Because common law is derived from judicial opinions deciding cases and controversies among parties to real disputes, it focuses on legal, not moral, rights and duties, and specifically on remedies for legal wrongs committed by one party against another or injuries to one party for which another party is legally responsible (12). Thus the common law does not enforce moral obligations or ethical principles, although many legal principles are based on moral theory and, in the case of research, codes of research ethics. While one's failure to act virtuously or adhere to moral principles may subject a person to moral opprobrium, the absence of virtue is not sufficient to warrant legal recourse.

Classification of Common Law Claims

Common law principles affecting research with human subjects are derived from more general principles applicable to all people and organizations. They are found primarily within the law of tort, or civil wrongs. Tort law assigns responsibility for certain duties, prescribes basic rules of conduct intended to prevent avoidable harms, and imposes penalties for unlawful conduct (13). The goals are typically described as deterring harm, compensating injury, and, sometimes, retribution for wrongs (14).

Tort law is enforced when a person brings a legal claim — called a cause of action — against another party (defendant) who has caused harm to the claimant (plaintiff) as a result of violating a legal obligation. The causes of action most relevant to research are intentional torts — including battery, fraud, intentional infliction of emotional distress, and invasion of privacy — and unintentional torts — specifically negligence, negligent infliction of emotional distress, breach of confidentiality, and products liability. Negligence is often thought to be the most likely basis for liability. However, most reported cases involve claims of battery (unauthorized touching), fraud, and misrepresentation — using people as research subjects without their knowledge or consent (15,16). Often several causes of action are brought in the same lawsuit, and these may be supplemented by actions for violations of statutes or constitutional rights. This article is limited to common law causes of action.

One can characterize the possible common law issues by (*1*) the type of legal claim (or cause of action) that might be brought by a research subject, (*2*) the type of defendant or entity claimed to be responsible for research harms, (*3*) the type of research subject, or (*4*) the nature of the research product or intervention, as summarized in Table 1. Elements in each of these categories can be combined in multiple variations to produce a staggering array of potential common law cases. There are more ways to classify the types of legal responsibility for research harms, however, than there are cases to use as examples. The full range of possibilities has not materialized in lawsuits, and there are relatively few published court decisions that address the common law duties and rights of researchers and subjects. Some consider this reassuring evidence of either the lack of harm caused by research or the negligible prospect of liability on the part of researchers. Others view the small number of cases as the tip of an iceberg of potential future litigation.

Table 1. Variables in Common Law Claims

1. Cause of action

- Intentional torts
  - Battery
  - Fraud, misrepresentation
  - Invasion of privacy
- Negligence
  - Research design
  - Research conduct
  - Informed consent
  - Failure to notify of later-discovered risks
  - Breach of confidentiality
  - Invasion of privacy
- Product liability
  - Design defects
  - Manufacturing errors
  - Failure to warn of risks
- Defenses
  - Charitable immunity
  - Sovereign immunity
  - Statute of limitations
  - Waiver, release
  - Preemption

2. Responsible party

- Individual investigator
- Research institution/employer
  - Institutional review board
- Research funder/sponsor
  - Private product sponsor
- Government

3. Research subjects

- Competent adults
  - Women
  - Fertile women
  - Pregnant women
- Vulnerable populations
  - Children
  - Fetuses, embryos
  - Incompetent adults
  - People with terminal illness
  - People in medical emergency
- Exploitable populations
  - Prisoners
  - Illiterate populations
  - Impoverished populations
  - Minority populations
  - Subordinates of investigators
  - Elderly populations

4. Product or intervention

- Pharmaceutical
- Medical device
- Biological product
- Diagnostic technique
- Surgical procedure
- Medical procedure
- Preventive intervention
- Health services
- Genetic therapy
- Tissue collection
- Psychiatric intervention
- Data collection
  - Epidemiological
  - Genetic
  - Sociodemographic

Injuries to Research Subjects

The number of research subjects to whom common law duties are owed is difficult to estimate. The U.S. General Accounting Office reports that the U.S. Department of Health and Human Services (DHHS) alone funds about 16,000 studies involving human subjects each year (for $5 billion) (17). Other federal and state agencies and private organizations that fund or conduct research significantly increase this number.

There is little empirical data on research injuries and even less on the proportion of research subjects who pursue legal remedies for their injuries. In 1976 the federal Department of Health, Education, and Welfare (HEW) Secretary's Task Force on the Compensation of Injured Research Subjects conducted a survey of researchers to estimate the number of injuries to subjects who had participated in research studies funded by the National Institutes of Health (NIH) and Alcohol, Drug Abuse, Mental Health Administration (ADAMHA) (18). That survey, which relied on telephone interviews with 331 investigators, reported 4957 injuries among 133,000 human subjects over the three preceding years (19). Research subjects who were injured represented just under 4 percent of all subjects who participated in such studies. The investigators characterized 3926 injuries as trivial, 974 as temporarily disabling, 14 as permanently disabling, and 43 deaths (fewer than 1 percent of subjects). The majority of injuries befell subjects who participated in so-called therapeutic research, which was defined as "an experimental program expected to benefit the research subject directly." Of the 39,216 subjects in these therapeutic research studies, 4246 (or 10.8 percent) were injured. In nontherapeutic studies, 711 (0.8 percent) out of 93,399 research subjects were injured. The survey was limited by reliance on reports by the principal investigators of the studies themselves and may understate actual injuries. The Harvard Medical Practice Study found that about 3.7 percent of hospitalized patients in 1984 were injured as a result of ordinary medical care (not research), which might be expected to result in fewer injuries than research (20). Without a similar study of research injuries, it is difficult to estimate the prevalence of research-related injuries that might justify claims of liability for personal injury suffered by research subjects.

There is no empirical study of the proportion of injured research subjects who seek legal redress for their injuries. As far as can be determined from published judicial decisions and anecdotal reports, nothing remotely approaching 4 percent of injured research subjects file common law claims against a third party. An Institute of Medicine committee reported that "the NIH Office of the General Counsel is only aware of three legal actions for research injuries where NIH was involved in the . . . twenty years" before 1994 (17). The Harvard Medical Practice Study found that only a tiny fraction (less than 2 percent) of patients injured as a result of negligent medical care (not research) actually file a claim for malpractice (21). The same is probably true for negligent research injuries.

There are several possible explanations for the small number of cases. Not all injuries are caused by unlawful

conduct that gives rise to a legal claim. The nature of research often precludes clear findings of negligence or other unlawful conduct. Research is done because, by definition, the safety and efficacy of what is being studied is not known (22). (This is distinct from the standard of care used in carrying out the research.) If the Secretary's Task Force's findings hold true today, the majority of injuries involve subjects who are ill so that it is often difficult to sort out whether an injury was caused by underlying illness or by the research study. Subjects may not distinguish between problems with the experimental product or intervention, and problems with the way the research is conducted. Also subjects should be aware that research necessarily entails risks and may assume that they cannot sue. Some subjects may not be aware that they were injured as a result of research. History suggests that the most common legal wrong in research has been the failure to tell research subjects that they are involved in research. However, if subjects are not injured, there are few legal remedies available. Many subjects may not be inclined to sue in any circumstances, especially in light of the time and expense required. Lawyers who represent clients on a contingency basis (receiving a percentage of the money award only if the action succeeds) are unlikely to take cases that have poor or uncertain prospects of success or low potential awards. On the other hand, some cases may be settled voluntarily before any legal claim is brought or before the case is tried or otherwise finally decided in court. Some research institutions voluntarily provide remedial medical care, insurance, or other assistance to subjects who are injured as a result of research.

Perhaps all that can be said is that no one knows how many people have been injured as a result of participation in research, but injuries are likely to befall a relatively small percentage of all research subjects, and in all probability, only a small proportion of these research-related injuries will give rise to legal claims (23).

COMMON LAW CAUSES OF ACTION AGAINST INVESTIGATORS AND RESEARCH ORGANIZATIONS

All investigators and organizations that design, supervise, carry out, or report research are accountable to research subjects for violation of their common law obligations. These duties include (*1*) determining that the proposed research is properly designed and can be conducted without posing unnecessary, avoidable, or unreasonable risks of harm to research subjects, (*2*) ensuring that each research subject who participates in the study has voluntarily agreed to participate with full knowledge of the potential risks of participation, (*3*) ensuring that all investigators are qualified and competent to carry out the research, and (*4*) ensuring that the research is in fact implemented properly and that the subjects' safety and welfare is protected (7).

These duties are derived both from the growing body of ethical literature, including "codes" or declarations of research ethics that help to create the standard of practice among researchers, as well as more deeply entrenched common law principles of self-determination and reasonable care (7,24). Many of these common law duties have been supplemented by the federal regulations that govern federally funded research (10,25). For example, the common law does not require an institutional review board (IRB) to review or approve research with human subjects, but federal regulations do. Arguably, IRB review and the threat of losing federal research funding may have improved compliance with common law duties as well as federal rules, or become the custom or standard of conduct for research institutions. In some states, violation of federal regulations can be considered negligence per se which eases a litigant's path to success. On the other hand, federal regulations do not grant research subjects a personal remedy against those who violate federal regulations. Although federal agencies may impose sanctions against violators, by withholding future funding to the researcher or organization, individual subjects are not compensated by such penalties. Thus the common law serves as the research subject's only source of rights to personal redress for harm.

The most common causes of action are described below.

Using Human Subjects Without Their Knowledge or Consent

The majority of litigated cases involve using human beings as research subjects without their knowledge or consent. The most horrific example — which generated the Nuremberg Code and sowed the seeds of codes of ethics in Western countries — was the Nazi physicians' medical experiments on concentration camp prisoners during World War II (26,27). Notorious American examples include the U.S. Public Health Service's Tuskegee study of syphilis in poor, black men, (5,28) federally sponsored cold war era studies of radiation exposure and poisoning, (29–31) and the Willowbrook study of hepatitis B in retarded children (4,32). However, less dramatic studies have also been conducted without consent (33).

More than a century ago, the U.S. Supreme Court said that "no right is more sacred, or is more carefully guarded, by the common law, than the right of every individual to the possession and control of his own person, free from all restraint or interference of others unless by clear and unquestionable authority of law" (34). The right to decide whether to permit anyone to violate one's own bodily integrity is a fundamental principle of common law (35). Informed consent is a "concept, fundamental in American jurisprudence, that the individual may control what shall be done with his own body" (36). Not even a physician who believes that medical care is necessary for a patient is permitted to act without the informed consent of the patient (37,38). Although the details of the legal cause of action have evolved over the past decades, the law has never permitted the involuntary treatment of a competent patient by a physician. Likewise no one is permitted to conduct research on any human being without that person's competent, voluntary, informed, and understanding consent (39).

Battery. At common law the failure to obtain consent is considered a battery — an unauthorized offensive touching (40). Researchers who use human beings as research subjects without telling them that they are

conducting a study or giving the subjects an opportunity to refuse to participate commit a battery. Battery is a straightforward cause of action that requires a plaintiff to prove that some form of offensive, intentional contact took place without the plaintiff's consent or against his will (41). The touching need not cause any physical harm to be unlawful. The wrong lies in the offense to personal dignity caused by invading the inviolability of the person without permission. Successful plaintiffs can recover money damages for battery. These can range from nominal amounts (e.g., $1) for minor intrusions that cause no harm to substantial awards for highly offensive acts or those that cause serious physical injury.

The offense of battery may be more common in the research context than it is in the realm of medical care. This is because physicians who provide medical care to patients are more likely to obtain consent at least to the treatment given, so that disputes tend to focus on whether the patient was advised of the risks of treatment, as discussed below. Some research studies, on the other hand, have been concealed entirely from subjects.

A notorious example occurred at the Jewish Chronic Disease Hospital in Brooklyn, New York, in 1963 (42). A researcher wished to study whether the human immune system could be used to prevent cancer. It was known that healthy people had strong defenses against injections of cancer cells from other people, while cancer patients did not, but it was not known whether the cancer patients' response was due to their cancer or their overall debilitation. Drs. Southam and Levin of the Sloan–Kettering Institute for Cancer Research injected cancer cells into 22 Jewish Chronic Disease Hospital patients who had diseases other than cancer to see whether their immune systems would reject the cancer cells. The subjects were told only that they would receive a test of their immunity; they deliberately were not told that cancer cells were injected under their skin because researchers thought this might cause them to refuse to be in the study. Three young staff physicians refused to participate and informed a member of the hospital board of directors who in turn notified the New York State Department of Education and the Supreme Court of Brooklyn. The state's highest court allowed the hospital director to inspect the subjects' medical records as part of an investigation into illegal and improper experimentation on patients (43). The licenses of the investigators were suspended for one year, but the suspension was later replaced by one year's probation (4). The patients themselves were not parties to the lawsuit, but the hospital instituted a policy of requiring informed consent in future experiments.

In *Mink v. University of Chicago*, a federal court described why the failure to tell subjects that they are being used as research subjects is a battery (44). The University of Chicago and Eli Lilly & Company conducted an experiment from 1950 to 1952 to see whether diethylstilbestrol (DES) would prevent miscarriages. They gave DES to women who came for prenatal care without telling them of the experiment or that the pills were DES. The court noted that the cause of action was battery, not lack of informed consent, because the researchers performed an action to which the women did not consent at all. The court compared their actions with performing unauthorized surgery. The administration of a drug without a person's knowledge fits within the meaning of offensive contact for purposes of battery. The fact that the women had consented to prenatal care did not mean that they had agreed to take experimental pills.

Instances of undisclosed research can give rise to other common law claims, including invasion of privacy and fraud and misrepresentation. Invasion of privacy — specifically, an unreasonable intrusion upon a person's seclusion or unreasonable publicity given to a person's private life or affairs — can occur when researchers seek out or disclose private information without the person's permission (45). Also possible is a cause of action for fraudulent misrepresentation, which includes a misrepresentation of fact or intention on the part of a researcher, the subject's reliance on the researcher's false statements, and resulting damages (46). Researchers may also be liable for failing to disclose a fact that would induce a person not to enter a study because researchers have a duty to provide all relevant information to prospective subjects. For example, in *Craft v. Vanderbilt University*, a group of women brought a class action claiming battery, fraudulent concealment, negligent misrepresentation, infliction of emotional distress, negligence, and invasion of privacy, as well as federal statutory claims, when they discovered, in 1993, that they had unknowingly been part of research studies decades earlier (47). In a study conducted from 1945 to 1947 by the university and the state of Tennessee, researchers sought to determine iron absorption in the uterus. Researchers gave 829 pregnant women patients in Vanderbilt's prenatal clinic a beverage containing the radioactive isotope Iron 59 but told them only that it was vitamins, "a cocktail" or "a sweet." The women were never told what the drink contained or that they were research subjects, even during a follow-up study in the 1960s to determine the long-term health effects of radiation exposure during pregnancy. That study found three deaths from cancer among children of the exposed mothers (and none among controls) that suggested a cause and effect relationship with the radioactive drink (48). The suit was settled for $10.3 million in 1998 (49).

Research conducted after World War II on the effects of radiation exposure has given rise to other lawsuits by surviving subjects or their families in the 1990s. Like most lawsuits, these assert multiple causes of action — slightly different legal wrongs — for the same injury. Where the subjects were not told that they were part of a research study or that they would be exposed to radiation, a claim of battery can be made. In one such experiment, the Massachusetts Institute of Technology fed Quaker Oats cereal with radioactive isotopes to children institutionalized at the Fernald School. A class action on their behalf was partially settled for $1.85 million in 1999 (50).

Where the research is misrepresented as medical care, a claim of fraud or misrepresentation is possible. For example, the plaintiff in *Stadt v. University of Rochester*, brought a claim of fraud, instead of battery, against the university hospital for injecting his 41-year-old mother

with plutonium without her consent (51). Janet Stadt was used as a subject in an Army research study of radiation effects in 1946 but allegedly was told that she was being treated for scleroderma. In 1972 she underwent additional tests, again without being told they were part of the study, and died of cancer in 1975. The failure to disclose the research was sufficient to allow a lawsuit based on fraud, although, in this case, the court converted the state common law claims into a federal claim against the federal government for violating the subject's right to bodily integrity protected by the Fourteenth Amendment to the U.S. Constitution.

A more complicated example is the Human Radiation Experiments conducted at Cincinnati General Hospital between 1960 and 1972 (52). There, at least 87 patients with inoperable cancer were given radiation in doses ranging from 25 to 300 rads — the level expected to be experienced by military personnel exposed to nuclear attack — to study the effects of radiation on human beings. The study was part of the Defense Department's cold war efforts to prepare for possible nuclear war. The patients were told that the radiation was treatment for their cancer, although it shortened their lives and caused nausea, vomiting, burns, and other suffering. The plaintiffs claimed the experiments were intentionally concealed from them, which would give rise to causes of action for battery and fraud. Although a consent form was used beginning in 1965, it said only that the patients were participating in scientific experiments without indicating the nature or purpose of the experiment or the risks of the high-dose radiation. For subjects who received this form, a cause of action for lack of informed consent (discussed below) would be possible. In May 1999 a judge approved a settlement of the class action lawsuit for $5.4 million, which provided an average of $50,000 to each family (53).

A notable exception to these general principles lies in research conducted by the U.S. military using military personnel as subjects. The armed forces exposed soldiers to radiation during a nuclear explosion without telling them they were subjects of an experiment on radiation exposure (54). The Central Intelligence Agency gave LSD to servicemen without their knowledge to study the drug's effects (55,56). Although the Federal Tort Claims Act permits the federal government to be sued for certain acts of negligence and other torts (57), military personnel who are "injured in the course of activity incident to [military] service" are prohibited from suing the federal government for damages for personal injury (56,58). The courts justify excepting military personnel from the remedies available to civilians for the reason that allowing civil damage claims would intrude on military discipline. In addition the federal government has been protected from liability for what courts construe as military acts, including the use of investigational vaccines among soldiers serving in the Gulf War (59). The fact that the Nuremberg Code was, in effect, a common law decision written by U.S. military judges to apply to wartime experiments, has been uniformly ignored by American courts in these cases (3). Thus the common law has afforded no remedy to military personnel who are subjects of research conducted by military or quasi-military officials.

Informed Consent. The common law doctrine of informed consent grew out of the principles underlying battery — bodily integrity, autonomy, and self-determination (7,39,40,60–62). While battery applies to cases in which no consent is given at all, informed consent applies to cases in which consent is given without sufficient information to render it meaningful (38,40). A person cannot make a meaningful decision in the absence of information about the benefits, risks, and consequences of the options. Ordinary lay people are not expected to have medical or scientific knowledge necessary to determine whether or not to participate in a research study. Thus the law imposes on researchers a duty to explain the research study and its potential risks and benefits to the prospective subject.

Explanation is especially important in research that uses patients as subjects. Individuals who seek medical care may fail to appreciate the uncertainty inherent in research or may assume that they are receiving proven medical care instead of an experimental technique (29,63,64). Subjects may find it difficult to keep in mind that the investigators do not assume the role of their personal physicians (65). In addition, unlike medical care, research necessarily entails unavoidable conflicts of interest for investigators who are obligated to protect the welfare of their research subjects but may also be eager to ensure the success of the study (66). This is particularly true when physicians act as investigators and use their patients as subjects (17).

The doctrine of informed consent emphasizes that every competent adult is completely free to accept or reject any medical or scientific intervention for any reason or for no reason at all. No competent adult can be forced to undergo medical treatment, even if it is certain to save his life (67,68). It should be clear, therefore, that no one can be forced to participate in research. There is almost never any justification for withholding information about a research study. (An exception may be permitted in certain behavioral experiments in which complete information will prejudice a subject's response during the experiment, but not the decision to participate, and where the subject will suffer no risk for lack of the information (69). In *Beno v. Shalala* (70), a family sued the Secretary of Health and Human Services seeking to invalidate her granting a waiver permitting California to conduct a work-incentive demonstration project to reduce welfare benefits by 1.3 percent and waive limits on income that beneficiaries could earn without losing their welfare benefits. The court found that the beneficiaries were human subjects of research but suggested that the benefit reduction was not large enough to require the informed consent of each beneficiary under specific federal law governing demonstration experiments.)

Although informed consent is required for both research and medical treatment, disclosure requirements have been more stringent for research than for medical care. As the *Belmont Report* concluded, informed consent standards applicable to patients in malpractice cases are not sufficient for research (7). At a minimum, disclosure must include (*1*) that fact that research is being conducted; (*2*) the purpose of the research, what will happen,

and why; (*3*) the requirements of participation; (*4*) what experimental agents and techniques will be used; and (*5*) the potential risks, as well as inconveniences, to the subject of participation. A cause of action for failure to obtain informed consent is treated as a negligence action because the researchers have a professional duty to provide information sufficient to permit a prospective subject to make a voluntary, informed decision. To succeed in an action for failure to obtain informed consent, a plaintiff must prove each of the following four things:

1. The defendant had a duty to disclose certain information to the subject (usually information about the risks of participating in the study).
2. The defendant did not disclose that information.
3. The undisclosed risk or problem occurred and caused physical injury to the subject.
4. The failure to disclose the risk or problem was the proximate cause of the subject's injury because a reasonable person in the subject's circumstances would not have consented to participate in the research if he had known of the undisclosed risk.

For example, in *Halushka v. University of Saskatchewan*, a student was awarded $22,500 from a university that failed to obtain his fully informed consent to research (71). The student volunteered for a study of circulatory response and was told that a new drug would be used. He was not told that the drug was an untested anesthetic nor that a catheter would be inserted through his heart to his pulmonary artery. During the experiment, the subject's suffered cardiac arrest, was resuscitated, and remained unconscious for four days. Ultimately he dropped out of his university studies because of inability to concentrate. The appeals court held that subjects of experimentation are entitled to more information than patients must receive, including the full and frank disclosure of all facts, probabilities, and opinions that a reasonable person might be expected to consider.

The courts that have considered the issue agree that the subject of research that uses an experimental agent or procedure must be told that the agent or procedure is experimental (72–76). The cases endorsing this basic rule tend to involve patients whose physician used an experimental medical device or surgical procedure during the course of medical treatment without telling the patient that the device or procedure itself was experimental. Several cases concerned the implantation of investigational intraocular lenses. For example, in *Kus v. Sherman Hospital*, Richard Kus agreed to surgery to implant an intraocular lens in his eye (77). Dr. Vancil used an investigational implant without telling Kus that the device was experimental. The hospital's IRB had required all consent forms for the surgery to specify that the lens was experimental, but Vancil removed that information from the consent form he gave Kus and other patients. There was no question that the physician was liable for the injury to Kus's eye caused by the implant because he failed to tell Kus that the device was experimental, and Vancil settled with Kus out of court. The court found that the hospital might be liable for its own failure to obtain Kus's informed consent where the hospital, as a participant in a study governed by federal regulations, assumed a duty to ensure that informed consent was obtained for all subjects in the study.

The first implantation of a totally implantable mechanical heart in a human being, Haskell Karp, resulted in a lawsuit following Karp's death shortly after the experimental surgery (78). Karp's widow claimed that her husband had not given his informed consent to the use of the artificial heart. She contended that Dr. Cooley emphasized that he would surgically repair Karp's own diseased heart and had described the implantable artificial heart as like a heart and lung machine used to sustain life during open heart surgery. However, the court found that the Karp had actually consented to the experimental surgery and that the consent form, albeit only 179 words, noted that this device "has not been used to sustain a human being and that no assurance of success can be made." It is unlikely that courts today would be as willing to accept such a vague, abbreviated description as evidence of full disclosure for such a dramatic experiment (79).

The question of what risks to disclose can be difficult in research where not all risks can be known in advance. For example, in *Whitlock v. Duke University*, Whitlock volunteered for a deep sea diving experiment and suffered permanent organic brain damage as a result, even though the research was conducted properly (80). The court held that the investigator had a duty to warn subjects of all risks that were reasonably foreseeable when the research began. The plaintiff had signed a consent form that warned of the risks of death and other unknown risks, but did not specifically mention permanent organic brain damage. Expert evidence showed that brain damage was not a foreseeable risk and had not happened in the past. Thus the investigators could not have foreseen that specific harm and therefore had no obligation to mention it. The plaintiff had no basis for recovering damages.

Risks to the subject include psychological, social, and financial risks. For example, some types of research can expose subjects to discrimination if they are publicly identified as having socially undesirable conditions or traits, such as drug abuse, sexually transmitted diseases, or HIV infection (81). Other types of information about a subject, including drug abuse and child neglect, can lead to criminal prosecution. Research involving genetic analysis may identify susceptibility to genetic diseases, which can give rise to serious psychological and emotional concerns, as well as affecting the ability to obtain insurance or employment (82–84).

Beyond the risks to the subject himself or herself, there may be other aspects of the research that warrant disclosure. For example, the Public Health Service studied uranium miners to learn whether they were at increased risk of cancer without telling the miners of the cancer risk (85). In that case the reason the subjects were chosen was an important piece of information that should have been disclosed. Genetic research can produce probabilistic information about family members who do not want to participate in a study. Genetic research such as family pedigree studies to identify patterns of gene transmission may present risks to familial relationships.

Another type of information is the use to which information or tissue collected from the subjects will be put. In *Moore v. Regents of the University of California*, the investigator used cells extracted from a subject's spleen, removed as part of standard therapy for hairy cell leukemia, to produce a lucrative cell line later patented by the university (86). Moore sued the investigators for converting his property — his tissue — to their own profitable use without his consent. The court decided that the researcher had a duty to inform Moore of its intent to develop a cell line from his tissue but, in a controversial decision, did not allow Moore to share in the profits made from his cells, even though they had been taken for that purpose without his knowledge or consent. (The court reasoned that Moore had relinquished his ownership interest in his cells because he had not expected to keep possession of them after his spleen was removed.) The court described the physician's duty to disclose broadly to include "personal interests unrelated to the patient's health, whether research or economic, that may affect the physician's professional judgment." In the case at hand, the court presumably reasoned that henceforth a subject could refuse to participate in the research if he did not want to donate his cells to a commercial operation. Theoretically, subjects could refuse to consent to participate unless they receive a share of the profits that result. Those options may be unrealistic if the research is conducted in conjunction with a person's medical treatment, as was the case with Moore. Patients may find it difficult, financially or emotionally, to obtain treatment from another physician who is not engaged in research.

Many of the first lawsuits involving informed consent to research involved experiments intended, at least in part, to help an individual patient — often called innovative therapy — rather than an organized research project with many subjects. Until the late twentieth century, courts took a dim view of such experimentation, holding physicians accountable for injuries resulting from methods or procedures that were not generally accepted in the medical profession (39,87,88). Such experiments were considered deviations from standard medical practice (89,90). However, some experiments were tolerated if no accepted therapy worked, the patient knowingly agreed, and the physician was sufficiently skilled (91).

Today few physicians conduct isolated experiments on their own initiative. Most research is conducted more formally at large institutions. Although few lawsuits have resulted, courts no longer appear to summarily reject such research as a deviation from accepted medical practice (92). However, misrepresenting an experiment resulted in a jury verdict against several California physicians who treated AIDS patients with a drug, Viroxan, made by one of the physicians at home without FDA approval (93). The injected drug caused tissue necrosis and the patients became ill without receiving standard therapy like AZT, Bactrim, or Pentamidine. The physicians were found liable for intentionally misrepresenting the drug and other unorthodox practices as "new," safe therapy that was better than conventional treatment, with intent to defraud the patients, who were awarded $925,000 in compensatory damages. The medical center was also found liable as a co-conspirator for failing to remove the physicians from its staff after learning of their unusual remedies. This suggests that highly unorthodox methods can give rise to a cause of action for fraud, as well as lack of informed consent and medical malpractice, where the "innovation" is not fully disclosed and the patient relies on the misrepresentation to his detriment.

The 1960s and 1970s saw the growth of research as a more systematic endeavor with increasing methodological sophistication as the common law developed more rigorous protection of individual subjects' self-determination with respect to research. As a result subjects are more likely to be aware that they are involved in a research study than they were several decades ago. However, the common law still has a role to play. Research projects that use subjects who might benefit from the experimental methods or procedures — so-called therapeutic research — continue to have difficulties with ensuring that subjects are fully informed (94). Numerous groups and commentators have criticized the persistent confusion of research with treatment, among researchers as well as subjects (29,39,62,66,95). Thus the importance of ensuring that all subjects are fully informed and that their consent is competent and voluntary has not diminished.

Research With Subjects Who Cannot Consent. The general principle that no one can be used as a research subject without his or her consent assumes that individuals are legally capable or "competent" to make the decision. For example, the doctrine of informed consent applies only to legally competent adults — those who are capable of understanding their circumstances, the proposed research study and its potential risks, and making and communicating a decision to participate or not (35,36,96). (All states presume that every person over 18 years of age is legally competent, unless a court has adjudicated the person to be incompetent.) Some research, however, seeks to use subjects who are not legally competent, either temporarily or permanently. This broad category includes adults who are unable to make or communicate an informed decision because of lack of consciousness, medication, pain, developmental disabilities, or mental disorders, as well as children (97). Such research raises difficult legal, as well as ethical, questions about whether incompetent persons can participate in research at all and, if so, whether some form of surrogate authorization is necessary or sufficient (98).

There are many examples of research studies that, rightly or wrongly, used incompetent adults and children as subjects (4,29,39,97–99). The ethical justification for using such subjects is that it is impossible to discover the etiology or find a therapy for conditions that render people legally incompetent or that affect only those who lack competence — such as schizophrenia or childhood leukemia — unless the investigational modality is tested in that very group of people as research subjects (97,98). In such cases the need for research results directly conflicts with the general principle prohibiting the use of

individuals as research subjects without their voluntary, competent and informed consent (100).

The states have the sovereign authority (the *parens patriae* power) to protect the safety and welfare of incompetent adults and children. Parents of children and legal guardians of incompetent adults also have the obligation to protect the safety and welfare of their children and wards and to act in their best interests. Whether such legal representatives have the legal authority to consent to the use of their children and wards as research subjects has not been finally decided in the common law.

There is ample precedent for the principle that incompetent adults have the common law right to *refuse* to participate in research, and that their legal representatives can refuse on their behalf. This assumption is based on an analogy to the right to refuse medical treatment (60). Virtually all state courts that have considered the issue have decided that incompetent adults have the same rights as competent adults to refuse *medical treatment*, even if the treatment would save the person's life (101,102). The right to refuse medical treatment is part of the common law right to bodily integrity and self-determination — the same right the allows competent individuals to refuse to participate in research. The U.S. Supreme Court has also assumed, without deciding, that the Due Process Clause of the federal Constitution protects the right to refuse treatment (67,68). The U.S. Supreme Court has also noted that individuals who are mentally ill — including those who are involuntarily committed to a mental hospital — retain a constitutionally protected liberty interested in avoiding unwanted medication (103,104). There is general agreement that a person who refuses or objects to participate in research must not be used as a research subject (97,98).

There is very little legal precedent for the prevalent assumption that a parent or guardian can *consent* to an incompetent person's participation in research. Legal guardians are obligated to act in the best interests of the incompetent person (105). Participation in research is rarely in the best interest of a subject. Where the research is intended solely to gain generalized knowledge, no benefit can be expected to accrue to the subjects. In the case of so-called therapeutic research, where an experimental technique offers the possibility of curing a disease suffered by the person and no standard or accepted treatment has proved effective for that person, one might argue that the person might benefit from participating in the research. However, the potential risks of the research must be weighed against any benefit. It could be argued that a surrogate decision maker should be able to consent to research that offers possible benefit to an incompetent individual as long as it carries little or no risk (106). It is more difficult to argue that a legal representative could consent to potentially beneficial research that also entails significant risks. Therefore it is possible that researchers can be liable for battery or failure to obtain informed consent if they use incompetent subjects in research, whether or not they obtain surrogate consent.

There is little case law concerning research with subjects who are legally incompetent to consent to participation. Most cases in which the courts have considered the problem of incompetence involved isolated experiments related to medical treatment for an individual patient rather than a research study with a defined study population and detailed protocol. Some courts have permitted experiments on an incompetent person if a responsible family member or guardian gives informed consent and the subject himself or herself does not appear to object (105).

One of the few court decisions describing common law as well as constitutional limitations on using incompetent individuals as research subjects involved a group of patients in hospitals and facilities licensed and operated by the New York State Office of Mental Health (OMH) (107). In *T.D. v. New York State Office of Mental Health*, the patients challenged OMH regulations that allowed them to be used as research subjects even though they were considered incapable of giving informed consent. The court found that the state regulations, which provided for surrogate consent, were unlawful because they had not been approved by the Commissioner of Health. The court also found that the regulations violated the common law and constitutional rights of the patients, but the Court of Appeals, New York state's highest court, noted that this part of the decision was unnecessary and therefore an inappropriate advisory opinion. Still it suggests what courts might decide in the future. The lower court recognized that the goal of achieving important medical advances might not always be compatible with the goal of protecting human rights:

> It may very well be that for some categories of greater than minimal risk nontherapeutic experiments, devised to achieve a future benefit, there is at present no constitutionally acceptable protocol for obtaining the participation of incapable individuals who have not, when previously competent, either given specific consent or designated a suitable surrogate from whom such consent may be obtained. The alternative of allowing such experiments to continue, without proper consent and in violation of the rights of the incapable individuals who participate, is clearly unacceptable (107).

The New York regulations analyzed in *T.D.* did not apply to federally funded research that complied with federal regulations. However, federal regulations do not yet address the participation of incompetent adults. Federal regulations do permit certain types of research with children under narrowly defined conditions (25). In 1996 the Food and Drug Administration (FDA) adopted a regulation to permit research using emergency medical technologies without the consent of individuals who are incompetent to consent to participate because they are temporarily unconscious or in pain as a result of an emergency medical crisis (108). Several states prohibit research with residents of mental institutions by statute. Others permit surrogate consent in carefully defined situations. In one case California's law permitting experimentation with incompetent persons was held to be limited to research studies and could not authorize a surrogate to allow a physician to use an experimental bone graft in the treatment of an incompetent patient (109).

Thus there remain significant gaps in the law with respect to whether and, if so, how children and adults who

are incapable of giving informed consent may participate as subjects of research. Several government agencies have recognized these gaps and have recommended regulations permitting people who are not legally competent to participate as subjects of research in certain circumstances, often with the informed consent of legally authorized representatives (97,110,111). The recommendations offer slightly different answers to such questions as what types of research should be permitted, who should be eligible to give surrogate consent, and what procedures should be used to protect research subjects. Although this is an area where legislation or regulations may prove useful to clarify individual rights and duties, the proposals would apply to specific jurisdictions, such as federally funded research or research conducted within a particular state. The common law, which is less likely to permit incompetent individuals to participate in research, will still apply to research that is not governed by federal regulations or specific state laws.

Liability for the Design and Implementation of Research

Negligence. Researchers have common law duties to design and carry out research properly and can be liable for injuries suffered by research subjects that are caused by negligence in the design or implementation of the research study itself (112). The fact that a research subject has consented to participate in the study and has been informed of the foreseeable risks of participation does not mean that the subject assumes the risk of the researcher's own negligence (113).

The law of negligence requires individuals and organizations to conduct themselves as reasonably prudent persons so as to avoid causing harm to others (13). In ordinary circumstances reasonably prudent conduct can be judged by the ordinary citizen, as represented by the jury in a jury trial. The standard of conduct to be observed by professionals (e.g., physicians) in the conduct of their profession, however, is that of an expert in the field, as established by the profession itself, for ordinary citizens are not expected to be familiar with specialized knowledge and skills. Those who conduct research are legally responsible to subjects who suffer injury as a result of their negligence (39,112,113). Thus organizations that design and supervise research, as well as investigators who carry out studies with human subjects, can be liable for the injuries they cause when they fail to conform their conduct to professional standards of care. Researchers, like physicians, can also be liable for intentionally or negligently disclosing confidential personal information about research subjects or invading their privacy without their consent.

A research subject who claims injury as a result of negligence must prove the following four things:

1. The researcher had a duty to the research subject.
2. The researcher breached that duty.
3. The research subject suffered physical injury.
4. The subject's injury was caused by the researcher's breach of his duty to the subject.

Violation of a statute or regulation can sometimes be considered to be negligence per se if the injured person belongs to the class of people that the law intends to protect (114). Private individuals cannot sue researchers merely because the researchers have violated federal law governing federally funded research with human subjects (115). However, if the statute imposes specific requirements on the researcher's conduct, injured persons may sue for common law negligence and use the statute as evidence of the standard of care that the defendant should have followed (116).

Individual Investigators. The case of *Vodopest v. MacGregor* illustrates negligence by an individual investigator (117). Patricia Vodopest suffered permanent brain damage from cerebral edema in a high altitude climbing study in the Himalayas in Nepal. The study was intended to test breathing methods as a way to prevent altitude sickness. Vodopest experienced symptoms of altitude sickness at 8700 feet, but MacGregor, the project leader who was also a nurse, discounted the symptoms and told Vodopest to "breathe away" the symptoms and continue climbing higher. By 11,300 feet, Vodopest had developed cerebral edema and had to be evacuated. Vodopest was able to prove all four elements of negligence in this case. As study leader, MacGregor had a duty to act responsibly to protect the safety and welfare of the research subjects. Because the study was designed to prevent altitude sickness, the investigators should have been able to recognize its symptoms and respond with medically appropriate care. MacGregor failed to recognize (or refused to acknowledge) obvious symptoms of altitude sickness (nausea, headache, dizziness, and mental confusion). She also failed to follow the standard of care for treatment, which required having the person descend. Vodopest suffered physical injury (permanent brain damage), and the evidence indicated that her injury was proximately caused by MacGregor's negligence.

Organizations. Organizations can be held responsible for negligent injury to research subjects in two ways. First, and most simply, they can be vicariously liable for negligent acts committed by their employees and agents (118). (The employees and agents themselves also remain personally liable for their own negligence. However, employees may have insufficient assets to satisfy a large judgment or their employers may agree to pay their liability awards directly or through liability insurance.) The doctrine of *respondeat superior* (from the Latin "let the master answer" for the wrongs of his servant) holds an employer legally accountable for the unlawful acts of its employees committed during the course of employment. The purpose of the rule is to encourage employers to supervise their employees to ensure that they act responsibly. For example, the plaintiffs in *Mink*, described above, sued both the University of Chicago, where the research took place, and Eli Lilly & Company, the DES manufacturer, for vicarious liability for the acts of their employees in failing to tell plaintiffs that they were given DES as part of a medical experiment (44). In *Schwartz v. Boston Hospital for Women*, a federal district court found that a hospital could be liable for a physician's failure to obtain a subject's informed consent to a study procedure where the hospital paid the physician as assistant project

director of a study of diabetic pregnancies (119). Similarly organizations can be held liable for the negligence of those who act as agents on their behalf, where the organization controls and directs the actions of the agent.

The second basis for organizational liability is direct corporate liability for the organization's own negligent acts or violations of duty. Organizations have duties to use care in the selection, retention, and supervision of their research staff and can be responsible for injuries caused by individuals who are incompetent or should not have been hired or retained by the organization (119,120). Organizations also have a duty to maintain a safe environment, which requires them to keep their premises safe and equipment in good working order to avoid preventable injuries. Plaintiffs in the *Mink* case also claimed that the corporations breached their own duties to notify the women about the experiment when they learned that DES could cause an increased risk of cancer in the children of women who took DES (44). The court agreed that both corporations had a duty to notify the women as soon as they became aware or should have become aware of the relationship between DES and cancer. However, the women were unable to recover damages on the failure to notify claim because they could not show that they had suffered any physical injury as a result of the failure to notify.

Two subjects in a 1960s study were awarded $8 million, including $5 million in punitive damages, by a 1999 jury verdict against investigator Dr. William Sweet and Massachusetts General Hospital, where the study took place (121). The study was intended to determine whether radiation to treat brain tumors could be focused selectively on the tumor without destroying other brain tissue by using boron neutron capture to selectively attract radiation. Subjects who were terminally ill with brain cancer had a boron compound injected into their arteries to see if it collected in the tumor. The compound caused severe illness and premature death in many subjects. The investigator argued that the subjects could not be harmed because they were already terminally ill, but the jury found that the review process was negligent in allowing the study to proceed at all.

Media reports of studies inducing or allowing psychosis in patients with schizophrenia at almost a dozen medical schools in the 1980s and 1990s illustrate several possible grounds for negligence, although few lawsuits have been brought (122). A study of schizophrenic patients at the University of California at Los Angeles (UCLA) which began in the 1980s was intended to identify schizophrenic patients who could function without antipsychotic medication because long term use of certain drugs can cause tardive dyskinesia, a condition producing involuntary movements for which there is no known treatment. Antipsychotic medication was withdrawn from schizophrenic patients who had recovered from acute psychotic disorders. The patient-subjects were observed until they relapsed and exhibited severe psychiatric symptoms of "bizarre behavior, self-neglect, hostility, depressive mood [or] suicidability" (123).

One possible negligence claim might be that the researchers breached their duty of care by designing the study so as to induce subjects to experience severe psychiatric symptoms that had been controlled by their medication. Put more generally, the claim might be that the study design posed unreasonable risks and should not have been conducted in that manner or, possibly, at all. Another might be that researchers failed to adequately monitor or treat subjects who experienced symptoms during the study, allowing them to suffer unnecessarily and possibly risking irreversible deterioration. In addition it might be possible to claim failure to obtain informed consent if the subjects were not adequately informed about the nature of the study and the risks it posed. Although the subjects were asked to participate in a research study, the original consent form was ambiguous, allowing an inference that study was linked to their medical care, and did not make clear that, unlike regular patients, the subjects would not receive medication unless and until they had a severe relapse (123). By the late 1980s, 88 percent of the subjects had suffered a relapse.

After the parents of one subject complained, the federal Office for Protection from Research Risks (OPRR) in DHHS investigated and required UCLA to change some of its internal monitoring procedures and modify the consent form to point out the risks of participation and the fact that the study was not intended to meet the subject's own personal medical needs (123). OPRR also investigated psychiatric challenge and relapse studies at the University of Cincinnati, University of Maryland, Bronx Veterans Affairs Medical Center, New York State Psychiatric Institute, and the National Institutes of Mental Health, and found similar problems with researchers' informed consent practices (122,124).

The families of two subjects sued UCLA in 1992 for fraud, deceit, lack of informed consent, and civil rights violations. Gregory Aller dropped out of college, threatened his mother with a butcher knife to exorcise the devil he believed inhabited her, and tried to hitchhike to Washington, DC, to assassinate then President Bush. His parents asked the researchers to give Greg his medication, and claimed they did not do so for many months. Antonio LaMadrid jumped off a 12 story UCLA building and died about three months after participating in the study (125,126).

