significantly affects quality of life of both the affected individual and his partner. In one study, ED had a negative impact on the sexual life of female partners, specifically on their sexual satisfaction and sexual drive.[191]

Prevalence and Incidence

The best data on the prevalence of ED in men have emerged from two cross-sectional studies that have used population-based sampling techniques, namely the MMAS[190,192,195,196] and the NHSLS.[7,188] The MMAS was a cross-sectional and longitudinal, community-based epidemiologic survey in which 1709 men, 40 to 70 years of age, residing in the greater Boston area, were surveyed between 1987 and 1989.[190] This survey revealed that 52% of men between the ages of 40 and 70 years were affected by ED of some degree; 17.2% of surveyed men reported minimal ED, 25.2% moderate ED, and 9.6% complete ED.[190,195,196] The NHSLS was a national probability survey of English-speaking Americans, 18 to 59 years of age, living in the United States.[7,188] This survey also revealed a high prevalence of ED in men; the prevalence of ED increased with increasing age.[7,188] These two studies and several other studies are in agreement that ED is a common problem worldwide.[7,188–197] In the U.S. civilian population, the prevalence of ED in men 20 to 39 years of age has been estimated to be 5.1%, and almost three times as high (14.8%) in men age 40 to 59 years of age. Men suffering from other medical problems, such as hypertension, diabetes, cardiovascular disease (CVD), and end-stage renal disease, have a significantly higher prevalence of ED than healthy men.[190]

There is a paucity of longitudinal data on the incidence of ED in men. In the MMAS, the crude incidence of ED in white men in the Boston area was found to be 25.9 cases per 1000 person-years.[192] The incidence rates increased from 12.4 cases per 1000 person-years for men 40 to 49 years of age to 29.8 cases per 1000 person-years for men 50 to 59 years of age and 46.4 per 1000 person-years for men 60 to 69 years of age.[192] In another study, incidence rates were derived from a survey of men seen at a preventive medicine clinic.[7] This study found the incidence rates of ED to be less than 3 cases per 1000 person-years among men less than 45 years of age and 52 cases per 1000 person-years among men 65 years of age or older. These studies suggest that 600,000 to 700,000 men in the United States develop ED each year.[195,196]

Risk Factors for Erectile Dysfunction

The risk factors for ED include age, diabetes mellitus, hypertension, smoking, medication use, depression, dyslipidemia, and CVD.[4–6,190,198–208] Advancing age is an important risk factor for ED in men[4–6,188,190]: less than 10% of men younger than 40 years and more than 50% of men older than 70 years have ED. In both the MMAS and the NHSLS, the prevalence of ED increased with each decade of life.[188,190]

Among the chronic diseases associated with ED, diabetes mellitus is the most important risk factor. In the MMAS, the age-adjusted risk of complete ED was three times higher in men with history of treated diabetes mellitus than in those without history of diabetes mellitus.[190,198] Fifty percent of men with diabetes mellitus will experience ED sometime during the course of their illness. In the MMAS, treated heart disease, treated hypertension, and hyperlipidemia were associated with a significantly increased risk of ED. Among men with treated heart disease and hypertension, the probability of ED was more than two times greater for smokers than for nonsmokers.[4–6,188,190] Smoking also increases the risk of ED in men taking medications for CVD. Cardiovascular disorders, including hypertension, stroke, coronary artery disease, and peripheral vascular disease, are all associated with increased risk of ED. Physical activity is associated with reduced risk of ED.[207]

Several reviews have emphasized the relationship of prescription medications and the occurrence of ED. In the MMAS, the use of antihypertensives, cardiac medications, and oral hypoglycemic drugs was associated with an increased risk of ED.[190] Thiazide diuretics and psychotropic drugs used in the treatment of depression may be the most common drugs associated with ED, simply because of the high prevalence of their use. However, a variety of drugs, including almost all antihypertensives, digoxin, histamine-2 receptor antagonists, anticholinergics, cytotoxic agents, and androgen antagonists, have been implicated in the pathophysiology of ED.[190]

Erectile Dysfunction as a Marker of Cardiovascular Disease

CVD and ED share common risk factors, such as diabetes mellitus, obesity, hypertension, smoking, and dyslipidemia.[199–207] ED precedes the symptoms of coronary artery disease by 2 to 3 years and cardiovascular events such as myocardial infarction or stroke by 3 to 5 years.[199–207] ED in men is associated with increased risk of death, particularly fatality due to CVD.[201] The presence of ED is a good predictor of subsequent coronary artery disease, especially in younger men, independent of traditional coronary risk factors, although it does not enhance the predictive ability of models that include traditional risk factors, likely reflecting the common pathophysiologic mechanisms of ED and coronary artery disease.[202] Men reporting ED are 1.3 to 1.6 times more likely to experience a cardiovascular event within 10 years than men without ED.[199–207]

Lower Urinary Tract Symptoms and ED

Epidemiologic surveys have reported a strong association of lower urinary tract symptoms (LUTS) with ED[208–214] even after adjusting for age and other risk factors. The Cologne Male Survey and

the Multinational Survey of the Aging Male revealed that the presence and severity of LUTS is an independent predictor of ED independent of age.[209] LUTS and age are stronger predictors of ED than all other risk factors, including diabetes, dyslipidemia, and hypertension. Considering that LUTS and ED are two common conditions in middle-age and older men, it is possible that this association reflects the coexistence of two highly prevalent conditions. However, there is growing evidence that the two conditions may be mechanistically linked, as the biochemical mechanisms that regulate bladder detrusor and cavernosal smooth muscle function share many similarities.[214,215] K^+ channels, especially calcium-sensitive K^+ channels (BK_{Ca} channels), Rho A/Rho kinase signaling, L-type calcium channels, and gap junctions are important mediators of both detrusor and cavernosal smooth muscle contractility and relaxation.[214,215] Increased myocyte contractility that characterizes both bladder detrusor dysfunction and ED may be mechanistically related to increased Rho kinase activity, impairments of K^+ channel function,[215] α-adrenergic receptor imbalance, and endothelial dysfunction. Additional proposed hypotheses include increased sympathetic activity and autonomic dysfunction, and alterations in nitric oxide generation or PKG activity in the detrusor and cavernosal smooth muscles.[214–216] Some therapies for LUTS, such as some types of surgical procedures and steroid 5α-reductase inhibitors, may worsen sexual dysfunction. α-Adrenergic blockers used in the treatment of LUTS can cause ejaculatory problems. Some PDE5 inhibitors have been approved for the treatment of LUTS.[215–218]

Ejaculatory Disorders

Ejaculatory disorders include premature ejaculation, delayed ejaculation, retrograde ejaculation, anejaculation, and painful ejaculation.[120–123] Recent surveys have highlighted the high prevalence and clinical importance of ejaculatory disorders.[10,120–123,219,220] Although the availability of oral PDE5 inhibitors has increased awareness of ED, ejaculatory disorders are at least as prevalent and may be even more prevalent than ED.[10,220]

Premature ejaculation, a common form of ejaculatory dysfunction in men, can be lifelong or acquired later in life, and it negatively affects interpersonal relationships, sexual satisfaction, and quality of life.[221,222] An ad hoc committee of the International Society for Sexual Medicine defined premature ejaculation as follows[222]:

> *a male sexual dysfunction characterized by (i) ejaculation that always or nearly always occurs prior to or within about 1 minute of vaginal penetration from the first sexual experience (lifelong PE [premature ejaculation]) or a clinically significant and bothersome reduction in latency time, often to about 3 minutes or less (acquired PE); (ii) the inability to delay ejaculation on all or nearly all vaginal penetrations; and (iii) negative personal consequences, such as distress, bother, frustration, and/or the avoidance of sexual intimacy.*

This definition of premature ejaculation is based on a multinational survey of men, 18 years or older, in stable heterosexual relationships, which found the median intravaginal ejaculation latency time (IELT) to be 5.6 minutes (range, 0.55–44.1 minutes)[223]; in this survey, 2.5% of men had an IELT of less than 1 minute and 6% of less than 2 minutes. Most men seeking treatment for lifelong premature ejaculation ejaculate within 1 minute after penetration, and nearly all ejaculate within 2 minutes.[224] Compared with patients with lifelong premature ejaculation, the men with acquired premature ejaculation are older and have a longer IELT.[222] The acquired premature ejaculation is often also associated with ED and other comorbid conditions, such as diabetes and CVD.

Some men who seek treatment for premature ejaculation do not meet the preceding definition established by the International Society for Sexual Medicine but express distress due to their perception of lack of control over the timing of ejaculation and the IELT to be shorter than they wish. Waldinger[225] proposed the terms *subjective premature ejaculation* and *variable premature ejaculation* to describe these men whose IELT is either consistently or inconsistently greater than 5 minutes but who are preoccupied with a perceived short ejaculatory latency or the lack of control over the timing of ejaculation. Specific duration criteria for defining premature ejaculation among men engaged in nonvaginal sexual activities have not been established.

The prevalence of premature ejaculation is not known; previous estimates of prevalence of 20% to 25% based on older definitions are likely inaccurate. Although there are no epidemiologic surveys based on the International Society for Sexual Medicine criteria or the DSM-5 definition of premature ejaculation, the experts have inferred from the data on the distribution of IELT that the prevalence is unlikely to be greater than 4%.[221,226,227]

The neurobiologic mechanisms of premature ejaculation are not well understood. 5HT (serotonin), oxytocin, and dopamine are involved as neurotransmitters in the central nervous system pathways that control ejaculation.[228,229] In preclinical models, serotonin delays ejaculation, and dopamine and oxytocin appear to stimulate ejaculation; these data have led to speculation that men with lower ejaculatory thresholds may either have deficient serotonin neurotransmission or 5HT 2C receptor hyposensitivity. The serotonin hypothesis is supported by data showing that SSRIs and the tricyclic antidepressant clomipramine increase ejaculatory control and delay ejaculation in men with premature ejaculation. The earlier theories that premature ejaculation is largely due to psychological factors such as anxiety or sequelae of early life sexual experiences have not been supported by recent data from clinical trials of pharmacologic agents. Genetic studies of the polymorphisms in the serotonin transporter protein (5HTTLPR) gene, oxytocin, serotonin, and vasopressin genes, and tandem repeats of the dopamine transporter gene (*DAT1*) have not yielded consistent association with premature ejaculation.[230–234]

Delayed Ejaculation

DSM-5 defines delayed ejaculation as a marked involuntary delay in ejaculation or absence of ejaculation on almost all or all occasions of partnered sexual activity, persisting for at least 6 months and causing distress to the individual.[235] A timing-based definition of delayed ejaculation has not been established. Because the median intravaginal ejaculatory latency in a multinational population-based survey was 5.4 minutes[223] and the 97.5th percentile value was 23 minutes, some experts have suggested that intravaginal ejaculatory latency greater than 25 or 30 minutes should be considered delayed ejaculation.[236]

Mild to moderate delay in ejaculation occurs with advancing age; older men with comorbid conditions are at a higher risk of delayed ejaculation.[237,238] Epidemiologic surveys have consistently found LUTS to be strongly associated with delayed ejaculation, even after adjusting for age.[208,238–240] Ejaculatory disorders are common after surgical treatment of benign prostatic hyperplasia including transurethral resection of the prostate.[241] Several drugs—SSRIs, highly selective α1-adrenergic blockers, steroid 5α-reductase inhibitors—can cause delayed ejaculation. The use of highly selective α1-adrenergic blockers such as tamsulosin and

silodosin can lead to marked delay or inability to ejaculate; ejaculatory dysfunction is less common with nonselective α-adrenergic blockers such as alfuzosin, doxazosin, and terazosin. The use of steroid 5α-reductase inhibitors such as finasteride and dutasteride is associated with increased risk of ejaculatory disorder. SSRIs can prolong intravaginal ejaculatory latency and cause delayed ejaculation in some middle-age and older men.[242] Excessive exposure to pornography and sexual abuse may reduce sexual desire, impair arousal, and lead to ejaculatory dysfunction.[243] Serum testosterone levels have not been consistently associated with delayed ejaculation.[244]

Retrograde Ejaculation

Retrograde ejaculation is the failure of the semen to be ejected out through the urethral meatus; instead, the semen is propelled backward into the urinary bladder.[120–123] Retrograde ejaculation can be the result of autonomic neuropathy associated with diabetes mellitus; sympathectomy; therapy with adrenergic antagonists, some types of antihypertensives, antipsychotics, or antidepressants; bladder neck incompetence; or urethral obstruction. Retrograde ejaculation due to diabetes-associated autonomic neuropathy is the second most prevalent ejaculatory disorder.[120–123] Following transurethral resection of the prostate, the bladder neck closure mechanism may be damaged. Patients remain continent because of a second, more distal, continence mechanism that is present in the region of the membranous urethra; however, many patients who have undergone transurethral resection of the prostate experience retrograde ejaculation. Ejaculatory disorders can lead to infertility among men.[120–123]

Current Definitions of Sexual Disorders in Women

The current definitions for female sexual disorders in DSM-5 are shown in Table 20.1.[45,46] A disorder is diagnosed only if there is clinically significant distress or impairment; additionally, the sexual dysfunction should not be more attributable to a nonsexual psychiatric disorder, to the effects of a substance (e.g., a drug of abuse, a medication), to a medical condition, or to relationship distress, partner violence, or other significant stressors.[45,46] Disorders are identified as early onset (lifelong) versus late onset (acquired).

Sexual Interest/Arousal Disorder

The DSM-5 definition addressing problematic desire merges sexual interest (motivation) with arousal and deemphasizes the need to have initial anticipatory desire.[245,246] Increasing evidence suggests that desire ahead of and at the outset of sexual engagement, although welcomed probably by both partners, is not mandatory for a woman's sexual enjoyment and satisfaction.[21,247–249] It is the inability to trigger desire and arousal during sexual engagement (as well as an absence of desire initially) that constitutes the disorder. Empirical support for the concept that arousal may precede desire and the two then coexist is now strong and includes data from older and younger women.[21,24,248] Therefore, merging of sexual arousal and desire difficulties into one disorder appears logical. However, validated questionnaires used to assess sexual function are based on models of sexual response in which desire is assumed necessary at the outset of engagement. This is now acknowledged as a serious limitation to research,[250] and the prevalence of what is currently understood to be *disorder* is not known.[37,249–257] Studies that simply report "low desire and distress" indicate prevalence of about 10%, not increasing with age.[37,255] Early research suggests that some two thirds of women diagnosed with HSDD would merit a diagnosis of SIAD as well. This research also indicated that women with both diagnoses have more severe and more numerous symptoms.[258]

Although, according to DSM-5, the SIAD diagnosis excludes situations where relationship issues, mood, medications, or illness are strong contributors to sexual dysfunction, in clinical practice most patients seeking help have risk factors including negative feelings for the partner and mood disorders.[252] Depression, either currently or in the past and even in the absence of a clinical diagnosis of depression, depressive and anxious thoughts and low self-esteem are found significantly more commonly in women with SIAD than in women without SIAD.[17,37,255]

Female Orgasmic Disorder

The prevalence of women's orgasmic disorder is not known, because many studies include women with low arousal who rarely reach orgasm.[14,37,255] Risk factors include anxiety about the partner's presence, fear of being vulnerable, fear of not being in control, and fear of intimacy.[14] These factors often stem from childhood (nonsexual) experiences.

Genitopelvic Pain/Penetration Disorder

The merging of former terms *vaginismus* and *dyspareunia* in DSM-5 has some merit. According to DSM-IV, the term *vaginismus* described (phobic) avoidance, involuntary pelvic muscle contraction, and anticipation of, fear of, or the experience of pain in the absence of structural or other abnormalities on examination. Some women who reported typical phobic avoidance of penetration received an initial diagnosis of vaginismus; however, in many such women, a physical examination had to be deferred until therapy enabled a thorough pelvic examination to be performed. However, in some of these women, a subsequent careful introital examination enabled by successful therapy could reveal allodynia of the vestibule. Thus, the initial diagnosis of vaginismus based on history would need to be changed to provoked vestibulodynia (PVD) after introital examination.

Reported prevalence of sexual pain varies between 20% and 35%.[259–263] PVD, which is the most common form of pain with penetration, affects some 16% of mostly premenopausal women, many of whom have had pain consistently from first attempts at penetration.[253] Risk factors for PVD include some personality traits—perfectionism, reward dependency, fear of negative evaluation—as well as harm avoidance, hypervigilance for pain, higher levels of trait anxiety, and shyness.[253] In a small subset, vaginal infections, such as vaginal candidiasis, appear to precipitate and maintain the condition.

In DSM-5, vaginismus is now included within genitopelvic pain/penetration disorder (GPPPD).[45] Risk factors for GPPPD include depression, anxiety, social phobia, somatization, and hostility. Some studies identify increased catastrophic thinking in women with vaginismus compared with women without pain or women with other forms of pain: moreover, women with vaginismus show greater disgust propensity.[253] There is no evidence that vaginismus is related to religious orthodoxy, negative sexual upbringing, or concerns about sexual orientation. Typically, there is extreme fear of vaginal entry, fear that harm will come from

something the size of a penis entering the vagina, and fear of damage by vaginal delivery.

Persistent Genital Arousal Disorder

Not included in DSM-5 but clinically an increasingly common and poorly understood entity is persistent genital arousal disorder, which involves spontaneous, intrusive, and unwanted genital arousal (e.g., tingling, throbbing, pulsating) in the absence of sexual interest and desire. The awareness of subjective arousal is typically, but not invariably, unpleasant. The arousal is unrelieved by one or more orgasms, and the feelings of arousal may persist for hours or days.[254] Persistent genital arousal disorder can be associated with a broad range of symptoms, of which the severity can vary from mild (and perhaps pleasant) to intrusive and distressing, and which can interfere with life. Prevalence is unknown.

Sexual Dysfunction in the Context of Endocrine Disease

We will focus on sexual sequelae of endocrine disease and its treatment, but in any given person, nonendocrine factors may be more important. These factors include psychological, relational, contextual, cultural, and nonendocrine medical influences—especially depression, hypertension, neurologic disease, and LUTS.[14] For patients with chronic disease, the disease itself, its treatment, and its psychological effects, plus interpersonal, personal, and contextual issues, affect sexual response.[14]

In healthy women, factors such as attitudes toward sex, feelings for the partner, past sexual experiences, duration of relationship, and mental and emotional health have been shown to more strongly modulate desire and arousability than do biologic factors.[14] Contrary to gender stereotypes, recent analysis of the 1035 sexually active adults who participated in the NHSLS in 1992 showed that men's physical sexual pleasure was more closely linked to relational factors than was the case for women.[37,188,191] Similarly, in a recent international study of midlife and older couples, men rated the importance of sex for closeness and intimacy to their partner more highly than did their female partners.[37] Qualitative research also suggests that both men and women note that positive self-esteem and feeling attractive enhance desire and arousal.[37,191] Sexual context is also important for both men and women.[191]

Endocrine Disorders and Sexual Dysfunction in Men

Androgen Deficiency Syndromes

Androgen deficiency in men is a syndrome characterized by a constellation of signs and symptoms associated with consistently and unequivocally low testosterone levels due to disorders of the testes, pituitary, or hypothalamus.[27,63,264] Androgen deficiency can occur either because of primary testicular dysfunction or as a result of disorders affecting the hypothalamus or the pituitary.[63] Common causes of primary testicular dysfunction include Klinefelter syndrome, uncorrected cryptorchidism, radiation and cancer chemotherapy, Yq microdeletions, human immunodeficiency virus (HIV) infection, orchitis, trauma, and torsion.[63] Secondary testicular dysfunction can result from systemic illness; excessive exercise; recreational drugs, especially opiates, anabolic steroids, marijuana, cocaine, and alcohol; pituitary and suprasellar tumors; hemochromatosis; hyperprolactinemia; and infiltrative disorders. Exclusion of these secondary causes of hypogonadism may then justify a diagnosis of idiopathic hypogonadotropic hypogonadism, which is a heterogeneous group of disorders characterized by disordered GnRH secretion.[63] Opioid use has emerged as an important cause of testosterone deficiency and sexual dysfunction. Similarly, in many men's health clinics, a substantial proportion of men receiving testosterone replacement therapy are former anabolic steroid users. The testosterone levels required to maintain sexual function in men are close to the lower limit of the normal male range.[65,144,155,158,265,266] Therefore, some men with pituitary tumors may remain asymptomatic until their tumor has grown substantially and testosterone levels have declined to a level below this threshold.

Androgen deficiency is an important treatable cause of HSDD in men. Therefore, men diagnosed with HSDD should be evaluated for androgen deficiency by measurement of testosterone levels using a reliable assay, preferably in an early morning fasting blood sample.[63] Although ED and androgen deficiency in men are separate disorders with distinct pathophysiologic mechanisms, the two can coexist in the same patient. Testosterone levels should be measured in men presenting with any form of sexual dysfunction because androgen deficiency is treatable; furthermore, androgen deficiency may be a manifestation of another underlying disease, such as a pituitary tumor, which may require additional evaluation and disease-specific intervention.

Diabetes and Sexual Dysfunction in Men

Men with diabetes mellitus are at increased risk of ED, retrograde ejaculation, and low testosterone levels. Peyronie disease is an important comorbid condition in older diabetic men with ED.[267–274] Men with diabetes have significantly lower scores for sexual desire, activity, arousal, and satisfaction,[268–274] in part due to the medical and psychological factors associated with diabetes, such as the variations in glycemic control, reduced energy, and altered self-image. Diabetes also is associated with increased risk of low testosterone levels.[63,275–280] In population studies, sex hormone–binding globulin (SHBG) and total testosterone are more strongly associated with diabetes risk than free testosterone levels; these data suggest that the observed association of testosterone with diabetes risk may be related to factors, such as obesity and inflammation, that alter SHBG.[279,280]

The prevalence of ED in men with diabetes increases with age and has been reported to be as high as 75% in some studies. ED in men with type 2 diabetes, even without other risk factors for coronary artery disease, may signal silent cardiac ischemia.[280–284] Among men with diabetes, those with ED are more likely to be older and smokers, and to have a longer duration of diabetes, poor metabolic control, untreated hypertension, neuropathy, microalbuminuria and macroalbuminuria, retinopathy, CVD, diuretic treatment, low testosterone levels, and psychological vulnerability.[270–273] The risk of ED generally increases with chronic elevation of hemoglobin A_{1c}.[270] Increased physical activity and consumption of small amounts of alcohol have been found to be associated with lower risk of ED.

Endothelial and smooth muscle dysfunction, autonomic neuropathy, and psychological and interpersonal issues contribute to sexual dysfunction in men with diabetes.[283,284] Endothelial dysfunction is evident in both penile blood vessels and nongenital vascular beds.[212] eNOS is reduced, possibly due to overexpression of arginase or lack of nicotinamide adenine dinucleotide phosphate (NADPH), which is an essential cofactor for NOS.[284–289] Additionally, accumulation of oxygen free radicals, including

those from advanced glycosylation end products, quench nitric oxide and attenuate the action of K^+ channels.[288,289] Men with long duration of diabetes may not be able to generate sufficient nitric oxide and cGMP within the cavernosal smooth muscle; thus, they may become unresponsive to PDE5 inhibitors. The reduction in NADPH is also associated with increased diacylglycerol and protein kinase C, and, consequently, increased smooth muscle contractility.[286] An increased activation of the Rho A/Rho kinase pathway may increase the sensitivity of cavernosal smooth muscle to calcium.[286] Autonomic neuropathy affecting the pelvic nerves may lead to both ED and ejaculatory dysfunction.[287]

Retrograde ejaculation and partial ejaculatory incompetence affect up to one third of men with diabetes.[290] Autonomic neuropathy in diabetes may be associated with dysfunction of the internal sphincter so that all or a part of the seminal fluid is propelled into the bladder.[287] Partial ejaculatory incompetence refers to the condition in which ejaculatory emission remains intact but the expulsion phase is inhibited; consequently, the semen trickles out of the penis and the experience of orgasm is altered in quality. The ejaculatory problems may be a cause of infertility.

Sexual Dysfunction Associated With Therapies for Benign Prostatic Hypertrophy

Benign prostatic hyperplasia is frequently associated with LUTS and sexual dysfunction.[208–214] Some α_1-adrenergic receptor blockers, such as tamsulosin, are associated with ejaculatory dysfunction.[291,292] Treatment of men with LUTS with 5α-reductase inhibitors has been associated with increased risk of ejaculatory disorder, ED, and decreased libido.[293,294]

Several surveys have reported the development of sexual symptoms, including loss of libido, ED, depressive symptoms and even suicidality, and cognitive symptoms in a subset of young men who have taken finasteride for alopecia.[295–298] These symptoms have been reported to persist even after discontinuation of finasteride, and this condition has been referred to as postfinasteride syndrome. Our recent investigations of men who developed sexual symptoms after using finasteride and whose symptoms persisted even after discontinuation of finasteride have revealed that these men do not have evidence of androgen deficiency, decreased peripheral androgen action, or persistent peripheral inhibition of SRD5A.[299]

Symptomatic finasteride users revealed depressed mood and fMRI findings consistent with those observed in men with depression.[299] The causal role of finasteride and the pathophysiology of these symptoms remain to be established.[299,300]

Hyperprolactinemia and Sexual Dysfunction

Hyperprolactinemic men often present with decreased libido or ED; 75% of men with macroprolactinomas and 50% of men with microprolactinomas report reduced desire or ED, and almost all have subnormal nocturnal penile erections.[301–305] Hyperprolactinemia affects 1% to 5% of men presenting with ED[302]; a fraction of these men have prolactin-secreting pituitary adenomas. Prolactin lowers testosterone levels through its inhibitory effects on GnRH secretion and on the pituitary gonadotrope response to GnRH. Most, but not all, men with sexual dysfunction and hyperprolactinemia have low testosterone levels.[301,302] Whether and how hyperprolactinemia directly affects erectile function through target organ effects is not well understood. Erectile function generally improves in hyperprolactinemic men following treatment with dopamine agonists.[304,305]

Sexual Dysfunction in Patients With Thyroid Disease

Hypothyroidism has been associated with increased risk of hypoactive sexual desire and ED.[306–310] The exact prevalence of sexual dysfunction in men with hypothyroidism is unknown. Free testosterone levels are lower in hypothyroid men than in control subjects and become normal after thyroxine replacement.[306–310] Serum LH and follicle-stimulating hormone levels are typically not elevated in men with primary hypothyroidism.[309] Hyperprolactinemia is noted in a small proportion of hypothyroid men.[309]

Free testosterone levels are typically normal in men with hyperthyroidism, but SHBG and estradiol levels are elevated, resulting in a high estradiol-to-testosterone ratio and gynecomastia in some hyperthyroid men.[308] Hyperthyroidism has been observed in a small fraction of men with ED.[310]

Sexual Dysfunction in Men With Metabolic Syndrome

Men with metabolic syndrome have a higher prevalence of ED than men without metabolic syndrome.[311–314] The risk of ED is correlated with the number of identified components of metabolic syndrome.[310–314]

Endocrine Disorders and Sexual Dysfunction in Women

Thyroid Disease in Women

Both hyper- and hypothyroid states have been found to be risk factors for sexual dysfunction, which mostly remits with return to a euthyroid state.[315–317] Studies are few and small, and the sexual dysfunction was assessed in these studies using neither modern psychometrically robust instruments nor the DSM-5 classification of sexual disorders. Comorbid depression is associated with sexual dysfunction in the context of thyroid disease.[27,315] There is some evidence that thyroid autoimmunity lessens sexual desire independent of altered thyroid status: euthyroid women with Hashimoto thyroiditis may report persistent loss of desire.[315–317] One research group found that women with nodular goiter have significantly more sexual dysfunction than control subjects. This group also had the highest body mass index.[317] It is not clear whether the sexual dysfunction in patients with thyroid disease is related to the underlying thyroid disease or to comorbid conditions or body image problems.

Hyperprolactinemia in Women

Hyperprolactinemia can be associated with increased risk of menstrual irregularities, amenorrhea, hypoestrogenemia, and galactorrhea.[79,318] Some studies find that women with hyperprolactinemia report greater overall dissatisfaction with sexual function and lower scores for sexual desire, arousal, lubrication, and orgasm than women with normal prolactin levels. The lower scores for sexual function and desire have also been found in women with hyperprolactinemia who have regular menses.[318] However, normal menstruation, younger age, and smaller size of prolactinoma are more likely to be associated with normal sexual function.[14] Prolactin inhibits GnRH pulses, attenuates gonadotropin response to GnRH, and is associated with reduced ovarian secretion of estradiol and androgens. Sexual outcomes in hyperprolactinemic women after treatment with dopamine agonists have not been well studied.

Diabetes in Women

A recent meta-analysis[319] including 3168 women with diabetes and 2823 control subjects from 26 studies confirmed that sexual

dysfunction is more frequent in women with diabetes than in age-matched controls. Compared with women without diabetes, the risk of sexual dysfunction was 2.27 and 2.49 times higher in women with type 1 and type 2 diabetes, respectively.[319] However, postmenopausal women with any form of diabetes did not demonstrate an increased risk of sexual dysfunction.

Sexual dysfunction in women with diabetes is complex, and the interrelationships between body mass index, fat distribution, diabetic complications, insulin resistance, inflammation, CVD, relationship satisfaction, and depression remain incompletely understood.[14,320,321] The increased prevalence of sexual dysfunction and lower Female Sexual Function Index (FSFI) score in women with diabetes may be related to body weight. This association would be in keeping with other studies showing an increased prevalence of sexual dysfunction in obese women[320–322] and in women with metabolic syndrome.[323,324] Unlike the situation in men with diabetes, sexual dysfunction has not been associated with the duration of diabetes or the presence of diabetic complications in the majority of studies. Most studies in women with type 2 diabetes are small, but one larger study of 600 women with type 2 diabetes confirmed depression and marital status to be independent risk factors for sexual dysfunction.[325]

Women's sexual response and satisfaction may be compromised by diabetes-associated changes in their well-being, mood, self-image, weight gain, recurrent vaginitis from candidiasis, or infertility.[319,320,322,325–335] In addition, genital sexual response may be compromised by autonomic neuropathy, endothelial dysfunction, and microvascular disease. Some, but not all, studies show increased prevalence of dyspareunia, orgasmic difficulties, and sexual dissatisfaction.[318] In women with type 1 diabetes, sexual dysfunction is mostly correlated to psychological factors including depression, anxiety, and marital status.[322,326,327,329] A large prospective study of 625 women with type 1 diabetes confirmed depression as a major predictor of sexual dysfunction.[333] Type 1 diabetes also may be associated with loss of genital sexual sensitivity and subsequent loss of orgasm.[336] Young women with diabetes on multiple insulin dose regimens had impaired arousal and lubrication, whereas those using an insulin pump had sexual function comparable to healthy age-matched women.[337]

Autonomic and somatic neuropathy may contribute to loss of genital sexual sensitivity. When there is less engorgement of the vascular sinusoidal tissue comprising the shaft, head, rami, and bulbs of the clitoris, massaging the structures during sexual stimulation may fail to elicit typical sexual sensations, compromise arousal, and limit the experience of orgasm.[338,339]

In animal studies, diabetes has been shown to impair vaginal smooth muscle relaxation responses to the neurotransmitters, particularly VIP and nitric oxide.[338] These studies also report decreased clitoral and vaginal blood flow to nerve stimulation, diffuse fibrosis of the clitoral and vaginal tissues, and reduced muscular layer and epithelial thickness in vaginal tissue. Endothelial dysfunction and reduced clitoral blood flow have been documented in women with diabetes.[339]

Most studies have not found increased prevalence of dyspareunia in women with diabetes. However, they are at higher risk of recurrent candidiasis, which may contribute to dyspareunia.

Metabolic Syndrome in Women

Metabolic syndrome has been shown to have a deleterious effect on women's sexuality, independent of diabetes and obesity.[14,27,340,341] This negative effect seems to be more prevalent in premenopausal women than in postmenopausal women.[14,27,340,341]

Polycystic Ovary Syndrome

Some studies have suggested that women with polycystic ovary syndrome may be less sexually satisfied and may regard themselves as less attractive than control subjects.[342–345] The presumption is that obesity and androgen-related symptoms may contribute to poor body image, which may increase the risk of sexual dysfunction.[27,320] However, it is not clear whether polycystic ovary syndrome per se, as opposed to obesity, is a risk factor for sexual dysfunction.[345,346] There is no evidence of heightened sexual desire from the higher androgen levels.

Congenital Adrenal Hyperplasia

Whereas the classic form almost always presents at birth with adrenal insufficiency and virilization in girls, nonclassic forms of congenital adrenal hyperplasia (NC-CAH) may present with signs of hyperandrogenism in childhood or adulthood, depending on the severity of the 21-hydroxylase enzyme deficiency.[347] The presenting features of 21-hydroxylase enzyme deficiency may include amenorrhea, anovulation, hirsutism, or oligomenorrhea with infertility. A recent study found women with NC-CAH had a lower total FSFI score, with lower sexual arousal, lubrication, sexual satisfaction, and more dyspareunia, plus higher depressive symptom scores compared with well-matched controls.[347] Women with classic and NC-CAH may show gender-atypical behavior[348]; in one study, male-typical role-playing in childhood correlated with reduced satisfaction with the female gender role and reduced heterosexual interest in adulthood.[349] Disturbed body image, repeated genital examinations, and genital surgery may also affect sexual function in women with classic congenital adrenal hyperplasia.[348] Decreased sexual frequency, sexual satisfaction, and sensuality, high rates of sexual avoidance, and difficulty with vaginal penetration and orgasm, regardless of whether they have undergone prior surgery, have been reported in women with classic and NC-CAH. Caring for these women requires careful individualized treatment of both androgen excess and psychosexual counseling.[350]

Pituitary Disease in Women

There is limited research on sexual function in women who have deficiencies of various pituitary hormones. Women with pituitary disease and gonadotropin deficiency may suffer from amenorrhea or menstrual irregularity or problems with sexual function, including decreased sexual desire and problems with lubrication or orgasm.[351] Although women with hypopituitarism have lower estradiol and testosterone levels than healthy menstruating women, the short- and long-term effects of replacing testosterone in women with hypopituitarism who are receiving estrogen replacement have not been well studied.[351,352] In one randomized trial of 51 women, testosterone therapy in women who were receiving estrogen therapy was associated with some benefit in sexual function and mood, compared with placebo, but with a higher frequency of androgenic side effects than placebo.[353] The effects of replacing dehydroepiandrosterone (DHEA) on sexual function and mood in women with hypopituitarism are also poorly understood.[351]

Adrenal Insufficiency in Women

In addition to deficiency of cortisol and aldosterone, women with adrenal insufficiency also have low levels of testosterone and DHEA.[27,354–363] Adrenal insufficiency in women has been associated with low health-related quality of life.[359] However, a 2010 larger study comparing 174 women with Addison disease with

740 age-matched healthy control subjects and with 234 women who had received a risk-reducing bilateral salpingo-oophorectomy (BSO) demonstrated that despite subnormal levels of androgens and androgen metabolites, the women with Addison disease reported higher sexual pleasure and less discomfort with intercourse than the normative control women.[360] Clinical trials of DHEA replacement in women with adrenal insufficiency have been small and mostly negative.[27,354–358,361,363] An earlier small trial in women with primary or secondary adrenal insufficiency reported greater improvements in sexual interest and satisfaction and in mood for women receiving DHEA compared with placebo[354]; however, four subsequent studies did not find significant improvements in sexual function.[355–358] In 2009, a meta-analysis of the 10 notably small studies concluded that DHEA therapy in adrenal insufficiency may result in small improvements in health-related quality of life and depression, but it had no effects on anxiety or sexual well-being.[363] Thus, there are insufficient data to support the routine use of DHEA in women with adrenal insufficiency. Unfortunately, given that the typical multiple factors underlying women's sexual dysfunctions and small studies with limited assessments of sexual function may not be helpful in evaluating benefit from absent hormones. In addition to being a prohormone for the intracellular production of testosterone and estrogen, DHEA is now known to have multiple direct actions, including the modulation of various receptors and synaptic transmission in the brain, where its concentration can be six times higher than in serum.[364,365]

Natural Menopause

A majority of women who discontinue previously needed postmenopausal estrogen supplementation develop signs of vulvovaginal atrophy, now termed *genitourinary syndrome of menopause* (GSM), which is a risk factor for sexual dysfunction.[259–263,366,367] However, symptoms from GSM may remit spontaneously within 1 year; risk factors for more severe symptoms are diabetes, younger age, and low body mass index.[263,366,367] The traditional notion that maintaining sexual activity will prevent symptomatic GSM has been refuted.[367] Subjective symptoms and objective signs of GSM correlate poorly.[368] Epidemiologic studies have not shown an increase in the prevalence of dyspareunia with age.[259–261] Clearly, not all postmenopausal women develop sexual symptoms of estrogen deficiency: of 1525 women followed from age 47 to 54 years, most did not experience sexual dysfunction.[262] It is likely that multiple factors contribute to sexual symptoms, including variations in the intracrine production of estrogen from adrenal precursors, the number and sensitivity of estrogen receptors, and the degree of sexual arousal or excitement at the time of vulval stimulation and vaginal entry.[369–371] Psychological factors rather than estrogen levels were shown to moderate symptoms when GSM is present.[371]

Most studies report a decrease in sexual desire with advancing age[372] that is not easily explained by hormonal deficiency alone. Adaptive changes occur in the brain in response to the reductions in circulating levels of sex hormones associated with age and menopause.[373,374] Sex hormones are produced locally within the brain: in women, steroidogenic enzymes and sex-steroid receptors in the brain are upregulated in response to decreased circulating levels of sex hormones.[373,374] We do not know whether there is biologic adaptation to reduced amounts of circulating sex hormones. In studies of age, menopausal status, and sexual function, the postmenopausal state has generally been negatively associated with desire, mainly among women who experienced low emotional intimacy with their partners. Similarly, the negative association between age and sexual desire was particularly pronounced in women experiencing little intimacy.[375]

Surgical Menopause

Surgical menopause is a state of both androgen and estrogen depletion of sudden onset and has often been viewed as a risk factor for sexual dysfunction. However, most women undergoing bilateral BSO for benign clinical indications do not develop sexual dysfunction. Three prospective studies found that women choosing BSO plus hysterectomy for benign indications did not develop sexual dysfunction over the next 1 to 3 years.[376–378]

A national survey of 2207 American women confirmed an increased prevalence of distress about low sexual desire in women with a recent BSO.[372] Thus, in women undergoing nonelective surgery, the thematic context of bilateral oophorectomy may impair sexual desire and function. For example, women who are treated for malignant disease or those who desire to preserve their fertility may experience greater distress about low sexual desire after BSO than those who undergo BSO for benign conditions. In the same survey, both older and younger women with a relatively recent BSO reported low sexual desire, per se, as often as age-matched subjects with intact ovaries.[372] Despite their continued hormonal deficit, women older than 45 years who underwent oophorectomy before menopause had fewer complaints of low desire than women of similar age with intact ovaries.[372]

A recent study of 1352 women showed no difference in the report of sexual ideation, sexual function, or sexual problems between women who have had and women who have not had bilateral oophorectomy.[379] Having thoughts about sex is less likely to be affected by contextual details including the sexual relationship than is sexual function or motivation for partnered sex.

The women who carry a *BRCA1* or *BRCA2* mutation and undergo BSO to lessen the risk of breast, ovarian, or fallopian tube cancer mostly remain satisfied with their decision for surgery.[380] However, after risk-reducing surgery, women reported significantly less sexual pleasure, more discomfort, and less frequent sex compared with controls.[381]

Aging-Associated Decline in Sex Hormone Precursors in Women

From the middle 30s to the early 60s, a woman's adrenal production of precursor hormones—DHEA, androstenedione, and DHEA sulfate—declines by 70%.[66,68] However, the trajectories of decline in these precursor steroids vary among women.[66–68] The relationship of the age-related decline in these circulating precursors to sexual function remains poorly understood. On the population level, variation in circulating levels of sex steroids and their precursors is related to variation in steroidogenic enzyme activities, such as 3β-hydroxysteroid dehydrogenase, 17β-hydroxysteroid dehydrogenase, 17,20-lyase, and aromatase, and to the variation in the plasma clearance of these hormones and precursors. Labrie and associates[68,369,382] have proposed that the androgen metabolites, most notably ADT-G, may serve as useful markers of ovarian and tissue production and activity of androgens in women. How the decline in total androgen activity with age may relate to sexual function has yet to be studied.

Selective Estrogen Receptor Modulators

Selective estrogen receptor modulators are a class of ligands that bind estrogen receptor subtypes and induce a unique profile of

tissue-specific gene expression. Accordingly, each selective estrogen receptor modulator may also be associated with a unique set of clinical responses. Ospemifene has estrogen antagonist action on breast and endometrium. Ospemifene, but not raloxifene or tamoxifen, can ameliorate the genital sexual symptoms of lack of estrogen.[383] Limited research suggests raloxifene and tamoxifen are not associated with sexual adverse effects.

Hormonal Contraceptives

The estrogen in combined systemic contraceptives increases SHBG and thus decreases available free testosterone. The decrease in sexual desire and subjective arousability in some women receiving oral contraceptives has been attributed to the decrease in free testosterone levels. However, to date, low desire has not been associated with testosterone levels, even when mass spectrometry methods are used.[66,67] Dyspareunia is an occasional consequence of very low estrogen formulations. Hormonal contraceptives exert multiple psychological and biologic actions, some of which may positively affect sexuality, for example, by reducing anxiety about unwanted pregnancy and diminishing dysmenorrhea.[384]

Androgen Insensitivity Syndrome

Women with complete androgen insensitivity syndrome have a female phenotype with full breast development but variable shallow vagina, which may require surgical intervention or progressive dilatation. Small cross-sectional studies indicate that women with complete androgen insensitivity are capable of a healthy sexual response with orgasms of self-stimulation and of intercourse to be possible despite complete androgen insensitivity.[385–389] However, these women are often confronted with complex psychosocial issues related to the mismatch between their genetic sex and their gender role, the timing of diagnosis and timing of disclosure to the woman, and infertility. Reduced sexual confidence, poor self-esteem, and depression are noted in these studies.

Assessment of Sexual Dysfunction

Assessment of sexual function is an important part of the evaluation of patients with endocrine diseases. Open-ended, nonjudgmental questions such as "Many men with diabetes notice changes in their erections or ejaculation—are you having any difficulties?" can facilitate further discussion of sexual problems. When sexual problems are identified, sensitive and respectful inquiry into their nature and the sexual context is necessary. Evaluating both partners together, as well as individually, can often uncover problems that may not be apparent in individual interviews.

Evaluation of Men With Sexual Dysfunction

There are four important considerations in the evaluation of men with HSDD. First, an important initial step in the evaluation is an interview of the couple to determine whether the patient primarily has ED or a sexual desire problem. Second, ascertain whether the couple has a relationship problem. Establish whether self-stimulation continues despite lack of desire for partnered sex. With the easy accessibility of Internet sites, sex alone, possibly on a frequent basis, may allow sexual expression despite relationship difficulties. Third, general health evaluation is necessary to exclude systemic illness, depression, and medication use. Serum total and free testosterone levels should be measured to exclude androgen deficiency because androgen deficiency is an important treatable cause of HSDD.

The diagnostic workup of men with ED should start with an evaluation of general health[5,6,390–396] (Tables 20.4 and 20.5). The presence of diabetes mellitus, coronary artery disease, peripheral vascular disease, hypertension, chronic kidney disease, stroke, spinal cord or back injury, a neurologic disorder, depression, and dementia should be verified. Information about use of recreational drugs such as alcohol, opioids, marijuana, cocaine, and tobacco, prescription medications, particularly antihypertensives, antiandrogens, antidepressants, antipsychotic drugs, and opioid analgesics, and nonprescription over-the-counter supplements is important because almost one fourth of all cases of impotence can be attributed to medications. A detailed sexual history should elicit the nature of relationships, partner expectations, situational erectile failure, performance anxiety, and marital discord. It is important to distinguish between inability to achieve erection, changes in sexual desire, failure to achieve orgasm and ejaculation, and dissatisfaction with the sexual relationship, as the etiologic factors vary with the type of sexual disorder.

A directed physical examination should focus on secondary sex characteristics, the presence or absence of breast enlargement and testicular volume; evaluation of femoral and pedal pulses; neurologic examination to determine the presence of motor weakness, perineal sensation, anal sphincter tone, and bulbocavernosus reflex; and examination of the penis to evaluate any unusual curvature, palpable plaques, or superficial lesions.[390–395]

The initial diagnostic workup in most men presenting with ED usually includes the measurement of hemoglobin, blood glucose and hemoglobin A_{1C}, blood urea nitrogen and creatinine, plasma lipids, and serum total and free testosterone levels. Further evaluation using more invasive diagnostic testing is limited to those men who do not respond to an empiric trial of oral PDE5 inhibitors; these patients should be referred to a specialist for detailed urological evaluation.

Self-reporting questionnaires are useful because many men with ED do not voluntarily disclose their sexual complaints to their health care provider.[390–393] The International Index of Erectile Function, for example, is a multidimensional scale consisting of 15 questions that address relevant domains of male sexual function, including sexual desire, intercourse satisfaction, orgasmic function, and overall satisfaction[390]; a short form is also available.[393]

The diagnosis of androgen deficiency should be made only in men with consistent symptoms and signs and unequivocally low early morning serum testosterone levels that are consistently below the lower limit of the normal range for healthy young men.[6,27,65,264] Because of the diurnal, pulsatile, and interday variations in circulating testosterone levels, and the known suppressive effects of food and glucose intake, total testosterone concentrations should be measured in a fasting state on two separate mornings. Serum testosterone levels should be measured using a reliable assay, such as liquid chromatography tandem mass spectrometry (LC-MS/MS) assays, which have become widely available from many commercial and research laboratories, and which offer a higher level of accuracy and precision than immunoassays, especially at the low levels present in hypogonadal men. Ideally, testosterone levels should be measured using an assay that has been certified by an accuracy-based

Questions Asked of One or Both Partners	
1. Sexual problems and reason for presenting at this time	Ask patients to describe sexual problems in their own words; clarify further with direct questions, giving options rather than leading questions, support and encouragement, acknowledgement of embarrassment, and reassurance that sexual problems are common.
2. Duration, consistency, and priority if more than one problem is present	Are problems present in all situations? Which problem is most troubling?
Context of sexual problems	Emotional intimacy between partners, activity or behavior just before sexual activity, privacy, sexual communication, time of day and fatigue level, birth control (adequacy, type), risk of STIs, usefulness of sexual stimulation, sexual knowledge.
3. Rest of each partner's sexual response, other than the given problem area	Both currently and before the onset of the sexual problems.
4. Reaction of each partner	How each has reacted emotionally, sexually, and behaviorally.
5. Previous help	Compliance with recommendations and effectiveness.
Questions Asked of Each Partner When Seen Alone[a]	
1. Partner's own assessment of the situation	Sometimes it is easier to disclose symptom severity (e.g., total lack of desire) in the partner's absence.
2. Sexual response with self-stimulation	Also inquire about sexual thoughts and fantasies.
3. Past sexual experiences	Positive and negative aspects.
4. Developmental history	Relationships to others in the home while growing up; losses, traumas, to whom (if anyone) was the patient close; was he or she shown physical affection, love, respect?
5. Past or current sexual, emotional, and physical abuse	Explain that abuse questions are routine and do not necessarily imply causation of the problems; it is helpful to ask whether the patient ever felt hurt or threatened in the relationship and, if so, whether he or she wishes to give more information.
6. Physical health, especially conditions leading to debility and fatigue, difficulty with mobility (e.g., in caressing a partner, performing self-stimulation), and difficulties with self-image (e.g., from obesity, Cushing syndrome, hypogonadism)	Specifically, ask about medications with known sexual side effects, including SSRIs, SNRIs, β-blockers, narcotics, antiandrogens, and GnRH agonists.
7. Evaluation of mood	A significant correlation of sexual function and mood (including anxiety and depression) warrants routine screening for mood disorder using either a questionnaire (e.g., Beck Inventory) or semistructured series of questions.

[a]Items 3 through 5 of the single-patient interview may sometimes be omitted (e.g., for a recent problem after decades of healthy sexual function).

STIs, Sexually transmitted infections; *SSRIs,* selective serotonin reuptake inhibitors; *SNRIs,* selective serotonin norepinephrine reuptake inhibitors; *GnRH,* gonadotropin-releasing hormone

Adapted from Basson R. Clinical Practice. Sexual desire and arousal disorders in women. *N Engl J Med.* 2006;354(14):1497–1506.

standardization or quality control program (e.g., the Hormone Standardization Program for Testosterone from the Centers for Disease Control and Prevention (CDC).[264] The advent of LC-MS/MS, the availability of a testosterone calibrator from the National Institute of Standards and Technologies, and the institution of the Hormone Standardization Program for Testosterone have greatly improved the accuracy of testosterone assays and reduced interlaboratory variability among CDC-certified laboratories.[264,397–400]

The reference ranges for testosterone in men reported by various laboratories vary substantially because of assay differences, calibrator differences, and differences in the reference populations used to generate ranges. Recently, under the auspices of the Endocrine Society and the Partnership for the Accurate Testing of Hormones, we have published harmonized reference range based on data from community-dwelling men from four large cohorts in the United States and Europe.[401] The harmonized reference range for total testosterone in healthy, nonobese young men (age 19–39 years) was 264 to 916 ng/dL (9.2–31.8 nmol/L).[401] This reference range can be applied to all CDC-certified total testosterone assays.

Circulating testosterone is bound with high affinity to SHBG and with lower affinity to albumin, orosomucoid, and cortisol-binding globulin; only 2 to 4% of circulating testosterone is unbound or free.[402] The alterations in SHBG concentrations can alter the total testosterone concentrations; therefore, in conditions that alter SHBG concentrations, such as obesity, diabetes, aging, liver disease, hypo- and hyperthyroidism, and intake of many medications, determination of free testosterone levels is necessary to assess androgen status.[402] Free testosterone concentrations can be measured using the equilibrium dialysis assays or calculated from total testosterone, SHBG, and albumin concentrations.[402] The direct tracer analogue free testosterone assays are used in many hospital laboratories, but they are inaccurate and should not be used.