A study of schizophrenia subtypes took place at University Hospital in Cincinnati in the 1980s with similar results. According to newspaper reports, a patient with schizophrenia sought treatment to adjust her medication dosage to prevent a possible manic episode (126). Lacking the resources to pay for treatment, she was enrolled in a challenge study, withdrawn from her medication, given a different medication, and then placed in restraints when her manic and delusional behavior erupted. Like several other studies, this one used a medication to cause or exacerbate psychiatric symptoms. She sued the researchers, but the case was dismissed because it was not brought within the statutory time limit.

Relatively few lawsuits have focused on negligence in carrying out research, as compared with failure to obtain consent. It may be that problems are more likely to arise from expected risks or lack of consent than from poor implementation of a study. In some cases research

subjects may be partly responsible for their own injuries if they deliberately or carelessly fail to follow instructions designed for their protection and are harmed as a result. The doctrines of contributory and comparative negligence reduce, and in some cases may eliminate, the damages to which an injured person would otherwise be entitled (127).

Increased publicity about research in the 1990s may encourage closer scrutiny of research design — and perhaps legal claims of negligence — in the future, especially where researchers are pushing the scientific envelope or stand to gain financially from the success of products they study. The research design was questioned in a gene therapy trial to test — for the first time in human beings — the safety of delivering genetic material missing in people with ornithine transcarbamylase (OTC) deficiency, a sometimes fatal genetic mutation that prevents the liver from breaking down ammonia (128). Among the review committee's concerns were the use of adenovirus as the vector for transmitting the OTC gene to the liver of subjects because of adenovirus's potential to cause liver damage and toxic, sometimes fatal, inflammatory reactions. There were also reservations about the method of infusing directly into the liver instead of into a distant blood vessel. In addition the study used healthy, asymptomatic patients with OTC deficiency as the first human subjects to receive the gene, instead of patients for whom an accepted regimen of diet and medications was not effective. In 1999 Jesse Gelsinger, an 18-year-old subject, died from an inflammatory response apparently caused by the adenovirus vector. Although there is no indication that any lawsuit will be brought, the circumstances illustrate the opportunity for claims of negligence against the investigators for using excessively risky methods in designing and carrying out the research and for exposing healthy volunteers to unreasonable risks.

Conflicts of interest among researchers who have financial interests in the products they investigate may trigger or provide supporting evidence for future legal claims (129,130). James Wilson, a researcher in the OTC gene therapy study, founded a company to sell the rights to his discoveries, including the liver-directed gene vector approach studied in the OTC gene therapy trial (128). The question is whether a researcher who stands to gain financially from the success of a product might neglect evidence of the product's risks, rush to use it in human subjects prematurely, or select a research design that poses unnecessary risks to human subjects. It is not clear whether disclosure of the researcher's financial interest is sufficient to preclude a claim that the researcher acted negligently or even fraudulently.

Duties to Third Parties. Research subjects may not be the only persons injured as a result of research. However, liability for negligence is predicated on violating a legal duty to the injured person, and in the absence of any duty to third parties, there is generally no liability to third parties. Indeed, excluding some groups, especially pregnant women, from participation in research studies was often thought to ensure freedom from liability to women and their offspring (131). This raises the question whether researchers have any duty to avoid harm to future generations. If so, may subjects waive any potential claim that a future child might have for injury? Such questions are most likely to arise in connection with clinical research with fertile or pregnant women, and sometimes fertile men, using investigational drugs with teratogenic effects or genetic material that may affect a fetus or future child (132,133). Although tort law has gradually extended its application to cases of prenatal injury in which fetuses are injured by intentional or negligent conduct, the causes of action available to children remain limited and the cases rarely involve research (134). In one example, however, the University of Chicago settled a lawsuit brought by the daughters of women who had received DES as part of an experiment in the 1950s (135). The daughters claimed to have an increased risk of cancer as a result of exposure to DES in utero. Future research involving germ-line gene transfer may expose the next generation to the effects of research with today's subjects (136).

Recently it has been recognized that not using research subjects who are representative of the populations that will ultimately use or be affected by the research may also raise liability concerns if the investigational product or service is later marketed. For example, if research subjects do not include women, the research may fail to discover adverse effects unique to women. If women are injured from using the product when later marketed, they might argue that the manufacturer or researcher negligently caused their injuries by failing to use a reasonable research design to identify possible risks to women (131). Researchers have begun to respond to concerns about inappropriately underrepresenting specific groups in their study populations (132). Ethical principles for research design include the equitable selection of research subjects, and federal regulations may include more specific requirements. In the long run this may create a standard of care in research design that requires a reasonably representative study population. So far this concern has not given rise to any cause of action for individuals who are excluded from research. In the late 1990s, however, a family sued UCLA because their Asian-American child was not admitted to its experimental elementary school, claiming that the use of race as an admission criterion violated the equal protection clause of the U.S. Constitution. The students enrolled were research subjects protected by federal and state research guidelines, but the case was limited to the constitutional issue. The court found the use of race was justified in order to select a representative sample of local students to ensure the validity of the research, and that research itself served the state's compelling interest in improving urban public education (137). Just as there is no legal right to be a research subject, there is no duty on the part of researchers to include specific individuals in a particular research study. On the contrary, there may be a duty not to include vulnerable or incompetent persons in some circumstances (7,97,105,138).

Products Liability. Product manufacturers can also be liable for negligence in the manufacture, design, or distribution of their products. A cause of action for negligence parallels the four part format for negligence described above. A person who is injured by a product

must prove that the manufacturer failed to adhere to the appropriate standard of care, which failure caused the person's injury (139). Manufacturers of specialized products, such as biotechnology products, are held to the standards of an expert in the field.

In the 1960s state courts began to adopt the doctrine of strict liability which holds manufacturers liable for injuries caused by defective products without requiring proof that the manufacturer acted negligently. The justification was partly that negligence could be presumed when a product turned out to be defective and partly because it was difficult for plaintiffs to obtain evidence of a manufacturer's internal manufacturing processes to prove negligence. In theory, strict liability focuses on the condition of the product, while negligence focuses on the conduct of the manufacturer. When a person is injured by a defective product (as opposed to the behavior of individuals), they often assert both negligence and strict liability claims. Courts, however, often analyze both types of claims under products liability, a special subset of tort law that borrows negligence principles from tort law as well as warranty principles from contract law (140). Manufacturers may also be liable for breach of express warranty or implied warranty of a product's fitness for a particular purpose or merchantability (141). These causes of action, although based in contract law, impose similar duties and are usually subsumed by products liability today.

Products liability law holds all manufacturers, sellers and distributors of products legally responsible under state common law for personal injuries caused by a defect in their products (140). The earlier *Restatement* summarized the rule as follows: "One who sells any product in a defective condition unreasonably dangerous to the user or consumer or to his property [is liable] for physical harm thereby caused to the ultimate user or consumer. . . ." (142). Product defects include (*1*) manufacturing defects or flaws, in which the manufacturing process contains an error that produces something different from the product intended by the manufacturer; (*2*) defects in product design, in which the product specifications themselves pose foreseeable risks of harm that could have been avoided or reduced; and (*3*) errors or omissions in directions or warnings that accompany the product (142–144).

Manufacturing defects, such as contamination, adulteration, or production errors, are rare in pharmaceutical and biotechnology products but have occurred less rarely in medical devices (145,146). A product design is considered defective if the product could have been designed in a different way that would reduce its inherent risks without significantly decreasing its utility or effectiveness (142–144). Whether a product could have been differently designed, however, is a technical question that depends on the state of scientific knowledge when the product was sold, the nature and results of product tests, and the feasibility of alternative designs (147). An experimental product can rarely, if ever, be accused of having a defective design while it is being studied precisely to determine whether the design is safe and effective. The fact of the research is ordinarily a defense against a claim of defect. In addition it is often difficult to sort out the cause of an injury to a research subject, especially where the product has not been widely tested or the injury might result from other sources to which the research subject was exposed. The most plausible claim would be that the product was not ready for testing in human beings, and that additional laboratory or animal studies would have revealed dangers before human being were harmed, which is really a claim of negligence. Thus manufacturers are not liable for a defective design of an experimental product as long as they conduct reasonable studies and do not use a product design that is foreseeably and unnecessarily dangerous.

The recently issued *Restatement* of products liability law contains a somewhat narrower definition of design defect for prescription drugs and medical devices, which requires proof that the product produces no net benefits for *any* class of patients or that no reasonable manufacturer would produce it if it knew of the defect (148). This permits the marketing of drugs and devices with serious risks as long as they may benefit at least one class of patients. Outside the realm of ordinary consumer products and asbestos, claims of defective design have been directed primarily at lawfully marketed, nonexperimental medical devices, such as the Dalkon Shield, the Copper-7 IUD, the Bjork-Shiley heart valve, and silicon-gel breast implants (149).

Defects in product distribution include errors and omissions in product directions and warnings. Manufacturers are responsible for failing to provide to the user a warning of dangers inherent in the use of the product, or for providing an inadequate warning that failed to alert the user to the danger (150). The cause of action is similar to a cause of action against a physician or researcher for failure to obtain informed consent (151,152). The theory is that a consumer would not have used the product and suffered an injury had he or she been warned of the risk that caused the injury. Warning defects have been claimed in a substantial proportion of lawsuits against manufacturers of licensed pharmaceuticals and vaccines (153). Manufacturers of prescription drugs and vaccines that can be obtained only from a physician are not required to issue warnings directly to patients or subjects of research. The "learned intermediary" rule holds the manufacturer responsible only for providing adequate warnings to the physician, who in turn is responsible for judging the appropriateness of the medicine for an individual patient and informing the patient of its risks and benefits (154–158). In the future, however, courts may decline to apply the learned intermediary rule in the case of some prescription drugs that are marketed by direct-to-consumer advertising if the physician has only a minor role in determining whether the patient should use the drug (159,160).

Human subjects who participate in research involving investigational products should be made aware that they could be exposed to risks. If subjects are adequately informed, their consent to participate means that they assume responsibility for the risks that have been disclosed to them. The investigator's duty to obtain the voluntary informed consent of subjects also protects the product manufacturer.

Products liability law focuses on commercially marketed products — those lawfully for sale or distribution

in the market. The new *Restatement* of products liability defines products as "tangible personal property distributed commercially for use or consumption" (161), and may not even apply to investigational products. (Although human blood and tissue qualify as products when they are sold or distributed commercially, most states have enacted blood shield statutes that limit liability for contaminated human blood and human tissue to liability for negligence.) It would not ordinarily apply to investigational products that are being tested in research studies before any commercial marketing. Such investigational products, like investigational new drugs, are not held out as safe or effective commercial products ready for marketing to consumers. Rather, they are being studied to determine their effectiveness and to identify possible defects and risks. Of course, some research studies commercial products that are already on the market. For example, two marketed products, such as diagnostic tests, may be compared for relative efficacy, or a product marketed for one purpose may be studied to determine whether it has another use, such as an "off-label" use of a drug that has been approved by the FDA for a different specific use.

In *Proctor v. Davis*, the Upjohn Company was found liable for failing to warn physicians of the risks of an off-label use of its corticosteroid suspension, Depo-Medrol, by injection near the eye to treat eye conditions (162). FDA had approved the drug for intramuscular, intrajoint, and intralesional use only. The court found that "Upjohn fostered and encouraged this unapproved use as experimentation on human beings" (162). The company gave ophthalmologists financial and technical assistance to test periocular use and write favorable reports. Although the company received reports of adverse reactions, including blindness, it did not issue any warning. The company's conduct was found to justify punitive damages of just over $6 million, as well as compensatory damages of over $3 million, to the plaintiff who lost his eye after the drug was injected in an off-label use.

Independent researchers — who are not employed by a manufacturer — are not likely to be subject to products liability unless they also qualify as commercial sellers or distributors who are engaged in the business of selling or distributing the products they study. Investigators ordinarily provide services, and services are not considered products. Courts are unanimous in refusing to categorize commercially provided services as products for purposes of strict products liability in tort. Thus strict products liability does not extend to professionally provided services, such as medical or legal help (163,164).

Most states have held that public policy should exempt hospitals, physicians, and dentists from liability for injury from products used to treat their patients, such as defective pacemakers, forceps, and syringes, even though similar product/service combinations have been the subject of liability (165). The justification for this exemption is that the need for medical care outweighs any need to hold providers strictly liable for the products they use or implant in medical treatment. However, courts do not ordinarily consider research to be part of medical care, so the public policy rationale may not apply to research. A few recent cases have found that liability might be imposed where a hospital or physician selected or sold the product (166,167). A few cases have held a hospital liable for injuries resulting from defective products that were not directly related to medical care, but neither did they relate to research (168,169).

Although most legal principles apply equally in the case of experimental and marketed products, few investigational products being tested in research studies are likely to qualify as commercial products or otherwise meet the criteria for products liability claims. Most new drugs, biologics, and medical devices are developed in compliance with FDA regulations governing investigational use, so the federal rules are the primary source of law governing such research with human subjects. A violation of federal regulations may be evidence of common law negligence in most states, although states vary with respect to whether such a violation should be considered negligence per se, evidence of a deviation of the applicable standard of care, or excluded from consideration as inflammatory and irrevelant to the issue of causation.

Institutional Review Boards. Most IRBs are created by hospitals, universities, and research organizations to comply with federal law as a condition of receiving federal funding for research. The institutions agree by contract (the "general assurance") with a federal agency (typically HHS, FDA, or DOE) to be bound by federal IRB regulations specifying general membership qualifications and obligations of an IRB (170). Thus IRB duties are defined in the first instance not by common law principles but by federal statutes and regulations — specifically the Common Rule — issued by virtue of the federal spending power (10).

Nonetheless, the institution retains significant discretion over IRB operations, determining procedures, funding and personnel (11). An IRB created by a hospital or university is typically part of that organization, and not a separate legal entity, so that the organization is legally responsible for IRB actions. A growing number of IRBs, however, are independent legal entities, not part of any hospital, university, or research organization, and therefore responsible for their own legal obligations. Some have been created by community research groups and by private commercial enterprises like pharmaceutical companies to review their own research studies. Others are independently organized and offer their services to any group that wishes to conduct clinical research, usually small commercial companies.

Two decades ago Robertson considered possible liability issues that IRBs and their parent organizations might face in theory, such as defamation of an investigator or termination of employment for conduct involving research (11). The rarity of reported claims against IRBs suggests that such concerns remain largely theoretical. There have been several publicized scandals but little litigation (171,172).

In theory, possible claims by injured subjects of research against an IRB might include IRB negligence in approving a study, failure to attach conditions to the study to protect subjects, failure to require adequate information or informed consent, negligent assessment of the study's

risks and benefits, failure to review ongoing research that poses risks to subjects, failure to stop research when subjects are being harmed, and failure to notify subjects of a significant risk or harm during or after study. IRBs may have a common law duty to act with reasonable care. In addition a violation of federal regulations might be considered to be evidence of negligence in many states. To hold the IRB liable, however, a subject would have to prove that the injury would not have happened but for IRB misconduct. There are many steps between IRB approval and injuries to subjects that could negate IRB responsibility: An approved study might not be funded or carried out, important information might not have been available, investigators might disregard IRB requirements in conducting the study, investigators might have prevented the injury, or the subject might not act on warnings provided. As a Texas court noted, "Other than disapproving all or part of a study, the IRB does not and cannot control the direction, results, or use of the research" (173).

A 1996 U.S. General Accounting Office (GAO) report on IRBs serving NIH studies outlines some difficulties experienced by IRBs that could, in theory, prevent them from living up to relevant standards of conduct (17). IRB review is labor intensive and subject to considerable time pressure, with some IRBs devoting only a few minutes to reviewing a protocol. Members may rely on a single primary reviewer for their assessment of a proposed study and miss key issues in the protocol. Most IRBs studied by the GAO were composed of volunteer members and few had training in ethics or federal regulations governing the protection of human subjects. Lay volunteers may be reluctant to challenge the opinions of members with scientific backgrounds who may empathize more with other investigators than with potential subjects. Most institutions with IRBs derive substantial income from research grants and may put institutional pressure on the IRB to approve protocols, thereby creating a conflict of interest. Most IRBs were reported to spend much of their time reviewing the informed consent form rather than whether the research design posed unacceptable risks to potential subjects. In addition there was little time for continuing review of ongoing research, which might discover problems.

Despite these potential difficulties, the GAO report confirmed that there had been few complaints against institutions or IRBs that review research funded by the federal DHHS (17). FDA issued only 31 "Warning Letters" to institutions noting serious deficiencies in IRB oversight of drug research. Deficiencies included allowing researchers to participate in IRB review of their own research and false claims that research studies did not require IRB review. FDA had never disqualified an institution from submitting research studies. On the other hand, FDA issued 99 sanctions against 84 individual investigators between 1980 and 1995. Most violations were minor; serious violations included forging a subject's signature to a consent document, failing to obtain informed consent, fabricating data to make subjects appear eligible for a study, falsifying laboratory tests, and failing to report adverse reactions to investigational drugs. However, a 1999 report of 1000 FDA spot checks found that 213 researchers failed to obtain necessary informed consent, 364 researchers failed to follow their research protocol, and 140 did not report adverse reactions experienced by research subjects (174).

These reports, as well as reports with similar findings by the Office of the Inspector General, suggest that IRBs may find it difficult to perform their legal duties adequately (175,176). If improvements are not made, they could be liable in the future if their wrongful actions cause harm. At the same time other factors argue against a significant upsurge in claims. Human subjects who are injured by research are more likely to have a cause of action against, and to sue, the investigator or the institution for research conduct that is unrelated to IRB actions. An IRB's contribution to any injury may be difficult to discover. Few nonmembers appear at IRB meetings, see its records, or are in a position to identify IRB misconduct.

Federal agencies that oversee IRBs are in a good position to discover problems and act directly to halt research that may threaten human subjects. In the late 1990s OPRR began to impose sanctions on research institutions that do not comply with federal regulations. In May 1999 OPRR suspended Duke University's authorization to conduct federally funded research with human subjects (177). The action was taken only after the university had been given an opportunity to improve its system and failed to respond adequately. OPRR has imposed similar suspensions at other institutions, including the University of Rochester, University of Southern Florida, University of Minnesota, Mt. Sinai, Rush-Presbyterian-St.Lukes Medical Center in Chicago, University of Illinois in Chicago, and University of Colorado (178,179). Reasons for suspensions varied but were consistent with the problems identified in the GAO report — failures to submit studies for IRB approval, inadequate consent procedures and records, failure to keep track of research studies after they began, and failure to document why studies were approved. Enforcement action by OPRR and FDA may herald more consistent and searching scrutiny of federally funded research. It may also encourage a re-evaluation of the entire system for protecting human subjects of research, including the use of IRBs themselves.

There have been a few lawsuits by individuals attempting to discover IRB records, often to use as evidence in their lawsuits against other parties. IRBs typically treat research protocols and investigators' reports on ongoing research as confidential and do not voluntarily release them outside the IRB, except to federal agencies that are entitled by statute to review IRB compliance with a general assurance. Federal regulations prohibit the disclosure of IRB records that identify individual research subjects. The common law, however, does not specifically protect IRB records from disclosure to investigators, subjects, or the public, or discovery in a lawsuit, although some state statutes may grant protection (180). Most state statutes that grant a privilege against discovery to hospital peer review committee proceedings and records do not apply to IRBs because IRBs are not peer review committees that oversee patient care (181). Nonetheless, even courts that have permitted

disclosure of IRB records have kept confidential the names of subjects, as well as a company's proprietary information about its investigational products (181,182).

One might argue that there is a scientific or academic privilege protecting against discovery of IRB records (183,184). Research data, however, do not appear to be privileged. Data may be protected from discovery where they are not relevant or necessary to a lawsuit, where disclosure would be unduly burdensome on the researcher, or to protect a researcher's interest in completing a study or in publishing conclusions first in a peer-reviewed journal (185,186).

The fact that IRB records are not automatically protected from discovery does not necessarily mean that IRBs have any obligation to publicly disclose them. For example, an Iowa Supreme Court decision found that a public hospital (not an IRB) was not required to make public its summaries of nosocomial infection data that the hospital was required by statute to collect (187).

What counts as IRB records is not clear. They could be limited to minutes of the meetings, so that research protocols and monitoring reports would not be covered (188). A litigant might be able to obtain more information, including the research protocol, from the researcher who conducted the research.

Defenses Against Liability

Researchers charged with liability for injuries to research subjects can interpose several defenses, in addition to simply denying the facts alleged in the claim, to defeat a cause of action.

Release of Liability. Under the doctrine of informed consent, because researchers must disclose the risks of research to all subjects who agree to participate in a study, subjects assume the risk of being injured as a result of the risks that were disclosed to them. An analogous principle of contract law may allow human subjects to release researchers from liability for the foreseeable risks of participating in research, as long as those risks were disclosed and the research was properly carried out (189). However, the general rule is that human subjects cannot release researchers from tort liability for the researcher's own negligence (190). In addition federal regulations forbid the use of any document that waives or otherwise excuses, releases, or indemnifies researchers from liability for injuries to research subjects in federally funded research (191): "No informed consent, whether oral or written, may include any exculpatory language through which the subject or the representative is made to waive or appear to waive any of the subject's legal rights, or releases or appears to release the investigator, the sponsor, the institution, or its agents from liability for negligence." As a practical matter, most IRBs are thought to reject attempts to use any such releases (192).

In *Vodopest v. MacGregor*, described above, the research subject Vodopest had signed a form releasing the investigators from "all liability, claims and causes of action arising out of or in any way connected with my participation in this trek" (117). The Supreme Court of Washington found that the release was against public policy and therefore void and unenforceable because it would release researchers from their own negligence in the conduct of research. The Court noted that if Vodopest had fallen off a trail, the release might have been effective because falling is an expected risk of climbing mountains and was not necessarily part of the research. However, Vodopest's injury specifically related to the research — monitoring subjects for high altitude sickness — and therefore liability could not be released. The court concluded, "The public's interest in the safety of human subjects and the public's interest in the integrity of legitimate and necessary research militate against allowing researchers to negligently conduct research with impunity."

Sovereign Immunity. Neither the federal nor a state government can be sued without its consent. Sovereign immunity — based on the ancient notion that the king can do no wrong — can be a defense to tort claims brought against officials, employees, and agents of state and federal governmental institutions, such as state universities and city hospitals (13). The Federal Tort Claims Act permits certain tort claims to be brought against the federal government (57). All states have enacted statutes that permit certain claims to be made against the state, although some states limit the amount of damages for which a state can be held liable. For example, Massachusetts limits its own liability for personal injury to $100,000 per claim (193).

Researchers who are employees or agents of state entities may be protected by sovereign immunity if they are acting on behalf of the state. A Virginia court applied sovereign immunity to protect a researcher from liability for a research subject's death after an overdose of asthma medication (194). The researcher was employed as an allergy fellow by the University of Virginia Hospital, a state university protected by sovereign immunity. The court found that the hospital's employees and agents were also protected if they (*1*) are subject to the control of the state and have little or no control over the patients they see, and (*2*) participate in activities in which the state has a strong interest, especially where the activity is not readily available in the private sector. The court also noted that a third factor ordinarily required for sovereign immunity in Virginia — that the employees have duties that require them to exercise a substantial degree of judgment or discretion in the activity complained — is likely to exist in most medical research studies. In this case the court found that the research was important to the state. However, not all research is necessarily important to the state or anyone else, and much research can be performed as well or better by the private sector. Thus the importance of the research is not necessarily a reliable factor for predicting whether specific research will be protected by sovereign immunity elsewhere.

Physicians who are independent contractors — not employees or agents — are not protected by sovereign immunity. They may also be liable for the negligence of public hospital employees, including residents, if their supervision of those employees is negligent (195).

Sovereign immunity protected an assistant attorney general of the State of New York from liability for

concealing the fact that a man's death from an injection of synthetic mescaline was the result of a covert experiment by the U.S. Army Chemical Corps to test the drugs as a chemical warfare agent (196). The assistant attorney general received absolute immunity because he acted as the lawyer for the state psychiatric institution in a lawsuit brought by the decedent's family. However, several federal attorneys representing the U.S. Army, which was not party to the lawsuit, were not entitled to immunity for their actions in fraudulently concealing the experiment and thereby depriving family members of their cause of action for battery.

Charitable Immunity. Some private, nonprofit, charitable organizations are also protected from liability for personal injury to patients and research subjects by the doctrine of charitable immunity. Massachusetts was the first state to adopt the doctrine, in 1876, and still retains it (197,198). However, charitable immunity has been repealed in most states, and states that still apply the doctrine have crafted so many exceptions that immunity is more the exception than the rule (120). The trend appears to be in favor of holding all private organizations liable for their own negligence. Reasons for ending charitable immunity include the fact that most research organizations that qualify as "charitable" for tax purposes are no longer charities in the historical sense, and also often purchase liability insurance to protect against depleting their assets (199). In addition the nineteenth-century assumption that patients who accept charity care must also accept the risk of harm is inconsistent with the premise that all patients and research subjects are entitled to the same legal safeguards (200). Nonprofit hospitals are among the few organizations that still qualify for the remnants of charitable immunity. Most private companies that conduct research in biotechnology are not charities and would not be protected.

Federal Preemption. Federal law sometimes supersedes (preempts) state common law, so individuals cannot use the state law as the basis for a lawsuit. In the absence of a federal statute explicitly preempting state law, however, there is a general presumption that federal law does not supersede state law, especially with respect to health concerns and common law claims of negligence and product liability (201). Even where a federal statute regulates an industry, the presumption against preemption of state common law actions remains (202,203). Although some products are subject to federal labeling requirements, few such laws specifically preempt state common law claims of failure to warn, inadequate directions or warnings, or fraudulent misrepresentation (204). Thus, federal preemption of state common law claims for personal injury is rare.

The Medical Devices Amendments of 1976 contain a provision that preempts state law safety or effectiveness requirements that differ from requirements for medical devices imposed by FDA under federal law (205). The Act states that "No State or political subdivision of a State may establish or continue in effect with respect to any device intended for human use any requirement—(*1*) which is different from, or in addition to, any requirement applicable under this chapter to the device, and (*2*) which relates to the safety or effectiveness of the device or to any other matter included in a requirement applicable to the device under this chapter." (This specific provision in the statute does not apply to drugs.) In *Medtronic, Inc. v. Lohr*, the U.S. Supreme Court found that the federal law did not preempt common law claims for personal injury resulting from certain medical devices that are not subject to specific review and premarket approval by FDA (206). In that case, which did not involve research, Lora Lohr claimed that her pacemaker lead had a defect that caused a complete heart block requiring emergency surgery and also that the manufacturer had not warned of the device's tendency to fail. The device was sold pursuant to the federal law's §510(k) premarket notification procedure, which does not require FDA approval of the device or its specifications before marketing (207). The Medical Device Amendments may preempt state common law claims involving a Class III medical device, which is subject to premarket review and approval with specific FDA requirements, but the precise scope of preemption has not yet been fully addressed by the Supreme Court. Aside from its limited scope, this preemption provision may have little effect on research subjects because it is limited to claims about the medical device itself and does not necessarily preclude claims concerning the conduct of research.

The federal Biomaterials Access Assurance Act of 1998 limits the liability of suppliers of raw materials and component parts that are used in medical devices (208). Independent suppliers (who are not organizationally related to a medical device manufacturer) are liable to individuals who are injured by an implanted medical device only if the parts supplied to make the implant did not meet the supplier's or device manufacturer's specifications. Suppliers who sell raw materials and component parts that are used in many different products are not ordinarily in a position to conduct the research necessary to ensure that their materials are safe for implantation in human beings. Medical device manufacturers remain responsible for ensuring that the resulting product complies with FDA requirements and may be sued by injured users. However, the supplier may be sued for its own negligence or intentional conduct if the device manufacturer demonstrates that the supplier's actions caused an injury and the device manufacturer should not be held solely responsible or will not be able to pay the full amount of damages awarded to the injured person.

Statutes of Limitations. A defense that is available to all public and private defendants is that a claim has been brought after the time permitted by law to begin a lawsuit. All states have "statutes of limitation" or "repose" that bar the bringing of a legal action, typically two to six years after the claim arose. The purpose of such statutes is to limit a defendant's exposure to potential liability and to encourage claims to be brought while evidence is still fresh and available (13). In an unusual decision, a California trial court dismissed a suit brought against the University of California at Los Angeles for fraud, deceit,

lack of informed consent and civil rights violations in a schizophrenia study because the plaintiffs had exceeded the five-year statute of limitations for bringing the case to trial after it was filed (209).

Different legal claims or causes of action often have different maximum time periods for bringing suit. Many states have shortened the statute of limitations for medical malpractice to two years, while the limit for ordinary negligence and other personal injury claims is typically three to six years. Several courts have held that the longer personal injury statutes of limitations (and not the medical malpractice statute) apply to cases involving research injuries, because research does not constitute medical care and does not create a physician–patient relationship — even if the research is conducted by physicians (47,52,210,211).

Most states apply a "discovery rule" that extends or "tolls" the time period in which a claim may be brought (13). The time does not begin to run until the date on which the plaintiff actually discovered or should have discovered that he or she had a legal claim (212). The discovery rule might be applied in cases of fraudulent concealment, in which investigators hid the fact of research from a research subject who suffered latent injuries, as in *Mink v. University of Chicago* or *Craft v. Vanderbilt University*, or if new information indicates a previously unsuspected causal relationship between an injury and earlier research (44,47). But the rule does not excuse a plaintiff with obvious injuries from acting on reasonably available information (74).

Because children are not ordinarily empowered by law to bring suit on their own behalf, many states toll the applicable statute of limitations until a child who has been injured reaches the age of majority, typically 18 years of age (13). Research sponsors and investigators who use young children as research subjects may be exposed to potential liability for many years. Some states have limited this exception by requiring that suit must be brought within a specific number of years following the injury, usually a longer period than the otherwise applicable time periods for adults.

CONCLUSION

The common law arguably offers the most comprehensive statement of legal principles for the protection of human subjects of research and redress for their injuries. Although the Common Rule is probably more familiar and influential, the common law is more comprehensive, in theory, than either federal regulations, which apply only to federally funded research, or state statutes, which address specific issues like fetal research. Moreover the common law is the only source of redress and compensation for human subjects injured as a result of research. Although the federal government can penalize investigators and researchers for violating federal rules, federal enforcement actions do not compensate research subjects personally.

Because they are the product of court decisions in particular disputes, common law principles are not easily summarized in a textbook. Caution must be used in extracting lessons from individual cases with particular facts. Reasonable people can disagree about precisely what is and is not required of researchers in specific circumstances. Moreover several issues have yet to be fully addressed in court decisions, including whether, and if so, when and how, individuals who are not legally competent might participate as human subjects of research; what, if any, duties investigators owe to people who are not subjects of their research; and whether, and if so, what kinds of conflicts of interest preclude researchers from conducting certain research.

Although the research enterprise — and the number of research subjects — is large and growing, there have been relatively few published court decisions addressing common law claims arising out of research. A majority of such lawsuits have complained of failure to tell subjects that research was being conducted at all. Few cases have been based on negligence in the conduct of research or invasion of privacy. In the absence of comprehensive empirical data on violations of legal obligations and injuries arising from research, it is hazardous to draw general conclusions about the incidence of particular problems from the few published court decisions and media reports.

Greater public visibility for research may focus new attention on the common law rights of research subjects and increase the potential for legal claims in the future. Publicity about cold war era radiation experiments conducted without the subjects' knowledge served to focus public awareness on the rights of human subjects in the 1990s and may have inspired lawsuits based on common law causes of action to compensate injured subjects or their families. A series of studies identifying problems and gaps in the current federal regulatory system may have encouraged federal agencies to initiate bolder enforcement of existing federal regulations governing federally funded research. Although these federal initiatives do not alter common law, they may lead to a more comprehensive restructuring of statutory legal protections for human subjects, which in turn may affect the scope of common law protections. The rise of biotechnology, new forms of financing research, innovative financial relationships between academe and private industry, and public–private partnerships between government and commercial enterprises all create new opportunities for research and for research subjects. These may foster a new era of public concern for protecting human subjects in research. Whatever form that concern takes, it is likely that the common law will remain the legal backstop for the rights of human subjects.

HUMAN SUBJECTS RESEARCH, LAW, FDA RULES

BARUCH BRODY
Baylor College of Medicine
Houston, Texas

OUTLINE

INTRODUCTION

In the United States, as in most other countries, a new drug cannot be marketed unless a national regulatory agency has determined that it is safe in, and effective for, its intended use. In order to establish that a new drug is safe and effective, research must be carried out on human subjects. In the United States, as in most other countries, this preliminary research on human subjects must be carried out with the concurrence of a national regulatory agency. The Food and Drug Administration (FDA) is the national regulatory agency that carries out both of these functions (concurring with the research and approving the drug as safe and effective) in the United States; it has other functions as well. FDA has issued many important rules governing the performance of both functions. These rules, and the ethical and policy issues raised by them, are the focus of this article.

Each FDA rule raises its own set of ethical and policy issues. But there are two themes that run through FDA's treatment of rules and it is helpful to identify them in advance. The first is the recognition that complex ethical and policy issues are best resolved by recognizing the legitimacy of many values, even if they are sometimes conflicting values, and by attempting to formulate rules that properly balance these different values. The second is the recognition that participation in research can be both a benefit and a burden to subjects, and the rules governing research need to reflect this dual nature of participation.

BRIEF HISTORY OF FDA

A series of national scandals led to the legislation that created FDA as we know it today (1,2,3). In 1906, in response to a national outcry related to false labeling and marketing of patent medicines, Congress passed legislation creating an agency to deal with adulteration or mislabeling of drugs. In 1938, in response to the sale of a liquid form of sulfanilamide which turned out to be poisonous and caused the death of more than 100 children, Congress passed a law prohibiting the sale of drugs in interstate commerce until the seller had submitted to that agency a New Drug Application (NDA) that demonstrated that the drug was safe in its intended use. In 1962, in response to the worldwide outbreak of phocomelia in children whose mothers had taken thalidomide during pregnancy, Congress passed a law requiring (*1*) that no drug be tested in human subjects until its sponsors submitted to that agency an Investigational New Drug (IND) application and (*2*) that no drug be approved for sale until the seller demonstrated in its NDA that the drug is effective as well as safe. FDA, as it exists today, is largely the product of these three legislative acts. Because these legislative acts were passed in response to scandals arising out of new drugs hurting those who used them, their emphasis was on the value of protecting research subjects and the general public.

FDA is also the product of its own regulatory responses to public criticisms. In response to criticisms raised through the 1970s and early 1980s that the FDA process took too long and resulted in useful drugs being available elsewhere but not in the United States (the "drug lag" claim), FDA issued in 1985 and 1987 new regulations, the NDA Rewrite (4) and the IND Rewrite (5), that were designed to speed up the approval process. In response to the demand for quicker access to drugs by desperate Acquired Immune Deficiency Syndrome (AIDS) and cancer patients, FDA developed in the late 1980s and the early 1990s the Treatment IND program and the accelerated approval programs. In response to the claim that it was insensitive to the needs of special populations, it developed in the 1990s policies relating to emergency room patients, geriatric patients, pediatric patients, and patients who were women of childbearing potential. Many of these regulatory changes were incorporated into the Food and Drug Administration Modernization Act of 1997 (6). Because these regulatory responses, and the resulting legislation, arose in response to concerns about overregulation and overprotection, their emphasis was on widening access of research subjects to the benefits of research and on speeding the availability of the results of research to the general public.

CURRENT PROCESS FOR NEW APPROVALS

The sponsor of a new drug begins the process by submitting an IND application to the FDA. The application must include information about the composition of the drug, information about preclinical testing of the drug (including animal studies), information about all proposed protocols for research on humans, information about the approval of those protocols by an independent Institutional Review Board (IRB), and information about the informed consent process proposed in such protocols. In certain special circumstances involving emergency research, that last requirement may be waived. The protocols may be for Phase I studies in a limited number of subjects designed primarily to study the effects of increasing dosages of the drug. For such studies, the FDA's focus in its review of the application will be on the safety of the proposed protocols. The protocols may be for Phase II or Phase III studies in larger numbers of patients designed to study effectiveness and the overall benefit–risk ratio of the drug. For such studies FDA's focus in its review of the application will also include the scientific quality of the studies to see whether they can generate the data that are sufficient to support an application for marketing approval.

Unless the FDA objects within 30 days (or a longer period if further information is requested of the sponsors), research on human subjects may commence. During that research period, the new drug is only to be provided to research subjects under the approved protocols. There has been a traditional exception for emergency use authorized by the FDA for an individual case. In recent years, in response to the AIDS crisis, the FDA has developed a Treatment IND Program under which whole classes of patients may receive a drug while large scale clinical trials are continuing; the details of that program are discussed below. In general, prior FDA approval is required to charge patients for drugs received in research protocols; in the case of drugs provided under the Treatment IND program, only notification of the FDA and nonobjection by the FDA is required. In either case, the price may not exceed the actual costs of manufacture, research and development, and handling of the investigational drug.

If the results of the research are satisfactory, the sponsors may file an NDA with FDA. This application must include information about the composition and production of the drug, about the proposed labeling for the drug, and about the research results which support the claim that the drug has a favorable benefit–risk ratio. FDA regulations provide an extensive description, to be analyzed below, of the research data that are required to support such a claim. Some of those requirements have been modified, in ways that will be described below, for the Accelerated Approval programs. FDA has 180 days to respond to a filing of an NDA, but that period is open to extension. In making a determination of the application's acceptability, FDA draws upon the expertise of advisory committees, but the final decision belongs to FDA. Congress has in

the last few years authorized FDA to charge user fees to those filing NDAs. The user fees have supported the hiring of additional staff, which has helped speed the NDA review process. Once the FDA responds with its approval, the new drug can be marketed in accordance with the approved labeling.

The set of regulations just described was developed for the approval of new drugs. It also applies to the approval of already approved drugs for new indications. The approval regulations are somewhat parallel to those governing the approval of new medical devices (7). Approval does not apply to new surgical procedures (as opposed to new devices that they may employ), to new testing services including genetic testing services (as opposed to new testing kits that they may employ), or to new physician uses of approved drugs for nonapproved purposes (as opposed to manufacturer promotion of such "off-label" new uses). The 1997 Food and Drug Administration Modernization Act partially addressed the "off-label" use issue by codifying the conditions under which manufacturers can distribute scientific information related to "off-label" uses (8). Much controversy exists both about the merits of these exceptions to the FDA's regulatory authority and about the new legislation related to "off-label" promotion.

FDA RULES FOR IND STAGE

Rules Governing Human Subjects Research

When a sponsor submits an IND application to the FDA, it must submit documentation that the proposed research protocols have been reviewed and approved by an appropriate IRB and that the protocols contain provisions for obtaining the informed consent of research subjects or their representatives. These requirements are consonant with the internationally accepted consensus about the conditions required for ethical research on human subjects.

All such research protocols must be reviewed and approved by an IRB that is independent of both the sponsors and the investigators. In approving the research, the IRB must determine that the following very standard requirements have been met (9):

- Risks to the subjects have been minimized and the remaining risks are reasonable in relation to the anticipated benefits.
- Selection of the subjects is equitable, and potentially vulnerable subjects are provided with additional safeguard.
- Informed consent has been obtained and documented.
- Privacy of subjects and confidentiality of data are protected.
- Adequate provisions are made for ongoing safety monitoring.

The requirements for the information that must be provided as part of the informed consent process are also standard. Subjects must be informed of at least the following (10):

- Purpose of the research, its duration, and the experimental procedures involved.
- Risks and benefits of participation and of the alternatives to participation.
- Extent to which research records are confidential.
- Any compensation and/or treatment for research related injuries.
- Right not to participate and right to discontinue participation.

Comparison to Federal Common Rule

In 1991 most federal agencies that conduct or sponsor research on human subjects adopted regulations governing human subjects research. Among these agencies was the Department of Health and Human Services (HHS) (11). The commonly adopted regulations are referred to as the Federal Common Rule. FDA did not adopt the Federal Common Rule, because of certain special features of FDA's regulatory process. The above-described FDA regulations closely resemble the Federal Common Rule. In 1996 FDA issued a description of the differences between its regulations and the Federal Common Rule (12). The three most important to be noted are the following:

- FDA regulations apply to all research submitted to it in IND applications and NDA submissions, regardless of the funding source for the research, while the Federal Common Rule only covers research funded and/or conducted by the relevant federal agency.
- FDA has developed special exemptions from the requirement of informed consent for emergency research; these will be described below.
- The Federal Common Rule has an elaborate system of reports by IRBs (called the assurance mechanism) to ensure that they meet the standards in the Federal Common Rule. No such system is imposed under the FDA regulations.

International Application of These Rules

As noted above, the FDA regulations apply to all research submitted to it, whether or not the research is conducted in the United States (13). Because of the significance of FDA approval in allowing access to the U.S. market, this requirement impacts greatly on the conduct of human subjects research in other countries. There are those who see this as a form of ethical imperialism, of the United States imposing its ethical standards on other countries. There are others who see this as a U.S. reaffirmation of fundamental moral truths, which remain true even in other countries that have not yet recognized their value. Both views assume that the standards are unique to the United States, and it is this assumption that is in error. It has recently been demonstrated that the essentials of the FDA standards have been broadly adopted throughout the world, even if the precise details vary from country to country, and that this broad adoption is strong evidence of the moral validity of FDA standards (14).

FDA regulations require that research conducted on human subjects in foreign countries meet the standards of

the Declaration of Helsinki, a declaration of the cross-national World Medical Association, rather than the standards of the FDA regulations. In fact the standards are very similar, reflecting the broadly accepted international consensus about human subjects research. Still, imposing the standards by reference to the Declaration of Helsinki clarifies that doing so is not a form of U.S. ethical imperialism. Moreover, if the country in which the research is conducted has its own more stringent standards on human subjects research, then FDA requires that those more stringent standards be met, showing respect for those stricter standards.

Exception for Emergency Research

The international consensus embodied in the FDA regulations requires that informed consent be obtained from all human subjects or from their representatives before the research is conducted. That requirement has often imposed great difficulties on those conducting vitally needed research on the management of medical emergencies. Such research often must be conducted as soon as possible after the patient-subject presents in the emergency room. The patient may be temporarily incompetent to give consent and no legally authorized individual may be present to give consent. Moreover the very short time frame for the effective use of the investigational intervention often precludes the possibility of accurately informing the competent subject and/or the available representative and giving them a meaningful choice about participation. So vitally needed research suffers from imposing that requirement of prospective informed consent. Even when there are enough subjects or representatives available and competent to give meaningful consent, so the research can go forward, that requirement has prevented many other noncompetent emergency patients from getting access to the most promising new interventions, and that seems inequitable. There are, then, important moral considerations favoring a waiver of the requirement of informed consent in these special circumstances (15).

There are, on the other hand, important moral considerations favoring retaining that requirement. To begin with, we should try to avoid violating the right of individuals not to be used as research subjects without their consent. Second, we need to protect these vulnerable subjects from being harmed by research to which they have not consented when (as often happens) the experimental interventions do not fulfill their promise.

Many proposals have been made as to how this value conflict should be resolved (16,17). One of the most promising is the regulations adopted by FDA in October 1996. FDA allows for an IRB to waive the requirement of prospective informed consent when (18):

- the subjects are in a life threatening condition and available treatments are unsatisfactory;
- animal and preclinical human studies support the likelihood of the intervention's being helpful;
- obtaining informed consent from the subjects or their surrogates is not feasible, so the clinical investigation cannot be carried out without the waiver; and
- additional procedural safeguards, as well as the usual IRB approval, are adopted, including attempting to find surrogates to obtain their consent and/or informing them and the subjects afterward, community consultation and notification, appointing an independent data safety monitoring board, and FDA approval.

If the values protected by the requirement of informed consent are absolute moral values, these regulations are inappropriate, since they allow for the waiver of the requirement of obtaining that consent. They are appropriate, however, if those values need to be balanced against the competing values of social need and potential subject benefit. As noted in the Introduction to this article, this type of balancing approach, which has recently won much favor among scholars, is characteristic of many of the FDA's newer rules.

Treatment INDs

In general, new drugs being tested under an IND may not be distributed for clinical use by patients not enrolled in research protocols. The one exception to this rule is the Treatment IND program which allows for the distribution outside of research protocols of some new drugs being tested for use in treating immediately life-threatening or serious illnesses (19).

The Treatment IND program, formally adopted by FDA in regulations in 1987, grew out of the experience with AZT for treating AIDS patients. In 1986, Phase II trials began for AZT. They were stopped after six months when it was clearly demonstrated that AZT was life-prolonging in the short run. An NDA was filed in December 1986 and approved in March 1987. From the time the drug was stopped until the application was finally approved, over 4000 patients received the drug outside any research protocol. This experience demonstrated the need for such a program in certain cases (20). From a moral perspective, the value of quicker access takes precedence in the relevant cases over the value of protecting desperate patients from not-yet-approved drugs. This is one more example of the need to balance values, rather than treating any one value as absolute, in research ethics.

Although the program was first introduced in response to the need for an AIDS drug not yet approved, it has been used to allow access to drugs for treating other conditions. In the first six years of the program, 28 Treatment INDs were issued. Nine were for AIDS-related drugs, 9 were for cancer-related drugs, and 10 were for drugs to treat other conditions (e.g., newborn respiratory distress syndrome and neurological conditions such as Alzheimer's dementia, MS, and Parkinson's disease) (21). Some Treatment INDs were issued after the clinical trials were completed but before the NDA was approved, while other INDs were issued while clinical trials were still being conducted.

Under the regulations the following are the requirements for issuing a Treatment IND (22):

- The drug is to be used for treating an immediately life-threatening condition (death will occur in a matter of months, or premature death will result from nontreatment) or a serious disease.

- There are no comparable or satisfactory treatments available.
- The drug is being investigated in controlled trials, or the trials have been completed and the sponsor is actively pursuing approval.
- For the drug to treat immediately life-threatening conditions, there must be a reasonable basis for believing that the drug may be effective and would not expose the patient to unreasonable additional risks. For the drug to treat a serious illness, there must be sufficient evidence of safety and effectiveness.

These provisions were adopted by Congress in the Food and Drug Administration Modernization Act of 1997 (23).

Special Rules for Genetic Research

Investigational biologic agents used for somatic cell and gene therapy must undergo the same process of FDA approval as other investigational agents (24). INDs must be secured for the research to begin, and NDAs must be approved before the agent can be distributed for general use. Until recently IRB and FDA approval of gene therapy protocols was not sufficient; a special NIH committee, the Recombinant DNA Advisory Committee (RAC), had to approve all federally funded research protocols. That requirement of additional approval has recently been eliminated, although RAC continues to review individual protocols, and it has been suggested that its authority to approve protocols be reinstituted.

Biologic agents pose special problems of product development which have received special attention by the FDA. Measures must be taken to control the biologic sources of the material, the production process, and the final product. These are necessary to deal with concerns both of safety and potency. The FDA issued in 1991 a *Points to Consider* document to clarify many of these technical issues (25).

In contrast to gene therapy, new forms of gene testing have not traditionally required FDA approval unless they use new testing kits; if they do, the kits, as opposed to the tests themselves, do require FDA approval. In recent years concern has been expressed about the proliferation of new genetic tests not employing new kits and not therefore being approved by any regulatory agency. Many feel that this allows for the marketing of tests that may not be analytically or clinically valid and useful, and that this can lead to a variety of problems for those being tested. Others have less concern, thinking that the decisions to use these tests should be left to the individuals in question, guided by their physicians or other health care providers. A recent report from a joint task force of the National Institutes of Health and the Department of Energy (26) supports the former approach, arguing that there is a need for review at a national level of new genetic tests before they enter into clinical practice and suggesting that the FDA does have the regulatory authority to conduct that review. It also points that if the FDA were to adopt this role, it would need to look at a broader set of issues, including the contribution of testing to producing better long-term outcomes, than the FDA usually does when reviewing lab tests. It remains to be seen whether this approach will be adopted.

FDA RULES FOR NDA STAGE

Traditional Rules for Adequate Evidence

The research conducted under an IND is designed to acquire data sufficient to support the approval of an NDA. In order to do that, the data must establish with a high enough degree of certainty that the drug has a sufficiently favorable risk–benefit ratio to justify its intended use. This section will review the FDA regulations related to the NDA approval process.

It is helpful in reviewing FDA regulations to understand that any drug approval process must answer two different, although related, questions, and that answers to these questions necessarily involve trade-offs among important values. The first of these questions is a *content* question: How should the values of effectiveness and safety be balanced in deciding whether the drug in question has a sufficiently favorable risk–benefit ratio? We want drugs that are effective. We also want drugs that are safe. But the most effective drugs often carry with them risks. The content question asks about how these two legitimate values should be balanced in deciding what is a sufficiently favorable risk–benefit ratio. The second of these questions is an *epistemic* question: How should the demand for adequate evidence and the demand for speedy approval be balanced in deciding that the evidence in question has established the drug's risk–benefit ratio? We want firm evidence that the risk–benefit ratio is sufficiently favorable. We want good drugs to be approved as soon as possible. But getting firm enough evidence often requires delays in the approval process. The epistemic question asks about how these two legitimate values should be balanced in deciding whether the evidence is firm enough so that the drug should be approved without further delay. The FDA regulations have much more to say about the epistemic question than the content question.

There is a special section of the NDA regulations that address the type of evidence required (27). The basic point of the section is that the FDA considers adequate and well controlled studies as the primary basis for supporting the claim that there is sufficient evidence to justify the approval of a NDA. The following characteristics of such studies are listed as essential:

- The study must involve a control group to compare with the treatment group in order for the drug's effect to be assessed quantitatively. Five types of control groups are identified. Four are concurrent control groups (placebo concurrent, dose-comparison concurrent, no treatment concurrent, and active treatment concurrent). For these types of control groups, subjects should be randomly assigned to the treatment group or the control group. The fifth type is a historical control group; in that type of study, randomization is not possible.
- Patients must be assigned to the treatment and control groups by a method that minimizes bias.

Randomization is the way to accomplish this in all concurrently controlled trials.

- Procedures such as blinding subjects and investigators must be adopted to minimize bias in the conduct or interpretation of the study.
- The protocol for the study must carefully define the population to be studied and the methods to ensure that the subjects are part of that population, the nature and duration of the treatment to be studied, the number of subjects to be studied, the methods to assess the response of the subjects, and the planned statistical analysis.

Based on its reading of the 1962 statute, FDA has traditionally insisted that two adequate and controlled studies provide sufficient evidence to justify the approval of an NDA. That is, of course, much more that just a point of statutory interpretation. It reflects the well-known scientific ideal that good scientific results are reproducible results. Nevertheless, such a requirement can often result in approval delays if the two trials are run sequentially, and additional costs even when the two are run concurrently. As part of its effort to develop a new balancing of values in response to the epistemic question, Congress, in the Food and Drug Administration Modernization Act of 1997, rejected that interpretation and left the need for a second trial to the discretion of the agency (28).

There are many important issues raised by this traditional set of rules. Probably the most controversial are those surrounding the choice of the control group, particularly when there already are available other drugs for treating the condition in question. From the perspective of easily getting well-established answers (the perspective of investigators, sponsors, and future patients), placebo or no treatment concurrently controlled trials are preferable because they allow for smaller and more easily interpretable studies. From the perspective of insuring access to at least some treatment (the perspective of the subjects and of their treating clinicians), dose-comparison or active treatment concurrently controlled trials are preferable. Both sets of values are legitimate, and the issue becomes one of how to balance the values. Several crucial official statements seem to support the use of only the latter types of control groups whenever an effective alternative treatment exists (29,30). This approach seems too absolute in stressing only the subject-centered values. FDA, by contrast, has stressed the scientific advantages of the first types of control groups, and has urged their use (with appropriate subject-protection mechanisms such as early rescue and minimization of study duration) except when existing treatments are life-prolonging (12). This approach seems to not sufficiently weigh the subject-centered values; it does not, for example, take into account the losses to subjects in the control group when existing therapies effectively limit morbidities and discomfort. What is needed in the case of each controlled trial is a careful look at all possible trial designs (different types of control groups and different types of protection mechanisms) and a determination of which best balances the research-centered values with the subject-centered values (31).

Accelerated Approval Rules

The accelerated approval rules, like the Treatment IND rules discussed above, arose in response to those suffering from AIDS demanding quicker access to promising drugs. They were joined in this demand by others, such as patients with cancer, who were dissatisfied with the available treatments and who wanted quicker access to promising drugs. Unlike the Treatment IND rules, the accelerated approval rules relate to final approval of the use of the drug, and not just to interim access while approval is being considered.

The accelerated approval rules apply to drugs being tested for the treatment of serious or life-threatening illnesses (32). The drugs in question must have the potential of providing meaningful therapeutic benefits to patients over existing treatments, either because patient response is improved with the new drugs or because patients are unresponsive to, or intolerant of, the existing treatments. The crucial provision of the rules is that such drugs can be approved on the basis of well-controlled trials that establish a favorable effect on surrogate endpoints (e.g., tumor shrinkage for cancer patients or reduced viral loads for AIDS patients), endpoints that are thought to be predictive of true clinical benefits (e.g., improved length of survival or decreased morbidity). This provision accelerates the approval because it is often possible to get data on surrogate endpoints quicker than data on true clinical benefits.

Critics have pointed to many examples where the use of surrogate endpoints has led to mistaken conclusions about the effectiveness of the new drugs as measured in terms of the true clinical benefits (33). They are certainly right to raise these concerns. Even after accelerated approval is given on the basis of data concerning surrogate endpoints, postmarketing studies of the effectiveness of the drug on true clinical endpoints need to be conducted when there is doubt about the effect on the true clinical endpoints. But this practice does not undercut the moral validity of the accelerated approval rules. There is rather a need to balance the demand for adequate evidence with the demand for speedier approval. The accelerated approval rules do so for drugs whose promise is supported by surrogate endpoint data but not fully established by true clinical endpoint data in cases where the patients are very sick and existing treatments are not helpful. The actual choice to use the new drugs will be made by patients with the advice of their doctors, but society will not stand in their way once promising surrogate endpoint evidence becomes available. When these provisions are coupled with the requirement of further studies as appropriate, they seem like a reasonable balancing of the competing values. The Food and Drug Administration Modernization Act of 1997 accepted this conclusion and incorporated the accelerated approval rules into the statute governing the FDA (34).

Rules Governing Special Populations

There are a number of populations that traditionally have been perceived as requiring special protection in the research setting. One such group is the elderly, who often

live in conditions of dependency, a dependency that makes them vulnerable to being exploited, and who sometimes suffer from impaired intellectual functioning that may impair their capacity to protect themselves. A second group is children, whose immaturity often impairs their capacity to protect themselves and whose dependency on their parents makes it difficult for them to make their own independent decisions about participation in research projects. A third group is women of childbearing potential, whose potential fetuses may require special protection. One way to provide special protection for these subjects is to exclude them from research, and this ethical concern is one of several factors that have often led in the past to the exclusion of these groups from research projects.

While this value of protection of the vulnerable is deserving of respect, there are other values that need to be considered as well, especially the value of justice. Individual members of excluded groups may unfairly be denied the personal benefit of obtaining access to promising new treatments. The exclusion of entire groups may result in the nongeneralizability of the results of the research to the members of the group, so they and their treating physicians are unfairly denied the basis for making decisions as to whether to use new treatments whose use in the general population is supported by the research in question (35).

In the earlier discussions of research ethics, greater emphasis seems to have been placed on the value of protecting the vulnerable from the risks of research. In recent years, as the benefits from participating in research have become better understood, more emphasis is being placed on balancing that concern with the justice-based concern of not excluding these individuals and groups from obtaining the benefits of research. As part of that more recent understanding, FDA has made several major initiatives in its rules dealing with these populations.

In 1989, in response to concerns about the exclusion of the elderly from research, FDA issued guidelines that, while explicitly not introducing further requirements for drug approval, provided recommendations about the inclusion of the elderly in research on drugs that are likely to have significant use in the elderly (36). The crucial recommendation was that the elderly should be included in such trials in reasonable numbers so that the patients enrolled in the trial reflect the patients who will use the drug if it is approved on the basis of the research. Following this recommendation would result only in the detection of fairly large age-related differences, but it was thought that those are the only differences important enough to be of concern.

These 1989 guidelines concerning the elderly were part of a larger effort in 1988 and 1989 by FDA to ensure that the subjects in research protocols were more representative of the population that would use the drug if it were approved (37). This more general effort also attempted to address the issue of the inclusion of women of childbearing potential in clinical trials. There is some controversy as to whether this effort was successful. The Government Accounting Office (GAO) claimed that there was a continuing problem, especially in connection with cardiovascular trials, while the FDA argued that the remaining differences resulted from the need to include more younger men because they were more vulnerable than younger women to cardiovascular disease. Nevertheless, FDA issued further clarifying guidelines in 1993 (38):

- Enough members of both genders should be included in order to detect "clinically significant gender-related differences," and the total study population should "reflect the population that will receive the drug when it is marketed."
- The integrated analysis of data from the trials should contain an analysis of gender differences in terms of both safety and effectiveness; additional studies might be required if these differences are significant enough.
- The definitive trials to support approval should employ gender-differing dosages if pilot pharmacokinetic studies reveal gender differences.
- Research protocols, unless specifically designed to study the effects of a drug during pregnancy, should include measures to minimize the exposure of fetuses to the drug being tested; the most important of these measures are pregnancy testing before administering the drug being tested and proper counseling about the selection and use of reliable methods of contraception.

In 1997 FDA proposed still further regulations to ensure that women of childbearing potential were included in clinical trials (39). These proposed regulations would only apply to trials of drugs intended for treating life-threatening illnesses. Unlike the above-discussed regulations, which have a direct effect only on the full set of data needed to secure approval and do not affect specific clinical trials, these proposed regulations will put constraints on certain trials. Under the proposed regulations, FDA can put a hold on trials, preventing further enrollment, if women of childbearing potential are being excluded because of fears of reproductive or developmental toxicities. FDA's argument for these proposed regulations is that such exclusion unfairly denies these women the choice to participate because of risks that can be minimized by the measures to minimize fetal exposure described above. These proposed regulations represent one further step in FDA's balancing of values in this complex area.

A third population for which FDA has developed special rules is the pediatric population. A very high percentage of the drugs used in the treatment of children have not been adequately tested for use in that population. In 1992, for example, 79 percent of the new drugs approved by FDA that could be used in children were approved without labeling for use in children because they had not been sufficiently studied in pediatric subjects (40). Based on 1994 data, the FDA identified the 10 most commonly used drugs in the pediatric population for which there was no pediatric labeling. The list included: albuterol inhalation for asthma, ampicillin injections for infection, and Prozac for the treatment of depression (41). These are serious drugs for serious medical problems, and their

pediatric use should be guided by better data. The lack of research data results in a fundamental ethical dilemma for pediatricians: Should they take the risk of using these new drugs without adequate information about their safety and efficacy at various dosages in children, or should they not use these drugs and risk denying to their patients valuable treatments? Clearly, policies that promote more testing of new drugs in children would help resolve this dilemma, and would constitute one more balancing of protecting subjects from research risks with insuring the access of patients to the benefits of research.

In 1994 FDA attempted to address this problem by adopting what can be called "the extrapolation" approach (42). According to that approach, FDA would allow labeling for pediatric use on the basis of clinical trials conducted with adults if there was sufficient pharmacokinetic and adverse reaction data from pediatric subjects to justify extrapolating the adult results of a favorable risk–benefit ratio to the pediatric population. That rule did not, however, require sponsors to conduct the studies required to justify the extrapolation. By 1997 FDA concluded that this approach had been inadequate to resolve the problem. It proposed supplementing that rule with an "including children" approach, similar to (although not exactly the same as) the approach it had adopted toward the elderly and toward women of childbearing potential. According to this proposed approach, the NDA application for drugs that represent a meaningful therapeutic advance and that are likely to be used in a substantial number of pediatric patients must include (unless a waiver is issued) data about safety, effectiveness, dosages, and mode of administration in the pediatric population. This proposal drew much criticism from those who were concerned with the cost of new drug development and from those who were concerned with the pace at which new drugs are approved for use in the adult population, but a version of it was adopted in 1998 (43).

CONCLUSION

As one reviews FDA's rules, two major themes clearly emerge. The first is the need to recognize that participation in research can be a benefit as well as a burden. It is this general recognition that has been central to the FDA's efforts to expand the types of subjects enrolled in clinical trials to include the elderly, children, and women of childbearing potential. The second is the need to balance values rather than to treat some as absolute. It is this general recognition that has led to FDA's rules on emergency research (which balances the need for informed consent with the individual and social need for emergency research), on Treatment INDs (which balances the need to complete clinical trials with the need for speedier access), and on accelerated approval (which balances the value of optimal evidence with the need for speedier access). These recognitions of the legitimacy of multiple values and of the need to balance them to arrive at optimal rules are a strength of FDA's rules governing human subjects research.

OUTLINE

INTRODUCTION

The U.S. Department of Health and Human Services (HHS) is the single largest supporter of biomedical research in the world. HHS conducts or supports more biomedical and behavioral research involving human subjects than all other federal agencies combined (1). It is not surprising, therefore, that HHS is charged by law to issue regulations for the protection of human research subjects. HHS has played and continues to play the leading role among U.S. departments and agencies in promulgating and implementing policies and protections for the rights and the welfare of human research subjects.

This article will present a brief history of the origins, development and astonishing growth of the HHS agencies, particularly that of the National Institutes of Health (NIH), and its laws, policies, programs, and regulations for the protection of human subjects involved in research.

ORIGINS OF FEDERAL SUPPORT FOR BIOMEDICAL RESEARCH

Marine Hospital Service

In 1798 the U.S. Congress authorized, and President John Adams signed into law, a bill establishing the federal Marine Hospital Service to care for sick and disabled seamen. No one living at that time could have foreseen that the Marine Hospital Service, a Division of the Department of the Treasury, would evolve into a complex network of federal departments and agencies that collectively support the world's largest health research enterprise.

Federal support for biomedical research did not begin for nearly a century after the health care service program for merchant seamen was initiated. The creation, in 1887, of the one-room Bacteriological Laboratory for investigation of cholera and other infectious diseases at the Marine Hospital on Staten Island, New York, initiated federal support of biomedical research dedicated to public health (2).

U.S. Public Health Service

The U.S. Congress gradually widened the responsibilities of the Marine Hospital Service, and assigned additional research responsibilities to its laboratory, designated as the Marine Hospital Service Hygienic Laboratory in 1891.

In 1902 the Marine Hospital Service was renamed the Public Health and Marine Hospital Service (MHS), and in 1912 the mission of the MHS was further broadened; the Service was reorganized and it was renamed the U.S. Public Health Service (PHS). Over the next decade, a small military unit called the Public Health Service Commissioned Corps was added to the PHS. The Corps was composed of trained medical and research personnel who dedicated themselves to the protection and promotion of the health of the U.S. population. PHS Commissioned Corps officers were placed under the command of the Surgeon General of the United States (SG). Members of the Corps were expected to accept assignment to areas of the country that were medically underserved, or assignment to areas of the country where an outbreak of disease created special demands for medical personnel. The officers of the Commissioned Corps frequently labored alongside their counterparts, civilian employees of the PHS agencies. From the earliest days of the Corps, some of its officers have been assigned to conduct or administer biomedical research programs.

The Chamberlain-Kahn Act of 1918 (40 Stat.L. 309) directed the SG to conduct a new research initiative into the causes, prevention, and cure of venereal diseases, and empowered the SG to initiate grants-in-aid to further such research. Accordingly in 1918, the SG authorized grants-in-aid-of-research to twenty five extramural (outside the

PHS) institutions. These grants were the first biomedical research awards involving human subjects made by the federal government to research institutions in the private sector. They mark the beginning of an unprecedented partnership involving academe, industry, and the general public (represented by the federal government).

Creation of Categorical Research Institutes

The Ransdell Act of 1930 (P.L. 71-251) reorganized, expanded and renamed the Hygienic Laboratory as the National Institute of Health. Over time the Ransdell Act served as a template for what eventually would become a cascade of legislation that created additional research institutes aimed at studying disease categories, or studying human organs that are subject to specific categories of disease. The National Institute of Health gradually became a federation of categorical research agencies called the National Institutes of Health (NIH).

The first of the new of categorical institutes (later called the National Institute of Mental Health) was authorized by Congress to carry out research into the causes, treatment, and prevention of mental and nervous disorders, and to conduct research into narcotics abuse (P.L. 71-357).

The Social Security Act of 1935 (P.L. 74-271) is often considered to be the high water mark of the pre–World War II Roosevelt administration because it entitles persons who qualify — for reasons of age or disability — to receive income from the federal government. However, few people recall that the Social Security Act also contained landmark provisions that authorized the PHS to advise and assist state and local health officials to offer services and conduct research to prevent the spread of disease within and across state lines, and to improve regional and local health programs. This responsibility has, for the most part, been assigned to the National Centers for Disease Control (CDC) in Atlanta, Georgia.

The Congress created the National Cancer Institute (NCI) in 1937 (P.L. 75-244). The new institute not only provided for grants-in-aid to study the causes, treatment, and prevention of the many varieties of cancer, but it provided for fellowships, personnel training, and cancer prevention and control programs within and across the several states. The legislation that established NCI served as a model for the subsequent establishment by statute of 24 additional institutes and centers that currently constitute NIH.

In 1939 PHS was transferred from the Treasury Department to the Federal Security Agency (FSA) (P.L. 76-19). In 1953 FSA was folded into the newly created Department of Health Education and Welfare (HEW) headed by a Secretary who is a senior cabinet officer. When the Department of Education was separated from HEW and established as a new Department in 1979, HEW was transformed into the Department of Health and Human Services (HHS) (3).

World War II: A Time of Change

The Second World War brought profound changes to health research in the United States. In 1941 President Franklin D. Roosevelt established a federal Committee for Medical Research (CMR) to address war-related disease and injury. The CMR carried out its responsibilities by issuing multiple contracts for targeted research. Spectacular results including, development of sulfanilimides, gamma globulin, adrenal steroids, cortisone, and a wide variety of new surgical techniques and treatment regimens, were credited to the CMR (4).

Enactment of the PHS Act with Section 301 Authority

The enthusiasm generated by successful wartime research efforts led by the CMR was channeled, following World War II, into unprecedented congressional support for biomedical research. Before World War II had come to a close, Congress responded to the success of wartime research by enacting the landmark PHS Act of 1944 (P.L. 78-410) that revised and consolidated into a single law, all of the authorities that governed the various PHS agencies. The PHS Act required major reorganization of PHS agencies. Most important, it gave the PHS unprecedented generic powers to support research "into [all of] the diseases and disabilities of man" (commonly known as "Section 301 authority"); and authorized the involvement of subjects in research conducted at PHS medical facilities. The significance of "301 authority" lay in the fact that the PHS agencies, especially NIH, were authorized to exploit promising research opportunities in basic research and in a wide variety of medical specialty fields without waiting for Congress to authorize such research. Thus, although the institutes of NIH were created with categorical missions, they were able to devote a large portion of their growing research budgets to basic research. The result was a spectacular expansion of the biological knowledge base. Similarly the institutes of the NIH, using "301 authority," were able to follow promising research leads without waiting for Congress to authorize and fund their efforts.

The NIH Clinical Center was erected in 1953 under Section 301 authority. Today Section 301 authority is seldom cited because Congress has created so many research programs targeted at specific diseases and disabilities that there is less need to invoke generic research authority. Furthermore Congress now recognizes that giving direction to specific research programs into diseases such as AIDS, heart disease, cancer, and diabetes is politically more attractive to the tax-paying public than giving nonspecific authority to support expansion of the biomedical research knowledge base. Much basic biological research is still supported by NIH, but it is called "cancer research" or "heart research" or "diabetes research," even though it focuses on basic biological structures and functions that may find application in many disease categories. Since the enactment of the PHS Act, virtually all federal legislated research initiatives have taken the form of amendments to the PHS Act that authorize or underwrite both intramural and extramural research programs.

Absence of Research Ethics Policies in Pre-war Years

The research agencies and programs of the U.S. government were created and repeatedly reshaped by the Congress during the first half of the twentieth century. It is

interesting to note, however, that during that same period of time, the Congress wrote no laws, held no hearings, and created no policies for the protection of human subjects involved in research.

By failing to provide either substantive or procedural ethical rules for research funded by PHS, the Congress tacitly implied that responsibility for the ethical conduct of research should be left almost entirely to awardee institutions and to the conscience of each investigator who conducted research supported by the federal government (5).

The absence of ethics policy governing research involving human subjects conducted or supported by the federal government can be explained by several factors. In the first place, the Hippocratic tradition of medicine was the centerpiece of the prevailing ethics of medicine and research conveyed to physicians in training, including those who would function as clinical research investigators. That tradition was imparted by mentors, role models, and institutional traditions. Bioethics was not recognized as a distinct discipline that lent itself to a methodological approach and systematic teaching. Biomedical ethics, including research ethics, was not taught, nor was it even available in the library collections of most of the medical schools of that period.

Many medical ethical problems were addressed by moral theologians teaching in educational institutions established and operated by religious denominations. These theologians systematically addressed fundamental questions of medical ethics, but because theological deliberations were grounded in religious faith, traditions and practice — as well as human reason — neither the Congress nor the Executive Branch demonstrated a strong interest in incorporating the opinions and conclusions of moral theologians into public policy. Furthermore, although a few theologians enjoyed broad knowledge of medical practice, few had credentials in research. Most theologians lacked credibility with the research community (6).

Second, the distinction between medical care and biomedical research was seldom made — by the Congress, by the public, by subjects of research, or even by research investigators themselves. Consequently the ethics of medical research (dedicated to systematic development of generalizable medical knowledge) was not clearly distinguished from the ethics of medical practice (dedicated to the best interests of each individual patient). Research subjects often assumed that research investigators were serving their best interests, whereas in fact the primary concern of research investigators was to gain generalizable knowledge for the sake of the public health. (This error is sometimes referred to as the "therapeutic mistake.") In some cases the best interests of subjects coincided with the development of new knowledge in research, but in most cases the interests of the subjects were subjugated to the development of general knowledge. Today the distinction between medical practice and medical research is widely recognized. Prior to World War II and for many years thereafter, it was seldom cited or acknowledged, even by the strongest proponents of research.

Third, prior to World War II, research subjects had often been patients of physicians whose medical practice evolved beyond standard care of patients into innovative therapy, and finally into carefully constructed research projects. Neither medical practitioners who evolved into research investigators, nor their patients who evolved into research subjects, seemed to recognize the fundamental change in their relationship. Rothman notes that research subjects of this period had a high level of trust in research investigators because they usually thought of the investigators as their private physicians. Public confidence in the ethical integrity of physicians who provided care to patients was at an all time high. That confidence was easily extended to physicians who crossed the threshold from practice to research (5).

As the funding of research by the federal government expanded, research became a full-time career for many investigators. Because their research cohorts were made up mostly of subjects referred to them by physicians, it gradually became less common for research investigators to have prior trust relationships with their research subjects.

Postwar Development

After the close of World War II in 1945, a series of laws created the National Institute of Mental Health (P.L. 79-487), the National Heart Institute (P.L. 80-655), and the National Dental Institute (P.L. 80-755). The Hill-Burton Act of 1946 (P.L. 79-725) authorized grants to states for the construction of hospitals and public health centers, each of which included a research component. The Omnibus Medical Research Act of 1950 (P.L. 81-692) created the National Institute of Neurological Diseases and Blindness and the National Institute of Allergy and Infectious Diseases.

As research funding components of NIH multiplied following World War II, the biomedical research budgets of PHS agencies, particularly that of NIH, experienced meteoric rises that reflected unprecedented enthusiasm for the support of research by the tax-paying public. Between 1946 and 1949 NIH budgets leaped from $180 thousand to more than $800 million (7).

In 1953 two events of great importance to medical research in general and to research involving human subjects in particular occurred. First, PHS, including SG and PHS Commissioned Corps, was transferred to the new HEW. Second, the NIH Clinical Center, a state-of-the-art research hospital, opened its doors. The Korean conflict was in progress at the time, and young American men (including physicians and scientists) were subject to military draft. Physicians who qualified as research fellows at the CC at that time were given credit for military service. Consequently keen competition for NIH Fellowships developed. Fellows from the NIH CC program subsequently assumed leadership roles in the research programs of medical schools and in private industry. As a consequence of NIH's "doctor draft," biomedical research in America not only expanded, but the quality of such research improved dramatically.

It is not surprising, therefore, that HHS (and its predecessor, HEW) played and continue to play a leading

role in the United States in providing protections for the rights and the welfare of human research subjects. That leadership was scarcely discernable after World War II, but since 1966 it has gradually expanded and has become increasingly prominent.

The HHS includes many agencies. The largest — measured in terms of disbursement of funds — are the Social Security Administration (SSA) and the Health Care Financing Administration (HCFA) that administers the Medicare program. Biomedical research supported by HHS is, with a few exceptions, conducted or supported by eight agencies that comprise PHS (9). (The eight agencies today include the Agency for Health Care Policy and Research, the Health Resources and Services Administration, NIH, the Indian Health Service, CDC, FDA the Substance Abuse and Mental Health Services Administration, and the Agency for Toxic Substances and Disease Registry.) The PHS agencies were, in the past, coordinated by the PHS administration, operating under the direction of the Assistant Secretary for Health (ASH) and SG (sometimes these positions have been held by a single person who was at both ASH and SG, at other times they were held by different persons). SG and ASH reported to the Secretary of HHS.

Beginning in 1998, the administrative Offices of ASH and SG have been absorbed into the offices of the Secretary of HHS. PHS agencies are expected to continue to report to the Secretary of HHS through ASH and SG, but an intermediate level of administration will largely disappear.

NIH is by far the largest biomedical research agency within HHS. NIH is currently composed of 25 institutes and centers. The fiscal year (FY) 1999 budget of NIH is $15.56 billion dollars (8).

In FY 1998 the CRISP data collection program showed that 27,782 research projects involving human research subjects were conducted or supported by HHS. The vast majority of these projects are supported by NIH. Because a study involving human subjects may involve as few as one or two subjects, and as many as 18,000 or more (e.g., the ongoing study on prevention of prostate cancer), it is nearly impossible to estimate how many subjects are involved in research conducted or supported by HHS.

First U.S. Policy for the Protection of Human Subjects

The most visible effect of the newfound public endorsement of research can be seen in completion of the NIH state-of-the-art Clinical Center (CC) in 1953. The CC is a 500-bed hospital dedicated exclusively to the conduct of research. Only subjects actively participating in research studies are eligible for admission to the Center. Even in the setting of an institution totally dedicated to research, it was tacitly assumed that research procedures involving Clinical Center "patients" should be conducted in accord with the traditional doctor-patient relationship — a relationship of trust in which the patient had reason to believe that the doctor was uniformly acting in the best interests of the patient. To require a formal process of informing subjects of the risks and benefits involved in research and eliciting informed consent was judged to be intrusive in the doctor-patient relationship. It was left to each research investigator to decide what information, if any, would be conveyed to "patients," whether a consent process was to be employed, and how the process would be recorded.

However, the decision not to intrude on the doctor-patient relationship that was mistakenly thought to be the same as the physician-patient relationship could not be applied to "normal volunteers." Normal volunteers, recruited from colleges in nearby states, served to provide "control data" that was compared with data derived from "patients" in clinical studies. Since normal volunteers were expected to take medical risks and to receive no direct benefit from their participation in research, they could not be identified as "patients." A special policy was developed by the CC for normal volunteers (9). The policy stated: (*1*) that informed consent would be obtained from normal volunteers prior to their participation in any research project, and (*2*) that a research project involving normal volunteers could go forward only if it had been approved by a committee of scientists. Once a committee of scientists had approved a research protocol involving normal volunteers, and the normal volunteers had consented to participate, responsibility for the normal volunteers' safety and health was assigned to the principal investigator conducting the research. Dr. Philippe V. Cardon, M.D. was assigned to supervise the program for normal volunteers. The program would, in subsequent years, provide the first template for the PHS policy that was to come.

A Policy Vacuum

During the 1950s the United States was simultaneously recovering from the human and materiel expenditures of World War II and focusing its attention on the increasingly complex nature of the cold war. The United States was also enmeshed in the Korean conflict. American citizens were dissatisfied with the ambiguous stalemate that ended military conflict in Korea but produced no lasting peace. The U.S. economy was expanding, and America turned its attention away from military conflict to fighting battles against disease. Little attention was given to the ethics of research. Within NIH attention focused more on the development of a fair and just peer review process (employed to decide which research projects were worthy of public funding) than on the rights and welfare of human research subjects.

In 1959 Senator Estes Kefauver (D.TN) began a series of hearings focused on the impact of the rising cost of prescription drugs on the health care costs of patients. In the course of the Kefauver hearings, the media revealed that hundreds of infants born to mothers who had taken the drug thalidomide were grotesquely deformed. By this time many American homes had television sets that brought graphic pictures of the thalidomide tragedy into their living rooms. Most of the babies affected by thalidomide were born in the United Kingdom, in Europe, or in Canada. Tragedy had been averted in the United States only because one FDA employee, Dr. Frances Kelsey, had demanded more animal tests before she would agree to its being prescribed for use by pregnant women in

the United States. Nevertheless, fear of a similar tragedy in this country preoccupied much of the nation.

Senator Kefauver quickly changed the focus of his hearings from the economics of drug testing to the safety of drug testing. He unveiled for the public the fact that drugs were commonly tested on patients without their knowledge. Physicians simply administered experimental pharmaceuticals without informing their patients that the drugs had not been tested for safety or efficacy. The Food and Drug Administration (FDA) had little authority to prevent the widespread practice, though it encouraged the presentation of animal data prior to licensing drugs for market use.

In 1962 Senator Kefauver, despite opposition from the pharmaceutical industry, was successful in persuading the Congress to enact the Kefauver-Harris amendments to the Food, Drug and Cosmetic Act (P.L. 87-781). The Act, as amended, required rigorous testing of drugs for safety and efficacy before they could be marketed. When the bill came to the floor of the Senate, Senators Jacob Javits and John Carrol introduced an amendment that required that subjects provide informed consent before being involved in the testing of investigational drugs.

The thalidomide episode seemed to prompt disclosure of other research problems. *The New York Times* carried a story of research involving the injection of live cancer cells into elderly, indigent, and possibly incompetent patients without their consent. These "charity" patients already were suffering from various forms of cancer, and the investigators wished to know whether their immune response systems would reject additional cancer cells. Drs. Southam and Mandel were found by the New York State Board of Regents to be "guilty of fraud or deceit and unprofessional conduct..." (10). Dr. Denton Cooley attempted transplantation of a sheep's heart into a dying human patient (11). He sought permission from no one. His act was soundly condemned as unethical by many of his colleagues in the medical community, but he did not violate any law or regulation. He defended himself by contending that he was acting in the best interests of his patient who died several days later.

Dr. James Shannon, the dynamic Director of NIH at the time, was alarmed by these incidents. He not only regarded them as violations of the rights of the research subjects, but he believed that they jeopardized the future of publicly supported medical research. Intense discussions began to take place in his office and across the NIH campus in Bethesda, MD, concerning appropriate professional ethical standards for the conduct of research. Questions of informed consent, minimizing research risks, excellence of research design, protection of subjects' privacy, and submission of research to review by other scientists were discussed. It was initially thought that NIH could not, without additional legal authority, impose standards of conduct on investigators who received support for their research from the agencies of PHS. Ethical behavior toward research subjects was considered to be a major responsibility of the research investigator.

Gradually the view emerged that federal agencies could place conditions, including ethical conditions, on the awards that they made to research institutions and their investigators. Dr. Shannon created a committee headed by Dr. Robert Livingstone to recommend a suitable set of protections for subjects involved in Public Health Service-supported research. Livingstone's report recommended making a careful assessment of "ethically responsible relationships" and an examination of the range and tenor of present professional ethical practices. The report concluded that "the NIH is not in a position to shape the educational foundations of medical ethics..." Shannon found this conclusion "wholly unsatisfactory" (12).

FORMULATION OF THE FIRST EXTRAMURAL FEDERAL POLICY

Concerns for the ethics of publicly supported research involving humans had been relatively dormant during the decade of the 1950s, at least until the thalidomide hearings raised serious questions about the conduct of research. The years from 1960 to 1972 provided a sharp contrast to the previous decade. A generation of young adults had grown to adulthood under the constant threat of nuclear destruction. Trust of science-based technology had gradually eroded. For a new generation of young Americans, suspicion of technology and fear of its misuse replaced the confidence and trust that had characterized the period following World War II. Virtually every kind of science-based technology was now viewed as a potential threat to health, well-being, or survival of the planet unless it was carefully controlled.

New federal regulatory agencies — the Environmental Protection Agency (EPA), the Occupational Safety and Health Administration (OSHA) — were created to make the environment and the workplace safer for all living things and especially for humans. Both old and new federal departments and agencies produced volumes of regulations to implement laws restricting perceived threats to the environment, public health, and public safety.

The new-found public suspicion of science and technology provided a dramatic and sharp contrast to the attitude of many in the research community who believed that "the scientific method rests [on] the integrity and independence of the research worker and his freedom from control, direction, regimentation, and outside interference" (13).

The director of NIH had few illusions about the difficulty of formulating an ethical framework that could serve as a guide for research involving human subjects. "To win general acceptance within, not only the medical research community, but also our society at large," Dr. Shannon wrote, "the final statement of principles should probably emerge from ... representatives of the whole ethical, moral, and legal interests of our society" (12, p. 152). Shannon knew that creating acceptable ethical guidance for research, and building a consensus for a statement of ethical principles, would be the work of many years. He also believed that the Congress would hold the PHS agencies, particularly NIH, responsible for failures to protect human subjects. He had the vision to see that failure to protect human research subjects was tantamount to a failure to protect the public support of biomedical research.

At Shannon's request Surgeon General William Stewart issued the first PHS extramural Policy for the Protection of Human Subjects. The policy was elegant, simple, and easy to understand. To this day, although it has been revised many times, the core of the policy remains essentially unchanged. Each awardee institution was required to file an Assurance of Compliance document with PHS stating that the institution would adhere to the following procedures.

> The awardee institution is to provide prior review of the judgment of the principal investigator or program director by a committee of his institutional associates. This review should assure an independent determination: (*1*) of the rights and welfare of the individual or the individuals involved [as subjects], (*2*) of the appropriateness of the methods used to secure informed consent, and (*3*) of the risks and potential medical benefits of the investigation (14).

It almost seemed that Henry K. Beecher, a prominent Harvard research investigator, wished to underline the importance of the policy when he published a shocking article in the *New England Journal of Medicine* in June 1966 (15). Beecher identified 22 research projects published in refereed research journals that, in the author's judgment, violated the rights of the research subjects involved. Because he enjoyed a prestigious position as a researcher in a leading academic institution, Beecher's article sent shock waves through much of the American research community. His article lent urgency and needed credibility to the new PHS policy.

Responsibility for implementing the PHS policy was assigned to the tiny Institutional Relations Branch of the Division of Research Grants within NIH. The process by which the policy was to be implemented required considerable clarification. It underwent minor revisions in the summer of 1966, and further revision in 1967. In 1969 the Surgeon General revised the policy to make it clear that the policy extended to behavioral and social science research as well as to biomedical research. The Institutional Relations Branch implemented the policy by negotiating Assurance of Compliance documents with each awardee institution. Few universities, clinics, and laboratories welcomed the policy, but after Beecher's article was published, most of them accepted the policy as inevitable.

Because the policy was directed toward extramural research, it did not apply directly to NIH's own intramural CC. It would be many years and many policy revisions later before the NIH intramural program came into full compliance with the policy that governed extramural institutions that received awards for research involving human subjects. Nevertheless, in 1966 Dr. Jack Masur, director of CC, appointed a committee headed by Dr. Nathaniel Berlin to update the CC policy of 1953. Masur was responding, in part, to the recently published PHS policy. Clinical Research Committees (CRCs) were created within the intramural programs of the categorical institutes (16). Consent of subjects (still referred to as "patients") was required only to the extent that the investigator was expected to make a note in each "patient's" chart that verbal consent had been obtained.

From the outset, the Institutional Relations Branch used education and negotiation as the primary tool of promoting compliance with the policy. Although the Institutional Relations Branch had authority to withhold awarded funds, for many years no sanctions were imposed on any institution for failure to comply.

In 1971 the PHS policy was revised by Dr. Donald S. Chalkley, director of the Institutional Relations Branch. The scope of the policy was expanded to cover all research supported by any agency, office, or unit within HEW (17). Consistent with the educational approach described above, the new HEW Policy for the Protection of Human Subjects (commonly described as the "Yellow Book" because of the color of the cover of the pamphlet in which it was published) not only set forth requirements that institutions were to meet (review by committee, informed consent, and evaluation of risks and benefits), but it provided a running commentary presenting reasons why these requirements were necessary.