Zakharov and colleagues[403] have shown that testosterone's binding to SHBG is a dynamic multistep process that includes heterogeneity in circulating isoforms of SHBG dimer, an allosteric interaction between the two binding sites on SHBG such that the binding affinities of the two binding sites on SHBG are not equivalent, and convergence to an energetically favored bound state in

TABLE 20.5 Directed Diagnostic Evaluation of ED

History

Ascertain Psychosexual History

Nature of sexual dysfunction: whether the primary problem is decreased desire, erectile dysfunction, premature or delayed ejaculation, or difficulty in achieving orgasms
Strength of marital relationship and marital discord
Depression
Stress
Sexual performance anxiety
Knowledge and beliefs about sexuality

Ascertain Risk Factors

Presence of diabetes mellitus, hypertension, hyperlipidemia, coronary artery disease, end-stage renal disease, and peripheral vascular disease
History of spinal cord injury, stroke, Alzheimer disease, or other neurologic disorder
Prostate or pelvic surgery
Pelvic injury
Medications such as antihypertensives, antidepressants, antipsychotics, opioid analgesics, and inhibitors of androgen production or action
Use of recreational drugs such as alcohol, cocaine, opiates, and tobacco

Ascertain Factors That Might Affect Choice of Therapy and the Patient's Response to It

Coexisting coronary artery disease and its symptoms and severity
Exercise tolerance
Use of nitrates or nitrate donors
Use of α-adrenergic blockers
Use of vasodilators for hypertension or congestive heart failure
Use of foods (e.g., cranberry juice) or drugs (e.g., erythromycin, protease inhibitors, ketoconazole, and itraconazole) that might affect metabolism of PDE5 inhibitors

Physical Examination

Ascertain signs of androgen deficiency, such as loss of body hair, eunuchoidal proportions, small testicular volume, or breast enlargement
Genital and perineal sensation to evaluate neurologic deficit from spinal cord lesion, previous stroke, peripheral neuropathy, or other neurologic disorder
Blood pressure and postural change in blood pressure
Evaluate femoral and pedal pulses and evidence of lower extremity ischemia
Penile examination to exclude Peyronie disease or other penile deformities

Basic Laboratory Evaluation That Should Be Performed in All Men With ED

Fasting blood glucose
Plasma lipids
Serum total and free testosterone level using reliable assays

ED, Erectile dysfunction; *PDE5,* phosphodiesterase 5.

which both sites are occupied.[403] The free testosterone levels computed using this dynamic multistep binding with allostery match closely the values measured directly by equilibrium dialysis.[403] These studies also showed that the published law of mass action equations based on a linear model of testosterone's binding to SHBG, in which one molecule of SHBG binds one molecule of testosterone with a single binding affinity constant, are erroneous.[403]

In men found to be androgen deficient, measurement of LH levels helps distinguish between testicular (LH elevated) and hypothalamic-pituitary (LH low or inappropriately normal) defects.[65] Men with hypogonadotropic hypogonadism may require measurement of serum prolactin, serum iron, and total iron-binding capacity; evaluation of other pituitary hormones; and a pituitary MRI.

There is considerable debate about the usefulness and cost-effectiveness of hormonal evaluation and the extent to which androgen deficiency should be investigated in middle-age and older men presenting with ED. In cross-sectional surveys,[65] only a small fraction of men with ED and low testosterone levels have been found to have space-occupying lesions of the hypothalamic-pituitary region.[301,302] The diagnostic yield of pituitary imaging to exclude pituitary tumor can be improved by limiting these procedures to men whose total testosterone level is less than 150 ng/dL or who have panhypopituitarism, persistent hyperprolactinemia, or symptoms of tumor mass.[301,302]

Between 8% and 10% of men with ED have low testosterone levels; the prevalence of androgen deficiency increases with advancing age.[158,404–406] The prevalence of low testosterone levels is not significantly different among men who present with ED and in an age-matched population.[159] These data are consistent with the proposal that ED and androgen deficiency are two common but independently distributed disorders.[159] However, it is important to exclude androgen deficiency in this patient population. Androgen deficiency is a correctable cause of sexual dysfunction, and some men with ED and low testosterone levels will respond to testosterone replacement. Androgen deficiency may be a manifestation of serious systemic disease and may have additional deleterious effects on the individual's health; for instance, androgen deficiency might contribute to osteoporosis and loss of muscle mass and function.

If the history, physical examination, and laboratory tests do not identify medical problems needing further workup, then a cost-effective approach is to prescribe a trial of oral PDE5 inhibitor, provided there are no contraindications (e.g., nitrate use).

Tests that evaluate the integrity of penile vasculature and blood flow[407,408] are not needed in most patients with ED, are reserved for patients in whom the results of these tests would alter the management or prognosis, and should be performed only by those with considerable experience with their use. The penile-brachial blood pressure index is a simple and specific, but not a sensitive, index of vascular insufficiency. It is rarely used today in the evaluation of ED.

Intracavernosal injection of a vasoactive agent such as PGE_1 can be useful as a diagnostic and a potential therapeutic modality. This procedure can reveal whether the patient will respond to this therapeutic modality and can facilitate patient education about the procedure and its potential side effects. Failure to respond to intracavernosal injection can raise the suspicion of vascular insufficiency or a venous leak that might need further evaluation and treatment.

Most men with ED do not need duplex color sonography, cavernosography, or pelvic angiography.[5,6,394,395,407] For instance, angiography could be useful in a young man with arterial insufficiency associated with pelvic trauma. Similarly, suspicion of congenital or traumatic venous leak in a young man presenting with ED would justify a cavernosography. In each instance, confirmation of the vascular lesion might lead to consideration of surgery. Duplex ultrasonography can provide a noninvasive evaluation of vascular function.[407]

TABLE 20.6 General Evaluation of Women Presenting With Sexual Dysfunction

Item	Comments
General health and past medical history[a]	
Medications[a]	Current and past medications
Aspects of chronic disease relevant to sexual life	Pain, fatigue, continence, self-image, mobility
Mood[a]	Depression, depressive symptoms, current and past
Relationship[a]	Type(s), satisfaction
Past sexual experiences	Positive, negative, coercive, abusive
Partner's sexual function[a]	
Previous therapy	Details and compliance
Motivation to address problems	Willingness to prioritize addressing sexual life now

Nocturnal penile tumescence testing is rarely needed for patients being evaluated for ED and is recommended only for a limited number of patients with a high clinical suspicion of psychogenic ED or situational problems, to document preoperatively poor penile rigidity, or for medical-legal reasons. Although recording of nocturnal penile tumescence in a sleep laboratory for successive nights can help to differentiate organic from psychogenic impotence, this test is expensive and labor intensive. The introduction of portable RigiScan (GOTOP Medical, St. Paul, MN) devices in 1985 has provided clinicians with a reliable means of continuously monitoring penile tumescence and rigidity at home.[408] It is a multicomponent device that the patient wears at bedtime for two to three nights. It has two wire gauge loops that are placed around the base and tip of the penis that record changes in penile circumference and rigidity. Data are stored and downloaded via a software program that allows for interpretation. For most cases, a careful history of nighttime or early morning erections provides a reasonable correlation with nocturnal penile tumescence and RigiScan studies.[408]

Evaluation of Women With Sexual Dysfunction

Sexual dysfunction is diagnosed by clinical interview and, when necessary, physical examination. After obtaining details of general and mental health, the sexual complaints are clarified (Table 20.6 and Fig. 20.9).

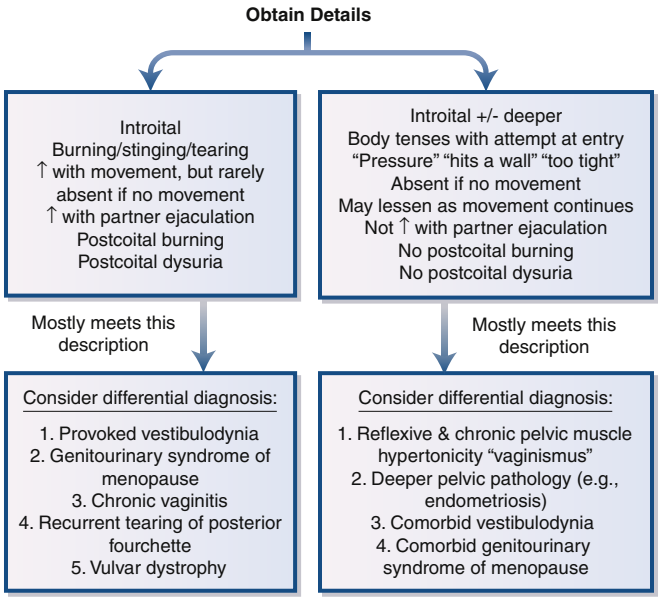
Sexual function questionnaires can be used to monitor treatment response but should not be used for establishing a diagnosis of sexual dysfunction in women.[409–411] One such instrument is the FSFI,[409,410] which was designed to monitor treatment response and not to diagnose sexual dysfunction in women who have not been clinically assessed. Moreover, the FSFI is based on the DSM-IV criteria of sexual disorders, which are grounded in the conceptualization of female sexual response beginning with conscious desire leading to a phase of arousal, then orgasm, and then resolution—these phases being in set order, discrete, and necessary for normal function. The limitations of the FSFI include the lack of recognition of triggered desire and the normality of beginning an experience that is sexually neutral; the possibility of sexual satisfaction without orgasm; a focus on partnered sex, which limits its use in women, who currently do not have a sexual partner;[410] and the limited period of assessment (the last 4 weeks), which may increase the risk of erroneous results during transient periods of stress or the partner's absence.[412] Although the FSFI has been used in many studies of women's sexual function, including those of women with endocrine disease, more contemporary instruments, such as the 17-question Natsal-SF, developed for the Natsal-3,[411] better reflect the importance of sexual satisfaction in contrast to many previous instruments. This attribute of the Natsal-SF instrument is particularly important, because patients may report satisfaction despite dysfunction, and dissatisfaction can occur in the context of a functional response[413]: women's satisfaction may or may not include orgasms.[246] A recent study confirms strong links between sexual satisfaction and sexual motivation.[414]

Physical Examination

Physical examination, including pelvic and genital examination, is part of routine care and can be reassuring to the patient by confirming normal anatomy and overall health. Unless dyspareunia is involved, it is not often that physical examination identifies the cause of sexual dysfunction. For some women with a history of coercive or abusive sexual experience, or previous traumatic medical experience, such examination may cause extreme anxiety and, unless sex is painful, may not be necessary. The reason for an examination—usually the presence of dyspareunia or loss of genital sexual sensitivity—and an explanation of what will and will not be done should be provided before the examination begins (Table 20.7 and Fig. 20.10, Parts 1 & 2 Assessment of GPPPD algorithm). If the woman prefers to invite her partner to be present, then a careful examination can be highly educational for both partners. In women with GPPPD with a marked component of vaginismus, the vaginal examination should be delayed until psychological therapy renders the examination possible and informative for both the patient (and partner if present) and the clinician.

TABLE 20.7 Evaluation of Genitopelvic Penetration Disorder—Part (2): the Detailed Genital Examination

Diagnoses (May Be Multiple)	Findings on Examination
Anatomic variations	Congenital (e.g., hypoplasia), past surgery or genital mutilation
Provoked vestibulodynia	No visual abnormalities on examination; Q-tip test to confirm allodynia of introital edge
Reflexive and chronic hypertonic pelvic muscles "vaginismus"	Palpation of pelvic muscles and their insertion into ischial spines confirms high tone, inability to do reverse Kegel maneuver
Genitourinary syndrome of menopause	Pallor, dryness, thinning, loss of turgor and elasticity and rugae, possible stenosis
Chronic vaginitis	Erythema, discharge, confirm by culture
Recurrent tearing of posterior fourchette	Taut fourchette, white line scars of past tears
Vulvar dystrophy (e.g., lichen sclerosus)	Abnormal mucosa typical of dystrophy
Deep pelvic pathology (e.g., endometriosis), bladder pathology	Tenderness, nodules in cul-de-sac, tender adnexae, pain with cervical movement or with bladder or uterine compression



• **Fig. 20.10** Evaluation of genitopelvic penetration disorder—part (1): the detailed history.

Laboratory Testing

The laboratory testing plays a small role in women's sexual evaluation. Estrogen activity is best evaluated by history and examination. The commercially available estradiol radioimmunoassays lack the sensitivity and precision required to measure the low concentrations present in the older woman; in addition, these assays do not measure estrone, the major estrogen after menopause. As discussed earlier, serum testosterone levels do not correlate with sexual function, even when LC-MS/MS assays are used.[66,67] The circulating testosterone levels may not reflect intracrine production, metabolism, or activity of androgens. Measurement of testosterone metabolites has been proposed as a marker of intracrine plus gonadal production of testosterone,[68] but the circulating levels of these metabolites have been shown to be similar in women with and without sexual dysfunction.[67,71,72] The clinical usefulness of androgen metabolites remains to be demonstrated. Currently available evidence does not support the usefulness of measuring serum testosterone concentrations in women with low sexual desire.[415] Fasting glucose, hemoglobin A_{1c}, prolactin, and thyrotropin should be measured if clinically indicated by the general health evaluation.

Management of Sexual Dysfunction in Men

Treatment of Hypoactive Sexual Desire in Men

There is a need to focus on the couple when the patient has a sexual partner. Treating the sexual dysfunction in the male partner improves the female partner's sexual function and satisfaction. Comorbid depression should be treated and relationship difficulties addressed. The efficacy of cognitive and behavioral therapies has not been evaluated systematically in men with HSDD. Testosterone therapy should be considered in men with HSDD who have androgen deficiency, even though there are no randomized trials of testosterone in men with HSDD.

Much of the information about the effects of testosterone on sexual desire has emerged from open-label trials of testosterone in hypogonadal men and a small number of randomized placebo-controlled trials of testosterone in hypogonadal men.[65,131,141,142,416–420] Most testosterone trials recruited men based on the presence of low testosterone levels alone, whereas a small number of recent trials required men to have low testosterone levels and one or more symptoms of testosterone deficiency.[131,141,142,146,416–420] Testosterone therapy in these trials has been associated with significant improvements in overall sexual activity, sexual desire, attention to erotic cues, and the duration and frequency of nocturnal penile erections.[65,131,416–419]

The Testosterone Trials were a set of several coordinated placebo-controlled trials, funded primarily by the National Institute on Aging, to determine the efficacy of testosterone in improving sexual function, physical function, and vitality in community-dwelling older men, 65 years or older, with low libido, mobility limitation, and/or fatigue, and an unequivocally low fasting early morning total testosterone level.[141] The eligible participants were required to have an average of two morning total testosterone levels less than 275 ng/dL measured using a CDC-certified LC-MS/MS assay.[421] Low libido was defined as the Derogatis Interview for Sexual Functioning for Men sexual desire domain score of less than 20. The eligible participants were assigned using the procedure of minimization to receive either 1% transdermal testosterone gel or placebo gel daily for 1 year. The testosterone dose was adjusted to achieve and maintain on-treatment testosterone levels between 400 and 800 ng/dL. The primary outcome was overall sexual activity. Assignment to the testosterone arm was associated with greater improvements in overall sexual activity, sexual desire, and erectile function than placebo.[141,142] Testosterone treatment improved most categories of sexual activity. The overall improvements in sexual desire and erectile function were modest but were

deemed clinically meaningful.[422] A carefully performed meta-analysis of randomized testosterone trials in hypogonadal men, who met the Endocrine Society's definition of testosterone deficiency, confirmed that compared with placebo administration, testosterone treatment is associated with greater improvements in sexual activity, sexual desire, erectile function, and satisfaction with sexual experience.[423]

Several points should be considered when initiating testosterone replacement therapy. First, testosterone treatment has been shown to improve some but not all domains of sexual function; testosterone improves sexual desire and erections but has not been shown to improve ejaculatory disorder. Second, testosterone treatment has been shown to be efficacious in improving sexual function only in men with unequivocally low testosterone levels and low sexual desire; it has not been shown to improve sexual function in men who have normal or low-normal testosterone levels. Third, there is enormous variability in on-treatment testosterone levels, especially with transdermal testosterone gels; a substantial fraction of hypogonadal men started on the initial dose of a transdermal testosterone gel will not raise their on-treatment levels into the target therapeutic range, and 5% to 10% may have supraphysiologic levels due to substantial variations in transdermal absorption and plasma clearance of testosterone. Unsurprisingly, nearly half of testosterone-treated men discontinue testosterone treatment after 3 months, and only about 25% are still on testosterone treatment after 12 months. Fourth, some men with HSDD may have relationship problems, which are not likely to be corrected by testosterone therapy. Finally, the long-term safety and efficacy of testosterone therapy has not been established.

Treatment of Erectile Dysfunction

The current practice employs a stepwise approach that first utilizes minimally invasive therapies that are easy to use and have fewer adverse effects and progresses to more invasive therapies that may require injections or surgical intervention after the first-line choices have been exhausted (Fig. 20.11). The physician should discuss the risks, benefits, and alternatives of all therapies with the couple. The selection of the therapeutic modality should be based on the underlying cause, patient preference, the nature and strength of the relationship with his sexual partner, and the absence or presence of underlying CVD and other comorbid conditions.[5,6,394,395] All patients with ED can benefit from psychosexual counseling.[5,6,394,395,424–428]

In the execution of good medical practice, treatment of all associated medical disorders should be optimized. In men with diabetes mellitus, glycemic control should be optimized, although improving glycemic control may not improve sexual function. In men with hypertension, control of blood pressure should be optimized and, if possible, the therapeutic regimen may be modified to remove antihypertensive drugs that impair sexual function. This strategy is not always feasible because almost all antihypertensive agents have been associated with sexual dysfunction; the frequency of this adverse event is less with converting-enzyme inhibitors and angiotensin-receptor blockers than with other agents.

First-Line Therapies

Psychosexual Counseling

The goals of psychosexual therapy are to reduce performance anxiety, develop the patient's sexual skills and knowledge, modify negative sexual attitudes, and improve communication between partners.[424] Counseling can be beneficial in both psychogenic and organic causes of sexual dysfunction[424–430] (Table 20.8).

An individual's focus on sexual performance rather than erotic stimulation is a major factor in the pathophysiology of psychogenic ED[424,425]; this behavior is referred to as *spectatoring*. Many experts recommend a *sensate focus* treatment approach, in which the couple avoids intercourse and engages in nongenital, nondemanding, pleasure-seeking exercises to reduce performance anxiety.[424]

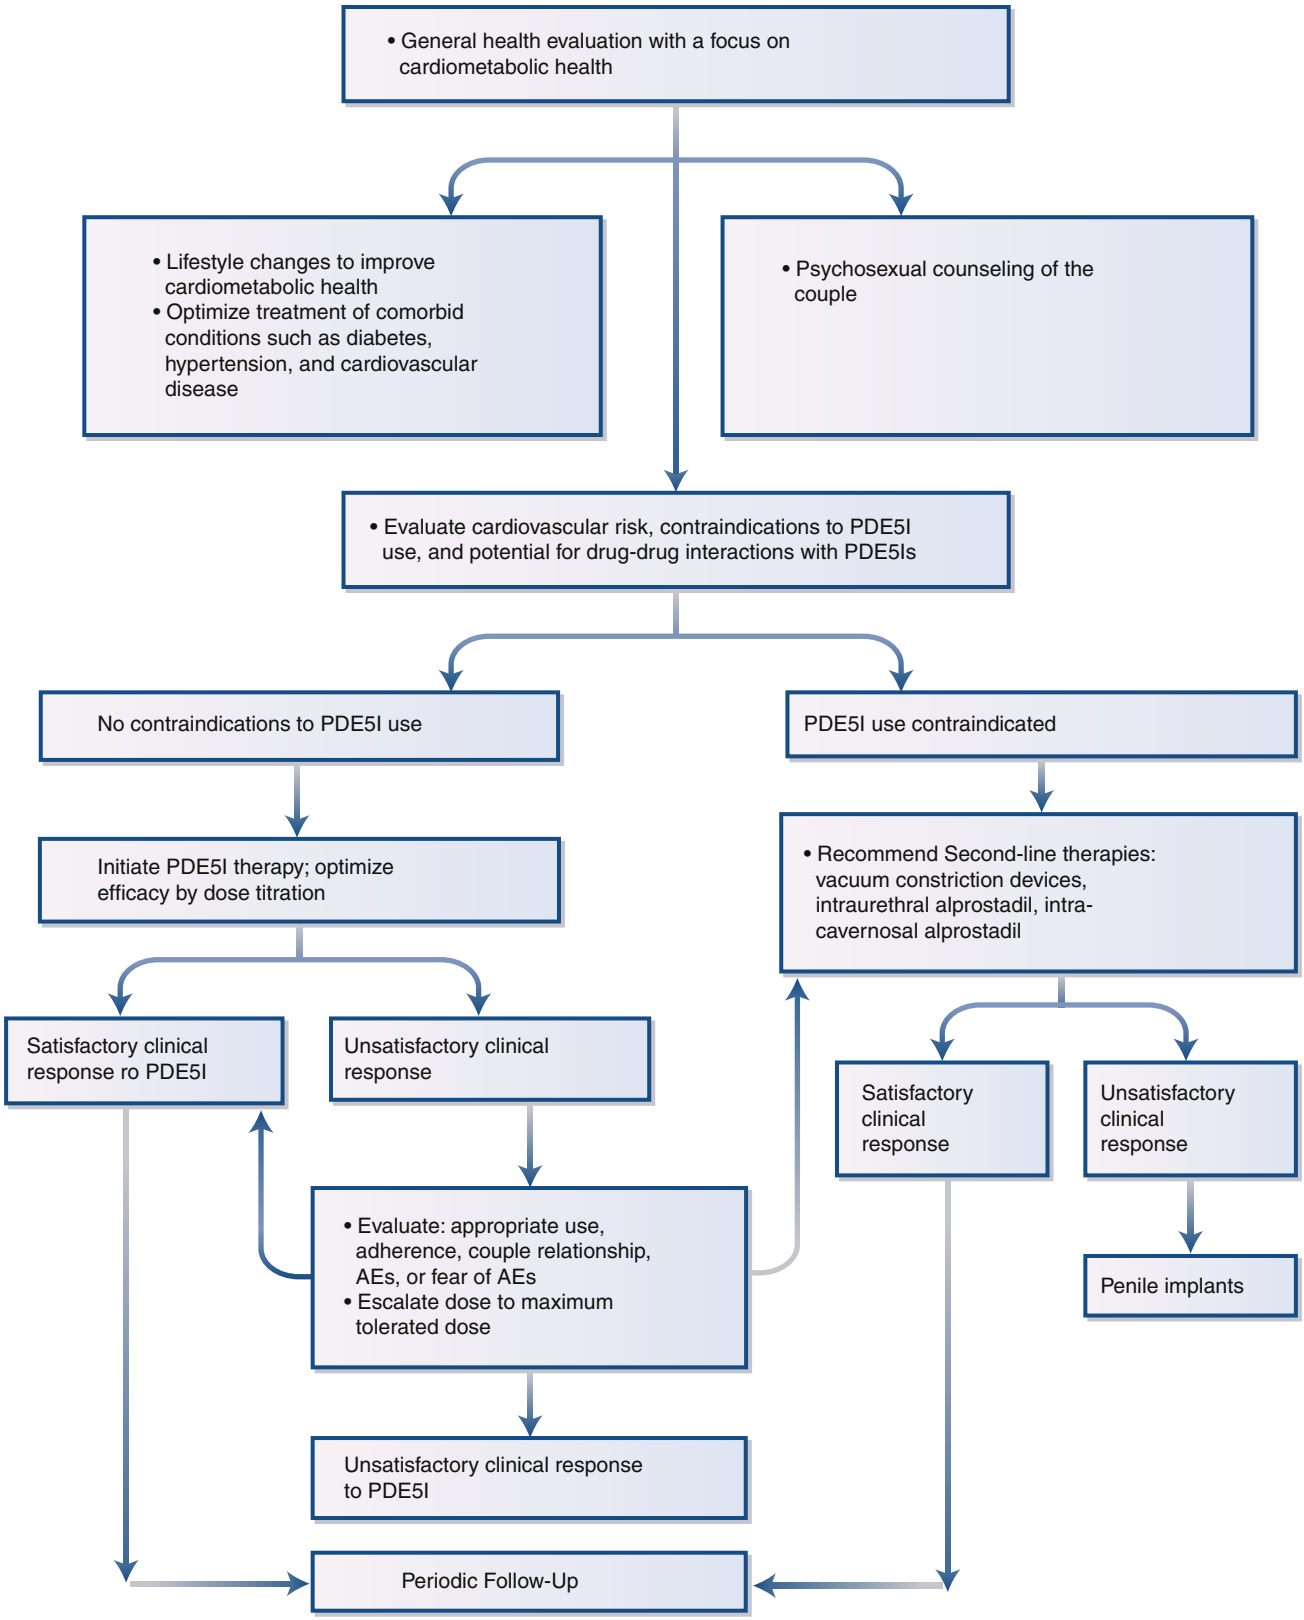
Involving the partner in the counseling process helps to dispel misperceptions about the problem, decreases stress, enhances intimacy and the ability to talk about sex, and increases the chances of successful outcome.[424] Counseling sessions are also helpful in uncovering conflicts in relationships, psychiatric problems, alcohol and drug abuse, and sometimes significant misperceptions about sex. As many men and women may harbor misinformation and unrealistic expectations about sexual performance and age-related changes in sexual function, cognitive restructuring techniques are helpful in correcting sexual myths and beliefs.[424] There is a paucity of outcome data on the effectiveness of this psychobehavioral therapy, but meta-analyses have reported benefit from group psychotherapy administered in conjunction with PDE5 inhibitors.[427]

Selective Phosphodiesterase 5 Inhibitors

Selective PDE5 inhibitors are safe and effective and have become widely accepted as first-line therapy for patients with ED, except in men for whom these drugs are contraindicated[4-6,106,108,394,395,430–432] (Tables 20.9 and 20.10). Selective PDE5 inhibitors are contraindicated in men using nitrates on a regular basis, in those with severe heart disease in whom sexual activity may not be safe, and in those with nonarteritic anterior ischemic optic neuropathy.[5,6,106,108,394,395,431,432]

Mechanisms of Action. Four classes of enzymes—NOS, adenylyl cyclase, guanylyl cyclase, and PDEs—play important roles in regulating the intracavernosal concentrations of cAMP and cGMP. Three isoforms of NOS catalyze the formation of nitric oxide from arginine using NADPH and oxygen as substrates: neuronal NOS (nNOS or NOS1), inducible NOS (iNOS or NOS2), and endothelial NOS (eNOS or NOS3). Nitric oxide activates soluble guanylyl cyclase to stimulate the production of cGMP from GTP, which then activates cGMP-dependent protein kinases to induce myosin phosphatase, inositol 1,4,5-trisphosphate receptor 1–associated protein, and some cation channels resulting in smooth muscle relaxation. PDEs hydrolyze cGMP, thus reducing its concentrations within the cavernosal smooth muscle.[107,108,111–113,433–436] Although PDE isoforms 2, 3, 4, and 5 are expressed in the penis, only PDE5 is specific to the nitric oxide–cGMP pathway in the corpora cavernosa.[436] PDE inhibitors sildenafil, vardenafil, tadalafil, avanafil, and udenafil are relatively selective inhibitors of PDE5.[107,108,111–113,433–459] These drugs block the hydrolysis of cGMP, thus promoting cavernosal smooth muscle relaxation. The action of these drugs requires an intact nitric oxide response, as well as constitutive synthesis of cGMP by the smooth muscle cells of the corpora cavernosa. By selectively inhibiting cGMP catabolism in the cavernosal smooth muscle cells, PDE5 inhibitors restore the natural erectile response to sexual stimulation but do not produce an erection in the absence of sexual stimulation.

Clinical Pharmacology. Although the four currently available PDE inhibitors have some structural similarities, they differ in their selectivity and pharmacokinetics (see Table 20.9). The



• **Fig. 20.11** An algorithmic approach to the treatment of men with erectile dysfunction. *AE,* adverse event; *PDE5I,* phosphodiesterase 5 inhibitor.

TABLE 20.8 Goals of Psychosexual Therapy in Men With Sexual Dysfunction

- Reduce performance anxiety; train the couple to avoid "spectatoring" and be "sensate focused"
- Identify relationship problems and improve partner communication and intimacy
- Modify sexual attitudes and beliefs
- Improve couple's sexual skills

Data from from Rosen RC. Psychogenic erectile dysfunction: classification and management. *Urol Clin North Am.* 2001;28(2):269–278.

common adverse effects of the available PDE5 inhibitors—headache, visual problems, flush, and myalgias—are related to nonselective inhibition of PDE isoforms 6 and 11 in other organ systems[108] (see Table 20.9). The selectivity of a PDE5 inhibitor is the ratio of its inhibitory potency for PDE isoforms other than type 5 relative to its inhibitory potency for PDE isoform 5.[108] For PDE6, tadalafil is the most selective and sildenafil is the least selective; for PDE11, vardenafil is the most selective and tadalafil is the least selective.[108] The retinal side effects of sildenafil are related to inhibition of PDE6 in the retina, whereas muscle aches experienced by a small fraction of men using tadalafil are related to inhibition of PDE11 in the skeletal muscle.[108]

Pharmacokinetics. After oral administration of sildenafil, peak plasma concentrations are achieved within 30 to 120 minutes, after which plasma concentrations decline, with a half-life of 4 hours[107,433–442] (see Table 20.9). Vardenafil achieves peak concentrations within 0.7 to 0.9 hour and has a half-life of 4 to 5 hours. The peak concentrations of tadalafil are achieved at 2 hours, and its half-life of 16.9 hours in young men is significantly longer than the half-lives of sildenafil and vardenafil. The half-life of tadalafil is even longer in older men (21.6 hours) than in young men (16.9 hours).[107,433–436] Because of the relatively short half-lives of vardenafil and sildenafil, these drugs should be taken 1 to 4 hours before the planned intercourse; in contrast, tadalafil, because of its longer half-life, does not have to be taken on demand, although it can be.[107,433–436] The second-generation PDE5 inhibitors avanafil and udenafil have a more rapid onset of action than the first-generation PDE5 inhibitors sildenafil, vardenafil, and tadalafil.[437–440]

Food, particularly a high-fat meal and large amounts of alcohol, can delay and decrease the absorption of sildenafil.[441,442] However, early pharmacokinetic studies have not reported changes in maximum serum concentrations or absorption rates of vardenafil or tadalafil due to food or moderate alcohol ingestion.[436]

Efficacy. Orally active, selective PDE5 inhibitors—sildenafil, vardenafil, avanafil, udenafil, and tadalafil—have been shown to be effective and safe in randomized clinical trials of men with ED.[4–6,439–465] In men treated with oral, selective PDE5 inhibitors, the rates of successful intercourse vary from 50% to 65%, and rates of improved erections vary from 70% to 75%.[439–455] Selective PDE5 inhibitors are effective in men of all ethnic groups and ages[439–465] who have ED due to a multitude of causes, although response rates vary in different patient subgroups.[439–465]

Introduced to the U.S. market in March 1998, sildenafil citrate (Viagra; Pfizer, New York, NY) was the first effective oral agent for the treatment of ED.[466] The efficacy of sildenafil has been demonstrated in men with organic, psychogenic, or mixed ED in multiple RCTs[443–450,466] and confirmed by meta-analyses of randomized trials.[446–448] In these trials, patients receiving sildenafil experienced greater increments in the number of successful attempts per month, penile rigidity, frequency of vaginal penetration, and maintenance of erection than those receiving placebo.[446–448] Increasing doses of sildenafil were associated with higher mean scores for the frequency of penetration and maintenance of erections after sexual penetration. The mean scores for orgasms, intercourse satisfaction, and overall satisfaction were also significantly higher in the sildenafil group than in the placebo group.[446–448] Sildenafil also is an effective treatment for ED in men with diabetes mellitus.[449,450] A meta-analysis of randomized clinical trials of sildenafil confirmed its efficacy in improving erectile function in men with diabetes mellitus.[450]

In the vardenafil efficacy trials, 5-, 10-, and 20-mg doses of vardenafil were all superior to placebo in improving erectile function domain scores; the improvements in erectile function scores were dose related.[451–457] Vardenafil improved rates of vaginal penetration, penile rigidity, intercourse success, and satisfaction with sexual experience in men with ED from diverse causes.[451–457]

Similarly, in randomized clinical trials, 2.5-, 5-, 10-, and 20-mg doses of tadalafil were each superior to placebo in improving erectile function scores.[458–462] The beneficial effects of tadalafil were dose related.[458–462]

Two new PDE5 inhibitors have been introduced recently in clinical practice. Avanafil has a very rapid onset of action because of its rapid absorption, which allows it to reach maximum circulating concentration in about 30 to 45 minutes.[437–439] Therefore, a majority of patients taking avanafil are able to engage in sexual activity within 15 minutes.[437–439] Udenafil also has a relatively rapid onset of action, with a time to maximum serum concentrations of 1.0 to 1.5 hours. It has been approved in Korea, Russia, and the Philippines, but not in the United States.[440]

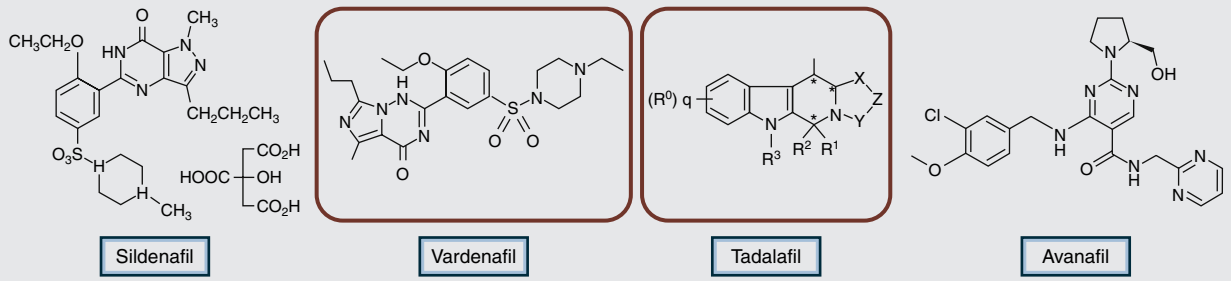
PDE5 inhibitors are effective in men with ED due to a variety of causes, including spinal cord injury and radical prostatectomy.[449,450] In general, baseline sexual function correlates positively with response to PDE5 inhibitors, and patients with diabetes mellitus or previous prostate surgery respond less well than patients with psychogenic or vasculogenic ED.[449,450] Because there is no baseline characteristic that predicts the likelihood of failure to respond to sildenafil therapy, a therapeutic trial of PDE5 inhibitors should be tried in all patients, except in those in whom it is contraindicated.[432]

Adverse Effects. In clinical trials, the adverse effects that have been reported with greater frequency in men treated with PDE5 inhibitors than in those treated with placebo include headaches, flushing, rhinitis, dyspepsia, muscle aches, and visual disturbances[108,432,463–465] (Table 20.11). The occurrence of headache, flushing, and rhinitis, a direct consequence of nonselective PDE5 inhibition in other organ systems, is related to the administered dose. These drugs do not affect semen characteristics.[467,468] No cases of priapism were noted in the pivotal clinical trials.

Several cases of nonarteritic anterior ischemic optic neuropathy have been reported after oral PDE5 inhibitor use.[469,470] This condition is characterized by the sudden onset of monocular visual loss due to acute ischemia of the anterior portion of the optic nerve in the absence of demonstrable arteritis. This may progress to partial or complete infarction of the optic nerve head, resulting in permanent visual loss or visual field cuts.[469,470] Although a cause-and-effect relationship with PDE5 inhibitor use has not been established, patients with history of sudden visual loss should not be treated with PDE5 inhibitors without ophthalmologic evaluation.

TABLE 20.9 Clinical Pharmacology of Selective PDE5 Inhibitors[a]

Feature	Sildenafil	Vardenafil	Tadalafil	Avanafil
Commercial name	Viagra	Levitra	Cialis	Stendra, Spedra
T_{max}	0.5–2.0 h	0.7–0.9 h	2 h	30–45 min
T½	3–4 h	4–5 h	16.9 h (young) 21.6 h (old)	5 h
Onset of erection (min)	30–60	15–45	20–30 min	15 min
Muscle selectivity (ratio of PDE6 IC_{50}/PDE5 IC_{50})	11 (most selective)	25	187 (least selective)	>100-fold
Retinal selectivity (ratio of PDE11/PDE5 IC_{50}), higher number indicates greater PDE5 selectivity	780	1160 (most selective)	5 (least selective)	>10,000-fold
Effect of food and alcohol	C_{max} decreased	Minimal change	No change	Absorption delayed
Protein binding	96%	94%	94%	98–99%
Bioavailability	41%	Not available	15%	Not available



[a]Comparative pharmacokinetic data are provided on the four oral selective PDE5 inhibitors that have been approved by the U.S. Food and Drug Administration. Additional PDE5 inhibitors such as udenafil and mirodenafil have been approved for use in some other countries. Selectivity refers to the ratio of the IC_{50} for a PDE isoform other than PDE5 to the IC_{50} for PDE5. A higher number implies greater selectivity. Sildenafil is more selective than tadalafil for PDE5 relative to PDE11, but it is less selective than tadalafil for PDE6 relative to PDE5.

C_{max}, Maximum plasma concentration; *IC_{50}*, 50% inhibitory concentration; *PDE*, phosphodiesterase; *T ½*, half-life; *T_{max}*, time to peak concentration.

Data from Haning H, Niewohner U, Bischoff E. Phosphodiesterase type 5 (PDE5) inhibitors. *Prog Med Chem.* 2003; 41:249–306; Bischoff E. Potency, selectivity, and consequences of nonselectivity of PDE inhibition. *Int J Impot Res.* 2004;16(Suppl 1):S11–S14; and Saenz de Tejada I, Angulo J, Cuevas P, et al. The phosphodiesterase inhibitory selectivity and the in vitro and in vivo potency of the new PDE5 inhibitor vardenafil. *Int J Impot Res.* 2001;13:282–290.

The U.S. Food and Drug Administration (FDA) has noted several reports of sudden hearing loss with and without vestibular symptoms, such as tinnitus, vertigo, or dizziness, in temporal relationship to administration of sildenafil, vardenafil, and tadalafil in postmarketing surveillance. Hearing loss was also reported in a few patients in clinical trials of these drugs.[471,472] Hearing loss has been noted in patients using sildenafil for the treatment of pulmonary arterial hypertension. Although a causal relationship has not been established, the temporal relationship between the use of PDE5 inhibitors and the onset of sudden hearing loss prompted the FDA to recommend changes in the product labeling for the drug class. A few observational studies have reported an association of PDE5 inhibitor use with an increased risk of melanoma and basal cell carcinoma; however, due to the lack of association between melanoma risk and the number of prescriptions filled, a causal relation has not been established.[473–475]

Cardiovascular and Hemodynamic Effects. In postmarketing surveillance of adverse events associated with sildenafil use, several instances of myocardial infarction and sudden death were reported in men using sildenafil in temporal relation to the ingestion of the drug[476]; many of these deaths occurred in individuals who also were taking nitrates. Because most men presenting with ED also have high prevalence of cardiovascular risk factors, it is unclear whether these events were causally related to the ingestion of sildenafil, underlying heart disease, or both.[476] In controlled studies,[477–480] oral administration of 100 mg of sildenafil to men with severe coronary artery disease produced only a small decrease in systemic blood pressure and no significant changes in cardiac output, heart rate, coronary blood flow, and coronary artery diameter. In a separate pooled analysis of five randomized, placebo-controlled trials of vardenafil,[479] the overall frequency of cardiovascular events was similar in both vardenafil- and placebo-treated men. However, vardenafil treatment was associated with a mild reduction in blood pressure (4.6 mm Hg decrease in systolic blood pressure) and a small increase in heart rate (two beats per minute).[480] This led the American Heart Association and other experts to conclude that preexistent coronary artery disease by itself does not constitute a contraindication for the use of PDE5 inhibitors[459,480–485] (Table 20.12).

Drug-Drug Interactions. Sildenafil is metabolized mostly by the CYP2C9 and the CYP3A4 pathways. Cimetidine and erythromycin, inhibitors of CYP3A4, increase the plasma concentrations of sildenafil. HIV protease inhibitors may also alter the activity of the CYP3A4 pathway and affect the clearance of sildenafil.[486] Conversely, sildenafil is an inhibitor of the CYP2C9 metabolic pathway, and its administration could potentially affect

TABLE 20.10 Guidelines for Optimizing the Use of Selective PDE5 Inhibitors

1. Men with ED are at increased risk for cardiometabolic disorders. Baseline evaluation should include general health evaluation, as well as screening for diabetes and cardiovascular risk. Patients should be counseled for lifestyle modification to improve overall health and reducing cardiometabolic risk.
2. All men with ED can benefit from psychosexual counseling.
3. PDE5 inhibitors are the first-line therapy for ED. The men who are prescribed PDE5 inhibitors should be counseled on their appropriate use guided by their clinical pharmacology.
4. Due to the substantial variation in metabolism of PDE5 inhibitors among men, the dose should be titrated to the maximum tolerated dose to maximize efficacy while avoiding dose-related adverse effects.
5. The metabolism of PDE5 inhibitors may be affected by drug-drug interactions with other drugs and foods that affect the CYP3A4 pathway. These interactions should be considered in dose selection.
6. PDE5 inhibitors may augment the vasodilator effects of nitrates. Therefore, PDE5 inhibitors should not be used in men taking daily doses of nitrates.
7. PDE5 inhibitors may produce hypotension when taken together with other vasodilator drugs, such as α-adrenergic blockers or antihypertensive medications. These interactions should be considered when prescribing PDE5 inhibitors in men who are using α-adrenergic blockers or other vasodilators.
8. In human immunodeficiency virus–infected men, consider potential drug-drug interactions between selective PDE5 inhibitors and antiretroviral drugs and antimicrobial agents.
9. Some men who do not respond to an on-demand PDE5 inhibitor may respond to the use of daily tadalafil, which is a U.S. Food and Drug Administration–approved regimen.

ED, Erectile dysfunction; *PDE5,* phosphodiesterase 5.

Data from Burnett AL, Nehra A, Breau RH, et al. Erectile dysfunction: AUA guideline. *J Urol.* 2018;200(3):633–641.

TABLE 20.11 Adverse Effects of Selective Phosphodiesterase Inhibitors

Common Adverse Effects

1. Headache
2. Flushing
3. Dyspepsia
4. Nasal congestion
5. Dizziness, lightheadedness
6. Back pain[a]
7. Myalgia[a]

Uncommon Adverse Effects

1. Abnormal vision[a]
2. Hearing loss
3. Nonarteritic anterior optic neuropathy

[a]These adverse effects are related to nonselective inhibition of phosphodiesterase isoforms in other tissues. Headache, flushing, and nasal congestion are related to the drug's mechanism of vasodilator action.

Data from Wespes E, Rammal A, Garbar C. Sildenafil no-responders: hemodynamic and morphometric studies. *Eur Urol.* 2005;48:136–139; Brock GB, McMahon CG, Chen KK, et al. Efficacy and safety of tadalafil for the treatment of erectile dysfunction: results of integrated analyses. *J Urol.* 2002;168:1332–1336; Morales A, Gingell C, Collins M, et al. Clinical safety of oral sildenafil citrate (Viagra) in the treatment of erectile dysfunction. *Int J Impot Res.* 1998;10:69–73; Katz EG, Tan RB, Rittenberg D, Hellstrom WJ. Avanafil for erectile dysfunction in elderly and younger adults: differential pharmacology and clinical utility. *Ther Clin Risk Manag.* 2014;10:701–711.

the metabolism of drugs metabolized by this system, such as warfarin and tolbutamide. Combined administration of sildenafil and ritonavir results in significantly higher plasma levels of sildenafil than sildenafil given alone.[486] There are similar interactions with other drugs, including saquinavir and itraconazole. Therefore, the doses of PDE5 inhibitors should be reduced appropriately in men taking protease inhibitors or erythromycin.

Grapefruit juice can alter oral drug pharmacokinetics by different mechanisms. Grapefruit juice given in normal amounts (e.g., 200–300 mL) or as whole fresh fruit segments can irreversibly inactivate intestinal CYP3A4, thus reducing presystemic metabolism and increasing oral bioavailability of PDE5 inhibitors.[487] Although the magnitude of this problem in clinical practice is unknown, it seems prudent to warn men who are contemplating the use of PDE5 inhibitors not to ingest more than a small amount of grapefruit juice.

The most serious interactions of PDE5 inhibitors are with the nitrates. The vasodilator effects of nitrates are augmented by PDE5 inhibitors; this also applies to inhaled forms of nitrates such as amyl nitrate or nitrites that are sold under the street name "poppers." Concomitant administration of the two vasodilator drugs can cause a potentially fatal decrease in blood pressure.[216–218]

PDE inhibitors should be used carefully in men taking α-adrenergic blockers. In men with congestive heart failure or those receiving vasodilator drugs, or those who are using complex regimens of antihypertensive drugs, blood pressure should be monitored after initial administration of PDE5 inhibitors.[216–218] Several trials have demonstrated the safety of administering PDE5 inhibitors in combination with α-adrenergic blockers in men with ED and LUTS.[216–218]

Therapeutic Regimens.[488] Men with ED are at increased risk for cardiometabolic disorders (see Table 20.10). Baseline evaluation should include general health evaluation and screening for diabetes and cardiovascular risk. Patients should be counseled for lifestyle modification to improve overall health and reducing cardiometabolic risk. All men with ED can benefit from psychosexual counseling. PDE5 inhibitors are the first-line therapy for ED. The men who are prescribed PDE5 inhibitors should be counseled on their appropriate use guided by their clinical pharmacology. Due to the substantial variation in metabolism of PDE5 inhibitors among men, the dose should be titrated to the maximum tolerated dose to maximize efficacy while avoiding dose-related adverse effects.

In most men with ED, sildenafil is started at an initial dose of 50 mg. If this dose is not effective yet does not produce any adverse effects, the dose should be titrated up to 100 mg or the maximum tolerated dose.[106,431,432,489,490] The dose adjustment should be guided by the therapeutic response to therapy and occurrence of adverse effects. Vardenafil should be started at an initial dose of 10 mg; the dose should either be increased to 20 mg or the maximal tolerated dose or decreased[490] to 5 mg depending on the clinical response and the occurrence of adverse effects. Tadalafil is started at an initial dose of 10 mg, with further adjustment of dose based on effectiveness and side effects. Tadalafil need not be taken more frequently than once every 48 hours. Avanafil should be started at an initial dose of 50 or 100 mg with further adjustment up to 200 mg. In men taking protease inhibitors (particularly ritonavir and indinavir), erythromycin, ketoconazole, itraconazole, or large amounts of grapefruit juice, the doses of PDE5 inhibitors should be reduced.

TABLE 20.12 Guidelines for the Use of Selective Phosphodiesterase Inhibitors in Men With Cardiovascular Disease

1. Do not administer selective PDE5 inhibitors to men taking long- or short-acting nitrate drugs on a regular basis.
2. If the patient has stable coronary artery disease, is not taking long-acting nitrates, and uses short-acting nitrates only infrequently, the use of selective PDE5 inhibitor should be guided by consideration of risks.
3. Do not administer selective PDE5 inhibitors within 24 hours of the ingestion of any form of nitrate.
4. Advise men about the risks of the potential interaction between selective PDE5 inhibitors and nitrates, nitrate donors, and α-adrenergic blockers. Concurrent use of nitrates, nitrate donors, or α-adrenergic blockers could result in hypotension that could be serious.
5. In men with preexisting coronary artery disease, assess the risk of inducing cardiac ischemia during sexual activity before prescribing PDE5 inhibitors. This assessment may include a stress test.
6. In men who are taking vasodilators and diuretics for the treatment of hypertension or congestive heart failure, consider the potential risk of inducing hypotension because of potential interaction between PDE5 inhibitors and vasodilators, especially in patients with low blood volume.

PDE5, Phosphodiesterase isoform 5.

Data from Cheitlin MD, Hutter AM Jr, Brindis RG, et al. Use of sildenafil (Viagra) in patients with cardiovascular disease: Technology and Practice Executive Committee [published erratum appears in *Circulation.* 1999;100(23):2389]. *Circulation.* 1999;99(1):168-177; Lue TF, Giuliano F, Montorsi F, et al. Summary of recommendations on sexual dysfunctions in men. *J Sex Med.* 2004;1:6-23.

Sildenafil and vardenafil are taken at least 1 to 2 hours before sexual intercourse and not more than once in any 24-hour period; because of its longer half-life, tadalafil need not be taken immediately before intercourse. Avanafil is taken 30 minutes before sexual intercourse.

Based on the results of the randomized clinical trials,[468,491,492] the FDA has approved 2.5 or 5 mg of tadalafil once daily for the treatment of ED. In the pivotal trials, men using 2.5 or 5 mg of tadalafil once daily experienced greater improvements in erectile function compared with those taking a placebo.[468,491,492] Subsequent open-label extension studies indicated that once-daily 5-mg tadalafil for up to 2 years was effective in maintaining improvements in erectile function.[468,491,492] The adverse events associated with once-daily administration of tadalafil included headaches, indigestion, back pain, muscle aches, nasal congestion, and flushing and were similar to those observed with on-demand tadalafil ingestion.[468,491,492] Once-daily regimen of tadalafil had no significant effect on semen or reproductive hormone levels.[468]

Use of PDE5 Inhibitors in Men With Coronary Artery Disease.[485] Excellent therapeutic guidelines have been published on this topic by expert panels from several societies.[106,431,432,481,490] To minimize the risk of hypotension and adverse cardiovascular events during the use of PDE5 inhibitors, the American Heart Association/American College of Cardiology has published a list of recommendations (see Table 20.12), which should be followed rigorously.[481]

Before prescribing PDE5 inhibitors, cardiovascular risk factors should be assessed. If the patient has hypertension or symptomatic coronary artery disease, the treatment of those clinical disorders should be addressed first.[485] The use of nitrates must be ascertained, because PDE5 inhibitors are contraindicated in individuals taking any form of nitrates regularly. PDE5 inhibitors should not be used within 24 hours of the use of nitrates or nitrate donors.[5,6,484,485]

Sexual activity can induce coronary ischemia in men with preexisting coronary artery disease[482]; therefore, men contemplating use of ED therapies should undergo assessment of their exercise tolerance. One practical way to assess exercise tolerance is to have the patient climb one or two flights of stairs. If the patient can safely climb one or two flights of stairs without angina or excessive shortness of breath, he can likely engage in sexual intercourse with a stable partner without inducing similar symptoms. Exercise testing may be indicated in some men with significant heart disease to assess the risk of inducing cardiac ischemia during sexual activity.[481–483] Selective PDE5 inhibitors have been shown not to impair the ability of patients with stable coronary artery disease to engage in exercise at levels equivalent to that attained during sexual intercourse.[481–483] Similarly, each of the three PDE5 inhibitors has been shown not to have significant adverse effects on hemodynamics and cardiac events in carefully selected men with ED who did not have any contraindication for the use of PDE5 inhibitors.[459,479–485] None of the PDE5 inhibitors adversely affects total exercise time or time to ischemia during exercise testing in men with stable angina.[459,479–485] In one recent analysis, treatment with PDE5 inhibitors for ED after a first myocardial infarction was associated with a reduced mortality and hospitalization for heart failure.[493] Another cohort study also reported reduced rates of myocardial infarction or other CVD events during the first 3 years after initiation of treatment with a PDE5 inhibitor for ED.[494]

Treatment of Patients Who Do Not Respond to PDE5 Inhibitors. Although oral PDE5 inhibitor therapy has revolutionized the management of ED, not all men respond to this treatment. The cumulative probability of intercourse success with sildenafil citrate increases with the number of attempts, reaching a maximum after eight attempts.[495] Based largely on these data,[495] the failure to respond to PDE inhibitor therapy has been defined as the failure to achieve satisfactory response even after eight attempts of either the highest approved dose (e.g., 100–mg sildenafil) or the highest tolerable dose of PDE5 inhibitor, whichever is lower. Many factors may contribute to apparent treatment failure, including failure to take the medication as recommended, suboptimal dose, dose-limiting adverse effects, absence of sexual stimulation, psychological issues, partner and relationship issues, incorrect diagnosis, and patient-specific pathophysiologic factors.[495–497] In clinical trials of PDE5 inhibitors, treatment failures were reported predominantly in men who had diabetes mellitus, non–nerve-sparing radical prostatectomy, cavernosal nerve damage, venous leak, and high disease severity.[495–497] In an evaluation of cavernosal smooth muscle biopsies in sildenafil nonresponders, Wespes and coworkers[497] found severe vascular lesions, as well as cavernosal smooth muscle atrophy and fibrosis, to be the underlying pathologic processes.