In July 1972 the public press uncovered details of the infamous Tuskegee Syphilis Study involving 600 black males from Macon County, Alabama Started in 1932, the study systematically denied treatment for syphilis to approximately 400 men who were afflicted with the disease (the other 200 men were used as control subjects). Subjects were not informed of their diagnosis. They did not know they were involved in a research study, and even after penicillin became the drug of choice to treat syphilis, they were denied treatment.

The Tuskegee Study received national publicity because of hearings held in the Senate Health Subcommittee chaired by newly elected Senator Edward Kennedy (D. MA). The study was conducted by a series of PHS investigators over a period of more than 35 years. Assistant Secretary for Health, Dr. Monty DuVal convened a committee chaired by Dr. Jay Katz, M.D., J.D., of Yale University to review the study. At the recommendation of Dr. Katz, the study was closed. HEW subsequently paid millions of dollars to survivors and to families of those who did not survive to compensate them for harms caused by the study. In FY 1995 HHS paid $2.8 million and in FY 1996 HHS paid $1.88 million in compensation to survivors and heirs of participants in the Tuskegee Syphilis Study (18). On May 26, 1997, President Clinton, on behalf of the U.S. nation, apologized to survivors of the study and to their families. (Despite the fact that HEW/HHS has paid compensation to subjects in the Tuskegee Study, it has never adopted a policy of providing compensation to injured subjects in other situations.)

The Tuskegee Study was given wide publicity in the media, and it triggered public disclosure of a number of other alleged research abuses relating to psychosurgery, fetal experimentation, and illicit experimentation involving contraceptives. All of these matters were aired in the Senate Health Subcommittee hearings held periodically between 1972 and 1974.

In the meantime Dr. Robert Q. Marston, who succeeded Dr. Shannon as director of NIH, made a decision to promote protections for the rights and welfare of human research subjects. In an address to the College of Nursing at the University of Virginia, he declared an obligation

on the part of society to carry out research aimed at improving the health of vulnerable populations and to protect the rights of vulnerable research subjects in the process (22).

Dr. Marston then created a PHS-wide drafting committee chaired by Dr. Ronald Lamont-Havers to revise and upgrade the HEW policy of 1971. The mandate to the PHS committee was based on the Marston talk at the University of Virginia. In 1972 Dr. Marston also upgraded the Institutional Relations Branch to a position within the Office of the Director, NIH. Marston changed the name of the office to the Office for Protection from Research Risks (OPRR). Dr. Chalkley, who had directed the Institutional Relations Branch, was named the first director of OPRR.

Largely as a result of the Kennedy hearings and the Tuskegee scandal, a series of legislative initiatives pertaining to research involving human subjects were introduced in Congress in 1973–74. These included a bill sponsored by Senator Kennedy to create a regulatory commission (similar to the Securities and Exchange Commission) to oversee research. Senator Walter Mondale (D. MN) introduced legislation to create a National Advisory Commission to study the impact of advances in science and technology on American society. Congressman Paul Rogers (D.FL) introduced a bill that called for a "National Advisory Commission for the Protection of Human Subjects of Biomedical and Behavioral Research" (20). Congressman Angelo D. Roncallo (D. NY) introduced legislation to ban federal support for human fetal research. Roncallo claimed, erroneously, that NIH had been conducting gruesome research involving live aborted fetuses ex utero (12). Senator Jacob Javits (R. NY) urged passage of legislation extending and strengthening the requirements for informed consent from research subjects. Congressman Rogers and Senator Kennedy cobbled together a bill that included some features of all of these legislative initiatives. Senator Kennedy indicated that he would support the compromise bill if HEW would publish regulations for the protection of human subjects. HEW then hurriedly transformed the HEW policy contained in the "Yellow Book" into regulatory form and published it as Regulations for the Protection of Human Subjects (21). The Congress then passed the pending compromise bill as Title II of the National Research Act (P.L. 93-348) signed July 12, 1974. The Act required: (*1*) that HEW promulgate regulations requiring institutions to ensure compliance with the regulations in a manner acceptable to the Secretary HEW (this requirement was completed prior to enactment of the law), (*2*) creation of a National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research to study a wide range of health research issues, (*3*) a temporary moratorium on fetal research to remain in place until such time as the National Commission reviewed the matter of fetal research and made recommendations concerning continuation of the moratorium, and (*4*) a special study of the impact of science and technology. To prevent the recommendations of the new Commission from being ignored, the Act contained a "forcing clause," that is, the Secretary of HEW was required by law to accept recommendations of the National Commission, or publish in the Federal Register reasons for not accepting them. The law also recommended that the commission be succeeded by a HEW Secretary's Ethics Advisory Board to address the question of federal funding of human fetal research and other matters that the Secretary might assign to it.

Between 1974 and 1978 hearings and deliberations of the National Commission, chaired by Dr. Kenneth Ryan of Harvard University, captured the attention of the research community and the media. The National Commission endorsed the approach taken by HEW in 45 CFR 46, and it incorporated much of the work of the PHS committee headed by Dr. Lamont-Havers. The commission recommended adding additional protections for pregnant women and human fetuses (1975), prisoner subjects of research (1977), children who are subjects of research (1978), and persons who are institutionalized because they are suffering mental infirmity. The National Commission deliberated for four years, and it published 9 reports. Perhaps its best known report is the *Belmont Report: Ethical Principles and Guidelines for the Protection of Human Subjects of Research* (22).

After the commission completed its work, the Secretary directed the Public Health Service to accept all of its recommendations and to implement them.

HEW Secretary's Ethics Advisory Board

In 1978 HEW Secretary Joseph Califano established the Secretary's Ethics Advisory Board (EAB) to review controversial biomedical ethical issues and to issue reports and recommendations concerning them. James Gaither, an attorney from San Francisco who had worked with Califano in the Johnson administration, was designated as chairperson. The first issue that the EAB addressed was whether HEW should fund human in vitro fertilization (IVF) research. Shortly after the EAB began its work, Louise Brown, the first "test tube" baby, was born in England as a result of the experimental work of Drs. Steptoe and Edwards. Enormous publicity followed the birth of Louise Brown, and considerable ethics debate both in England and the United States followed the publicity. In the United States several research investigators submitted applications for federal support for human IVF research. Suddenly the deliberations of EAB were followed by reporters from all the major media and from the tabloid press as well. In May 1974 EAB issued a Report and Conclusions: HEW Support of Research Involving Human In vitro Fertilization and Embryo Transfer. While the board stopped short of recommending to the Secretary that such research should be funded, it unanimously declared that such research, if it meets certain conditions, is acceptable from an ethical standpoint. On the basis of the report, Secretary Califano was preparing to authorize investigators seeking support for human IVF research to compete for awards when he became engaged in a controversy with Hamilton Jordan, assistant to President Carter. The President fired Califano and replaced him with Patricia Harris. Secretary Harris had little interest in the ethical questions pertaining to research and never took action on the recommendations of EAB. EAB issued reports on (*1*) fetoscopy (recommending

that the department make funds available for the procedure), (*2*) nosocomial (hospital-induced) infections (recommending that the public be allowed to see data maintained by CDC showing the rate of hospital-induced infections), and (*3*) clinical trial Data (recommending that investigators be allowed to withhold release of preliminary clinical trial data under the provisions of the Freedom of Information Act).

In 1980 Secretary Harris failed to re-charter EAB, and its remaining budget was transferred to the newly created President's Commission for the Study of Medicine and Biomedical and Behavioral Research.

REVISION OF HHS RULES FOR THE PROTECTION OF HUMAN SUBJECTS

During the final two years of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research and for several years thereafter (1976–1980), a PHS committee chaired by the director of OPRR scrutinized hundreds of public comments on the reports of the National Commission and, in the light of those reports and the public comment on them, revised and expanded the regulations for the Protection of Human Subjects (45 CFR 46) last issued in 1974.

The work was completed in the final months of 1980. The proposed regulations included (*1*) Subpart A: Generic Regulations Providing Protections for all Human Subjects participating in Research; (*2*) Subpart B: Additional Protections for Research Involving Pregnant Women and Human Fetuses; (*3*) Subpart C: Protections for Prisoners involved in Research; and (*4*) Subpart D. Protections for Children involved in Research. HHS Secretary Harris signed the regulations on January 19, 1981, and they were published in the Federal Register six days later.

In addition to the recommendations made by the National Commission, the PHS drafting committee created some categories of research that were exempt from the regulations, and other categories that would allow for expedited review by the chairperson of the institutional review board or a person designated by the chair. The exempt and expedited categories were created precisely to reduce the workload of IRBs that were already heavily burdened. They were welcomed by the research community that felt that a reasonable trade-off had occurred — greater protections for high-risk research and fewer safeguards for research involving negligible or minimal risks.

In 1978 Congress enacted legislation that created a new ethics Commission called the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research (23). Although the bulk of the work of the President's Commission was dedicated to ethical concerns in the delivery of health care, the commission issued two reports that dealt directly with the system of protections for human research subjects. It also issued a report on research involving genetic engineering (24).

From the point of view of federal policies for the protection of human subjects, the most important contribution of the President's Commission was the following set of recommendations: (*1*) All federal departments and agencies should adopt regulations of HHS, (*2*) the Secretary of HHS should establish an office to coordinate and monitor governmentwide implementation of the regulations, and (*3*) each federal agency should apply one set of rules for the protection of human subjects consistently to all research conducted or supported by the federal government (25).

The Secretary of HHS, through ASH, designated OPRR as the "lead" office to develop a common set of regulations across the government. However, OPRR was dealing with reduced budgets and severe restrictions on its outreach due to downsizing. Requests for personnel and budgets to carry out the Secretary's orders were denied. OPRR approached each agency in the federal system with a request for compliance with the recommendations of the President's Commission. Most of the agencies replied that they too were facing downsizing and could undertake no new initiatives. Nevertheless, OPRR was able to obtain some backing from the Office of Management and Budget on the ground that what was proposed was a simplification of a complex regulatory structure. The initial response from the agencies was disheartening. Each was willing to adopt the HHS rules — but with conditions attached. Each agency had different conditions so that, if all had been accepted, there would have been little left of the HHS Regulations for the Protection of Human Subjects that were used as a model for the proposed new governmentwide regulations. The tortuous process of winning agreement from all of the departments and agencies continued for more than seven years. Finally, the OPRR, after rebutting objections from the President's legal advisor, was able to gain support from the Office of the President's Science Advisor and from OMB. On June 18, 1991, final clearance was obtained. Sixteen departments and agencies, in addition to the HHS, simultaneously published the "Common Rule."

APPLICATION OF THE REGULATIONS TO WOMEN AND MINORITIES

As noted above, the Common Rule was based, in many ways, on the recommendations of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research. That commission tended to regard biomedical research as risky and dangerous. It feared that persons who were sociologically disadvantaged would be exploited as research subjects. It was concerned that the burdens of research would fall on the poor, the uneducated, minority groups, and women. All of these were regarded as "vulnerable" populations. However, in the decade of the 1980s, a long period passed when there were few reports of research injuries or deaths. Furthermore, with the coming of the AIDS epidemic, most persons infected with HIV found that the best care, and the most advanced "treatment" for AIDS, could be obtained by participation in clinical trials. Consequently the protections that had been employed to prevent exploitation of the disadvantaged were now seen as discriminatory because they offered protections that served to discourage overinvolvement of these populations in research.

Furthermore, in the late 1970s and early 1980s the feminist movement identified many forms of discrimination against women. Women's rights became a major national political issue. Along with other concerns for women's

rights came the awareness that many drugs administered to women had not been tested in women. Physicians, fearing malpractice suits, began to warn women that the drugs they were prescribing had not been tested in women and that women must be willing to take them at their own risk. Dr. Bernadine Healy, who became director of NIH in 1987, made repeated demands on the Congress for increased funding of research involving women. Dr. Healy created the Office of Women's Health Research at NIH and dedicated discretionary research funds to projects related to women's health (26).

Although AIDs research was gradually modified to include women, complaints that women, especially pregnant women whose offspring might be infected with HIV, were excluded from highly desirable research were given wide publicity. Clinical studies that a decade before had been considered to be a heavy burden for pregnant women were now considered to be a prized benefit (20).

CURRENT PROBLEMS

The history of federal protections for human subjects continues to develop. In 1994 President Clinton created the Advisory Committee on Human Radiation Experiments (ACHRE) that dealt with some 4000 studies sponsored by the federal government that exposed human subjects to radiation. Most of these studies were conducted prior to the existence of any federal policies or regulations. Although much of the information concerning these studies is incomplete and fragmentary, ACHRE identified some cases of clear abuse and recommended compensation for those who had suffered injury as a result of such studies. ACHRE further identified serious deficiencies in the current system for protecting the rights and the well-being of human subjects (27).

Partly in response to ACHRE's report, President Clinton issued an Executive Order establishing the National Bioethics Advisory Commission (NBAC) to address questions dealing with the adequacy of federal regulations, particularly regulations for the protection of the cognitively impaired. This commission has attempted to address the implementation of the Common Rule and has raised the question whether the location of OPRR within the NIH constitutes an apparent conflict of interest. Since NIH funds research, OPRR can easily be caught in a position of opposing its own agency if it decides that NIH-funded research is not being conducted in compliance with federal regulations. Partly as a consequence of the possible conflict of interest, a decision has been made to transfer OPRR to the Office of the Secretary of HHS.

NBAC also has issued reports on the ethics of research involving human cloning, and research involving persons who are cognitively impaired. The list of issues pertaining to human subjects that could be explored or revisited by NBAC is almost endless (28).

Research involving human subjects funded by the U.S. government is expanding each year. The United States is already the largest single source of such funding, and such research appears to be a growth industry. Slowly but surely such research has come under increasing public scrutiny and regulation. Some believe that much more needs to be done. Others believe that overregulation may stifle the biological revolution that is extending human life, conquering disease, and providing better health not only to Americans but to humans in every part of the globe. The new millennium offers new and ever more complex challenges to the twin goals of advancing biomedical and behavioral science and protecting the rights and welfare of human research subjects.

Dayton, OH

OUTLINE

INTRODUCTION

This article discusses the legal implications of research involving somatic cell gene transfer for the treatment of human disease. The genetic process is based on the transfer of normal genetic material (deoxyribonucleic acid, or recombinant DNA) from another organism into a diseased human being. Gene delivery can be achieved by either directly administrating the gene-containing viruses or DNA to the blood or tissues (i.e., in vivo) or indirectly introducting cells manipulated in the laboratory to harbor foreign DNA (i.e., in vitro). Gene therapy seeks to treat disease in an individual person by the administration of normal DNA rather than a drug (1). This therapy would be available at all stages of human development.

Somatic cell gene transfer is distinct from medical interventions that target the manipulation or engineering of germ-line cells (i.e., eggs and sperm) (2), although the ethical distinction has been questioned by some writers (3). Additionally therapeutic gene transfer is distinct from genetic manipulations done for personal enhancement. Although both forms of cell gene transfer attempt to "improve" the human body, therapeutic manipulations aim at normalizing a person with a genetic disease or abnormality, while genetic enhancement tries to optimize some designated area of a normal person's body or performance (e.g., athletic prowess) (2).

Recently there has developed much enthusiasm in the scientific and public communities about the therapeutic potential of genetic manipulation at the individual patient level (4). It has followed the successful efforts of biologists who in 1998 cultivated human embryonic stem cells. These embryonic stem cells are the primordial human cells from which an entire person may be created, via fertilized human eggs (ova) that are implanted in the uterus (5). As philosopher Daniel Callahan has stated it:

> [N]o excitement [in the biomedical arena] has quite matched that which genetic research has engendered. The claim in its behalf is sweeping and radical: genetic research and its clinical application promise to finally bring medicine to the root causes of disease.
>
> Once these casual, molecular mechanisms are understood, clinical medicine and medical technology will be in a superb position to eliminate many, if not most, of the deadliest diseases (6, p. 70).

According to a 1995 federal report:

> Somatic gene therapy is a logical and natural progression in the application of fundamental biomedical science to medicine and offers extraordinary potential, in the long-term, for the management and correction of human disease, including inherited and acquired disorders, cancer, and AIDS. The concept that gene transfer might be used to treat disease is founded on the remarkable advances of the past two decades in recombinant DNA technology (1, p. 1).

The positive potential of somatic cell gene transfer was recognized in a 1982 report of the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research (7) and in a 1984 report of the Office of Technology Assessment (OTA) (8).

LEGAL REGULATION OF HUMAN SUBJECTS RESEARCH

Research involving somatic cell gene transfer in human beings is governed by the same federal laws that apply to human subjects research generally, namely regulations codified at 45 Code of Federal Regulations Part 46. These 1981 regulations define research as "a systematic investigation, including research development, testing and evaluation, designed to develop or contribute to generalizable knowledge," 45 Code of Federal Regulations §46.102 (d). The requirements established by these regulations apply explicitly to all human subjects research that is federally funded, although most research-sponsoring institutions subject all of their human subjects protocols to these requirements. Compliance with federal regulations is overseen by the Office of Protection from Research Risks (OPRR), which Congress in 1999 placed in the Office of the Secretary, U.S. Department of Health and Human Services.

Under federal law, research protocols utilizing humans as research subjects must be reviewed and approved by a local, interdisciplinary Institutional Review Board (IRB) whose composition includes at least one public

member (9). The IRB is supposed to evaluate the ethical implications of several aspects of a research protocol, including the following items, in terms of human subjects protection:

- Fairness or equity of subject selection
- Minimization of risks to subjects (including nonphysical risks, e.g., inconvenience and financial or loss of privacy costs), and whether any foreseeable risks are justified by reasonably expected direct, indirect, or social benefits
- Sufficiency of the informed consent process and its documentation
- Sufficiency of confidentiality safeguards

Questions have arisen regarding the propriety and degree of IRB involvement in evaluating the scientific merit of research proposals. The most cogent position is that usually the scientific merits of a research proposal cannot be disentangled from ethical considerations of subject protection. As a 1998 report (10, p. 32) asserted, "Any research involving humans entails some risk. Even for research in which the risk to subjects is minimal, the risk should not be taken unless the research has scientific merit."

In addition to federal requirements, a number of individual states have enacted their own statutes or promulgated regulations that apply to human subjects research generally. State requirements may be more, but not less, stringent in terms of human subjects protection than those created by federal law, and they apply with full force to research on somatic cell transfer.

One Canadian working group has suggested a detailed schema for IRB review of gene therapy/gene transfer protocols. This schema proposes that the IRB delve in depth into the following aspects of research protocols in this sphere: background and justification; research design; procedures; confidentiality; subject selection; risks, discomforts, and benefits; and information to subjects (11).

Another potential source of regulation is the civil justice system under which an individual human subject may sue investigators and/or the institutions and sponsors for injuries resulting from a negligently conducted experiment (12). The extent of possible liability exposure under traditional or novel tort theories remains uncharted at this time, but certainly investigators and their institutions will need to develop and implement appropriate risk management strategies to minimize that exposure (13).

SPECIFIC LEGAL ISSUES IN HUMAN GENE TRANSFER RESEARCH

Conflation of Research and Therapy

Background on the Confusion. The tremendous potential of somatic gene transfer technology to correct or manage many serious human diseases and abnormalities has been vastly oversold thus far, to both the scientific and general public communities. This excessively exuberant publicity has created, or at least fostered, a widespread confusion among members of the public who comprise the pool of potential human subjects for gene transfer research protocols regarding the important distinction between medical interventions that are properly categorized as therapy, on one hand, versus medical interventions more correctly considered research studies, on the other (14,15).

The terminology frequently used by many of those who participate in or report on this activity illustrates, and contributes to, the conflation of therapy and research in the public's mind. When terms such as "gene therapy research," "patient," "immunotherapy," "vaccine," "drug," and "cure" are repeatedly employed in this context, the public impression is established and strengthened that this form of medical intervention must be undertaken primarily for the benefit of the individual person receiving the recombinant DNA from another organism. As one set of authors has observed, "The call of activists, patients, researchers, and regulators for greater access to research protocols emerges as a symptom of the overselling of medical research as therapy." (14, p. 43) Although the commonly used terminology represents the long-range aspirations of researchers, it neglects the reality that interventions currently being studied in clinical trials are a significant way off from achieving the status of accepted therapies.

Properly understood, the practice of accepted therapy consists of professionally agreed-upon interventions that are expected to provide direct, personal benefit to an individual patient. By contrast, research has new, generalizable knowledge as its primary aim; any direct or indirect benefit enjoyed by specific human subjects, while certainly welcome, is quite secondary and incidental (16). Recognizing that overselling the current capabilities of gene cell transfer misleads potential human subjects into expecting personal benefit as a direct consequence of their participation, an NIH panel has advised more restraint by investigators and their sponsors in presenting information about this activity to the public (1).

"Informed" Element of Informed Consent. Federal regulations and common law doctrine (17) mandate that individuals may participate as human subjects in biomedical and behavioral research protocols only if and when they have given consent to such participation that is voluntary, competent, and informed. Widespread public failure to accurately distinguish between research and therapy in the gene cell transfer context is manifested by a tendency on the part of many people to already see this intervention as a benefit to which there is a right rather than as a hazard from which vulnerable people might need external protection (14). This popular attitude presents investigators and IRBs with a major challenge for ensuring that the process of informed consent operates in this sphere.

The 45 Code of Federal Regulations §46.116 (a) (1) requires that in seeking informed consent for research participation, each potential subject must be provided with "a statement that the study involves research, [and] an explanation of the purposes of the research ...." Fulfilling this requirement obligates the investigator to make clear to each potential subject that the protocol

is intended to gather generalizable information that may help others in the future who have the same disease or abnormality as the subject, but that any immediate, personal benefit to that particular person would be unexpected and merely incidental to the research endeavor. In the written consent document that the possible participant is asked to sign, the educational effort about the research versus therapy distinction ought to be promoted by replacing misleading words like "treatment," "patient," and "therapy" with more accurate terms such as "potential subjects," "potential participants," "research," and "experiment." (15, p. 51).

Many human subjects in gene therapy research might benefit from long-term follow-up by the investigators. However, there often will be practical difficulties in the capacity of investigators and their institutions to conduct such follow-up over a sustained period of time. These limitations should be explicitly described to potential subjects as part of the informed consent process (18).

"Desperate Use" Exception. The widespread confusion regarding the research versus therapy status of gene cell transfer today is illustrated by the "desperate use" exception that has been officially recognized as a circumstance where gene cell transfer investigators are legally authorized to conduct transfer interventions on a person without first complying with the ordinary informed consent requirements. The "desperate use" exception for gene transfer research is modeled after earlier-created "emergency use" exceptions authorizing the conduct of limited types of research in the absence of timely informed consent from the participant (19,20). Although the "desperate use" exception has been defended on grounds of compassion for afflicted individuals who have no other available alternatives (an argument that assumes the likelihood of some direct benefit for that specific patient/subject), some commentators question the wisdom of this exception in light of the present dearth of scientific knowledge about the actual benefits of gene transfer (15, pp. 49–50). There also is concern that, despite the lack of any scientific basis, the "desperate use" exception was recognized nonetheless as a result of pressure brought on Congress by patients, and over the strong scientific objections of the NIH's Recombinant DNA Advisory Committee (RAC) (15, pp. 49–50).

Voluntariness When the Subject Is Also a Patient. Voluntariness is an essential element of informed consent for research participation. The 42 Code of Federal Regulations §46.116 provides, "An investigator shall seek such consent only under circumstances that provide the prospective subject or the representative [of a decisionally incapacitated subject] sufficient opportunity to consider whether or not to participate and that minimize the possibility of coercion or undue influence."

Voluntariness is jeopardized in the gene transfer research context when, as is ordinarily and logically the case, potential human subjects are recruited from the ranks of patients who are currently under a physician's care for the precise disease or abnormality that is the focus of the research protocol. Many lay persons (as well as clinicians) have difficulty making the distinction between the patient seeking direct, immediate therapeutic effect from a medical intervention and the research subject altruistically contributing to generalizable knowledge of practical application only to others in the future. This confusion also impairs the "informed" element of informed consent. As a result patients may imagine, or accurately perceive, subtle or more blunt pressure to participate in research protocols as a way to continue access to whatever therapeutic treatment they are currently receiving, even though federal law expressly forbids investigators to conditionally link together research participation and the continued availability of standard treatment in that fashion.

As one commentator has noted, "Most of the persons enrolled in gene transfer research to date are a special class of research subjects — namely, sick persons who present special vulnerabilities and require special protections not relevant to healthy, 'normal' subjects." (15, p. 52) Clinical investigators and IRBs are legally and ethically challenged to establish an environment in which patients' perceived compulsion to "volunteer" for gene transfer research protocols solely in order to preserve their present patient status is eliminated or reduced as much as possible.

Conflicts of Interest. Investigators in gene transfer research involving human subjects may have actual or apparent conflicts of interest of two different sorts (21). First, since many potential human subjects for these research protocols are current patients receiving care for the exact disease or abnormality that the protocol intends to study, the clinical investigator may also occupy the professional role of attending physician currently caring therapeutically for the person (patient) that he or she is recruiting to now also become a research subject. This dual investigator/clinician position can easily contribute to the conflation of research and therapy in the minds of many patients/potential human subjects as just discussed, raising implications for both the voluntary and informed elements of informed consent to research participation. At the very least, the informed consent process — as enforced by IRBs — ought to require that potential human subjects be told in understandable lay terms about the dual investigator/clinician role, the distinction between the goals and expectations of research versus the goals and expectations of therapy, and the various kinds of professional and financial incentives that the treating clinician has to enroll his or her patients into research protocols for which that clinician also serves as investigator.

A second source of possible conflict of interest arises when the investigator in a gene transfer research protocol is also an investor in, or otherwise holds some financial stake (e.g., as a paid consultant), in a corporation that stands to profit financially from positive results of the particular study. A number of ethical commentators have argued that, as a matter of informed consent, financial interests of the investigator in the conduct or outcome of a study should be fully disclosed to potential human subjects at the time that their participation in that study is solicited (22–24).

Proxy Consent When the Subject Is a Child. As noted by one geneticist:

> Often the individual for whom DNA treatment [sic] is proposed is a very young child and thus unable to give consent except via proxy. In-depth counseling of the proxy — often the parents — should be provided to ensure full review of the state of knowledge concerning the risks of changing the DNA: what the known risks are, as well as what is unknown. The relative risks and benefits of alternative treatments and options should be fully discussed (25, p. 570).

The challenge of using minors as research subjects is exacerbated by the fact that many of them will achieve adulthood during the follow-up phase of the research.

> Thus, it may be necessary to obtain assent at the time of enrollment as well as consent at adulthood. This must be done in a way that both protects the rights of the patient [sic] to withdraw from research at any time and yet encourages follow-up, which may provide benefits to both the individual and society (26, p. 661).

National Institutes of Health (NIH) Oversight

In addition to the generic federal and state regulations applicable to human subjects research and common law principles of informed consent, gene transfer research involving human subjects that is funded by the federal government through the National Institutes of Health (NIH) also may be influenced by specific policies of that executive agency. Specifically, Section 402(b) (6) of the Public Health Service Act, as amended, codified at 42 United States Code §282(b) (6), established the NIH Recombinant DNA Advisory Committee (RAC). According to this Technical Committee's May 27, 1997, Charter, its function is to "advise the Director, NIH, concerning the current state of knowledge and technology regarding DNA recombinants, and recommend guidelines to be followed by investigators working with recombinant DNA." Review of specific protocols is conducted initially by the Human Gene Therapy Subcommittee (HGTS). The RAC is governed by the provisions of the Federal Advisory Committee Act, as amended, 5 United States Code Appendix 2.

ACKNOWLEDGMENT

Some of the writing of this entry took place while the author was the 1998–99 Dr. Arthur Grayson Memorial Distinguished Visiting Professor of Law and Medicine, Southern Illinois University School of Law, Carbondale, IL.

Washington, District of Columbia

OUTLINE

INTRODUCTION

The intention to establish an activity, linked to a major U.S. government science research program, directed at Ethical, Legal, and Social Issues (ELSI) was announced to an unsuspecting world on October 1, 1988, by Dr. James D. Watson, the co-discoverer with Francis Crick of the structure of the deoxyribonucleic acid (DNA) molecule. Watson was accepting the directorship of the newly created Office of Human Genome Research at the National Institutes of Health (NIH). Together with the Office of Health and Environmental Research (now the Office of Biological and Environmental Research) at the U.S. Department of Energy (DOE, which had been supporting genome research on a modest scale for the prior two years), these programs were preparing to map and sequence the human genome in its entirety, an estimated 3.2 billion nucleotides. In response to a question about dealing with the societal implications, Watson said that he thought that a small percentage of the research budget, initially 3 percent, should be used to study the implications of mapping and sequencing the human genome. Thus, even before the formal beginning of the Human Genome Project (HGP) in 1990, project managers, researchers, and lawmakers recognized that increasing knowledge about human biology and personal genetic information would raise a number of complex issues for individuals and society and that the agencies ultimately paying for the research needed to engage in anticipating its impacts. In response to Congressional mandates for identifying and defining such issues and developing effective policies to address them, DOE and NIH have devoted 3 to 5 percent of their annual HGP budgets, since the outset of HGP, to studies of the project's ELSI. [Much of this early history is well described in Cook-Deegan]. These expenditures for ELSI research by DOE and NIH now total nearly $85 million dollars.

DOE, which initiated HGP from roots in its radiation biology programs dating from the establishment of the Atomic Energy Commission (DOE's predecessor) in 1947, has for most of its 53-year history been an agency whose top priority was producing the materials necessary for the U.S. nuclear arsenal. This in turn made it an appropriate place to support studies of the biological effects of the radioactivity that characterizes the materials needed for nuclear weapons. Over the years, the greatest fear about radiation and radioactivity derived from its well-known capacity, first established by Herman Muller in the 1920s, to cause mutations and various forms of cancer. Mutations are alterations in the arrangement or sequence of the specific informational units in the genome, all made up of DNA. Just as a refrigerator magnet passed over a prerecorded cassette tape can alter the music on the tape, so too can various radiation exposures alter the information content of the DNA in the genome. To better devise tools and methods for assessing radiation effects, it is helpful to begin with knowledge of the original information prior to any exposures (e.g., the prerecorded music on the cassette *before* the magnet passes near it). This was DOE's rationale for initiating HGP. Additional reasons for DOE's activity included the availability of advanced technologies from the DOE National Laboratory system (e.g., for DNA fragment isolation, DNA sequencing, and computational analysis of sequences), better understandings of genetic contributions to workplace susceptibilities (given the particular nature of DOE facilities, characterized by mixed radioactive and toxic material waste), and the extensive experience of DOE with managing large interdisciplinary projects. For NIH, knowing the sequence of the human genome is the substrate for exploring what all the gene products do, how aberrations in them can lead to diseases, and how variations in individual genomes can lead to variation in individual humans. Thus both agencies had important and compelling mission-related reasons to participate in genome research. For the constituencies of both agencies, and for the larger general public, the genome project promised (and to a considerable degree has begun to deliver) many benefits in the way of new technologies, new industrial entities in the biotechnology sector of the economy, and new approaches to a better understanding of human biology in health and disease.

Still, there were worries about uses of genetic information, often of a very personal nature, that would not be welcomed by society. Early workshops enumerated several major ones. Among these were the implications of being able to predict future illnesses well before any symptoms or medical therapies existed; potential abuses of

the privacy of genetic information by employers, insurers, direct marketers, banks, credit raters, law enforcement agencies, and many others; the availability of large amounts of genetic information in largely unprotected data banks; and the possible discriminatory misuse of genetic information. One hypothetical outcome, albeit perhaps an extreme one, of the wide use of genetic screening would be the creation of a new genetic underclass, leading to a host of new societal conflicts and exacerbating others of long standing. Additional concerns included the difficulties that physicians (many of whom had little genetics in their medical school curricula) would have in incorporating rapidly advancing genomic knowledge and technologies into practice, especially in an Internet enabled world where a patient often might know more about a particular condition than his or her physician. As biotechnology entered the business world, issues of whether gene sequences could (or should) be patented arose. In addition, since newly discovered genes often lead first to a test for the presence or absence of alleles associated with a disease, and the demand for a new test could be high, tension could be forseen between the natural economic imperative to sell a new test and the uncertainty of the significance of test results when the strength and nature of the putative disease association was not clear (e.g., BRCA1 and susceptibility to breast and ovarian cancer). As genetic advances rushed forward, there was concern that a variety of communities, from specific groups such as judges in the court system, to high school biology classes, to legislators, the press, MDs of various specialties, nurses, ultimately to the wider public, could not keep up. One group of concern were genetic counselors, who were appreciated as vital to helping patients and their families understand the implications (to the degree they were understood at all) of genetic test results; as a community, genetic counselors are recognized to be in drastically short supply.

The ELSI component of HGP began by emphasizing the privacy of genetic information, its safe and effective introduction into the clinical setting, fairness in its use, and professional and public education. In 1991, recognizing the breadth of this scope, DOE narrowed its ELSI focus to concentrate on genetic education, privacy and fair use of personal genetic information, the implications of intellectual property protection (e.g., patenting) of genes, and genetics and the workplace. As its portion of the total ELSI program, DOE has supported peer-reviewed studies on the uses, impacts, and implications of personal genetic information in various settings the ownership, access, and protection of genetic information in computerized databases, tissue and sample archives, and the commercialization of products of genome research. DOE also supports studies of ways in which society and its institutions deal with ELSI issues surrounding the complex (and common) multigenic conditions and disease susceptibilities most of us fear. One of DOE's goals is to ensure the wisest possible distribution of the knowledge from HGP to the general public as well as to the scientific, academic, minority, judicial, medical, educational, sociological, and political communities.

To avoid unnecessary duplication of effort by their two independent ELSI programs, DOE and NIH have collaborated on a number of activities and maintained close communications over the years. In addition to the NIH–DOE Joint ELSI Working Group, which periodically consulted with program staff and assisted in coordination of the ELSI programs, collaborations also involved several research projects, joint conferences and workshops, and programs supported with other agencies, organizations, and commercial companies. DOE and NIH collaborated in supporting the ELSI Research Planning and Evaluation Group (called ERPEG), a successor to the ELSI Working Group.

EDUCATION ACTIVITIES

In keeping with the long-standing commitment of DOE to education, the DOE ELSI program has emphasized the promotion of knowledge about the HGP and its ELSI implications to such groups as institutional review boards, medical professionals, genetic researchers, judges, policy makers, and the public. These efforts have included conferences, seminars, publications, videos, Web sites, and radio and television programs. A few examples are given below (a more complete listing is available at *http://www.ornl.gov/hgmis*) maintained by the Human Genome Management Information System (HGMIS) at the DOE Oak Ridge National Laboratory. Although not an ELSI program, HGMIS helps the DOE Human Genome Program fulfill its educational commitment by making information accessible to scientists, policy makers, and the public about the program's goals, funded research, implications, and applications. HGMIS carries out this mission by publishing and distributing documents and information both in print and via its Web site, which serves a wide and varied audience that includes the general public, scientific investigators, and medical professionals. One HGMIS product is the *Human Genome News*, the newsletter of the U.S. Human Genome Project. This Newsletter, originally jointly sponsored by both the DOE and the NIH Genome Programs, facilitates communication among genome researchers and informs the broader public about the project.

The DOE ELSI program has sponsored, in whole or in part, several widely distributed booklets on the genome project. These include *To Know Ourselves*, by Douglas Vaughan, an overview of the underlying science of the Human Genome Project; the *DOE Primer on Molecular Genetics*, by Denise Casey, an introduction to the basic science of genetics; *Your World, Our World*, a magazine dealing with the science of genomics and its ELSI implications designed for grades 7 through 10 by the Pennsylvania Biotechnology Association, in cooperation with the Alliance for Science Education; *Your Genes, Your Choices*, a book and video designed for low-literacy adults, by Catharine Baker and Maria Sosa of the American Association for the Advancement of Science (AAAS); and a comprehensive bibliographic database of publications related to ethical, legal, and social issues surrounding the genome project and including thousands of books and articles from 1990 to 1995, compiled by Michael Yesley of the DOE Los Alamos National Laboratory.

The DOE ELSI program has also assisted with video documentary projects including, "Medicine at the Crossroads," a four-part documentary jointly sponsored with NIH, produced by George Page and Stefan Moore at WNET/Thirteen in New York and shown around the country on public television in the spring of 1993. A book, *Medicine at the Crossroads: The Crisis in Health Care* by Melvin Konner, also resulted from this series. Another documentary that DOE ELSI supported was a WGBH series, "The Secret of Life," produced by Paula Apsell and Graham Chedd and shown in the fall of 1993. "A Question of Genes," a two-hour television documentary produced by Noel Schwerin, looked at a series of families and individuals challenged by the outcomes of genetic testing for inherited diseases. This was broadcast on the Public Broadcasting System in September 1997, and it received an Emmy nomination. "Seeking Truth, Finding Justice," a three-hour television documentary series, is now in production by Noel Schwerin now of Backbone Media. This series will explore the impact of cutting-edge science (e.g., genetic technology) on the courts and its profound effect on democratic institutions, people's relationships, and notions of truth, justice, and individual rights.

DOE ELSI has also supported two radio programs. For the Spanish-speaking public, DOE ELSI has supported the broadcast of 50 Spanish-language radio episodes within a nationally syndicated science and technology series, produced by The Self Reliance Foundation in Santa Fe, NM. "The DNA Files," a nationally syndicated series of radio programs on the social implications of human genome research, by SoundVision Productions in Berkeley, CA was broadcast over National Public Radio stations in November 1998.

Other DOE education activities have included a web site launched by the Shriver Center in Waltham, MA called "The Gene Letter," (now called GeneSage) a freely available, online quarterly ELSI newsletter for interested professionals and consumers (*http://www.genesage.com/professionals.html*). The San Francisco Exploratorium and the Smithsonian's Museum of American History each received DOE/ELSI support in 1995 for exhibits on genetics and the HGP. "Diving Into the Gene Pool" was on display at the Exploratorium from April to September 1995. Most recently, at Stanford University, a project is producing an interactive multimedia CD-ROM medical education course for physicians, most of whom have received little or no training in clinical applications of molecular genetics. It is expected that many other groups will benefit as well from such a resource.

Over the years, DOE ELSI has supported many workshops and conferences to explore and educate audiences about the genome project and ELSI. Among the more notable of these have been a May 1997 meeting at the University of Maryland in Baltimore to inform minority communities about HGP and to make the aspirations and interests of these communities better known to genome project scientists and policy makers. In September 1996 DOE and NIH jointly sponsored a major conference at Tuskegee University on "Plain Talk about the Human Genome Project," which addressed some of the HGP's implications for African-Americans. An updated compilation of all the conference talks was published in 1997. The Cold Spring Harbor DNA Learning Center on Long Island conducted several workshops early in the Genome Program to inform opinion leaders and public policy makers on genomics and the genome project's implications for society. In a three-year DOE and NIH project that began in 1990, the Baylor College of Medicine and the Texas Medical Center Institute of Religion organized two national conferences on genetics, religion, and ethics. This project led to a book, *On the New Frontiers of Genetics and Religion* (1995). In April 1998, a symposium attended by about 850 people on "The Human Genome Project: Science, Law, and Social Change in the twenty-first Century" was held at the Whitehead Institute for Biomedical Research. Following the symposium, which was supported in part by DOE, a CD-ROM containing the meeting syllabus, transcripts of all plenary talks, and links to relevant Web sites, were distributed to over 4000 people. A second conference in this series was held in Spring 2000.

Education for Professional Groups

The Einstein Institute for Science, Health, and the Courts has convened workshops around the country for more than 1500 federal and state judges. These workshops, conducted since 1994 and continuing through 2002 (with co-funding from the National Instititue for Environmental Health Sciences of NIH), prepare judges for the expected onslaught of cases that will involve some aspect of genetics. In addition, the Summer 1997 issue of *The Judges' Journal of the American Bar Association*, with support from DOE, was devoted to "Genetics in the Courtroom." This project has a particular priority in the DOE ELSI program, since in our litigious society it can be anticipated that the courts will be the place of last resort for many issues. Many judges are touchingly honest about their very limited science education and their feeling of being ill-prepared since several recent decisions of the U.S. Supreme Court have assigned responsibility for deciding what scientific evidence is allowed into court to the trial judges and, for federal courts at least, altered the criteria by which scientific evidence must be judged before it is admitted. There are many potential issues for the courts, including numerous ones that are not rooted in medical practice. Issues from forensic uses, the penalty phase after a felony conviction, adoption cases, cases of the custody of a minor or of an incompetent parent, inheritance cases, liability, and many others may be influenced by assertions of genetic causation or involvement. Courts will have little alternative but to deal with cases arising from assertions that "my genes were responsible" cloaked in various guises.

Institutional review boards (IRBs) are responsible for overseeing clinical research procedures at such institutions as hospitals and research facilities, particularly protocols that might affect the rights and welfare of human research subjects. Increasingly complex ethical, regulatory, and scientific issues are proving challenging to these boards, which often are composed largely of nongenetic professionals. To assist IRBs in reviewing genomic protocols, expecially those involving human

subjects and tissues, a project with the Public Responsibility in Medicine and Research is focusing on educating IRBs in the special language, technologies, and issues that typify these protocols.

Curricula

The DOE ELSI program has supported the production and dissemination of a number of curricula for high schools on the genome project and its implications. These have included a nationwide series of workshops created by the Cold Spring Harbor Laboratory in New York which introduce high school biology teachers to a laboratory-based unit on human DNA polymorphisms (genetic differences) and the ELSI aspects of the genome project. An innovative program initiated at the University of Washington, Seattle, allows high school students to perform DNA synthesis and sequencing in the classroom. Local teachers, as well as those from other states, attend a weeklong summer workshop in Seattle and receive continuing assistance with the experiments through equipment and technical advice after they return home. This program has allowed high school students to actually contribute DNA sequence to the human genome project database making them participants in the project.

The Biological Sciences Curriculum Study (BSCS) group in Colorado Springs has produced 4 high school modules for the DOE ELSI program, roughly every two years since 1993. The first was, "Mapping and Sequencing the Human Genome Program: Science, Ethics, and Public Policy," followed by "The Human Genome Project: Biology, Computers, and Privacy." The third module was "Nontraditional Inheritance and the Nature of Science." Most recently BSCS has released "Genes, Environment, and Human Behavior" which deals with complex traits and behavioral genetics. At California State University in Los Angeles, an ELSI-funded project has translated into Spanish the first BSCS module for use by students and their parents in selected high schools where the majority of the student body is Hispanic. In conjunction with other local and national organizations, the University of Kansas Medical Center trained over 175 high school science teachers annually as state "resources" in molecular genetics and the latest biotechnology methods. In a "trainer of trainers" model, they then prepared thousands of additional teachers, who are now reaching millions of students. At the Fred Hutchinson Cancer Research Center in Seattle, a researcher has established an electronic educational resource on the Web for republishing classic genetics literature (both papers and monographs). This project helps promote a foundation for understanding the new genetics and genome technology (*http://www.esp.org*). A more complete list of educational curricula developed with support from the DOE ELSI program is available at *http://www.ornl.gov/hgmis*.