Patients may not take the medication appropriately because of inadequate instructions, failure to understand the instructions, adverse effects, or fear of adverse effects.[495–497] Oral PDE5 inhibitors are taken optimally 1 to 2 hours before planned intercourse. The medication is unlikely to be effective if it is taken immediately before intercourse; a high-fat meal and large amounts of alcohol may further affect the maximal serum concentrations of sildenafil citrate. Similarly, patients may not take the appropriate dose because of side effects or fear of side effects. The men who have been misdiagnosed as having ED and whose primary sexual

disorder is unresponsive to PDE5 inhibitors may be incorrectly deemed treatment failures. For instance, men with HSDD, Peyronie disease, or orgasmic or ejaculatory disorder would not be expected to respond to PDE5 inhibitors. The anxiety associated with resumption of sexual activity and unresolved relationship and partner issues can attenuate response to treatment. The sexual partner may not be willing or able to engage in sexual activity because of relationship issues, sexual disorder, or real or perceived health issues. Because erotic stimulation is necessary for local production of nitric oxide, which then stimulates the production of cGMP, PDE5 inhibitors do not induce spontaneous erections and may not be effective in inducing erections in the absence of sexual stimulation.

Patients who report lack of satisfactory response to initial administration of PDE5 inhibitors should be asked about the time of drug administration, the dose taken, and adverse effects experienced. Psychological and partner issues should be evaluated. The dose of PDE5 inhibitor should be increased gradually as tolerated. Some men who do not optimally respond to on-demand PDE5 inhibitors may respond to daily low-dose tadalafil (2.5 or 5 mg), which is an FDA-approved regimen.[498–500] Should the patient not respond to maximal tolerable doses of PDE5 inhibitors, the PDE5 inhibitors can be combined with vacuum devices or intraurethral therapy. Second-line therapies, such as intracavernosal injections, should be pursued. The men who are unresponsive to oral PDE5 inhibitors and second-line therapies may find penile implant an acceptable alternative.[495]

Cost-Effectiveness of Phosphodiesterase 5 Inhibitor Use for Erectile Disorder. Several studies have evaluated the economic cost of treating ED in men in managed care health plans.[501–505] One simulation estimated sildenafil citrate cost to be approximately $11,000 per quality-adjusted life year.[503] This amount is less than that for many other accepted treatments for medical disorders that cost $50,000 to $100,000 per quality-adjusted life year; thus, the cost-effectiveness of PDE5 inhibitor therapy compares favorably with other accepted medical therapies. Other analyses have concluded that PDE5 inhibitors and vacuum constriction devices are the most cost effective of all available therapeutic options.[501–505] Several recent analyses have shown that the financial burden imposed by patients with ED on managed care plans is surprisingly small.[501–505] In one such cost-utility analysis, the monthly cost of providing ED-related treatment services in a health plan with 100,000 members amounted to less than $0.10 per member.[503] Thus, the failure of many insurance companies to cover the cost of PDE5 inhibitor therapy is not informed by cost-utility analyses.

Second-Line Therapies

Vacuum Devices for Inducing Erection

The vacuum devices typically consist of an acrylic cylinder, a vacuum pump, and an elastic constriction band.[506–508] The cylinder fits over the penis and is connected to a vacuum pump. The negative pressure created by the vacuum within the cylinder draws blood into the penis, producing an erection. An elastic band slipped around the base of the penis traps the blood in the penis, maintaining an erection as long as the rubber band is retained. The constriction band should not be left in place for more than 30 minutes. In addition, only vacuum devices with a pressure-limiting mechanism should be recommended to prevent injury due to high vacuum.

Limited data on the efficacy of vacuum devices from open-label trials indicate that these devices are safe, relatively inexpensive, and moderately effective.[506–508] They can impair ejaculation, resulting in entrapment of semen. Some couples dislike the lack of spontaneity engendered by the use of these devices. Partner cooperation is important for successful use of these devices.[508]

Intraurethral Therapies

An intraurethral system for delivery of alprostadil called *MUSE* (medicated urethral system for erection; VIVUS, Menlo Park, CA) was released in 1997. Alprostadil is a stable, synthetic form of PGE_1, which stimulates generation of cAMP and activation of protein kinase A. Activated protein kinase A stimulates K^+ channels, resulting in K^+ efflux from the cell. In addition, protein kinase A–mediated processes result in a net decrease in intracellular calcium, favoring smooth muscle cell relaxation.

Alprostadil, when applied into the urethra, is absorbed through the urethral mucosa into the corpus cavernosum. In comparison to intracavernosal injection of PGE_1, intraurethral alprostadil is easier to administer and has a lower frequency of adverse effects, particularly penile fibrosis.

Alprostadil is available in 125-, 250-, 500-, and 1000-µg strengths. Typically, the initial alprostadil dose of 250 or 500 µg is applied in the clinician's office to observe changes in blood pressure or urethral bleeding secondary to misapplication of the device into the urethra.

Initial randomized, placebo-controlled studies reported 40% to 60% success rates, defined as having at least one successful sexual intercourse during a 3-month study period.[509–511] In clinical practice, only about a third of men using intraurethral alprostadil will respond.[512]

Common side effects of intraurethral alprostadil are penile pain and urethral burning in up to 30% of patients[509–512]; its use also may cause dizziness, hypotension, and syncope in some users. Intraurethral alprostadil can cause mild burning or itching in the vagina of the sexual partner. Intraurethral alprostadil should not be used by men whose partners are pregnant or planning to get pregnant.

Intracavernosal Injection of Vasoactive Agents

The use of intracavernosal injections of vasoactive agents has been a cornerstone of the medical management of ED since the early 1980s (Table 20.13). Patients can be taught to inject a vasoactive agent into their corpora cavernosa using a 27- or 30-gauge needle prior to the planned intercourse. Erections occur typically 15 minutes after intracorporal injection and last 45 to 90 minutes. Although intracavernosal injection therapy is highly effective,[513–520] it is associated with higher complication rates than oral therapy and should be used only by practitioners who are experienced in the use of this therapy and who can provide emergency medical support to their patients in the event of a serious adverse event, such as priapism.

Although several different agents—PGE_1, papaverine, and phentolamine—have been used alone or in combination,[513–521] only intracavernosal PGE_1 has been approved for clinical use. The long-term data on the efficacy and safety of intracavernosal therapy are sparse.

Several formulations of alprostadil (PGE_1) are commercially available (Caverject, Pharmacia, Stockholm, Sweden; Prostin VR, Pharmacia; Edex, Schwarz Pharma, Milwaukee, WI). PGE_1 binds to PGE_1 receptors on the cavernosal smooth muscle cells, stimulates adenylyl cyclase, increases the concentrations of cAMP, and is a powerful smooth muscle relaxant. The usual dose is 5 to 20 µg, and response to therapy is dose related and should be titrated.[513–519]

In one placebo-controlled efficacy trial, the intracavernosal alprostadil injection resulted in satisfactory sexual performance

TABLE 20.13 Guidelines for Intracavernosal Therapy

1. Do not prescribe intracavernosal therapy to men who have psychiatric disorders, hypercoagulable states, or sickle cell disease; those who are receiving anticoagulant therapy; or those who are unable to comprehend the risks or take appropriate action should complications occur.
2. Designate a physician or a urologist to be available to handle emergencies related to complications of intracavernosal injections, such as prolonged erection and priapism.
3. Instruct the patient in the injection technique, the risks of intracavernosal therapy, and the steps to be taken in the event of prolonged erection or priapism.
4. Administer the first injection in the office and observe the blood pressure and heart rate response. This provides an excellent opportunity for educating the patient, observing adverse effects, and determining whether the patient will respond to intracavernosal therapy.
5. Start with a low dose of alprostadil, and titrate the dose based on the erectile response and the duration of erection. Adjust the dose of alprostadil to achieve an erection that is sufficient for sexual intercourse but that does not last more than 30 minutes.
6. If the erection does not abate in 30 minutes, the patient should be instructed to take a tablet of pseudoephedrine or terbutaline, or an intracavernosal injection of phenylephrine. If this is not effective, the patient should call the designated physician or the urologist, and go to the emergency room.

after more than 90% of administrations, and approximately 85% of men and their partners reported satisfactory sexual activity.[513] Intracavernosal alprostadil is more effective than intraurethral alprostadil.[517]

The common adverse effects of intracavernosal therapy include penile pain, hematoma, formation of corporal nodules, penile fibrosis, and prolonged erections.[513–520] Despite the effectiveness of this approach in producing rigid erections, many patients do not relish injecting a needle into their penis; therefore, it is not surprising that long-term dropout rates are high. Intracavernosal injections should not be used in patients with sickle cell disease, multiple myeloma or leukemia, hypercoagulable disorder, anatomic deformation of the penis, or penile implants.

Intracavernosal injections of papaverine, phentolamine, forskolin, and VIP have also been used, although these agents are not approved by the FDA.[521] Papaverine, derived originally from the poppy seed, is a nonspecific PDE inhibitor, which increases both intracellular cAMP and cGMP. It has a greater propensity to induce priapism and fibrosis with long-term use, and efficacy and long-term safety data from randomized, placebo-controlled trials are lacking. Therefore, there is insufficient information to evaluate its efficacy and safety.

Phentolamine is a competitive α_1- and α_2-adrenergic antagonist that contributes to smooth muscle relaxation. As a single agent it is minimally efficacious, but it has been used to potentiate the effects of papaverine, VIP, and PGE_1.[521] Randomized clinical trial data on its efficacy and safety are lacking. Therefore, there is insufficient information to evaluate its efficacy and safety.

Various combination of these drugs are available as "bi-mix" or tri-mix" depending on the number of drugs included in the formulation. Tri-mix, a combination of papaverine, phentolamine, and PGE_1, obtained from compounding pharmacies, is often used in urologic practices even though it is not an FDA-approved drug.

Priapism is a serious concern with the use of intracavernosal injection therapy. In patients who develop a prolonged or painful erection with PGE_1, either 5 mg of brethane or 60 mg of pseudoephedrine, administered orally, may be of benefit. If priapism persists longer than 4 hours, patients should be instructed to seek medical care in which aspiration alone or with the injection of an α-adrenergic agent is used to induce detumescence. If this fails, surgical therapy may be needed to reverse a prolonged erection; otherwise, anoxic damage to the cavernosal smooth muscle cells and fibrosis can occur.

Third-Line Therapies

Penile Prosthesis

The penile prostheses are invasive and costly, but they can be an effective method for restoring erectile function for patients with advanced organic disease who are unresponsive to other medical therapies, have significant structural disorders of the penis (e.g., Peyronie disease), or have suffered corporal loss from cancer or traumatic injury.[522–524]

Penile implants are paired supports that are placed in each of the two erectile bodies. There are two basic types of penile implants: (1) hydraulic (fluid filled), referred to as inflatable prostheses, and (2) malleable, semirigid rods, which are bendable but always remain firm in the penis.[522–524] Penile prostheses come in a variety of lengths and girths. Implantation surgery usually takes less than an hour and in most cases can be done as an outpatient procedure under general or regional anesthesia.

Infection, perforation of the corpora during device placement, extrusion or migration of the device, and mechanical malfunction are the most common problems with penile prostheses. With recent improvements in materials and design, the chance of mechanical malfunction has decreased to 5% to 10% in the first 10 years.[522–524] Infection occurs in 1% to 3% of cases, but infection rates can be higher in revision surgery, especially in men with diabetes mellitus.

The total cost of penile prosthesis implantation varies from $3,000 to $20,000, depending on the type of device used and the community in which the procedure is performed. There are no randomized efficacy trials, but retrospective analyses have reported that greater than 80% of patients and 70% of partners are pleased with their prosthesis.[522–525]

Testosterone Replacement in Androgen-Deficient Men Presenting With Erectile Dysfunction

Randomized trials have shown that testosterone replacement therapy improves erectile function, sexual desire, overall sexual activity, and satisfaction with intercourse in hypogonadal men who have low sexual desire; meta-analyses of randomized trials have confirmed these findings. Testosterone treatment does not improve sexual function in men with ED who have normal testosterone levels.[27,65,143,144,160] It is not known whether testosterone replacement improves sexual function in men with ED and borderline serum testosterone levels. Not all men with ED and low testosterone levels will experience improvements in their libido and overall sexual activity with testosterone replacement therapy;[27,65,143,144] the response to testosterone therapy even in this group of men is variable because of the coexistence of other disorders, such as diabetes mellitus, hypertension, CVD, and psychogenic factors.[27,143,144,160]

ED in middle-age and older men is a multifactorial disorder, often associated with other comorbid conditions such as diabetes mellitus, hypertension, CVD, medications, peripheral vascular disease, psychogenic factors, and chronic kidney disease.

Therefore, it is not surprising that testosterone treatment alone may not improve sexual function in all men with androgen deficiency. Testosterone induces NOS activity,[137,138] has trophic effects on cavernosal smooth muscle and ischiocavernosus and bulbospongiosus muscles,[139] increases penile blood flow,[163] and is essential for achieving venous occlusion.[136] These observations have led to speculation that testosterone might improve response to PDE5 inhibitors; however, as discussed earlier, data from randomized trials have not shown the superiority of testosterone over placebo in improving erectile function in men with ED who have low testosterone levels and in whom the PDE5 inhibitor dose has been optimized.[166] However, it is possible that in men with ED who have testosterone deficiency, correcting testosterone deficiency first by testosterone replacement therapy may augment subsequent response to PDE5 inhibitors. In addition, testosterone replacement therapy in hypogonadal men with ED may improve libido and overall satisfaction with sexual experience, and may have other beneficial effects in correcting anemia, as well as improving bone mineral density and bone strength.

Therapies With Either Unproven Efficacy or Limited Efficacy Data

There are insufficient efficacy data to support the use of trazodone[526] or yohimbine[527] in men with ED. The literature on the effectiveness of herbal therapies is difficult to interpret because of lack of consistency in product formulations and potencies, contamination of herbal products with PDE5 inhibitors, poor trial design, and paucity of randomized clinical trial data.[528–532] One randomized trial of Korean red ginseng reported this product to be effective in the treatment of ED[529]; these data need further confirmation. Icariin is a flavonoid, derived from several species of plants, whose extracts have been known in herbal medicine to produce aphrodisiac effects and enhance erectile function.[532] Dipyridamole also inhibits PDE5 and can augment the effects of nitric oxide. 4-Methylpiperazine and pyrazolopyrimidine, components of the lichen *Xanthoparmelia scabrosa*, have also been claimed to inhibit PDE5.[531] The use of these or other herbal therapies is not recommended.[531] Apomorphine also functions as a dopamine agonist and acts centrally to initiate erection; its main adverse effects are nausea and dizziness.

Gene Therapy and Erectile Dysfunction

The goal of gene therapy for ED is to introduce novel genetic material into the cavernosal smooth muscle cells to restore normal cellular function and produce a therapeutic effect.[533–535] Gene therapy has been proposed as a treatment option for diseases that have a vascular origin, such as arteriosclerosis, congestive heart failure, and pulmonary hypertension.[533–535] ED may be particularly amenable to gene therapy because of the easily accessible external location of the penis,[533–535] which permits direct injection into the corpora cavernosa. A tourniquet placed around the base of the penis limits entry of the injected material into the systemic circulation. This is a distinct advantage of the gene therapy of penile diseases over gene therapy for other systemic diseases, because introduction of the genetic material into the systemic circulation can potentially induce adverse systemic effects due to insertion of the material into an incorrect organ or vascular bed. Additionally, in the penis, only a small number of cells need to be transfected, because the interconnection of smooth muscle cells in the corpus cavernosum by gap junctions allows second messenger molecules and ions to be transferred to other interconnected smooth muscle cells.[533–535] The low turnover rate of the vascular smooth muscle cells of the penis allows the desired gene to be expressed for long periods of time.

The strategies of gene therapy for ED treatment have focused on the molecules that regulate corporal smooth muscle relaxation or neovascularization[533–535] (Table 20.14). Several candidate genes have been explored, including the maxi-K^+ channel, penile-inducible NOS, eNOS, VIP, CGRP, vascular endothelial growth factor (VEGF), the brain neurotrophic factor angiopoietin 1, neurturin (a member of the glial cell line–derived neurotrophic factor family), superoxide dismutase, IGF1, PKG1α, and Rho A/Rho kinase[533–543] (see Table 20.14). Several vectors have been used to transfer exogenous genes, including adenoviruses, adeno-associated viruses, retroviruses, sindbis viruses, replication-deficient retroviruses, liposomes, naked DNA, and gold nanoparticles.[533–549]

Garban and associates[536] first demonstrated that gene therapy can be performed in the penis by utilizing naked complementary DNA (cDNA) encoding the penile-inducible *NOS* gene leading to physiologic benefit in the aging rat. Christ and colleagues[537] injected hSlo cDNA (which encodes the human smooth muscle maxi-K^+ channel) into the rat corpora cavernosa and demonstrated increased gap junction formation and enhanced erectile responses to nerve stimulation in the aged rat. Adenoviral constructs encoding the eNOS and CGRP cDNAs were shown to reverse age-related ED in rats.[538,539] In these studies, both eNOS and CGRP expression were sustained for at least 1 month in the corpora cavernosa of the rat penis. Five days after transfection with the AdCMVeNOS or AdRSVeNOS viruses, aged rats had significant increases in erectile function as determined by response to cavernosal nerve stimulation and pharmacologic injection of endothelium-dependent vasodilator acetylcholine and PDE5 inhibitors.[538,539] In one study, intracavernosal injection of adeno-associated virus construct carrying the brain-derived neurotrophic factor gene improved erectile function after cavernosal nerve injury.[543] This neurotrophic factor purportedly restored neuronal NOS in the major pelvic ganglion, thus enhancing the recovery of erectile function after bilateral cavernous nerve injury.[543] In other studies, intracavernosal VEGF injection and adeno-associated virus-mediated VEGF gene therapy were each shown to reverse venogenic ED in rats.[540,541] These other preclinical studies using gene therapy targets such as CGRP, superoxide dismutase, and Rho A/Rho kinase provided proof of concept that in vivo gene transfer can be accomplished technically. The translation of these preclinical data into human trials has been slow and unsuccessful so far.

Ion Channel Innovations Inc. has completed a phase I trial of slow K^+ channel gene therapy in men with ED.[99,545,546] In this trial, hMaxi-K, a "naked" DNA plasmid carrying the human cDNA encoding for the gene for the α-subunit of the human smooth muscle maxi-K^+ channel, was injected directly into the penises of 11 men with ED. Patients who received the highest dose of hMaxi-K experienced significant improvements in their erectile function that was sustained for the 24-week duration of the trial. This trial demonstrated the feasibility and safety of injecting naked DNA into the human penis.[545,546] A trial of hMaxi-K in patients with overactive bladders is ongoing. Phase I gene therapy trials using VEGF and hepatocyte growth factor have been conducted in patients with peripheral vascular disease and chronic limb ischemia; these trials have reported low frequencies of serious adverse effects. However, phase II studies have not confirmed

TABLE 20.14 Physiologic Targets for Gene Therapy

Gene Target	Vector and Mechanism	Reference
Nitric oxide isoforms	Increase eNOS, nNOS, and iNOS activity in the cavernosal smooth muscle	Champion 1999; Bivalacqua 2000, 2003, 2005; Gonzalez-Cadavid 2004; Kendirci 2005; Wessels 2006
PIN	Antisense and short hairpin RNA constructs targeting PIN	Magee et al., 2007
Maxi-K^+ channel	Transfer of maxi-K^+ channels using a plasmid vector that carries the *hSlo* gene encoding the α-subunit of the maxi-K^+ channel; first human trial demonstrated the safety and feasibility of gene therapy in humans	Christ et al., 2002, 2004, 2004; Melman 2003, 2005, 2006, 2007, 2008; So et al., 2007
PKG1α	Replication-deficient recombinant adenoviruses carrying PKG1α	Bivalacqua et al., 2007
VEGF	Transfer of VEGF cDNA into rat corpora cavernosa to promote neovascularization	Rogers et al., 2003; Buchardt et al., 2005; Dall'Era et al., 2008
Angiopoietin 1	Adenovirus-mediated transfer of human angiopoietin 1	Ryu et al., 2006; Jin et al., 2010
BDNF	Transfer of BDNF using adeno-associated virus	Rogers et al., 2005; Gholani et al., 2003
Neurotrophin 3 gene	Transfer of neurotrophin 3 gene using HSV vector	Bennett et al., 2005
Neurturin	Neurturin, a member of glial cell line–derived neurotrophic factor family	Kato et al., 2009
VIP	Transfection of corpora cavernosa of streptozotocin-treated diabetic rats using pcDNA3 carrying VIP cDNA	Shen et al., 2005
CGRP	Adenoviral transfer of CGRP in aged rats	Bivalacqua et al., 2001; Deng 2004
Superoxide dismutase	Adenoviral-mediated gene transfer of extracellular superoxide dismutase injected into the corpora cavernosa	Bivalacqua 2003; Brown 2006; Lund 2007
IGF1	Adenoviral-mediated gene transfer of IGF1	Pu et al., 2007

BDNF, Brain-derived neurotrophic factor; *cDNA,* complementary DNA; *CGRP,* calcitonin gene–related peptide; *HSV,* human syncytial virus; *IGF1,* insulin-like growth factor 1; *NOS,* nitric oxide synthase (epithelial [e], inducible [i], or neuronal [n] isoforms); *PIN,* protein inhibitor of NOS; *PKG,* protein kinase G; *VEGF,* vascular endothelial growth factor; *VIP,* vasoactive intestinal protein.

Data from Melman A, Davies K. Gene therapy for erectile dysfunction: what is the future? *Curr Urol Rep.* 2010;11(6):421–426; Harraz A, Shindel AW, Lue TF. Emerging gene and stem cell therapies for the treatment of erectile dysfunction. *Nat Rev Urol.* 2010;7(3):143–152; Strong TD, Gebska MA, Burnett AL, et al. Gene and stem cell therapy for erectile dysfunction. *Int J Impot Res.* 2005;17(Suppl 1):57–63.

efficacy. Thus, the early therapeutic promise of gene therapy has yet to be realized. Successful gene therapy may require introduction of multiple gene products using vectors with higher efficiency of transfection of a larger number of target cells and more prolonged action than can be realized with the current generation of vectors. Additional concerns about long-term safety, sustained gene expression, and efficiency of gene delivery and expression remain to be fully addressed.

Potential of Stem Cell Therapy for Erectile Dysfunction

The past decade has seen considerable interest in the transplantation of stem cells derived from bone marrow, adipose tissue, or skeletal muscle into the corpora cavernosa.[550–558] However, even when injected within the corpora cavernosa, the stem cells escape rapidly from the penis and hone into the bone marrow.[550–558] The mechanism of the reported improvements in intracavernosal pressure after stem cell injection into the corpora cavernosa remains unclear.[553] The safety and efficacy of stem cell therapy in humans has yet to be demonstrated. It remains to be demonstrated whether transplanted human mesenchymal stem cells (hMSCs) can differentiate into functional cavernosal smooth muscle cells and restore erectile capacity in men with ED. In addition, long-term outcomes including the tumorigenic potential of these transplanted progenitor cells are unknown.

hMSCs may also be attractive gene delivery vehicles because these cells can replicate in vitro as well as in vivo, thus potentially providing a large pool of cells.[554,555] Initial studies have demonstrated that rat mesenchymal stem cells, expanded and transfected ex vivo and implanted into the corpora cavernosa, are capable of expressing the gene product of interest.[550–555] Stem cell therapy using stem cells carrying angiogenic or neurotrophic genes or proteins is also being explored. Although several animal studies have reported improved erectile function with hMSC transplantation, few studies have shown evidence of long-term stem cell survival in the cavernosal smooth muscle or evidence of differentiation of the transplanted stem cells into endothelial cells or cavernosal smooth muscle cells.[550–558]

Management of Retrograde Ejaculation

Case reports have claimed benefit from methoxamine, imipramine, midodrine, and ephedrine; however, randomized clinical trial data are lacking.[559–561] Induction of fertility in men with retrograde ejaculation may require retrieval of sperm from the urinary bladder after sexual stimulation or electrostimulation of the prostatic nerve plexus per rectum plus assisted reproductive techniques, such as intrauterine insemination or in vitro fertilization with or without intracytoplasmic sperm injection using the retrieved sperm.[562–565]

Management of Sexual Dysfunction in Women

Psychotherapeutic methods are the mainstay of management of female sexual dysfunction (Fig. 20.12). A systematic review of literature on the psychogenic aspects of sexual dysfunction by the 2016 International Consultation on Sexual Medicine committees found strong literature support for the routine investigation of personal, interpersonal, and contextual factors in women.[566] This type of assessment facilitates treatments such as cognitive behavioral therapy (CBT), mindfulness-based cognitive therapy (MBCT), and sex therapy approaches.

Management of Low Desire and Arousal in Women

In the management of SIAD, the circular model of sexual response (see Fig. 20.1) can serve as a useful basis for discussing which areas are problematic with one, or preferably both, partners (Table 20.15; see Fig. 20.1. When insufficient emotional intimacy is identified, the normality of low interest to be sexual can be clarified, and referral for couple counseling may be indicated. When the lack of sexual context and stimuli are contributing factors, simply emphasizing the requirement of appropriate environment and sufficiently erotic stimuli is usually sufficient, but referral to a sex therapist may be appropriate. Nonsexual distractions, fears about sexual outcome, self-monitoring of sexual response, anxiety, low self-image, and depression can interrupt the mental appraisal of stimuli. These issues can be explained and addressed. The main modalities of treatment for SIAD are cognitive therapy, sex therapy, and psychoeducation (see Table 20.15).

Psychoeducation

Psychoeducation includes providing information while simultaneously soliciting the woman's thoughts and feelings, which are then addressed and processed. It also includes dispelling widespread myths about sexuality in women (e.g., the absence of desire preceding sexual activity denotes sexual dysfunction). Bibliotherapy with self-help reading material or videos can be helpful. For some women, information on anatomy and physiology is necessary.

Cognitive Behavioral Therapy

CBT can assist the woman to recognize, challenge, and, in time, change her negative and often catastrophic self-view imposed by underlying illness, endocrine problems, or infertility. Some of the exaggerated or catastrophic thoughts amenable to cognitive therapy include "sex is only for healthy women," "I am no longer fertile, so I am no longer sexually attractive," and "if intercourse is painful, then no one will want me." Identifying these biased/maladaptive thoughts is the first step: CBT then attempts to practice changing such thoughts. A growing body of data has provided empiric support for the benefit of targeting cognitions and emotions during sex to increase physical and subjective arousal.[39,567–570]

Mindfulness-Based Cognitive Therapy

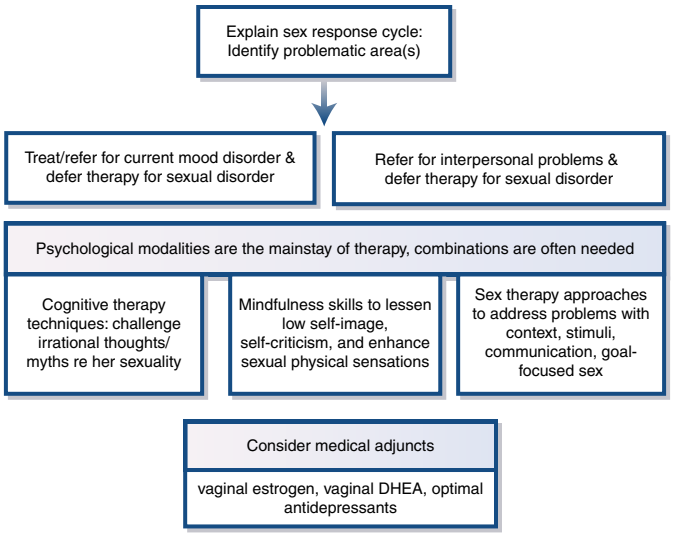
Mindfulness has been shown to be of benefit for women with sexual dysfunction,[568,569,571] who are medically healthy, women with pelvic cancer,[570] and in those with PVD.[571] Mindfulness is an Eastern practice of meditation and relatively new to Western medicine: the learned skill is to be fully present and accepting of all that is sensed in that moment. Attention is enhanced by the gradual ability to identify thoughts arising in that moment, be they future- or past oriented, and not to engage in them but ultimately view these negative or positive thoughts more distantly, as if they are just sensations not dissimilar to physical sensations. The practice of mindfulness focuses the attention on and acceptance of sexual sensations rather than on self-monitoring. Functional brain imaging performed before and after mindfulness training supports the clinical finding that such training lessens self-referencing of sensations and emotions, including pain and anxiety.[573–575] Resources for mindfulness practice in the community and through the internet can be offered.

Recently, an adapted form of CBT blended with mindfulness was defined—the treatment is called *mindfulness-based cognitive therapy*, or MBCT. Regular mindfulness practice is an integral component of MBCT. As with CBT, the skill of detecting maladaptive thoughts, including those that are critical or evaluative, is learned but with simple observation of their presence and an acknowledgment that they are just mental events, not necessarily the truth; there is no focus here to change thoughts. MBCT has been used to treat anxiety disorders and depression and has been adapted to treat arousal and desire disorders and chronic pain of PVD.[568,569,572,576]

Detailed treatment manuals for CBT and MBCT for clinicians with separate versions for patients have been developed; these manuals provide sufficiently detailed information for non–mental health professionals and non–sexual medicine specialists to provide CBT and MBCT to small groups of women. This small group format is consistently rated as beneficial.[577]

Sex Therapy

Sex therapy usually focuses on sensate focus exercises whereby each partner takes turns giving and receiving sensual and, later on, sexual touches, caresses, and kisses. Initially, genital areas and breasts are off-limits. The idea of any goal or expectation



• **Fig. 20.12** Algorithmic approach to the management of female sexual dysfunction. Sexual dysfunction in women is strongly linked to mental health. Therefore, evaluation of mental health and relationship issues is an important component of the evaluation of women with sexual dysfunction. Psychological therapies are the mainstay of treatment of women's sexual disorders with growing evidence of benefit from mindfulness-based cognitive therapy. Topical estrogens or vaginal dehydroepiandrosterone (DHEA) may be useful in a subset of women with menopausal urogenital symptoms.

TABLE 20.15 Management of Sexual Interest and Arousal Disorder in Women

Problematic Phase of SRC	Details of Phase Problem	Management Options
Sexual context problematic	Interpersonal	Explain usual need for emotional closeness +/– counseling referral
	Environmental	Explain usual need for privacy, personal preferences regarding surroundings
Sexual stimuli insufficient	Nonphysical, physical nongenital, genital nonpenetrative	Give information, ↑ sexual communication, consider sex therapy or referral
	Deterrents (e.g., partner's hygiene, alcohol use)	Information, consider couple counseling referral
Processing of stimuli problematic	Depression/dysthymia	Refer to mental health
	Fatigue-chronic illness, poor sleep	Non–goal-oriented sex, address sleep
	Too late in day	Explanation
	Chronic pain	Time pain meds, +MBCT for pain Rx
	Medications: opioids, SSRIs, SNRIs	Consider vortioxetine, bupropion, mirtazapine, vilazodone
↓ Genital sensations	Sensations muted or fleeting	Mindfulness (e.g., body scan)
	Onset with menopause	Vaginal DHEA, vaginal estrogen
↓ Mental sexual arousal	Physical arousal too similar to feelings of anxiety	MBCT, mental health referral
	Distractions, "busy mind"	Mindfulness practice

DHEA, Dehydroepiandrosterone; *MBCT,* mindfulness-based cognitive therapy; *SNRIs,* serotonin and norepinephrine reuptake inhibitors; *SSRIs,* selective serotonin reuptake inhibitors; *SRC,* sexual response cycle.

is put aside. Together, the couple and the clinician decide as to when breasts and genital areas are to be included. Ultimately, the act of intercourse (or vaginal penetration with a dildo) may be included—but not as the focus.

Outcome of Psychological Treatments for Women's Sexual Dysfunctions

Data are limited regarding the long-term effects of psychological treatments for women's sexual dysfunction. Systematic review and meta-analysis of controlled clinical trials for female and male sexual dysfunction published before 2009[578] concluded that psychosocial interventions for sexual dysfunction were efficacious. A more recent meta-analysis of the 11 reported trials of MBCT for women's sexual dysfunction concluded that all aspects of sexual function and subjective sexual well-being exhibited significant improvement during mindfulness-based therapy, with moderate effect sizes.[579]

For women with sexual dysfunction associated with the hormonal changes arising from breast cancer treatment, a systematic review suggests that the most effective interventions are couple-based psychoeducational interventions that include an element of sex therapy.[580] The American Society of Clinical Oncology 2018 guideline recommends psychosexual counseling along with addressing estrogen deficiency–related dyspareunia.[581]

Management of Women's Orgasmic Disorder

Management is guided by the details of the difficulties reaching a high level of arousal and being free to let the orgasm occur (Table 20.16).

Although CBT and mindfulness training have been used in clinical practice to treat women with orgasmic disorder, outcome research is sparse. A 2013 meta-analysis found evidence of benefit with CBT and mindfulness training in symptom severity and sexual satisfaction for women with orgasmic dysfunction.[578] To date, there is no pharmacologic treatment for orgasmic disorder. In one trial with highly selective inclusion criteria, sildenafil was reported to improve orgasm dysfunction associated with SSRI use.[582] In a small trial, transdermal testosterone did not improve sexual function compared with placebo as measured by the Sabbatsberg Sexual Self-Rating Scale as the primary outcome.[583] The strategies to treat antidepressant-associated orgasmic disorder include the use of medications that are less likely to impair sexual function, such as vortioxetine, vilazodone, mirtazapine, and bupropion.[584]

Management of Genitopelvic Pain/Penetration Disorder (Dyspareunia and Vaginismus)

The most common type of dyspareunia is PVD, which affects about 12% to 18% of women.[585] PVD and the other common type of dyspareunia—that stemming from vulvovaginal atrophy—are typically associated with pelvic muscle hypertonicity and reflexive involuntary contractions when penetration is anticipated. DSM-5 therefore merges the previous terms of *dyspareunia* and *vaginismus*. The use of transperineal ultrasound for pelvic floor muscle morphometry in women with PVD has confirmed abnormalities both at rest (e.g., small levator hiatus area, small anorectal angle suggesting increased tone) and with maximal contraction. These findings are thought to be consistent with weakness and poor control of pelvic muscle.[586] Pelvic floor physiotherapy is frequently a component of sexual pain management (see Table 20.7 and Fig. 20.10)

Management of Provoked Vestibulodynia

There is no definite association between PVD and endocrine status, but recent investigation of the presence of polymorphism in the guanine triphosphate cyclohydrolase gene (*GCH1*) is of interest. Specific single nucleotide polymorphisms in the *GCH1* gene are associated with reduced pain sensitivity. Although no correlation between PVD and the pain-protective *GCH1* polymorphism was found, patients with PVD using oral contraceptives and carrying a specified *GCH1* polymorphism had higher pain

TABLE 20.16 Management of Orgasmic Disorder in Women

Etiology	Management
Insufficient arousal	Manage as for sexual interest/arousal disorder
Antidepressant induced	Consider switch to vortioxetine, bupropion, mirtazapine, vilazodone
Clitoris "too sensitive"	Information on deeper clitoral bulbs, non-genital stimuli, G spot Vibrator to vulva away from clitoris
General need to be in control	Mental health referral, use of vibrator may bypass this difficulty
Orgasmic alone but not with partners	Encourage couple sexual communication; consider psychology referral regarding fear of intimacy and fear of vulnerability

sensitivity.[587] This finding is in keeping with the clinical experience that some women with PVD benefit from discontinuing oral contraceptives.[588]

Randomized trials of oral and topical medications for PVD including tricyclics, anticonvulsants, lidocaine, fluconazole, cromolyn, and nifedipine gave similar results in analgesic benefit compared with placebo.[589] Investigational botulinum toxin was statistically inferior to placebo in reduction of sexual distress.[589] Because medical treatments for PVD have been unsatisfactory, an interdisciplinary biopsychosexual approach is currently encouraged.[590,591]

Although rarely chosen by women, surgical vestibulectomy may be of benefit in a small subset of women; however, there are numerous exclusions for vestibulectomy,[592] and benefit is obtained mostly in women with acquired as opposed to lifelong histories. Other common negative prognostic factors for successful vestibulectomy include comorbid muscle tightening, widespread allodynia of the introital margin, involvement of the Skene duct openings, unwillingness to have sex therapy if offered, and comorbid depression and anxiety. Negative prognostic factors for all treatment modalities include disgust and contamination sensitivity, erotophobia (the tendency to respond with negative effects to sexual cues), and coexistence of depression and anxiety.[593]

Personality traits of women with PVD, including negative self-evaluation and fear of negative evaluation by others, predispose to self-labeling as sexually substandard or even sexually inadequate. The stress model of pain posits that sexual stress not only contributes to the chronic pelvic muscle hypertonicity but also maintains a heightened reactivity of the pain circuitry from top-down modulation afforded by neuroplasticity.[589,593–595] The cause of the sensitization within the nervous system has not been established with certainty, but internal stress appears to be a likely cause. Women with PVD report higher levels of premorbid depression and anxiety, as well as perfectionism, reward dependency, fear of negative evaluation, increased prevalence of type D personality, self-dislike, harm avoidance, hypervigilance for pain, and shyness compared with women without PVD.[596–600]

Given that mood disorder is so commonly comorbid with PVD, management needs to address both pain and depression/anxiety. There is evidence of sustained benefit from CBT.[601] Catastrophic thinking, amenable to CBT approaches, is particularly common in women with PVD.[602] The lack of self-acceptance apparent in women with PVD, considered to be a pain-maintaining stress, is potentially amenable to MBCT given that a key component of MBCT is acceptance. A brief mindfulness-based group intervention was more efficacious in reducing both cotton swab–induced vestibular pain and psychological measures of pain in comparison to a waitlist control.[572,577] In a study of women with PVD, group MBCT was recently compared with group CBT, finding similar benefit in all secondary endpoints, but improvements in reported pain with vaginal penetration after MBCT were greater than those reported after CBT.

Management of Phobic Reflex Pelvic Muscle Contractions Component of Genitopelvic Pain/Penetration Disorder (Vaginismus)

Heightened pelvic muscle tone, often along with muscle tension elsewhere, may be the only physical findings in women reporting dyspareunia or painful but unsuccessful attempts at penetration. Often guided by pelvic floor physiotherapists, management involves progressive desensitization and progressive vaginal accommodation using a variety of relaxation techniques and vaginal inserts.[603] The term *dilators* is preferably avoided, because women fear that their therapy is going to (painfully) stretch the vagina. In-clinic physical therapy has been associated with better outcomes than traditional guidance for insert therapy at home.[604] Psychotherapies, including mindfulness and CBT, are often used to reduce anxiety.[605]

Testosterone Therapy for Women With Sexual Dysfunction

As discussed earlier in this chapter, testosterone deficiency has not been demonstrated in women diagnosed with sexual dysfunction, either by measurement of blood levels or by measurement of androgen metabolites. Several randomized trials of testosterone therapy have been conducted, mostly in postmenopausal women. These testosterone trials were conducted largely in women distressed by reduced sexual desire since their menopause. The eligibility criteria for these trials did not meet the DSM-IV diagnostic criteria for HSDD, or for the newly coined SIAD of DSM-5.

The first series of randomized trials showed a statistically significant improvement in the numbers of satisfactory sexual encounters (SSEs) in women randomized to testosterone: on average, SSEs increased from two to three per month to five per month in women on active drug and to four per month in women receiving placebo. Testosterone was given transdermally in the form of a patch with a nominal testosterone delivery of 300 μg/day. Doses of either 150 or 450 μg/day were not effective.[606] Serum testosterone and dihydrotestosterone concentrations exceeded the upper limits of the target serum concentrations of these hormones in a significant number of women receiving testosterone.[607] Women on an active drug reported further improvements in arousal, pleasure, orgasm, self-image, and responsiveness to a statistically significantly greater extent than did women receiving placebo.

These testosterone trials focused mostly on surgically menopausal women, but one testosterone patch study included naturally menopausal women[608] with comparable results. Two testosterone studies recruited naturally and surgically menopausal women who were not receiving estrogen therapy. One of these studies reported a significant increase in SSEs in the naturally menopausal women from the active drug but not in the smaller subgroup of surgically menopausal women.[609] Only 464 of the 814 participants completed treatment, with similar distribution of high discontinuation rates in all three arms. A second study of 272 naturally

menopausal women, of whom a total of 73% of the participants were not receiving systemic estrogen therapy, showed a significant increase in SSEs.[610]

On the basis of these studies, all by the same sponsor, the transdermal testosterone patch was approved in Europe, but not in North America or elsewhere, for the treatment of surgically menopausal women with persistently distressing low sexual desire despite adequate systemic estrogen therapy. Although approved, the patch is no longer available in Europe because of low sales.

In contrast to the previous studies, two large phase III RCTs by a different sponsor of 1172 postmenopausal women, approximately half of whom received systemic estrogen, showed *no* benefit of transdermal testosterone in the form of a gel over placebo.[611] Full study details are not available because these two studies have not been published. The entry criterion of distressingly reduced sexual desire after menopause was similar to the previous randomized trials; endpoints were the numbers of SSEs per month and the level of sexual desire as assessed using a daily diary.

A dose-response study of menopausal women with past hysterectomy with or without bilateral oophorectomy and with low testosterone levels (free testosterone <3.5 pg/mL) found that some aspects of sexual function improved compared with placebo, but only in those receiving the 25-mg weekly intramuscular testosterone dose and not the 12.5-mg or lower doses. All treatment doses increased circulating testosterone concentrations above those of regularly cycling women—the 25-mg dose leading to 10 and 20 times the physiologic levels of total and free testosterone, respectively.[612] Even at these doses, sexual receptivity, pleasure, orgasm, or problems with sexual function did not improve.

There is very little information available on the effects of testosterone in premenopausal women. One study of 261 women who experienced loss of their former sexual satisfaction reported minimal benefit from testosterone.[613]

A systematic review concluded that currently available evidence does not support the measurement of serum testosterone levels in the evaluation of women with low libido.[415]

Testosterone Plus a Phosphodiesterase Inhibitor

Studies have begun to evaluate the efficacy of a pharmacologic dose of testosterone (0.5 mg sublingually) to improve attentiveness for erotic cues in women with low desire.[614] The testosterone was combined with sildenafil, a PDE5 inhibitor, to facilitate genital congestion. In those women who at baseline already showed high levels of subconscious attention bias for erotic cues (as measured by a masked version of the emotional Stroop task), this drug combination had no effect, and in fact, testosterone alone *reduced* attention to erotic cues. However, the women with lower arousability or sensitivity to erotic cues at baseline showed increased physiologic genital congestion and increased awareness of the genital sensations and of sexual desire when they subsequently viewed an erotic video. Recent dose-finding studies found that 0.5 mg of sublingual testosterone, but not 0.25 mg, plus 50 mg of sildenafil increased SSEs compared with baseline and compared with either drug alone. For women with higher arousability but presumed to have more inhibiting thoughts, 0.5 mg of sublingual testosterone plus 10 mg of buspirone increased SSEs compared with baseline and compared with either drug alone.[615] The safety of intermittent use of, albeit temporary, markedly supraphysiologic testosterone therapy is totally unknown.

Limitations of Trials of Testosterone Therapy in Women

A major limitation of testosterone trials to date is the targeted population. Studies have recruited women with decreased desire since menopause, most of whom retained the ability to be aroused and sexually satisfied on at least some (on average 50%) occasions. Thus, an absence of sexual desire between sexual encounters has been the focus. However, research confirms this to be well within the range of normal female sexual experience. The majority of 3250 multiethnic middle-age women in the SWAN cohort indicated that although moderately or extremely sexually satisfied, they never or very infrequently felt desire.[616] In an online survey of 3687 younger women, 1865 were assessed to be without evidence of sexual dysfunction, specifically confirming their easy sexual arousal—close to one third of this group rarely or never began a sexual experience with a sense of sexual desire.[617] As noted earlier in this chapter, an incentives/motivations model of human sexual response is now considered to more accurately reflect sexual experience, desire for sex per se being just one of many reasons or incentives for sex. When absent at the beginning of a sexual encounter, desire can be triggered along with arousal after effective stimulation.

Women able to have satisfactory sexual experiences 50% of the time are thought unlikely to have a biologic cause of dysfunction to merit any hormonal therapy.[618–620] The trials did show improvements in desire and response domains using validated sexual questionnaires; however, increasing the degree and frequency of pleasure and arousal currently experienced by study subjects does not necessarily imply that improvements would be observed in women with a consistent absence of pleasure and arousal.[618]

There has been criticism of the use of statistical significance alone to evaluate the difference between the powerful placebo effects and active drug treatments in the area of women's sexual dysfunction—especially that of low desire.[621,622] It is suggested that effects might be better reported in terms of the percentage of participants no longer meeting current criteria for sexual dysfunction.[621] As noted, the women in the testosterone trials were not recruited on the basis of a clinical diagnosis of sexual dysfunction but based on confirmation of low desire after menopause that caused distress.

Risks of Testosterone Therapy

Long-term safety data are lacking; published safety data from trials of up to 12 months' duration are reassuring.[622] There are theoretical reasons to consider exogenous testosterone as either a risk factor or a protective factor for breast cancer; high endogenous testosterone may be associated with an increased risk.[351,620] A high endogenous testosterone-to-estrogen ratio can increase the risk of metabolic syndrome and CVD.[623] However, some data suggest that low SHBG may be related to the risk of diabetes, metabolic syndrome, and CVD.[624] In the Melbourne Women's Midlife Health Project, weight gain and free androgen index, but not total testosterone, were strong predictors of CVD risk.[625] Similar results were observed in a 9-year follow-up of the SWAN cohort.[626] In this study, the free androgen index was positively and SHBG was negatively associated with the development of obesity. Weight gain preceded changes in the free androgen index and SHBG. The expert panel of the Endocrine Society noted that the association between the free androgen index, CVD risk factors, and the metabolic syndrome phenotype appears to be more driven by obesity and low SHBG rather than testosterone.[351] In a very recent prospective study of postmenopausal women, higher levels of testosterone were associated with an increased incidence of CVD and coronary artery disease, whereas higher estradiol levels were associated with a lower incidence of coronary artery disease.[627]

In most randomized trials, testosterone therapy has been administered in the background of concurrent estrogen therapy.[351] However, the present advice is to only initiate estrogen therapy

close to menopause, noting the increase in CVD when initiated after 10 years' post menopause.[628] This risk not only limits use of combination therapy but, theoretically, also testosterone alone given its aromatization to estrogen.

The Endocrine Society task force noted (1) the limited safety data (median follow-up, 4 months; range, 6 weeks to 2 years) and (2) the efficacy data focus on sexually responsive women without the common comorbid conditions including depression or antidepressant treatment. The task force requested a meta-analysis of transdermal testosterone RCTs; the gel studies, however, were excluded because they are only published in abstract form.

Needed Research in the Area of Testosterone Supplementation

Further research is needed in women with low sexual interest/incentives and low arousal (and typically few orgasms) to reflect the prevalent clinical situation and to merit a diagnosis of SIAD. It is of note, however, that in the study of 125 women with and 125 women without HSDD, when no group differences in androgen activity were found, 55% of the women with HSDD also met criteria for SIAD.[629]

Women diagnosed with SIAD and in remission from depression but taking antidepressants and women who, despite treatment, still score in the depressive range again reflect the clinical situation. Given that depression typically blunts sexual response, it has been an exclusion factor in clinical trials, as has the use of antidepressant therapy, but the reality is that mood disorder and its treatment commonly accompany complaints of low sexual desire.[629–631] Not only is depression the factor most robustly linked to low desire in otherwise healthy women, but also depression frequently determines the presence of sexual dysfunction even when other medical conditions including diabetes are comorbid.[14]

Oral Dehydroepiandrosterone for Sexual Dysfunction in Healthy Women

Small trials of DHEA have been conducted in older healthy women. A 2014 systematic review and meta-analysis to evaluate the benefits and risks of systemic DHEA therapy for postmenopausal women[632] included 15 randomized trials that were generally considered at high risk of bias and were of short duration. Statistically, DHEA use was marginally significant for desire, and there were no other significant improvements to outcome. The quality of evidence was considered low to moderate for benefit and very low for long-term harm. A more inclusive systematic review (38 studies but with 8 having fewer than 50 participants) found benefit in 11 studies, noting that the main benefit was for postmenopausal women.[633] Importantly, recruitment has not focused on women clearly diagnosed with sexual disorder with or without relatively low serum DHEA.[634,635] Recent research revealed benefits from 50 mg of DHEA daily to reduced genital sexual sensitivity attributed to oral contraceptives.[636]

Local Dehydroepiandrosterone Therapy for Sexual Dysfunction in Healthy Women

Local vaginal DHEA therapy has recently been approved for postmenopausal women with GSM. Treatment was found to improve vaginal symptoms of dryness and dyspareunia and all domains of sexual function. Moreover, all steroids, measured by mass spectrometry methods, remained in the postmenopausal range. Specifically, ADT-G remained constant. This delivery of precursor hormones to the target tissue may allow strictly local estrogen and androgen actions and may be a preferable choice for women in whom any systemic estrogen therapy is undesirable, such as those receiving aromatase inhibitors for breast cancer, who can develop severe vulvovaginal atrophy. Rodent work suggests that local DHEA's beneficial effect on genital sexual sensitivity might stem from its potent stimulatory effect on vaginal nerve fiber density.[637] The increase in desire is interesting given lack of systemic increase in testosterone and minor increase in serum DHEA. Restored feedback from augmented genital response may be relevant. However, a caveat is that trial participants were recruited on the basis of symptoms from GSM, not on the diagnosis of SIAD. When part or all of the sexual dysfunction stems from loss of reward due to loss of genital +/– nongenital sexual sensations, vaginal DHEA can be tried after explaining that this use of an approved medication is off-label (see Table 20.15).

Estrogen Therapy for Women With Sexual Dysfunction

Local vaginal therapy is recommended for dyspareunia associated with GSM. Low doses of estrogen can be supplied by a Silastic vaginal ring, vaginal cream, or a mucoadhesive vaginal tablet with similar benefit and low systemic absorption. Use of estradiol, 10 μg twice weekly, and the Estring (Pfizer, New York, NY) (a Silastic ring containing estradiol, placed high in the vaginal vault) results in serum levels of 4.6 and 8.0 pg/mL, respectively. Progesterone is usually considered unnecessary for endometrial protection. Smaller doses of these formulations of estrogen are being investigated (e.g., 10 μg rather than 100 μg estradiol cream, 0.03 mg rather than 0.2 mg estriol vaginal pessaries) or have already been approved (e.g., 10-μg rather than 25-μg estradiol vaginal tablets). When local estrogen does not ameliorate GSM-associated dyspareunia, comorbid PVD may be present.[638]

Of concern is that women using aromatase inhibitors and vaginal estrogen may show a small increase in serum estradiol levels.[639] Small increases in estradiol are reported from use of both the estradiol ring and the former 25-μg vaginal tablet, but not from a new 4-μg vaginal capsule and only on day 1 from a 10-μg capsule.[640] A combination of 0.03 mg of estriol and lactobacilli was found to benefit GSM symptoms without systemic absorption.[641] In another recent study of women receiving aromatase inhibitors, both 5 mg of vaginal testosterone three times a week or an estradiol-releasing ring showed benefit to signs of atrophy, sexual interest, and sexual dysfunction.[642] A small number of patients in the testosterone arm sustained estradiol elevations and high treatment-induced testosterone levels. Systemic absorption of testosterone could increase serum estrogen through aromatization. Previously, using a lower dose of testosterone (150–300 μg daily), no significant estradiol elevation was reported at 4 weeks.[643] Vaginal DHEA is now being trialed in breast cancer patients, given the lack of systemic uptake of estrogen or testosterone. The American Society of Clinical Oncology recommendations include offering vaginal DHEA to women on aromatase inhibitors who have current or past breast cancer and have not responded to previous treatment.[581] A study of 300 μg of vaginal testosterone nightly showed benefit to dyspareunia without estrogen effect on maturation index or reduction of visible signs of GSM and without increase in serum testosterone or estrogen. The benefit is presumed to be from vasodilatation alone.

Of particular relevance to women with past breast cancer is a 2013 report of a hyaluronic acid vaginal gel improving dyspareunia in 85% of women, comparable to women receiving vaginal estriol.[644]

Vaginal Lubricants and Moisturizers

Nonhormonal preparations are often a first choice for women with and without histories of estrogen-sensitive tumors. Other causes of reduced lubrication include hypothalamic hypogonadism, radiation, non–nerve-sparing surgeries for pelvic cancer, and medications such as ultralow-dose combined contraceptives, GnRH agonists, antihistamines, and anticholinergics, as well as breastfeeding or lack of any sexual arousal. Lubricants reduce friction and are applied just before intercourse. Moisturizers also reduce friction but are used two or three times weekly to maintain moisture over the long term. Hyaluronic acid can be used alone or in combination with aloe vera and tea tree oil. There is some evidence that hyaluronic acid can benefit the urinary symptoms of GSM—such symptoms can lessen sexual motivation. Many preparations are marketed, but many clinicians recommend coconut oil, which is usually nonirritating, longer lasting, inexpensive, and thought to be bacteriostatic and fungistatic; however, it is not compatible with latex condoms. Water-based lubricants can dry out quickly. They may contain glycerin (to increase moisture retention), which may promote yeast infections or sexually transmitted infections such as herpes and HIV, and possibly promote chronic bacterial vaginosis. Parabens may be added to deter microbial growth but may cause irritation and increase the risk of HIV or herpes transmission, and these additives do have ultraweak estrogenic activity. Replens (Church and Dwight, Ewing, NJ), which contains a patented bioadhesive that attaches to vaginal cells and preserves moisture, has received more study than most products and was shown to increase elasticity, lower pH, and benefit dryness and dyspareunia. Silicone products are suitable for sensitive skin, do not alter vaginal pH, and are longer lasting, but they are expensive and must be washed off with soap and water—and are also extremely flammable. Lubricants that are iso-osmolar so as to preserve sperm motility are recommended when conception is wanted.

Systemic Estrogen

When systemic estrogen is needed for other menopausal symptoms, it is sometimes necessary to give additional local estrogen for dyspareunia. In contrast, for some women, ultralow-dose (0.014 mg/day) systemic transdermal estradiol may be sufficient for all menopausal symptoms, including dyspareunia.[646] If systemic supplementation improves insomnia and dyspareunia, then sexual motivation would logically be expected to increase, but this has not been vigorously studied. No significant differences were found between estrogen and placebo groups in reported sexual satisfaction in the Women's Health Initiative trial.[647] However, sexual dysfunction was not a primary focus of that trial, women with marked menopausal symptoms were excluded, and the instruments used to assess sexual function were substandard. The Kronos Early Estrogen Prevention Study results suggest that the transdermal, rather than oral, route may be more likely to benefit sexual function, but again, the participants were not recruited on the basis of sexual dysfunction.[648]

Ospemifene—the only approved estrogen receptor modulator for GSM—is another alternative to estrogen. Its estrogenic effects on vulvar and vaginal tissues restore the maturation index, vaginal pH, and dyspareunia.[649] However, its theoretical safety on breast tissue is not established.

Approved But Not Recommended Medication for the Former DSM-IV Hypoactive Sexual Desire Disorder

Flibanserin—a 5HT1A agonist and a 5HT2A antagonist studied originally for potential benefit to depression—was trialed by different pharmaceutical companies and received limited FDA approval for the treatment of HSDD. This approval is despite benefit being similar to placebo and serious risk of harm.[650] There are strict contraindications to alcohol and to medications that inhibit CYP3A4, including oral contraceptives and fluconazole. Safety concerns include hypotension, syncope, somnolence, fatigue, and potential carcinogenicity. Overall risks of sedation or hypotension-related events were 28.6% with flibanserin versus 9.4% with placebo. Two recent meta-analyses have been based on both published and unpublished RCTs.[651] Meta-analysis showed that flibanserin led to a mean increase of 0.49 satisfying sexual events per month.[652] There was an increase of 0.3 (range, 1.2–6.0) on the desire subscale of the validated questionnaire, which was considered not to differ from placebo. Recruited women reported two to three rewarding sexual experiences each month at baseline (i.e., the participants did not have SIAD). Due both to safety concerns and to the short duration of studies and questionable accuracy of 4-week recall along with marginal efficacy, approval had been denied and additional safety studies recommended. Surprisingly, despite lack of additional efficacy data, but with data ruling out driving impairment and assessing alcohol's enhancement of side effects in 23 men and 2 women, on June 4, 2015, an FDA advisory committee voted 18 to 6 to accept approval of flibanserin, although with reservations. Fifteen members endorsing its approval declared their reluctance to do so. A recent review of scientific knowledge on flibanserin to date seriously questioned its use, noting the tenuous risk-benefit profile along with prohibitive prescribing restrictions and doubtful presence of sexual disorder in trialed women.[653]

Transgender Endocrinology

STEPHEN M. ROSENTHAL AND VIN TANGPRICHA

CHAPTER OUTLINE

KEY POINTS

- Transgender people express a gender identity that differs from the gender implied by the sex assigned (recorded) at birth.
- A number of biological, environmental, and cultural factors likely influence one's gender identity.
- Youth with gender dysphoria should undergo an evaluation by a qualified mental health/gender specialist to confirm the diagnosis and to screen for other coexisting mental health concerns.
- Youth deemed eligible to initiate hormone therapy generally start with gonadotropin-releasing hormone agonists at Tanner stage 2 to halt puberty and at the appropriate time start gender-affirming hormone therapy of the desired gender.
- Transfeminine adults with confirmed gender dysphoria will start on a regimen of estrogen and androgen-lowering medications.
- Transmasculine adults with confirmed gender dysphoria will start on testosterone therapy.
- Only limited data currently exist regarding long-term outcomes of pubertal suppression and of gender-affirming hormone use in transgender youth.
- The long-term risks of gender-affirming hormone therapy are relatively few when hormone levels remain in the physiologic range; however, monitoring of potential adverse events is still recommended until long-term risks can be better ascertained.

Introduction

During the last decade there has been increasing public awareness of individuals whose gender identity is not aligned with their physical sex characteristics. Concurrently there has been an increasing number of gender nonconforming/transgender individuals seeking medical services to enable development of physical sex characteristics consistent with their affirmed gender identity. This chapter will review relevant terminology/definitions, diagnosis and prevalence of gender dysphoria (GD), mental health comorbidities, studies that shed light on the biological determinants of gender identity, current treatment models, barriers to care, and priorities for research.

Definitions and Diagnosis of Gender Dysphoria

Terminology and definitions used in this chapter are summarized in Table 21.1.

Prevalence of Gender Nonconforming Identity

Based on state-level population-based surveys, a 2017 report from the Williams Institute of the University of California–Los Angeles School of Law indicated that 0.6% of US adults and 0.7% of youth age 13 to 17 years identify as transgender.[1] A recent international review reports transgender prevalence estimates ranging from 0.5% to 1.3% of birth-assigned males and from 0.4% to 1.2% of birth-assigned females, representing an estimate of 25 million transgender people worldwide.[2] Of note, there has been a striking inversion in the sex ratio of adolescents with GD, with a predominance of birth-assigned females in recent years.[3]

Biological Determinants of Gender Identity

Compelling data have emerged supporting the concept that gender identity is not simply a psychosocial construct; rather, it reflects a complex interplay of biological, environmental, and

TABLE 21.1 Definitions From the Endocrine Society 2017 Guidelines

Term	Definition
Biological sex, biological male or female	These terms refer to physical aspects of maleness and femaleness. As these may not be in line with each other (e.g., a person with XY chromosomes may have female-appearing genitalia), the terms *biological sex* and *biological male* or *female* are imprecise and should be avoided.
Cisgender	This means "not transgender." An alternative way to describe individuals who are not transgender is *nontransgender people*.
Gender-affirming (hormone) treatment	See "gender reassignment."
Gender dysphoria	This is the distress and unease experienced if gender identity and designated gender are not completely congruent. In 2013, the American Psychiatric Association released the fifth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-V), which replaced *gender identity disorder* with *gender dysphoria* and changed the criteria for diagnosis.
Gender expression	This refers to external manifestations of gender, expressed through one's name, pronouns, clothing, haircut, behavior, voice, or body characteristics. Typically, transgender people seek to make their gender expression align with their gender identity, rather than their designated gender.
Gender identity/experienced gender	This refers to one's internal, deeply held sense of gender. For transgender people, their gender identity does not match their sex designated at birth. Most people have a gender identity of man or woman (or boy or girl). For some people, their gender identity does not fit neatly into one of those two choices. Unlike gender expression (to come), gender identity is not visible to others.
Gender identity disorder	This is the term used for gender dysphoria/gender incongruence in previous versions of DSM (see "gender dysphoria"). The International Statistical Classification of Diseases and Related Health Problems, Tenth Edition (ICD-10) still uses the term for diagnosing child diagnoses, but the upcoming ICD-11 has proposed using *gender incongruence of childhood*.
Gender incongruence	This is an umbrella term used when the gender identity and/or gender expression differs from what is typically associated with the designated gender. Gender incongruence is also the proposed name of the gender identity–related diagnoses in ICD-11. Not all individuals with gender incongruence have gender dysphoria or seek treatment.
Gender variance	See "gender incongruence."
Gender reassignment	This refers to the treatment procedure for those who want to adapt their bodies to the experienced gender by means of hormones and/or surgery. This is also called *gender-confirming* or *gender-affirming treatment*.
Gender-reassignment surgery (gender-confirming/gender-affirming surgery)	These terms refer only to the surgical part of gender-confirming/gender-affirming treatment.
Gender role	This refers to behaviors, attitudes, and personality traits that a society (in a given culture and historic period) designates as masculine or feminine and/or that society associates with or considers typical of the social role of men or women.
Sex designated at birth	This refers to sex assigned at birth, usually based on genital anatomy.
Sex	This refers to attributes that characterize biological maleness or femaleness. The best-known attributes include the sex-determining genes, the sex chromosomes, the H-Y antigen, the gonads, sex hormones, internal and external genitalia, and secondary sex characteristics.
Sexual orientation	This term describes an individual's enduring physical and emotional attraction to another person. Gender identity and sexual orientation are not the same. Irrespective of their gender identity, transgender people may be attracted to women (gynephilic), attracted to men (androphilic), bisexual, asexual, or queer.
Transgender	This is an umbrella term for people whose gender identity and/or gender expression differs from what is typically associated with their sex designated at birth. Not all transgender individuals seek treatment.
Transgender male (also: transman, female-to-male, transgender male)	This refers to individuals assigned female at birth but who identify and live as men.
Transgender woman (also: transwoman, male-to-female, transgender female)	This refers to individuals assigned male at birth but who identify and live as women.
Transition	This refers to the process during which transgender persons change their physical, social, and/or legal characteristics consistent with their affirmed gender identity. Prepubertal children may choose to transition socially.
Transsexual	This is an older term that originated in the medical and psychologic communities to refer to individuals who have permanently transitioned through medical interventions or desired to do so.

From Hembree WC, Cohen-Kettenis PT, Gooren L, et al. Endocrine treatment of gender-dysphoric/gender-incongruent persons: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab*. 2017;102:3869–3903; by permission of the Endocrine Society.

cultural factors. Studies that shed light on biological determinants of gender identity are derived principally from three biomedical disciplines: genetics, endocrinology, and neuroscience, highlights of which are summarized in this chapter. The intent in focusing on biological underpinnings of gender identity is not to pathologize or to identify a mechanism that can be "fixed." Instead, the purpose is to underscore biological variation in gender identity that may in turn destigmatize gender-variant individuals and decrease health disparities for gender minorities.

With respect to genetics, a recent study notes heritability estimates for gender identity in the range of 30% to 60%.[4] A study in twins supporting a role for genetic factors in gender identity outcome demonstrated a 39.1% concordance for what was previously called *gender identity disorder* (based on the *Diagnostic and Statistical Manual of Mental Disorders* [Fourth Edition] [DSM-IV] criteria) in 23 monozygotic female and male twin pairs, but no concordance in 21 same-sex dizygotic female and male twin pairs or in 7 opposite-sex twin pairs.[5] A number of investigators have sought to identify polymorphisms in specific candidate genes (e.g., the androgen receptor, estrogen receptor, and aromatase) that may be more prevalent in transgender individuals in comparison to a control population of nontransgender individuals; however, such findings have been inconsistent and lacking strong statistical significance.[6–9]

With respect to endocrine considerations, it should be noted that most transgender individuals do not have a disorder/difference of sex development (DSD). However, studies in individuals with DSDs have informed our understanding of the role that hormones (prenatal/early neonatal androgens, in particular) may play in gender identity development. For example, in studies of 46,XX individuals raised female with virilizing congenital adrenal hyperplasia (CAH) caused by mutations in the *CYP21A2* gene, there was a greater degree of female-to-male transgenderism in comparison to what would be expected based on prevalence estimates in a control population.[10,11] In a meta-analysis of 250 adults with this condition raised female, while nearly 95% accepted a female gender identity, 5.2% reported either a male gender identity or gender dysphoria.[11] This rate is higher than what would be expected for a transgender prevalence of 0.6% to 0.7% in recent population estimates.[1] A relationship between severity of disease and gender identity outcome was demonstrated in a study of adult 46,XX individuals with classic 21-hydroxylase deficiency: Three of the 42 patients (7.1%) with the salt-wasting form had gender dysphoria; no gender dysphoria was reported in the less severely affected individuals.[10] A study in 46,XX youth with the same condition found that of 43 individuals with either salt-wasting or simple virilizing CAH, 12.8% demonstrated cross-gender identification that was considered to be independent of gender role behavior.[12] In contrast, no cross-gender identification was noted in a nearly equivalent number of 46,XY individuals with virilizing CAH due to mutations in the *CYP21A2* gene or in a nearly equivalent number of controls (age-matched relatives).[12] A role for prenatal/early natal androgens in gender identity development is also supported by studies in a variety of other hormonal and nonhormonal DSDs, as recently reviewed.[13]

With respect to brain and gender identity, some studies in transgender individuals carried out before treatment with gender-affirming cross-sex hormones have demonstrated that some sexually dimorphic structures (both gray and white matter) are more closely aligned with a person's gender identity than with their physical sex characteristics.[14,15] In addition, some functional studies (e.g., analysis of hypothalamic blood flow in response to smelling odorous compounds or brain imaging studies carried out during mental rotation tasks) have demonstrated that patterns typically observed to be sexually dimorphic were more closely aligned with gender identity than with physical sex characteristics, even before cross-sex hormone treatment in both transgender adults and adolescents.[16–18]

Care of Transgender Youth

Gender dysphoria that either worsens or emerges with onset of physical puberty implies a high likelihood of a transgender identity during adulthood.[19] Given the complexity of gender dysphoria—and of adolescence itself—it is essential that gender dysphoric youth undergo a thorough evaluation by a qualified mental health/gender specialist. A psychodiagnostic evaluation is important not only to determine the presence or absence of gender dysphoria but also to assess for the presence of other mental health concerns that may co-occur. While the majority of gender dysphoric children and adolescents do not have an underlying severe psychiatric illness, it is important to recognize that there is an association of gender dysphoria and autism spectrum disorder.[19–21]

Based on pioneering work from the Netherlands, care of transgender youth has been primarily informed by clinical practice guidelines (CPGs) from the Endocrine Society (ES) and cosponsoring organizations and by standards of care (SOCs) from the World Professional Association for Transgender Health (WPATH).[22,23] These documents endorse the use of pubertal blockers in GD adolescents using gonadotropin-releasing hormone (GnRH) agonists at Tanner stage 2 of pubertal development (testicular volume ≥4 mL for assigned males at birth; initial stage of breast budding for assigned females at birth). Considered fully reversible treatments, GnRH agonists, by pausing puberty in this clinical setting, provide additional time for gender-identity exploration without the pressure of continued pubertal progression and prevent irreversible development of secondary sex characteristics associated with puberty that are not aligned with the person's gender identity. Such undesired physical changes include a prominent Adam's apple, lowered voice, male bone configuration, and potentially tall stature in assigned males at birth; conversely, breast development, female body habitus, and potentially short stature in assigned females at birth.[22] A recommended baseline and follow-up protocol for physical examination and laboratory monitoring during pubertal suppression is outlined in Table 21.2. While GnRH agonists are the preferred option for pubertal suppression, this treatment is costly and often inaccessible. Other options for pubertal suppression include depot and oral progestins.[22,24]

Adolescents who continue to meet the criteria for gender incongruence and gender dysphoria may request phenotypic transition with sex steroids. While age-specific recommendations for initiation of sex steroids in gender dysphoric adolescents are not delineated in the WPATH SOCs, the most recent version of the ES CPGs recommends initiating treatment "using a gradually increasing dose schedule after a multidisciplinary team of medical and mental health professionals has confirmed the persistence of gender dysphoria/gender incongruence and sufficient mental health capacity to give informed consent, which most individuals have by age 16 years."[22] Table 21.3 provides a protocol for induction of puberty in such adolescents; Table 21.4 provides recommendations for baseline and follow-up physical examination and laboratory evaluation during induction of puberty.

An important change in the current ES guidelines is the acknowledgment that there may be compelling reasons to start

TABLE 21.2 Endocrine Society Guidelines for Baseline and Follow-Up Protocol for Physical Examination and Laboratory Monitoring in Transgender Children During Pubertal Suppression With a GnRH Agonist

Every 3–6 Months

Anthropometry: height, weight, sitting height, blood pressure, Tanner stages

Every 6–12 Months

Laboratory: LH, FSH, E2/T, 25(OH)D

Every 1–2 Years

Bone density using DXA

Bone age on X-ray of the left hand (if clinically indicated)

25(OH)D, 25-Hydroxyvitamin D; *DXA,* dual-photon absorptiometry; *E2,* estradiol; *FSH,* follicle-stimulating hormone; *LH,* luteinizing hormone; *T,* testosterone.

From Hembree WC, Cohen-Kettenis PT, Gooren L, et al. Endocrine treatment of gender-dysphoric/gender-incongruent persons: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab.* 2017;102:3869–3903.

TABLE 21.3 Endocrine Society Guidelines for Induction of Puberty in the Affirmed Gender

Induction of female puberty with oral 17β-estradiol, increasing the dose every 6 months:
- 5 μg/kg/day
- 10 μg/kg/day
- 15 μg/kg/day
- 20 μg/kg/day
- Adult dose = 2–6 mg/day

In postpubertal transgender female adolescents, the dose of 17β-estradiol can be increased more rapidly:
- 1 mg/day for 6 months
- 2 mg/day

Induction of female puberty with transdermal 17β-estradiol, increasing the dose every 6 months (new patch is placed every 3.5 days):
- 6.25–12.5 μg/24 hours (cut 25-μg patch into quarters, then halves)
- 25 μg/24 hours
- 37.5 μg/24 hours
- Adult dose = 50–200 μg/24 hours

For alternatives once at adult dose, see Table 21.5.

Adjust maintenance dose to mimic physiologic estradiol levels (see Table 21.6).

Induction of male puberty with testosterone esters increasing the dose every 6 months (intramuscularly or subcutaneously):
- 25 mg/m^2/2 weeks (or alternatively, half this dose weekly, or double the dose every 4 weeks)
- 50 mg/m^2/2 weeks
- 75 mg/m^2/2 weeks
- 100 mg/m^2/2 weeks
- Adult dose = 100–200 mg every 2 weeks

In postpubertal transgender male adolescents, the dose of testosterone esters can be increased more rapidly:
- 75 mg/2 weeks for 6 months
- 125 mg/2 weeks

For alternatives once at adult dose, see Table 21.5.

Adjust maintenance dose to mimic physiologic testosterone levels (see Table 21.7).

From Hembree WC, Cohen-Kettenis PT, Gooren L, et al. Endocrine treatment of gender-dysphoric/gender-incongruent persons: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab.* 2017;102:3869–3903; adapted from Hembree WC, Cohen-Kettenis P, Delemarre-van de Waal HA, et al. Endocrine treatment of transsexual persons: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab.* 2009;94:3132–3154.

TABLE 21.4 Endocrine Society Guidelines for Baseline and Follow-Up Physical Examination and Laboratory Monitoring in Transgender Children During Induction of Puberty

Every 3–6 Months

Anthropometry: height, weight, sitting height, blood pressure, Tanner stages

Every 6–12 Months

In transgender males: hemoglobin/hematocrit, lipids, testosterone, 25-hydroxyvitamin D

In transgender females: prolactin, estradiol, 25(OH)D

Every 1–2 Years

Bone mineral density (BMD) using dual-energy X-ray absorptiometry (DXA)

Bone age on X-ray of the left hand (if clinically indicated)

BMD should be monitored into adulthood (until the age of 25–30 years or until peak bone mass has been reached).

For recommendations on monitoring once pubertal induction has been completed, see Tables 21.5 and 21.6.

25(OH)D, 25-Hydroxyvitamin D.

From Hembree WC, Cohen-Kettenis PT, Gooren L, et al. Endocrine treatment of gender-dysphoric/gender-incongruent persons: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab.* 2017;102:3869–3903; adapted from Hembree WC, Cohen-Kettenis P, Delemarre-van de Waal HA, et al. Endocrine treatment of transsexual persons: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab.* 2009;94:3132–3154.

sex hormone treatment before the age of 16 years in some adolescents with gender incongruence and gender dysphoria.[22] Delaying sex hormone treatment until age 16 years in an adolescent whose puberty was blocked at Tanner stage 2 could not only be detrimental to bone health, but also keeping someone suspended in an early pubertal state until this age could isolate the individual further from age-matched peers, with potentially negative consequences for emotional well-being.[22]

When puberty is initiated with gradually increasing doses of sex steroids, the initial levels will not be sufficient to suppress endogenous sex steroids. In transgender females, it is therefore recommended that GnRH analog treatment (or an alternative antiandrogen) be continued until gonadectomy.[22] Since some transgender young adults may opt not to have gonadectomy, long-term studies are necessary to examine the potential risks of prolonged GnRH analog treatment. In transgender male adolescents, GnRH analog treatment can typically be discontinued once adult levels of testosterone have been reached.[22] If uterine bleeding occurs, a progestin can be added.[22,25]

Some transgender adolescents first come to medical attention when they are already in the later stages of puberty or are postpubertal. Transgender males can be treated with testosterone alone; transgender females are treated with a combination of estrogen and an agent that blocks testosterone secretion and/or action using protocols similar to those used in transgender adults (see later discussion on hormone therapy in transgender adults).

With respect to estrogen treatment, 17β-estradiol (transdermal, oral, or parenteral) is preferred to conjugated (e.g., Premarin) or synthetic estrogens (e.g., ethinyl estradiol) since conjugated and synthetic estrogen levels cannot be monitored in the serum, and ethinyl estradiol is associated with an increased risk for venous thromboembolic disease and death from cardiovascular causes in adult studies (see later discussion on hormone therapy in transgender adults).

Some transgender adolescents seek surgical procedures to bring their bodies into closer alignment with their gender identity. The

current ES guidelines recommend that gender-affirming genital surgery involving gonadectomy and/or hysterectomy not take place until the patient has reached at least 18 years of age or the age of legal majority in his or her country.[22] With respect to breast surgery/mastectomy for transgender males, the current ES CPG notes that some adolescents may consider this procedure before age 18 years, though there is insufficient evidence to recommend a specific age requirement. Rather, the ES CPG suggests that clinicians determine timing of this procedure based on the physical and mental health status of the individual patient.[22]

Outcomes of Current Treatment Models for Transgender Youth and Potential Adverse Effects

Mental Health Outcomes

Only limited outcomes data are currently available to support the ES guidelines and WPATH SOCs for care of transgender youth. A study from the Netherlands evaluated the mental health in 55 transgender adolescents/young adults at three time points: before the start of GnRH agonist treatment (average age 13.6 years), at the start of cross-sex hormone treatment (average age 16.7 years), and 1 year after gender-reassignment surgery (average age 20.7 years). Following the completion of this three-stage approach to care, gender dysphoria was resolved, general psychologic functioning steadily improved, and a sense of well-being based on standardized survey results was noted to be equal to or greater than that seen in age-matched controls from the general population.[26] None of the study participants regretted treatment.[26]

Potential Adverse Effects of Pubertal Blockers in Transgender Youth

There are potential adverse effects of pubertal suppression with GnRH agonists in transgender youth. The primary risks include impaired bone mineral density (BMD), compromised fertility, and unclear effects on brain development, body mass index (BMI), and body composition, as recently reviewed.[27]

Skeletal Health

With respect to skeletal health, a 6-year longitudinal study assessed BMD in 34 transgender adolescents (15 transgender females, 19 transgender males) at the start of GnRH agonist treatment, at the start of cross-sex hormone treatment, and at age 22 years, following gonadectomy at a minimum age of 18 years (at which time GnRH agonist was stopped and cross-sex hormone treatment was continued). During the 6-year study period, there was a significant decrease in lumbar spine areal BMD Z-scores (relative to natal sex) in the transgender females, with a similar trend in the transgender males, suggesting either a delay in attainment of peak bone mass or an attenuation of peak bone mass itself.[28] The authors acknowledged potential study limitations, including a relatively small number of participants, use of relatively low doses of cross-sex hormones during the initial period of that phase of treatment, and a lack of information regarding vitamin D levels, dietary calcium intake, and weight-bearing exercise, all of which can influence BMD.[28] Particularly during GnRH agonist treatment, it would seem important to ensure adequate intake of calcium and vitamin D to encourage weight-bearing exercise and to routinely monitor levels of 25(OH)D.[24]

A separate study investigated bone turnover markers as well as BMD in transgender adolescents who underwent GnRH agonist treatment followed by cross-sex hormone therapy (the latter at about the age of 16 years, similar to previous reports). At baseline, bone mineral apparent density (BMAD) in the lumbar spine was lower in young (bone age <15 years) transgender female adolescents versus young (bone age <14 years) transgender male adolescents.[29] Bone turnover markers and BMAD Z-scores decreased following GnRH agonist treatment in the younger transgender adolescents, while an increase in BMAD was seen after 24 months of cross-sex hormone treatment in the younger transgender adolescents (bone age as previously noted) and older transgender adolescents (bone age ≥15 years in transgender females and ≥14 years in transgender males).[29]

A 22-year follow-up study of the first described gender dysphoric adolescent, treated initially with GnRH agonist and subsequently with cross-sex hormones, found that BMD was in the normal range for both sexes when evaluated at 35 years of age.[30]

Fertility

It is essential that an informed consent process and a discussion about implications for fertility precede any treatment of transgender youth with pubertal blockers and/or gender-affirming sex hormones. Transgender adolescents may wish to preserve fertility, which may be otherwise compromised if puberty is suppressed at an early stage and the patient subsequently pursues physical transition with gender-affirming sex hormones. In vitro maturation of human germ cells has not yet been achieved, though promising studies have been carried out in mice.[31] Late pubertal and fully pubertal adolescents have the option of cryopreservation of mature sperm or eggs.

Brain

Few studies have thus far investigated potential adverse effects of GnRH agonists on the brain in transgender adolescents. A cross-sectional study in gender dysphoric adolescents treated with GnRH agonist, in comparison to untreated gender dysphoric adolescents, showed no significant compromise of executive functioning, a developmental milestone thought to reflect prefrontal brain activation and to be typically achieved during puberty.[32] A 28-month longitudinal study in a single pubertal transgender adolescent undergoing GnRH agonist treatment reported lack of significant variation in brain white matter fractional anisotropy, thought to be a measure of brain maturation, and a nine-point drop in operational memory testing after 22 months of pubertal suppression.[33] Further longitudinal studies are needed to determine the impact of GnRH agonist treatment on brain development and function in transgender adolescents.

Body Mass Index and Body Composition

The impact of GnRH agonist treatment of transgender adolescents on BMI and body composition has also been studied. While variable results have been reported with respect to BMI,[28,34] a decrease in lean body mass percentage and an increase in fat percentage were reported after 1 year of treatment with GnRH agonist in both transgender male and female adolescents.[35] In an earlier study, 1 of 27 adolescents treated with GnRH agonist developed significant weight gain, though BMI was above the 85th percentile before treatment.[35]

Potential Adverse Effects of Gender-Affirming Sex Hormones in Transgender Adolescents

Few studies have thus far evaluated potential adverse effects of gender-affirming sex hormones in transgender adolescents. A study from the Netherlands in 28 transgender female adolescents treated primarily with gradually increasing doses of 17β-estradiol

for 1 to 3 years described no change in blood pressure, BMI standard deviation score, lean body mass percentage, or fat percentage (despite the presence of a desired female pattern of fat distribution). No abnormalities were seen with creatinine or with liver enzymes, and there was no change in hematocrit or hemoglobin A1c. One individual developed hyperprolactinemia, though this was seen in the context of high-dose ethinyl estradiol treatment to limit statural growth.[36]

A study from the United States assessed potential adverse effects of gender-affirming sex hormones in 116 transgender adolescents and young adults (44 transgender females and 72 transgender males treated with 17β-estradiol or testosterone, respectively). Following 17β-estradiol treatment, no abnormalities were reported in blood pressure, BMI, hemoglobin/hematocrit, lipids, renal and liver function studies, and prolactin. Following testosterone treatment, there was an increase in BMI and hemoglobin/hematocrit (3 of 44 individuals developed supraphysiologic hematocrit levels) and a decrease in high-density lipoprotein (HDL) cholesterol. No abnormalities were reported in blood pressure, renal and liver function studies, and hemoglobin A1c.[37]

Care of Transgender Adults

Because adults are able to more clearly articulate their gender identity and most adults have a gender identity that is fixed, any physician with the knowledge and expertise to diagnose gender dysphoria can manage and prescribe gender-affirming hormone therapy in adults with gender incongruence/gender dysphoria (GI/GD). Endocrinologists and other physicians with expertise should evaluate individuals with GI/GD for eligibility and readiness for hormone therapy and should serve as a liaison between mental health providers and surgeons. Endocrinologists should follow updated national/international guidelines on how to initiate and monitor hormone therapy in GI/GD individuals and serve as a resource for medical professionals in the community. In some instances, co-management with an endocrinologist along with another hormone prescriber may be necessary if there are other coexisting mental health or medical comorbidities.

The initial encounter with a transgender adult should include a history of the duration and severity of the gender dysphoria and a careful review of chronic medical issues that can be exacerbated by hormone therapy. An assessment of the individual's family and social support structure is important to determine if the timing of hormone therapy is appropriate (especially if not currently living in the affirmed gender role) or if additional social support is needed prior to starting hormone therapy. It is important to discuss any history of depression and to assess suicide since transgender individuals are at increased risk.[38,39] The prescription of an antidepressant medication or urgent referral to a mental health provider may be necessary. Finally, the endocrinologist should carefully review the letter provided from the mental health provider if the individual has already been receiving counseling. It is not a requirement to have a mental health referral in adults as stated in the ES guidelines[22]; however, in cases where the severity and duration of gender dysphoria are not quite clear and where there may be other mental health concerns that impact the gender transition, a mental health referral may be helpful.

Follow-up visits with the endocrinologist should focus on the response of the gender-affirming hormone therapy on the individual's gender dysphoria and mood. The endocrinologist should continue to assess the individual's social support structure and environment. The endocrinologist should also assist in any legal matters that arise, such as gender or name change, and referral to surgical specialists for gender-affirming surgery when the timing is appropriate.

Hormone therapy protocols have been developed to mimic the sex steroid (testosterone and estradiol) concentrations in the expected reference range for males and females. Many centers around the world have utilized different preparations and delivery methods of sex steroid hormones along with adjunctive treatments to achieve this goal. Over time, these protocols have been refined and adopted by other clinics around the world. These protocols involve careful titration of hormone doses according to the blood concentrations of sex steroid hormones until a steady-state concentration is achieved. The ES guidelines recommend a number of different hormone regimens that can be used for transgender

TABLE 21.5 Endocrine Society Recommendations for Hormone Therapy in Transgender Adults

TRANSGENDER FEMALES[a]	
Estrogen	
Oral	
Estradiol	2.0–6.0 mg/day
Transdermal	
Estradiol transdermal patch (new patch placed every 3–5 days)	0.025–0.2 mg/day
Parenteral	
Estradiol valerate or cypionate	5–30 mg IM every 2 weeks 2–10 mg IM every week
Antiandrogens	
Spironolactone	100–300 mg/day
Cyproterone acetate[b]	25–50 mg/day
GnRH Agonist	3.75 mg SQ (SC) monthly 11.25 mg SQ (SC) 3-monthly
TRANSGENDER MALES	
Testosterone	
Parenteral testosterone	
Testosterone enanthate or cypionate	100–200 mg SQ (intramuscularly) every 2 weeks or SQ (subcutaneously) 50% per week
Testosterone undecanoate[c]	1000 mg every 12 weeks
Transdermal testosterone	
Testosterone gel 1.6%[d]	50–100 mg/day
Testosterone transdermal patch	2.5–7.5 mg/day

[a]Estrogens used with or without antiandrogens or GnRH agonist.

[b]Not available in the United States.

[c]1000 mg initially followed by an injection at 6 weeks then at 12-week intervals.

[d]Avoid cutaneous transfer to other individuals.

From Hembree WC, Cohen-Kettenis PT, Gooren L, et al. Endocrine treatment of gender-dysphoric/gender-incongruent persons: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab.* 2017;102:3869–3903.

TABLE 21.6 Endocrine Society Recommendations for Physical Examination and Laboratory Monitoring in Transgender Women

1. Evaluate patient every 3 months in the first year and then one to two times per year to monitor for appropriate signs of feminization and for the development of adverse reactions.
2. Measure serum testosterone and estradiol every 3 months.
   a. Serum testosterone levels should be <50 ng/dL.
   b. Serum estradiol should not exceed the peak physiologic range: 100–200 pg/mL.
3. For individuals on spironolactone, serum electrolytes, particularly potassium, should be monitored every 3 months in the first year and annually thereafter.
4. Routine cancer screening is recommended, as in nontransgender individuals (all tissues present).
5. Consider bone mineral density testing at baseline. In individuals at low risk, screening for osteoporosis should be conducted at age 60 years or in those who are not compliant with hormone therapy.

From Hembree WC, Cohen-Kettenis PT, Gooren L, et al. Endocrine treatment of gender-dysphoric/gender-incongruent persons: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab*. 2017;102:3869–3903.

adults (Table 21.5) and a protocol for monitoring for potential adverse events (Table 21.6). In general, when hormone therapy is taken under medical supervision, the risks of adverse events are low likely due to the careful attention not to exceed supraphysiologic concentrations.[40] However, it is important to note that self-treatment with hormone therapy still remains common in countries where hormones can be obtained without prescription, particularly in the developing world.

Transfeminine Hormone Therapy

Estrogen

Several formations of estrogen have been used in the past, including synthetic estrogens (e.g., diethylstilbestrol, ethinyl estradiol), conjugated estrogens (Premarin), or estradiol. Estrogens can be given by several routes of administration, including orally, transdermally, or intramuscularly/subcutaneously (see Table 21.5). Studies have demonstrated that conjugated estrogens and synthetic estrogens are associated with increased risks of thromboembolism and thus are no longer recommended for use by the ES guidelines.[22] Another issue with conjugated estrogens and synthetic estrogens is their inability for physicians to measure these drugs in blood and/or estimate equivalent estradiol levels, which impairs efforts to avoid supraphysiologic exposure to estrogen.

The most commonly prescribed and common route of administration of estrogen is oral estradiol due to its convenience, cost, and relatively good safety profile. The dose of oral estradiol is titrated to a serum estradiol range of 200 to 300 pg/mL.[41] Liang et al[42] reported that oral estradiol doses in the range of 2 to 7.5 mg daily in combination with spironolactone will result in serum estradiol concentrations between 50 and 200 pg/mL in transwomen followed in the United States for over 3 years. In transwomen followed in the European Network for the Investigation of Gender Incongruence (ENIGI), oral estrogen is prescribed to those under age 40 at 4 mg daily in combination with cyproterone acetate; estradiol levels reach 100 to 200 pg/mL.[43]

Transdermal estrogen, presumed to be less stimulatory of prothrombotic proteins, is preferred in transgender women over the age of 40 due to the increased risk of thromboembolic disease.[44] In the Netherlands, all transgender women are switched to transdermal estrogen after age 40.[45] In an academic endocrinology practice in Austria, 162 transwomen were prescribed primarily transdermal 17β-estradiol. They found no cases of thromboembolism after a mean follow-up time of 64 months.[46] However, in 676 transgender women prescribed oral estradiol followed in the United States, only one person developed a thromboembolism after a mean follow-up time of 1.9 years.[47] Therefore it is unclear at this point if oral or transdermal formulations are equally as safe for use in transgender women. There have been no head-to-head studies that have studied these two methods of administration.

Testosterone-Lowering Agents

Most published transfeminine hormone regimens involve the use of a testosterone-lowering agent in combination with estrogen therapy (see Table 21.5). Testosterone-lowering agents allow for estrogen therapy to induce secondary sex characteristics unopposed from the actions of testosterone, and thus a lower dose of estrogen is required. There are three commonly prescribed testosterone-lowering agents, spironolactone, cyproterone acetate, and GnRH agonists.

Spironolactone is most commonly used in the United States for its widespread availability and ease of administration. It is taken orally once or twice a day in doses ranging from 100 to 300 mg total daily (see Table 21.5). Spironolactone was developed for its antagonism of the mineralocorticoid receptor and as a potassium-sparing diuretic. Less is known about the precise mechanism by which spironolactone lowers testosterone, but it is widely appreciated in cisgender men to cause gynecomastia likely due to antagonism of the androgen receptors, increased clearance of testosterone, increased conversion of testosterone to estradiol, and direct inhibition of testosterone production.[48,49] Largely retrospective studies based in the United States on the effectiveness of spironolactone to lower testosterone concentrations in transgender women report mixed results.[42,50] Unfortunately, no prospective randomized controlled trial has been conducted to examine estrogen regimens with or without spironolactone.

In Europe and parts of Asia, cyproterone acetate has been commonly used as the testosterone-lowering agent. Cyproterone acetate is taken orally, between 25 and 50 mg daily. Cyproterone has progestin-like activity and lowers testosterone by lowering gonadotropin levels. A recent study in transgender girls found that cyproterone acetate monotherapy resulted in lower gonadotropins and lower total and free testosterone, which were associated with favorable physical changes, including less facial hair and increased breast growth.[51] However, there have been some recent concerns associated with cyproterone acetate that are not seen with spironolactone, including increased incidence of hyperprolactinemia and meningiomas.[52–54]

In the United Kingdom, GnRH agonists are primarily used to lower testosterone in transgender women.[55] These medications are highly effective in lowering levels of gonadotropins and lowering testosterone to nearly undetectable levels. Some of the limitations of GnRH agonists are the high cost of therapy and the lack of long-term data with this approach.

5α-Reductase Inhibitors

5α-Reductase inhibitors such as finasteride or dutasteride have not been routinely recommended for use in transgender women

since they do not lower serum concentrations of testosterone and they have a higher cost. In addition, there have been concerns regarding an increased risk of sexual dysfunction and depression as reported in cisgender men.[56–58] Since there is an increased rate of depression and suicide in the transgender population,[38,39] these medications should not be used as antiandrogens in first-line therapies. However, 5α-reductase inhibitors may have a role in transgender women who have androgenetic alopecia and who do not achieve an adequate response to spironolactone.[59]

Progesterone

Many transgender women request progesterone as part of their gender-affirming hormone regimen despite the lack of any high-quality data to support its use. Several websites and forums have suggested that progesterone may enhance breast development and areolar darkening based on anecdotal reports. A population-based survey of more than 100 transgender women living in New York City revealed that 17% of transgender women were taking progesterone.[60] The Endocrine Society guidelines do not make a recommendation for the use of progesterone as part of a gender-affirming hormone regimen. The Guidelines for the Primary and Gender-Affirming Care of Transgender and Gender Nonbinary People by the University of California–San Francisco (UCSF) Center of Excellence for Transgender Health mention the use of progesterone as a treatment option, with the caveat that there are limited high-quality data supporting its effectiveness.[61] Concerns raised about the use of progesterone include data from cisgender postmenopausal women indicating increased risk of stroke when progesterone is taken in combination with conjugated estrogens.[62] There currently is insufficient evidence to support the use of progesterone for transgender women. Physicians and other clinicians should discuss the known risks of progesterone with transgender women who ask for progesterone therapy and make a shared decision of whether a trial of progesterone is indicated.

Transmasculine Hormone Therapy

The main hormone used for transgender men for gender-affirming therapy is testosterone. Testosterone esters (cypionate or enanthate) can be given intramuscularly every 1 to 2 weeks or subcutaneously weekly[63] (see Table 21.5). In a small retrospective study of 22 transgender men who received both intramuscular and subcutaneous testosterone at some point during their gender transition, all preferred testosterone administration subcutaneously.[63] Testosterone undecanoate is a longer-acting testosterone that can be given by intramuscular injection every 12 weeks and is also well tolerated among transgender men as reported by a prospective study of 17 transgender men in Europe.[64] Transdermal preparations of testosterone as gels or patches are also an option for treatment of transgender men. In Europe, but not in the United States, testosterone is available orally as testosterone undecanoate, which is becoming less commonly prescribed because of its short half-life, which requires dosing three to four times daily.

The goal of the testosterone therapy is to reach serum testosterone concentrations in the range expected for cisgender men and to induce male secondary sex characteristics, including increased body and facial hair, deeper voice, increased muscle mass, and cessation of menses (see Table 21.6). Testosterone will also reduce (but not completely eliminate) the gender dysphoria, as the physical changes will better align with the patient's gender identity.

TABLE 21.7 Endocrine Society Recommendations for Physical Examination and Laboratory Monitoring in Transgender Men

1. Evaluate patient every 3 months in the first year and then one to two times per year to monitor for appropriate signs of virilization and for development of adverse reactions.
2. Measure serum testosterone every 3 months until levels are in the normal physiologic male range[a]:
   a. For testosterone enanthate/cypionate injections, the testosterone level should be measured midway between injections. The target level is 400–700 ng/dL to 400 ng/dL. Alternatively, measure peak and trough levels to ensure levels remain in the normal male range.
   b. For parenteral testosterone undecanoate, testosterone should be measured just before the following injection. If the level is <400 ng/dL, adjust dosing interval.
   c. For transdermal testosterone, the testosterone level can be measured no sooner than after 1 week of daily application (at least 2 hours after application).
3. Measure hematocrit or hemoglobin at baseline and every 3 months for the first year and then one to two times a year. Monitor weight, blood pressure, and lipids at regular intervals.
4. Screening for osteoporosis should be conducted in those who stop testosterone treatment, are not compliant with hormone therapy, or who develop risks for bone loss.
5. If cervical tissue is present, monitor as recommended by the American College of Obstetricians and Gynecologists.
6. Ovariectomy can be considered after completion of hormone transition.
7. Conduct subareolar and periareolar annual breast examinations if mastectomy is performed. If mastectomy is not performed, then consider mammograms as recommended by the American Cancer Society.

Potential Adverse Effects of Gender-Affirming Sex Hormones in Transgender Adults

In general, gender-affirming hormone therapy is safe when prescribed under medical supervision with monitoring of circulating hormone levels to ensure that these values remain in the physiologic range (Table 21.7; see also Table 21.6).[40] However, there have not been any head-to-head studies on which hormone preparations are the safest to use in this population, and increased risks of several conditions associated with gender-affirming hormone therapy have been identified and should be considered.

Potential Risks Associated With Transfeminine Hormone Therapy

Venous Thrombosis and Pulmonary Embolism

Thromboembolism is the most well-studied and most serious complication resulting from transfeminine hormone therapy, primarily from estrogen. Earliest reports found a 45-fold increase in the expected incidence of venous thrombosis and/or pulmonary embolism in Dutch transgender women taking primarily ethinyl

estradiol and cyproterone acetate.[44] After changing the route from oral to transdermal estrogen in transgender women above the age of 40, the risks of thromboembolism declined to 20-fold.[45] A more recent review of 10 cohort studies based in Europe and Canada found a low incidence of thromboembolism in transgender women on oral estradiol in the range of 2 to 4 mg daily or transdermal estradiol 0.1 to 0.2 mg/day.[65] A cohort study from Austria found no thromboembolic events in 162 transgender women followed for a mean of 5 years exclusively treated with transdermal estradiol, cyproterone acetate, and finasteride, suggesting improved safety with transdermal formulations of estrogen. In a systematic review of 23 studies, representing 3231 subjects, venous thromboembolism was found in 56 subjects and had a prevalence between 0% and 5% in the individual studies.[66] The study subjects ranged between 19 and 44 years of age and were followed between 3 months and 41 years. In a European cohort of 214 transgender women, the cases of venous thromboembolism before and after gender-affirming hormone therapy increased from 9.2 cases to 60.7 cases per 1000.[66] In a large cohort based in the United States of more than 7000 transgender women followed in a managed health care system, the rates of venous thromboembolism increased starting after 5 years following the initiation of estrogen therapy compared to a reference group of cisgender men and women.[67]

Estrogen is likely the cause for the increased incidence of thromboembolism given its known mechanism for promoting prothrombotic factors and given evidence from clinical trials of cisgender women on estrogen therapy. However, there are other factors that increase the risk of thromboembolism in transgender women, including the formulation of estrogen, the route of administration, postoperative state (especially following gender-affirming surgery), and age.[65] The ES guidelines recommend the use of estrogen compounds that can be measured in blood and against synthetic or conjugated estrogens, which make monitoring blood levels difficult.[22] Transgender women should hold their estrogen therapy for a period of time prior to gender-affirming surgery, typically 2 to 3 weeks.[65]

Myocardial Infarction and Cerebrovascular Accidents

Most cohort studies in transgender women show low rates of myocardial infarction (MI) or cerebrovascular accidents (CVA). In the Maraka et al systematic review,[66] they found only 14 MIs and 8 CVAs among 3231 subjects. However, in the European ENIGI cohort,[67] the cases of MI and CVA found in transgender women initiating on gender-affirming hormone therapy increased from 4.7 to 18.7 and 23.4 per 1000, respectively. In a cohort of over 7000 transgender women followed in the United States, the risks of CVA appear to increase after 7 years following the initiation of hormone therapy, while in contrast, there does not appear to be an increase in MI compared to cisgender women and men. The ES guidelines recommend that clinicians evaluate for risk of cardiovascular disease, but there are no current recommendations on prevention or treatment in transgender women who have risk factors.[22]

Hypertriglyceridemia

In a systematic review of 29 studies, gender-affirming hormone therapy with estrogen in transgender women was associated with increased levels of triglycerides by 31.9 mg/dL (95% CI, 3.9–59.9) at 24 months with no significant increase in low-density lipoprotein (LDL) or HDL cholesterol for up to 24 months. In transfeminine youth, no changes in triglycerides but an increase in HDL cholesterol were seen after 24 months.[68] In another study of transfeminine youth, there were no changes seen in lipids after treatment for up to 35 months.[37] It is not known whether the changes in triglycerides seen in adult transgender women are clinically meaningful and/or result in an increased risk of cardiovascular disease in the long term.

Hyperprolactinemia

Early reports of prolactinomas occurring in transgender women and animal studies suggesting that estrogen may induce the growth of lactotroph cells prompted the Endocrine Society to recommend screening for hyperprolactinemia in transgender women.[69,70] However, in the majority of these cases, the transgender women were also taking the antiandrogen cyproterone acetate. Defreyne et al demonstrated that prolactin levels declined significantly after discontinuation of cyproterone acetate therapy following orchiectomy.[53] Furthermore, in a study conducted in Canada, transgender women who were prescribed cyproterone acetate had much higher increases in prolactin compared to transgender women prescribed spironolactone as the antiandrogen drug.[71] These studies suggest that cyproterone has a more stimulatory impact on prolactin secretion than estrogen. In fact, a recent study in the United States, where transgender women were treated with estrogen and spironolactone, demonstrated no significant rise in prolactin concentrations.[54]

Osteoporosis

Adequate estrogen therapy is protective against bone loss in transgender women. In an early study of 20 transgender women, lower luteinizing hormone (LH) and follicle-stimulating hormone (FSH) concentrations (markers of estrogen adequacy) were associated with a lower rate of decline in bone mineral density at the lumbar spine.[72] In a cohort of 231 transgender women, 1 year of gender-affirming hormone therapy resulted in a significant increase in BMD at the lumbar spine and hip.[73] A recent systematic review of 13 studies representing 392 transgender women found that gender-affirming hormone therapy was associated with increased lumbar BMD at 12 and 24 months.[74] However, despite the positive effects of gender-affirming hormone therapy on bone density, transgender women have been reported to have lower expected BMD prior to the initiation of hormone therapy.[75] Therefore BMD screening may be indicated in those transgender women who have risk factors for osteoporosis as recommended by the Endocrine Society.[22]

Breast Cancer

Transgender women have been reported to develop breast cancer in a few case series, raising the concern that gender-affirming hormone therapy may be associated with increased risk of breast cancer.[76] Data from the North American Association of Central Cancer Registries (NAACCR) report increased proportional incidence ratios (PIR) of breast cancer compared to cisgender men (PIR 20.7: 95% CI, 15.0–27.9) but lower PIR of breast cancer compared to cisgender women (PIR 0.2: 95% CI, 0.1–0.2). Similarly, in a large cohort of US transgender women followed at Kaiser Permanente, the risk of breast cancer was increased compared to cisgender men but the same as compared to cisgender women.[77]

Liver Dysfunction

Early reports from Dutch transgender women found elevations in liver enzymes in 10% (88 of 816) of the cohort initiated on gender-affirming hormone therapy. However, a third of these cases

were related to hepatitis B infection and alcohol, and another quarter were only transient elevations lasting less than 6 months. The Endocrine Society initially recommended routine measurement of liver enzymes in transgender women, but subsequent reports showed that most changes in liver function due to gender-affirming hormone therapy were transient and did not result in any permanent liver abnormalities. Thus the recommendation for routine monitoring of liver enzymes was removed in the 2017 guidelines update.[22,37,78,79]

Potential Risks Associated With Transmasculine Hormone Therapy

Erythrocytosis

Gender-affirming therapy with testosterone in transgender men is commonly associated with increases in red blood cell mass and hematocrit due to stimulation of erythropoietin.[80] Several cohort studies of transgender men report significant increases in hemoglobin and hematocrit, but very few studies have demonstrated serious consequences from these increases.[81–83] The ES guidelines recommend maintaining hematocrit below 55% to avoid adverse events rising from increased red cell mass.[22] Some clinics have advocated reduction of red cell mass with phlebotomy, but there are no trials examining this approach in terms of improving safety.[50]

Hyperlipidemia

A recent systematic review found that testosterone therapy in transgender men results in lowered HDL cholesterol, higher LDL cholesterol, and higher triglycerides.[30] In transgender boys, testosterone therapy also results in lowered HDL cholesterol and higher triglycerides over a period of 2 years.[34] However, there are insufficient data to determine if this adverse pattern of lipids results in long-term cardiovascular events. Data from a cohort of transmasculine adults indicate that the risks of MI are not increased.[67] Routine pharmacologic therapy to improve lipid parameters is not indicated given the available evidence in low-risk individuals.