Exploring Public Policy Issues

There are many public policy issues raised by advances in genome research and no ELSI program could hope to explore all of them. At the outset of the HGP, when the scope of potential ELSI issues was uncertain, DOE and NIH jointly supported a study by the Institute of Medicine to address a variety of issues raised by the rapid proliferation of predictive genetic tests in otherwise healthy individuals. This study led to the 1994 publication of *Assessing Genetic Risks: Implications for Health and Social Policy*, a report with recommendations for the use of genetic information in healthcare. Concentrating on Florida and Georgia, researchers at Morehouse School of Medicine and the University of Florida explored differences among state-supported programs for genetic testing, screening, and counseling. Jointly sponsored with NIH, this 1992 to 1994 project addressed the issue of confidentiality in a mobile society of broad ethnic diversity. A series of published papers resulted from these studies.

At the University at Albany in New York a project is examining confidentiality concerns raised by the possible misuse of DNA-based test results in the managed-care (MCO) setting. This setting presents unique ethical dilemmas because the MCO is both payer and provider and because physicians, and quite often, testing laboratory personnel are MCO employees. Additionally, a significant fraction of working Americans get their health care through MCOs. The uses they make of genetic information are a valid concern of ELSI.

Many disorders associated with mental retardation have genetic contributions, with Down syndrome and fragile X syndrome the most common, and new genetic findings from HGP pose very difficult ethical questions and legal and social concerns to those with disabilities and their family members. To address these concerns, The Arc of the United States developed and distributed a series of reports, fact sheets, and a workshop training package to all 1100 of the organization's chapters.

Threats to privacy based on genetic testing in various circumstances have been cited often as reasons for ELSI research and societal concern. The fair use of genetic information raises particularly difficult practical and philosophical problems related to access and disclosure. Third parties such as insurers, employers, adoption agencies, and educational institutions may feel they need access to genetic data having predictive or diagnostic value, while others feel that such access will lead to discrimination and decisions based too heavily on genetics. The DOE ELSI program has focused on a broad range of genetic privacy issues from the perspectives of several disciplines, including philosophy, social science, and law. Through grants and commissioned papers, the program has supported studies to consider such factors as attitudes toward genetic privacy in different populations, the need for appropriate measures to protect genetic information in various contexts, and evolving policies of private institutions and state, federal, and foreign governments in this area. These studies were designed to help increase the growing body of knowledge and to promote informed discourse leading to policy development.

A study by a leading social scientist at Columbia University related existing social science work on privacy to anticipated genetic-privacy issues. This study also examined current privacy-protection measures, debates over the need to update privacy protection, and implications for social and legal policies to deal with expected

future genetic testing and applications of genetic data. The results will appear in book form. To strengthen the dialogue between the professional genetics community and federal policy makers, a congressional fellowship program was initiated in 1995. This program allows genetic professionals to spend a year as special legislative assistants on the staff of members of Congress or on congressional committees. The fourth fellow (of a planned five) began her fellowship at the beginning of 2000. Under a grant to the Library of Congress, Philip Kitcher, a philosopher at the University of California, San Diego, researched genome ELSI issues and wrote *The Lives to Come: The Genetic Revolution and Human Possibilities* (2). The book explores both the science and the ethical and moral dilemmas arising from the genome project and concludes by arguing that society should make active use of genetic testing to avoid the worst genetic conditions that presently are not amenable to medical therapies, but involve horrific suffering, for example conditions such as Tay-Sachs disease.

In a project jointly sponsored by NIH and DOE, researchers at the University of California, Berkeley, conducted a major study between 1992 and 1997 to illuminate the processes by which genetic screening and genetic concepts of health and illness were integrated into the health concerns of high-risk families. This study focused on issues of privacy, stigmatization, and discrimination and how these issues were managed within family and institutional networks in two contrasting communities: one in which the disorder was generally recognized as race-associated (sickle cell disease) and the other in which this association was not part of the public consciousness (cystic fibrosis). Interestingly, cases are being identified of individuals of the "wrong" community with these conditions, namely Cacausians with sickle cell disease and African-Americans with cystic fibrosis. A series of scholarly papers and book chapters have resulted.

DOE sponsored a workshop on "Medical Information and the Right to Privacy" in June 1994 in Washington, DC, which led to the book *Genetic Secrets*, edited by Mark Rothstein of the University of Houston (3). A compilation of chapters written by leading experts, the book explores the full range of issues related to genetic privacy, particularly focusing on issues arising from the possible use of genetics in the workplace, a particular focus of the DOE ELSI program.

Privacy Legislation

Focusing on privacy concerns, some proposed legislation has attempted to establish a legal framework of fair practices for health information and to regulate its access, disclosure, and use. A draft bill (the Genetic Privacy Act), was drawn up in 1995 by George Annas of the Boston University School of Public Health to assist legislators. The bill proposed that access to information in genetic data banks should be regulated during sample collection and when it is stored, disclosed, and used. Several state lawmakers used language and concepts from this draft bill in drawing up proposals for legislation in their own states. The Genetic Privacy Act and Commentary is on the Web (http://www.ornl.gov/hgmis). In 1994 a Shriver Center study surveyed existing bills and laws with a view to drafting model legislation for protecting the privacy of personal genetic information. They found that state legislative efforts to regulate the use of such data have increased, particularly in employment and insurance, but major gaps and deficiencies in statutory coverage persist. From 1997 to 1998, Mark Rothstein determined the effects of a unique Minnesota law limiting employee medical records to job-related matters, with a view to using the law as a model for protecting genetic privacy in the workplace. He found that the Minnesota law had little impact because people were not aware of it. A journal article describing this study was published in 1998. At this writing, numerous state measures affecting genetic privacy have been passed, but each is somewhat different from the others, and no federal legislation focused on this issue has been passed by both the House of Representatives and the Senate of the United States.

Data Banks

Interest in forensic DNA data banks is growing, with all states except Massachusetts having laws that authorize the collection of samples from convicted felons. Two separate DOE studies carried out at the Shriver Center in Waltham, Massachusetts, focused on the growing practice of banking individuals' DNA or genetic data in forensic, academic, military, and commercial settings. These studies involved research on privacy in these settings and on developing and refining proposed policies and guidelines. One project, which reported widespread uncertainty about the types of sample releases that are legally or ethically prohibited, led to the production of a 28-minute video called *Banking Our Genes*. [Video: Fanlight Productions (800/937-4113)] Another study carried out a survey of life insurance companies and showed that they were more interested in obtaining existing genetic test information than in performing new tests on applicants. Company ratings based on genetic conditions reflect a considerable degree of subjectivity rather than actuarial data. How this will evolve as HGP nears completion and technologies make the acquisition of personal genetic profiles easier and less expensive is an ongoing ELSI challenge.

Patents

Since 1996 Rebecca Eisenberg at the University of Michigan Law School has explored the role of patents in transferring technology generated by the genome project to society at large. This issue, which was not expected to be a concern at the outset of HGP, exploded suddenly when, in 1991, NIH filed patent applications on ESTs (expressed sequence tags, which are short sequences of DNA from a gene that is known to be expressed in a cell). While this specific application was rejected by the Patent and Trademark Office in 1993 and NIH elected not to appeal the rejection, many other biotechnology companies have aggressively sought patent protection on genetic information. One company, Incyte Pharmaceuticals in California, has been awarded a patent on ESTs. Eisenberg now is conducting a study with Michael Heller on the trend toward privatization and patenting of the early stages of

biomedical and microbial genome research. A series of influential publications has resulted from this work.

CONCLUSION

The continuing importance of ELSI studies is rooted in the basic fact that each person has a unique genome that both identifies her or him as an individual and has predictive implications for her or his future health. An "ideal" or "perfect" genome does not exist, even if such a concept could be defined. All genomes contain many small differences that could severely and adversely affect health under different circumstances or if not influenced or masked by other genes. This information has potential value to other people and groups who may have their own agendas. Thus, while HGP's potential benefits are enormous for medicine, bioremediation, agriculture, and many other socially and economically important areas, we must remain alert to the more problematic implications as well.

HGP is rapidly moving to its goal of obtaining the complete human reference DNA sequence by 2003 and a useful "working draft" by Summer of 2000, well ahead of the original schedule. All of us will therefore face, much sooner than anticipated, many questions surrounding differences in our individual sequences, uncertainties regarding their significance for health and longevity, and the implications of knowing about these subtle distinctions before the biological effects are understood. Although many ELSI issues are not novel to the genome project, they nonetheless remain challenging and need to be addressed. Only by dealing directly and openly with such issues through the collective best efforts of bioethicists, scientists, policy makers, and the public can the benefits of genome research be realized and the difficulties minimized.

The ELSI programs have had significant impacts, both in terms of the research and other activities they have supported, but also in other tangible ways. Within DOE, ELSI has led to the creation of parallel programs, particularly the BASIC (Bioremediation and its Societal Implications and Concerns) program element of the larger Natural and Accelerated Bioremediation Research (NABIR) program. NABIR is focused on exploring biological approaches to the legacies of radionuclide wastes created by the 50-year history of the nuclear weapons programs of DOE and its predecessor agencies. DOE also has an obligation to address the challenges of human subjects experimentation associated with this legacy. Outside of the DOE, ELSI has contributed to the creation of the National Bioethics Advisory Commission (NBAC) attached to the White House Office of Science and Technology Policy. NBAC has a charter to explore both human subjects issues and genetic information issues. The creation of NBAC also takes cognizance of the challenges that will result from the novel technologies arising from HGP, among them genechips and microarrays. These technologies, and others, will make it easier to acquire accurate and precise information about specific genetic variations present (or absent) from large numbers of people and to correlate them with clinical conditions.

Just as genome scientists need to become active participants in the discussion of these difficult issues, so too must the bioethicists, lawyers, social scientists, and other "ELSI scholars" learn the relevant genetic science so that these very important dialogues remain firmly grounded in scientific reality. This is an area where much remains to be done and where dialogue and crosstalk are less in evidence (and sometimes less enthusiastic) than could be wished. There is also a major challenge for the private sector that has aggressively entered genomics to a degree exceeding even the public sector, spurred by the promise of commercial yields from patents on human and other genes. What one company does can influence the way other companies are regarded and the way their products are received. The genomics revolution (it is nothing less) will have major impacts on our lives in the twenty-first century, and we must use all the wisdom and insights of our intellectual and political ancestors to inform us and to build on as we try to make wisely the many difficult and momentous decisions that lie ahead. These decisions will have great impacts on the lives of our children and our society years into the future.

INFORMATION SOURCES

Abstracts for current and past ELSI projects can be found in the DOE Human Genome Program reports and in Contractor-Grantee workshop reports all of which are available on the HGMIS Web site (*http://www.ornl.gov/hgmis*)

ACKNOWLEDGMENT

I want to acknowledge the valuable and helpful suggestions of my colleagues in the DOE Office of Biological and Environmental Research (OBER). I particularly want to acknowledge contributions from Ari Patrinos, Marvin Frazier, Mike Riches, and Betty Mansfield (Oak Ridge National Laboratory).

OUTLINE

INTRODUCTION

The development of biotechnology is in France, as in other European countries, moving ahead strongly. Today the ethical debate, which has urged the reevaluation of new biotechnologies and commercial dynamics of the biotechnology industry, is also proceeding in full swing at the level of the general public, special interest group, government structures, and research facilities.

Although France is considered as being behind in comparison with the United States in industrial development and innovative entrepreneurship support, it is, without a doubt, competitive in life sciences research as well as for legal and ethical rules on biotechnology.

There has always been a high regard for life-sciences research in France, where pioneering advances were made in certain fields; the classic example is Louis Pasteur's contributions in microbiology, and later vaccinology. There were also major contributions by André Lwolff, François Jacob, and Jacques Monod (his achievement recognized internationally by the 1965 Nobel Prize in Medicine) to molecular biology in the discovery of the role of messenger ribonucleic acid (mRNA), and by Pr. Jean Dausset to knowledge in organ and tissue transplantation regarding the major histocompatibility complex (MHC). More recently in the field of virology a French team at the Pasteur Institute in Paris, directed by Pr Luc Montagnier, won acclaim with their discovery of HIV1 which is responsible for AIDS.

ACADEMIC INVOLVEMENT

In the academic sphere the research in biotechnology is directed by sizable institutions for research and

technology. The Centre National de Recherche Scientifique (CNRS), National Center of Scientific Research comprises a large networks of university laboratories in which fundamental research in science and technology, including biotechnology, is carried out. In 1999, 25,400 people were employed in about 1300 CNRS research and service units throughout France and the French territories. The Institut National de la Santé et de la Recherche Médicale (INSERM), National Institute of Health and Medical Research is another such large organization dedicated to the "research, understanding and bettering of the human condition, with the main aim of promoting health for all." Created in 1964, INSERM includes 275 research laboratories and a community of over 10,000 scientific and medical professionals. Of special interest for bioethics INSERM houses a collection of 3000 books and 100 specialized journals on ethics in the Documentation Center on Ethics of Life Sciences and Health (CDEI). There are also the National Institute for Agricultural Research (INRA), the Centre d'Energie Atomique (Center for Atomic Energy) (CEA), and public universities which, like CNRS and INSERM, are under the direction of the Minister of Education, Research, and Technology.

INNOVATION AND ENTERPRISING IN BIOTECHNOLOGY

Before the law on innovation and research was passed on July 12, 1999, it was difficult for scientists working for public institutions to create their own companies to commercialize their innovative technologies. As a matter of fact, those scientists who are government employees cannot easily take part or become a partner in a private firm. The new law will allow French academic research to evolve into commercial enterprises.

Besides, the Ministry for National Education, Research and Technology (MENRT) a national database on biotechnologies, be set up, called "Biotechnologies/France," (1). The MENRT objective, among other things, is to show the wide range of French biotechnological activity and to promote the work abroad, as well as to inform and educate the public.

Biotechnology Companies

Until recently there were only around one hundred biotechnology companies in France. Their number has started to increase with the organization of an association called France Biotech and also the Syndicat National de l'Industrie Pharmaceutique (SNIP), the National Union of the Pharmaceutical Industry. The situation is helped by administrative efforts at the local level in the creation of regional "biopoles," or concentrations of biotechnology-related resources, and in facilitating the founding of biotechnological enterprises.

French biotech industry therefore may be said to be experiencing a full expansion, which is in keeping with a long tradition of quality scientific research. Health-related biotechnology companies in France employed in 1999 around 2000 people with a market of two billion French francs. Industrial and agricultural biotechnology has been strong in France since the 1970s within large pharmaceutical companies. Associated start-up companies could be seen by the 1980s, although without much development in technology transfer. Since 1990 the biotechnology industry in food and agriculture has seen another surge in the development of new companies.

Public Interest Groups

In French biotechnology research, associations and foundations, such the Centre d'Etudes de Polymorphisme Humain (CEPH), or (Center of Studies for Human Polymorphism), play an important role in upholding public interest. Their combined effort with the French government has led to expanded research and technological innovation in networking projects on the human genome (e.g., the first mapping of the human genome and in the robotics field, the newly designed "GenHomme" project) and on plant genomics (e.g., Genoplante, dedicated to transgenesis and genetically modified organisms).

The recent governmental projects aimed at fostering collaborations between various public and private laboratories have led to a concentration of start-up biotechnology companies in the area of genomics, and most of them are located in the Genopole (or "Genomic Valley") in Evry, near Paris.

THE "BIOETHICS LAWS"

History

Turning to the legislation on biotechnology, we find in France a historical consciousness of the ethical debate that has been cultivated and influenced by a strong collective memory of Nazi ideology and the disclosures of the Nuremberg proceedings (1947), by the Universal Declaration of Human Rights, and by the works of the World Medical Association, namely the Declaration of Helsinki. The translation of the human into legal terms in France has thus been difficult and attempted in consideration of issues in bioethics, specifically those that have arisen with the explosion of information coming from discoveries in molecular biology.

To rise to the challenge, France formulated the three Lois de Bioéthique, or "bioethics laws," of July 1994 (2), which specifically address medically assisted procreation, the protection of the embryo, and diagnostic medicine. These laws, which were among the first pieces of legislation adopted on the subject, were proceeded by numerous preparatory studies, beginning with the 1988 report by Guy Braibant, *Sciences de la vie, de l'éthique au droit* (Life sciences, from ethics to law) (3). Also intrinsic to the creation of the bioethics laws is the large work completed by Nöelle Lenoir in 1991, *Aux frontières de la vie* (4).

Une éthique biomédicale à la française (At the frontiers of life: French biomedical ethics) as well as *Les science de la vie et les droits de l'homme: bouleversement sans contrôle ou législation à la française? Questions clefs et réponses contradictoires*, (Life sciences and human rights: tumbling out of control or French legislation? Key questions and contradictory answers) by Senator F. Serusclat (1992) were also influential (5). The work continued in 1994 with a report by M.P.J.F. Mattéi, *La vie en questions:*

pour une éthique biomédicale (Life in questions: toward a biomedical ethic) (6). Punctuating these is a series of advisory reports issued by the Comité Consultatif National d'Ethique pour les sciences de la vie (CCNE, the National Consultative Ethics Committee for life sciences), created in 1983, the first committee of its kind (7). In addition, existing legislation such as the Caillavet law of 1976, which regulated organ donation, and regulations relative to the protection of people participating in biomedical research (1988), thus defining their legal status, were taken into consideration, namely the Law of Huriet Sérusclat, December 20, 1988 (modified July 1994).

Already present in the Code Civil were the principles of the inviolability and nonobjectification of the human body, which have been reaffirmed by the bioethics laws. The idea of the protection of the human body has been expanded as the necessary consideration of a persons' totality, including the genetic identity has become apparent.

It is to the credit of the bioethics laws that introduced into the Code Civil is a chapter on the respect of the human body. In this regard the law ensures the primacy of the person, prohibiting all diminution of their dignity and guaranteeing the respect for the human being from the beginning of his or her life. It is also interesting to note that the Conseil Constitutionnel (which is charged with controlling the conformity of the laws with the French Constitution) asked, with the formation of the bioethics laws, that the laws enunciate the set of principles designed to ensure the constitutional preservation of human dignity.

General Principles

The principles at the origin of the bioethics laws include (8):

- previous consent for all procedures that relate to the integrity of the body;
- the prohibition of all modification of heritable genetic material with eugenic ends and prohibition of all intervention aiming at affecting the descendants of the person concerned;
- noncommercialisation of the human body, therefore prohibiting the selling of organs and tissues;
- anonymity with regard to the donation of organs, elements, or products of the human body;
- the impossibility of contesting the familial relations or descent of a child for reasons related to medically assisted procreation;
- the regulation of the utilization of genetic tests and techniques of medically assisted reproduction;
- the regulation of information related to the donation of organs.

The bioethics laws thus offer very specific regulations on essential procedures that protect human dignity. The laws strive to consider the ethical issues brought up by each relevant technological step. They have arisen from the general apprehension of the ethical implications of biotechnology for the human and living organisms. The largely governmental initiative has materialized via the promulgation of numerous legislative reports and regulations, which leave little room for individual initiative. The ultimate aim of the heavy control of research in general, and biotechnology in particular, is to avoid at all costs, any legal lacunae. Nevertheless, the body of extremely complicated and rich legislation that has resulted is highly technical and, because of continual developments in this technology, eternally incomplete.

Provisions

The first of the bioethics laws is in the Code Civil, law 94-653 of July 29, 1994, which pertains showing to respect for human life. This law covers the study of the genetic characteristics of a person and the identification of a person via genetic fingerprinting, protection of the embryo, and filiation (legal status relations between one person and his or her descendants) in cases of medically assisted procreation.

On the respect for the human body, the law clearly prohibits any contravention from the beginning of life (Article L. 16), although the point at which life begins is not fully defined by French law. The human body is considered as inviolable (Article L. 16-1), and the integrity of the human body may only be challenged in cases where the intervention is therapeutic (Article L. 16-3). Any action challenging the integrity of the human species is prohibited, including all eugenic practices designed to select the sex of the embryo, and any modification of the genetic characteristics, with the exception of research directed at the prevention of genetic diseases (Article L. 16-4). No remuneration may be given to a person who agrees to submit to medical experimentation or to donate parts or products of his or her body (Article L. 16-6). Of interest is Article L. 16-7 which officially renders null and void any contract relevant to procreation or gestation regarding a third party. This is relevant to the donation of gametes and also to the issue of contracting surrogate mothers, which is prohibited. Any information on the identification of an organ donor, and the person who received the organ is strictly confidential (Article L. 16-8). Neither the donor's family nor the recipient may learn the identity of the other, and only in the case of medical necessity may the doctor of the patient receiving the donation have access to such information.

The second law (94-654) of July 29, 1994, relates to the donation and utilization of human fetal tissues, cells, and other parts, medically assisted reproduction and prenatal diagnosis. It is known as the Code de la Santé Publique (Public Health Code). This law also addresses organ donation from persons living and deceased, organ transplantation, the donation, use and conservation of fetal tissues, cells and products, medical assistance to procreation, and specific regulations regarding the donation and utilization of gametes. Notably this law prohibits in vitro fertilization (IVF) for the purpose of research or experimentation and has enacted a ban on all embryo experimentation, with certain exceptions for medical research. In line with the principle of noncommercialization of the human body, the law prohibits the creation and use of embryos for commercial or industrial purposes. In addition no remuneration may

be received for an embryo. The same principle is applied to parts of the fetus, including tissues, cells and organs. Because of the large number of surplus embryos resulting from in IVF procedures, and the therapeutic possibilities associated with breakthroughs in cloning, the mandatory five-year legislative review of this law has been the subject of much public debate.

There is also an information protection law that has been modified by a third bioethic law; law 94-548 of January 1, 1994, on the confidentiality of personal data, amending law 78-17 of January 6, 1978, on information, medical records, and access, and the confidentiality of personal data for research purposes in the field of health.

Medically Assisted Reproduction

The extent to which the laws control certain technical processes, and their features related to the protection of human dignity within the letter of the law, are topics of notable interest. A look at the procedures of medically assisted reproduction can provide a good idea of the legislations' effect.

By the reproduction legislation and the decrees that have followed, France has instituted a highly organized structure to oversee medically assisted reproduction cases. These laws regulate public hospitals and private clinics alike. In particular, the Commission Nationale de Médicine et de Biologie de la Reproduction et du Diagnostic Prénatal (CNMBRDP, National Commission for Biological and Reproductive Medicine and Prenatal Diagnosis) was created by decree in April 1988. The members convene regularly, give advice, and authorize IVF practices in individual cases (which must also be further ratified by the Minister of Health). This committee has been responsible for the elaboration of several decrees on reproductive medicine and prenatal diagnosis. As a result the techniques pertaining to medically assisted reproduction are strictly codified to the point where practically every necessary act is the object of a specific decree.

Medically assisted reproduction procedures are in fact covered by La Sécurité Sociale, the French national health insurance. Thus economically the procedure is available to the general population. The whole process is therefore mitigated by the state via Sécurité Sociale, the organization that actually reimburses the expenses related to these procedures.

Under the law 94-654, medically assisted reproduction is restricted to couples whose infertility is due to a medically diagnosed pathology or who have the aim of avoiding the transmission of a serious disease to their offspring (Article L. 152-2). The couple must consist of a man and woman who are of reproductive age, and are either married or can prove that they have lived together for at least two years. Both members must be alive and consenting. An embryo may only be conceived in vitro for the purposes of medically assisted reproduction, and it must be conceived with the gametes from at least one member of the parental couple. In exceptional cases a couple may decide to donate, via written consent, an embryo to another couple who qualifies for medically assisted reproduction and for whom the technology has not been successful (Articles L. 152-4 and 5). In this case the whole process is mediated by a judge. The donating and receiving couple remain anonymous; only for therapeutic reasons may the doctor have access to non-personal medical data regarding the donating couple and no payment may be received for the embryo (Article L. 152-5).

The excess embryos are kept frozen for a period of five years, and each year a letter is sent to the parent couple regarding the options of using the embryos for reproductive purposes and the continuation of embryo storage. The involvement of a third party as a gamete donor is only permitted in cases where the use of the couple's own gametes has not been successful, and the donation and utilization of gametes is also controlled by law. The donor must be part of a couple who has already procreated, and written consent for the donation is required of the donor and his or her partner (Article L. 673-1). Written consent is also required by both members of the receiving couple. Artificial insemination with fresh sperm or a mixture of sperm samples is prohibited, and the use of gametes coming from one donor is limited to the creation of five embryos (Articles L. 673-3 and 4).

The establishments practicing medically assisted reproduction technology must be authorized by decree. Authorization is accorded by the CNMBRDP and is for five years only. All establishments and laboratories authorized to practice medically assisted reproduction technology or prenatal diagnosis must present an annual written report of their activities to the Minister of Health, and must register the gametes and embryos that they hold in storage (Article L. 184-2).

The Code Pénal imposes a range of fines and prison terms, along with the temporary or permanent revocation of the right of the establishment to practice medically assisted reproduction or related activities. In addition any professional personally involved in a violation is subject to a maximum of 10 years suspension from professional activity. The nature of the sanctions include the taking of gametes from a living person without her consent, which is punishable by five years imprisonment and a fine of 500,000 FF. (Article L. 675-9). The same sanctions apply in obtaining gametes by payment of any kind, except that authorized to prepare and properly conserve the cells (Article L. 675-10).

Divulging information relative to the identity of a person or couple who have donated gametes and the couple who received them is punishable by two years imprisonment and a fine of 200,000FF. (Article L. 675-11). The same penalty is applied for the procurement of gametes from a living person without performing the required sanitary tests for transmissible diseases and proceeding with artificial insemination with fresh or mixed sperm samples.

Revision of "Bioethics Laws"

Taking into account the evolutionary nature of science, the bioethics laws include a legal exception requiring that they be reviewed every five years, thus underscoring the difficulty of reconciling the progress of the life sciences

and respect for the essential values necessary for the preservation of human dignity.

The philosophical principles that form the basis of the laws were formulated with scientific progress in mind, and thus to guide the evolution of the bioethics laws along with the evolution of science. Consequently the bioethics laws were to be reviewed in 1999, and a certain number of modifications are in view to take effect during the year 2000.

Today several basic ethical questions still remain unresolved regarding for instance the legal status of the embryo. The debate in France today is at the level of whether an embryo should or should not, from the first step of development, be considered as a potential human being. While considered, this question was not answered in full with the creation of the bioethics laws, and it has been raised once again with the first five-year revision of the laws, notably concerning the embryo research issue, nowadays forbidden in France. On this issue the French Conseil d'Etat proposes, in a recent report of November 1999, to permit research on frozen embryos no longer intended for a parental project. In performing such the research, the embryo in question cannot be used later for reproductive purposes (9).

On human reproductive cloning, all proposals that have been submitted to the French government, for the revision of the bioethics laws, consider that existing French rules do not suffice to make clear the prohibition in France of such practices. In this context it is clear that new legislation will be taken to forbid human reproductive cloning activities. However, therapeutic cloning could, in certain conditions, be allowed.

COMITE NATIONAL CONSULTATIF D'ETHIQUE POUR LES SCIENCES DE LA VIE ET DE LA SANTE

A highly significant reference body for decisions in bioethics is the National Consultative Ethics Committee for Health and Life Sciences (CCNE) established in 1983 via presidential decree and enacted with the law of July 29, 1994. CCNE is an independent body with the aim of forming opinions and publishing recommendations on ethical issues arising with technological progress in the fields of biology, medicine, and health. The group us comprised of 40 individuals. The president and 5 members of the main philosophies and religious faiths are chosen by the president of the republic, 19 members are engaged due to their qualifications and interest in ethical issues, and 15 are research scientists. Topics may be referred to the CCNE by government officials, a university or establishment for higher education, a public institution, or foundation working in research, technology development or health issues, other persons, or committee members themselves. So far the committee has revisited topics as necessary, in keeping with scientific developments or social issues. CCNE opinions are considered by legislators both in the development and drafting of new laws (10).

Such has been the case with the CCNE Opinion 1 on *the sampling of human embryonic tissue for therapeutic, diagnostic, and scientific purposes*. CCNE has revisited it under various subheadings in several Opinions since 1984. This was shortly after its formation, and CCNE then expressed the Opinion that the human embryo must be considered a potential human person and therefore must never be subjected to in utero experimentation, CCNE further prohibited the commercial or industrial use of living embryos and any remuneration for embryo tissue samples. The same sentiments appeared in Opinion 8 (1986) *on the research and use of in vitro human embryos for scientific and medical purposes*. The emphasis again is on human dignity, with the conclusion that fertilization should not be done for research purposes alone and must exclude any form of industrial or commercial use. These conclusions, among others, are reflected in the bioethics laws of 1994.

Of further interest, the CCNE developed, in Opinion 1, the policy that the use of embryonic tissue for therapeutic purposes must be exceptional and, *considering the present state of scientific knowledge*, justified by certain criteria including the rarity of the disease to be treated, the absence of alternative, equally effective therapies, and a benefit to the recipient, such as survival. An important factor of this policy is the suggestion that the successful development of scientific knowledge may alter the ethical issues at hand. As exemplified by the bioethics laws, this emphasis on the ethical consideration of new technologies has been incorporated directly into legislation.

This policy was applied in a CCNE report in 1997 in which there was re-evaluated the use of embryos in research in light of new technology: the creation of embryonic stem (ES) cell lines from human blastocysts obtained by IVF. Although such research was earlier prohibited under the bioethics laws, with agreement with previous CCNE reports, the CCNE concluded that the therapeutic possibilities of developing this technology actually weighed in favor of a modification of law. This modified opinion is a part of the CCNE's report on the five-year evaluation of the bioethics laws.

CCNE has addressed many other ethical issues and through its Opinions has presented a rich discussion of national position on ethics in technology and health issues. Among the other topics discussed by CCNE are AIDS, drug abuse in the workplace, local ethics committees, human genome research, the utilization of placebos in therapeutic trials involving antidepressants, the care of autistic children in France, and xenotransplantation to name only a few (5).

RESEARCH ETHICS

The Use of human subjects in research is addressed by the law Huriet-Sérusclat of December 20, 1988, modified in July 1994, on the protection of persons participating in biomedical research. The two main objectives of this law are the regulation of biomedical research on humans and the creation of a system of regional Consultative Committees for the Protection of Medical Research Subjects (CCPPRBs). CCPPRBs are charged with reviewing proposals for biomedical research projects as regulated under the law Huriet-Sérusclat. Established by the Minister of Health according to regional needs, CCPPRBs are independent and have legal

standing. Members are chosen by the regional government representative or the head regional committee from various specialities in the biomedical field to ensure the committee's independence with regard to ethical, social, psychological, and legal issues.

Under the law, the institution supporting the research project (whether public or private), called the sponsor, is responsible and held liable for any harm that comes to the subject as a result of the experiment. The investigator, the person directing or supervising the experiment, must be a medical doctor. Two kinds of research projects are distinguished under the law: those with direct therapeutic benefit to the subject and those without. The evaluative criteria for the two classes of research differ in order to better protect the subjects. In the case of research without direct therapeutic benefit to the individual, for example, there must not be any foreseeable serious risk to the participants health, and the research must be aimed at people of the same age group, or with the same disease or handicap as that of the of participant. There must further be no alternative way of performing the studies.

In research proposed to have direct therapeutic benefit to the subject, a limited risk to the subject is permissible. However, any risk must be weighed against the potential benefit.

CCPPRB, in their evaluation of research proposals, applies the ethical principle of protection of human dignity which are specifically codified in the law. CCPPRB may consider, for example, the recruitment methods used for the study and check that the methods respect the confidentiality of the subject. In keeping with noncommercialisation and nonobjectification of the human body, and noncoercion of the subject, there must be no volunteer remuneration, save the cost (or loss) to the subject in participating. The recruitment of certain subjects is restricted by law, such as pregnant women, people without health insurance, children, prisoners, the mentally ill, and people in critical medical conditions. Informed consent is required; volunteers must be informed by a medical doctor of the objective, methodology, and duration of the research and of the possible benefits or risks. Consent must be expressed clearly in writing.

CCPPRB also review the scientific validity of proposals. It adheres to three general principles: that all biomedical research on humans must be founded on the current state of scientific knowledge and sufficient preclinical experimentation, that the foreseeable risk of a project must be proportionate to the benefit to the subject or the research interest, and that biomedical research must be aimed at raising scientific understanding of the human being and the methods for ameliorating its condition. CCPPRB shall consult with local and institutional ethical committees if necessary.

REGULATION OF GENETICALLY MODIFIED ORGANISMS

The development of genetically modified organisms (GMOs) destined for food products and for pest control in agriculture has been a big topic of public debate in France over the past decade. The government's position has shifted concerning the different uses of GMOs and changed several times. This is essentially due to very strong public protest against GMOs. Although administrative regulatory groups (Commission Nationale de classement des recombinaisons génétiques in vitro, later Commission de génie génétique) and specifical rules (decree of July 30, 1985, and AFNOR guidelines), have been in place since 1975 and 1985, respectively, the controversy in France, as in several other European countries, erupted around 1990 with the enactment of the European Council Directives 90/219/EEC on the Contained Use of GMOs and 90/220/EEC on the Deliberate Release into the Environment of GMOs. It should be mentioned that the contained use of GMOs refers to use within the laboratory, and this use has not been a subject of controversy. However, the release and marketing of GMOs affects a larger public which is concerned about the accidental release of such organisms into the environment and other risks associated with their use in food and agriculture.

The two European Directives provide the foundation for regulations regarding GMOs in France; they were transcribed into a single French law 92-654 July 13, 1992, related to the control, utilization, and release of GMOs. This regulation falls under the rubric of environmental protection and modifies a preexisting law 76-663 of July 19, 1976, related to classified installations for environmental protection.

Overall, the European Directives defined two major points. The first was the clear separation within the regulatory framework of the contained use of GMOs and their release into the environment, which includes marketing in the later stages. The second was the establishment of national authorities in all European member states to deal with application procedures as defined under the Directives. In France, although the two Directives have been transcribed into national law under one regulation, two separate national authorities have been established, one dealing with contained use and one dealing with release into the environment and marketing.

Contained Use

The national authority for the contained use of GMOs is the Commission on Genetic Engineering (CGG), which operates under the State Secretary of Research. The purpose of the CGG is to determine measures of confinement suitable to the risks of the use of GMOs, the processes used to obtain them, and the utilization of genetic engineering technologies.

CGG itself is comprised of experts in genetic engineering, public health, and environmental protection plus a member of the parliamentary office for evaluation of scientific and technological options (OPECST). It may also bring in any necessary experts.

Deliberate Release

The deliberate release of GMOs into the environment is mediated by the Commission du génie biomoléculaire (CGB, the Commission on genetically bioengineered organism field releases, or the Commission on Biomolecular Genetics). CGB is responsible for risk assessments related to the release of GMOs into the environment, and advises

the Minister of Agriculture and the Permanent Technical Committee of the Selection of Plants and Cultivars (CTPS). CGB is composed of scientists in genetic engineering, public health, and environmental protection, a member of OPECST, consumer groups, and concerned professionals. It is required to produce an annual report.

The conditions for the release and marketing of genetically modified plants, seeds and seedlings, are given by decree 93-1177 of October 1993 and European Council Directive 94/15/EEC on the data needed for the application. The Directive was transcribed into French law by an Order of September 21, 1994.

The authorization of genetically modified plants must also come from the Minister of Environment and the Minister of Agriculture. Notification of releases are done at the local level, at the town hall. In addition, as with all plants, GMOs must be authorized and recorded as official varieties by CTPS. Marketing authorization comes from CTPS and generally requires two years of agronomic testing which must be accompanied by the opinion of the Superior Counsel of Public Hygiene.

Additional legislation relevant to GMOs includes decree 94-46 of January 6, 1994, which sets the conditions for the deliberate release of cleaning substances or products containing GMOs that may enter human or any animal diet through contaminated tools that come into contact with any drink or food substance. The planned release of pharmaceuticals composed of or containing GMOs is regulated under decree 94-359 of May 5, 1994, related to phytopharmaceuticals control. Finally, decree 95-487 of April 25, 1995, sets the conditions for the deliberate release of genetically modified animals.

Public Debate

In France, even with protective legislation in place, the introduction of GMOs into agriculture has met with much public resistance. The main problem is that there are still too many unknowns with regard to the safety of GMOs to humans, animals, and the environment.

For the French public a series of recent technology-related European biological disasters, namely the scandal of HIV contaminated blood and the "Mad Cow" disease problem, have brought home the importance of risk assessment and the precautionary principle. In addition the central place of the French cuisine in the food culture demands more vigilant regard of the process by which foods are produced and of the differences between industrial and nonindustrial produce. The tendency is to see genetically modified food as an aberration or degradation of the natural product. Besides the alarm about the safety of GMOs and the active movement by the agricultural community against GMOs, a real problem of acceptability based on food aesthetics exists in France.

The Precautionary Principle

Precaution is born of the concern the public, has about the risks that may exist in the uncertainty of scientific knowledge and the possibility of blunders creating grave and irreversible damage. New forms of risk are being considered starting with the environment and the effect on food. The issues focus on how to anticipate the risks and resolve them. Human safety is considered a civil right; this logic is used in decision making to regulate conduct in situations of uncertainty and to guide the regulatory process with prudence.

The precautionary principle is therefore enscribed at the heart of democracy. It must not be taken as a matter of fear but rather as a basic right. Society exercises precaution as it learns from past experiences and uses that information in mitigating future risks. The realm of the precautionary principle is at the interface of science, politics, and law. The principle responds to a priority of our century: safety.

Covering the domain of the environment in French law is law 95-101 of February 2, 1995 (the Law Barnier) on environmental protection. The idea behind it is that in the absence of certainty, scientific knowledge and cutting-edge technology must not defer the adoption of effective and proportionate measures designed to prevent the risk of serious and irreversible damage to the environment at an economically acceptible cost. A report about the precautionary principle from Pr. Philippe Kourilsky and Pr. G. Viney, requested by the Prime Minister, is in progress.

Several structures have been put in place with law 98-535 of July 1, 1998, relative to the reinforcement of sanitary surveillance and the sanitary control of products destined for use by humans. The agencies replace the Agence du Médicament (January 1993) (Medicines Agency) and the Agence Nationale du Médicament Vétérinaire (the National Agency for Veterinary Medicine).

In the surveillance and sanitary control system we find the following groups: the Institut de Veille Sanitaire (the Institute for Sanitary Surveillance), and two new agencies charged with alerting the public when there appear any menace to public health, of any origin. These are the Agence Française de Sécurité Sanitaire des Produits de Santé (AFSSAPS, or French Agency for Sanitary Security of Health Products) and the Agence Française de Sécurité Sanitaire des Aliments (French Agency for Food Sanitary Security). Finally, an institution named the Comité National de la Sécurité Sanitaire (National Committee for Sanitary Security) governs the functioning of these structures.

Unlike the developments leading to the bioethics laws, the regulation of GMOs was not preceded by a large body of government papers and public debate. Rather, the government and public involvement has mostly occurred after the fact, and its effect can be seen in the changes in French policy regarding GM plants over the past decade. In 1995 authorization by the Commission du Génie Biomoléculaire made France the first country to propose the marketing of transgenic corn from Novartis, which received wide European approval in December 1996. The cultivation of Novartis corn in France was authorized in February 1998, and in September of that year the authorization to market Novartis corn cultivated on French soil was revoked by the Conseil d'Etat. In December 1998 the Conseil d'Etat brought the problem of the cultivation of Novartis corn before the European Court of Justice, and in June 1999 the French Minister of the

Environment joined with Ministers of the Environment of several other European member states to declare a moratorium on new authorizations for the marketing of GM plants.

Highlighting the recent public debate on GMOs, and government involvement, is the Conférence de Citoyens (or the Citizens Conference on the Utilization of GMOs in Food and Agriculture), a public discussion event orchestrated by the Parliamentary Office for Evaluation of Scientific and Technological Options (OPECST) in 1998. OPECST'S administrative structure is devoted to technology assessment, with the goal "to inform Parliament of scientific and technological options in order, specifically, to make its decisions clear," as established by Act 83-609 of July 8, 1983. OPECST is an independent organization to which only members of Parliament may refer matters for study. OPECST then "collects information, launches study programmes and carries out assessments." In the Conférence de Citoyens, a representative sample of 15 people was chosen through a survey to participate in a panel of citizens in a public discussion with a panel of experts and government officials with competence in GMOs issues related to food and agriculture. The citizens had two weekends of training prior to the conference, in order to furnish them with an understanding of the principles and issues at hand. The conference was a two-day public media affair, where the panel of citizens posed questions to and entered into discussion with the panel of experts. The conclusions of this panel of citizens is published in annex to the OPECST report on biotechnology in food and agriculture: *From Understanding Genes to Making Use of them*.

Other OPECST reports relevant to biotechnology include topics of biotechnology and the agro-food industry, biodiversity, the life sciences, human rights, and the landmark review of the Lois Bioéthiques, *Application of Law No. 94654 of 29 July 1994 concerning the Donation of Human Body Parts and Products, Medical Assistance with Reproduction, and Prenatal Diagnosis*, by Alain Claeys M.P. and Senator Claude Huriet, 1999 (11).

Despite the strong resistance to the marketing of GMOs, several releases, mostly in the form of field trials, are underway. According to a report published by the European Commission Joint Research Centre, there have been 485 summary notifications for the release of GMOs in France between October 21, 1991, and October 1, 1995. Since each notification covers either the release of one GMO at several sites or an ensemble of GMOs at one site, this number does not represent the total number of test sites in France since 1991, which is much larger. The tests have included 188 strains of transgenic corn, 106 strains of oilseed rape, and 61 strains of sugar beet, among several other species of plants, and they have been conducted by a number of international companies and included French companies and French public research institutions. So, while negative public opinion has had a large influence on the marketing and cultivation of GM plants in France, the number of summary notifications for the environmental release of GMOs in France for research purposes is actually the highest in Europe.