Uterine and Cervical Cancer

The risk of cancers of the reproductive tract in transgender men appears to be comparable to the risk of cisgender women; therefore, the ES guidelines recommend screening based on remaining organs as recommended for the general population. Among transmasculine adults receiving care in the Kaiser Permanente system in the United States, the risk of cervical cancer was not increased compared to matched cisgender women.[77] There were no cases of uterine cancer reported.

Barriers to Care and Priorities for Research for Transgender Youth and Adults

While there have been significant advances in our understanding and management of transgender youth and adults, many questions remain. There are limited efficacy and safety data regarding current treatment models, with minimal available data regarding the use of GnRH agonists in gender-nonconforming youth younger than 12 years of age, of gender-affirming sex hormones in adolescents younger than 16 years of age, and long-term risks (>10 years) on cardiovascular disease and cancer. Questions also arise regarding the dose and choice of hormone therapy in elderly transgender adults. Furthermore, GnRH agonists and gender-affirming sex hormones are off-label for GI/GD youth and adults, can be expensive (GnRH agonists and transdermal preparations of hormones, in particular), and are often denied by insurance companies. In addition, while new clinical programs for the care of gender-incongruent youth have emerged in many parts of the world in recent years, there are still relatively few such programs, and patients are often required to travel long distances to receive care. Gender-affirming surgical procedures are only performed at a few centers and are often not a covered benefit under insurance. The success and long-term complication rates of these procedures are not known. Finally, formal training for medical providers is not universally available, and there is often prejudice and misunderstanding. Further training and further prospective studies focused on long-term safety and efficacy are needed to optimize health care for transgender youth and adults.

Endocrine Changes in Pregnancy

JOSHUA F. NITSCHE, GLENN D. BRAUNSTEIN, AND SARAH L. BERGA

CHAPTER OUTLINE

KEY POINTS

- The impact of pregnancy on the endocrine system is profound and begins with very early production of human chorionic gonadotropin from the trophoblast occurring at implantation.
- Changes in maternal metabolism during pregnancy prioritize fetal growth, including hyperinsulinemia, insulin resistance, increased plasma lipids, and more efficient plasma amino acid transport.
- Increased maternal adipose stores account for a small fraction of maternal weight gain during pregnancy.
- Pharmacokinetics and pharmacodynamics of many medications change during pregnancy due to increased glomerular filtration rates and blood volume.
- The cardiac demand of pregnancy may cause hemodynamic destabilization in women with preexisting heart disease.
- Placental sex is the same as fetal sex, and sex differences in placental responses to exposures translate into sex differences in the developmental origins of adult disease.
- Universal transplacental bidirectional trafficking of maternal, placental, and fetal cells and deoxyribonucleic acid (DNA) occurs. Detecting cell-free fetal DNA in maternal circulation enables noninvasive screening for fetal aneuploidy and other conditions. Persistent postpartum microchimerism has been linked to autoimmune endocrinopathies in later life in both mother and offspring.

Placental Development

Normal placentation requires a coordinated series of events beginning with fertilization. The fertilization rate following unprotected regular intercourse during a single menstrual cycle is 25% to 30%. However, in approximately one-third of conceptions there is either failure of implantation or clinical or subclinical spontaneous abortion.[1]

For the first 5 days, preimplantation development takes place within the fallopian tube. During this period, the zygote undergoes cleavage division and, at least through the eight-cell stage, the blastomeres remain totipotential. In the 16-cell stage, differentiation of the innermost cells into the *inner cell mass* and the surrounding cells into the *trophectoderm* occurs. The inner cell mass develops into the fetus, and the trophectoderm gives rise to the placenta and membranes. On approximately day 5 or 6 after fertilization, the blastocyst enters the uterus, but implantation does not occur for another 1 to 2 days. Implantation occurs after the zona pellucida disappears from around the embryo.[2]

Recent developments in embryo culture during in vitro fertilization (IVF) have allowed embryos to mature to the blastocyst stage, which in turn allows biopsy of the trophectoderm. The trophectoderm cells are then tested for euploidy or aneuploidy and, if a suitable probe is available, single gene disorders.[3]

Implantation is a complex process that involves apposition of the microvilli present on the trophectoderm cells with pinocytes (fused microvilli) on the endometrial cells, followed by removal of fluid between the cells through pinocytosis by the endometrial cells, a process stimulated by progesterone.[4] Progesterone synthesis by the corpus luteum is stimulated and sustained during this time and for the first 6 to 7 weeks of pregnancy by secretion of human chorionic gonadotropin (hCG) by the trophoblast cells. The hCG is first detected in the maternal serum 6 to 9 days after conception.[5] Embryo attachment is enhanced through the expression of a variety of adhesion molecules, including mucins, integrins, and trophinin, a trophoblast-specific cell membrane adhesion protein, as well as cytokines, growth factors, and a variety of transcription factors encoded by homeobox genes.[4,6]

After the trophoblast attaches to the endometrium during the "window of implantation" 6 to 10 days postovulation, the embryo invades the endometrium through a complex process involving matrix metalloproteinases and differentiation of the trophectoderm into *cytotrophoblasts* or *syncytiotrophoblasts*. The syncytiotrophoblasts are multinucleated cells formed by the fusion of cytotrophoblasts. The cytotrophoblasts form a column of cells that invade the endometrium, form anchoring villi, and enter the maternal vasculature, eventually replacing the endothelial layer of the endometrial and myometrial spiral arterioles with a layer of cytotrophoblasts (vascular trophoblasts).[7] This process converts the high-resistance, low-capacity uterine vessels into low-resistance, high-volume vessels, essential for growth of the placenta and fetus.[8] At the site of implantation, the endometrial cells undergo decidualization, enlarging and increasing their metabolic activity with enhanced production of tissue inhibitors or metalloproteinase, extracellular matrix proteins, cytokines, and growth factors that modulate the extent of trophoblast invasion and influence trophoblast function.[4,5,9]

The trophoblast cells secrete several angiogenic proteins, including vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), and basic fibroblast growth factor (bFGF), which stimulate blood vessel development within the villi.[10] The syncytiotrophoblasts form an outer layer of cells in the chorionic villi, between the cytotrophoblast cells and the maternal blood space on the exterior surface. Only three tissues separate fetal blood from maternal blood: (1) the endothelium of the fetal vessels in the villi, (2) connective tissue, and (3) the trophoblasts; this form of placentation is referred to as *hemochorial*. Thus in addition to hCG secretion, which is responsible for maintaining early pregnancy, progesterone secretion, required for continuation of pregnancy after the luteal-placental shift, and the synthesis and secretion of other hormones and growth factors (Table 22.1), the syncytiotrophoblasts provide the major site for transportation of oxygen and nutrients to and removal of waste from the fetus.

Substances are transferred across the placenta through transcellular pathways that include carrier-mediated transport (e.g., immunoglobulin G through the Fcγ receptor) and simple extracellular diffusion. The degree of transplacental passage of a hormone from the mother to the fetus through diffusion depends on (1) the rate of placental blood flow; (2) the maternal concentration of the free or readily dissociable hormone; and (3) the molecular mass, lipid solubility, charge, and degree of placental metabolic degradation of the hormone. Maternal-to-fetal transfer occurs for hormones smaller than 700 Da, but the placenta is not permeable to hormones larger than 1200 Da.[11]

The trophoblast also anchors the placenta and fetus to the uterus and helps to protect the fetus, which contains paternal antigens, from rejection by the maternal immune system. This immunologic protection may be mediated by high concentrations of progesterone at the trophoblast-maternal interface and the expression by the trophoblasts of a histocompatibility complex antigen, human leukocyte antigen G (HLA-G), which exhibits reduced polymorphism in comparison with other major HLA antigens.[12] The mass of the trophoblast increases logarithmically during the first trimester, followed by a more gradual increase throughout the remainder of pregnancy. Trophoblastic mass closely correlates with maternal serum concentrations of human placental lactogen (hPL) and pregnancy-specific β_1-glycoprotein throughout pregnancy and with hCG during the first trimester but not during the subsequent trimesters.[13]

TABLE 22.1 Placental Products

Hypothalamic Analogs
Gonadotropin-releasing hormones
Corticotropin-releasing hormone
Urocortin
Somatostatin
Growth hormone–releasing hormone
Ghrelin
Thyrotropin-releasing hormone
Dopamine
Neuropeptide Y
Enkephalin
Pituitary Analogs
Chorionic gonadotropin
Placental lactogen
Chorionic corticotropin
β-endorphin
α-Melanocyte-stimulating hormone
Placental variant growth hormone
Oxytocin
Steroid Hormones
Estrogens (estriol, estradiol, estetrol)
Pregnenolone
Progesterone
Other
Activins
Inhibins
Follistatin
Relaxin
Calcitonin
Leptin
Parathyroid hormone–related protein
Erythropoietin
Renin
Interleukins
Nitric oxide
Transforming growth factor β
Tumor necrosis factor α
Epidermal growth factor
Insulin-like growth factor type 1
Insulin-like growth factor type 2
Insulin-like growth factor binding protein 1
Colony-stimulating factor 1
Basic fibroblast growth factor
Corticotropin-releasing hormone-binding protein
Platelet-derived growth factor
Vascular endothelial growth factor
Endothelin 1
Anandamide (endocannabinoid)
Hepatocyte growth factor
Oncomodulin

Sex Differences in the Placenta

There is now a substantial body of literature describing physiologic differences between men and women and how these differences impact numerous acute and chronic conditions and diseases. Some of these sex differences, such as differences in life

span and differential risk for and outcomes related to chronic conditions such as cardiovascular and cerebrovascular disease, have been recognized for decades. Ongoing investigations have revealed a burgeoning list, suggesting that sex differences are the norm rather than the exception. There are sex differences in frequency and manner of presentation as well as in pathophysiology and pharmacology. Examples of diseases and conditions that demonstrate sex differences include systemic lupus erythematosus, thyroid disease, osteoporosis, diabetes mellitus, Alzheimer disease, and schizophrenia. Differences may be strictly biologic (sex) or due to sociocultural disparities (gender) interacting with biologic predilections.[14] For example, women are at an increased risk of systemic lupus erythematosus, thyroid disease, and osteoporosis; men are at increased risk of cardiovascular disease and schizophrenia. There are also sex differences in responses to acute insults such as trauma, sepsis, and surgery, with women often responding more favorably than men.[14–19]

Two important determinants of pathophysiology of the conditions and diseases are sex and age. We now recognize that sex differences begin during fetal and early neonatal life.[20–25] Thus sex differences interact with aging from conception. The epidemiology surrounding the impact of these very early events is often referred to as the *developmental origins of health and disease* (DOHAD) or *fetal origins of adult disease* (FOAD). Sex differences in the fundamental processes mediating embryogenesis and intrauterine fetal development are just beginning to be understood. Insults during intrauterine life such as natural disasters, death of a family member, and severe maternal anxiety or depression are associated with an increased risk of neurodevelopmental disorders (depression, anxiety, schizophrenia, and autism) in the offspring.[26] A classic epidemiologic example is the famine produced by the invasion of the Netherlands in 1940.[27] Women in their second trimester during this time had male but not female offspring with an increased risk of schizophrenia as adults. In most cases female offspring are more resilient and male offspring more susceptible to the negative effects of gestational insults. Recent data suggest that sex differences in developmental risk are mediated by sex differences in the placental response to common exposures and stressors. It is often not appreciated that because the placenta derives from the same cell mass as the embryo that the placenta has a sex. However, the placenta does not have a gender because gender refers to sociocultural constructs and behaviors related to sex-related expectations and stereotypes.

Sex chromosomes and gonadal steroids are thought to play a large role in mediating sex differences in placental and fetal responses to exposures.[28] Total and free testosterone levels are higher in male fetuses as expected; however, so are levels of the female sex hormone estradiol.[29] However, testosterone is a more potent inhibitor of cytokine production in explants from female compared to male placentas, suggesting female fetuses may be more sensitive to the effects of testosterone than male fetuses.[28] Indeed, sex-specific hormone action may be the norm and not just confined to sex steroids.

In addition to global sex differences described earlier, evidence is accumulating that epigenetic modifications also play a role in gating differential sensitivity between the sexes to common exposures. At baseline, female placentas demonstrate increased expression of immune-regulating genes (*JAK1, IL2RB, Clusterin, LTBP, CXCL1,* and *ILR1L1*), while in males, placental genes reported to mediate graft versus host disease and inflammation (*HLA-DQB1, HLA-DOA1, HCP5, NOS1, FSTL3*, among others) are more highly expressed.[30] Overall the sex differences in physiology appear to produce a less reactive female and more reactive male placental phenotype. This would better equip female placentas to buffer the embryo from insults during critical periods of development. The protection provided by a female placenta is in keeping with the long-known improved mortality and morbidity due to prematurity in female compared to male neonates.[31–33]

Although sex differences in gene expression profiles that drive placental structure and function are now well described, epigenetic changes also play a role. Studies using the established mouse model of early prenatal stress have identified DNA methyltransferases (DNMT)[34] and O-linked N-acetylglucosamine transferase (OGT)[35,36] as top candidates for primary roles in the epigenetic changes. A major function of OGT is to stabilize enhancer of zeste homolog 2 (EZH2), a histone H3K27 methyltransferase that leads to global repression of transcription. As OGT is X-linked and escapes X inactivation in the placenta, levels are twice as high in the female placenta.[35,36] The lower levels of OGT in males would lead to a globally reactive phenotype in the placenta. More targeted regulation of expression may be mediated through DNMT1, which, in conjunction with the methyl-binding protein MeCP2, results in DNA methylation and repression of specific genes. DNMT1 is more highly expressed at baseline in the female placenta and is further increased with maternal stress in female but not in male placentas.[34] Again this would further contribute to a reactive male placental phenotype that could leave male fetuses at greater risk of complications from maternal stress.

Maternal Adaptations to Pregnancy

To some extent, every maternal organ system is altered in pregnancy. The impact of pregnancy on the endocrine system is profound and begins very early with the production of hCG from the trophoblast at implantation. The effects on many other organ systems are more gradual and may not appear until later in pregnancy. While the vast majority of these changes are hormonally mediated, some organ systems are also affected by the anatomic alterations caused by the enlarging uterus or the physiologic increase in maternal blood volume. It is critically important for the clinician to understand these changes when caring for pregnant women, as many physical exam findings, laboratory values, and imaging findings that would be viewed as abnormal and of great concern outside of pregnancy can be normal and reassuring in pregnant women.

Physiologic Adaptations

During pregnancy some amount of weight gain is expected, with overweight and obese women expected to gain less than normal or underweight women. Excessive gestational weight gain has been associated with a number of adverse neonatal[37,38] and maternal outcomes.[39–43] Given this association and the increasing prevalence of obesity among women of childbearing age, the Institute of Medicine (IOM) recommended an updated set of guidelines regarding weight gain in pregnancy based on the woman's prepregnancy body mass index[44] (Table 22.2).

In recent years many experts and medical professional organizations with a stake in the obesity epidemic have proposed further subdividing obesity (body mass index [BMI] >30) into class I (BMI 30–34), class II (BMI 35–39), and class III (BMI ≥40).[45] The IOM guidelines did not further refine their recommendations for weight gain based on level of obesity, citing a lack of evidence regarding proper weight gain in women with very high BMI. While this more specific classification system is helpful for

TABLE 22.2 Weight Gain During Pregnancy

	TOTAL WEIGHT GAIN		RATES OF WEIGHT GAIN SECOND AND THIRD TRIMESTERS	
Pre-pregnancy BMI	Range in kg	Range in lb	Mean (range) in kg/week	Mean (range) in lb/week
Underweight (<18.5 kg/m^2)	12.5–18	28–40	0.51 (0.44–0.58)	1 (1–1.3)
Normal weight (18.5–24.9 kg/m^2)	11.5–16	25–35	0.42 (0.35–0.50)	1 (0.8–1)
Overweight (25–29.9 kg/m^2)	7–11.5	15–25	0.28 (0.23–0.33)	0.6 (0.5–0.7)
Obese (≥30 kg/m^2)	5–9	11–20	0.22 (0.17–0.27)	0.5 (0.4–0.6)

consistency in categorizing patients for epidemiologic or clinical studies, it is not clinically meaningful as the impact of obesity on maternal health has a much more linear relationship than the abrupt classification system would suggest. As with the BMI classification schema proposed by the IOM, the subclassification of obesity also groups large numbers of patients into the high end of the scale (i.e., class III). Such patients are often encountered in current clinical practice as the prevalence of women of childbearing age with BMI over 40 is approximately 7.5% overall and as high as 15% among certain ethnic groups.[46]

It is important to remember that only a small portion of the recommended weight gain is due to an increase in maternal adipose stores. For example, in a normal weight woman with a weight gain of 12.5 kg, 9.25 kg are due to factors other than maternal adipose stores (fetus accounts for about 3.4 kg, placenta for 0.65 kg, amniotic fluid for 0.8 kg, uterus for 1 kg, breasts for 0.4 kg, blood for 1.5 kg, extravascular fluid for 1.5 kg).[14] Thus only 3.25 kg is due to the increase in maternal adipose stores. If one considers the weight gain goal for overweight and obese women (5–9 kg) and assumes that most will be expected to gain 9.25 kg of nonadipose weight during pregnancy, there should be a negligible increase and potentially a decrease in adipose stores in these women if IOM guidelines are followed.

The volume of the uterine cavity increases from 10 mL in the nonpregnant state to an average of 5 L at term, and blood flow through the uteroplacental circulation reaches 450 to 650 mL/minute, approximately a 10-fold increase.[47] To maintain appropriate perfusion of the mother and the fetal-placental unit, systemic blood volume increases throughout pregnancy and is 40% to 45% higher at term than in the nonpregnant state. The plasma volume increases by about 45% to 50% as a result of aldosterone-stimulated sodium and water retention. The red cell mass increases approximately 20% because of increased production, resulting from a twofold to threefold increase in erythropoietin secretion. The net effect is a physiologic decrease in the hematocrit by about 15% at term.[47]

The increase in uterine blood flow, while essential to maintain the fetus and placenta during pregnancy, carries a risk of severe hemorrhage surrounding delivery. Laceration of a vessel during a vaginal delivery can lead to heavy bleeding due to the high rate of blood flow to the uterus, cervix, and vagina. Bleeding can be life threatening if it tracks into the retroperitoneum where a large amount of blood can accumulate before symptoms prompt an evaluation and confirmation of the diagnosis. Damage to a branch of the uterine artery during a cesarean section can lead to bleeding rapid enough to require intraoperative blood transfusion to replace ongoing blood loss. For these reasons, elective operations are typically avoided in the third trimester. Fortunately, there are also maternal adaptations that lessen the potential impact of these and more typical amounts of blood loss. The physiologic drop in hematocrit during pregnancy leads to less red cell mass lost per a given volume of blood. This allows women to maintain oxygen-carrying capacity after volumes of blood loss that would lead to advanced stages of shock in nonpregnant individuals.[48]

The renal blood flow and glomerular filtration rate (GFR) increase rapidly and peak during the second trimester, and a 50% increase in creatinine clearance results in a reduction in the serum creatinine level. Atrial natriuretic peptide (ANP) levels increase during pregnancy and may be in part responsible for increased renal blood flow, GFR, 24-hour urine volume, and natriuresis.[49] An alteration in the osmotic thresholds for the release of vasopressin and activation of the hypothalamic thirst centers, possibly caused by an extragonadal effect of hCG, lead to an approximately 4% reduction in serum osmolality (~10 mOsm/kg).[50]

It is important to consider the increase in GFR and blood volume when treating women with medications that are cleared in the kidney. Many medications, both prescription and over the counter, are cleared in this way, including aminoglycosides, β-lactams, antiviral agents, antifungal agents, histamine (H_1 and H_2) blockers, among others. Some of these medications require dose adjustments due to increased GFR of pregnancy. Adjustments in dose are particularly relevant for antiepileptic drugs, the plasma levels of which can become subtherapeutic if not monitored and steadily increased over the course of pregnancy. Although all the reasons for the increased drug requirement in pregnancy are unclear, it is likely that the increase in the volume of distribution is a contributing factor.[51] This is also true of low-molecular-weight heparins, a preferred anticoagulant in pregnancy. Although only a small portion of the drug is cleared in the kidney, the increased GFR of pregnancy is thought to contribute to the much larger doses required in pregnant women to maintain effectiveness.[52]

Several hemodynamic changes are induced by the low-resistance, high-capacity uteroplacental vasculature, which, in many respects, acts like an arteriovenous shunt. The large quantities of estrogens, progesterone, prostaglandins, and angiotensin present during pregnancy are thought to mediate these changes. Other changes include an increase in the heart rate by 10 to 15 beats/minute, a 30% to 50% increase in cardiac output, resulting from increased stroke volume in early pregnancy and heart rate during the third trimester, a reduction in diastolic blood pressure of 10 to 15 mm Hg with little or no change in systolic pressure, and an approximately 20% reduction in peripheral vascular resistance.[47]

While these increases in cardiac demand are easily met by most pregnant women, for some, particularly those with preexisting

coronary artery or structural heart disease, the added strain can threaten the health of both mother and baby. Although women with a history of myocardial infarction (MI) with normal left ventricular function tolerate pregnancy well, women with poor hemodynamics with significant left ventricular injury are discouraged from attempting pregnancy as maternal morbidity and mortality are markedly increased.[53] In women with structural heart disease, particularly Eisenmenger syndrome, the increase in cardiac output and blood volume can overwhelm an already impaired heart leading to arrhythmia, congestive heart failure, pregnancy loss, and maternal death.[54]

In pregnancy the pulmonary vascular resistance is reduced by about one-third, and pulmonary tidal volume increases by about 30%. The latter, which results in a respiratory alkalosis that is compensated by increased bicarbonate excretion by the kidneys, increases in minute ventilatory volume by 30% to 40%. There are no changes in respiratory rate, maximum breathing capacity, or forced or timed vital capacity. However, there is an approximately 40% reduction in the expiratory reserve because of the elevation of the diaphragm by the enlarged uterus.[47]

While these changes do not increase the risk of pregnant women contracting respiratory infections such as influenza and bacterial pneumonia, their morbidity and mortality are notably increased during pregnancy. This was most recently noted in the 2009 H1N1 pandemic, in which pregnant women accounted for 5% of the deaths but made up only 1% of the population.[55] Pregnant women were also more likely to be hospitalized with pneumonia,[56] but they did not appear to be at an increased risk of infection compared to the general population.[57]

Gastrointestinal tract function is altered during pregnancy. Gastric emptying time is unchanged until labor, when it becomes prolonged. Reduced lower esophageal sphincter tone and displacement of the abdominal contents by the pregnant uterus result in a marked increase in gastroesophageal reflux. Motility of the intestine is also reduced, contributing to nausea and vomiting early in pregnancy and constipation that is common later in pregnancy. Decreased motility of the gallbladder leads to an increased gallbladder volume and reduced emptying of bile after meals, producing a more lithogenic bile and increasing cholelithiasis risk during pregnancy.[47]

Metabolic Adaptations

Numerous changes in maternal metabolism occur in pregnancy to ensure that the fetus has a consistent supply of metabolic fuel during in utero development. These changes include hyperinsulinemia, insulin resistance, increased plasma lipids, and more efficient plasma amino acid transport.[58] As a result of these alterations, maternal energy requirements are met predominately by lipolysis, allowing glucose and other carbohydrates to supply the energy needs of the fetus. This shift in maternal fuel utilization can be conceptualized as an accelerated starvation. Although carbohydrates are readily available in the maternal circulation, insulin resistance reduces entry of glucose into maternal cells, thereby limiting her use of carbohydrates for energy. To compensate, maternal cells turn toward lipid metabolism for energy-producing levels of ketones similar to that seen after prolonged fasting.[59] The increased maternal low-density lipoprotein (LDL) and very low-density lipoprotein (VLDL) that occur in pregnancy[60,61] are also thought to be the main cholesterol supply for steroid hormone production in the placenta, as the placenta has very low hydroxymethylglutaryl–coenzyme A (HMG-CoA) reductase activity and thus limited ability to produce cholesterol from acetate in situ.[62]

The underlying causes of the shift in metabolic fuels during pregnancy are largely understood, but significant gaps in knowledge persist. It is clear that the increasing levels of hPL and human placental growth hormone (hPGH) reduce insulin receptors and glucose transport.[63] However, to what extent glucagon and cortisol, which demonstrate strong diabetogenic effects outside of pregnancy, play a role in this process has not been thoroughly investigated.

Maternal Endocrine Alterations

Pituitary Gland

The anterior pituitary gland enlarges by an average of 36% during pregnancy, primarily because of a 10-fold increase in lactotroph size and number. This enlargement increases the height and convexity of the pituitary that is observed on magnetic resonance imaging (MRI). Somatotroph and gonadotroph numbers are reduced, and there are no changes in corticotroph or thyrotroph numbers.[64] The size of the posterior pituitary gland diminishes during pregnancy.[65]

The marked increase in estrogen levels during pregnancy enhances prolactin synthesis and secretion, and maternal serum prolactin levels increase in parallel with the enlargement of the lactotrophs. At term, the mean serum prolactin concentration is 207 ng/mL (range, 35–600 ng/mL), in contrast to a mean of 10 ng/mL in nonpregnant, premenopausal women.[66] Prolactin also is present in the amniotic fluid and appears to be primarily of decidual origin because the decidua actively synthesizes prolactin. Amniotic fluid prolactin levels are 10 to 100 times higher than in the maternal circulation in early pregnancy. Serum prolactin levels return to the baseline of nonpregnancy approximately 7 days after delivery in the absence of breastfeeding. With breastfeeding, the basal prolactin levels remain elevated for several months but gradually decrease; however, with suckling, there is a brisk rise in prolactin levels within 30 minutes.[64]

Although rare, pituitary tumors do occur in women of childbearing age. While most are diagnosed prior to pregnancy, some are diagnosed for the first time in pregnancy. The most common type of tumor is a prolactinoma, which (as the name implies) is due to an overgrowth of lactotrophs. Prolactinomas, and other pituitary tumors, are typically classified based on size, with those less than 10 mm in diameter designated *microadenomas* and those greater than 10 mm in diameter designated *macroadenomas*. The increase in pituitary size during pregnancy can lead to complications in women with prolactinomas. In a study of 352 women with untreated microadenomas, 2.3% experienced visual disturbances, 4.8% experienced headache, and 0.6% experienced diabetes insipidus. The rates of complications were much higher in 144 women with macroadenomas, with 15.3% experiencing visual disturbances, 15.3% experiencing headache, and 2.14% experiencing diabetes insipidus.[67] In cases of symptomatic tumor expansion in pregnancy, the dopamine agonist bromocriptine can be safely used and is successful in reducing tumor size and symptoms in the majority of cases.[68] Cabergoline, a more selective dopamine 2 receptor agonist and the preferred treatment outside of pregnancy, also appears safe, but there is less experience with this drug in pregnancy. Transsphenoidal resection of the pituitary is occasionally needed if rapid tumor growth occurs or symptoms persist despite bromocriptine treatment.

Growth hormone (GH) levels in maternal serum remain unchanged throughout pregnancy, although the source of immunoreactive GH during gestation changes due to placental

production of the hormone. Relaxin, secreted by the corpus luteum of pregnancy, and estrogens stimulate GH secretion during early pregnancy.[69]

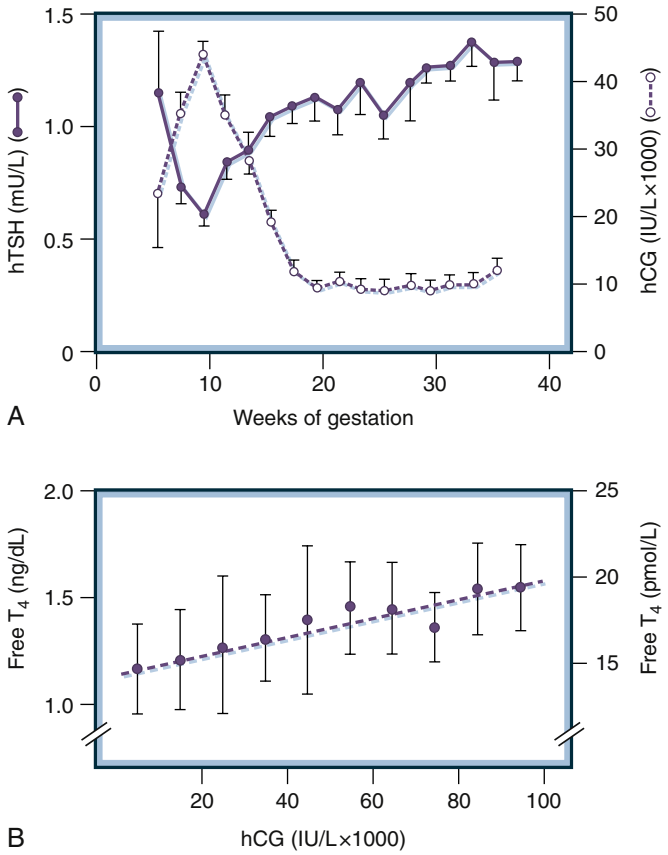
Pituitary GH is known as GH1 or hGH-N; its messenger ribonucleic acid (mRNA) and GH1 secretion decrease after week 25 of pregnancy, and beginning in the fourth month of gestation, the placental syncytiotrophoblasts secrete a variant of GH (called GH2 or hGH-V) in a nonpulsatile pattern. In concert with the different sources of GH during the first and second halves of pregnancy, the GH response to provocative stimuli differs in each half. Insulin hypoglycemia or arginine infusion results in an enhanced GH response during the first half of gestation, and during the second half the response is decreased compared with the response in nonpregnant women.[64]

Maternal serum concentrations of insulin-like growth factor type 1 (IGF1) are elevated during the second half of pregnancy, probably through the combined effect of the placental GH variant and hPL, which is evolutionarily related to GH and prolactin. hPL has somatotropic biologic activity, and its serum concentration increases throughout pregnancy, paralleling that of IGF1.[70] It is likely that the suppression of GH1 synthesis and secretion is caused by the high IGF1 concentrations, which in late pregnancy are five times higher than those in nonpregnant women.[71]

Although the placenta synthesizes and secretes biologically active gonadotropin-releasing hormone (GnRH), pituitary gonadotropin production decreases throughout pregnancy, as indicated by a marked reduction in gonadotropin immunoreactivity in the gonadotrophs beginning at 10 weeks of gestation and by a reduction in serum levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH).[64] Suppression is probably mediated through the elevated blood levels of ovarian and placental sex steroid hormones and by placental production of inhibin. Suppression is incomplete because administration of exogenous GnRH leads to release of gonadotropins, although the response is blunted compared with that of nonpregnant women and does not return to normal until a month after birth.[71]

The mean concentrations of human thyroid-stimulating hormone (thyrotropin or hTSH) during the first trimester are significantly lower than in the second and third trimesters or in the nonpregnant state.[72] Much of this early decrease may be accounted for by the intrinsic thyrotropic activity of hCG. The nadir in TSH in maternal serum corresponds to the peak concentration of hCG at 10 to 12 weeks after the last menstrual period, demonstrating a reciprocal relationship between the rising hCG levels and falling hTSH concentrations[72,73] (Fig. 22.1A). Higher hCG levels are associated with higher T4 levels (see Fig. 22.1B). Despite the lower mean hTSH during early pregnancy, the hTSH response to exogenous thyrotropin-releasing hormone (TRH) is normal.[64]

Maternal adrenocorticotropic hormone (ACTH, or corticotropin) levels rise during pregnancy, increasing fourfold over concentrations in the nonpregnant state between 7 and 10 weeks of gestation. There is a further gradual rise to weeks 33 to 37, when a mean 5-fold increase over prepregnancy values is found, followed by a 50% drop just before parturition and a marked 15-fold increase during the stress of delivery.[74] The ACTH concentration returns to the prepregnancy level within 24 hours of delivery. The pituitary gland and placenta are sources of circulating ACTH during pregnancy, and exogenous corticotropin-releasing hormone (CRH) stimulates the release of ACTH from both tissues in a dose-dependent manner.[47] Biologically active CRH is synthesized and secreted by the placenta and, to a lesser extent, by the decidual and fetal membranes, but unlike the inhibitory



• **Fig. 22.1** (A) Concentrations of serum thyrotropin (hTSH, *filled circles*) and human chorionic gonadotropin (hCG, *open circles*) throughout pregnancy. Between 8 and 14 weeks of gestation, there is a significant negative correlation between the individual hTSH and hCG levels (p <0.001). Each point represents the mean (± standard error). (B) Linear regression of maternal serum free thyroxine (T_4) and hCG concentrations during the first half of gestation (p <0.001). (From Glinoer D, de Nayer P, Bourdoux P, et al. Regulation of maternal thyroid during pregnancy. *J Clin Endocrinol Metab.* 1990;71:276–287.)

effect on pituitary CRH, glucocorticoids stimulate the expression of placental CRH.[75]

The relationship between CRH and ACTH is altered during pregnancy. Although biologically active CRH would be expected to stimulate ACTH production, the qualitative patterns of CRH production, which show an exponential rise during the sixth month of gestation, and ACTH secretion, which demonstrates a more gradual rise during pregnancy, are quite different. The lack of a significant correlation between maternal plasma CRH and ACTH during pregnancy suggests that factors such as the elevated levels of free cortisol in the maternal serum may modulate the response to CRH. The circadian rhythm and the ability to respond to stress are maintained throughout pregnancy; however, the ACTH response to exogenous CRH during the third trimester is blunted, whereas the responsiveness to vasopressin is maintained, suggesting that the elevation of CRH in the maternal serum downregulates the responsiveness to CRH.[74]

Arginine vasopressin (AVP) concentrations in the maternal serum are similar to those in nonpregnant women. During pregnancy, however, there is increased synthesis of AVP, which is offset by the increased metabolic clearance of the hormone through destruction by a trophoblast-derived cysteine aminopeptidase (i.e., vasopressinase), which rises throughout pregnancy in parallel

with the increase in trophoblastic mass.[76,77] The osmolar set-point for thirst is reduced, and the release of AVP is related to the 10-mOsm/kg average decrease in plasma osmolality during pregnancy, possibly reflecting an extragonadotropic effect of hCG.[48] Taking into account the reduced set-point, the AVP response to dehydration and water loading is normal.

Oxytocin levels progressively increase in the maternal blood and parallel the increase in maternal serum levels of estradiol and progesterone. The levels increase further with cervical dilation and vaginal distention during labor and delivery, stimulating contraction of the uterine smooth muscles and enhancing fetal expulsion.[78] Uterine oxytocin receptors also increase throughout pregnancy, resulting in a 100-fold increase in oxytocin binding at term in the myometrium.[79]

Thyroid Gland

The thyroid gland enlarges by an average of 18% during pregnancy.[72] Enlargement is associated with an increase in the size of the follicles with increased amounts of colloid and enhanced blood volume. This enlargement may be a response to the thyrotropic effect of hCG and asialo hCG, which may account for some of the increase in serum thyroglobulin concentrations observed during pregnancy. Although clinically contraindicated, experimental evidence suggests that enhanced iodine (^{131}I) uptake by the maternal thyroid gland reflects the combined effects of hCG stimulation and reduction of the blood levels of iodide by increased renal iodide clearance.[72]

Rising estrogen concentrations during pregnancy induce increased hepatic synthesis of thyroxine-binding globulin (TBG) and enhanced sialylation of TBG, which decreases its metabolic clearance rate.[73] The results are a twofold increase in TBG and increased total thyroxine (T_4) and triiodothyronine (T_3) levels in maternal serum throughout pregnancy,[73] whereas for most of the gestation, the free T_4 and free T_3 concentrations remain normal. There are no significant changes in the levels of thyroxine-binding prealbumin, but albumin levels are decreased because of the increase in vascular volume.

While hyperthyroidism is rather rare, hypothyroidism is relatively common in women of childbearing age. When managing a pregnancy complicated by hypothyroidism, it is important to note that the pregnant woman is the source of T_4 and T_3 for the fetus throughout the first trimester. As a result, the maternal thyroid hormone replacement requirements increase as early as the fifth week of gestation. Although requirements often plateau in the second trimester, they continue to increase well into the third trimester in many patients. Increased doses of thyroid hormone are needed in 50% to 85% of women, and the total dose may increase as much as 50%.[80,81] Thus in women with preexisting hypothyroidism, it is necessary to check thyroid function at the first prenatal visit to determine if additional thyroid hormone replacement is necessary. Alternatively, the dose can be empirically increased when pregnancy is confirmed prior to any laboratory assessment of thyroid function.[82] Intermittent monitoring throughout pregnancy is warranted every 4 to 8 weeks to make certain replacement remains adequate as gestation progresses. Routine screening for undiagnosed hypothyroidism in pregnancy is controversial and is not currently endorsed by the American Thyroid Association (ATA), American College of Obstetricians and Gynecologists (ACOG), or the Endocrine Society.[83–85] Instead, a targeted screening approach has been adopted based on risk factors such as family or personal history of thyroid disease, prior head or neck radiation, morbid obesity, or age greater than 30 years.

Parathyroid Glands

During pregnancy, approximately 30 g of calcium is transferred from the maternal compartment to the fetus, with most of the transfer occurring during the last trimester. Maternal total serum calcium levels decrease during pregnancy, with a nadir at 28 to 32 weeks related to the decrease in albumin levels that accompanies the increase in vascular volume. However, the albumin-adjusted total calcium and the ionized calcium concentrations actually rise slightly above this level in the nonpregnant state.[86] The urinary calcium excretion rate increases in parallel with the increased GFR, and intestinal calcium absorption undergoes a twofold increase.[86]

Although some studies have suggested that parathyroid hormone (PTH) levels increase during pregnancy, measurements of intact PTH levels by two-site immunometric assays indicate that they are within the normal, nonpregnancy range throughout pregnancy. In contrast, the circulating concentrations of PTH-related protein (PTHrp) increase throughout pregnancy.[87] Many normal tissues produce this protein, and the source of the elevated levels during pregnancy is unclear, although the two most likely sites are the mammary tissue and the placenta.[87] This protein is probably involved in placental and mammary gland calcium transport.

The serum levels of 25-hydroxyvitamin D are unchanged during pregnancy, but the estrogen-induced rise in vitamin D–binding globulin results in a twofold increase in 1,25-dihydroxyvitamin D ($1,25[OH]_2D$) concentrations in maternal serum.[86] There is also a rise in the biologically active free fraction of $1,25(OH)_2D$, which may reflect both increased maternal renal 1α-hydroxylase activity and the synthesis and secretion of $1,25(OH)_2D$ by the placenta.[86] This increase in the active metabolite of vitamin D may be responsible in part for the enhanced intestinal calcium absorption.

Although hyperparathyroidism and hypoparathyroidism are uncommon, they both can lead to serious complications in pregnancy. Pregnancy is somewhat protective in women with hyperparathyroidism because calcium uptake by the fetus helps lower maternal calcium levels. Although women with hypercalcemia in pregnancy often have mild to moderate symptoms of nausea, vomiting, pain, and renal colic,[88] some experience more serious complications such as nephrolithiasis, pancreatitis, hypertension, bone disease, and hypercalcemic crisis.[89] A crisis can be difficult to treat as many of the agents used in nonpregnant patients, such as bisphosphonates and plicamycin, are avoided because of concern for the fetus. Calcitonin can potentially be used as it does not cross the placenta; however, its benefits and safety in pregnancy have not been sufficiently investigated.[90]

Hypoparathyroidism typically poses fewer serious risks, but it can lead to both maternal and fetal fractures if sufficiently severe.[91,92] These complications can generally be prevented with sufficient oral calcium and vitamin D supplementation. As mentioned earlier, a significant amount of maternal calcium is consumed by the fetus during gestation. This often requires a steady increase in calcium (1–1.5 mg of elemental calcium per day) and vitamin D (up to 50,000–100,000 units/day or more) throughout pregnancy to maintain normal maternal serum calcium homeostasis.[93]

Pancreas

Hyperplasia and hypertrophy of the beta cells in the islets of Langerhans are probably the result of stimulation by estrogen and progesterone.[94] During early pregnancy, the glucose requirements of the fetus lead to enhanced transport of glucose across the placenta by facilitated diffusion, and maternal fasting hypoglycemia may be present. Although basal insulin levels may be normal, there is

hypersecretion of insulin in response to a meal. Because the half-life of insulin is not altered during pregnancy,[95] this increase represents an increase in synthesis and secretion. The results are enhanced glycogen storage and decreased hepatic glucose production.

As pregnancy progresses, the levels of hPL rise, as do the levels of glucocorticoids, leading to the insulin resistance found during the last half of pregnancy.[96] Thus, in late pregnancy, glucose ingestion results in higher and more sustained levels of glucose and insulin and a greater degree of glucagon suppression than in the nonpregnant state.

Adrenal Glands

As a result of the hyperestrogenemia of pregnancy, hepatic production of cortisol-binding globulin is increased. The increased production results in a doubling of the maternal serum levels of cortisol-binding globulin, which in turn results in decreased metabolic clearance of cortisol and a threefold rise in total plasma cortisol by week 26, when the levels reach a plateau until they rise at the onset of labor.[74,97] The rate of cortisol production and the plasma free cortisol concentrations are also increased.[92] The enhanced cortisol production is due to an increase in the maternal plasma ACTH concentrations and hyperresponsiveness of the adrenal cortex to ACTH stimulation during pregnancy.[74] Cortisol secretion follows that of ACTH, and the diurnal rhythm is maintained during pregnancy.[97] Despite the elevated free cortisol levels, pregnant women do not develop the stigma of glucocorticoid excess, possibly because of the antiglucocorticoid activities of the elevated concentrations of progesterone.

Levels of androstenedione and testosterone, whether they are of adrenal or ovarian origin, are elevated because of the estrogen-induced increase in hepatic synthesis of sex hormone–binding globulin. However, the free androgen levels remain normal or low. The adrenal production rates of dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulfate (DHEAS) are increased twofold, but the maternal serum concentration of DHEAS is reduced to one-third to one-half the nonpregnancy levels because of the enhanced 16-hydroxylation and placental utilization of 16-hydroxydehydroepiandrosterone sulfate in estrogen formation. Adrenal medullary function remains normal throughout pregnancy. Thus 24-hour urine catecholamine and plasma epinephrine and norepinephrine levels are similar to concentrations in the nonpregnant state.[98]

Fortunately, hypercortisolism is rare in pregnancy as the disorder often leads to menstrual disturbance and infertility. While outside of pregnancy hypercortisolism is most commonly caused by an ACTH-producing pituitary[99] adenoma (so-called Cushing disease), when encountered in pregnancy it is more likely due to primary adrenal hyperplasia (so-called Cushing syndrome). This discrepancy may be due to the lower degree of menstrual disturbance in patients with primary adrenal hyperplasia.[100] The high levels of cortisol in both conditions can lead to hypertension, diabetes, preeclampsia, and even maternal death. Cushing syndrome in pregnancy it also associated with a 43% risk of preterm delivery and a 6% risk of stillbirth.[74]

Renin-Angiotensin System

Plasma renin substrate levels are increased as a consequence of the effects of estrogen on the liver. Renin levels are also increased, and increased renin activity results in increased levels of angiotensin II, which leads to an 8-fold to 10-fold increase in aldosterone production and serum aldosterone levels.[74] The aldosterone levels peak in midpregnancy and are maintained until delivery.

Despite their baseline elevations, the various components of the renin-angiotensin-aldosterone system demonstrate normal responses to positional changes, sodium restriction, and sodium loading. The elevated aldosterone levels do not lead to an increase in serum sodium, a decrease in serum potassium, or an increase in blood pressure, which again may reflect the high progesterone concentrations, which are capable of displacing aldosterone from its renal receptors. Another mineralocorticoid, 11-deoxycorticosterone, shows a 6-fold to 10-fold increase in concentration at term.[45] Elevated levels of this hormone are due to estrogen-induced extraglandular 21-hydroxylation of progesterone produced by the placenta.[101]

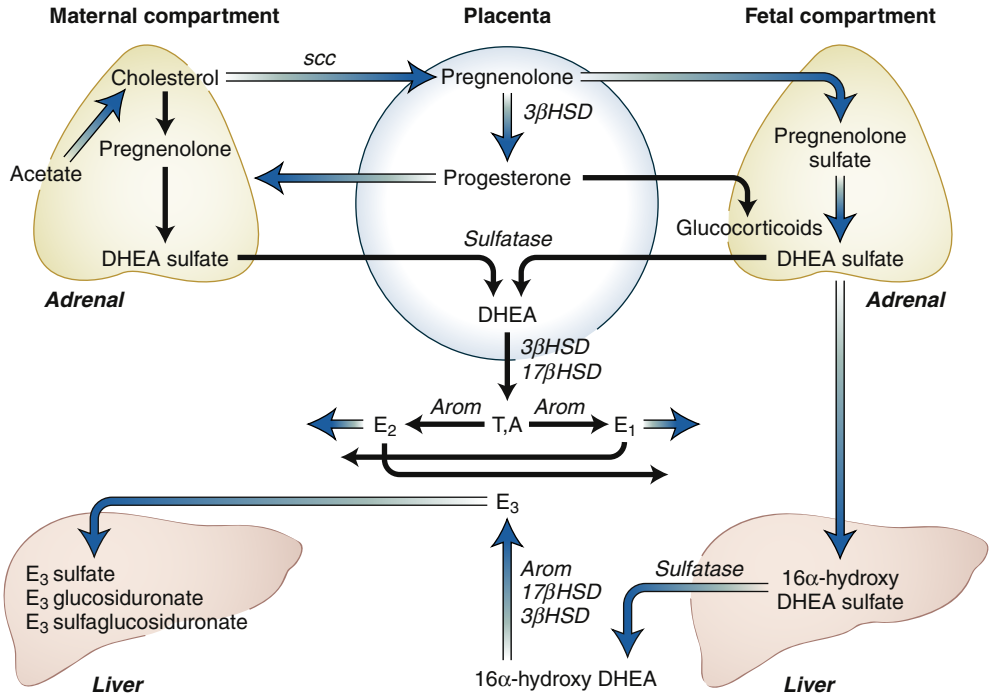
The prevalence of hypertension in women of childbearing age has steadily increased over time and is now a common problem encountered by obstetric providers. Outside of pregnancy, angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) are widely used in the treatment of hypertension, particularly in people with diabetes, as they have been shown to slow the progression of diabetic nephropathy.[102] ACE inhibitors have been linked to oligohydramnios, fetal renal dysplasia, and fetal calvarial hypoplasia.[103] As a result, this group of medications is avoided in pregnancy. Although ARBs have not been shown to have the same adverse fetal effects, they are also typically avoided in pregnancy.[104] Patients on these medications should be switched to alternative agents prior to or in the first trimester of pregnancy. Methyldopa is the best studied antihypertensive medication in pregnancy and is safe for use at any point in gestation.[105] Although less well studied, the calcium channel blocker nifedipine appears to be safe for the fetus and is often used in pregnancy.[106] Beta blockers are often used, but these medications have been associated with an increased risk of fetal growth restriction[107]

Placental Hormone Production

Sex Steroid Production From the Maternal-Fetal-Placental Unit

Sex steroid production in the adult ovary has been classically described as a "two-cell process," wherein the theca cells convert cholesterol to progesterone, testosterone, and other androgens but are then unable to produce estrogen as the theca cells lack the crucial enzyme aromatase. This enzymatic obstacle is overcome by the nearby granulosa cells, which have an abundance of aromatase and take up androgens and rapidly convert them to estrogens.[108] A similar strategy using multiple locations and cell types is also utilized in the massively increased sex steroid machinery of pregnancy. In this system, both the maternal and fetal adrenal glands interact with the placenta to produce very large amounts of progesterone and estrogens. This dependence has led to the concept of the *maternal-fetal-placental unit*.[109] These interactions are outlined in Fig. 22.2.[110,111]

The placenta, like the theca cell of the ovary, has the enzymes necessary to produce progesterone. However, the placenta has very low levels of HMG-CoA activity, so it utilizes cholesterol from the maternal circulation as a substrate for progesterone production.[112] Cholesterol is delivered to the placenta by VLDL, LDL, and HDL, as receptors for all these lipoproteins are present in the syncytiotrophoblast. Cholesterol is converted to pregnenolone by the enzyme CYP11A1,[109,113] which is in turn converted



• **Fig. 22.2** Steroidogenesis in the maternal-fetal-placental unit. *AROM,* aromatase-enzyme complex; *DHEA,* dehydroepiandrosterone; *HSD,* hydroxysteroid dehydrogenase; *SCC,* cholesterol side-chain cleavage enzyme.

to progesterone by 3β-hydroxysteroid dehydrogenase (3βHSD). The placenta also lacks the enzyme 17α-hydroxylase and cannot convert progesterone to androgens even though it has sufficient aromatase activity to convert androgens into estrogens.[114] Thus progesterone is not further modified in the placenta, and approximately 90% is released into the maternal circulation. However, placental progesterone is also an important substrate for production of glucocorticoids and mineralocorticoids in the fetal adrenal glands.[109,113]

The trophoblast lacks 17α-hydroxylase and 17,20-lyase (CYP17) activities and therefore cannot directly convert progesterone to estrogen. Pregnenolone produced in the placenta enters the fetal compartment, where it is taken up by the fetal zone of the adrenal cortex, which also synthesizes pregnenolone from fetal LDL cholesterol. Pregnenolone is conjugated with sulfate by fetal steroid sulfotransferase in the fetal liver and adrenals to form pregnenolone sulfate and is converted in the fetal adrenals to 17α-hydroxypregnenolone sulfate and then DHEAS by 17α-hydroxylase and 17,20-lyase (CYP17) activities.[115]

The DHEAS enters the fetal circulation and undergoes hydroxylation in the fetal liver to form 16α-hydroxy-DHEAS, which is converted to 16α-DHEA in the placenta through the action of placental sulfatase. Further metabolism in the trophoblast by 3βHSD1, 17βHSD, and aromatase (CYP19) leads to the generation of estriol, which is quantitatively the major estrogen in the maternal circulation during pregnancy. The maternal liver actively conjugates estriol with glucosiduronate and sulfate, which are excreted into the urine. Approximately 90% of the estriol present in the maternal serum and urine is derived from fetal precursors, and therefore measurement of estriol levels in serum or urine serves as an index of fetal well-being.[115]

DHEAS from both the fetus and mother is also taken up by the placenta and converted to estradiol by the actions of sulfatase, 3βHSD1, 17βHSD, and aromatase or to estrone by sulfatase, 3βHSD1, and aromatase. An estrogen unique to pregnancy, estetrol, is generated by 15α-hydroxylation of 16α-DHEAS in the fetal adrenal followed by enzymatic conversion by placental sulfatase, 3βHSD1, 17βHSD, and aromatase.[115]

Protein Hormones

Human Chorionic Gonadotropin

Chemistry

Human chorionic gonadotropin is a glycoprotein composed of two dissimilar subunits, α and β, which are noncovalently linked through hydrophobic bonding. This molecule shares structural homology with the other glycoprotein hormones, human luteinizing hormone (hLH), hFSH, and hTSH. These hormones have α-subunits that contain the same sequence of 92 amino acids and differ only in their carbohydrate composition; the β-subunits differ in both amino acid and carbohydrate structure and are responsible for the biologic and immunologic specificity of the heterodimeric (intact) hormones. The 22,200-Da β-subunit of hCG is composed of 145 amino acids. Approximately 80% of the first 115 amino acids are homologous to those in the β-subunit of hLH. hCG has an additional 24 amino acids on its carboxyl-terminal end that enhance its biologic activity.

Both subunits of hCG contain two oligosaccharide chains attached to asparagine residues through N-glycosidic linkages, and the β-subunit contains in addition four O-serine–linked oligosaccharide units in the carboxyl-terminal peptide. The carbohydrate composition of hCG contains microheterogeneity and affects hormone clearance and biologic activity. The tertiary structure of hCG is determined by the carbohydrate composition and multiple disulfide bonds within each subunit. The β-subunit contains five disulfide bonds; the β-subunit has six. In each of the subunits, three of the disulfide bonds form a cysteine knot, similar to that found in PDGFβ and transforming growth factor β (TGFβ).[116]

Biosynthesis

The single α-subunit gene, located on chromosome 6, is actively expressed in both the cytotrophoblast and syncytiotrophoblast. In contrast, the β-subunit is encoded by a cluster of six genes located on chromosome 19 in proximity to the hLHβ gene. Three of the hCGβ genes are actively transcribed during pregnancy, primarily in the syncytiotrophoblast, which synthesizes and secretes free subunits and intact hCG. After synthesis of the protein core, each subunit is glycosylated, undergoes further post-translational modification through trimming of the carbohydrate, then combines to form intact hCG.[116]

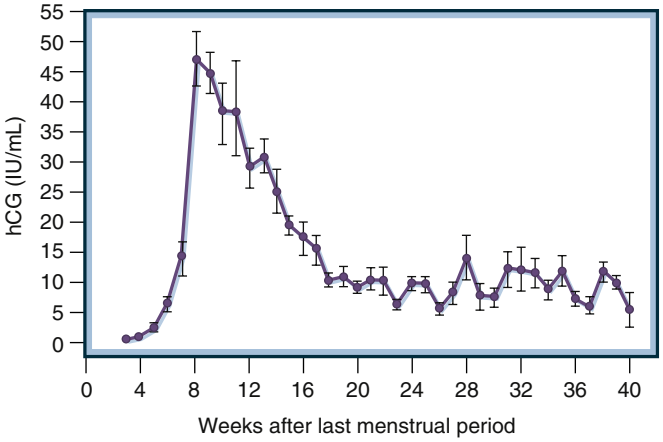
Secretion of hCG differs from that of many of the other placental proteins, whose secretory pattern parallels that of the trophoblastic mass. hCG is first detected in maternal serum 6 to 9 days after conception.[5] The levels rise in a logarithmic fashion, peaking 8 to 10 weeks after the last menstrual period, followed by a decline to a nadir at 18 weeks, with subsequent levels remaining constant until delivery[117] (Fig. 22.3). The placenta also secretes free subunits. During the first 13 weeks of pregnancy, relatively more β-subunit is synthesized than α-subunit, and throughout the remainder of pregnancy the opposite occurs.[118] In addition, a hyperglycosylated form of α-subunit *(big α)* that is unable to combine with free α-subunit is secreted into the maternal serum.

The physiologic factors that regulate hCG secretion in vivo are unknown. Much of the data concerning factors that stimulate or inhibit hCG synthesis and secretion have been derived from in vitro studies and are difficult to extrapolate to the in vivo situation. There is strong circumstantial evidence that GnRH, synthesized in both the cytotrophoblast and syncytiotrophoblast, may be an important factor in hCG secretion. This peptide is identical to hypothalamic GnRH and stimulates placental hCG production both in vitro and in vivo, whereas GnRH antagonists decrease basal hCG secretion.[116,119,120]

Immunohistochemical staining for GnRH in placental tissue is highest at 8 weeks of gestation and lower afterward,[121] roughly paralleling the pattern of hCG production, as do the circulating levels of GnRH measured in maternal serum.[120] In addition, the placenta contains GnRH receptors.[122] Placental GnRH release is stimulated by cyclic adenosine monophosphate (cAMP), prostaglandin E_2 (PGE_2), prostaglandin F_2 (PGF_2), epinephrine, epidermal growth factor, insulin, and vasoactive intestinal peptide (VIP), factors also noted to increase hCG secretion in vitro.[116,119,123]

Two other peptides synthesized by the cytotrophoblast, activin and inhibin, also modulate GnRH and hCG secretion; activin increases both, and inhibin inhibits the action of GnRH on the syncytiotrophoblast.[119] Increases in hCG production have also been found after trophoblast exposure to FGF, calcium, glucocorticoids, and phorbol esters.[119] Decreased production occurs with TGFβ, follistatin, and progesterone.[119] The decidua may also influence hCG production through paracrine mechanisms.[9] Decidual interleukin-1 stimulates hCG secretion in cultured trophoblasts,[124] while decidual prolactin and an 8-kDa to 10-kDa decidual protein inhibit hCG production.[125]

Finally, hCG may autoregulate its own production to some extent. hCG receptors are present on the surface of trophoblastic cells, and the addition of hCG to placental cells in culture stimulates cAMP production as well as proliferation and differentiation of the cytotrophoblasts into syncytiotrophoblasts.[116] Both hCG mRNA and hCG production are stimulated by analogues of cAMP or agents that activate adenylate cyclase, probably through a protein kinase.[116,119] Thus the net effect of an increase in syncytiotrophoblast mass and cAMP would be an enhancement of hCG secretion.



• **Fig. 22.3** Mean (± standard error) levels of maternal serum human chorionic gonadotropin (hCG) throughout normal pregnancy. (From Braunstein GD, Rasor J, Danzer H, et al. Serum human chorionic gonadotropin levels throughout normal pregnancy. *Am J Obstet Gynecol.* 1976;126:678–681.)

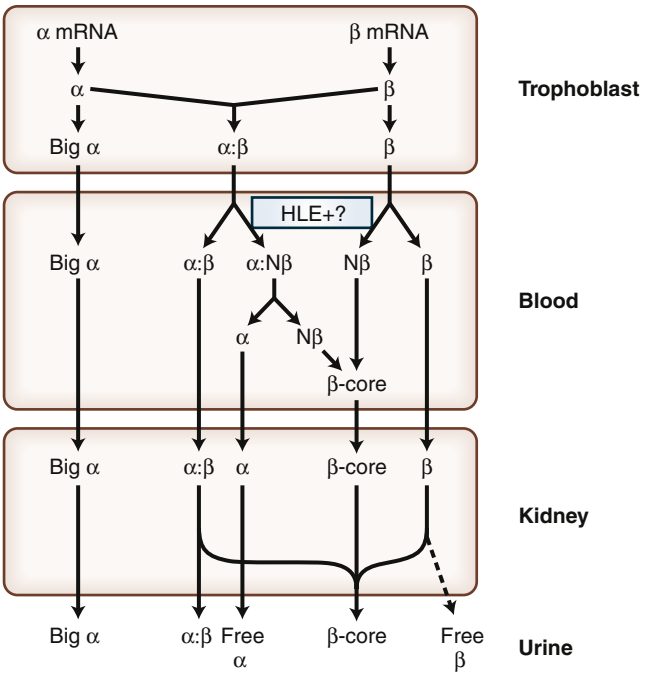
The placenta is not the only site of hCG synthesis. Immunoreactive hCG has been found by immunocytochemistry or by immunoassay of extracts of a wide variety of normal tissues, including the spermatozoa, testes, endometrium, kidney, liver, colon, gastric tissue, lung, spleen, heart, fibroblast, brain, and pituitary gland,[126] and the hormone has been shown to be synthesized in some fetal tissues.[116] The pituitary gland appears to be the major source of hCG or an hCG-like material present in nonpregnant individuals. Immunoactive and bioactive hCG have been partially purified from pituitary glands; the material is secreted in vitro by fetal pituitary cells and is shown by immunocytochemistry to be present in gonadotroph-type cells that do not contain hLH or hFSH.[126,127]

Immunoreactive hCG has been measured in sera from normal, nonpregnant individuals, with the highest concentrations found in postmenopausal women.[127,128] In postmenopausal women, this material is secreted in a pulsatile fashion in parallel with hLH pulses, and during the normal menstrual cycle, the immunoreactive hCG shows a midcycle peak concomitant with the hLH peak.[129] In both men and postmenopausal women, GnRH stimulates secretion of the hormone, whereas its secretion is inhibited by oral contraceptives in women and by a GnRH agonist in agonadal men.[128,130]

Both gestational and nongestational trophoblastic tumors secrete hCG and its free subunits. The sources of hCG secretion in nongestational trophoblastic neoplasms are the syncytiotrophoblastic cells and in seminomas are the trophoblastic giant cells.[130] In many instances, the tumors produce incomplete forms of hCG or its subunits, and differences in carbohydrate content from the hCG in pregnancy have been especially apparent. A wide variety of nontrophoblastic tumors also secrete hCG, although the predominant moiety appears to be the free β-subunit of hCG.[130,131]

Metabolism

After it is secreted, hCG exhibits a biexponential clearance from the circulation with a fast half-time ($t_{1/2}$) of 6 hours and a slow $t_{1/2}$ of close to 36 hours. In contrast, the free β-subunit has a 41-minute fast $t_{1/2}$ and a slow $t_{1/2}$ of 4 hours, and the free α-subunit has a 13-minute fast $t_{1/2}$ and a 76-minute slow $t_{1/2}$.[132] Approximately 22% of the intact hormone appears in the urine unchanged; the rest undergoes metabolic degradation (Fig. 22.4). One of the early steps is proteolytic cleavage ("nicking") of the β-subunit at



• **Fig. 22.4** Proposed pathways for metabolism of human chorionic gonadotropin (hCG). *α:β,* intact hCG; *α:Nβ,* hCG with nicked β-subunit; *Big α,* hyperglycosylated form of the α-subunit; *CTP fragment,* carboxy-terminal fragment; *HLE,* human leukocyte elastase; *mRNA,* messenger RNA; *Nβ,* free nicked β-subunit. Val44-Leu45 and Gly47-Val48. Human leukocyte elastase, present in macrophages and leukocytes, appears to be responsible for some of the nicking of the α-subunit.[132]

Nicked hCG is unstable and dissociates into free α-subunit and nicked free β-subunit. The latter is further metabolized, primarily in the kidney, to produce the β-core fragment, which is composed of the β-subunit amino acids 6 to 40 disulfide bridged to amino acids 55 to 92, trimmed of a portion of carbohydrate, and has a molecular mass of 10,479 Da.[133] This fragment is the major form of immunoreactive hCG present in the urine in pregnancy. In normal pregnancy, the urine also contains variable quantities of the hyperglycosylated form of α-subunit, free α-subunit, free β-subunit, nicked hCG, nicked free β-subunit, carboxyl-terminal fragments of the β-subunit, and fragments of the α-subunit.[132]

Physiologic Functions

Most, if not all, of the physiologic functions of hCG occur after interaction of the hormone with the hLH-hCG receptor. The receptor gene is located on chromosome 2 and encodes for a G protein–coupled receptor with seven hydrophobic transmembrane domains and a large extracellular amino terminus that binds to hCG (and hLH). The receptor is part of a superfamily of receptors, including those for hFSH, hTSH, AVP, VIP, PTH, and receptors for a variety of biogenic amines and neurotransmitters.[116] The hCG-receptor interaction results in increased cAMP production and, in some tissues, increased phosphoinositide turnover.[132]

Because of the close structural homology of the hLH-hCG receptor with the other glycoprotein hormone receptors, hCG may interact with the hTSH and hFSH receptors and thus has weak intrinsic hTSH and hFSH biologic activity. As previously noted, the hTSH-like activity of hCG is clinically manifested during normal pregnancy by the reciprocal decrease in maternal hTSH at the time of the hCG peak between 8 and 12 weeks after the last menstrual period. It is especially important in patients with hydatidiform moles and other forms of trophoblastic disease, in which hCG levels may exceed 100,000 IU/L and result in clinical thyrotoxicosis[72,73] (see Fig. 22.1).

One of the major functions of hCG during pregnancy is the "rescue" of the corpus luteum during the conception cycle.[134] During a menstrual cycle without conception, progesterone concentrations in the serum increase for the first 6 to 7 days of the luteal phase, followed by a plateau of 3 to 4 days and then a decrease, resulting in the shedding of the endometrial lining. After conception and implantation, the corpus luteum continues to secrete progesterone and 17-hydroxyprogesterone for another 4 to 6 weeks. The maternal serum progesterone and 17-hydroxyprogesterone concentrations then decrease, indicating a marked diminution in corpus luteum function.[135] The fall in 17-hydroxyprogesterone concentrations continues, but the drop in progesterone levels is only transient. This marks the transition from dependence on ovarian progesterone production to placental progesterone secretion (the luteal-placental shift). As previously noted, luteectomy during the first 50 days after the last menstrual period is associated with a decline in progesterone levels and expulsion of the products of conception. After a therapeutic abortion, progesterone levels also drop rapidly.

Thus the fetal-placental unit is responsible for the signal to maintain the corpus luteum. The data supporting the notion that hCG is that physiologic signal include the following:

- The presence of hLH-hCG receptors on the corpus luteum
- The early production of hCG by the implanting trophoblast
- The dose-dependent increase in cAMP, progesterone, and estradiol from luteal cells cultured in vitro after exposure to hCG
- The parallel rise of progesterone and hCG in early pregnancy
- The enhanced progesterone secretion and prolongation of the menstrual cycle in nonpregnant women given exogenous hCG during their luteal phase

The inability of hCG to prolong the life of the corpus luteum of pregnancy beyond the sixth to eighth week of pregnancy appears to be due to homologous desensitization of the adenylate cyclase system and the inhibitory effects of high estrogen levels on progesterone synthesis through inhibition of 3βHSD1 and $\Delta^{5\text{-}4}$-isomerase in the corpus luteum.

Another physiologic role for hCG is in the differentiation of fetal male genitalia through stimulation of the hLH-hCG receptors on the fetal testicular Leydig cells during the period when differentiation of wolffian duct structures and development of the external genitalia occur. The maximum testosterone production per unit weight of the testes coincides with the maximum binding of ^{125}I-labeled hCG to the fetal testicular receptors at 10 to 12 weeks of development, and fetal Leydig cells produce cAMP and testosterone in vitro after exposure to hCG. The hCG concentrations in fetal serum parallel the fetal testicular testosterone levels at a time when the amount of fetal pituitary hLH is not sufficient to stimulate testosterone production.[136]

There are several other possible actions of hCG during normal pregnancy. In vitro, hCG stimulates the differentiation of cytotrophoblast to syncytiotrophoblast and hence may play an important

paracrine role in regulating syncytiotrophoblast mass and production of trophoblast hormones.[125,137] Additional data supporting this autoregulatory effect of hCG include the in vitro stimulation of placental synthesis of cAMP, activation of glycogen phosphorylase, and incorporation of radiolabeled galactose and leucine into placental proteins upon exposure to hCG.[136] hCG stimulates the secretion of VEGF from the cytotrophoblast, which may be important for placental angiogenesis.[116] Vasodilation of myometrial blood vessels mediated by hCG binding to vascular hCG receptors may enhance uterine blood flow in early pregnancy.[116] The fetal zone of the adrenal releases DHEAS in response to hCG exposure in vitro, and therefore hCG may have adrenocorticotropic activities in concert with fetal pituitary ACTH and placental ACTH.[136]

It has also been suggested that hCG plays a role in the immunosuppression that occurs during pregnancy. Many early studies on this topic were hampered by the use of impure preparations of hCG or the presence of preservatives such as phenol that may alter the end-points of the test systems used to define immunosuppression. In addition, the immunosuppressive effects may be due to gonadal steroid secretion in response to the hCG in the in vivo models used in some of the studies.[138] Relaxin secretion from the corpus luteum is stimulated by hCG both in vivo and in vitro.[116]

Finally, the decrease in osmotic threshold for thirst and AVP release during pregnancy is clearly related to hCG.[77] Whether this decrease is due to a direct effect of hCG or an indirect effect through stimulation of gonadal steroids or interaction with hLH-hCG receptors present in vascular smooth muscle is unclear.

Gestational Trophoblastic Disease

Gestational trophoblastic disease (GTD) includes complete and partial hydatidiform moles, choriocarcinoma, and placental-site trophoblastic tumor.[139] Complete molar pregnancy is the most common variety, occurring in 1 to 2 in 1000 pregnancies. Patients usually present with vaginal bleeding, a uterus that is larger than expected for the duration of pregnancy, anemia, and excessive vomiting. Pathologically, trophoblast hyperplasia, marked edema of the chorionic villi, and absence of fetal tissues are observed. In contrast, partial moles demonstrate focal trophoblast hyperplasia and villous swelling and often have fetal tissues with congenital malformations. Approximately 20% of patients with complete moles develop persistent trophoblastic disease, whereas only 2% to 4% of patients develop persistent disease after partial molar pregnancy. Persistent trophoblastic disease also can occur after a normal term pregnancy and in pregnancies that end in spontaneous or induced abortion.

Choriocarcinoma is the most aggressive malignant form of persistent trophoblastic disease and may involve complications from local uterine disease, such as bleeding and rupture of the uterus, or from the effects of metastases, especially those involving the liver, lungs, and brain. The least common form of GTD is placental-site trophoblastic tumor, which is derived from the intermediate trophoblast and is often associated with vaginal bleeding and amenorrhea.[139]

All of these neoplasms secrete hCG, free β-subunit, and often additional forms of these molecules. With the exception of placental-site trophoblastic tumor, which secretes relatively low amounts of hCG, the serum and urine concentrations of hCG roughly parallel the tumor burden and also provide prognostic information. Thus hCG measurements in concert with clinical and radiologic findings, especially vaginal ultrasonography findings, are useful for making the diagnosis of GTD. On rare occasions, false-positive, low level hCG results may be found in some women who have heterophilic antibodies and other interfering substances in their sera. This may lead to a misdiagnosis of GTD. Since these substances are not excreted in the urine, a urine pregnancy test will be negative in the presence of such "phantom hCG."[139]

Hydatidiform moles are initially treated with uterine dilatation and evacuation with or without adjunctive single-agent chemotherapy with methotrexate or actinomycin D. Approximately 90% of patients with low-risk, persistent trophoblastic disease are cured by single-agent chemotherapy; 75% of patients with high-risk, metastatic disease are cured by multiagent chemotherapy, including etoposide, methotrexate, actinomycin D, cyclophosphamide, and vincristine. Serial hCG measurements are invaluable for monitoring as they accurately reflect the effect of therapy on the tumor.[139]

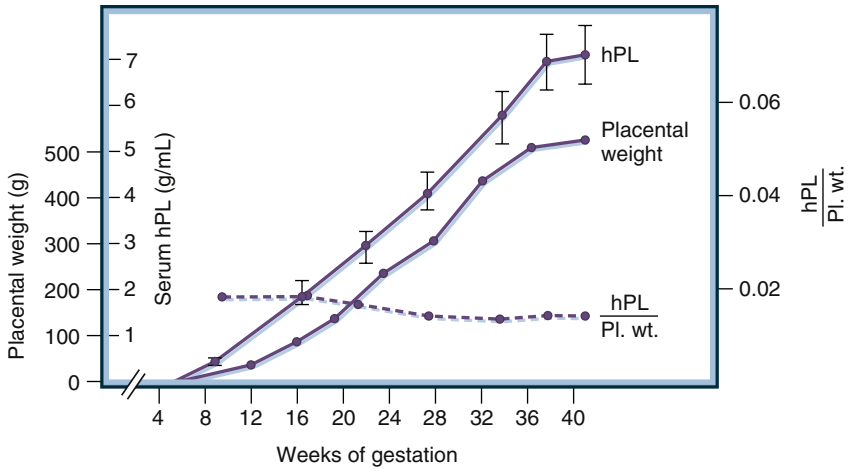
Human Placental Lactogen

Also called chorionic somatomammotropin, hPL is a single-chain, nonglycosylated polypeptide composed of 191 amino acid residues and two disulfide bridges, with a molecular mass of 21,600 Da.[70] It is closely related chemically and biologically to both GH (85% amino acid homology) and prolactin (13% amino acid homology). The hGH-hPL gene cluster is located on the long arm of chromosome 17 and consists of five genes—one coding for pituitary hGH (hGH-N), one for placental hGH (hGH-V), and three for placental hPL (hPL-L, hPL-A, and hPL-B, of which only hPL-A and hPL-B are transcribed).[140]

hPL is synthesized and secreted by the syncytiotrophoblast and is detected in maternal serum between 20 and 40 days of gestation. The maternal serum levels rise rapidly and peak at 34 weeks, followed by a plateau[70] (Fig. 22.5). Both the serum concentrations and placental hPL mRNA concentrations are closely correlated with placental weight and syncytiotrophoblastic mass.[141] The maternal serum concentrations at term average between 6 and 7 μg/mL; at that time, on the basis of the 9-minute to 15-minute $t_{1/2}$ of disappearance from the circulation, the placental production rate of hPL is in excess of 1 g/day. The fetal serum levels are 1/50 to 1/100 of the maternal levels.[140]

The physiologic in vivo regulation of hPL synthesis and secretion, other than the constitutive production related to placental mass, is unknown. Several studies have examined the possible role of nutrients in hPL secretion in pregnant women. Neither acute hyperglycemia nor hypoglycemia appeared to alter the hPL concentrations, although prolonged glucose infusions decreased and prolonged fasting increased the concentrations.[70,118] Arginine infusions, dexamethasone administration, and changes in plasma free fatty acid levels did not affect the maternal hPL concentrations.[142,143] Glucose, estrogens, glucocorticoids, prostaglandins, epinephrine, oxytocin, TRH, GnRH, and L-dopa have been examined in in vitro systems and found to be without consistent effects.[144–147]

Angiotensin II, IGF1, phospholipase A_2, arachidonic acid, and epidermal growth factor stimulated hPL release in vitro.[119,148] Epidermal growth factor probably enhances production through promotion of cytotrophoblast-to-syncytiotrophoblast differentiation.[148] Apolipoprotein AI also stimulated hPL synthesis and release through cAMP-dependent and arachidonic acid–dependent pathways.[70,149,150] Because changes in the maternal plasma apolipoprotein AI concentrations parallel those of hPL during pregnancy, it is likely that this apoprotein, alone and as part of circulating HDL, is important in the secretion of hPL.[150]



• **Fig. 22.5** Placental weight (Pl. wt.), maternal serum concentrations of human placental lactogen *(hPL),* and the ratio of hPL to Pl. wt. during pregnancy. (From Selenkow HA, Saxena BN, Dana CL. Measurement and pathophysiologic significance of human placental lactogen. In: Pecile A, Finzi C, eds. *The Feto-Placental Unit.* Amsterdam: Excerpta Medica; 1969:340.)

hPL has a number of biologic activities that are qualitatively similar to those of hGH and prolactin and can bind to both the hGH and prolactin receptors.[151] In various bioassay systems, hPL had weak somatotropic and lactogenic effects.[151,152] It appears to be a major regulator of IGF1 production, and during pregnancy hPL concentrations are correlated with those of IGF1.[70,151] HPL also affects the metabolism of maternal nutrients. It stimulates pancreatic islet insulin secretion, both directly and after carbohydrate administration,[151] and is a diabetogenic factor during pregnancy through its promotion of insulin resistance. It enhances lipolysis, leading to a rise in free fatty acids, which may in part be responsible for the insulin resistance.[151]

The various biologic activities of hPL have led to the hypothesis that the role of hPL during pregnancy is to provide the fetus with a constant supply of glucose and amino acids.[151] The hPL-stimulated lipolysis allows the mother to utilize free fatty acids for energy during fasting, allowing glucose, amino acids, and ketone bodies to cross the placenta for use by the fetus. In addition, hPL has actions in the fetus, promoting amino acid uptake by muscle and stimulating protein production, IGF1 production, and glycogen synthesis.[152]

Despite the proposed importance of hPL in maternal and fetal metabolic homeostasis during pregnancy, its absence does not appear to impair pregnancy. Deficient or absent hPL production related to gene defects has been described in several women who experienced normal pregnancies and delivered normal infants.[153]

Placental Growth Hormone

Placental GH, hGH-V, is synthesized and secreted by the syncytiotrophoblast.[70] Alternate splicing of the hGH-V gene results in two nonglycosylated isoforms with molecular masses of 22 and 26 kDa.[70,140] The 22-kDa variant may also be glycosylated and circulate as a 26-kDa protein.[140] HGH-V is detected in the maternal plasma from 10 weeks of gestation and peaks during the third trimester[70,133,154] (Fig. 22.6).

HGH-V has somatotropic activity and stimulates IGF1 production, and the increase in IGF1 concentrations may in turn be responsible for the suppression of maternal pituitary hGH secretion[152] (see Fig. 22.6). Unlike pituitary hGH, hGH-V is not secreted in a pulsatile fashion, nor is it released from the trophoblast by growth hormone–releasing hormone (GHRH), but it is inhibited by glucose. It has been estimated that at term, 85% of the GH biologic activity in maternal serum is due to hGH-V, 12% to hPL, and only 3% to pituitary hGH.[155] Within 48 hours of delivery, pituitary hGH secretion returns to normal.

Human Chorionic Corticotropin

The syncytiotrophoblast synthesizes an ACTH-like peptide, human chorionic corticotropin (hCC), as well as several pro-opiomelanocortin–derived peptides, including β-lipotropin, β-endorphin, and α-melanocyte–stimulating hormone.[74] The maternal serum concentrations of ACTH increase as pregnancy progresses, and the elevation of free cortisol levels during pregnancy may be related in part to both placental hCC and pituitary ACTH production.[74]

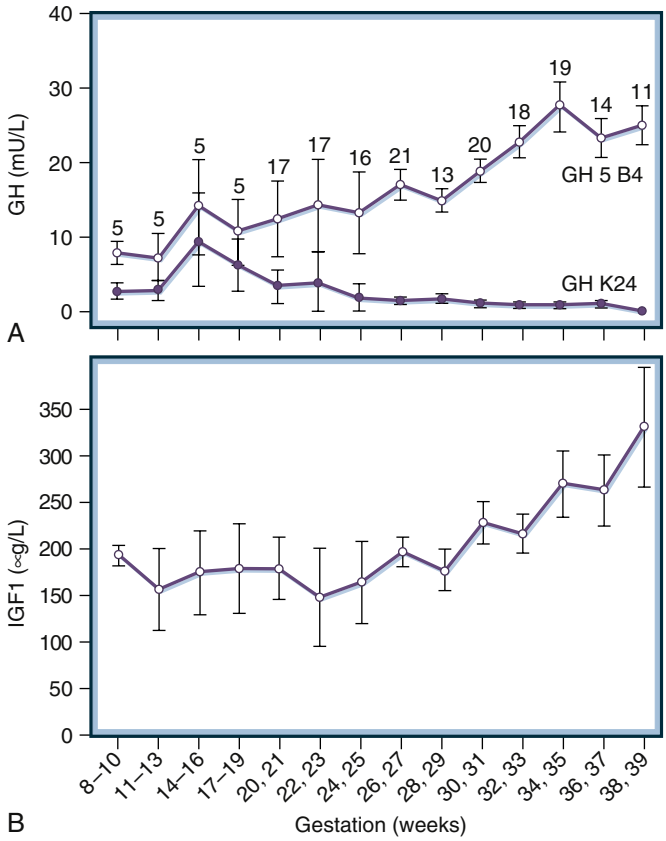
hCC secretion is stimulated by CRH, which is probably the most important factor regulating the local production of the peptide through paracrine or autocrine mechanisms, or both, because it is also produced by both the cytotrophoblast and the syncytiotrophoblast. Unlike the situation with the pituitary, glucocorticoids and oxytocin also stimulate hCC release from placental cultures.[75] Indeed, the resistance of maternal plasma ACTH concentrations to suppression after glucocorticoid administration may reflect the placental hCC contribution to the total pool of circulating immunoreactive ACTH.[74]

Hypothalamic Peptides

Gonadotropin-Releasing Hormone

Both the cytotrophoblast and the syncytiotrophoblast synthesize and secrete GnRH, which has the same chemical structure and biologic activity as hypothalamic GnRH.[119,121] Although the GnRH mRNA levels in the placenta are similar throughout gestation, the highest concentrations of the peptide in the placenta and serum are found during the first trimester and correlate with the mass of the cytotrophoblast and peak hCG concentrations.[121,156]

In vitro, GnRH production by placental explants or purified trophoblasts is stimulated by prostaglandins, epinephrine, activin, insulin, epidermal growth factor, VIP, estradiol, and estriol, and secretion is reduced by inhibin, progesterone, and κ-opiate and μ-opiate agonists.[155,157] The syncytiotrophoblast contains low-affinity GnRH receptors, whose concentrations parallel the hCG secretory pattern.[122]



• **Fig. 22.6** Mean (± standard error) of plasma human growth hormone (GH) (A) and insulin-like growth factor type 1 (IGF1) (B) levels throughout pregnancy. The number of individual assays of GH and IGF1 at each gestational stage is indicated in (A) at the top of the vertical bars. *GH 5 B4,* placental GH (GH2); *GH K24,* pituitary GH (GH1). (From Mirlesse V, Frankenne F, Alsat E, et al. Placental growth hormone levels in normal pregnancy and in pregnancies with intrauterine growth retardation. *Pediatr Res.* 1993;34:439–442.)

Because GnRH stimulates hCG secretion by placental explants and purified trophoblast cells in vitro, with the response of early to midtrimester placentas being greater than that of term trophoblast, it is reasonable to conclude that GnRH is an important autocrine or paracrine regulator of hCG secretion.[155] The hCG-stimulatory effect of GnRH can be blocked by administration of a GnRH antagonist.[158] Because GnRH stimulates metalloproteinases in cytotrophoblasts, the peptide may be important during implantation.[159]

Corticotropin-Releasing Hormone

Both the cytotrophoblast and the syncytiotrophoblast synthesize and secrete a 41–amino acid peptide that is identical to hypothalamic CRH.[119,160] CRH mRNA is first detected in trophoblast at 7 weeks of gestation. The levels remain low during the first 30 weeks of pregnancy but rise 20-fold during the final 5 weeks, a pattern that is parallel to the rise of CRH content in the placenta and concentrations in maternal plasma.[102] In maternal plasma, CRH circulates bound to a 37-kDa protein that is synthesized by the placenta, liver, and brain and that reduces the biologic activity of the CRH.[75,160]

In vitro, placental CRF production is stimulated by prostaglandins (E_2 and $F_{2\alpha}$), norepinephrine, acetylcholine, oxytocin, neuropeptide Y, AVP, angiotensin II, and interleukin-1. Glucocorticoids have been shown to increase both CRH mRNA and peptide, whereas in the hypothalamus suppression is found. CRH secretion is reduced by progesterone and nitric oxide donors. The placenta contains CRH binding sites, and the addition of CRH to cultured placental cells results in a dose-dependent increase in hCC, β-endorphin, and α-melanocyte–stimulating hormone secretion.[74,119,160] Thus it is likely that CRH has an autocrine or paracrine effect in the placenta.

Whether CRH has a physiologic effect on the maternal pituitary secretion of ACTH is unclear; the circulating CRH may be biologically inactive because of the binding protein. However, just before parturition, the binding protein concentration decreases by approximately 50% and the CRH levels rise.[74,160] At this time, CRH stimulates the synthesis and release of prostaglandins from the decidua, amnion, and chorion, which enhances cervical ripening.[161] The myometrium contains CRH receptors, and CRH may increase myometrial contractility.[102] Thus CRH may have a role in initiating and promoting parturition. CRH may also stimulate the fetal pituitary production of ACTH, which in turn may lead to increased fetal adrenal DHEA production and ultimately estriol synthesis by the fetoplacental unit.[160] In addition to CRH, the syncytiotrophoblast and fetal membranes secrete urocortin 1, which in vitro stimulates placental ACTH, PGE_2, and activin secretion through the CRH receptor.[162]

Endocrinology of Pregnancy and Parturition

Roles of Estrogens and Progesterone

Although it is an oversimplification, viewing the maintenance of pregnancy versus the initiation of labor as a balance between the effects of progesterone and estrogen, it is helpful to conceptualize this very complicated process. Progesterone has long been known to be essential for pregnancy; in fact its name is a contraction of the term *progestational steroid hormone*. It is essential from the very beginning of pregnancy as interruption of its production prior to 7 weeks of pregnancy leads to pregnancy loss.[163] Later in pregnancy is it thought to maintain uterine quiescence by limiting the production of prostaglandins and the expression of genes such as ion channels, oxytocin receptors, prostaglandin receptors, and ion channels involved in the contraction machinery of the uterus.[164,165] Progesterone's role in maintaining uterine quiescence is also illustrated in the benefits of progesterone supplementation to prevent preterm birth and is now the standard of care in women at high risk for preterm birth.[166]

Estrogen clearly has a role in the endocrinology of pregnancy, but it appears less important than progesterone both during pregnancy and labor. During pregnancy estrogen enhances the uptake of LDL in the syncytiotrophoblast to aid in steroid production, increases uterine blood flow to allow for adequate gas exchange and nutrient transport across the placenta, and causes hypertrophy of mammary tissue to prepare the breasts for lactation.[109]

In many animal models it has been clearly demonstrated that a decline in progesterone concentration, either spontaneous or induced, is sufficient to initiate labor.[167] However, in women there is no clear spontaneous drop in progesterone levels in the weeks leading up to labor. While this may seem contradictory at first, there is mounting evidence that functional progesterone withdrawal does occur in humans despite a constant level of the hormone throughout late gestation. The progesterone receptor (PR) has two distinct isoforms, PR-A and PR-B. PR-B is thought

to mediate most of progesterone's effects of uterine quiescence by activating progesterone responsive genes and suppressing estrogen receptor (ER) production. PR-A, on the other hand, predominantly acts as a repressor or PR-B. The onset of labor is associated with an increase in the relative levels of PR-A compared to PR-B in the myometrium, suggesting a functional decrease in progesterone activity occurs in humans as it does in other mammals.[168–172]

This functional decrease occurs in concert with an increase in ER expression, which in turn produces a contractile uterine phenotype in preparation for labor, including an increase in myometrial gap junctions and prostaglandin production. The nonessential role of estrogen in pregnancy and labor is demonstrated in pregnancies complicated by placental sulfatase deficiency. These pregnancies generally continue to term, despite the very low estrogen production throughout pregnancy. Although there is a delay in the onset of labor and the uterus is relatively refractory to prostaglandins and oxytocin, labor does ultimately occur spontaneously and inductions of labor, although difficult, can be successfully carried out.[173]

Role of Prostaglandins

There is overwhelming evidence for the role of prostaglandins as mediators of labor.[164,165] Their production is carefully compartmentalized within the uterus, with PGE_2 confined to the fetal membranes, $PGF_{2\alpha}$ in the decidua, and PGI_2 in the myometrium. Although structurally very similar, the different prostaglandin species can have opposing effects, adding to the complexity of how prostaglandins regulate uterine activity. While the PGE_2 produced by the fetal membranes and PGI_2 produced by the myometrium inhibit uterine activity, the $PGF_{2\alpha}$ produced by the decidua is a potent uterotonic,[174] an action that is exploited in the treatment of postpartum hemorrhage. $PGF_{2\alpha}$ production is suppressed in pregnancy with prostaglandin levels in the gravid uterus being lower than those found in the nongravid uterus at any time during the menstrual cycle.[175,176] Later in pregnancy, and particularly at term with the onset of labor, $PGF_{2\alpha}$ levels of prostaglandins increase in maternal serum and amniotic fluid.[174]

The physiology of prostaglandins in the labor process is extensively exploited in modern obstetrics. Procontractile prostaglandins, such as PGE_1, are commonly used for cervical ripening and induction of labor.[177] Postpartum hemorrhage due to uterine atony is very effectively treated by administration of PGE_1 or $PGF_{2\alpha}$.[178] Furthermore, inhibitors of prostaglandin synthesis, such as indomethacin, are among the most potent tocolytic agents used in the treatment of preterm labor.[179]

Role of Oxytocin

Oxytocin is a polypeptide hormone produced in the hypothalamus and stored in the posterior pituitary gland. It is one of the first endogenous compounds discovered to play a role in human labor, and it is one of the few medications to receive US Food and Drug Administration (FDA) approval for specific use in pregnancy. It has long been known to produce uterine contractions, and it is frequently used for induction of labor and to treat postpartum hemorrhage due to uterine atony.[178] Oxytocin mediates its effects by binding to G protein–coupled receptors that are present throughout the uterus. The receptors are preferentially distributed in the uterine fundus, with lower levels found in the lower uterine segment and cervix, corresponding to the increased contractility of the fundus compared to the lower uterine segment.[180]

Although the levels of oxytocin do not detectably increase as pregnancy progresses until late in the second stage of labor,[180] receptor concentrations increase up to 100-fold in the first trimester and up to 300-fold in the third trimester of pregnancy.[180] The increase in receptors, mediated predominantly by estrogen, leads to the increased sensitivity of the myometrium to oxytocin in the second trimester.[180]

Use of Placental Hormones in Genetic Screening and Pregnancy Outcomes

Modern biochemical screening for Down syndrome, other aneuploidies, and less common genetic disorders rely heavily on assessing hormones and other proteins produced by the placenta. For example, maternal levels of hCG and pregnancy-associated plasma protein-A (PAPP-A) are combined with a measurement of fetal nuchal translucency in a first-trimester screening. In general, hCG levels are higher in pregnancies affected by Down syndrome and lower in pregnancies affected by trisomy 18 than euploid pregnancies. PAPP-A levels are lower in pregnancies affected by the common aneuploidies (i.e., Down, trisomy 13, trisomy 18) than in euploid pregnancies.[181,182] For screening in the second trimester, hCG is combined with estriol and inhibin-A—all of which are produced by the placenta—and alpha-fetoprotein (AFP)—which is predominantly produced by the fetus. Estriol is lower in pregnancies affected by Down syndrome and other trisomies, whereas levels of inhibin-A are higher in pregnancies affected by Down syndrome compared to euploid pregnancies.[183] Although not designed to do so, the hormone levels assayed in these genetic screening tests can provide some clues to other genetic conditions and even help predict future pregnancy complications. For example, very low levels of estriol are seen in pregnancies complicated by placental sulfatase[184] deficiency and Smith-Lemli-Opitz syndrome,[185] a disorder in which an enzymatic defect in the cholesterol synthesis pathway leads to a disturbance of all steroid hormones, including estriol. These analyte patterns are summarized in Table 22.3.

It is now well established that certain abnormal maternal serum analytes used in genetic screening are associated with pregnancy complications later in pregnancy in euploid nonanomalous fetuses. The association is strongest for elevated maternal serum AFP (MSAFP) and inhibin-A, which are both associated with an increased risk of fetal growth disturbance and intrauterine fetal death. Elevated inhibin-A is also associated with an increased risk of preterm birth.[184,186,187] Once discovered, these pregnancies are often monitored by serial fetal ultrasounds to assess for growth disturbance and ongoing documentation of fetal well-being if abnormal growth is found. Although the association is less well established, an abnormally low PAPP-A in a euploid pregnancy is associated with growth restriction and stillbirth, preterm birth, and preeclampsia.[188] Both low first trimester PAPP-A and increased second trimester inhibin-A have been associated with an increased risk of preeclampsia. The correlations between abnormal serum analytes and pregnancy complications are outlined in Table 22.4.

Noninvasive Prenatal Testing and Microchimerism

Transplacental bidirectional trafficking of maternal, placental, and fetal cells occurs universally in pregnancy, beginning around 6 to 7 weeks of gestation and peaking at term. Both fetal and maternal

cells persist indefinitely in the host.[189] In addition to fetal cells, the maternal circulation also contains fetal cell free DNA. The cell free DNA from maternal circulation can be sequenced and used to screen for fetal aneuploidy. This approach is termed *noninvasive prenatal testing* (NIPT). The technique is generally thought to be highly sensitive and specific for fetal aneuploidy, but it also suffers from the same pitfalls as trophectoderm biopsy in that mosaicism may be difficult to detect and, when detected, to interpret. Nonetheless, the availability of NIPT has resulted in a marked increase in its use in high-risk patient populations defined as pregnant women older than 35 years and those with a prior abnormal NIPT screen, abnormal ultrasound, and family history of aneuploidy. The superior accuracy of NIPT compared with conventional screening methods has led to significant decreases in the number of invasive diagnostic procedures, in addition to a concomitant decrease in the number of procedure-related fetal losses.[190] The introduction of NIPT significantly decreased the use of screening using placental hormone patterns in high-risk but not in low-risk populations.[191] While NIPT is more accurate, it is also more expensive. Furthermore, invasive fetal karyotyping is still recommended to confirm abnormal screens regardless of screening method.[192] Improving screening technologies and decreasing costs are likely to propel the use of NIPT, but wise application will also require improved patient and provider appreciation of its limitations.[193]

More intriguing than the utilization of fetal cell free DNA in maternal circulation for prenatal screening, however, is the putative contribution of persistent maternal and fetal microchimerism to the fetal origins of adult disease and long-term postpartum maternal health. Indeed, microchimerism apparently persists indefinitely, as fetal cells have been found in maternal circulation decades after birth and can be transmitted from grandmother to grandchild.[194] While both maternal and fetal microchimerism have been implicated as causes of autoimmune diseases, including endocrine disorders such as autoimmune thyroid disorders and type 1 diabetes,[195] microchimerism may also provide benefits, including enhanced tissue repair or rejuvenation and slowed aging via transmission of stem cells. Microchimerism has been hypothesized to protect the host from the development of certain types of cancer.[195] Thus acute and persistent maternal and fetal microchimerism can be adverse, neutral, or beneficial, depending on factors such as HLA match or mismatch, persistence, microchimeric cell mass, and other factors as yet to be determined. The "discovery" of persistent microchimerism years after parturition adds a new dimension to our understanding of the endocrine changes and consequences associated with pregnancy.

The "Fourth Trimester" and the Parental Brain

The physiologic and homeostatic endocrine and metabolic adaptations of pregnancy profoundly impact all maternal and fetal tissues, including the maternal brain. While delivery is a relatively abrupt transition and represents the greatest risk for

maternal and neonatal mortality and morbidity, a new set of endocrine, metabolic, psychologic, and sociocultural challenges follows delivery. Indeed, pregnancy permanently imprints both mother and child and determines the future health of both, both acutely and chronically. Acutely, following delivery, lactation and infant sleeping and feeding patterns present an immediate and enormous set of challenges that elicits maternal endocrine, metabolic, and psychologic adaptations that differ remarkably from those of pregnancy. Placental hormone levels fall acutely and the neuroendocrine axis responds. The catch-phrase for the adaptations related to immediate adjustment following delivery is the "fourth trimester." Short shrift has been given to the term and the many endocrine and other adaptations that follow. What we do know is that adverse pregnancy outcomes such as gestational diabetes and preeclampsia not only heighten the risk for maternal cardiovascular health[195–200] but also pose sociocultural adjustments that are only just beginning to be identified. Not all women are equally able to meet the endocrine and metabolic challenges of normal, much less complicated, pregnancy and delivery. While the hormones of pregnancy prepare the maternal brain for "nesting" and facilitate lactation and care of her infant, we know far less about the endocrine and metabolic impact of pregnancy and parenthood on the longer term health of women and men. Common knowledge suggests that pregnancy poses differential challenges to each sex or, in the case of same-sex liaisons, to the gestational and nongestational parent. The psychologic challenges of parenting are often termed "parental brain."[201] Postpartum maladaptation may result in syndromal postpartum psychiatric disorders, and this burden seems to fall exclusively to the gestational parent.[202] Our current view is that the abrupt withdrawal from the hormonal milieu of pregnancy that is associated with parturition creates an endocrine challenge that overwhelms the endocrine, metabolic, and sociocultural adaptation of vulnerable individuals. Further, we are beginning to recognize that pregnancies complicated by gestational diabetes, hypertension, and other maternal and fetal medical conditions heighten the risk for future maternal disease. Particularly, we now know that gestational diabetes predisposes to maternal diabetes after gestation and that gestational hypertension is a harbinger of later maternal cardiovascular disease. Psychologic sequelae of pregnancy such as postpartum depression also appear to heighten the risk not only of later syndromal psychiatric conditions but also endocrine and cardiovascular conditions. A team approach is needed at both scientific and clinical levels if we are to ensure both individual and population health. In particular, women should be queried by health care providers about medical and psychiatric complications during and after pregnancy so that risk assessment, screening, surveillance, and interventions are adjusted appropriately.[203]

Summary

The endocrine, metabolic, psychologic, and sociocultural changes associated with pregnancy and parturition represent a coordinated and cooperative set of homeostatic responses that facilitate maternal and fetal health. Normal pregnancy represents an enormous challenge, and complications of pregnancy such as preeclampsia and gestational diabetes predispose the mother and her offspring to endocrine, metabolic, cardiovascular, immune, and other conditions after pregnancy. A better understanding of the physiology and pathophysiology of pregnancy and its aftermath is required for appropriate medical and societal care.

Endocrinology of Fetal Development

HARSHINI KATUGAMPOLA, EVELIEN F. GEVERS, AND MEHUL T. DATTANI

CHAPTER OUTLINE

KEY POINTS

- The placental-fetal endocrine environment is created by a spectrum of placental hormones and growth factors and a variety of fetal endocrine adaptations to the intrauterine environment.
- Disordered thyroid, parathyroid, pituitary, pancreas, and gonadal development can be associated with clinical endocrine phenotypes.
- The fetal adrenal cortex, the para-aortic chromaffin system, and the intermediate lobe of the pituitary are prominent fetal endocrine glands.
- Fetal adrenocorticotropic hormone is required for adrenal cortex steroidogenesis. Paradoxically, adrenal steroidogenesis leads to production of mostly inactive steroids such as pregnenolone and dehydroepiandrosterone.
- Some adrenal steroids are converted by the fetal adrenal gland and liver to provide substrates for placental estrone and estradiol production.
- The anterior and posterior pituitary lobes develop from oral ectoderm and ventral diencephalon. Pituitary hormone secretion starts at 8 to 10 weeks' gestation.
- Thyroid hormone synthesis starts at 11 weeks' gestation. Circulating T_4 increases to maximal levels after 35 weeks' gestation, but maturation of hypothalamic-pituitary control and response of thyroid gland to thyroid-stimulating hormone develops in the third trimester.
- In the presence of *SRY*, the sex-determining region of the Y chromosome, male gonadal differentiation starts at 7 weeks of gestation. Development of Leydig cells leads to an increase in fetal testosterone production from week 10 and stimulates differentiation of the primitive mesonephric ducts into bilateral ductus deferens, epididymides, seminal vesicles, and ejaculatory ducts. Dihydrotestosterone stimulates male differentiation of the urogenital sinus and external genitalia.
- Active calcium transport across the placenta occurs in the third trimester to maintain fetal calcium concentrations and is dependent on parathyroid hormone–related protein.
- Calcium-sensing receptor and fibroblast growth factor 23 are required for normal neonatal calcium and phosphate metabolism.
- Growth of the fetus involves complex interactions between environmental, epigenetic, and genetic factors. Insulin-like growth factors are important for fetal growth and are regulated mainly by transplacentally derived nutritional substrate. Hormones most important for postnatal growth, including T_4, growth hormone, and gonadal steroids, have a limited role in fetal growth.
- Fetal hormonal systems are programmed to maintain anabolism with minimal perturbation. Production of catabolic and thermogenic hormones is limited, and effects of hormones altering metabolic substrate supply and distribution pathways are muted.
- Transition to extrauterine life involves the adrenal cortex and autonomic nervous system in the immediate postnatal period. Longer term transition to an intermittent nutrient supply and transient substrate deficiency requires maturation of secretory control mechanisms for the parathyroid hormone–calcitonin system and the endocrine pancreas.

The unfolding of our understanding of mammalian pregnancy and fetal development represents one of the dramatic chapters of scientific progress during the past half-century. Human pregnancy necessitates an ensemble of autocrine, paracrine, and endocrine networks that coordinate maternal-placental-fetal communication. The evolution of a pregnancy is accompanied by dramatic changes in the hormonal milieu. This is a time of potential vulnerability but tremendous plasticity and involves complex genetic, cellular, and hormonal interactions that serve to create a unique, protective intrauterine environment for the developing fetus (Table 23.1).[1] An orchestra of signaling molecules, transcription factors, and epigenetic events regulates embryo implantation, placentation, and ultimately the maintenance of pregnancy until the onset of parturition with transition of the fetus to extrauterine life. It is becoming increasingly clear that the intrauterine environment not only enables fetal development; it also has a significant impact on the lifelong health of an individual, as well as exerting multigenerational effects. This chapter reviews our current understanding of the transplacental passage of hormones, fetal endocrine development and hormone production, adaptations of the fetal endocrine systems to extrauterine life, and programming of developing fetal endocrine systems.