SUMMARY

As a summary we present a list of the principal official French regulatory and consultative groups in the field of biotechnology:

- Commission Nationale de Informatique et des Libertés (CNIL) (law of January 6, 1978)—National Data Protection Commission
- Comité Consultatif de Protection des Personnes dans la Recherche Biomédicale (CCPPRB) (law of December 20, 1988)—Consultative Committee for the Protection of People in Biomedical Research
- Commission de Génie Génétique (CGG) (decree of May 11, 1989)—Commission on Genetic Engineering.
- Commission d'étude de la dissémination des produits issus du génie biomoléculaire (decree of February 23, 1993)—Commission on genetically bioengineered organism field releases, or the Commission on Biomolecular Genetics
- Comité Consultatif National sur le traitement de l'information en matière de recherche dans le domaine de la santé (law of July 1, 1994, and decree of May 9, 1995) Consultative Committee on the treatment of data in research in the health sciences.
- Comité Consultatif National d'Ethique pour les sciences de la vie de la santé (CCNE) (decree of February 23, 1993)—National Consultative Ethics Committee for Health and Life Sciences.

CONCLUSION

To conclude this overview on Biotechnologies and Bioethics in France, we note that France has had 15 years of reflection concerning the ethical and legal issues generated by new technologies in the life sciences. By instituting the bioethics laws of 1994, the government took a step that brought the message to the Minister of Social Affairs, Simone Weil at the time, that the law established "the primacy of ethics over technique." The French politic has thus had the objective of prohibiting eugenic or commercial derivations and sharing with society the choices that the scientific world cannot assume alone. Must ethics be legislated? This is the route that France has chosen; it has preferred a strict legal framework to less constraining guidelines. However, France has inaugurated an unusual statute with this legislation, the provision of a five-year review; a wise decision that will hopefully help avoid conflicts between the progression of scientific research and the general ethic of our society, which is concerned with prevention of eugenics and the appropriation of human by human.

OUTLINE

INTRODUCTION

In Germany biotechnology is expected to be a prominent future industry ranking as high in perceived economic importance as today's information and communication technologies. However, public opinion is sharply divided between advocates of strong public sector involvement in this emergent field of cutting-edge industrial and scientific research and those who fear, for various reasons, that biotechnological "progress" means above all else overrated promises, technoeconomic determinism, and more "colonialization of the lifeworld" (Jürgen Habermas) at ever deeper levels of somatic existence. The resistance against biotechnology has for a long time been focusing on possible risks unique to genetic engineering. Since no strong evidence for this supposition has come forth, lately the "risk debate" has lost much of its momentum. The arguments that appeal to economic shareholders, and to patients and other stakeholders of medical and pharmaceutical progress, are winning as far as the public is concerned. Recent innovations in Germany's legal culture, partly owing to legislation on the level of the European Union (EU) of which Germany is a member state, support the trends on the scope, ease, and speed of patenting. In this sense, one could say that biotechnology in Germany is well on its way of becoming "normal" business.

GOVERNMENTAL SUPPORT OF BIOTECHNOLOGY

In Germany, in the recent past, advancement of biotechnology was a topic of strong political controversy. Many studies were made of public opinion in the 1980s and 1990s and showed that the public perception of biotechnology, specifically the perception of cutting edge genetic technology, tended to be more negatively biased in Germany than in other countries within the EU. At the same time, spokespersons from the economic sector and ministerial representatives of the federal government designated biotechnology as one of the "key technologies," as a field of promising research activity and economic interest for the future of Germany's economy. The federal government's perspective on biotechnology is richly documented in a 1985 official declaration by the Ministry for Research (1). (For a sceptical appraisal of this perspective from a sociological vantage point, see Ref. 2, for an optimistic one from the vantage point of a large life sciences enterprize, see Ref. 3.)

The tension that shaped the state administration's political discourse on biotechnology during the 16 years in which the Christian Democratic Party (CDU) was the ruling majority party in Germany did not ease after the Social Democrats (SPD) 1997 return to power. It also shaped the discourse on biotechnology of nongovernmental organizations that either promoted the advancement and acceptance of biotechnology or a control of developments in biotechnology which they perceived as politically dangerous or ethically unsound.

Political Economy of Biotechnology in Germany

Because of the long product development times in biotechnology, experts claim that the technical application

of knowledge produced by the biological sciences will not become a palpable reality until sometime after the year 2000. Forecasting studies of the commercial use of biotechnology have estimated that in Germany it will reach around $2 billion by the year 2000 (compared to $1.25 billion in 1995), with a growth rate of up to 25 percent a year depending on specific products. For the state governments, such estimates serve mainly (*1*) to justify support measures for research and development in biotechnological sectors and (*2*) to provide hope against the prevalent impression that economic globalization will mean a growth of joblessness for Germany's economic system. Current estimates are that the biotechnological employment potential in Germany will be at well over 100,000 jobs in 2000. Commercial biotechnology alone is expected to account for up to 40,000 jobs (as compared to 19,000 in 1992), with up to 50,000 additional jobs in the supplier and services sector and another 20,000 jobs in universities or related to academic research. In 1999 roughly 500 firms with substantial or basic biotechnological profiles were counted in Germany (4).

The Federal Ministry for Education, Science, Research, and Technology (Bundesministerium für Bildung, Wissenschaft, Forschung, und Technologie, BMBF), has long supported the biotechnology industry in Germany. BMBF has consistently worked at improving the framework for biotechnological research and development in Germany by giving suitable incentives to industry and start-up companies, and by maintaining the quality of research institutes through state aid in appropriate core areas. In biotechnology the government has effectively assumed the role of a supervisor aiming systematically at creating productive economic alliances, among scientists and promoting a favorable political environment for such alliances. This policy was the focus of an important report (5) on future technology that was sponsored by BMBF and produced by the Karlsruhe-based Fraunhofer-Institut für Systemtechnik, a leading German institute for systems analysis.

One such remarkable initiative is the BioRegio competition (*BioRegio-Wettbewerb*) launched in 1995. This competition enables the best among the biotechnology-regions in Germany to come up with economic strategies to reach new goals. Incentives are given that focus on existing financing, funding, and investment potentials. Out of all proposals a jury selects the three regions with the most convincing biotechnology concepts. In the second phase these three regions receive priority in the appropriation of funds from the Biotechnology 2000 program of BMBF. Currently, the annual funds earmarked for the project are around $110 million. The BioRegio contest has become a way of establishing priorities that helps allocate BMBF funds for biotechnology. The total funding was about for the first phase starting in 1996 $0.6 billion, and this amounts to a clear signal of the priority given the development and implementation of new technologies in the biosciences and molecular medicine. The financial resources of BMBF are envisaged to support basic research, nonuniversity research institutions, and special federal government projects. In the first round, 17 German regions competed. In late 1996 a commendation was given to the Rhine-Neckar Triangel, Munich, and the Rhineland, and the Bioregion of Jena received a special commendation from the jury for its BioInstruments initiative. The BioRegio competition has fueled the regions' desire to be able to boast as many company start-ups as possible. It has cleverly used the traditional federal nature of Germany and the independence of the regions to initiate an upswing in biotechnology in many locations simultaneously. Moreover the project grants provided by the BMBF's BioFuture program (with an allotted $8 million for the year 2000) are, in principle, available to all applicants regardless of region.

Another development of the government's BioRegio contest was the creation in 1996 of a "virtual enterprise" located geographically in the triangle of the university cities of Braunschweig, Göttingen, and Hanover. This has become the largest self-contained research region for natural and engineering sciences in Germany. This virtual enterprise, called BioRegioN, is designed as a network of dense communication and extensive cooperation among more than one hundred scientific institutes, industry-related facilities, and administrative offices (5). A special consulting Web site for handling issues of financing and siting is available to entrepreneurs who want to start up new biotech firms. Support is available on legal matters concerning the use of genetially modified plants and permits for genetic engineering work as well as for marketing and project organization. Moreover BioRegioN offers research institutes and companies in the region the opportunity to make presentations at German and international trade fairs.

A 1995 study by the federal Minister for Education, Science, Research, and Technology revealed that almost half of the surveyed small and medium-sized companies saw a lack of equity as an essential impediment to innovation. Germany seems to have much ground to cover in catching up in the use of venture capital. In 1995 only 6 of the more than 100 capital investment companies were fully venture capital companies specializing in nascent technological businesses. Partly, this poor showing is due to the absence of large institutional investors, for example, pension funds, in Germany. Recently this problem has been debated as due to Germany's underdeveloped shareholders' culture. However, in 2000 it is becoming easier for biotechnological start-up firms to attract venture capital because a number of banks have set up special services in response to this conspicuous problem.

In the legal realm the federal government has been urging a more flexible legal framework for biotechnology in Germany. In accordance with European directives, the federal government has moved in favor of standardizing the safety and application regulations that open up scope for more efficient methods, with more flexible structure and organization while maintaining risk protection. Germany also pioneered in the implementation and commercialization of biotechnological research and development by an initiative in 1996 that facilitates patenting procedures for research findings. The federal government has further regulatory responsibility for the German contribution to the Human Genome Project.

Since the late 1980s expenditure on research and development (R&D) has declined in Germany in relation to

the gross domestic product (GDP). Between 1988 and 1994 R&D expenditure decreased from 2.88 to 2.33 percent. As a results there were considerable declines in research. In expenditure on R&D in the industrial sector declined even more, and public funds have not been able to compensate for the loss of funds. There has been much cause for political concern, particularly in view of the fact that Germany's industries depend heavily on R&D. Moreover, funding for R&D in the biotechnology sector has remained comparatively low in Germany in relation to corresponding activities in other European countries. As a result there is much concern about the efficiency and selectivity in the government's discourse on biotechnology. Funds and human capital need to be managed specifically in prominent future-oriented and pioneering aspects of R&D. The same applies to state aid. Correspondingly the bioindustrial sector has articulated concerns on how to improve the conditions for commercializing results of "pure" biological research in Germany.

Furthermore there are continual concerns about identifying the appropriate policies in order to correct institutional and financial inflexibility currently prevailing in research establishments. Increasingly academe, especially biology and chemistry departments, has had to confront criticism, voiced in the economic sector as well as by curricular commissions and higher education authorities, as to obsolete training and career structures, outdated conceptions of autonomous research ("freedom of science"), and lack of openness for teaching inter- and transdisciplinary skills and methods. An often-cited fact is that German universities have a share of less than 1 percent in biotechnological patent applications compared to about 15 percent in the United States.

To sum up, the record of the federal government's efforts reflects a fairly robust political majority consensus on creating an innovation-friendly framework for biotechnology. This policy encounters opposition for ideological reasons mainly from the "fundamentalist" wing within the Green politial party (DIE GRÜNEN). Apart from the somewhat special case of the Green party, what opposition there is to public policies in support of "biotechnological progress" is scattered across the other three major political parties and seems to be independent of party-line orientations. Owing to the majority political consensus, the government's budgetary preferences for R&D in the biosciences and biotechnology, despite falling overall rates for R&D funding, has not encountered serious political roadblocks.

Technology Assessment and Public Participation

In German law, administrative procedures for high-risk technologies generally involve an element of public participation. The 1990 Genetic Engineering Act, for example, made a public hearing (*Erörterungstermin*) a legal prerequisite for every license application to release genetically modified plants. The former public knowledge condition stipulated that the public notification of the project involve display of the submitted documents and provide for public opportunity to lodge objections and a public hearing. Anyone could make written objections, and these were then discussed at the hearing. In 1993 there were three hearings on applications for the release of genetically modified potatoes, sugar-beets, rape, and maize. The hearings each received between a few hundred and 20,000 written objections. The procedure, it turned out, frustrated both sides. For this reason, the provision of direct public participation was removed and substited by a much less demanding requirement for a written submission with the first amendment to the Genetic Engineering Act in 1994 (6).

Among the German people there is the feeling that industry and politics, and to some extent even the biological sciences, lack credibility, transparency, and democratic accountability in biotechnical matters. Neither concerted effort for citizen debate by the government nor various public relations campaigns by the biotech-industry have so far been able to dispell this attitude. Sociologists are apt to explain this as indeterminate suspicion caused by a knowledge gap. Nevertheless, no number of publications in every media form has translated into a corresponding degree of knowledge among the population. This knowledge gap itself requires more clarification. Political scientists concerned with technology assessment point to the fact that with certain exceptions, such as the citizens' forums in Baden-Württemberg (8) managed by one of Germany's leading institutes for technology asessment (Akademie für Technikfolgenabschätzung, Stuttgart), there has been too little open public discussion of the opportunities and risks of biotechnology. Pounding out information packages is one thing. Promoting attitudinal change through free and open public dialogue is quite a different thing. Government and industry have been strong on the former but weak on the latter communication policies.

Observations on cases where the general public was invited to take part in decision-related discussions (e.g., about sites for genetic engineering plants) indicate a number of recurring deficits and problems: (*1*) Those in positions of responsibility often fail to answer the questions that really concern critics and the public at large. This might be so because such questions tend to be of a fundamental nature. Frequently they concern consequences of technology on a broad cultural and societal scale. (*2*) Sometimes exaggerated expectations are aroused regarding the technical and economic potential of genetic engineering. The much-hyped gene therapies for cancer are a case in point regarding "red" (i.e., medically related) biotechnology. Other prominent examples are furnished by unrealistic pronouncements about expected positive impacts of biotechnology on employment and economic growth figures. (*3*) The depiction of biotechnology in the mass media is disturbingly polarized. Industry-financed advertising campaigns are apt to present progressive biotechnology as a safe panacea, whereas professional journalists writing in the mass media tend to capitalize on hypothetical risks of biotechnology (9,10). Consequently any balanced reporting that is both interesting and beyond obvious partisan interests is structurally disadvantaged and blotted out.

Between 1991 and 1993 a technology assessment (TA) of crop plants with genetically engineered herbicide resistance in agriculture was organized by the Wissenschaftszentrum Berlin, Germany's leading sociological research

center (11). Herbicide resistance was chosen as the subject for TA because it seemed to be sufficiently relevant and controversial. It could be expected that a broad spectrum of developmental problems of modern biotechnology would be considered in the process, such as (*1*) the possible risks of transgenic plants, (*2*) the toxicological and ecological effects of the use of nonselective herbicides, (*3*) the future of genetic resources, (*4*) the advantages and disadvantages for farming, (*5*) the long-term safeguarding of world food supplies, and (*6*) the ethics of plant manipulation.

This pioneering TA project was not merely a forum of experts for evaluating the state of knowledge on the possible consequences of a technology; rather, it provided an arena in which the social conflicts related to the introduction of a new technology could be articulated and discussed in an exemplary manner. The procedural scheme was somewhat conventional in taking an emerging technology-induced development as its starting point for an analysis of possible desirable and undesirable consequences. The goal of technology-induced TA is to determine the political actions that might be necessary in order to cope with that technology. Critics of the Berlin herbicide resistance TA project called instead for a "problem-induced" approach. The starting point would shift to the social problem the technology purports to help solve (e.g., the agricultural problem of weed control). In problem-induced TA, various ways of tackling the problem would be compared (e.g., solutions by intensive industrial farming in comparison to solutions provided by ecological farming). Any comparisons would take questions of larger social context and fundamental political issues into account. The decisive question for transgenic herbicide resistance technology when considered from a "problem-induced" TA-perspective would have been whether the technology was needed and what kind of farming was socially desirable and ecologically acceptable. Problem-induced TA was found to be more demanding in terms of time, money, and other resources than the technology-induced approach. In retrospect, the Berlin project aimed at a broad and demanding interpretation of TA with resources appropriate only for dealing with narrow TA.

Participants from research institutions, industry, environmental groups and other NGOs, and governmental agencies (totaling 48 groups) reflected the interests and positions of the ongoing political concerns over biotechnology. Among them were outspoken advocates and critics. The debates that normally take place outside the TA procedure and only heat up as soon as results of "closed" TA are made public, were internalized in the procedure. TA became a social dialogue between representatives of opposing positions. After a series of meeting, the participants had to define a study framework, evaluate the results of expert reports, and discuss any conclusions. The idea was that a dialogical framework would promote a rational form of discussion. Whether this expectation was fulfilled remains an open question. As a matter of fact, shortly before the final meeting was to take place, the environmental associations announced their withdrawal.

The Berlin TA project reenergized the scientific and public debate in Germany on the proper form, scope, and aim of assessment of biotechnology and other new technologies. There is now emerging a consensus that a narrow TA is necessary but not sufficient for the democratic governance of technological development to florish. The narrow TA is essentially an investigatory strategy aiming at the production of information where the validity of such information is conditioned by truth-claims and not by the factual acceptance by a majority of participants. The narrow TA is not to be conflated with purely political dialogues or consensus conferences where discussion focuses on goals and criteria of desirable development for society. The narrow TA contributes factual information about potential risks and expected advantages. Citizens have a right to identify the state of knowledge on politically controversial subjects. The TA procedures can at least advance answers as to whether publicly declared risks actually exist, whether claimed advantages exist, and so forth. Criticism of the methods, scientific and otherwise, through which the procedure arrives at its conclusions must also be submitted to the scrutiny of the public. Consequently technology-induced assessments, though narrow, must not be so narrow to involve only scientific experts. All stakeholders are to be considered in any political conflict over a new technology for a rational assessement of factual and other validity-claiming and procedural fairness.

LEGAL ASPECTS: SALIENT STRUCTURES IN THE REGULATION OF BIOTECHNOLOGY

Germany's Genetic Engineering Act (Gentechnikgesetz, GenTG) adopted in 1990 seeks to regulate the approval and registration procedures for genetic engineering facilities and for genetic engineering work geared to research and commercial purposes on microorganisms (viruses, bacteria, fungi, parasites) and macroorganisms (plants and animals). The GenTG does not cover reproductive medicine nor the use of somatic gene therapy.

The GenTG, in its amended 1993 version (12), is intended to safeguard the life and health of humans, animals, and plants; to protect the environment as an integrated system; to shield property from possible risks of genetic engineering methods and products; to prevent any such risks from emerging, and to create a legal framework for research, development, promotion and use of the scientific, technical and commercial possibilities of genetic engineering.

The GenTG legally defines a consensus-building processes within a network of agencies that share decisional power, political responsibility, and scientific competence concerning the issues that arise within the scope of the GenTG's regulatory framework. The network defined by the GenTG comprises four principal actors on the national level: (*1*) the Biological Federal Institute for Agriculture and Forestry (Biologische Bundesanstalt für Land- und Forstwirtschaft) that is situated within the Federal Minstry of Food, Agriculture and Forestry, (*2*) the Federal Environmental Protection Agency (Umweltbundesamt), in cases of animal applications, (*3*) the Federal Research Center for Virus Diseases in Animals (Bundesforschungsanstalt für Viruserkrankungen der Tiere).

In accordance with relevant European Community Directives, Germany's GenTG determines that a scientific body, namely (*4*) the Robert Koch–Institute (RKI) in Berlin, integrate the relevant consensus-building processes into resulting decisions. The RKI's Department of Genetics and Genetic Engineering serves as the institutional base of special advisory committee set up by the RKI, the Central Advisory Committe for Biological Safety (Zentrale Kommission für Biologische Sicherheit). This committee comprises a broad range of scientific and socially relevant points of view. Its 30 expert members come from micro- and cell biology, genetics, hygiene, virology, ecology, the trade unions, occupational safety, economics, research-promoting organizations and environmental protection organizations.

European Community Law and German Law

On the national level of law, the German GenTG implements directives of European law. Mainly three directives of the European Council are relevant: (*1*) Directive 90/219/EEC (13) stipulates joint measures to be implemented for the application of genetically engineered microorganisms in contained situations in order to safeguard human health and the environment. (*2*) Directive 90/220/EEC (14) on the intentional environmental release of genetically modified organisms (GMOs) serves both to promote the formation of the single European market for methods and products of genetic engineering and to constrain this process by the observance of suitable environmental and health protective considerations. (*3*) Directive 90/679/EEC (15) contains minimum requirements for the protection of employees in countries of the European Community against exposure to safety and health hazards caused by biological substances.

Unlike Germany's GenTG, the European Community directives include no special liability provisions. Approvals based on the directives focus on the genetic engineering product and not on the genetic engineering facilities, whereas the German GenTG prescribes extreme hazard liability for the operator of the facility concerned. In the European Community directives, hearings are only an optional feature. In the German GenTG, public hearings remain a legal requirement in approval procedures for operating sites, notwithstanding that the 1993 amendment of the GenTG narrows this requirement to commercial projects classified as "risky" or "very risky." (There are four legally recognized safety levels ranging from 0, no risk, to 4, very risky.) Despite these comparatively more demanding national requirements, the GenTG in its 1993 amendment fully exploits the scope for simplification and acceleration of approval procedures contained in the directives on the legal level of the European Union (EU).

In specific, the legal framework that regulates genetic engineering in Germany contains the following legal ordinances:

1. Genetic Engineering Safety Ordinance (*Gentechnik-Sicherheitsgesetz*) (16). This Ordinance is the most important legal ordinance. It consists of safety requirements for genetic engineering work, risk assessment of organisms, and safety measures in laboratory and production facilities, greenhouses, and animal facilities. Also covered are occupational safety, and sewage and water treatment, requirements that have to be met by project managers and biological safety engineers.
2. The amended Genetic Engineering Hearings Ordinance (*Gentechnik-Anhörungsverordnung*) (17). This Ordinance restricts public hearings to approval procedures for safety levels 3 and 4 of commercial projects. It regulates the formalities of hearings. It allows simplifications and modifications that favor the operator while still serving the purpose of protection.
3. Amended Genetic Engineering Records Ordinance (*Gentechnik-Aufzeichnungsgesetz*) (18). This amendment specifies the content, structures and time period for genetic engineering records. The amended Ordinance for the first time included environmental release in the range of requirements. The amendment introduced simplifications for safety level 1 projects. The safekeeping periods prescribed for records amount to 10 years for safety level 1 and 30 years for levels 2 to 4 and for environmental release. Laboratory logbooks are not an admissible substitute for proper records.
4. Amended Ordinance on Genetic Engineering Procedure (*Gentechnik-Verfahrensverordnung*) (19). This amendment regulates the formal documentation requirements to be met by facility operators in the registration and approval procedures for genetic engineering facilities, genetic engineering work, and environmental release and introduction of GMOs. The amendment has again enabled simplifications, clarifications, and accelerations. A distinction is made between genetically engineered "minor" and "major" plants.
5. Amended Ordinance on the Central Commision for Biological Safety (*Verordnung über die Zentrale Kommission für die biologische Sicherheit*, ZKBS) (20). This amendment describes the tasks, capabilities, and internal structure of the ZKBS.
6. Federal Cost Ordinance to the Genetic Engineering Act (*Bundeskostenverordnung zum Gentechnikgesetz*) of 1991. This Ordinance stipulates the fees and charges for offical acts performed by the Robert Koch–Institute as a senior federal authority. Fees for granting approval for environmental release range from $3,000 to $80,000, and fees for obtaining approval of introduction into circulation from $4,000 up to $170,000 for extremely expensive procedures.
7. Genetic Engineering Participation Ordinance (*Gentechnik-Beteiligungsverordnung*) (21). This Ordinance regulates participation of the European Council, the European Commission, and the authorities of the member states of the EU and those of the European Economic Area in the approval procedures for environmental release and introduction as well as in procedures for any supplementary measures based on the German Genetic Engineering Act. It is the

legal basis of the Robert Koch–Institute's obligation to observe set time limits in transferring received applications (for environmental release or introduction) to the European Commission. It also details the institute's right to information if such applications are submitted in other EU member states.

Intellectual Property Rights and Patenting

Industrial property rights are protected in Germany by the 1980 Patent Act (*Patentgesetz*, PatG) (22,23), by the 1973 Agreement on Granting European Patents (24) and the Species Protection Act (*Sortenschutzgesetz*) (25). PatG provides comprehensive regulation of all aspects regarding the patented item, such as patenting preconditions, effects of the patent, patent-granting procedures, revocation proceedings, patent infringements and their consequences. PatG is a major economic and political instrument for promoting innovation. The granting of exclusive rights over a limited time for the exploitation of inventions provides incentives. Inventors are rewarded, early revelation and dissemination of technical findings and know-how are safeguarded.

The German PatG, in keeping with European agreements, excludes from patenting any method invented exclusively for surgically or otherwise treating or diagnosing maladies of the human or animal body. Gene therapies, according to this criterion, are not eligible for patenting, whereas biopharmaceutical products produced by gene therapies are eligible. Ruled out from patentability are discoveries that are not inventions. By this criterion, nucleic acids, and more or less complete indications of sequences of nucleic acids, do not qualify for patent protection if the availability of the substance is merely based on a discovery. Likewise the PatG excludes "essentially biological" methods for breeding plants or animals, or creating new plant or animal species. Microbiological methods and their products, however, are eligible for patenting. Until recently this implied that there was no patent protection at all for generic creations like transgenic plants and animals. In comparison to the United States and Japan, this put the German bioindustry at serious disadvantage with regard to plant and animal biotechnological creations.

Things have changed somewhat with a recent amendment to PatG. The new rules of the General Agreement on Tariffs and Trade (GATT) took effect in Germany in 1995. All member countries must now modify their national intellectual property right laws so that they match with the new agreement on trade-related intellectual property rights (TRIPs). Since the issue of TRIPs and their discretionary leeways continue to be notoriously controversial, the GATT negotiations stipulated a review period in 1999 for the enforcement of the agreement on TRIPs. In September 1999 the GATT–TRIPs agreement was accepted by the European Patenting Organization in the format of the European Biopatents Directive, which in turn was enacted by the European Patent Office in Munich. Whereas former article 53b of the European Patent Agreement clearly ruled out the patenting of plant varieties and animal species, the recent Biopatents Directive allows for a much more patent-friendly legal interpretation on these crucial points. However, the acceptance of the Biopatents Directive in Germany and the EU generally is so far only provisional, pending a ruling by the Supreme Chamber of the European Patent Office on a number of complaints about would-be patented genetically modified plants and, moreover, pending the European Supreme Court's decision on complaints against "the patenting of life" that have been filed by Italy and the Netherlands.

In the issue of deregulating European (and hence also German) patenting restrictions the parliamentary assembly of the European Council (*Europarat*) in Strassbourg is pitted against the bureaucracy of the European Commission (*Europäische Kommission*) in Brussels. In September 1999 the former organization, representing 42 European states, has recommended that patenting of genes, cells, tissue, and organs be prohibited altogether, whether they be of human beings, animals, or plants (the key argument is that these entities are discoverable but not inventable). Interestingly the former organization is perceived in the political public sphere as having far more democratic standing than the latter. This makes it easier for biotechnology critics to capitalize on the issue of patenting by interpreting it as an antagonism between a democratically incorporated humanistic ethos and the organized commercial interests of business corporations and their lobbies.

Consumer Sovereignty and "Novel Food"

Big agro- and food companies began promoting in the second half of the 1990s the prospect that within a few years a new generation of genetically modified novel food products would attract consumers through the appeal of both superior quality (longer lasting and tastier fruits and vegetables) and lower prices as compared to natural food. Commercially, this confident vision continues to prevail.

Public outrage at biotechnologically produced or modified "novel" food is reflected in German food legislation. This legislation took the form of the Food and Consumer Act (*Lebensmittel- und Bedarfsgegenständeverordnung*), numerous follow-up ordinances, and regulations pertaining to specific products (e.g., milk legislation), plus directly applicable EU law. The aim of this legal framework is to safeguard human health and to protect the population against fraud and deception. All provisions apply equally to standard products and products manufactured by genetic engineering methods. Specific differences, however, remain. The GenTG, with its special regulations on introducing products into circulation, refers to food products or food ingredients that contain or consist of GMOs. However, these regulations do not apply to food products or food ingredients that are manufactured from GMOs without containing any such organism. These foods remain subject to the "general food law."

Thus regulatory uncertainty exists about the proper implementation of the EU novel food regulation (NFR). As far as genetic engineering is concerned, NFR refers to (*1*) introducing novel food products and novel food ingredients into circulation within the EU; (*2*) food products and ingredients that are "novel" in the sense that they were previously not widely used for human consumption in member states; (*3*) products and ingredients that contain

or consist of GMOs, or (*4*) products and ingredients that were manufactured from but do not contain GMOs.

Exempt from the regulation are food additives, flavorings and extraction solvents. They are subject to other special EU regulations. This exemption has recently become the focus of much public concern. In one interpretation at least, it creates a gap in the generally desirable principal goal of NFR, namely to ensure that novel food products and food ingredients do not pose a hazard for the consumer. According to NFR, approval decisions for novel food check for environmental compatability in order to prevent any harmful effects of GMOs on the nonhuman environment. In addition the Scientific Food Committee of the EU must give an opinion on all aspects of food that relate to public health.

One considered hazard is that novel food differs so greatly from comparable products and ingredients it intends to replace that normal consumption patterns would result in nutritional deficiency in people. However, the hazardous nutritional deficiency argument, though frequently marshaled by ecological consumer organizations and other critics of "Frankenfood," fails concerning mere additives, flavorings, and the like. Another critical argument — call it the consumer sovereignty argument — has better logic. It has also drawn more public support. It is a second explicit goal of NFR to ensure that nutritional improvements (biotechnological or otherwise) do not lead to consumer confusion. This goal is subverted, according to the consumer sovereignty argument, if consumers who (for whatever reasons) repudiate novel food completely lack the necessary information for making fully informed choices in following their convictions.

The appeal of the consumer sovereignty argument becomes lost if companies begin to discharge their requirement for full consumer information in a way that turns labels for food products into something like the patient information leaflets that accompany prescription drugs. Legally, how much leeway biotech-food companies have for their labelling policy is defined by conditions that are already quite demanding: (*1*) Food products containing or consisting of GMOs must be labelled under all circumstances. (*2*) They must also be labelled if the use of genetic engineering methods means that they are no longer equivalent to an existing food product or ingredient. "Not equivalent" means that a scientific assessment based on appropriate analysis of existing data indicates that the tested features differ from conventional food products or ingredients. Accepted limited values for natural fluctuations in these features are to be taken into account. If a product or ingredient is no longer seen as equivalent, the label must indicate the changed features or characteristics along with the method used to bring about this change (so-called method labeling). (*3*) The label must also indicate substances that are not present in existing equivalent food products and that could affect people with certain health problems like allergies or that could foreseeably violate ethical or religious dietary restrictions.

The preamble of NFR states that a label may declare that a food or ingredient is not a novel product in the sense of the regulation. A label "free of genetic engineering" or "without genetic engineering" is allowed, pending proper definition. Germany submitted a proposal to the EU in 1998 for defining this label, and still is awaiting approval. The proposal aims to require that labels state whether raw materials from transgenic plants, enzymes, or additives for flavoring, and the like, were derived from GMOs or used in food production. This would include animal feed and feed additives derived from transgenic organisms, even if the end product (e.g., milk from cows fed on transgenic soy) is chemically indistinguishable from the product of animals fed conventionally. What is decisive is that the labelled products must be garanteed not to have been in contact with genetic engineering. To give an example, though genetically modified barley, transgenic hops, or genetically modified yeast are not commercially available in Germany, most beers cannot be labelled "without genetic engineering" because conventional yeasts are fed GMOs during their fermentative reproduction.

ETHICAL ASPECTS: CATEGORIES, ASSESSMENTS, AND CONTROVERSIES

Genetic engineering and the underlying molecular biological research is viewed, in Germany as elsewhere, as cutting-edge biotechnology. In the public's mind genetic biotechnology comes in three colors: It is red if its application is mainly medically related (in the diagnosis and treatment of diseases), green if mainly related to agriculture and food, and gray if used for purposes of environmental conservation and the protection of natural resources, ranging from pollutant disposal to environment-friendly bio-mining processes.

If a 1995 survey of public opinion is any indication, the percentages of positive (+), neutral, and negative (−) attitudes toward certain applications of biotechnology are nearly the converse of each other in terms of the red and green ends of the spectrum of applications. The most positive results were for the diagnosis of incurable diseases, 75+ and 7− out of 100; negative attitudes increased for treatment of cell diseases, production of vaccines, use of modified bacteria to reduce oil pollution in the soil, modification of crop resistance against insects or plant diseases, breeding laboratory animals for pharmaceutical research. The most negative result was for the modification of the taste, keeping quality or appearance of food, 8+ and 76− (26,27). The basis for these attitudes is probably a mix of conceptions. Clearly, the big differences in the attitudes are to some extent due to the fact that the different practices to which biotechnology is applied are loaded with different ethical background beliefs. Biotechnology and genetic engineering in particular continues to be perceived in public opinion as something special resisting easy assimilation to "normal" new technologies (e.g., energy, information, and communication technologies). The new biotechnology is mysterious and evokes a pandora's box. The negative attitude persists despite an increasing evidence that genetic engineering biotechnology keeps dispelling all initially raised claims of associated high and unusual risks compared to other large-scale new technologies. Public risk perception, even if well informed, and moral public opinion are surprisingly independent of each other.

Recent analyses (28) of public debate about and public perception of genetic engineering in Germany point to the fact that it would be unrealistic to expect broad acceptance of such biotechnology to be achieved by media campaigns, improved distribution of information, inclusion in school-curricula, and the like. All that can be realistically expected is that a consensus on the acceptability of a limited number of specific applications where the application is, and is perceived to be, juridically regulated and politically controlled in ways that ensure that relevant ethical convictions (whether rooted in rational and secular views or in religious comitments) that are held by substantial groups of citizens are being respected.

In reaction to the strategically insurmountable momentum of ethical beliefs concerning biotechnology, the European Association for Bioindustries (EuropaBio), a business interest nongonvermental organization in Europe representing 45 multinational corporate members and 4 national associations that total around 600 small and medium-sized biotechnology enterprises, created an Advisory Group on Ethics (AGE) in 1997. The first task set for AGE was the crafting of a document on *Core Ethical Values*. This code of ethics has achieved adherence among EuropaBio members independent of their respective national legislation, and it contains commitments to ethical values and ethically important goals in all major fields of biotechnological applications. It is less specific and less stringent than the *Convention on Human Rights and Biomedicine* (29) that was crafted by the Council of Europe. The convention was officially adopted in 1997 and already ratified by six member states, though not by Germany. At present the hub of distinctively ethical normative regulation of biotechnology in Germany is informal in nature (by nonmandatory codes of ethics) rather than formal (by actual law).

The use of philosophical arguments of applied ethics in Germany is still very tentative. Four well established centers dominate the research: The Academy for Ethics in Medicine located in Göttingen, the Center for Ethics in the Sciences in Tübingen, the Center for Ethics and Science in Bonn, and the European Academy for the Study of Technology in Bad Neuen-Ahrweiler (30). Each of these major centers has invested a considerable part of its capacity into biotechnological research. The growing literature on bioethics generally in Germany is replete with attempts to appropriate arguments that have already come to enjoy some currency in contexts of applied ethics in England or the United States. This fact could attest to a level of similarity in the ethical problems raised by global progress in biotechnology independent of the cultural contexts. Such similarity could also reflect a level of homogeneous academic discourse layering itself over heterogeneous cultural and moral inclinations at an intuitive level. At the level of theory, it is noteworthy that one of the above-mentioned centers, the Center for Ethics in the Sciences, addresses social ethics. Unlike prevalent notions of principlism (e.g., the bioethics principles addressed at the Kennedy Institute in the United States), a social ethics approach emphasizes all reliable moral considerations that have already been worked out in cultural traditions and affect the target practices. Moreover a social ethics approach works with what is, technically speaking, a "wide reflective equilibrium methodology" and takes into account a wide spectrum of religious, juridico-legal, and other relevant normative textures and theories in modern society, modern law, technological progress, risk asessment, and so on. As the qualifier "social" indicates, a social ethics approach has its integrative frame in taking seriously the impact that the foreseeable social change is likely to make a on moral conceptions that shape a society (30).

Gray, Green and Red

Gray Biotechnology. Although gray biotechnology is frequently hailed by the government as a dynamic and commercially rewarding field (32), there is at present hardly any ethical controversy about gray biotechnology. Speculating about the deeper reasons for the comparative moral inconspicuousness of gray biotechnology could be interesting, but it is safe to say is that a good reason is that no dramatic accident has occurred up to now. Absent something like gray biotechnology's Chernobyl, public attention will continue to focus on the more salient perplexities in red and green biotechnological developments (33). A recent development in public debate is an attempt to add ethical merit to gray biotechnology by pointing out its potential for political strategies of sustainable development. Such strategies enjoy much political enthusiasm in Germany and they have large support among the public. Interpreted optimistically, sustainable development presents itself as a viable response to most of today's pressing environmental problems.

Green Biotechnology. In public debate the following points provide most of the standard argument in favor of green biotechnology: Because of global population growth, and limited agriculturally utilizable terrain, the food problems of future generations must be solved by an environmentally friendly increase in yield and by the production of high-yield, low-cost food by means other than conventional methods in agriculture and in the foodstuff industry with new biotechnological methods and products. This argument is invoked for justifying genetic engineering based strategies for maximizing agro-industrial turnover as well as for associated strategies for minimizing the deployment of herbizides and insectizides in combination with suitably modified crops.

Despite efforts to provide an ethical underpinning for green biotechnology by linking it to moral responsibility for future generations, the vision of green biotechnology has not fared well in Germany (34). Many people have reservations or even reject its use in agriculture and in the food industry. Surveys indicate that the public sees no adequate benefits that could compensate for existing negative expectations and anxieties. For the individual consumer, it is obviously of major significance that products of green biotechnology have concrete and palpable advantages. By contrast, most advantages of biotechnologically "improved" food that have been touted by the biotechnology industry do not refer directly enough to the final product. Public relations campaigns designed

to swing consumer attitudes in favor of bio-food are widely recognized as poorly concealing the fact that the would-be advantages are essentially commercial advantages on the side of bio- and agro-industrial entrepreneurs, and not on the side of the Consumer. At the moment, consumers do not perceive the show-cased advantages (e.g., the Flavrsavor tomato) as personally benefiting. Even tangible product improvements like longer shelf lives for fruit and vegetables do not automatically result in greater consumer appreciation in the face of the ample range of food products offered in Germany and in advanced capitalist countries generally. Also there is an as yet small, but in economic terms increasingly important, segment of the population that cherishes "natural" food products notwithstanding its comparative cost disadvantage.

General knowledge about green (genetic) biotechnology, especially about food stuff production, is not very good on the average in the population. Attitudes toward food are frequently characterized by culturally validated consumption patterns and a good deal of wishful thinking concerning the quality and the production process of preferred food. These attitudes are not shaped by rational choices in terms of cost–benefit calculations in everyday shopping. This, the green biotech-industry has been very slow in realizing. Many German consumers are afraid not only that gene technology is creeping surreptitiously into their food without their consent, but also that they are being misused as guinea pigs by agro-industrial corporations. Highly sensitive analytical techniques (e.g., PCR) can detect even minute quantities of transgenic ingredients, like soybeans used in the production of soya oil. Soya products are used in thousands of different foods. The fact, much publicized in the media, that Monsanto's "Roundup Ready" genes can now be detected even in tofu made from soya that was grown on controlled ecological farms engenders in consumers an insidious feeling of powerlessness. On the other hand, with the attractiveness of modern lifestyle preferences mounting, more people are becoming interested in consuming "functional" (e.g., high energy) foods. It will be interesting to observe how prevailing patterns of resistance to green biotechnology in Germany will change when vitamin enhanced vegetables and fruits become available in the supermarkets (35).

Red Biotechnology. Advocacy for red biotechnology in Germany mainly follows the conventional argument of medical utility: "Our rapid increase in understanding molecular genomics and genetic engineering has brought us to the brink of a health care revolution. Biotechnology brings the tools (gene therapy, recombinant proteins, and cellular therapies) for not only curing common diseases but also many rare diseases." The medical promises of biotechnology have materialized so far mainly in the pharmaceutical sector. For instance, in 2000 there were 42 (compared to 29 in 1998) medical drugs with genetically engineered components fully licensed in Germany (36).

Unsurprisingly, genetic engineering technologies and diagnostic techniques based on molecular genetics are generating most of the moral perplexity found in red biotechnology. In Germany as everywhere, great anxiety is being raised about the benefits of somatic cell gene therapy. Any original enthusiasm was dampened by the medical profession failing to deliver on the goods that had been promised by biotechnological advances. Ironically, somatic gene therapy has turned out to be technically more intractable than first thought but ethically less perplexing. At first arguments likening somatic gene therapy to other forms of transplant therapy won the day in the German debate. A trail-blazing government report on the chances and risks of gene-technology concluded as early as 1987 that "somatic gene therapy is a special form of transplant therapy" and that the "transfer of genes must be evaluated in the same way as the transfer of living material" (37). The German Association of Physicians (*Bundesärztekammer*) followed with similar policy statements in 1989. If successful therapies were available, many people would view the prospect of somatic gene therapy as less problematic than organ transplants.

Germ line gene therapy is ethically taboo in Germany, and it is legally prohibited by the 1990 Embryo Protection Act (*Embryonenschutzgesetz*) (38,39). This act prohibits (*1*) the sale, use, or acquisition of in vitro fertilized eggs for all purposes other than for an intended pregnancy. It also prohibits (*2*) the generation of more than three embryos per cycle in in vitro fertilization (IVF) procedures, (*3*) the selection of sex, (*4*) fertilization involving gametes from dead persons, (*5*) deliberate altering of the genomic information of gametes intended for procreation, (*6*) embryo cloning, and (*7*) the production of animal-human chimeras. These restrictions (with the exception of 2) in Germany's national law overlap more or less with relevant articles of the aforementioned European Convention on Bioethics (Articles 13, 14, and 18). However, the Convention has not yet been, and probably will never be, juridically implemented in Germany. The Convention has been politically attacked by relevant groups of stakeholders (e.g., by organizations representing the interests of disabled people) as being unduely liberal especially in matters foremost concerning research on subjects incapable of giving informed consent. The ethical arguments against germ-line gene therapy, cloning, and enhancement genetics that have gained most currency in Germany are (*1*) the violation of human dignity in identity-altering genomic manipulations and thus the integrity of human beings, and (*2*) the slippery slope of socially amplified genetic discrimination which recalls the outragious practices of Third Reich "eugenics." The metamorphosis of "healing" into "enhancement" and the interpretation of "eugenics" as "breeding" easily evokes the image of human beings treated as cattle. Many people in Germany associate eugenics not only with mass murder policies by totalitarian states but also with sexism and a patriarchal attitude toward women (40,41). This dramatic subtext of eugenics in Germany tends to distract from the disquieting fact that socially conditioned value-of-life judgments and selective decisions enter often into the "private" realm of parental responsibility as more and more prenatal diagnostics becomes a matter of course in "normal" pregancies.