TABLE 23.1 Features of the Fetal Endocrine Environment

Placental Hormone Production
Estrogens
Progesterone
Neuropeptides
Growth factors

Neutralization of Hormone Actions
Growth hormone
Cortisol
Thyroxine
Catecholamines

Unique Fetal Endocrine Systems
Fetal adrenal cortex
Para-aortic chromaffin system
Intermediate lobe of the pituitary

Prominent Fetal Hormones or Metabolites
Vasotocin
Calcitonin
Cortisone
Reverse triiodothyronine (rT_3)
Sulfated iodothyronines
Ectopic neuropeptides

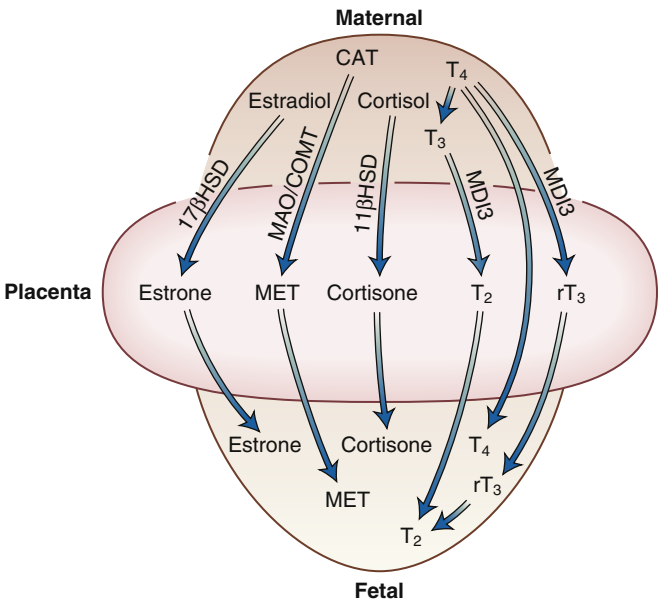
Fetal Endocrine System Adaptations
Adrenal-placental interactions
Testicular control of male phenotypic differentiation
Developmentally regulated growth factor control of fetal growth
Neuropeptides and fetal water metabolism
Parathyroid glands and placental calcium transport
Catecholamine and vasopressin responses to hypoxia
Cortisol programming for extrauterine exposure
Catecholamine and cortisol control of extrauterine adaptation
Perinatal hormonal programming

Placental Transfer of Hormones

The placenta forms the materno-fetal interface, delivering nutrients and oxygen to the fetus and acting as a selective barrier. The placenta demonstrates remarkable capacity to adapt to adverse environments and lessen their impact on the fetus. Placental transfer of hormones decreases with increasing molecular weight, and those larger than 0.7 to 1.2 kDa have little or no access to the fetal compartment.[2] Maternal hormones therefore play a very limited role in the fetal endocrine milieu. Hormones that do cross the placenta may be metabolized en route (Fig. 23.1), including steroid hormones (cortisol), thyroid hormones (T_3, T_4), estradiol, and catecholamines.[3–6]

The concentration of maternal cortisol is almost 10-fold higher than that in the fetus. Placental cells contain an active 11β-hydroxysteroid dehydrogenase type 2 (11βHSD2) that catalyzes conversion of maternal cortisol to inactive cortisone.[7] Synthetic glucocorticoids, such as dexamethasone or betamethasone, can bypass this protective mechanism resulting in exposure of the fetus to steroid hormones. While this is used acutely for its beneficial effects on fetal lung maturation in cases of threatened preterm delivery, chronic use may produce adverse effects on blood pressure, blood glucose, and memory, as demonstrated in rodent models,[8–10] as well as impacting negatively on placental and fetal growth.[11] Clinical use of single or multiple courses of glucocorticoid treatment in the obstetric management of threatened preterm delivery continues, but treatment for other proposed indications lacking robust evidence (e.g., use in pregnancy to reduce virilization of a fetus with congenital adrenal hyperplasia [CAH]) should take place only in a research setting with careful auditing.[12,13]

Estrogens modulate many intrauterine processes throughout gestation, and the balance between estrogens and progesterone in



• **Fig. 23.1** Placental neutralization of biologic activity of hormones during maternal-fetal transfer. The neutralizing enzymes, 17β-hydroxysteroid dehydrogenase (17βHSD) and 11βHSD, are shown (see text for details). *CAT,* catecholamines; *COMT,* catechol *O*-methyltransferase; *MAO,* monoamine oxidase; *MDI3,* type 3 iodothyronine monodeiodinase; *MET,* metamachines; *rT_3,* 3,3′5′ (reverse) triiodothyronine; *T_2,* diiodothyronine; *T_3,* 3,5,3′-triiodothyronine; *T_4,* thyroxine.

utero is thought to be critical to the maintenance of pregnancy, fetal maturation, and the onset of parturition. The placenta produces vast amounts of estrogens in the form of estradiol, estrone, estriol, and estetrol. The estrogen products released from the placenta depend on the nature of the substrate available. Estradiol is the primary estrogen circulating at term. In addition, significant levels of estriol and estetrol are also found in the maternal circulation, and they increase particularly late in gestation. These hydroxylated forms of estrogen are produced in the placenta, using substrates from the combined efforts of the fetal adrenal gland and liver. Though the primary site of estrogen biosynthesis is the placenta, the placenta lacks the cytochrome P450 enzyme CYP17 and accordingly is unable to synthesize estrogens de novo.[14] Placental estrogen biosynthesis relies on a supply of C_{19} androgens, mainly dehydroepiandrosterone (DHEA) and its sulfoconjugate, DHEA sulfate (DHEAS), derived principally from the fetal and maternal adrenal cortex.[14–16] By term, estradiol and estrone concentrations are 100-fold higher than those of nonpregnant women, and estriol concentrations are 1000-fold higher.[16] The developing fetus is protected from excessive estrogen exposure by conversion of active estradiol to inactive estrone by placental 17β hydroxysteroid dehydrogenase.[5]

During the first trimester, transplacental passage of thyroid hormones from the maternal circulation to the fetus is important for neurodevelopment. Placental tissue contains an iodothyronine inner ring monodeiodinase, which deiodinates most of the thyroxine (T_4) to inactive reverse triiodothyronine (rT_3) and converts active 3,5,3′-triiodothyronine (T_3) to inactive diiodothyronine.[6,17] Inappropriately high concentrations of iodothyronines are associated with fetal loss,[18] and the quantity and complement of thyroid hormones passing across the placenta are therefore carefully regulated. There is, however, some transplacental passage of T_4 to the fetus in early pregnancy,[19–21] and epidemiologic data report impairment to intellectual function and behavior in infants born to mothers with mild untreated or subclinical hypothyroidism,[22] although this may also be due to placental passage of thyroid peroxidase (TPO) antibodies.[22]

Catecholamine-degrading enzymes in placental tissue include monoamine oxidase and catechol O-methyltransferase, and both metanephrine and dihydroxymandelic acid metabolites of catecholamines are present in placental homogenates (see Fig. 23.1).[23]

Ectopic Fetal Hormone Production

A number of hormones appear to have a much broader tissue distribution in the fetus, although their functional roles in utero are uncertain, and indeed ectopic hormone production is not always associated with endocrine manifestations.

Human chorionic gonadotropin (hCG), a heterodimeric glycoprotein hormone produced in abundance by the placenta, is preferentially secreted into maternal circulation. hCG and luteinizing hormone (LH) (a structural and functional homolog of hCG, produced by the anterior pituitary gland) bind to the same transmembrane glycoprotein hCG/LH receptor; however, hCG binds with higher affinity. Maternal serum hCG concentrations exponentially increase and reach a peak by about the end of the first trimester, followed by a rapid decline.[24] The fetal circulation also contains low concentrations of hCG; it has been shown that fetal kidney, liver, and testes from human fetuses 16 to 20 weeks old produce immunoreactive and bioactive hCG in vitro.[25,26] hCG is also found in fetal ovary, kidney, lung, adrenal, thymus, spleen, and muscle[27]; hCG/LH receptors have been demonstrated in fetal kidney, liver, pancreas, lung, small and large intestines, and adrenals.[28] Although the role of hCG in the fetus is largely unknown, it is able to stimulate production of DHEA[29] and additionally stimulates testosterone production by Leydig cells, which is essential for masculinization of fetal tissues.[30] hCG signaling in other tissues may be important for their growth and differentiation. The presence of fetal nongonadal hCG/LH receptors suggests mediation of the pleiotropic actions of hCG in the growing human fetus.[31]

Ectopic production of adrenocorticotropic hormone (ACTH), derived presumably from a pituitary-independent pro-opiomelanocortin (POMC) parent molecule, has been shown with ACTH-like immunoreactivity present in relatively high concentrations in neonatal rat pancreas and kidney.[25] POMC is also secreted by the neuroendocrine cells of fetal lung. POMC is known to alter adrenal sensitivity to ACTH; this interplay between fetal pituitary, lung, and adrenal may regulate adrenal response to stress or the onset of parturition.[32] The fetal lung neuroendocrine cells synthesize other hormones in addition to POMC, including vasoactive intestinal peptide (VIP) and serotonin, although the function of these is unknown.[32]

Hypothalamic neuropeptides (thyrotropin-releasing hormone [TRH], corticotropin-releasing hormone [CRH], growth hormone–releasing hormone [GHRH]) are present in a variety of adult tissues, particularly pancreas and gut, as well as in fetal gut and tissues derived from it.[33–35] In neonatal rat pancreatic and gastrointestinal tract tissues, high concentrations of TRH and somatostatin immunoreactivity have been reported, in contrast to low hypothalamic concentrations.[36,37] Furthermore, pancreatectomy, rather than encephalectomy, results in a significant reduction of circulating TRH concentrations in the neonatal rat. In the sheep fetus, thyroid hormones modulate pancreatic and gut TRH concentrations.[38] TRH and somatostatin are also present in the human neonatal pancreas and detectable in the circulation, with both hormones derived mostly from extrahypothalamic sources.[39–42] These data suggest a role for extrahypothalamic TRH in the control of fetal pituitary thyroid hormone secretion before the near-term maturation of hypothalamic TRH. The role of extraneural somatostatin in the fetus remains uncertain.

Ghrelin is a hormone with potent GH-releasing activity, produced by rat and human gastric endocrine cells and by the pituitary, hypothalamus, and placenta. Ghrelin protein has also been identified in the endocrine cells of the fetal lung in decreasing amounts from embryonic to late fetal periods, and its expression was maintained in neonates.[43] Fetal lung is therefore an additional source of circulating ghrelin, whose functions at the respiratory tract level remains to be clarified.[43,44]

CRH is a peptide hormone released by the hypothalamus; however, human placenta, fetal membranes, and decidua also express CRH that is identical to hypothalamic CRH, and from the second trimester the placenta is the major source of CRH secretion. The circulating concentrations of CRH increase 1000-fold as pregnancy progresses,[45] reaching values of 0.5 to 1 nmol/L at term; normal values in nonpregnant women are lower than 0.01 nmol/L. In the last 12 weeks of gestation, CRH plasma concentrations rise considerably, peaking during labor and then falling precipitously after delivery.[46,47] Umbilical cord blood levels and amniotic fluid levels of CRH are similarly increased in late gestation.[48] Fetal CRH concentrations are lower than those in maternal circulation (50 vs. 1000 pmol) but are still quite substantial compared with those in men and nonpregnant women. Unlike

hypothalamic CRH, placental CRH gene expression and production can be stimulated by glucocorticoids.[49] This positive feed-forward system is a unique feature of placental CRH and indicates a distinct role in pregnancy. The fetal adrenal and pituitary express CRH receptors.[50,51] In vitro experiments using cultured primary adrenal cells suggest that in vivo placental CRH stimulates pituitary ACTH secretion, driving fetal HPA activation and directly stimulating adrenal steroid production, as well as affecting fetal adrenal responsiveness to ACTH, thereby indirectly promoting steroidogenesis.[51–53] It appears that during most of pregnancy CRH-binding protein (CRH-BP) binds most of the circulating CRH in the fetal and maternal compartment, which likely serves to tightly control the activity of placental CRH.[54] At the end of pregnancy, there is increased bioavailability of CRH due to a fall in levels of its binding protein, which results in an exponential increase in maternal CRH concentrations from 35 weeks of gestation to term.[45] The steep rise and peak in CRH has been proposed as an initiator of parturition by forming a feed-forward loop that leads to increased production of adrenal androgens and hence placental estrogen.[45]

Fetal Endocrine Systems

The fetus has a unique hormonal network that combines not only its own maturing endocrine systems but also that of the corpus luteum, placenta, and maternal hormones. Fetal endocrine organs develop from early in the first trimester in a carefully coordinated manner, and their abnormal development can impact on a wide range of other systems in the body.

Pituitary

Human Hypothalamic-Pituitary Development

The fetal forebrain is identifiable by 3 weeks' gestation and the diencephalon and telencephalon by 5 weeks; Rathke pouch, the buccal precursor of the anterior pituitary gland, separates from the primitive pharyngeal stomodeum by 5 weeks' gestation.[55–57] The neural components (hypothalamus, pituitary stalk, and posterior pituitary) are largely developed by 7 weeks of gestation, and the bony floor of the sella turcica is also present by that time, separating the adenohypophysis from the primitive gut.

Hypothalamic neurons containing the neuropeptides somatostatin (SS), growth hormone–releasing hormone, thyrotropin-releasing hormone, and gonadotropin-releasing hormone (GnRH) are present in hypothalamic tissue by 10 to 14 weeks of gestation. Interconnecting fiber tracts are demonstrable by 15 to 18 weeks. Maturation of the pituitary portal vascular system continues through 30 to 35 weeks when the system becomes functional with portal vascular extension into the hypothalamus.

The definitive Rathke pouch comprises proliferative progenitors that gradually relocate ventrally. A proliferative zone containing SRY (sex-determining region Y-box 2 *[SOX2]*–expressing) progenitors is maintained in the mouse embryo in a periluminal area and persists in the adult.[58–60] This can give rise to all cell types within the anterior pituitary. Specialized anterior pituitary cell types (lactotropes, somatotropes, corticotropes, thyrotropes, and gonadotropes) are present between 7 and 16 weeks.[57] The cellular differentiation of the five distinct hormone-producing cell types in the anterior pituitary is a highly regulated and coordinated process; however, the final differentiation is still unclear. Secretory granules are present within anterior pituitary cells by 10 to 12 weeks and all pituitary hormones can be identified by immunoassay between 10 and 17 weeks.[57,61] Thus the anatomy and biosynthetic mechanisms that make up the hypothalamic-pituitary neuroendocrine transducer appear functional by 12 to 17 weeks of gestation.

Anterior Pituitary and Target Organs

Two distinct components of the pituitary become evident during embryogenesis: the adenohypophysis (anterior and intermediate lobes) and neurohypophysis (posterior lobe).[62–65] The three lobes of the mature pituitary gland have a dual embryonic origin: The anterior and intermediate lobes are derived from oral ectoderm; the posterior pituitary originates from the infundibulum, a specific region of the developing central nervous system (CNS) that forms in the midline of the ventral diencephalon. Much information has been derived from the mouse as a model organism for pituitary development in mammals, but fate map studies have shown that these processes are similar in all vertebrate species studied, including zebrafish, amphibians, chicks, and rodents.[66–69] In the mouse, the first signs of pituitary development occur at 7.5 days postconception (dpc) with the development of the hypophyseal placode, a thickening of the ectoderm in the midline of the anterior neural ridge (Fig. 23.2). At approximately 9 dpc the placode invaginates dorsally to form a rudimentary Rathke pouch, the primordium of the anterior and intermediate lobes. By 10.5 dpc, the overlying neuroectoderm evaginates to form the infundibulum from which the posterior pituitary and pituitary stalk will derive, which then comes into direct contact with Rathke pouch. The juxtaposition of Rathke pouch and the diencephalon is maintained throughout the early stages of pituitary organogenesis. This close relationship is required for tissue interactions between neural and oral ectoderm, which are critical for the initial stages of pituitary specification. The iterative nature of the inductive interactions required for pituitary morphogenesis makes it very sensitive to both loss-of-function and gain-of-function mutations.[70]

Intermediate Pituitary Lobe

The intermediate lobe of the pituitary gland is prominent in both the human and the sheep fetus. Intermediate lobe cells begin to disappear near term and are virtually absent in the adult human pituitary, although the intermediate lobe in the adult of some lower species is anatomically and functionally distinct.[71] The major secretory products of the intermediate lobe are α-melanocytic-stimulating hormone (α-MSH) and β-endorphin, both derived from cleavage of the POMC molecule.[72] Cleavage of POMC in the anterior lobe results predominantly in corticotropin and β-lipotropin formation. In rhesus monkeys and humans, the fetal pituitary contains high concentrations of compounds resembling α-MSH and corticotropin-like intermediate lobe peptide (CLIP).[73] In the human fetus, α-MSH levels decrease with increasing fetal age.[74] The circulating concentrations of β-endorphin and β-lipotropin are high in the fetal lamb, and the ratio of β-endorphin to β-lipotropin increases during hypoxic stimulation of the anterior pituitary.[75] Because hypoxia provokes corticotropin release and β-lipotropin production from the anterior pituitary, these data have been interpreted to suggest that basal β-endorphin levels in the fetus originate in the intermediate lobe. α-MSH and CLIP may play a role in fetal adrenal activation, and α-MSH may play a role in fetal growth.[76,77] The processing of pituitary POMC in the human fetus by the end of the second trimester is similar to that in the adult, but the role of these intermediate lobe peptides in the fetus remains obscure.[78]

Posterior Pituitary

The posterior lobe comprises axonal projections of neurons, which traverse the pituitary stalk and median eminence at the base of the

hypothalamus. The neurons originate from hypothalamic magnocellular bodies termed the supraoptic, suprachiasmatic, and paraventricular nuclei. The former two release arginine vasopressin and the latter releases oxytocin.[79]

The fetal neurohypophysis is well developed by 10 to 12 weeks of gestation and contains both arginine vasopressin (AVP) (also called antidiuretic hormone, ADH) and oxytocin (OT).[80,81] In addition, arginine vasotocin (AVT), the parent neurohypophyseal hormone in submammalian vertebrates, is present in the fetal pituitary and pineal glands and in adult pineal glands from several mammalian species, including humans.[82] AVT is present in the pituitary during fetal life from 11 to 19 weeks, is secreted by cultured human fetal pineal cells during the second trimester, and disappears in the neonatal period.[81,82] In adult mammals, instillation of AVT into cerebrospinal fluid inhibits gonadotropin and corticotropin release, stimulates prolactin (PRL) release by the anterior pituitary, and induces sleep; however, the physiologic importance of these effects remains unclear. The role of AVT in the fetal pineal gland is unknown. Recent work shows a role for oxytocin in the development of the neurovascular interface in the posterior pituitary.[83] By 40 weeks, the concentrations of AVP and OT approximate 20% of those in adults. Fetal pituitary oxytocin concentration, detectable by 11 to 15 weeks, exceeds AVP concentration by 19 weeks. The AVP-oxytocin ratio falls progressively thereafter.

In the fetal sheep, the baseline fetal plasma AVP concentrations are similar to maternal levels after midgestation. During the last trimester of gestation, fetal hypothalamic and pituitary responsiveness to both volume and osmolar stimuli for AVP secretion are well developed, and AVP exerts antidiuretic effects on the fetal kidney.[80,81] Baseline plasma levels of AVT in fetal sheep during the last trimester approximate values for AVP and OT.[82] Presumably this AVT is derived from the posterior pituitary, but the stimuli for AVT secretion in the fetus are not defined. The neurohypophyseal peptides are synthesized as large precursor molecules (neurophysins) and processed to bioactive amidated peptides.[84] Enzymatic processing involves progressive cleavage of carboxyl terminal–extended peptides, sequentially producing (for OT) OT-glycine-lysine-arginine (OTGKR), OTGK, OTG, and OT. Similar progressive processing yields AVP-glycine and AVP from the AVP neurophysin. Enzymatic processing of neurophysins matures progressively in the fetus so that early in gestation fetal plasma contains relatively large concentrations of the extended peptides.[84] For OT, the ratio of OT-extended peptides to OT in fetal sheep serum is approximately 35:1 early in gestation and 3:1 late in gestation.[84]

In the fetus, AVP appears to function as a stress-responsive hormone. Perhaps the major potential stress for the fetus is hypoxia, and the response of AVP to hypoxia is increased compared with the maternal response and with fetal AVP responses to osmolar stimuli.[81,85–87] Plasma AVP concentrations in human cord blood are elevated in association with intrauterine bradycardia and meconium passage.[86] The vasopressor action of AVP may be important in the maintenance of fetal circulatory homeostasis during hemorrhage and hypoxia; AVP has a limited effect on fetoplacental blood flow.[81,88] Fetal hypoxia is also a major stimulus for catecholamine release. There is little information on interactions between AVP and catecholamines during fetal hypoxia, but both fetal hypoxia and AVP stimulate anterior pituitary function.[88] A role for AVP as a corticotropin-releasing hormone is established in the adult, and the ovine fetal pituitary responds separately and synergistically to AVP and CRH early in the third trimester.[89] The role of AVP in controlling fetal corticotropin release seems to decrease

with gestational age. It is not known whether AVT functions as a corticotropin-releasing hormone in the fetus.

OT receptors have been demonstrated in human fetal membranes at term, and AVP receptors have been found in renal medullary membranes of newborn sheep.[82,90,91] Both AVP and AVT evoke antidiuretic actions in the sheep fetus during the last third of gestation, and both hormones act to conserve water for the fetus by inhibiting fluid loss into amniotic fluid through the lungs and kidneys.[81,82] Water channel receptors (aquaporins 1, 2, and 3) are present in the human fetal and newborn kidney, and the ability of the newborn infant to regulate free water clearance in response to volume and osmolar stimuli has been demonstrated.[92] Whether AVT exerts its effects through AVP receptors or separate fetal AVT receptors is not clear. Maximal concentrating capacity by the fetal kidney is limited to about 600 mmol/L. This limitation is not related to inadequate AVP stimulation but to inherent immaturity of the renal tubules.

Lack of AVP is associated with diabetes insipidus (DI) and with a failure to retain water in the body, leading to polyuria and polydipsia. Although most cases of DI are from acquired causes such as pituitary germinoma, craniopharyngioma, or Langerhans cell histiocytosis, the condition may rarely be due to mutations in the AVP-neurophysin gene or to other congenital causes such as septo-optic dysplasia or holoprosencephaly. Mutations in *WFS1* are associated with autosomal recessive Wolfram syndrome that includes diabetes insipidus, diabetes mellitus, optic atrophy, and sensorineural hearing loss.[93]

Hypothalamus and Pituitary Stalk

The anatomy of the developed hypothalamus is well understood. It extends from the anteriorly located optic chiasm to the posteriorly located mammillary body and is organized into distinct rostral-to-caudal regions: preoptic, anterior, tuberal, and mammillary. The organ is subdivided into three medial-to-lateral regions: periventricular, medial, and lateral.[94] Contained within the medial region are the preoptic nucleus, the anterior hypothalamus, the dorsomedial nucleus, the ventromedial nucleus, and the mammillary nuclei. The lateral zone comprises the preoptic and hypothalamic areas.[94]

As Rathke pouch invaginates, part of the ventral diencephalon evaginates ventrally to form the infundibulum and, later, the posterior pituitary lobe and pituitary stalk. The pituitary stalk acts as a physical connection between the pituitary gland and brain and contains the hypophyseal (hypothalamic-pituitary) portal system as well as the neuronal connections traversing across the hypothalamic median eminence. These neurons originate from the supraoptic, suprachiasmatic, and paraventricular nuclei, which are large hypothalamic magnocellular bodies located within the periventricular region of the hypothalamus.[94] Within the median eminence itself at the base of the hypothalamus is the capillary bed into which the widely dispersed hypothalamic parvocellular neurons secrete hypophysiotrophic hormones. These stimulate the release of the seven anterior/intermediate pituitary lobe hormones via the hypophyseal portal system. The parvocellular neurons also secrete oxytocin and arginine vasopressin, although at much lower concentrations than the magnocellular neurons, with the parvocellular-derived arginine vasopressin acting synergistically with corticotropin-releasing hormone in regulating ACTH release. It is therefore evident that it is the hypothalamus acting through the pituitary gland that is the central mediator of growth, reproduction, and homeostasis.[55]

Deciphering hypothalamic development during embryogenesis has proved difficult, perhaps due to its anatomic complexity and diverse collection of cell groups and neuronal subtypes. There is a dearth of data defining the genetics and the signaling and marker molecules involved in their delineation and identification.[95,96] A dual novel role for fibroblast growth factor (FGF)3/FGF10 was identified in innervation and vascularization of the prospective vertebrate hypothalamic region, acting as chemoattractive cues to the neurohypothalamic neurons.[97] Little is known about the molecular mechanisms governing the formation of the hypothalamus, and genetic expression studies within the hypothalamus have knock-on effects on multiple neuronal subtypes and downstream physiologic processes. Studies are slowly elucidating hypothalamic development, and this will in time elaborate the processes involved.

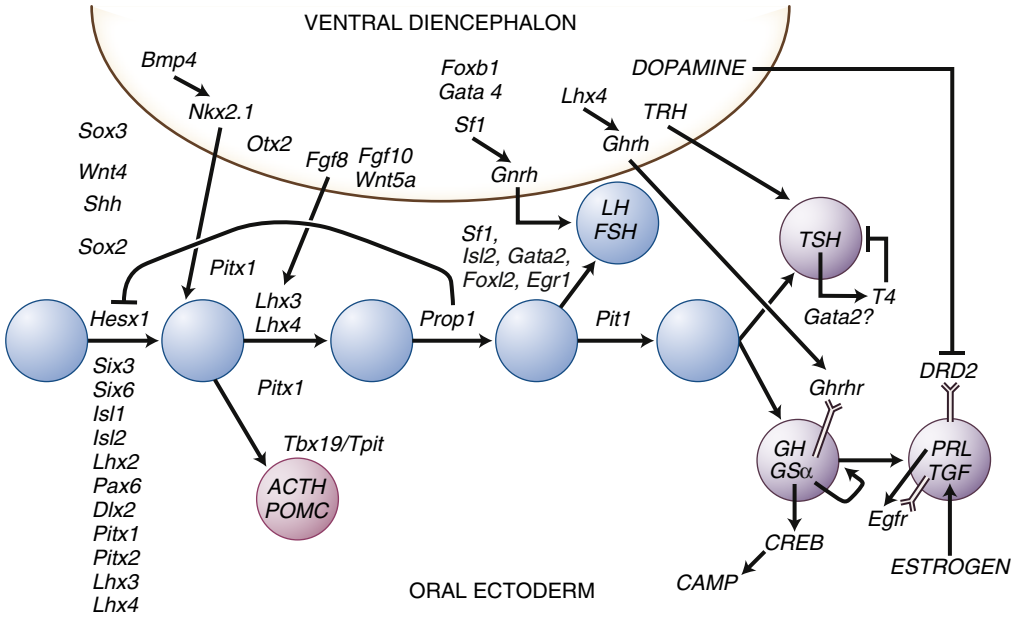
Genes Involved in Pituitary Disease

Complex genetic interactions dictate normal pituitary development.[55] A cascade of signaling molecules and transcription factors plays a crucial role in organ commitment, cell proliferation, cell patterning, and terminal differentiation. The final product is a culmination of this coordinated process (Fig. 23.3).

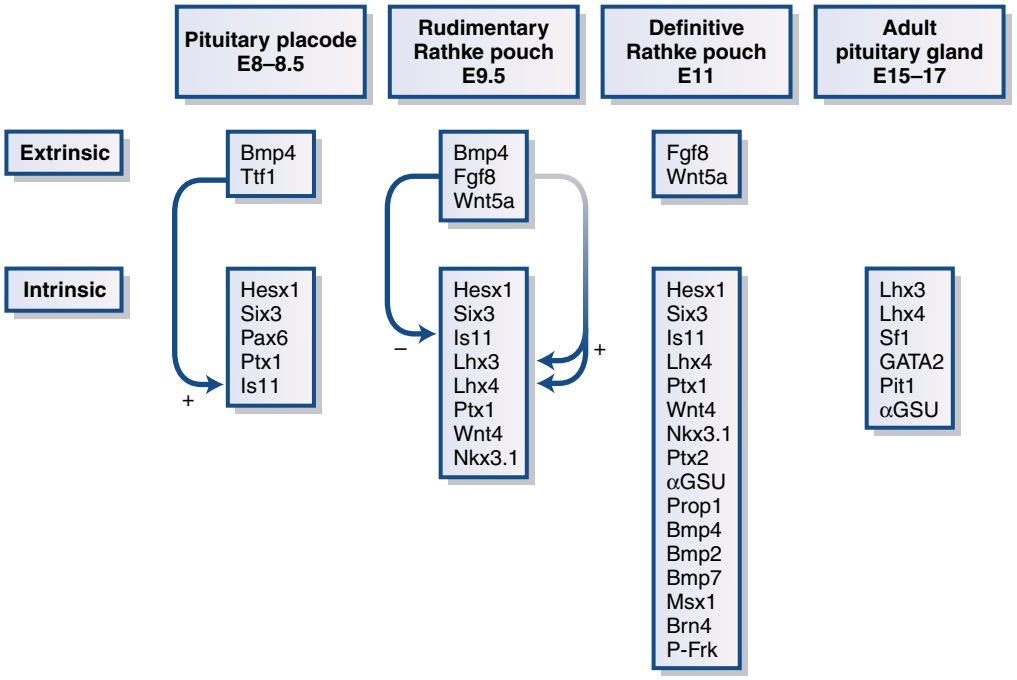
Initially, cells within the primordium of the pituitary gland are competent to differentiate into all cell types. After expression of the earliest markers of pituitary gland development, such as homeobox gene expressed in embryonic stem (ES) cells *(Hesx1),* further signaling pathways are established from within the gland and ventral diencephalon that direct these cells toward terminal differentiation into mature hormone-secreting cell types. Signaling molecules and transcription factors are expressed sequentially at critical periods of pituitary development, and expression of many of these factors is subsequently attenuated (Fig. 23.4). Genes expressed early are implicated in organ commitment but are also implicated in repression and activation of downstream target genes that have specific roles in directing the cells toward a particular fate.

Spontaneous or artificially induced mutations in the mouse have led to significant insights into human pituitary disease, and identification of mutations associated with human pituitary disease have in turn been invaluable in defining the genetic cascade responsible for the development of this embryologic tissue. Mutations involved specifically in human hypothalamic-pituitary disease are listed in Table 23.2 and briefly discussed in this section.

Extrinsic molecules within the ventral diencephalon and surrounding structures, such as bone morphogenetic proteins 2 and 4 (BMP2, BMP4), FGF8, sonic hedgehog (SHH), wingless (Wnt4), thyroid transcription factor 1 (TTF1; also called Nkx2-1), and molecules involved in Notch signaling, play critical roles in early organogenesis.[55,56,97] Recent studies in the mouse have shown that a close interaction between oral ectoderm and neural ectoderm is critical for initial development of the pituitary gland. Rathke pouch develops in a two-step process that requires at least two sequential inductive signals from the diencephalon. First, induction and formation of the rudimentary pouch are dependent upon BMP4; second, FGF8 activates two key regulatory genes, LIM homeobox 3 *(LHX3)* and LIM homeobox 4 *(LHX4)*, that are essential for subsequent development of the rudimentary pouch into a definitive pouch. BMP4 and FGF8 are present only in the diencephalon, not in Rathke pouch. Murine mutations within the gene encoding *TTF1/Nkx2-1* (also called thyroid-specific enhancer binding protein), which is expressed only in the presumptive ventral diencephalon, can cause severe defects in the development of the diencephalon and the anterior pituitary



• **Fig. 23.3** Schematic representation of the developmental cascade of genes implicated in human pituitary development with particular reference to pituitary cell differentiation.



• **Fig. 23.4** Transcription factors and signaling molecules involved in anterior pituitary development.

gland. Conditional deletion of *RBPJ*, which encodes the major mediator of the Notch pathway, leads to conversion of the late (pituitary-specific transcription factor 1 [Pit1]) lineage into the early (corticotroph) lineage. Notch signaling is required for maintaining expression of prophet of Pit1 *(PROP1)*, which is required for generation of the Pit1 lineage. Attenuation of Notch signaling is necessary for terminal differentiation in Pit1 cells and for maturation and proliferation of the GH-producing somatotrophs.[98]

Mutations of the sonic hedgehog *(SHH)* signaling pathway *(SHH, TGIF, ZIC2, PTCH1, GLI2)* and the transcription factors sine oculis–related homeobox 3 *(SIX3)*, teratocarcinoma-derived growth factor 1 *(TDGF1)*, and *FOXH1/FAST1* have been identified in patients with holoprosencephaly, with and without hypothalamic-pituitary defects.[99–103] Mammalian *SIX6* and *SIX3* are vertebrate homologues of Drosophila optix, and expression of these are restricted to the developing eye and brain. *SIX6* knockout mice have hypoplastic pituitaries, may be blind, and fail to progress through the estrous cycle with resultant infertility. *SIX3* and *SIX6* are transcription factors of importance for pituitary lineage specifications, in particular gonadotropic cell lines.[104]

Mutations in *FGF8* have also been identified in association with both holoprosencephaly associated with diabetes insipidus and Kallmann syndrome (KS).[62,105] Mutations in *HESX1* have been identified in patients with septo-optic dysplasia (SOD; a

TABLE 23.2 Comparison of Murine and Human Hypothalamic-Pituitary Development Phenotypes

Gene	Protein	Murine Loss-of-Function Phenotype	Human Phenotype	Inheritance (Murine and Human)
HESX1	HESX1	Anophthalmia or microphthalmia, agenesis of corpus callosum, absence of septum pellucidum, pituitary dysgenesis, or aplasia	Variable: SOD, CPHD, IGHD with EPP Anterior pituitary hypoplastic or absent Posterior pituitary ectopic or eutopic Frequency of mutations: <1%	Dominant or recessive in humans, recessive in mouse
OTX2	OTX2	Lack of forebrain and midbrain, olfactory placode, optic placodes	Anophthalmia, APH, ectopic posterior pituitary, absent infundibulum Frequency of mutations: 2%–3% of anophthalmia/microphthalmia cases	Heterozygous: haploinsufficiency/dominant negative
SOX2	SOX2	Homozygous null mutants: embryonic lethal Heterozygous mice and further dose reduction: poor growth, reduced fertility, CNS abnormalities, anophthalmia; pituitary hypoplasia with reduction in all cell types	Hypogonadotropic hypogonadism; APH, abnormal hippocampi, bilateral anophthalmia/microphthalmia, abnormal corpus callosum, learning difficulties, esophageal atresia, sensorineural hearing loss, hypothalamic hamartoma Frequency of mutations: 3%	De novo haploinsufficiency in humans, heterozygous mutation associated with haploinsufficiency in mouse
SOX3	SOX3	Poor growth, weakness, craniofacial abnormalities, ACC, hypothalamic and infundibular abnormalities	IGHD and mental retardation, hypopituitarism; APH, infundibular hypoplasia, EPP, midline abnormalities Frequency of mutations: 6% (duplications), 1.5% (mutations)	X-linked recessive in both mice and humans
GLI2	GLI2	N/A	Holoprosencephaly, hypopituitarism, craniofacial abnormalities, polydactyly, single nares, single central incisor, partial ACC Frequency of mutations: 1.5%	Haploinsufficiency in humans
FGF8	FGF8	Holoprosencephaly, reduction of vasopressin and oxytocin, reduced GnRH neurons	Holoprosencephaly, hypogonadotrophic hypogonadism, ACTH and TSH deficiencies, diabetes insipidus	AR in both human and mouse; AD in some cases
LHX3	LHX3	Hypoplasia of Rathke pouch	GH, TSH, gonadotropin deficiency with pituitary hypoplasia ACTH insufficiency variable Short, rigid cervical spine Variable sensorineural hearing loss Frequency of mutations: 1.3%	Recessive in both
LHX4	LHX4	Mild hypoplasia of anterior pituitary	GH, TSH, cortisol, and gonadotropin deficiency, persistent craniopharyngeal canal and abnormal cerebellar tonsils; APH, ectopic/eutopic posterior pituitary, absent infundibulum Frequency of mutations: 1.2%	Recessive in mouse, recessive/dominant or recessive in humans
PROP1	PROP1	Hypoplasia of anterior pituitary with reduced somatotropes, lactotropes, thyrotropes, corticotropes, and gonadotropes	GH, TSH, PRL, and gonadotropin deficiency Evolving ACTH deficiency Enlarged pituitary with later involution Frequency of mutations: 1.1% sporadic cases, 29.5% familial cases	Recessive in both
POU1F1	POU1F1 (PIT1)	Anterior pituitary hypoplasia with reduced somatotropes, lactotropes, and thyrotropes	Variable anterior pituitary hypoplasia with GH, TSH, and PRL deficiencies Frequency of mutations: 3.8% sporadic cases, 18% familial cases	Recessive in mouse, dominant/recessive in humans
ARNT2	ARNT2	Anterior pituitary hypoplasia, TRH, somatostatin, oxytocin and CRH deficiencies, reduced vasopressin neurons	TSH, GH, ACTH deficiencies, DI, small anterior pituitary, vesicoureteric reflux, renal impairment, visual impairment, neonatal seizures with progressive microcephaly	Autosomal recessive
PNPLA6	PNPLA6	N/A	Oliver-McFarlane syndrome; trichomegaly, congenital hypopituitarism and retinal degeneration with choroidal atrophy; hypogonadotrophic hypogonadism	Autosomal recessive
TCF7L1	TCFL1	Forebrain, eye and pituitary deficits	Septo-optic dysplasia with variable hypopituitarism	Autosomal dominant

ACC, Agenesis of corpus callosum; *ACTH,* adrenocorticotropic hormone; *APH,* anterior pituitary hypoplasia; *AR,* androgen receptor; *CNS,* central nervous system; *CPHD,* combined pituitary hormone deficiencies; *EPP,* ectopic posterior pituitary; *GH,* growth hormone; *IGHD,* isolated growth hormone deficiency; *N/A,* not applicable; *PRL,* prolactin; *SOD,* septo-optic dysplasia; *TSH,* thyroid-stimulating hormone.

combination of pituitary, eye, and midline forebrain defects), combined pituitary hormone deficiencies (CPHDs), and isolated growth hormone deficiency (IGHD).[55,106] Mutations in *SOX2* and *OTX2* have been described in association with severe eye defects, hypogonadotropic hypogonadism, and variable hypopituitarism.[107–111] Mutations and genomic duplications in *SOX3* have been identified in patients with hypopituitarism with and without learning defects.[112]

Mutations in the gene encoding the LIM homeodomain transcription factor *LHX3* have been identified in patients with hypopituitarism, neck abnormalities, and sensorineural deafness, whereas mutations in *LHX4* have been identified in patients with hypopituitarism, which can be lethal, and cerebellar abnormalities.[113–115] Mutations in genes expressed later in pituitary development, such as *PROP1* and *POU1F1* (previously known as *PIT1*), are associated with more specific pituitary phenotypes (variable GH, thyroid-stimulating hormone [TSH], ACTH, PRL, and gonadotropin deficiencies and often a large anterior pituitary that later involutes with *PROP1* mutations; GH, TSH, and PRL deficiencies with *POU1F1* mutations), in keeping with a role for these genes in cellular proliferation and differentiation and hormone secretion.[55,116–118] Mutations in the T-box transcription factor *TBX19/TPIT* have been described in patients with early-onset isolated ACTH deficiency.[119] Mutations in *TSHβ* have been associated with central hypothyroidism.[120] More recently, mutations and deletions of *IGSF1* have been associated with TSH and variable GH and PRL deficiencies associated with macro-orchidism. Immunoglobulin superfamily, member 1 (IGSF1) is a glycoprotein that is expressed in the pituitary and testis. The function of the gene remains unclear but it may be involved in TRH signaling.[121,122] Central hypothyroidism may be more prevalent than previously thought, affecting up to 1 in 16,000 neonates in the Netherlands where screening is via a combination of T_4 and TSH.

Rare recessive biallelic inactivating mutations in *TRHR*, namely p.S115-T117del and p.A118T, have been reported in three affected individuals from two unrelated pedigrees with central congenital hypothyroidism (CCH), with absent TSH and prolactin responses to exogenous TRH.[123,124] More recently, the p.P81R missense mutation described in isolated CCH highlights the importance of the second transmembrane helix in mediating TRH receptor activation via hormone binding, making it the first deleterious missense *TRHR* defect that gives rise to CCH.[125] In addition, a recently identified novel homozygous mutation, p.I131T, that decreases TRH affinity was identified in an overweight patient with CCH and normal stature.[126]

The X-linked transducin β-like protein 1 (*TBL1X*) gene is a component of the thyroid hormone receptor–corepressor complex, mutations that have been previously associated with sensorineural hearing loss.[127,128] In a recent study, six mutations in unrelated pedigrees with isolated CCH have been identified.[129] Like *IGSF1*, *TBL1X* is associated with an X-linked form of TSH deficiency.

PCSK11 mutations result in ACTH deficiency, hypoglycemia, hypogonadotrophic hypogonadism, obesity, GH deficiency, and DI. In a study of 13 children with proprotein convertase 1/3 (PC1/3) deficiency, an autosomal recessive disorder caused by rare mutations in the proprotein convertase subtilisin/kexin type 1 *(PCSK1)* gene, obesity and severe malabsorptive diarrhea were associated with a number of endocrine abnormalities. PC1/3 is an endoprotease that processes many prohormones expressed in endocrine and neuronal cells. Failure of enteroendocrine cells to produce functional hormones resulted in generalized malabsorption. Additional endocrine abnormalities that developed with disease progression included central DI, GH deficiency, primary male hypogonadism, adrenal insufficiency secondary to ACTH deficiency, and hypothyroidism.[130]

The hypothalamic-pituitary-gonadal axis is the key regulator of sex development and reproduction, processes that are initiated through the decapeptide GnRH. GnRH is produced and released after the successful migration during embryogenesis of GnRH neurons from the olfactory placode, across the cribriform plate, to the hypothalamic arcuate nucleus, where they are detectable from about 9 weeks of gestation. These neurons are then projected into the hypothalamic median eminence. It has recently been reported that the number of GnRH neurons in the brain at the end of the first trimester is fivefold higher (~10,000) than previously described in the hypothalamus.[131] New insights from three-dimensional (3D) imaging include the presence of GnRH neurons in nonhypothalamic areas, raising the possibility of nonreproductive roles for GnRH.[131]

A functional connection with respect to GnRH is detected by 16 to 20 weeks' gestation. This hormone is released in a pulsatile fashion and binds to its receptors on pituitary gonadotrophs, which in turn respond by synthesizing and releasing the gonadotropins LH and FSH. These bind to their cognate receptors in the gonads, where they stimulate the production of sex steroids, such as androgens or estrogens, and stimulate gametogenesis. The sex steroids then regulate gonadotropin secretion via negative feedback at the level of the hypothalamus or pituitary. Congenital disorders of gonadotropin secretion include normosmic isolated GnRH deficiency causing hypogonadotropic hypogonadism and KS, a disorder characterized by hypogonadotropic hypogonadism, anosmia/hyposmia, cleft lip/plate, sensorineural hearing loss, dental anomalies, synkinesia, and renal abnormalities.

Mutations in a number of genes have been reported to date in Kallmann syndrome, including *KAL1, CCDC141, FEZF1, IL17RD, SEMA3A*, *SEMA3E,* and *SOX10.*[105,132–134] Pathogenic variants in *CHD7, FGF8, FGF17, FGFR1, DUSP6, SPRY4,* and *FLRT3, HS6ST1*, *NSMF (NELF), PROK2, PROKR2,* and *WDR11* cause both KS and normosmic hypogonadotropic hypogonadism.[134,135] Variants in encoding prokineticin receptor 2 and prokineticin 2 (*PROKR2* and *PROK2*, respectively) have been identified in approximately 9% of patients with Kallmann syndrome.[136] Prokineticins are secreted cysteine-rich proteins that possess diverse biologic activities, including effects on neuronal survival, gastrointestinal smooth muscle contraction, circadian locomotor rhythm, and appetite regulation.[136] Prokineticins PROK1 and PROK2 act through their G protein–coupled receptors PROKR1 and PROKR2, which are expressed in the olfactory bulbs. PROK2 functions as a chemoattractant for neuronal progenitors, which follow a rostral migratory stream. *Prokr2*$^{-/-}$ mice have reduced LH in the pituitary, small gonads, and abnormal olfactory bulb formation, but *Prokr2* seems to be dispensable for normal pituitary formation.[84,85] Variations in *PROKR2* have also been associated with hypopituitarism, pituitary stalk interruption syndrome, and septo-optic dysplasia but are unlikely to be causative in isolation and likely only contribute to the phenotype, including KS, in combination with other genetic mutations or environmental factors.

Heterozygous pathogenic variants or microdeletions in *CHD7* can also cause CHARGE syndrome, characterized by *c*oloboma, *h*eart abnormalities, choanal *a*tresia, *r*etardation of growth and development, *g*enital hypoplasia, and *e*ar abnormalities.[137] The

genital abnormalities in CHARGE syndrome are caused by hypogonadotropic hypogonadism and are frequently accompanied by olfactory defects and cleft lip/palate.[138]

Mutations in a number of genes have also been identified in association with normosmic hypogonadotropic hypogonadism, and these mutations include genes encoding GnRH1 and its receptor GnRHR, kisspeptin *(KISS1)* and its receptor KISS1R, and neurokinin B (encoded by tachykinin 3 *[TAC3]*) and its receptor TACR3.[134,139–142]

Recently, mutations in genes such as *RNF216*, *OTUD4, STUB1,* and *PNPLA6* have been found in syndromic forms of GnRH deficiency that have associated features such as ataxia and dementia, as part of Gordon Holmes syndrome *(RNF216*, *OTUD4*, *STUB1)* and Boucher-Neuhäuser syndrome *(PNPLA6).*[143–145] *RNF216*, *OTUD4,* and *STUB1* are involved in protein ubiquitination; *PNPLA6* encodes an enzyme involved in the production of the neurotransmitter acetylcholine.

Other genes implicated in syndromic forms of hypothalamic-pituitary disease include *GLI3*, a component of the SHH signaling pathway, haploinsufficiency of which results in Pallister-Hall syndrome associated with polydactyly, hypothalamic disorganization, hypothalamic hamartoma, and hypopituitarism.[146,147] *PITX2* mutation has been identified as one cause of Axenfeld-Rieger syndrome, including ocular, dental, and hypothalamic abnormalities.[148] Pitx2-null mutant mice manifest pituitary hypoplasia and decreased *GHRH receptor (GHRH-R), GH, FSH, LH,* and *TSH* gene expression.[148]

Mutations in *ARNT2* are associated with severe pituitary insufficiency, including GH, TSH, and ACTH deficiencies, and diabetes insipidus with progressive microcephaly, seizures, severe visual impairment, severe learning difficulties, and abnormalities of the renal and urinary tracts.[149] Aryl hydrocarbon receptor nucleus translocator 2 (ARNT2) is a basic helix-loop-helix transcription factor critical for normal development of the paraventricular and supraoptic nuclei.

Deficient anterior pituitary with variable immune deficiency (DAVID) syndrome is a rare disorder comprising central ACTH deficiency and common variable immune deficiency (which can be mild, absent, or develop at a later stage), and a small anterior pituitary has been described in this condition. The syndrome is caused by mutations in *NFKB2*.[150]

Rare isolated pituitary hormone deficiencies have been associated with mutations in the respective hypothalamic-releasing hormones or the releasing hormone receptors (e.g., familial GH deficiency due to *GHRH-R* mutations), TSH deficiency due to *TRHR* mutations, and gonadotrophin deficiency due to *GNRHR* mutations.[123,140,151]

Far fewer mutations have been identified to account for abnormalities of the posterior pituitary and stalk. Pituitary stalk interruption syndrome comprises a thin or absent pituitary stalk, an ectopic posterior pituitary, and small or absent anterior pituitary, usually accompanied by pituitary hormone deficiencies. Roundabout *(robo)* genes, first identified in Drosophila, encode Robo proteins that belong to the immunoglobulin superfamily of protein secreted by midline glial cells and play a role in axon guidance. Whole exome sequencing recently identified *ROBO1* variants in 25 patients with pituitary stalk interruption syndrome (PSIS); however, functional studies were not performed to support causality.[152]

However, no genetic etiology has been identified in most cases of congenital hypopituitarism, which suggests a role for other unidentified genes or environmental or epigenetic factors.

Growth Hormone and Prolactin

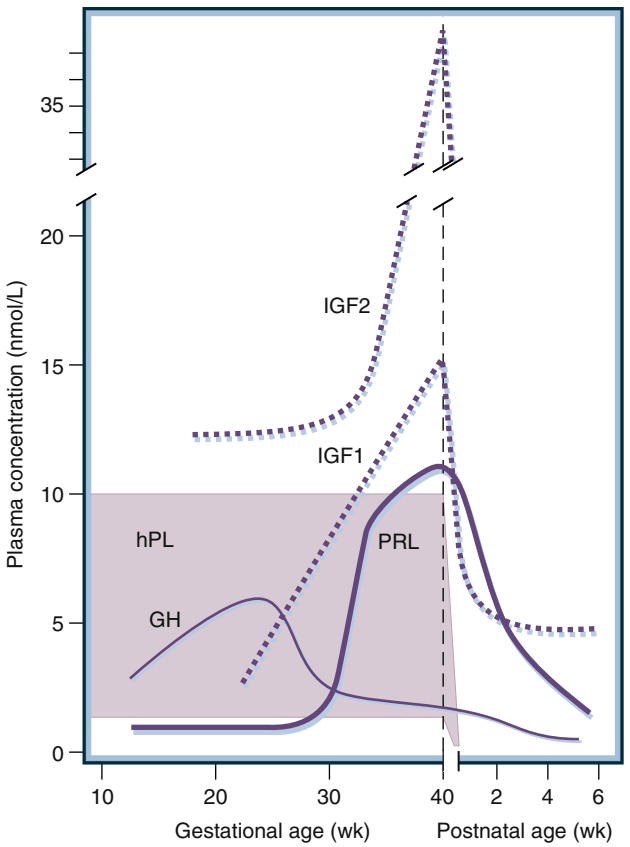
The fetal pituitary gland can synthesize and secrete GH by 8 to 10 weeks' gestation. Pituitary GH content increases from about 1 nmol (20 ng) at 10 weeks to 45 nmol (1000 ng) at 16 weeks. Fetal plasma GH concentrations in cord blood samples are in the range of 1 to 4 nmol/L during the first trimester and increase to a mean peak of approximately 6 nmol/L in midgestation. Plasma GH concentrations fall progressively during the second half of gestation, to a mean value of 1.5 nmol/L at term.[57] The responses of plasma GH to somatostatin and GHRH and to insulin and arginine are mature at term in human infants.[57,153] The high plasma GH concentrations after development of the pituitary portal vascular system at midgestation may reflect unrestrained secretion.[57] Whatever the mechanisms, control of GH secretion matures progressively during the last half of gestation and the early weeks of postnatal life, so that mature responses to sleep, glucose, and l-dopa are present by 3 months of age. GH secretion is already pulsatile soon after birth in humans,[154] but trough concentrations are still higher than in later life so that random GH sampling can be used to detect GH deficiency in the neonatal period, which is not possible at a later age.[155]

The ontogenesis of fetal plasma PRL differs significantly from that of GH; concentrations are low until 25 to 30 weeks' gestation and increase to a mean peak value of approximately 11 nmol/L at term (Fig. 23.5).57 Pituitary PRL content increases progressively from 12 to 15 weeks. PRL release increases in response to TRH and decreases in response to dopamine. Brain and hypothalamic control of PRL matures late in gestation and during the first months of extrauterine life.[57,153] The marked increase in fetal plasma PRL concentration in the last trimester parallels the increase in fetal plasma estrogen concentrations, although it lags by several weeks.[57,153]

Postnatally, GH acts through receptors in liver and other tissues to stimulate production of IGF1 and, to a lesser degree, IGF2. Prenatally, GH receptor mRNA levels and receptor binding are low in fetal liver, although receptor messenger ribonucleic acid (mRNA) is present in other fetal tissues.[57] The growth of anencephalic fetuses is almost normal, suggesting that factors other than GH stimulate fetal IGF production. Nutrition plays an important role.[156,157] PRL receptors are present in most fetal tissues during the first trimester of gestation, and it is likely that lactogenic hormones have a significant role in organ and tissue development early in gestation.[61,157]

Human chromosome 17q22-24 contains a growth hormone/placental lactogen (GH/PL) gene cluster containing five related genes: *GH-N* encodes pituitary growth hormone; *GH-V* encodes placental growth hormone; and *hPL-A, hPL-B,* and *hPL-L* encode placental lactogens (also called chorionic somatomammotropins [CS]). The major circulating placental lactogens derive from the *hPL-A* and *hPL-B* genes. *GH-V* differs in 13 of the 191 amino acids of *GH-N* and is produced in the syncytiotrophoblast.[158] It rises sharply after midgestation to a peak at 34 to 37 weeks, and within 1 hour after delivery of the placenta it disappears from the circulation.[159] Placental *GH-V* is secreted into the maternal circulation and reduces insulin sensitivity in the mother and so spares glucose and other nutrients for transplacental delivery and fetal growth.