The German Research Association (*Deutsche Forschungsgemeinschaft*, DFG) cooperates with the BMBF in managing Germany's part within the global Human

Genome Project. The German Human Genome Project (DHGP), established in 1995, has a budget of about $30 million a year (42). Integral to DHGP is a program for the study of ethical, legal, and social issues. Between 1996 and 1999, during the first phase of this ELSI-program, seven interdisciplinary conferences were sponsored with a budget totaling about $0.3 million. Theses conferences ran the gamut of interesting topics, but very little overarching direction was achieved besides a set of general topics that function as preferences when new project grants are offered. Conferences were held on (*1*) Genetic Knowledge and Human Self-Understanding, (*2*) Talking Human Genetics: Verbal Communication, Knowledge and Genetic Make-Up (43), (*3*) The New Genetics: From Research into Health Care. Social and Ethical Implications for Users and Providers (44), (*4*) Predictive Genetic Tests, (*5*) Ethical and Legal Problems in the Patenting of Genetic Information, (*6*) Postgenomics? Historical, Techno-Epistemic and Cultural Aspects of Genome Projects, (*7*) The Human Analyzed (45). For the second phase of the DHGP's ELSI-program, these preferences are (*1*) ethical, legal, and social aspects of human genome research in practice (e.g., informed consent, protection of privacy for genome-related information, questions of patenting and of the commercialization of research), (*2*) the application of genetic testing (e.g., quality of genetic counseling and diagnotics, genetic testing beyond the confines of medical human genetics, aspects of health care economics), and (*3*) the cognitive apraisal and the social context of human genome research (e.g., social and cultural differences in the handling of genetic knowledge, impact of genetic knowledge on the concepts of prevention and malady, and sociological metaresearch on the human genome project itself).

The DHGP has not raised much protest in comparison with other contested technologies in Germany (like nuclear energy). What moral outcry there is applies indiscriminately to the global Human Genome Project. Prominent are arguments on the subversion of human dignity in critical debates about bioethics, and this is perhaps more pronounced in Germany than else where. There is a mixed coalition of small groups of diverse political orientation that oppose any research with a potential for furthering prenatal selection of human traits and other forms of what they perceive as genetic discrimination. Some of these groups are radically suspicious of the integrity of bioethics as a scholarly discipline (46). Besides such insignificant "fundamentalist" opposition against biotechnology, major nongovernmental organizations, such as *Gen-ethisches Netzwerk*, have developed a highly differentiated dissentious culture of counterexpertise and civic mobilization, and brought forth excellent journals (e.g., *Gen-ethischer Informationsdienst*, *Wechselwirkung*, *Politische Ökologie*) for critically monitoring developments in biotechnology (47).

Arguments Against "Patenting Life"

Patents, trademarks, and copyrights, are forms or intellectual property protection. The practical point of such protection is to ensure, for a certain period of time, that the individual or a corporation that rightfully claims to have invented that product or technology maintains an exclusive right to make, use, and sell a new product or technology. Any intellectual property rights regime can be construed as a purportedly legitimate compromise between industry's desire to capitalize on its investments in technological development and the prima facie justified claim of society to benefit from the knowledge and resources of its members in a terrain of activities that are only made possible by that society. However, embedded in the normative texture of the (amended) German patent law is a moral component that goes beyond those moral considerations of commutative justice that are pertinent to societally useful inventions and investments.

This moral amendment can best be understood by considering which exclusions from patentability of biotechnological inventions are claimed specifically on ethical grounds. As it turns out, not patentable in Germany (and generally in those EU member states that have implemented Article 6 of the Directive 98/44/EC) are processes (*1*) for cloning human beings, (*2*) for modifying human germ-line genetic identity; (*3*) for use of embryos in industrial or commercial capacities; (*4*) for modifying the genetic identity of animals that are likely to cause them suffering without any substantial benefit to human or animal, and (*5*) for creating new animals from genetic modifications.

The popular claim against permitting the patenting of genetic sequences in living organisms ("no patents on life") makes the following key arguments:

1. Patenting would blur the conceptual distinction between discovery and invention for the sake of vested private interests. It upsets the carefully established balance, controlled by that distinction, between a monopolistic commercial privilege and an associated benefit for the common good.
2. Patenting would regionally and globally threaten genetic diversity. For pharmaceutical, food, and seed companies, and the biotechnology firms behind them, the ability to scan, pick from, and patent the world's biological diversity harbors prospects of great new sources of revenue. But the emphasis on finding and isolating plants and other living matter with the most marketable traits leads to the decline of other plant species, since only the cultivation of those species that are required for the creation of new varieties becomes constantly reenforced. Tailoring property rights to the privatization of genetic resources that have been engineered and patented also promote crop monocultures. A study by the German Parliament's Office of Technology Assessment concludes that in comparison to conventional methods, no substantial risk of loss of biodiversity obtains for the use of genetic biotechnology in plant and crop cultivation (48).
3. Patenting of genetically modified seeds would cause farmers individually and in developing countries to incur extreme economic strain. The economic

incentive of royalties set by intellectual property rights would benefit the technically advanced countries (being the principal producers of economically valued biotechnologically modified seeds and crops).

4. Patenting would encourage "biocolonialism" and "biopiracy." Genetic resources should be treated as a common heritage of humankind, with the moral implication that any commercial use of a genetic resource whose origin can be determined to belong to a certain country must also benefit the people living in that country. (A recent example is the Indian Neem tree and its pharmaceutical exploitation by an English medical drugs corporation.) This argument overlaps with argument 2 in that the ability of business companies to gain monopolies over what were formerly freely available community resources (seeds, plants, and even microorganisms) is assumed to have devastating effects on both human communities and the protection of biodiversity.
5. Patenting would in the long run slow down the development of medical drugs; similarly it would stifle the advancement of very successful conventional techniques of animal breeding and plant cultivation.

In order to underscore the ethical meaning of these five issues, they can be summarized as concern over (*1*) greed, (*2*) loss of biodiversity, (*3*) exploitative commercialization, (*4*) biotechnological colonialism, and (*5*) misplaced utility. There is one further argument that is harder to categorize because it taps into a more general resentment against economic globalization. This is that (6) permissive biotechnological patenting engenders an ethically undesirable shift away from treating people as bearers of human dignity toward an image of people as biological material. This attitude is a possible outcome of colonialization of the nature by economic interests that turn genetic and cellular materials and human (and nonhuman) organisms into potential sources of revenue.

Interestingly, the last argument is not confined in its scope to genetic engineering. It can be applied to patenting in many areas of biotechnology. The argument comprises complex cultural consequences. The idea of life being something not of human making, or something beyond what human ingenuity may try to control, is deeply engrained in European culture. The outcry against patenting life captures a concern that, theologically speaking, scientists might be attempting to play God. Biotechnological patenting would give them license to play God. Yet this resistance to patenting could also be spelled out in less elevated terms. The more commonsense attitude is that whatever can be done is going to be done. This attitude which used to be a flippant remark on uncontrollable technical progress is now gradually being displaced by the realization that whatever pays off is going to be done. The anxiety over biotechnology patenting bespeaks widespread fears over uncontrollable market forces unleashed by economic globalization.

OUTLINE

INTRODUCTION

Japan spends a high percentage gross domestic product (GDP) on research relative to other nations, and biotechnology spending is a high priority (1). The public in Japan is well educated, and is aware of biotechnology, perceiving both benefits and risks of most applications, and has a reasonable degree of bioethical maturity. Most of the regulation of modern biotechnology is through guidelines and directives issued from numerous government ministries. Among the many ethical issues that have been discussed, trust in authorities is one of the central public policy issues that must be dealt with in the future policy toward biotechnology in Japan.

GENETIC ENGINEERING AND BIOTECHNOLOGY IN JAPAN

Japan is one of the world leaders in modern biotechnology, producing about half of the world's antibiotics, building on a long history of fermentation technology (2). Biotechnology itself, as the use of living organisms to produce goods or services, has a history as long as the humans who have shaped the environment (3). While some may consider biotechnology to be a term more suited to genetic engineering and cell manipulation, to consider its ancient origins is important when we look at the ethical issues it raises and the legal approaches that have evolved. This is especially apparent when we look at the origin of bioethics in Asia, because the links to the past are more emphasized there than in Europe or North America, where terms like "gen-ethics" have arisen (4).

There have been several surveys of the progress of the policy decisions behind Japanese biotechnology research (5–7). The government and industry promoted biotechnology throughout the 1980s, and it was then predicted that by the year 2000 bioindustry would represent 10 percent financially of the Japanese economy (8), with 90 percent of this in traditional industries such as fermentation of food and drink. There have been some joint government and industry efforts to promote biotechnology, including the Bioindustry Development Centre (BIDEC), now called

the Japan Bioindustry Association (JBA), a private think-tank of the Ministry of International Trade and Industry (MITI). The Science and Technology Agency (STA) also has invested in public acceptance of biotechnology. The prefix "bio" has been attached to many new words in the spoken Japanese language, like biocandy or biocosmetics, but perhaps not more so than in the argot of most other countries (9).

There is a very positive view of the contribution of science to improving the quality of life and economy. Research spending in Japan, at 3 percent of GDP, is the highest level in the world, with U.S.$120 billion being spent in the 1996 fiscal year (10). The United States spends about 2.5 percent of GDP of which 0.5 percent is earmarked to the defense industry. About 15 percent of the funding in Japan is from the government, which is close to that of the United States (16 percent) but less than that in the UK (23 percent) or France (37 percent) (11). Between 1996 and 2001 the Japanese government increased spending on research by almost 50 percent.

Agricultural applications were slow to develop, with few field releases of genetically modified organisms (GMOs) in Japan. Although the Ministry of Health and Welfare released guidelines to assess applications for foods and food additives made from GMOs in 1992 (12), at present most of the 30 foods accepted by the regulatory committee are from foreign imports. Despite the efforts to promote biotechnology, there appear to have been some bottlenecks caused by strict or bureaucratic regulations. Up to 1994 there had been 13 GMO field trials compared with over 1000 in the United States by that time (13). However, Japan leads the world effort in sequencing the rice genome.

The Human Genome Project (HGP) had its origins in Japan in the early 1980s, and the genetics programs have been on the rise but without much thought given to ethical, legal, or social impact (ELSI) issues (14). In the 1998 government budget, U.S.$149 million was allocated for genome research (15), and industry also made significant contributions as in other research areas. For example, Takeda Chemical Company was the leading patent claimer in a 1995 survey of world patents on human gene sequences (16), and it also obtained exclusive rights to use of the genetic database bought by SmithKline Beecham from the Institute for Genomic Research in 1992.

PUBLIC ACCEPTANCE OF BIOTECHNOLOGY

The public acceptance of biotechnology in Japan is reasonably high, somewhere in between the attitude in the United States and that in Germany (3,9,17). A number of studies on public acceptance since 1991 have described the bioethical concerns that different groups within Japan have toward biotechnological applications. It may be that the Japanese have the highest familiarity with the word "biotechnology" in the world. In 1991 two surveys found that 97 percent had heard of the word (9), and close results of 94 percent in 1993 (3) and 89 percent in 1995 were confirmed by Hoban (18). Clearly, there is at least high recognition of the word, since programs on genetics and biotechnology are seen on Japanese television almost daily and developments in the field are covered by most major newspapers. There are many science magazines, though they are more in the style of the English language *Scientific American* than of the *New Scientist*.

The importance of medical care, agriculture, and aquaculture to human life is generally acknowledged among the peoples of large societies. The question, is, however, to what extent are the attitudes toward the use of organisms to provide these goods, universal, and the relationships with the organisms and ecosystems that provide the organisms universal, as well as the attitudes to the consumption of the products? To answer this question we need to consider a number of strategies. First, we can look at the use of organisms and new products by different groups with in a society and compare the results. For example, do the people eat meat? Although in Japan meat was not eaten widely a few decades ago, thought to be due to Buddhist influence, it is very difficult to find meals which are strictly vegetarian now. Do the people farm animals in open spaces or in factory farms? In Japan land constraints mean that most animals are in factory farm situations, except in Hokkaido during the warm seasons. We have further to standardize for environmental and economic conditions, and look at the religious traditions.

The religious traditions include guidance on ethical issues, answers to problems that are faced around the world. In one sense looking at the end result of choices, the adoption of science and technology products by consumers, is the best description of acceptance of science and technology. However, if we only look at the consumption statistics we may still not understand the reasons behind the choices, and whether, for example, there was really much choice for the consumer in the home environment and society. The ideal model would say that a consumer determines what products are best, but this may not be apparent in a world dominated by large commercial interests, trade groups and associations, and connections among producers, retailers, and regulators. Since Japan is not self-sufficient in any major species of food (even rice is imported for processed rice products), it is going to be dependent on exporters. However, purchasing power means selection among suppliers, and some new practices in air freight have been introduced in Japan that enable the import of live seafoods and many fresh fruits and vegetables. The market proportion of organic foods and pesticide-free foods has been increasing, though surveys find this to be more for reason of interest in health than for environmental concern (3). Some supermarkets provide nongenetically modified soybean products, like tofu (bean curd), and significant resistance to the products of GMOs emerged in late 1998 and continued through the year 2000.

Another strategy that is used to judge public acceptance is to look at cultural tradition in determining what could be adopted. Schmid in 1991 observed that public acceptance of biotechnology is high, "reflecting a high level of education and information within Japanese society, and the specific way of reaching decisions, which usually involve lengthy discussions with all groups" (7). However, if one asked the Japanese public if they had been involved in the decisions associated with the promotion of biotechnology, it is very doubtful that anyone would say yes. Decision-making in Japan tends to exclude

public participation (13), although certain applications of biotechnology like organ transplantation technology have introduced the idea of individual choice in use of the technology (19), as will be discussed below. In Japan the strong public support of biotechnology is something that cannot be conclusively obtained from public opinion surveys. There is a predominant cultural attitude among the Japanese not to create friction with those they disagree with. Therefore protest movements and oppositions toward biotechnology are small and lack unity. The major outlet for dissent is the media, through discussion forums in magazines, newspapers, and television chat-shows.

The survey strategy that allows us to look at what individuals will accept, and their reasons for this, must be supplemented in Japan by topics covered in small group discussion forums. The survey results from Japan, and also from other Asia-Pacific countries (3), compared with the rest of the world, reveal an important distinction in the main concerns people have about biotechnology. They want to protect nature, not because of its value or property, but simply because it is there. The bioethics part of risk assessment, which elsewhere takes precedence over the analysis and prediction of risks, is combined with the value of avoiding harm and the benefits of doing good or beneficence. The assessment of risk in biotechnology involves both the potential to change something and the potential to do harm (20). The extent to which a change is judged to be a subjective harm depends on human values, whether nature should be "intransient" or modified. Open survey questions in all countries reveal that the major determinant of moral acceptability of a technology is whether it is perceived to be unnatural, or morally acceptable (3,9,17,21).

In the 1993 International Bioethics Survey (3), when asked about specific developments of technology, including in vitro fertilization (IVF), computers, pesticides, nuclear power, biotechnology, and genetic engineering, both benefits and risks were cited in open comments by many respondents in Japan as in Australia, Hong Kong, India, Israel, New Zealand, the Philippines, Russia, Singapore, and Thailand. In Japan 74 percent saw biotechnology as worthwhile, which was less than the 85 percent in the 1991 survey (9) but still a high positive response. In both years 37 percent said that they had not worried about its development. Thirty percent of those who cited a benefit in 1993 said it would help humanity, 19 percent said agriculture in general, and 15 percent said science. About a half did not describe any benefit or concern. In addition to those who saw it as unnatural, another common response was of human misuse.

In the 1997 telephone surveys (17), a single question on the perceived impact of seven areas of science and technology was used. Comparisons with the data from the European Commission, Eurobarometer 46.1, reveal that there is more optimism about solar energy, new materials, and space exploration in Japan (and New Zealand and Canada) but similar optimism toward computers, information technology, and telecommunication in the EU. There is less optimism about biotechnology and genetic engineering in Japan (with New Zealand being even lower). Only 62 percent in Japan thought that biotechnology would improve the way we live in the next 20 years, 12 percent thought biotechnology would make things worse, and 4 percent said they perceived no effect, with 22 percent saying they do not know. For genetic engineering 54 percent saw it as worthwhile, 12 percent as making things worse, and 7 percent as having no effect. In 1991, 76 percent in Japan said that genetic engineering would be a worthwhile area to explore, while 20 percent were extremely worried about the consequences (9). In 1993, 57 percent said that genetic engineering was worthwhile scientific research, while 15 percent still had a lot of worries about it. In Japan there does not appear general trend against genetic engineering over time, unlike the situations observed in Europe (22) or New Zealand (17).

When people were asked in 1997 to say what came to mind on hearing the term "biotechnology," 8 percent expressed a concern and 4 percent expressed a positive view of science, but most people just said "something technical" (17). In all Asian countries there is strong support for certain kinds of environmental release of GMOs (3). Plant genetic engineering is regarded more favorably than microbe, animal, or human genetic modifications (23), except for gene therapy for diseases like cancer, which is received very positively in Japan (24,25). Despite the concern expressed about genetic engineering, in 1997, 35 percent in Japan said they would buy genetically modified fruits if they tasted better, suggesting a positive image of the products. However, only 8 percent said current regulations are sufficient to protect people from any risks connected with modern biotechnology.

JAPANESE LAW AND BIOTECHNOLOGY

There are few specific laws on modern biotechnology in Japan but rather a series of regulations by the different Ministries. Many scientists and people in industry claim that these regulations have inhibited research development, which is a different view from the public as shown above.

The modern Japanese Constitution was drafted by the occupation forces after the Second World War, was reviewed by the Japanese government, and voted into force by the Japanese Diet (Parliament) in 1948. It has had almost no changes since then, reflecting a trend for laws to become fixed. It includes 31 Articles on the rights and duties of the people. The right of people to life, liberty, and the pursuit of happiness, to the extent that it does not interfere with public welfare, should be the supreme consideration of the law and government (Article 13). Two articles are relevant to access to biotechnology:

1. *Article 11*. The people shall not be prevented from enjoying any of the fundamental human rights. The fundamental human rights guaranteed to the people by this Constitution shall be conferred upon the people of this and future generations as eternal and inviolable rights.
2. *Article 25*. All people shall have the right to maintain the minimum standards of wholesome and cultured living. In all spheres of life, the State shall use its

endeavors for the promotion and extension of social welfare and security, and of public health.

Article 25 assumes a welfare state but does not have much legal meaning. It does not vest in each individual a concrete right that can be enforced by the judicial process, as such type of right comes into force only through implementing legislation. There are six major Codes in addition to the Constitution. Many medical procedures and medical protocol are regulated by specific legal Acts. The Civic Code is concerned with family and inheritance and was completely amended after the Second World War. The Criminal or Penal Code includes some relevant Articles. When there is a more specific law and it conflicts with a general code, the specific law usually takes precedence. Administrative guidance by government agencies and local authorities plays the more significant role in many of the biotechnology issues. The power in the guidance is that the Ministries have the power to grant licenses or permissions. There is little legislation on recent bioethical issues.

The basic philosophy of the Japanese health care system is universally mandated, government-provided health insurance coverage. There is little choice over which insurance scheme a person must join. Employees must join the one statutory plan offered by their employers, and self-employed persons must join the plan administered by the local government or by their trade associations (26). In the year 2000 a public long-term care insurance program will provide for some extra services for the elderly or chronically sick, such as home help, visiting nurses, or day care (27).

The Preventive Vaccination Law established a national program for influenza vaccination in 1976. The Law was weakened in 1987 by removing its obligatory nature, and was further weakened in 1993 with the broadening of exceptions and the removal of provisions that penalized parents who failed to have their children vaccinated. Influenza vaccination is performed annually in children aged 3 to 15 years in certain target groups. However, it has not been very effective, and has recently been recommended for young children only (28). Since 1987 it has been easy for parents to refuse influenza vaccinations, resulting in large differences among the various kindergarten, primary, and junior high schools. Between 1951 and 1965, 169 persons died because of reactions to vaccination. Articles 16 to 19-4 provides for a system of national compensation, under which there are set reimbursements for injuries. For example, in April 1992 a death was compensated by 20.5 million yen, with funeral costs of 140,000 yen. A pension after 18 years of age was 2,925,900 yen for the first category of disability and 1,910,500 yen for second class of disability (29).

A controversy erupted in 1993 over the high incidence (1 in 400) of side effects from a MMR (mumps, measles, rubella) vaccine made and used in Japan. It was withdrawn after the media released unpublicized government risk data. In 1994 no MMR vaccine was offered to children because the government refused to use the U.S. vaccine, which has a 20-year history of safe use with almost no side effects. The scandal reveals that the Japanese Ministry of Health and Welfare has been attempting to encourage Japanese industry by not using a foreign vaccine, while risking public health with a vaccine with 100 to 200 times more side effects. Parents who want their children vaccinated had to pay about U.S.$80 for a vaccine that was previously free (29).

Another sign of the support for the biotechnology industry is the system of drug reimbursement, and the overuse of antibiotics in Japan. One of the embarrassments of the Japanese health care system is the corruption that is implicit in the way drug prices are set and reimbursement is made, and the contributions from pharmaceutical companies to doctors who use their drugs. The Japanese are the world's highest spenders on prescription drugs (30). Almost all general practitioners and hospitals have their own pharmacies for outpatients. Every two years the Ministry of Health and Welfare sets the "official" prices for all drugs. These prices are used to determine the charges to patients and the national health insurance systems. However, pharmaceutical companies offer drugs to hospitals at a discount. The permitted discount is 10 percent, which means there is even official sanction of the scheme to have financial reimbursement for dispensing prescription drugs. In practice, the current discounts are 20 to 30 percent or more in competitive markets. This means that hospitals and doctors benefit from prescribing drugs, and it explains why the consumption of drugs is so high.

The average use of antibiotics is 3 times the U.S. average and 20 times the United Kingdom average (29). There is concern over methicillin resistant *Staphylcoccus aureus* (MRSA) infections and deaths, which are relatively common in Japan. In one old person's home in Chiba, Japan, 12 residents out of 80 were infected with MRSA in 1992. Many products are allowed to support the presence of a large local pharmaceutical industry.

Before a new drug is approved for use, the Central Pharmaceutical Affairs Council within the Ministry of Health and Welfare must examine the results of toxicity tests, animal tests, and clinical trials. The basic policy is outlined in the Notice No. 645 of 1967, on "Control of the manufacture of and trade in pharmaceutical products: approval of manufacture and import of medicaments." Drugs must pass three phases of clinical trials:

1. Phase I is to check a drug's safety in humans.
2. Phase II is to access its therapeutic index (the response rate and severity of side effects) in selected populations of patients for whom the drug is intended.
3. Phase III is to determine whether the new treatment is better than existing ones.

All these tests are done at universities or research organizations at the request of pharmaceutical companies, and there have been cases of bribery (29). There is pressure today for more of the trial results to be presented in scientifically refereed journals, but until now much of the data has been either in internal documents or in the drug companies' own journals. International standardization of tests in 1991 in the United States, Europe, and Japan avoided some duplication of tests and halved the length of long-term studies. In practice, when a drug has passed phase two trials, it may be widely prescribed in "trials,"

and there are some top-selling drugs that are said to be anticancer drugs which are only prescribed in Japan (30). The Phase III trials can become part of the pharmaceutical companies' marketing plan. There are also widespread issues of lack of informed consent in such clinical trials at the Phase II and Phase III level because most patients do not know what medicine they are being given.

The government can suspend production by a company if it fails to report details of clinical trials, especially if these involve deaths. On May 20, 1994, the chairman of Japan's fourth largest pharmaceutical wholesaler resigned to take public responsibility for insider trading among employees, and for the sale of sorivudine, which has led to the deaths of 18 people. The company had reached settlements by May 1994 with 10 of the 23 families of patients who died or had serious consequences as a result of the using drug. The penalty of a 105-day suspension of production at the Nippon Shoji Kaisha, Ltd. Okayama prefecture factory in response to the company failing to report the deaths of two persons during clinical trials of sorivudine occurred on September 2, 1994. This is the longest suspension of products that has ever occurred because of an infringement of the Drugs, Cosmetics, and Medical Instruments Law (31). It also gave time for reflection on the system of clinical trials in general (32).

The journals that publish the results are often the same journals that sponsor the trials or make the drug (32), and all major pharmaceutical companies are also involved in research on production of new drugs using modern biotechnology methods. Another feature of Japanese biotechnology is that most research is conducted in large established companies, usually multinational, rather than the small biotechnology companies that are a feature of North America. However, it could be that the sponsorship links are just more obvious than elsewhere.

Despite the blood donation system, which in 1991, saw 8,861,137 persons donate blood, 6.5 percent of the population, there is also a large import of blood, since Japan uses more blood per person than any other country in the world. The Product Liability Law passed unanimously by the National Diet on June 22, 1994, came into effect from July 1, 1995. It virtually excludes any liability on transfusion products. "Complications of blood transfusion such as those caused by contamination of viruses whose complete removal by existing technology is impossible cannot be considered as product defects" (33). There have been compensation claims paid to some of the blood transfusion victims of delayed implementation of heat treatment procedures to eliminate HIV from imported blood products (34) and some officials were sentenced to prison.

Patent claims on products in Western countries are recognized in Japanese patent cases, and there have recently been cases involving the use of recombinant DNA products. The approval of such products is independent of the patent claims. A Japanese court rejected a claim by Hoffman-Roche that a Japanese company infringed its patent on interferon, but the case will be appealed (29). The sales of interferon has rapidly been rising since it was approved for use against chronic hepatitis C. An Osaka local court in January 1991 decided that the company Toyobo cannot market tissue plasminogen activator (TPA) because it conflicts with the Japanese patent given to Genentech in January 1991. Genentech licensed two other companies to sell TPA in Japan. TPA has been sold in Japan since May 1991. The case involving the rights to sales of erythropoietin (EPO) in Japan was solved out of court. EPO has also a very large market in Japan where kidney transplant rates are low.

Privacy of communication is guaranteed in the Constitution. Article 21 of the Constitution guarantees freedom of assembly and association as well as speech, press, and all other forms of expression. Censorship is prohibited, and secrecy of any means of communication must not be violated. There is the Law on the Protection of Computer Information on Individuals, which states that government agencies are prohibited from using the information on individuals for purposes other than the original purpose for which the files were compiled. Any person may require a government agency to disclose the information on themselves that is stored in the computer, and if necessary, demand its alteration. It could be interpreted to mean the truth of any health check information entered into a computer must be revealed following a person's request.

If someone informs others of the medical data of a person, for example, the result of genetic screening test to an employer, Section 134-1 of the penal code could apply. If the person who leaked the information is a national employee, he or she will be punished by the Law on Government Employees. There is still debate over how to control life insurance companies' questioning on the results of genetic tests, but other family history data and smoking are currently used in deciding policies.

For any medical intervention, physicians are required to obtain consent to medical treatment according to the Medical Practitioner's Act, Article 23. The Supreme Court, in 1949, (Decision 3.1) said that the obligation for treatment is based on assessing what can reasonably be expected in view of the knowledge and experience that ought to characterize the average physician. However, in practice and in court cases in the 1980s and 1990s, the doctrine of informed consent has yet to be fully recognized (35,36) as a right for patients to be told all information. Nevertheless, more doctors are starting to use informed consent, and truth telling in cancer cases has also been increasing (37).

Organ transplantation using cadaver donors, especially those that are determined to be dead by brain death criteria, is rare. A law permitting such transplants, and allowing whole brain death criteria to be used for determination of death if patients themselves have signed a donor card to that intent and if family members do not object to it, was passed in 1997. Until then, Law No. 64 (Article 4.17) enabled cornea transplantation since 1958, while in 1979 the Act Concerning the Transplantation of Cornea and Kidney was passed allowing kidney transplants. Kidney transplants since 1979 have been from both live and dead donors, with prior consent and family approval. In the mid-1990s there were few transplants from brain dead donors while the new organ transplant law was being debated. There was much

discussion of the issue and whether it was related to any particular Japanese ethos or just suspension of the medical profession (14,19,38). From 1968, when the first heart transplant was performed, until 1997 there had been wide debate on the question in Japan, which was a rare, if not unique, occasion for extensive public debate on a biotechnology process. Live liver donations were possible but most patients had to seek heart and liver transplants overseas.

Until 1996 the 1948 Eugenic Protection Law governed the use of abortion services in Japan. The number of abortions conducted is declining, but it is still high among developed countries, and in 1996 the title was changed to Mother's Body Protection Law (39). After World War II, the Japanese government changed the population policy into "to stabilize and not to increase" from "to increase." How to popularize family planning became the primary policy in health care of postwar Japan. At the same time the Eugenic Protection Law was promulgated in 1948, and Japan became the second largest populated country after the Soviet Union in the liberalization of induced abortion.

The Eugenic Protection Law was a modification of the Preventive Law of Offspring with Hereditary Diseases (*das Gesetz zur Verhuetung erbkraanken Nachwuchses*), 1933 of Germany under Hitler, combined with a liberal view of induced abortion (39). In June 1996, however, some inappropriate parts of this law were amended by the omission or elimination of the eugenic articles, and the title of this law changed from Eugenic Protection Law to Mother's Body Protection Law.

Fetal diagnosis and selective abortion, while not explicitly allowed under these laws, is however, widely practiced when the pregnancy could cause psychological distress to the mother or economic hardship, both of these being acceptable reasons under the law for induced abortion. The marketing of genetic diagnosis and triple marker biochemical tests is governed under existing laws for pharmaceutical products and devices. Abortion is restricted to the period in which the fetus is not viable outside of the uterus, and this period is determined by the notification from the Ministry of Health and Welfare, currently being 22 weeks. The Japan Society of Human Genetics has voluntary guidelines on use of genetic screening (40).

IVF and assisted reproductive technology for married couples are guided by the voluntary guidelines of the Japan Society of Obstetrics and Gynecology (JSOG), and moves to introduce a law have been resisted by the medical community (41). The first baby was born after IVF and embryo transfer (ET) in 1983, and there was much media attention. There are significant differences in attitude among infertile couples, medical practitioners, and the general public on the technology (3,9,42). Most Japanese obstetricians belong to JSOG, and after the first baby was born they rushed to form an ethical committee concerning IVF ET. This committee consisted of 14 members of JSOG. While listening to the opinions of representatives from the mass media and highly educated laypersons, in October 1983, they wrote and announced a statement to the Society of Obstetrics and Gynecology. Even though it was a little too late, this was probably the first time that a Japanese medical society made and announced ethical guidelines for its members. The statement is as follows (29,39):

1. The Method should only be used for women who are judged unable to become pregnant by any other medical method.
2. The individual implementing this Method must be a qualified doctor who has mastered a high standard of knowledge and technology in the field of reproductive medicine. Every procedure and treatment should be carried out with the utmost care. The procedures and expected results of the Method should be sufficiently explained to the applicants concerned prior to implementation of the Method. Upon obtaining consent from the applicants, and acknowledgment should be filled out and signed by the applicants and retained by the doctor.
3. The applicant receiving the Method should be married, have a strong desire for a child, and be in satisfactory mental and physical condition for pregnancy, delivery, and raising of a child. It must be possible to successfully conduct retrieval of mature ova, implantation into the uterus and maintenance of pregnancy.
4. The fertilized ovum should be carefully handled in respect to the basic moral values of life.
5. When implementing the Method, no gene manipulation is permitted.
6. The privacy of the couple and their delivered child should be respected and protected according to relevant laws and regulations.
7. Considering the importance of the Method, the organization using it should provide opportunities to hear opinions from individuals other than those directly concerned.

The number of babies born through IVF/ET has now reached an annual total over 10,000 since the first case in 1983 in Japan. Surrogacy, however, is not permitted, though foreign surrogacy agencies have been used by Japanese clients, and at least two agencies operate for U.S. surrogacy businesses in Japan (29).

Artificial insemination by donor sperm (AID) is conducted largely through the Obstetrics and Gynecology Department of Keio University, Tokyo. AID has no law to regulate it, and it started in 1948 (39). Now there are about 500 attempts at AID a year at Keio University, and about 250+ births per year. Each sperm donor is used for up to 15 pregnancies, and only married women are accepted. Keio University is the most public about its program. Other institutes do not admit having a program. The guidelines used are those of Keio University and Japan Society of Obstetrics and Gynecology. Since a conference discussion of the Japanese Association of Civil Law in 1953, many legal scholars have construed the law to allow the AID baby of a married woman to be a legitimate child of her husband, so long as the procedure was carried out according to the current practice, but there is still no specific law.

Preconception sex selection has been investigated in Japan, but in a 1993 survey, 76 percent said that if they had only one child they would want a girl, suggesting

that traditional ideas of family inheritance are discounted by many people (29). The reason why more people wish to have a girl than a boy, which is in contrast to many other Asian countries, may be because girls are considered cuter, or better caregivers for elderly parents. Following its announcement in 1986, the Ethical Committee of JSOG, and at the same time, the newly founded Ethical Committee of the Japan Medical Association (JMA) came to about the same conclusion in September 1986. That is, it was decided that this procedure should only be adopted to prevent the creation of conceptuses with severe sex-linked recessive genetic disorders.

The details of the Ethical Committee of JSOG's statement are as follows (39):

1. Any individual implementing the Method must be a qualified physician who has mastered a high standard of knowledge and technology in the field of reproductive medicine.
2. A physician intending to implement the Method must be previously registered with the Society according to the specified format. It is also desirable that the results be reported to the Society.
3. Before application of the Method, the physician should sufficiently explain the procedures and expected results to the individual(s) concerned, and should obtain their written consent.

It is also against the guidelines of the Ministry of Health and Welfare to generally inform parents the sex of the fetus during routine prenatal ultrasound diagnosis.

The Ministry of Health and Welfare in Japan set up a special Ethics Committee to assess applications for gene therapy in 1994. The Ministry of Education also made guidelines and set up a separate committee (with seven overlapping members). In university hospitals, drugs already need the approval of both Ministries, and so does gene therapy. The first protocol was approved by Hokkaido University in 1994 allowing research on one child with ADA deficiency. Approval was given by both ministries. The guidelines are basically those of the National Institutes of Health (NIH) in the United States. The guidelines rule out germ-line therapy and until 1999 limited cases to terminal illnesses without effective therapy. However, they only require verbal informed consent, not the written consent that may be determined by local hospitals policies. Japanese scientists and public strongly support the use of gene therapy (24,25), but progress has been slow due to regulatory delays. There is also a lack of domestic vector production, and many trials that are considered are in collaboration with U.S. companies. Japanese people disapprove of use of enhancement genetics in surveys, unlike tendencies seen in China, India, or Thailand (25).

In Japan by 1994, DNA fingerprinting had been used in 180 criminal investigations, but it had only been used 12 times as evidence (29). It is more common to use blood typing and other methods, but it is being introduced in the same manner as other modern forensic techniques. By 1997 advertisements to fathers to check their real genetic relationships to children had appeared in popular magazines, without apparent regulation.

JAPANESE CULTURE, BIOTECHNOLOGY, AND BIOETHICS

The data from modern public opinion surveys needs to be interpreted in the context of the cultural heritage of Japan. The relationships of human beings within their society, within the biological community, and to nature and God are a fact of prehistory; therefore we cannot precisely define the origins of bioethics (3). One of the major elements that needs to be considered in Japanese bioethics is the history of polytheism and animism. However, during the expansion of agriculture and paddy fields over 500 years Japan has seen similar disregard for the environment as have Western countries, suggesting that religious belief does not overcome economic or self-interest (43). The decision to burn a forest and plant a crop is a bioethical decision, and we can see that almost all possible land has been utilized for agriculture, industry, or urban life, with wilderness area remaining only in those regions that proved difficult to exploit.

Japanese ethics is a mixture of Buddhist and Confucian influences combined with a later Shinto influence, and more recently Western influences. From the fifth and sixth centuries the medical profession was restricted to care for the privileged classes. With the centralization of government in the seventh and eighth centuries, there was established a bureau of medicine, and by the Yoro penal and civil codes, there was created an official physician class. The shortages of doctors opened the profession to others. After the Heian period (800–1200) the government-sponsored health service was replaced by a council of professional physicians. In the sixteenth century a code of practice was drawn up the physicians that is very similar to the Hippocratic code and is called the Seventeen Rules of Enjuin (44).

In all areas of public policy, committees of experts work together with bureaucrats to issue reports and guidances. There is a Ministry for the Environment that attempted to introduce a law to govern genetic engineering in 1992, but it was blocked in a power struggle between resistant academics and the Ministries for Agriculture, Forestry, and Fisheries, the Ministry of Education, Science, Culture, and Sports, the Ministry for International Trade and Industry, the Science and Technology Agency and the Ministry of Health and Welfare — all who had their own regulations and committees on biosafety and release of GMOs (9). The first two guidelines had been introduced in 1979 by the Ministry of Education, Science, Culture, and Sports, and the Science and Technology Agency. In 1986, following the OECD recommendations, the other three Ministries also introduced guidelines. Given the interministry division of duties, it is not surprising that the smaller, then Agency for the Environment, could not push through a law claiming it had jurisdiction for all GMO releases over the other Ministries. Each Ministry has revised its guidelines gradually but has kept control over its traditional areas, the same as other biotechnology applications and research.

For the medical discipline, in addition to the Ministry of Education, Science, Culture, and Sports and the Ministry of Health and Welfare, there is a Council of Medical Ethics established under the provisions of Article 25 of the Medical Act. It is an advisory body

supervised by the Minister of Public Welfare, consisting of the presidents of the Japan Medical Association, the Japanese Dental Association, and scholars and staffs from related administrative departments. It functions to take administrative measures to eliminate physicians and dentists who commit acts of malpractice or unethical acts. If the media exposes a scandal, then usually top officials or Ministers must resign, an investigatory committee may be established, and then there is a proclamation of policy change. However, Japanese politics is dominated by long-term stability, as the ruling parties and coalitions have been in power except for a year since the Second World War.

Currently Japanese medical ethics is under change (35), recognizing that Japanese society contains people with a similar diversity of views to that of Western countries. The hesitant introduction of bioethics is more related to the structure of Japanese society than to any difference in a person's attitude in Japan or the Western countries (13,19). This fact emerged from opinion surveys where individuals were asked to give their reasons for their responses to bioethical issues regarding genetic manipulation or screening. There was at least as much variety expressed by members of the general public in Japan as there has been in other countries (3).

It must be noted that in terms of equity of access to biotechnology applications, apart from access to prenatal genetic screening and gene therapy, and novel treatments for rare diseases, most other applications of modern biotechnology are accessible to all under the universal medical coverage system. There have been criticisms of the health research system in Japan (45). Open debate is still not common, and this may be the greatest public policy need in biotechnology.

THE FUTURE AND TRUST

In summary, considering the two sides of bioethics, descriptive and prescriptive, a key issue is trust. If we describe the ethical issues that people think are associated with biotechnology in Japan, we find great diversity, the same as in other countries. One common feature, however, is a lack of trust in the process and the policy makers. The prescriptive ethics, or processes that can be used to make decisions and/or the range of decisions that can be made, has been influenced by the relativism that is perceived as correct in Japan. This means rather than one absolute view being right or wrong, we should respect the view of others and not challenge them. This is enshrined in the Constitution and also is in the spirit preserved in the choices given over acceptance of brain death for organ donors (though the family can override the decision of an individual).

While people should not judge, policy must be formulated. What is good for one person may not be good for the broader society, and the global nature of agricultural economics and environmental impact mean we have to think far beyond the small field trial of a GMO. Prescriptive bioethics not only calls for certain factors to be included in decision making but that certain groups of people be involved. Different groups of people may call for different levels of risk assessment, and of what constitutes a significant risk. Therefore a central question is who can be trusted, and how the public in Japan can regain trust in authorities.

In the 1997 survey, when given a range of bodies, international organizations like the United Nations and WHO were considered the best placed bodies to regulate modern biotechnology by 62 percent in Japan compared to 34 percent in Europe (17), reflecting another cultural value that the opinions of those outside the country may be more trusted than the opinions of policy makers within the country. Europeans and North Americans prefer their local authorities. Therefore the legal tolerance limits of acceptable risk and harm as broadly outlined in international covenants such as the Declaration of Human Rights, the UNESCO Universal Declaration on the Human Genome and Human Rights, and international treaties on environmental protection, have been well accepted as a cultural norm and something to aspire to. Japan is less likely to break with world opinion than, for example, the United States, which regards national autonomy as a higher ideal.

In the same question, industry was more trusted to regulate modern biotechnology than public authorities, the reverse of other countries surveyed (17). This may reflect that by 1997 there was very little trust left in the government in Japan, not that industry is particularly well trusted compared to consumer organizations or university scientists. In the 1991 survey, when asked how do you think biotechnology should be regulated, 62 percent of the public chose the option standards and practices agreed upon jointly by industry and government, with 19 percent saying by the government alone, and 2 percent by industry alone, and 5 percent by individual researchers (9). There was more support for government expressed by scientists and high school teachers who were included in the same survey.

The distrust of authorities by the Japanese does not stem from lack of knowledge. Surveys of the different groups in Japan showed that educated people have as much concerns; in fact biology teachers considered there to be more risk from genetic engineering than the general public (9,17). The risk perceptions among scientists had a tendency to be more concrete than among the public, but all groups expressed a wide variety of concerns. In related questions on the risks of genetic engineering to animals and humans, only 16 percent expressed concerns that it meant interfering in nature (9). However, as in most countries among Japanese academics, industry scientists, and public authorities, there are still claims that increased knowledge is correlated to decreased perception of risk. This is not supported by empirical studies. The balancing of benefit and risk is necessary for bioethics, and it is the most effective indicator of the bioethical maturity of a society (46). The use of surveys can provide us with knowledge of the degree to which a society can make well-reasoned, "mature" judgment rather than offer impulsive, "childish" views based on immediate gain.

In late 1997 one of the government agencies, the Council for Science and Technology of the Science and Technology Agency, established a bioethics committee and

a special committee to consider legislation on human cloning (47). The Agency, however, has been criticized for allowing meetings to be closed to public participation, despite claiming as its mission the universal response of all Ministries to a problem where "open and nationwide debate and public consensus is needed." Many Japanese people, of course, are aware that debates do not reach the public, so they rely on opinions expressed by selected experts. Several Ministries have started to open to the public meetings on bioethical issues like brain death and gene therapy, but otherwise most meetings stay closed.

Bioethical decision making involves recognition of the autonomy of all individuals to make free and informed choices provided that they do not prevent others from making informed choices. This is consistent with democratic principles, and the extent to which a society has accepted this is the one criteria of the success of bioethics. However, the structured paternalism of Japanese society is built on the idea that only the views of so-called experts (*sensei*) should be heard (13). It also means that their views should not be questioned, in accordance with the traditional paternalistic Confucian ethos. Medicine is "an Article of Jin," the expression of loving kindness (*Jin*) by the health care professional (34). The main theme of Confucianist ethics was the maintenance of moral discipline for the nation, society, and the home, and it was to the benefit of rulers and family leaders. Therefore it is not surprising that many of the authorities in Japanese society share this ideal because it means respect for them, and hence the rejection of an autonomous development of bioethics (13). They may promulgate the idea that Japanese are different as an attempt to prolong the Confucian ethic.