Human placental lactogen (hPL) is structurally homologous to GH but functionally closer to prolactin and is secreted directly into both fetal and maternal circulations. hPL is first detected in the mother at 6 weeks of gestation to reach a peak of 5000 to 7000 ng/mL at 32 to 35 weeks; fetal hPL concentrations, however,

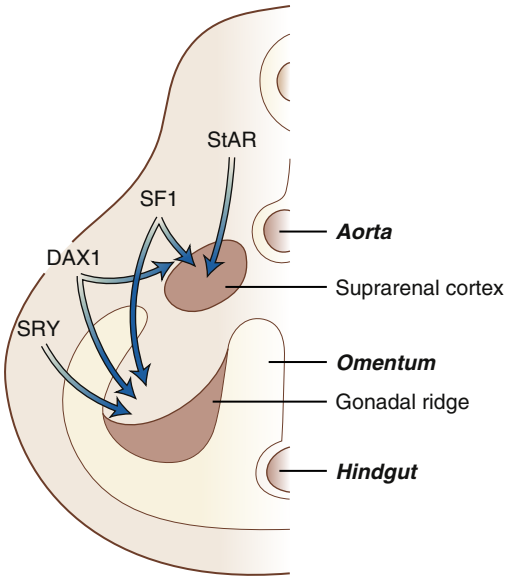


• **Fig. 23.5** Patterns of change of fetal plasma human placental lactogen (hPL), growth hormone (GH), prolactin (PRL), insulin-like growth factor 1 (IGF1), and insulin-like growth factor 2 (IGF2) during gestation and in the neonatal period. The *shaded area* indicates the range of fetal plasma hPL concentrations. (Data from Bennett A, Wilson DM, Liu R, et al. Levels of insulin-like growth factors I and II in human cord blood. *J Clin Endocrinol Metab*. 1983;57:609–612; Kaplan SL, Grumback MM, Aubert ML. The ontogenesis of pituitary hormones and hypothalamic factors in the human fetus: maturation of central nervous system regulation of anterior pituitary function. *Recent Prog Horm Res*. 1976;32:161–243; Bala RM, Lopatka J, Leung A, et al. Serum immunoreactive somatomedin levels in normal adults, pregnant women at term, children at various ages and children with constitutionally delayed growth. *J Clin Endocrinol Metab*. 1981;52:508–512.)

approximate to 20 to 50 ng/mL at term. hPL concentrations increase with placental mass and are higher in twin than singleton pregnancies. Lactogens affect insulin production, hypothalamic gene expression, and leptin action in the mother and so maintain metabolic homeostasis while providing the substrates for nutrition for the fetus and newborn infant. Studies in rodents suggest that maternal hyperphagia is mediated by progesterone and prolactin.[158] At least in rodents, evidence suggests that prolactin and placental lactogen signaling through the PRL receptor is essential for the increase in β-cell mass.[160]

Adrenal

An appreciation of human adrenal development is essential to appropriately understand adrenal physiology as well as the pathologic basis of many congenital adrenal disorders. Furthermore, understanding the regulation of adrenal development sheds light on the emerging critical role the fetal adrenal plays as a component of the fetoplacental unit during pregnancy. The uniqueness of the human fetal adrenal was largely overlooked until 1911



• **Fig. 23.6** Hemi cross section of a 5-week human embryo showing the locations of the adrenal primordia (suprarenal cortices) and gonadal ridges. Steroidogenic factor 1 *(SF1)* is involved in testicular and ovarian development. *SRY* is the single critical regulator of testicular embryogenesis. Inactivation of the *DAX1* gene leads to adrenal hypoplasia. The steroidogenic acute regulatory protein (StAR) is the rate-limiting factor for adrenal steroidogenesis (see text for details).

when Starkel and Węgrzynowski, two Polish medical students, described the fetal zone (FZ) for the first time as an immature cortex, which undergoes involution in the first years of life.[161] At the same time, Elliott and Armour published the article, "The Development of the Cortex in the Human Suprarenal Gland and Its Condition in Hemicephaly," which described the unique FZ.[162] The transient FZ is not present in most mammals and appears to be unique to humans and a few higher primates.

Embryology

The adrenal appears as the bipotential adrenogonadal primordium (AGP) at 28 to 30 dpc in humans[163] due to expression of the transcription factor, steroidogenic factor 1 (SF1, NR5A1), a nuclear receptor essential for adrenal development and steroidogenesis (Fig. 23.6). The adrenal cortex is derived from a thickening of the intermediate mesoderm, known as the gonadal ridge, in contrast to the adrenal medulla, which is derived from the ectoderm.

The AGP cells give rise to the steroidogenic cells of the adrenal gland and the gonad. The gonadal cells migrate caudally. Those cells that are more medial, expressing the highest levels of SF1, migrate retroperitoneally to the upper pole of the mesonephros to form the adrenal primordium at 33 dpc. At about 48 dpc, sympathetic neural crest cells begin migrating to the area where the adrenal primordium (AP) is developing. These cells coalesce and differentiate into the catecholamine-producing chromaffin cells of the adrenal medulla after birth. Following neural crest invasion, the AP becomes encapsulated, resulting in the formation of a distinct organ just above the developing kidney. By 50 to 52 dpc, there are two distinct zones within the cortex: The larger inner FZ contains eosinophilic cells with high levels of expression of steroidogenic enzymes; the smaller outer definitive zone (DZ) is composed of tightly packed cells with much lower levels of steroidogenic enzyme expression. A third cortical zone, the transitional zone (TZ), becomes identifiable from about 14 weeks

postconception (wpc). The TZ lies between the DZ and FZ, containing cells with histologic appearances of both.[14]

The fetal adrenal undergoes tremendous growth as pregnancy progresses largely due to an increase in size of the FZ, which accounts for 80% to 90% of the gland's mass by midgestation.[164,165] The fetal adrenal itself forms 0.4% of body weight at term, weighing 3 to 5 g with a relative size 10-fold to 20-fold that of the adult adrenal.[14] Growth is paralleled by functional development, specifically steroidogenesis for production of androgens from the FZ, with brief periods of increased cortisol secretion. These steroids maintain intrauterine homeostasis and prepare the fetus for life ex-utero. FZ cells robustly express cytochrome P450 17 alpha (P450c17α), a bifunctional enzyme with both 17 hydroxylase and 17,20 lyase activities that converts pregnenolone to DHEA. DHEA is sulfated to DHEAS, which is subsequently aromatized by the placenta to estrogens.[14]

Immediately after birth the FZ rapidly involutes and remodels by a process involving apoptosis of cells in its inner region with a concomitant decrease in adrenal androgen secretion.[163] The weight of the adrenal gland drops by 50% within the first 2 weeks after birth,[166] and the FZ is absent by 6 months of age in most cases. Whether the timing of fetal adrenal involution is determined by gestation or by birth is controversial. FZ androgen production has been reported to persist in infants born prematurely[167]; however, a more recent sonographic study demonstrated a similar pattern of adrenal involution within the first 2 weeks after birth in all neonates examined, regardless of their gestational age at birth.[14]

Cells with zona reticularis morphology are detectable in human adrenal cortex from around 3 years of age until a continuous ZR forms at around 6 years of age and adrenal androgen synthesis recommences, a stage referred to as adrenarche.[168] The DZ and TZ give rise, respectively, to the zona glomerulosa and zona fasciculata of the developing adult adrenal cortex.

Transcriptional Regulation of Adrenal Development

Insight into the genetic regulation of adrenal development has been gleaned from human and animal models of disordered development. The spatiotemporal expression of key genes is critical. Genes involved in the formation of the intermediate mesoderm and urogenital ridge affect kidney, adrenal, and gonadal development; those affecting AGP development affect both adrenal and gonadal development, and there are also those that specifically affect AP development.

The earliest stages of adrenal development appear to be regulated by a number of transcription factors (e.g., ODD1, SALL1, FOXD1/FOXD2, WT1, SF1, DAX1), coregulators (e.g., CITED2), signaling molecules (e.g., SHH/GLI3, WNT3/WNT4/WNT11), matrix proteins (e.g., SPARC), and regulators of telomerase activity (e.g., ACD). The transcription factors most significant for early development of the AGP have emerged as *SF1* and *DAX1* (dosage-sensitive sex reversal, adrenal hypoplasia congenita [AHC], X-chromosome factor, NR0B1).[169–171] As well as expression in the adrenal cortex, these genes are also expressed in the gonads, hypothalamus, and pituitary tissues. In the absence of *SF1* expression, the adrenal gland does not form.[163] *Sf1*-knockout mutant mice manifest adrenal and gonadal agenesis, gonadotropin deficiency, and absence of the hypothalamic ventromedial nucleus.[170] Severe disruption of *SF1* in humans can cause adrenal dysfunction, although most pathogenic variants in *SF1* in humans cause impaired testicular development and Leydig cell dysfunction rather than adrenal insufficiency. Heterozygous loss-of-function mutations in *SF1* in humans result in 46,XY and 46,XX DSD, complete gonadal dysgenesis, and primary adrenal failure.[170] No cases of homozygous *SF1* mutations have been reported to date. Current data indicate that, while Wilms tumor 1 (WT1) regulates *Sf1* expression in the AGP, Cbp/p300-interacting transactivator with Glu/Asp-rich carboxy-terminal domain 2 (CITED2) expression in the AGP is necessary for proper differentiation of the AP.[163]

SF1 upregulates DAX1, which is itself a negative regulator of SF1 transcriptional activity and hence steroidogenesis. It is unclear how disruption of SF1 and its negative regulator can cause similar defects; however, DAX1 can function as a coactivator for SF1 transcriptional activity in steroidogenic cells when expressed at high levels. Inactivating *Dax1*/*DAX1* mutations in mice and humans are associated with gonadotropin deficiency and adrenal hypoplasia.[170] Knockdown of *Dax1* results in premature differentiation of mouse adrenocortical progenitor cells, and adrenal failure occurs as the reservoir of stem/progenitor cell pluripotency is depleted. Pathogenic variants or deletions of *DAX1* in humans are well established as the cause of X-linked adrenal hypoplasia congenita (AHC).[172]

Transcription factors involved in the early formation of the rodent urogenital ridge include *Odd1, Wt1, Sall1, Pbx4, Wnt4, FOxD1,* and *FoxD2*. *Wt1* knockout mice have renal and gonadal anomalies and lack adrenal glands, and in humans, germline *WT1* mutations cause defects in gonad and kidney formation.[171] *Pbx1* knockout mice die in utero with multiple organ defects that include adrenal agenesis and impaired testis development. *Wnt4*-null mutant mice, in contrast, have impaired kidney development from 15 dpc, masculinization of XX females, müllerian duct agenesis, and abnormal adrenal glands with reduced steroidogenic enzyme expression. A homozygous missense mutation in *WNT4* in humans was shown to be associated with renal agenesis, gonadal defects, and adrenal hypoplasia from 19 weeks' gestation. *Sall1*-null mutants have severe kidney dysgenesis or agenesis and hypoplastic adrenal glands at birth. Heterozygous mutations in *SALL1* result in Townes-Brocks syndrome, which comprises renal and genital abnormalities. The murine model that phenocopies the deletion seen in Townes-Brocks syndrome shows absent adrenal glands and kidneys and hypoplastic gonads at 16 dpc.

Signaling Pathways in Adrenal Development

Sonic hedgehog, a member of the vertebrate hedgehog (Hh) family of secreted ligands, performs numerous crucial roles during embryonic development and is required in the adult for tissue maintenance, differentiation, and the regulation of stem cell populations. SHH signaling is required for normal adrenal development, at a later stage than SF1 and DAX1, and is expressed in the AP in cells just beneath the capsule.[173–175] It has long been thought that undifferentiated, pluripotent stem cells exist in the adrenal cortex to maintain homeostasis in the adult. The precise origin of adrenocortical cells is debatable, and their origin remains ambiguous. Studies focused on a downstream activator of the hedgehog pathway, glioma-associated oncogene homolog 1 (zinc finger protein) (Gli1), provide evidence that the adrenal capsular cells also give rise to the DZ. Gli1-expressing cells are specifically located in the adrenal capsule and do not express SF1. In vitro this subpopulation of cells is capable of giving rise to SF1-expressing differentiated adrenocortical cells during embryonic development.[174] Shh expression marks cortical progenitors,[173] and Shh-expressing cells give rise to all steroidogenic cells in cortical zones. Homozygous deletion of Shh in murine embryos is lethal; however, analysis of their adrenal gland at 14.5 and 16.5 dpc indicates that the adrenal primordium forms but is much smaller than in the wild type.[174,175]

Several lines of evidence suggest that β-catenin plays an important role in adrenal zonation and maintenance. Activation of the β-catenin pathway is restricted to the ZG,[176] and ectopic expression leads to the activation of ZG markers in ZF cells.[87] Members of the R-spondin *(Rspo)* gene family have recently been identified to be expressed from E12.5 onward within mesenchymal cells surrounding the forming adrenal.[177] R-spondins are signaling molecules that positively regulate the β-catenin signaling pathway. This study showed capsular RSPO3 signals to the underlying steroidogenic compartment to induce β-catenin signaling and imprint glomerulosa cell fate. SHH in turn signals back to recruit capsular cells to form the adrenal cortex, at least during development. This study therefore identifies the adrenal capsule as a crucial signaling center that is continuously required for proper zonation.

FGF signaling controls early developmental processes such as anterior/posterior patterning and organogenesis.[178] FGFs are a large family of secreted glycoproteins that bind to four signaling FGF receptors, FGFR1 to FGFR4. FGF signaling interacts with SF1 and SHH signaling.[179] *Fgfr2* and *Fgfr4* are expressed in the developing adrenal cortex. Embryos with a global *Fgfr2IIIb* deletion have hypoplastic adrenal glands,[179] and deletion of both isoforms of *Fgfr2* from steroidogenic tissue recapitulates this phenotype and causes male-to-female sex reversal, implying that *Fgfr2* is not necessary for AGP formation but is required for the subsequent growth and development of the adrenal gland.[180] Epidermal growth factor (EGF) stimulates proliferation of both the fetal and definitive zones. The fetal adrenal expresses high levels of IGF2 mRNA and protein, which are responsive to ACTH.[15] IGF2 augments ACTH-stimulated expression of steroidogenic enzymes and stimulates steroid hormone production in fetal adrenal cortical cells.

Cyclin-dependent kinase inhibitor 1 C *(CDKN1C, P57KIP2)* is a paternally imprinted gene located on chromosome 11p.15, which encodes the CDKN1C protein, an inhibitor of cell cycle progression. Variations in *CDKN1C* or its genomic imprinting can lead to adrenal pathology.[171] Loss of function of *CDKN1C* results in Beckwith-Wiedemann syndrome (BWS), an overgrowth syndrome with increased susceptibility to adrenal carcinoma. IMAGe (intrauterine growth restriction, metaphyseal dysplasia, AHC, and genital anomalies) syndrome is a rare multisystem disorder[181] that mirrors the features of BWS and is caused by gain-of-function mutations in *CDKN1C*. Most affected individuals are born small and develop skeletal abnormalities. Males present with genital malformations, including micropenis and undescended testes and urethral anomalies, but the most clinically important component of the syndrome is adrenal insufficiency that causes salt wasting, hypoglycemia, and shock due to loss of both mineralocorticoid and glucocorticoid synthesis and that can be life threatening shortly after birth.[181]

Fetal Adrenal Steroidogenesis

The fetal adrenal expresses five steroidogenic apoenzymes as in the adult gland: CYP17A1 (P450c17, 17-hydroxylase/17-20-lyase), CYP21A2 (P450c21, 21-hydroxylase), CYP11A1 (P450scc, side-chain cleavage), CYP11B1/CYP11B2 (P450c11/aldosterone synthase). The fifth enzyme, expressed by the smooth endoplasmic reticulum, exhibits both 3βHSD and Δ^4, Δ^5-isomerase activities.[14] The spatiotemporal expression of these results in differences in zonal activity of these enzymes, and transcription of steroidogenic genes is tightly regulated.[14] Steroid production from the fetal adrenal has important roles in the maintenance of intrauterine homeostasis and in the maturation of the fetus in preparation for postnatal adaptation to extrauterine life. Vast quantities of cholesterol are required as a precursor for steroid production; they are obtained through low-density lipoprotein receptors on the cell surface as well as intracellular synthesis of cholesterol from acetate. As in the adult adrenal, cholesterol use for steroids is tightly controlled by the expression of steroidogenic acute regulatory (StAR) protein, which regulates transport of cholesterol to the inner mitochondrial membrane, where CYP11A converts it to pregnenolone. Sphingosine-1-phosphate lyase (SGPL1) is an endoplasmic reticulum enzyme, ubiquitously expressed in tissues. This enzyme mediates irreversible cleavage of the lipid signaling molecule sphingosine-1-phosphate. Several recent studies report mutations in SGPL1 resulting in primary adrenal insufficiency and steroid-resistant nephrotic syndrome.[182,183]

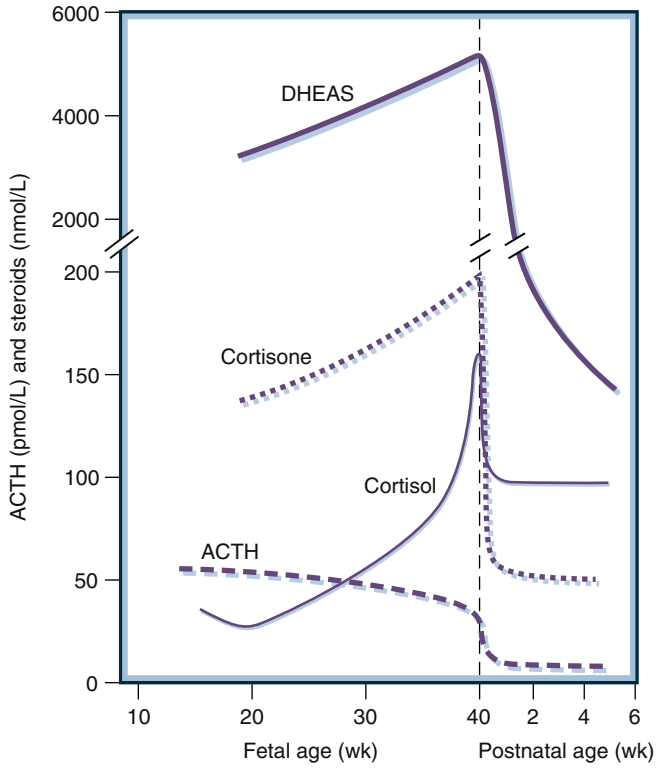
During most of gestation, the fetal adrenal lacks 3βHSD2, preventing cortisol and aldosterone synthesis and directing steroid production toward DHEA production. High expression of SULT2A1 in the FZ accounts for sulfation of most of the Δ^5 steroids produced, including DHEA and pregnenolone. DHEA is sulfated in the FZ to DHEAS, which is then converted by placental aromatase to estrogens.[14]

The TZ produces cortisol, with an early peak from 8 to 9 wpc coinciding with transient expression of 3βHSD2.[184] The hypothalamic-pituitary-adrenal (HPA) axis is sensitive to glucocorticoid-mediated feedback at this time; 46,XX fetuses with steroidogenic defects (e.g., in CYP21 or CYP11) lack cortisol and have an elevated ACTH drive that results in excess production of fetal androgens at a time when the genital and scrotal folds are sensitive to androgen exposure, resulting in virilization of female genitalia.[184] Cortisol can retard fetal and placental growth and so is converted to biologically inactive cortisone by the enzyme 11βHSD2 in placental and fetal tissues. In this way the fetus is protected from high concentrations of cortisol in utero. Concentrations of circulating cortisone in the fetus at midgestation are fourfold to fivefold higher than cortisol concentrations (Fig. 23.7).

The pattern of enzyme maturation in the fetal adrenal suggests that cortisol production does not occur de novo from cholesterol until 30 weeks' gestation, but some production using progesterone as precursor probably occurs earlier.[15] During the third trimester, expression/activity of 11βHSD2 drops and selected fetal tissues, including liver and lung, express 11βHSD1 so that glucocorticoids are available to the fetus to promote the maturation of fetal organs, including the lung and brain. This increase in fetal cortisol production has an important role for extrauterine survival (see "Transition to Extrauterine Life"). The number of glucocorticoid receptors in the sheep fetal hypothalamus increases at term, at the time of increasing glucocorticoid concentrations, suggesting that some process in the fetus allows the normal autoregulation of glucocorticoid receptors to be overridden at term.[185] Mice lacking GR function manifest enlarged and disorganized adrenal cortices, adrenal medullary atrophy, lung hypoplasia, and defective gluconeogenesis. They appear normal at birth but are not viable.

Postnatally, biologically active cortisol predominates over cortisone in the circulation. Healthy term infants have initial pulsatility of cortisol secretion and can develop a circadian rhythm from as early as 1 month after birth, although there is considerable individual variability. There is, however, no consensus about the definition of a "normal" cortisol concentration in preterm infants.

Antenatal steroids for a threatened preterm delivery have clear beneficial effects, with a reduction in mortality and morbidity, but there are consequences of such early high steroid exposure, and long-term effects are unknown. The HPA axis is highly susceptible



• **Fig. 23.7** Patterns of change of fetal plasma adrenocorticotropic hormone *(ACTH),* cortisol, cortisone, and dehydroepiandrosterone sulfate *(DHEAS)* during gestation and in the neonatal period. The trend of average values is shown for each hormone in nanomoles per liter. Notice the broken scale for DHEAS. (Data from Geller DH, Miller WL. Molecular development of the adrenal gland. to programming during development. Unlike the endogenous glucocorticoids that are inactivated by 11βHSD2 in the placenta, synthetic glucocorticoids readily cross the placenta. In the fetal sheep, hypothalamic and pituitary glucocorticoid receptors are present at midgestation, and corticotropin suppressibility can be demonstrated by the midpoint of the third trimester of gestation.[185]

Longitudinal follow-up of the offspring of women treated with betamethasone for threatened preterm birth has shown that individuals exhibit insulin resistance 30 years after treatment, particularly women. Previous antenatal treatment of the fetus of a mother whose previous child had CAH by administering dexamethasone orally to the mother at 8 to 12 wpc was found to reduce fetal androgens and hence the virilization of female fetuses, but due to paucity of high-quality evidence in terms of efficacy and safety this should be regarded as a highly controversial experimental treatment.[13] The constant dexamethasone dose used can result in cortisol concentrations that exceed physiologic fetal concentrations by around 60-fold. To date, a number of side effects and adverse associations have been reported, including neurologic abnormalities in the offspring.[13]

Use of steroids postnatally to prevent or treat chronic lung disease in preterm infants facilitates earlier extubation and reduces the risk of chronic lung disease, but it is associated with hyperglycemia, hypertension, gastrointestinal bleeding and perforation, hypertrophic cardiomyopathy, growth failure, and cerebral palsy and thus cannot be recommended.[186] Trials involving more physiologic doses of hydrocortisone are currently underway, but all systemic and inhaled steroids are associated with adrenal suppression in neonates.

Early low-dose hydrocortisone treatment has been reported to improve survival in very preterm infants without bronchopulmonary dysplasia. In an analysis of secondary outcomes of the PREMILOC (Early Low-Dose Hydrocortisone to Improve Survival Without Bronchopulmonary Dysplasia in Extremely Preterm Infants) randomized clinical trial of extremely preterm infants, early low-dose hydrocortisone was not associated with a statistically significant difference in neurodevelopment at 2 years of age.[187] Further randomized studies are needed to provide definitive assessment of the neurodevelopmental safety of hydrocortisone in extremely preterm infants.

The human fetal adrenal gland is capable of aldosterone secretion near term with the development of the zona glomerulosa, and fetal plasma aldosterone concentrations in infants who are born by caesarean section are threefold or fourfold higher than maternal concentrations.[188] Vaginal delivery and maternal salt restriction increase concentrations in both mother and infant. The increased aldosterone concentrations in the fetus are a result of increased fetal adrenal secretion and persist during the first year of extrauterine life. There is poor correlation between plasma renin activity (PRA) and aldosterone concentrations in cord blood.[189] Mineralocorticoid receptors (MRs) are present in fetal tissues from 12 to 16 weeks' gestation.[190] MR immunoreactivity is detectable in fetal kidney, skin, hair follicles, trachea and bronchioles, esophagus, stomach, small intestine, colon, and pancreatic exocrine ducts. The role of MRs in these fetal tissues remains unclear. MR knockout mice appear normal at birth but demonstrate defects in mineralocorticoid and renin-angiotensin system functions in the postnatal period.[191]

Angiotensin II concentrations in the sheep fetus are similar to maternal values, and blockade of fetal production with angiotensin-converting enzyme (ACE) inhibitors decreases the fetal glomerular filtration rate.[192] Both subtypes of angiotensin receptors, AT_1 and AT_2, are detectable in various tissues, including kidney, early in fetal development.[191] Hormonal factors modulate fetal renal AT gene expression in sheep: Angiotensin II suppresses both AT_1 and AT_2, and cortisol increases AT_1 gene expression in kidney and lungs.[193] The role of the fetal renin-angiotensin system is not clear; rather than modulating renal sodium excretion through aldosterone, it may maintain renal excretion of salt and water into amniotic fluid to prevent oligohydramnios.[192] The mechanism for the high aldosterone concentrations in the fetal and neonatal periods remains unclear.

Aldosterone affects renal sodium excretion in the fetal sheep and in premature infants.[189] Manifestations of mineralocorticoid deficiency in the newborn term infant can occur because of aldosterone deficiency or competition for binding to renal MRs by other steroids such as 17-hydroxyprogesterone. Relatively reduced glomerular filtration in the newborn limits sodium loss initially, but by 1 week of age, aldosterone deficiency produces the characteristic manifestations of hyponatremia, hyperkalemia, and volume depletion.

Hormonal Regulation of Adrenal Development

The hormonal regulation of adrenal development is not understood. A major stimulus to fetal adrenal function is fetal pituitary ACTH, a 39–amino acid peptide secreted from the anterior pituitary gland under control of CRH. ACTH binds to the transmembrane receptor melanocortin 2 receptor 2 (MC2R), specifically in adrenocortical cells, and exerts its effect through downstream cyclic adenosine monophosphate (cAMP) and Ras/MEK/ERK signaling pathways. The growth-promoting effects of ACTH are mediated in part through the stimulation of locally produced growth factors such as insulin-like growth factor 2 (IGF2) and fibroblast growth factor β (FGFβ).[163] During development, as the outer DZ emerges, ACTH participates in the regulation of steroidogenesis, cell differentiation, and cell growth.[163] While adrenocortical growth and differentiation are independent of ACTH during the first trimester of human pregnancy, ACTH begins to play an essential role in the morphologic and functional development of the adrenal gland after 15 weeks' gestation.[194]

In vivo ACTH stimulates steroid production by activating StAR and increasing delivery of substrate cholesterol to P450scc.[188] In vitro ACTH directly stimulates DHEAS and cortisol production, and in vivo excess ACTH is clearly involved in driving the high androgen concentrations seen in fetuses affected with CAH. The HPA axis clearly functions early in fetal life, but anencephalic fetuses, which lack pituitary ACTH, have adrenals that contain a fairly normal complement of steroidogenic enzymes and retain their capacity for steroidogenesis.[171] Furthermore, growth and rising steroid production by the fetal adrenal during pregnancy are not paralleled by increasing concentrations of fetal plasma ACTH. A possible explanation for this paradox is that there may be gestational age–dependent alterations in responsiveness of the fetal adrenal tissue to ACTH. Thus it appears that both ACTH-dependent and ACTH-independent mechanisms regulate fetal adrenal steroidogenesis.

The presence of all CRH peptides and their receptors in the adrenal suggests that the CRH system can function locally within human and rodent adrenals. An important source of CRH is the human placenta, which releases CRH into the fetal circulation. As gestation advances, CRH concentration increases. The remarkable increase in placental CRH production at the end of gestation has been suggested to contribute to the parturition process by forming a feed-forward loop that leads to increased production of cortisol and DHEA/DHEAS in human fetal adrenals. Studies have shown that CRH stimulates cortisol production in primary cultures of fetal adrenocortical cells by elevating the mRNA levels of steroidogenic acute regulatory protein and other steroidogenic enzymes, including *3βHSD2, CYP21A2,* and *CYP11B1*. In addition, CRH enhances the adrenal response to ACTH, further driving the production of cortisol and DHEA/DHEAS.[51] *CRH* gene knockout in mice leads to neonatal death due to pulmonary hypoplasia, suggesting that CRH-stimulated glucocorticoid production is essential for adrenergic chromaffin and normal lung development. Circulating CRH concentrations are elevated in the fetus, largely from extrahypothalamic and placental sources. The circulating concentrations of CRH increase 1000-fold as pregnancy progresses[45] and reach values of 0.5 to 1 nmol/L at term; normal values in nonpregnant women are lower than 0.01 nmol/L. At the end of pregnancy, there is increased bioavailability of CRH due to a fall in levels of its binding protein. This results in an exponential increase in maternal CRH concentrations from 35 weeks' gestation to term.[45,195] Postpartum, CRH normalizes to nonpregnant levels within 24 hours of delivery in keeping with the fact that the placenta is the primary source.[45,195] This placental CRH is bioactive, and concentrations correlate with maternal cortisol concentrations, suggesting that this circulating placental CRH plays a role in stimulating maternal corticotropin release. Midgestation fetal plasma corticotropin concentrations average about 55 pmol/L (250 pg/mL), levels that maximally stimulate fetal adrenal steroidogenesis, and concentrations are higher throughout gestation than in postnatal life, although they fall near term (see Fig. 23.7).[25,188]

The Fetal-Placental Unit

The paradox of human fetal adrenal function is that steroidogenesis is programmed by the steroidogenic enzyme expression pattern (e.g., relative 3βHSD deficiency) to produce inactive products (including DHEA and pregnenolone and their sulfate conjugates).[188] Much of the DHEA is converted to 16-hydroxy-DHEAS by the fetal adrenal and fetal liver. As previously discussed, this is designed to provide a substrate for placental estrone and estradiol production: 16-hydroxy-DHEA undergoes metabolism to estriol in the placenta. Fetal DHEAS production and maternal estriol concentrations increase progressively to term; DHEAS production approximates to 200 mg/day near term.[25] In pregnant baboons with placental estrogen production suppressed by administration of an aromatase inhibitor, the volume of the FZ of the fetal adrenal increased markedly.[196] This effect was reversed by administration of inhibitor plus estrogen, suggesting that estrogen selectively suppresses FZ growth and development during the second half of primate pregnancy. It is proposed that this represents a feedback system to regulate secretion of fetal adrenal DHEA, thereby maintaining normal fetal-placental function and development.[196]

Adrenal Insufficiency

Adrenal insufficiency is a rare condition that may occur secondary to ACTH deficiency or is primary resulting from adrenal failure. The mature ACTH peptide is cleaved from the larger precursor molecule, POMC, together with other small peptides such as β-endorphin and α-MSH and β-MSH. Defects in ACTH synthesis, processing, or release can lead to secondary adrenal hypoplasia resulting in neonatal hypoglycemia, prolonged jaundice, or collapse. Given that mineralocorticoid secretion is largely independent of ACTH secretion, it is preserved, and salt loss is therefore unusual. Nevertheless, mineralocorticoid deficiency can be an issue in some patients with ACTH insensitivity. Low serum concentrations of ACTH, absence of hyperpigmentation, and presence of associated features such as pale skin, red hair, diarrhea, and obesity (*POMC*/*PC1* mutations) are important diagnostic clues.

The presence of multiple pituitary hormone deficiencies (e.g., GH, ACTH, TSH, gonadotropins, vasopressin, and PRL) may point to a diagnosis of multiple pituitary hormone deficiency, often in association with structural abnormalities of the pituitary gland, eye abnormalities, and forebrain abnormalities (septo-optic dysplasia). Signs such as those of congenital hypothyroidism, hypoglycemia, congenital hypogonadotropic hypogonadism (micropenis, undescended testes), and severe postnatal growth failure may be suggestive of the diagnosis. A number of single-gene defects have now been associated with congenital hypopituitarism (e.g., mutations in *HESX1*, *SOX3*, *OTX2*, *GLI2*, *ARNT2*, *LHX3*, *LHX4,* and *PROP1*).[55,149,197] Occasionally ACTH insufficiency may not be present at the time of diagnosis but may develop progressively with time.

Recessive mutations in the T-box factor *TPIT (TBX19)* have been identified in patients with severe, early-onset isolated ACTH deficiency with profound hypoglycemia, prolonged jaundice, and sudden neonatal death.[118] *TPIT* is required for the specification, maturation, and maintenance of both precorticotroph and premelanotroph populations and for the suppression of gonadotroph fate. It is also required to activate the expression of POMC in conjunction with the transcription factor PTX1. Murine transgenesis resulted in ACTH and glucocorticoid deficiencies, adrenal hypoplasia, and pigmentation defects in mice deleted for *TPit.*[118] Sixty-five percent of patients with severe congenital isolated ACTH deficiency are found to have *TBX19* mutations, but mutations are not found in partial or later-onset ACTH deficiency.[198]

ACTH resistance can occur in a number of well-defined entities, such as defects in the ACTH receptor (MC2R), familial glucocorticoid deficiency (FGD) type 1 (FGD1), in MC2R accessory protein (MRAP, FGD2), or as part of the triple-A syndrome (alacrimia, achalasia, addisonism; also known as Allgrove syndrome, caused by defects in ALADIN/*AAAS*). These disorders are characterized by isolated glucocorticoid deficiency, hyperpigmentation, and markedly elevated concentrations of ACTH.[199,200] Nevertheless, approximately 15% of individuals with triple-A syndrome have evidence of mineralocorticoid insufficiency, those with the most severe loss of function manifesting hyponatremia on presentation. Recently, mutations in *NNT* (nicotinamide nucleotide transhydrogenase), *GPX1* (glutathione peroxidase 1), and *MCM4* (mini-chromosome maintenance-deficient-4 homologue) have been found as a cause of FGD.[201–203] Mutations in *MCM4* were found in an Irish Traveller community and result in late-onset, less severe glucocorticoid deficiency, short stature, and natural killer cell deficiency due to increased chromosomal breakage. Mutations in *GPX1* and *NNT*, involved in detoxification of reactive oxygen species, can also result in FGD.[204]

Primary adrenal failure may be caused by congenital adrenal hypoplasia (or AHC).[205] This results in severe salt-losing primary adrenal failure in early infancy or childhood, although milder, delayed-onset forms of the condition exist. The most common form of the condition is X-linked. Patients have mutations in the nuclear receptor DAX1 *(NROB1)*; in addition to adrenal failure, the males suffer from hypogonadotropic hypogonadism. Rarely, patients present with isolated mineralocorticoid deficiency with normal cortisol concentrations; however, glucocorticoid deficiency usually develops later. *DAX1* is expressed in ES cells, steroidogenic tissues (gonads and adrenals), the ventromedial hypothalamus (VMH), and pituitary gonadotrophs. It acts as a transcriptional repressor of other nuclear receptor pathways but is also involved in maintenance of pluripotency of stem cells.[206]

Heterozygous and homozygous mutations in SF1 have been associated with adrenal failure in 46,XY phenotypic females, as well as in at least one 46,XX girl, although the latter phenotype is rare.[205] Mutations in SF1 have also been associated with gonadal dysgenesis in 46,XY individuals in the absence of adrenal insufficiency.[207] Additionally, SF1 mutations have been associated with primary ovarian failure, but this is rare.[208,209]

Various forms of congenital adrenal hyperplasia may be associated with variable adrenal failure (e.g., mutations in *CYP11A1*, *StAR*, *HSD3B2*, *CYP17*, *CYP21A2*, *CYP11B1*) with varying degrees of genital ambiguity. The enzyme P450c11 (aldosterone synthase), which is found in the ZG, has 11β-hydroxylase, 18-hydroxylase, and 18-methyloxidase activities and catalyzes all the reactions needed to convert 11-deoxycorticosterone (DOC) to aldosterone. Mutations in the gene encoding the enzyme are associated with isolated mineralocorticoid deficiency. Functional mineralocorticoid deficiency with severe salt loss resulting in hyponatremia and hyperkalemia may also arise as a result of mutations in the *MR* or in the gene encoding the epithelial sodium channel (ENaC).

Primary adrenal insufficiency due to adrenal hypoplasia can be classified into nonsyndromic and syndromic (triple-A syndrome, IMAGe syndrome, Irish Travellers syndrome) types, and up to 30% of patients have no cause identified. Whole exome sequencing of patients with syndromic primary adrenal insufficiency and a striking phenotype of a multisystem disorder, including myelodysplasia, infection, growth restriction, adrenal hypoplasia, genital anomalies, and enteropathy, revealed mutations in the *SAMD9* gene (MIRAGE syndrome).[210,211] A diagnosis of adrenal insufficiency must be prompt in view of the potential life-threatening consequences of glucocorticoid and mineralocorticoid deficiencies to the infant.

Thyroid Development

Embryology

The thyroid gland, one of the first endocrine organs to develop, is derived from contributions of two anlagen: By 22 dpc a midline thickening of the pharyngeal floor (median anlage) forms as the precursor of the T_4-producing follicular cells. Paired ultimobranchial bodies originating from the fourth pharyngobranchial pouches (lateral anlagen) give rise to the parafollicular calcitonin-secreting (C) cells.[21]

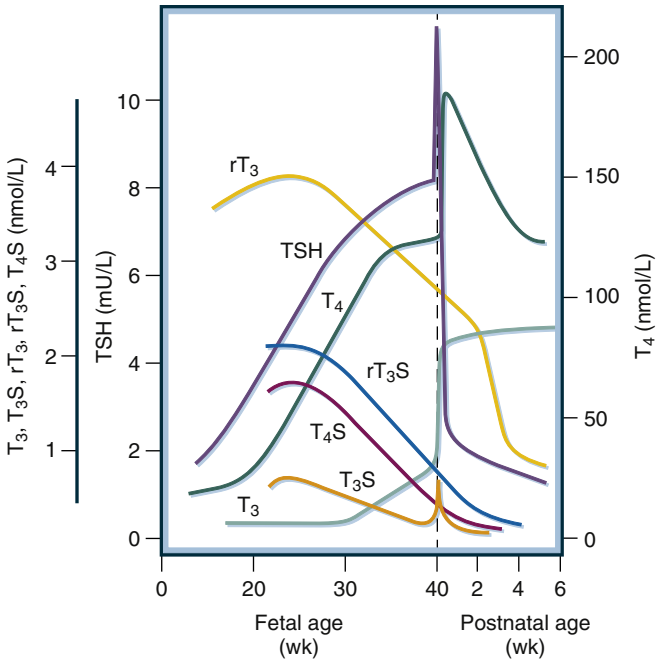
The thyroid precursor cells migrate caudally between 28 and 48 dpc, proliferate, and expand laterally, a process known as lobulation. The lateral and median anlage fuse at around 44 dpc, and during descent the developing thyroid retains an attachment to the pharynx by an epithelial stalk known as the thyroglossal duct.[212] By 37 dpc this structure that connects the median anlage with the floor of the buccal cavity (a point later known as the foramen cecum on the developing tongue) has usually disappeared and the only remnant of the duct is the foramen cecum itself.[212] An ectopic thyroid and a persistent thyroglossal duct or cyst may occur because of abnormal thyroid descent.

By 51 dpc, the gland comprises two lateral lobes with a connecting isthmus, and it reaches its final position below the thyroid cartilage by 9 wpc. At 10 wpc, the fetal thyroid gland weighs about 80 mg and at term 1 to 1.5 g. Terminal differentiation begins at around 60 dpc, only after migration is complete. Differentiation is evidenced by expression of the genes encoding the TSH receptor *(TSHR)*, the sodium-iodide symporter *(NIS)*, thyroglobulin *(Tg)*, and thyroperoxidase *(TPO)*, and results in formation of follicles and functional capacity.[213] Production of thyroid hormones is stimulated by TSH and requires an adequate supply of iodine. By 70 dpc colloid is visible histologically and the thyroid gland expresses *Slc5a5*, encoding the 13-transmembrane domain glycoprotein NIS, enabling uptake of iodine and synthesis of thyroid hormones. Thyroid hormones can be detected in the thyroid from 9 wpc and in fetal blood from 10 wpc.[214–217]

Thyroid Hormone Biosynthesis

Pituitary and plasma thyrotropin (TSH) concentrations begin to increase during the second trimester in the human fetus, at about the time that pituitary portal vascular continuity develops (Fig. 23.8).

In the rat, expression of the *Tshr* gene is significantly upregulated on fetal day 17, and this is accompanied by significant



• **Fig. 23.8** Patterns of change of fetal plasma thyroid-stimulating hormone (TSH), thyroxine (T_4), triiodothyronine (T_3), reverse T_3 (rT_3), and iodothyronine sulfates (T_4S, rT_3S, and T_3S) during gestation and in the neonatal period. The patterns for T_4S and rT_3S are based on limited 30-week data. (Data from Roti E. Regulation of thyroid stimulating hormone [TSH] secretion in the fetus and neonate. *J Endocrinol Invest*. 1988;11:145–158; Fisher DA, Klein AH. Thyroid development and disorders of thyroid function in the newborn. *N Engl J Med*. 1981;304:702–712; Santini F, Chiovato L, Ghirri P, et al. Serum iodothyronines in the human fetus and the newborn: evidence for an important role of placenta in fetal thyroid hormone homeostasis. *J Clin Endocrinol Metab*. 1999;84:493–498.)

growth and rapid development in terms of structure and function. The expression of *Tg* and *TPO* is increased, and thyroid follicles are seen with thyroid hormonogenesis, suggesting that the TSHR has an important role to play in these events. Murine mutation of the *Tshr* gene is associated with the *hyt/hyt* phenotype, which exhibits severe hypothyroidism and a hypoplastic but normally located thyroid gland with a poorly developed follicular structure. In humans, a similar phenotype is observed in babies of mothers with potent TSHR-blocking antibodies and in babies with severe loss-of-function mutations in *TSHR*.

Although onset of fetal thyroid hormone synthesis starts at the end of the first trimester, levels are low and necessitate a high dependency on maternal thyroid hormones during pregnancy. Overt maternal hypothyroidism has been shown to be associated adversely with pregnancy outcomes, including miscarriage and premature delivery, as well as adverse perinatal and neurocognitive outcomes in offspring. The effects of subclinical maternal hypothyroidism or hypothyroxinemia are less clear. Using a zebrafish model, the ontogeny of the hypothalamic-pituitary-thyroid axis and its negative-feedback regulation by thyroid hormones has been characterized. Embryonic exposure to excess thyroid hormone during a developmental time window resulted in long-term dysregulation of pituitary function by apoptosis of developing thyrotrope cells.[218] These findings are relevant in the context of maternal hyperthyroidism due to maternal Graves or overreplacement of pregnant hypothyroid women in the first trimester with levothyroxine.

Plasma thyrotropin concentrations increase progressively during the last half of gestation. Plasma concentrations of T_4-binding globulin and total T_4 increase progressively, from low levels at 14 to 16 wpc to maximal levels at term. Free T_4 concentrations increase with the increase in T_4 production. The increases in plasma TSH and T_4 concentrations during the third trimester reflect progressive maturation of hypothalamic pituitary control and of thyroid gland responsiveness to TSH. Pituitary TSH secretion is responsive to hypothyroxinemia and to TRH early in the third trimester.[215] The period of parallel increases in fetal TSH and free T_4 concentrations during the latter half of gestation is followed by sequential surges of TSH and free T_4 in the early neonatal period and a final slow equilibration of the TSH/free T_4 ratio to adult values during infancy and childhood.[219–222] This sequence includes coordinated maturation of hypothalamic TRH secretion, pituitary TRH sensitivity, thyrotropin negative-feedback control, and thyroid follicular cell responsiveness to TSH. Fetal serum TRH concentrations are higher than in maternal blood, which is the consequence of extrahypothalamic (placenta and pancreas) TRH production and decreased TRH degradation in fetal serum. Functionally, the fetus progresses from a state of both primary (thyroidal) and tertiary (hypothalamic) hypothyroidism at midgestation, through a state of mild tertiary hypothyroidism during the final weeks in utero, to a fully mature hypothalamic-pituitary-thyroid axis by 2 months after birth.

The adult thyroid follicular cell can modify iodine transport or uptake with changes in dietary iodine intake, independent of variations in serum TSH concentrations.[223,224] Before 36 to 40 weeks' gestation, the thyroid gland lacks this autoregulatory mechanism and is susceptible to iodine-induced inhibition of thyroid hormone synthesis.[224,225] The fetal thyroid follicular cell, when exposed to high circulating levels of iodide, is unable to reduce iodide trapping and prevent the high intracellular iodide concentrations that produce the blockade of hormone synthesis referred to as the *Wolff-Chaikoff effect*. Failure of the immature thyroid to exhibit autoregulation is probably due to failure of downregulation of thyroid cell membrane NIS units, which may be related to the absence or reduced iodination of an 8-kDa to 10-kDa protein in the thyroid follicular cell.[223,224] In addition to maturation of autoregulation, thyroidal responsiveness to TSH increases during the last trimester.[21]

The metabolism of thyroid hormones occurs through a progressive series of monodeiodinations.[219,226] Three deiodinase enzymes act to remove an iodine atom from the outer (phenolic) ring or the inner (tyrosyl) ring of the tetraiodothyronine (T_4) molecule thus, respectively, activating or inactivating the hormone. The deiodinases are encoded by separate genes and share sequence homology. Most of the circulating biologically active T_3 in adults is derived by outer-ring monodeiodination of T_4 in liver and other nonthyroidal tissues; biologically inactive rT_3 derives from inner-ring deiodination of T_4 in peripheral tissues. The type I enzyme (D1), an outer-ring monodeiodinase, is a high–Michaelis constant (K_m) enzyme inhibited by propylthiouracil (PTU) and stimulated by thyroid hormone. It deiodinates T_4 to T_3 and rT_3 to T_2. D1 also has inner-ring deiodinase activity, converting T_3 to T_2. Activity of D1 is low throughout gestation. The type 2 outer-ring monodeiodinase (D2) is a low-K_m enzyme that is insensitive to PTU and inhibited by thyroid hormone. It deiodinates T_4 to T_3 and rT_3 to T_2, and it is highly expressed in brain and pituitary. Type 3 monodeiodinase (D3) inactivates T_4 and T_3 via inner-ring deiodination of T_4 to rT_3 and of T_3 to T_2; it is highly expressed in fetal tissues and placenta. D1 is largely responsible

TABLE 23.3 Deiodinase Expression in Human and Rodent Tissues

Tissue	D1	D2	D3
Brain	X	X	X
Pituitary	X	X	
Thyroid	X	X[a]	
Liver	X		X[b]
Kidney	X		
Ovary	X		X
Ear		X[a]	
Heart		X[a]	
Muscle		X[b]	
Skin		X	X
Testes		X	X
Uterus		X	X
Brown fat		X	

[a]Expressed in human only.
[b]Expressed only in fetus.
Modified from St. Germain DL, Hernandez A, Schneider MJ, et al. Insights into the role of deiodinases from studies of genetically modified animals. *Thyroid.* 2005;15:905–916.

for the production of T_3 that escapes from the cells, especially liver and kidney, into the circulation; D2 is responsible for the production of local tissue T_3. Inactive rT_3 also diffuses out of most tissues to appear in plasma.

Iodothyronine deiodinases belong to a family of selenoproteins. Selenium is an essential trace element required for the biosynthesis of selenoproteins. Selenocysteine insertion sequence (SECIS) binding protein 2 (SBP2) represents a key factor for the insertion of selenocysteine into selenoproteins. Recently, mutations in the *SBP2* gene have been described that lead to a multisystem disorder with deficiencies of multiple selenoproteins, resulting in growth retardation, myopathy and skin photosensitivity, nonketotic hypoglycemia, colitis, and infertility.[227,228] Due to abnormal D2 activity, T_3 is low, T_4 and rT_3 are increased, and TSH is slightly elevated. As selenoproteins also serve as antioxidants, tissue damage may be related to increased concentrations of reactive oxygen species (ROS).[228,229]

The distribution of the deiodinases has been characterized in rodent and human tissues (Table 23.3).[230] D2 is detectable by midgestation and plays an important role in supplying T_3 to developing brain tissue, regulating thermogenesis in brown adipose tissue in the neonatal period, and regulating pituitary TSH secretion. D3 activity is present in placenta, liver, and perhaps fetal skin, accounting for the higher concentrations of rT_3 in the fetus and limiting the metabolic effects of thyroid hormones during much of fetal life. There is little conversion of T_4 to circulating T_3 via D1 deiodination until midgestation in the human fetus; plasma T_3 concentrations are low (<0.2 nmol/L or <15 ng/dL) until 30 weeks' gestation, after which the mean value increases to 0.7 nmol/L (50 ng/dL) at term (see Fig. 23.8).[231] On the other hand, fetal brain T_3 concentrations are 60% to 80% of those in the adult by fetal age 20 to 26 weeks owing to D2 activity. In the presence of fetal hypothyroidism, D2 increases while D3 decreases in an effort to maintain near-normal brain T_3 concentrations.

Sulfation is active in fetal tissues, and the predominant thyroid hormone metabolites in the fetus are iodothyronine sulfates.[219,232,233] High levels of phenolsulfotransferases (SULT) have been characterized in fetal liver, lung, and brain by midgestation. SULT activities decrease rapidly in the neonatal period.[233] In the last third of gestation in fetal sheep, the mean plasma production rates for T_4 and metabolites (in micrograms per kilogram of body weight per day) are as follows: T_4, 40; T_4 sulfate (T_4S), 10; rT_3, 5; rT_3S, 12; T_3, 2; and T_3S, 2. All metabolites are biologically inactive except T_3 and perhaps T_3S, so 90% of the T_4 metabolites in the fetus are biologically inactive.[232] The sulfated metabolites accumulate in fetal serum as a result of the low D1 activity in fetal tissues and because the sulfated iodothyronines are not substrates for D3.[223,234] The production rate of T_3 increases progressively between 30 weeks' gestation and term because of maturation of D1 activity in the liver and other tissues and because of decreasing D3 activity in placenta.[21,233] In fetal sheep, hepatic D1 activity increases progressively during the last trimester.[235]

It has long been assumed that thyroid hormones passively diffuse into cells. However, several classes of cell membrane iodothyronine transporters have been described, questioning this hypothesis.[236–238] These transporters belong to different families of organic anion, amino acid, and monocarboxylate solute carriers, including the organic anion transporting polypeptide (OATP) family and the solute carrier family 21 (SLC21).[236–238] The significance of these transporters is not yet clear, but mutation of the human monocarboxylate transporter 8 (MCT8), a member of the SLC21 family shown to be a specific thyroid hormone transporter present in developing brain, leads to a syndrome of combined thyroid dysfunction and psychomotor retardation (X-linked Allan-Herndon-Dudley syndrome).[239,240] *Mct8* expression in neonatal mice has been localized to neurons in the olfactory bulb, cerebral cortex, hippocampus, and amygdala. Presumably, all thyroid hormone–sensitive cell populations express iodothyronine membrane transporters. A cell surface T_4 receptor has been characterized as an $\alpha_V\beta_3$ integrin that serves as the initiation site for T_4-induced activation of the mitogen-activated protein kinase (MAPK) pathway for angiogenesis and perhaps actin polymerization and neuronal migration.[241] The ontogenesis and significance of these cell surface receptors and membrane transporters in fetal development remain to be further defined. Recent studies have suggested that MCT8 is also required for normal thyroid hormone secretion, in addition to its role as a thyroid hormone transporter.[242] Brain damage in human fetuses is already induced in utero.[276] Treatment options for patients with MCT8 deficiency are limited. PTU blocks thyroid hormone production and inhibits conversion of T_4 to T_3. PTU, in combination with levothyroxine, has shown limited metabolic benefits but no effect on neurologic features. To date, two thyromimetics, diiodothyropropionic acid (DITPA) and triiodothyroacetic acid (TRIAC), are under investigation.[277,278] DITPA has been used in a small number of patients from age 9 months; it has been shown that DITPA crosses the placenta and reaches neuronal target cells in mice, inducing a T_3-like effect.[277,278] DITPA may therefore be a future candidate for in utero treatment of MCT8 deficiency.

Thyroid Hormone Action

Classic thyroid hormone actions are mediated via functional thyroid hormone nuclear receptors (TRs), members of the steroid/retinoid/vitamin D family of nuclear transcription factors. Two genes code for the receptors: *THRA* on chromosome 17 encodes

TABLE 23.4 Predominant Thyroid Hormone Receptor Subtype Functions in Developing Mice

Brain	Thermogenesis
TRα1, TRβ1	TRα1, TRβ1, TRβ2
Pituitary TSH secretion	Inner ear
	TRα1, TRβ2
	TRβ2, TRα1
Pituitary GH secretion	Retina
	TRβ2
	TRα1
Bone maturation	Intestine
TRα1	TRα1
Liver	Heart
TRβ1	TRα1

GH, Growth hormone; *TR,* thyroid hormone receptor; *TSH,* thyroid-stimulating hormone.