The bioethics debate may be the catalyst required to transform Japan from a paternalistic democracy. People of any country have at times resisted rapid change, and the globalization of ethics, ideals, and paradigms (may cause) ethnic and national identities to be changed, or lost, especially those of countries with unique cultural histories. How countries approach globalization is a fundamental question, but many individuals in countries with access to common news media have already answered the question by their converging lifestyles and values. To the extent that human rights and the environment are more respected, this trend is to be encouraged.

When Japan opened its doors to Western society in the nineteenth century, it was introduced to a newly emerged science and scientific paradigm that was only part of the fabric of Western society. Meanwhile Western society has continued to evolve, and bioethics has emerged. There has been a series of meetings on bioethics initiated in Japan, both through the Japan Association of Bioethics founded in 1987 and through international seminars on topics such as the Human Genome Project (48–51). There are several bioethics centers and university departments at which it is possible to do research in bioethics, but no degree course is specialized only in bioethics. An early part of this development has included importing and debating ethical approaches, but the current phase has opened up a multidisciplinary dialogue that has included the public in the discussion and development of its diverse, indigenous ethical traditions. Modern biotechnology may be the stimulus to transform Japanese public policy to better encourage people's involvement in technology decisions.

OUTLINE

INTRODUCTION

The development of biotechnology is intense in the Scandinavian countries, Denmark, Finland, Iceland, Norway, and Sweden. In a sense this development is a natural continuation of a long tradition originating with the Swedish botanist and professor of medicine, Carl von Linné (1707–1778). Linnaeus was eager to learn everything there is to know about nature; he and his disciples traveled the world to collect information about both natural and human resources, information that he then systematized and described in detail. Linnaeus lived at a time when the significant economic potential of science was first being recognized in Swedish political life, and he furthered this development. The Swedish historian of science, Tore Frängsmyr, has described this contribution as part of the Linnaeus heritage:

> He himself helped spread the new economic thinking and often maintained that natural history, his own science, formed the basis of any sound economy. Both agriculture and industry used nature's products, so knowledge of the three realms was fundamentally important. . . .Linnaeus was very willing to put his branch of science at the service of the economy. At the request of the Riksdag, he made three long journeys in the 1740s to different provinces — to the islands of Öland and Gotland in the Baltic, to Västergötland in the west, and to Skåne in the southern Sweden. The aim was to inventory and list the "utilities," i.e., natural resources, ores and tree species, edible plants and berries, animals that were suitable as food or had good pelts, waterways that could be used to power mills, anything that could be put to economic use (1, pp. x–xi).

Linnaeus wrote of the wonders of wide open landscapes, and of plants, and insects that filled him with awe and religious inspiration, but he was able to combine his feelings of reverence with a commitment to putting these wonderful natural resources to use. Linnaeus was a biotechnologist of mind in a very modern sense. In a way he was also a forerunner of the contemporary interest in social aspects of the implementation of biotechnology in different sectors of society. He said that it was not enough to understand the wonders and utilities of natural resources, one must also understand the society in which the new science is going to be implemented. Accordingly

Linnaeus devoted a great deal of his time to describing the local customs and traditions he encountered on his journeys. He was interested in how people lived, what kind of food they ate, their housing conditions, and their cultural values.

The Linnaeus tradition of combining passionate interest and erudition in biology with concern for social and cultural values is not only a source of inspiration for Scandinavian scholars and scientists, but it has international significance. One might add the value of also acknowledging the limits of biological understanding as an explanation of complex human behavior and social phenomena. This, however, is not part of the Linnaeus heritage. He was too much of an optimist and an ardent adherent to the faith in progress that characterized science in the eighteenth century. The respect for the limits of science and circumspection with regard to what can be rightfully claimed as knowledge is Kantian. As Frängsmyr observes, Linnaeus was not a man of the Enlightenment in the philosophical sense (2).

Scandinavia is rich in natural resources, with long-standing traditions in fishing, forestry, and agriculture. As may be expected, plant and animal breeding have become focal points for strategic developments in biotechnology. Strategic research programs in many areas of biotechnology range from basic research in gene technology and protein engineering to the application of the new biological tools in agriculture, forestry, fishery, and medicine. As the international projects for the mapping of the human genome approach completion, major efforts are being made to develop technological platforms for understanding the function of proteins encoded by the discovered genes. Bioinformatic tools are being developed in order to help scientists at universities and in the biotech industry make use of the results in molecular biology and information technology.

Finland, Norway, and Sweden are well known for their large forests and their timber exports. Accordingly there is a special emphasis in these Scandinavian countries on the development of forest biotechnology. There is a chain of research groups in the universities and in the forest industry working on the biological production of forest biomass and tree fibers in cooperation with groups interested in the utilization of tree fibers for pulp and paper production. Plant biotechnology is the field in which the application of the research results most often meets the general public. The development of photosynthetic starch utilizes familiar products such as barley and potato. The use of transgenic tools in order to produce plant oils and fats that can replace fossil products are other examples generally accepted by the public.

Genetic research and the general use of biotechnologies have become intrinsic to many fields of medicine, in both clinical and nonclinical contexts. Genetic intervention has become a continually expanding concept referring to medical genetics as practiced by clinical geneticists, to laboratory pathology and clinical chemistry, and to many medical subspecialties in between. A number of initiatives in Scandinavia in genetic medicine with solid links to industry and academy have been taken in fields such as genetic diagnosis, gene therapy, pharmacological genomics, drug development, and nucleic acid research. One goal has been to open new avenues for the development of vaccines against viral, bacterial, and parasitic infections and their immunopathological consequences.

For centuries the populations of Finland, Iceland, Norway, and Sweden have been relatively homogeneous. Until the latter half of the twentieth century, immigration to these countries was rather limited. As a result many parts of these countries may be characterized as genetically isolated. This fact, together with the long-standing tradition of keeping records of the citizens in church books, in national health registers, and through social security numbers, has provided a strong impetus to research in population genetics and genetic medicine.

Universities in Scandinavia are governmentally funded, but close collaboration with industry in joint research and development structures is well established. Many companies take part in cooperative efforts with scientists and scholars at the universities. The figures vary among the Scandinavian countries, but it is estimated that as much as 30 to 60 percent of research funding at the universities comes from nongovernmental sources. This situation has given rise to an ongoing ethical discussion in the scientific community with industry and public authorities on the conflict of values related to vital research in medical and pharmaceuticals. The scientific community firmly upholds a principle of openness, arguing that research results should be made public for two reasons. First, it should be available to other scientists for them to build upon in their work. Second, accessibility to the results ensures a critical scrutiny of methods and scientific claims. With regard to clinical research, however, the universities lack the commercial means necessary for bringing scientific results into medical application in the form of new drugs and new treatment. In the interest of patient seeking cures, therefore, it seems that the much-celebrated principle of openness must be reconciled with commercial interests related to the seeking of patents (or immaterial rights). Accordingly, it has become increasingly common for university departments to sign contracts with industry in which they agree to postpone publication of results in order to secure funding for clinical and nonclinical research in biotechnology. The issue is not settled, however, and from time to time heated debate occurs over how to balance public and commercial interests in an ethically acceptable manner.

PUBLIC CONCERNS: WHY? OR WHY NOT?

Several surveys in the Scandinavian countries have revealed a skeptical attitude toward biotechnology among the general public (3–5). The average Scandinavian citizen has lower expectations of positive effect on everyday life of biotechnology compared with the average citizen in Europe. Significantly, however, public perception varies depending on the kind of biotechnological application involved. Genetic medicine receives the highest support, followed by the use of biotechnology for food production and plant and animal breeding.

There may be several explanations for Scandinavian skepticism toward biotechnology. There is a long-standing tradition of public environmental concern that may explain public resistance, at least in part. The general public wants justification in terms of likely benefits for society at large, as well as assurances concerning safety issues, before they approve of new technology. There have been rather frequent calls for moratoria on implementation, pending investigations into the consequences of biotechnological applications for different sectors of society. Recently a moratorium was proposed in Sweden regarding xenotransplantation. Proofs of estimated benefits and well-founded assurances of safety claims were demanded before a new technology could be accepted. This was what had happened with nuclear energy technology, and it seems to apply in biotechnology as well. While people in other regions of the world may be more accepting and open-minded, Scandinavians are inclined to ask why instead of why not, when confronted with this new technology. In the United States it might be the other way around (6).

The public surveys conducted in Scandinavia demonstrate that the common assumption that more information about biotechnology and its applications will result in a more favorable opinion toward this technology is false. Both scientists and industry often consider lack of knowledge to be the big factor behind low acceptance figures for biotechnology. A European survey from 1993, however, followed by a similar survey done in Norway in 1995, found high levels of knowledge together with low degrees of acceptance (3,7). More information, according to the analyses of these surveys, means more nuanced opinions among people, who are able then to make their own judgments about the various biotechnological applications. Applications within medicine are often highly regarded, whereas applications in the animal-breeding industry or in the production of genetically modified food products are met with much skepticism. According to the surveys, people have fundamental values that remain unchanged despite the availability of more information. Those who are skeptical from the start might well change their arguments, but they will not so easily change their attitudes. Nonetheless, it remains to be proved that there is no correlation between basic knowledge in biology and attitudes toward biotechnology. A common finding in the Scandinavian surveys is that within the population knowledge of biology, in general, and of molecular biology or genetics, in particular, is low. This may not be unique to the Scandinavian countries. Research and development in biotechnology challenges traditional biological concepts of the educated person. The skeptical attitudes toward biotechnology may be tied to old ideas about the biological world, ideas that have been made obsolete by new findings.

In Scandinavia opponents of biotechnology are often found among political and activist groups working with environmental issues. There are two issues that have galvanized resistance toward biotechnology and may be related to an insufficient knowledge of biology or to an outdated understanding of biology. The first deals with the view that natural ecological systems are fragile. The second takes up the idea of the sanctity of a species.

Value surveys among young people show a strong inclination toward environmental concerns (8). Fundamentally the concern for protection of the environment is connected with a resistance to biotechnology. Behind the resistance, there is a belief that the creation of transgenic plants and the release of genetically modified organisms will destroy the natural ecological balance, a balance that is said to be very fragile. Opposition to biotechnology is then an intrinsic part of a concern about changes to the natural ecological systems that must be based on a careful examination of likely consequences to the conditions of a specific ecosystem. This is not a controversial point. However, the more fragile the natural ecological system is, the more strictly this principle must be interpreted and applied. Anyone who has seen the local ecological effects of a discharge of an oil-tanker or who has seen how several plant and animal species have disappeared from the flora and fauna will notice that the ecological balance is very fragile. Against this background, the principle of caution must be applied in a very strict sense. But it is not clear that this is always true in the larger perspective. Seabirds die, and sea plants and sea microbes die from oil contamination, but the ecological system has recuperated rather quickly. Ecological systems may be vulnerable in one sense, but there is good evidence that they are robust even after devastating attacks on their balance (9). At the level of the ecosystem, it seems really not to be a matter so much of whether one species or another disappears but that the overall life-maintaining capacity must prevail. Ecological systems have further proved to be self-preserving in the sense that they do not easily admit new species to be created nor allow modified species to survive the complex steps of an organism's reproductive cycle. Against the background of this biological evidence, one can argue that nature as such is not fragile, and therefore the principle of caution should not be applied in a very strict sense. Depending on which stand one takes regarding the fragility of nature, one could have a different opinion regarding the release of genetically modified organisms in nature. If the biological knowledge of the dynamic capacity of ecological systems is communicated, acceptance figures related to biotechnology at large may improve, even if specific applications might be resisted for good biological reasons.

Respect for the natural boundaries among species seems to be the basis of the line of argument taken by opponents of the production and use of transgenic animals and plants for research, new food, or new medical substances. This view also sees nature as fragile and may be likewise based on a limited knowledge of biology. Aristotle was the first person to suggest that each species is determined by a specific idea. Aristotle's starting point was the Platonic theory of ideas, but he rejected the theory that ideas exist independently of the sense world. For Aristotle ideas are found in the phenomena of nature. They are present within the phenomena as teleological forces. Each species carries a fundamental purposiveness present as a formative power, a purposiveness that determines its characteristics and its relationships with other species. This fundamental purposiveness cannot be changed. Human beings must instead be attentive to this inner formative power of nature. Here one might recognize a certain Aristotelian inspiration in the opposition toward biotechnology that asks the scientists to

keep the boundaries of species sacrosanct (10). Research in plant and animal biotechnology entailing the creation of new transgenic organisms does not respect natural borders such as species barriers.

The Aristotelian conception of a species, however, has long been obsolete. After Gregor Mendel, the essentialist concept of species was replaced by a purely statistical concept. A species is the sum of an arbitrary selection of characteristics. A species does not carry an inner purposiveness but has a basis in a statistical description of its biological or practical purpose (11). This biological fact about life challenges the popular view held by many Scandinavians that the differences among species are sacred and must not be transgressed.

However, the more prevalent view of nature is that the present state of balance must not be disturbed. Humanity is not entitled to manipulate the genetic basis of life in cells. Among the general public, the ethical arguments are seen largely to respond to the idea of a normativity in nature. Particularly among the younger population the belief is that there is a "natural order of things" to which humanity ought to adjust (12). The values of the younger population reflect concerns about animal welfare and frequently refer to animal rights. Animals are believed to have natural rights the same as human beings. This attitude represents a shift in the value system of Scandinavia. Skepticism about biotechnology can be explained therefore, at least in part, by reference to beliefs of the kind described. Surveys in other parts of Europe, however, indicate that distrust of the biotech industry is based on its unwillingness to assume responsibility for environmental and safety concerns (13,14). Consumer organizations have pointed to the reluctance of the food industry to provide information to consumers on genetically modified products. Added to that is the distrust among the general public of the capacity of regulatory authorities to monitor these developments.

BIOBANKS AND THE DUAL INTERESTS OF THE CITIZEN

The Scandinavian National Health Service has increased dramatically the use of registers. Health information has long been available in the form of cancer registers, disability registers, cause-of-death registers, and health service registers. With the aid of social security numbers, these registers have proved to be valuable in social medicine and in epidemiological research. Developments in DNA research have brought to the register concept now further health information in the form of tissue cultures, tissue sections, and blood samples. The rise in the number of biological information banks, or biobanks, has become the focus of several governmental investigations in the Scandinavian countries. Denmark has taken the lead in proposing legislation to protect sensitive information and the value of privacy that are at stake in this practice (15).

The Scandinavian PKU (phenylketonuria) registers and biobanks are familiar to the general public, since a blood sample is taken from every newborn baby. During a workshop organized by the Nordic Committee on Biobanks in 1997, Bent Nørgaard-Pedersen from Statens Seruminstitut in Copenhagen described the development and potential of this kind of register (16). In Denmark, a nationwide screening of newborns for PKU has been carried out since 1975. Filter paper blood samples are taken 5 to 7 days after birth, and Guthrie blood tests are used for the analysis. The parents are informed about the sampling and the storage of the samples. They have the option of declining on behalf of their newborn babies, essentially to exercise an informed refusal. The agenda of the biobanks is to store laboratory and clinical data as well as the filter samples for future research. The biobank provides the valuable data needed for (*1*) diagnosis and treatment of phenylketonuria, (*2*) control of previously performed analyses, (*3*) quality assurance for diagnosis, (*4*) new analyses, in order to check for other diseases, and (*5*) research projects using biochemical, genetic, and environmental marker analyses. The register has been approved by the Health Ministry. All research projects using material or information from a biobank in Denmark must be approved both by a research ethics committee and, in special cases, by the national data surveillance authority.

Ethics committees play a central role in the regulation of the use of the biobanks for research purposes in all Scandinavian countries. They have a difficult task to strike a balance between the values that are at stake. To understand this function, a distinction must be made between two fundamental citizen concerns. On the one hand, the individual citizen as a potential patient has interest in the efficient storage and use of the biobanks as tools for new medical treatment and for the development of new drugs. From this viewpoint it is not good if one pharmaceutical company obtains exclusive rights to, and therefore a monopoly on, the information in a biobank. This would prevent other scientists and companies from working with the material and posing other scientific questions of potential interest for the health and well-being of the citizens. On the other hand, if a company is denied exclusive rights, it may not find it worthwhile to invest in the first place. Since the cost of research and development in the field of biotechnology greatly exceeds what most governments can afford to invest on their own, such a policy would not be beneficial to actual or future patients.

It is a difficult and delicate task for Scandinavian governments to find an ethically acceptable balance between these two extremes. The costs involved are also a challenge for the scientific community, health professionals, and the health authorities. They have yet to agree on efficient procedures for storing, sharing, and distributing biobank samples. Without rules and guidelines that take into consideration the interests of patients (actual and future), scientists, universities, and industry, there is a great risk that the doctors and scientists who control the freezers and the drawers containing the samples will not be able to cooperate and coordinate their efforts, both within and across national borders.

Against the interest of the citizen in efficient stewardship there is a no less important interest in protecting his or her integrity. The individual citizen must have sufficient safeguards to guarantee that the information contained in

the samples is not used in a way that is harmful to him or her. A problem is that no one yet fully understands the potential for the abuse of knowledge yielded by the medical information contained in tissue samples combined with hereditary and environmental factors. A particular problem is that the information acquired and processed is of relevance not only for the individual who is the source of the sample but also for genetic relatives of this individual. A stumbling block in the ethical discussion of biobanks is the formulation of necessary and sufficient rules of informed consent.

Article 22 of the Convention on Human Rights and Biomedicine by the Council of Europe from November 1996 states: "When in the course of an intervention any part of a human body is removed, it may be stored and used for a purpose other than that for which it was removed, only if this is done in conformity with appropriate information and consent procedures." This decision of the Convention has been the focus of intense discussion in Scandinavia in the effort to create ethically responsible legislation on biobanks. If the rule of informed consent is taken too rigidly, much of the epidemiological research will be precluded, with the consequence that advances in health improvement dependent on that knowledge will be lost. On the other hand, it must be acknowledged that the information gathered about the individuals might violate their integrity.

There is reason to believe that Scandinavia's long experience in providing medical benefits for patients by using health information registers will facilitate the application of a nuanced rule of informed consent that is sensitive to the values at stake for all concerned parties. In cases where no issues of integrity are at stake, or are inconsequential to the individual who is the origin of the sample, and the risks of harm are negligible, the consent procedures may be conducted in accordance with health and well-being as the primary objectives. The Danish model of informed refusal might be appropriate for some research protocols. In other cases, when more is at stake for the individual from which the sample has been taken, stricter rules, including written informed consent procedures, might be appropriate. If information and consent procedures are formulated too rigidly, they may be detrimental to the individual that the convention seeks to protect. There is a need for different information and consent procedures for different research and medical practices (17).

THE CAUTIOUS LEGISLATIVE APPROACH

Legislation affecting biotechnology is not the same among the different Scandinavian countries. Norway has enacted strict regulation. Sweden appointed a Gene-Ethics Committee as early as 1982, and its task was to conduct an inquiry into ethical, humanitarian, and social issues arising from genetic engineering. The report was completed in 1984 (18). After several years of public discussion, a law restricting research on fertilized human eggs was passed in 1991 (19). It stated a time limit of up to 14 days when research can be done on fertilized human eggs, and it allows eggs to be frozen and stored for up to one year. The storage time limit was later extended to five years (20). With some variation, there are now similar regulations in the other Scandinavian countries. The Swedish law is unique in one important aspect. The 1991 Swedish law not only prohibits the implantation of a fertilized egg that has been subject to experimentation, it also rules out all kinds of experiments directed toward altering heritable characteristics. Germ line gene therapy cannot be practiced; neither can it be studied for a potential future application. The law has prohibited the development of this research, and as such it is unique both in Scandinavia and presumably the rest of the world.

Laws have also been passed which regulate plant biotechnology and the release of genetically modified organisms (GMOs). On the whole, however, there have been relatively few attempts to regulate the field through legislation. One is given the impression that Scandinavian parliamentarians and governments do not want to create special legislation for biotechnological research and development. They first try to apply existing regulation for the safety of patients within the health care Acts or, with regard to ecological concerns, in the environmental acts (21). The Scandinavian countries also have long traditions of ethical review provided by specially appointed scientific-ethical committees and of public ethical debates. The scientific-ethical committees are well regarded and they are often asked by the legislators to take on a large responsibility in analyzing and judging the acceptability of research. Finland has until very recently relied exclusively on a system of ethical committees, instituted on a voluntary basis by the scientific community (the Finnish proposition RP 229/1998 on medical research). Denmark has legislation that supports the ethical committee system; a characteristic is the large presence of ordinary citizen representatives on the committees, although the legislators do not direct the review process normatively. Both Norway and Sweden are fundamentally dependent on a voluntary system. In Sweden, however, the recent parliamentary commission on research ethics has proposed that there should be a law stating that research on human subjects or human tissue should be the object of examination and approval by a research ethics committee from the university in question (22). In summary in the Scandinavian countries, legislation is believed to be too blunt an instrument for use on biotechnology, since developments occur at a rapid pace and new scientific facts are produced in an unending flow.

SPACE FOR SELF-REGULATION

Now and then there is public demand for stricter regulation. It turns out that the balancing mechanism is most often more moderate legislation and self-regulation on the part of scientists and industry. Part of the explanation behind this mechanism in the Scandinavian countries is the readiness of scientists to go public and express their own moral concerns. Until very recently, there have been few animal rights activists engaged in these activities such as in other parts of the

world. The American scientist Andrew Rowan (personal communication), a writer on the science and ethics of animal research, has suggested a plausible explanation for this difference (23). Rowan has noted that scientists in Scandinavia went public and expressed their moral concerns with regard to animal research almost from the start. They invited representatives of nongovernmental organizations to a public dialogue on the means and ends of scientific research. These animal ethics discussions led to review by specially appointed ethics committees that included a substantial number of lay members (24). The scientists expressed concern about animal welfare, but they could also explain the necessity of using animals as experimental models in order to provide cures for both humans and animals suffering from diseases. Thus the scientists achieved two goals: they brought ethical and policy issues related to research into the public debate, and they secured self-regulation for the scientific community.

The willingness of scientists and the biotech industry in Scandinavia to assume the moral responsibilities associated with a certain latitude for self-regulation can further be seen in the area of animal breeding and husbandry. Over many years, there has emerged a Nordic profile with regard to breeding goals in which the focus is not only on production traits but also on efforts to stabilize or improve the genetic level of functional traits related to animal welfare (25). According to this breeding ideology, increased birthweight of calves is not a value in itself, but must be related in a significant way to the health and well-being of the animals. Thus it comes as no surprise that the "Belgian Blue" (known as the monstrous bull because of its extremely large muscles) has met with great resistance not only from the public but also from the breeders in Scandinavia. Health, calving performance, quality of udder and teats, and fertility have long been vital breeding goals in addition to production traits.

Many scientists active in biotechnology research and development in Scandinavia seem to act in accordance with a maxim that has a certain Kantian ring to it (10). The maxim is general in nature, and does not specify any concrete goals of action. It is here suggested as the codification of a long tradition of moral thinking in bioscience and is also reflected in regulations created by the public authorities monitoring development in this field. Its role is as an aid in sorting out the value conflicts related to specific proceedings and applications of bioscience. The maxim may be formulated thus:

> Act in your biotechnology research and development so that you protect the health and well-being of human beings and animals; minimize their suffering; protect biological diversity; and make use of natural resources so that justice prevails and a contribution is made to a sustainable development.

PUBLIC CONSENSUS CONFERENCES IN DENMARK AND NORWAY

Among the Scandinavian countries Denmark and Norway have created their own ways of including public opinion in dialogues on biotechnology. The usual form a dialogue takes is for the bioscience community to engage the public in different activities related to popular science. These activities are important means for bridging the confidence gap between scientists and the public, but they are not enough. What is needed is a dialogue where the questions of the public are allowed to set the agenda and direct the discussion. This is what has been established in Denmark through the Danish Board of Technology for many years, and has recently emerged in Norway under the auspices of the National Committees for Research Ethics and the Norwegian Biotechnology Advisory Board. The early experiment of Denmark have been described and discussed at length within the European consensus conference context (26). These conferences are described as meetings that enable technology assessments to be made by an expert panel and a panel of concerned citizens (27). Issues like gene therapy, the handling of genetic information, and genetically modified food products have come under intensive discussion. The panel of citizens directs the proceedings and decides what questions to ask and what experts to engage. This panel then puts together a consensus report of their opinions regarding the questions discussed.

THE BILL ON MEDICAL DATABASES IN ICELAND

Iceland has passed an Act on a Health Sector Database and a Bill on Medical Databases that are particularly interesting for Scandinavia. The Icelandic population (270,000) is considered to be optimal for such a database for three main reasons. It is a homogenous population, health records are good and reliable, and the Icelanders are cooperative and positive toward research. These three features taken together are, to a great extent, shared by Finland, Norway, and Sweden.

The Health Sector Database, which draws on information from the entire Icelandic population, may be consulted for the purpose of discovering new drugs, developing new or improved methods for prognostic or diagnostic purposes and treatment of diseases, seeking the most effective solutions in the operation of health systems, or for medical reports or other comparable purposes in the health sector. The Bill elicited severe criticism from medical doctors, researchers, ethicists, and lawyers. The Ethics Council of the National Director of Health analyzed the implications of this Bill for the patient's right to privacy and for the relationship of confidentiality between doctors and patients. The Council has also worked on the ethical aspects of the intended bill on biosamples.

Public acceptance of biotechnology in Iceland is quite high. The criticism comes rather from professionals: the Bill on Medical Databases met with substantial resistance in the scientific community. A national survey in 1998 showed, however, that 75 percent of the Icelandic population is willing to have depersonalized information from their health records in a central database available for biotechnological research (V. Arnason, personal communication) (28).

ETHICAL, LEGAL, AND SOCIAL ASPECTS OF GENOME AND GENE TECHNOLOGY RESEARCH IN SWEDEN

A safe and wise implementation of genetic engineering and biotechnology in different sectors of society requires the

cooperation of scholars working in well-developed multidisciplinary research environments. In 1999 the Swedish Foundation for Strategic Research initiated a national research program with the aim of stimulating research focused on the ethical, legal and social implications of genome research and its implementation in different sectors of society (29). The following areas of research or fields of interest have been identified as examples of areas and fields that will be addressed in the program.

Public Perceptions and Values

It is not enough to be able to master the new gene technology tools. It is also important to understand the values and the formation of norms in the society where the new technology is integrated. As described at the beginning of this article, this perspective is part of the Linnaeus heritage. Values, attitudes, beliefs and worldviews reflect the larger impact of gene technology. Developments on genetic technology have challenged established concepts of health, illness, disease, and human integrity. Changes in concepts and changes in popular notions about these concepts are to be investigated. What are the underlying motives and views supporting certain beliefs about health and disease, about being human, or about the relationship between humans and animals? How do people classify their views? What are the general perceptions and evaluations of risks?

Genetic Medicine

Advances in molecular biology have provided medicine with powerful tools for diagnosis and for monitoring diseases and their treatment. Gene therapy may still be years away from becoming established medical practice, but several clinical trial protocols have been approved. The most urgent problems described in the research programs are related to genetic diagnosis and the handling of genetic information about individuals and families. The communication of risk and risk-related issues in relation to single-gene disorders is also an important area for research. Clinical practice is in need of the contributions of psychologists, anthropologist, ethnologists, and theologians who have the skills to map the wide spectrum of individual responses to the implications of genetic medicine. Polygenic and multifactorial conditions must be addressed besides the problems associated with the development of treatments for common genetic disorders. In this regard there are many questions about the rules and guidelines for the involvement of human subjects in clinical trials and related research, and for the storage and utilization of tissue samples in genetic research. As gene therapy gives way to cell therapy and the use of stem cell biology provides opportunities for the replacement of organs of the body, there will be calls for ethical and psychosocial interpretations of this development. If xeno-transplantation is considered, to what extent is implantation of an animal organ a violation of human dignity? What does it mean for human identity?

Genetic Engineering in Agriculture, Forestry, and Fishery

Agriculture, forestry, and fishery are areas in which gene technology will enable the development of new characteristics and breeding traits with a strong economic potential for big industry. The need is for research that focuses on practical problems encountered by scientists, industrialists, and policy makers in this area. Among the issues in need of attention there are many problems relating to four areas: (*1*) the intentional release of transgenic plants into the environment, (*2*) the introduction of genetically modified foods into the market place, (*3*) transgenic animal research, and (*4*) the impact of agriculture and plant biotechnology on developing countries.

From an ethical perspective, a society free of risks is neither possible nor desirable. Vital values in terms of survival, better food, health, and well-being are at stake, and these values have to be weighed and balanced against each other. The approach to risk assessment is expected to be normalization of risks (i.e., toxicological, allergenic, health hazards, ecological) through a comparison of risks associated with gene technology with the risks posed by conventional and future technologies for breeding and development.

In risk assessment there are six general ways of considering what can be expected. Preferably these questions will be taken together in regard to multidisciplinary projects.

1. What is the risk? (Potential risk identification)
2. How likely is the risk to occur? (Quantifying the probability of occurrence)
3. What is the severity and extent of the effect if it occurs? (Quantifying the effects)
4. What are the expected benefits?
5. Is the risk acceptable? (Normalization of the risk and risk–benefit analysis)
6. How important is risk assessment for different actors?

Implementation of Gene Technology

No one disputes the fact that gene technology will constitute an important economic sector in society. However, before the development of gene technology from science to commercialization can occur, several steps must, be taken. Even knowledge on how to go about this process is incomplete. On the one hand, gene technology could provide economic growth by stimulating the development of new industries. On the other hand, no companies have yet produced services and products of the anticipated quality. The gap between optimism and slow reality points to an equally important question on how companies that can harm the environment to create new products can achieve economic growth. Then there is still the problem of access to and use of genetic information, both commercially and noncommercially. All these concerns involve questions of intellectual property, questions of confidentiality and privacy, and questions of equity.

Within plant biotechnology and within pharmaceuticals, there has been a rapidly growing concentration of control in a few hands. Large corporations have bought out small companies. The issue of labeling is soon becoming a nonissue. Nongenetically modified soya is now more a thing of the past. The need is becoming urgent to clarify what is happening in biotechnology with regard to both

the scientific developments and the economic regulation of corporations taking over the developments.

The funding of plant and animal biotechnology needs to be investigated, likewise the funding in the production of medical products and diagnostics. Pharmaceutical companies have made enormous investments where there are indications of possible breakthroughs. Human diseases are expected to be treated with products not yet foreseen. Who will pay the bill? Who will be able to afford the new treatments? What will be the prioritization scheme in the health care sector? What price will be paid for success in biological and genome research?

GENETICS IN DIALOGUE WITH OTHER DISCIPLINES

It has long been obvious that there is a genetic history to many human diseases. Recent research, however, indicates that there is also a genetic component in more complex human behavior. If it can be proved that language behavior and learning ability express hereditary variability, the consequences will be great for established theories within disciplines such as linguistics and educational research. The old question about nature and nurture that has been so vividly discussed in relation to evolutionary theory is reactivated. Of particular interest is the development in brain research in which complex phenomena such as memory function and emotions may soon be comprehensively described in chemical terms. How is human society going to survive in a culture in which everyone is aware of the genetic components of one another? No doubt, in these new emerging fields of research geneticists, evolutionary theorists, linguists, philosophers and scholars in educational theories need to collaborate on such perplexing issues.

CLOSING REMARK

Clearly, any nation hoping to compete in the international economy must bring itself to the cutting edge of research and development in biotechnology. Without an investigation of the ethical and social implications, there is the danger that political decisions and legislation will be premature and not based on good, strong knowledge. There is also the risk that vital values related to health and survival will be neglected. In all five Scandinavian countries, there is a growing interest in the ethical implications of new technology. A number of ethics committees have been formed at various levels. Questions about the ethical implications of new technology are also recurrent themes in the media and in parliamentary debates. An interesting phenomenon in these discussions is that saying no to new technology is often believed to be of greater moral significance than saying yes. "Better safe than sorry" and "Safety first" seem to be the primary guiding principles of the debate on biotechnology. To be sure, when important issues are at stake such as survival, health, and well-being, there is great moral responsibility assumed in saying no or yes. A society free of risks is neither possible nor desirable, since, when vital values are at stake, these values must be balanced against one another. A "no" to biotechnology may deprive society of enormous benefits from research in bioscience and biotechnology. There may be good reasons to say no to certain problematic innovations. However, whether one says yes or no, this should be done only after a careful risk assessment and a weighing of the pros and cons.

ACKNOWLEDGMENT

I am grateful to Peter Sandoe, Per Sandberg, and Vilhjalmur Arnason for providing valuable background information and texts regarding ethical, legal, and policy issues in their countries. I am also grateful to Knut Erik Trany and Sharon Rider for valuable comments on an earlier version of this article.

OUTLINE

INTRODUCTION

The 1980s were a turning point for biotechnology. Prior to 1980, biotechnology applications in Switzerland were limited to the industrial sector and a few, pioneering academic institutions such as the Swiss Federal Institutes of Technology in Zurich (ETHZ) and Lausanne (EPFL). In the 1980s, more and more leading Swiss institutions and Small and Medium size enterprises (SMEs) began using molecular biology and genetic engineering techniques for all types of applications in the life sciences. It soon became clear that the potential of biotechnology to benefit society was immense, if provided with the proper environment for its development.

Various groups and organizations in Switzerland, such as the Swiss Academy of Technical Sciences, the Swiss Coordination Committee for Biotechnology, the Board of the Swiss Federal Institutes of Technology, and the State Secretary for Science and Education, launched several proposals in order to induce national efforts for the promotion and development of biotechnology. In 1989, the Swiss Science Council (SSC) mandated the Swiss Coordination Committee for Biotechnology to perform a comparative study on national and international biotechnology R&D programs, their goals and development strategies. Swiss science policy makers used this document (1) to lay the foundation for the first nationwide biotechnology program, subsequently approved by the Swiss Parliament and initiated in 1992. This was the beginning of the Swiss Priority Programme Biotechnology (SPP BioTech).

PAVING THE WAY FOR THE DEVELOPMENT OF SWISS BIOTECHNOLOGY

Organization and Goals of SPP BioTech

SPP BioTech is financed through the Swiss National Science Foundation (SNSF). Its goal for 1992 through

2001 is to ensure the international competitiveness of Swiss biotechnological research and development (2,3). The program is applications-oriented, and it aims to bring basic and applied research closer to the development stage by encouraging synergistic collaborations among universities, research institutes, and private industry. Fields of biotechnology where Switzerland already holds a strong position are strengthened, while fields that need encouragement are given an opportunity to fortify their bases, through the setting of relevant research priorities that ease technology transfer in Switzerland.

From among the broad range of modern biotechnology applications possible, it would be impossible for a small country like Switzerland to fund all activities equally. Therefore SPP BioTech has created a number of modules based on a thorough assessment of the national research capacity and was able to consolidate applied biotechnology research in Switzerland as listed in Table 1.

In its goal of strengthening biotechnological research in Switzerland, SPP BioTech has not neglected the peripheral activities necessary for bringing technology innovations into society. SPP BioTech supports scientific activities that use modern biotechnology to help achieve sustainable development and efficient use of resources in industrial processes and agricultural systems. The program also recognizes the important role of continuing education in biotechnology for young researchers, and funds are accordingly allocated for Ph.D.s, postdocs, visiting scholars, and junior group leaders. In addition the program includes a unit of study concerning biotech-related issues that have significant interest for the public.

The SPP BioTech program has prioritized addressing public concerns regarding applications in biotechnology in a timely and informative manner. The level of public acceptance for technology applications can determine the speed at which development proceeds in certain critical research areas. It is for this reason that the agencies BATS (Biosafety Research and Assessment of Technology Impacts), BICS (Biotechnology Information Center), and Unitectra (technology transfer) were created under the aegis of the SPP BioTech.

The research activities within the SPP BioTech gradually proceeded from ideas and goal-oriented basic research to practical applications of the achieved results. The program comprised three distinct phases with a total budget of approximately 100 million Swiss francs:

Table 1. Research Modules of the SPP BioTech

Processes for the production and purification of proteins for medical applications
Biotechnology: bioengineering and biocatalysis
Food biotechnology (started in 1996)
Bioelectronics and neuro-informatics
Biosafety research and development of biotechnology
• Biotechnology Information and Communication (BICS Agency)
• Biosafety Research and Technology Assessment (BATS Agency)
• Technology Transfer (Unitectra)
Biotechnology of higher plants
SPP BioTech education program

- *Buildup phase, 1992 to 1995.* Focus on applications-oriented R&D, by introducing collaborative ventures involving universities, research institutions, and industries; begin technology transfer activities in the transfer of products, methods, and services.
- *Consolidation and Extension of Collaboration with Industry, 1996 to 1999.* Continue applications-oriented research and concentrate on successful strategies; extend and intensify contacts with industry; motivate SMEs to join; speed up technology transfer (including the creation of new SMEs).
- *Harvest and termination (outphasing), 2000 to 2001.* Continue the most successful and productive projects; focus on development aspects and technology transfer in order to exploit the achievements.

Participation in SPP BioTech has also helped a large number of research teams find easy access to Framework IV Programs of the European Union (EU). The success rate for Swiss applicants (36 percent for the first call in 1995) was by far above the European average (26 percent).

Achievements and Impacts of the SPP BioTech

Through SPP BioTech there have been created centers of competence and nationwide networks for biotechnology research (see Figure 2). Biotechnological activities at ETHZ and EPFL have been strengthened. An Institute for Neuro-Informatics, is now jointly operated by the University of Zurich and the Federal Institute of Technology, Zurich.

Further SPP BioTech has provided support for bioelectronics research and applications of this technology for the development of biomedical equipment. There has been created a nationwide network for Swiss biosafety research on recombinant and "naturally" occurring organisms. Universities and government institutions are closely collaborating in the field of plant biotechnology in developing a more sustainable agriculture.

Since 1996, SPP BioTech has promoted innovative research food biotechnology for healthier and safer dairy products. Technology transfer between academe and industry has been facilitated and given a priority.

Research Network in Biotechnology

A significant part of modern biotechnology research at Swiss universities occurs outside of the SPP BioTech. A survey carried out by Unitectra in 1997 (4) revealed more than 300 research groups active in various fields. There has been estimated, overall, between 350 and 400 biotech-oriented academic research groups in Switzerland (see Table 2).

Funding of Research in Biotechnology

At present, there are three types of public funding for biotechnology research in Switzerland (see Fig. 1):

- Funding of basic research projects (individual projects) directly via the Swiss National Science Foundation (SNSF).

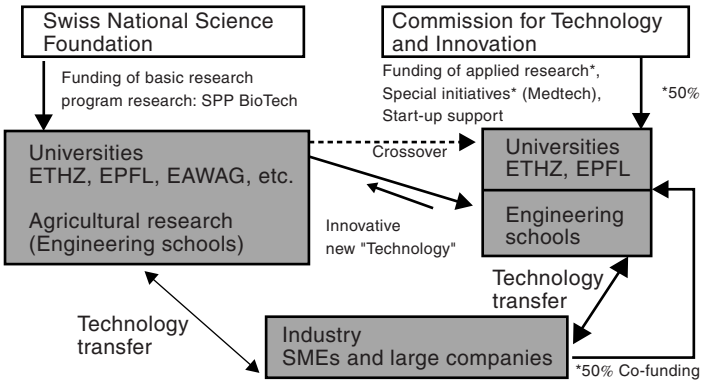

Figure 1. Funding, knowledge and technology flow.

Table 2. Main Areas of Interest of Research

Core area of nucleic acid technology (122)
Pharmaceutical biotechnology (for therapeutics and diagnostics) (69)
Agro/plant biotechnology (58)
Bioengineering, fermentation/reactor design (41)
Environmental biotechnology (27)
Bioinformatics (25)
Bioelectronics (23)
Biotransformation (22)
Biosafety (23)

Note: Number of research groups involved is given in parentheses.

- Funding of target-oriented program research (projects coordinated in units) via SNSF, with a strong emphasis on technology transfer at the precompetition level.
- Funding of applications-oriented R&D via the Commission for Technology and Innovation (CTI) (industry finances 50 percent of these projects).

In future developments of Swiss biotechnology, CTI will play a more important role. In 2001 SPP BioTech will be terminated. It can be assumed that a large number of SPP BioTech research teams will find new SNSF funding within the framework of the newly established National Centres of Competence in Research (NCCR), which are now in the evaluation phase. In the crucial attempts to organize smooth transitions, at present many researchers on SPP BioTech teams have already taken advantage of the extensive research network created by the SPP BioTech to access additional CTI and/or industrial funding.

USING RESEARCH RESULTS TO CREATE NEW JOBS

Technology Transfer — Universities Warming Up to Private Industry

The top researchers at Swiss academic institutions are a significant reservoir for of new inventions. Swiss academe thus provides opportunities for cooperative ventures with the private sector in the creation of start-up companies. This has been an important trend in the biotech industry worldwide, since many innovative concepts have emerged from the academic environment.

An example of the growing interest of companies in such ventures is the agreement signed in the fall of 1999 between Novartis, the Neuroscience Centre of the University of Zurich, and the Federal Institute of Technology Zurich. Under the agreement Novartis will fund research projects for up to 40 million Swiss Frances over a period of 10 years.

All Swiss universities are public. In recent years universities have further been given a high degree of administrative autonomy. In the course of these changes, ownership to all inventions resulting from research performed at the university has also been transferred from the state to the university. Corresponding laws are either in preparation or are enforced already, such as in Berne, Geneva, and Zurich.

Technology transfer has gained a lot of attention at universities in recent years and is strongly supported. Most universities in the meantime have established policies and technology transfer offices that support cooperative activities with the private sector, and provide support for faculty members on issues such as sponsored research agreements, the protection of intellectual property, licensing, and the creation of spin-off companies. Whereas technology transfer in the past was handled with mixed success by individual scientists, it is now being administered more professionally. Pragmatic and flexible guidelines for technology transfer are designed to facilitate interactions between academe and the private sector.

Increasingly academic researchers are considering the creation of spin-off companies as an interesting alternative or complement to their standard career paths. The high degree of entrepreneurial spirit among young academics is mainly due to the reduced job security in the large multinational companies that have all undergone significant restructuring in recent years due to the trends for globalization and the resulting mergers and acquisitions. Entrepreneurship at universities is even encouraged by various successful programs. A good example is Venture 98, a national business plan competition for university scientists organized by McKinsey & Company and the Federal Institute of Technology (ETH) in Zürich. More than 20 percent of the 215 projects submitted were in the field of biotechnology and life sciences, and they have spawned a number of companies. A similar subsequent program called Venture 2000 was launched in November 1999.

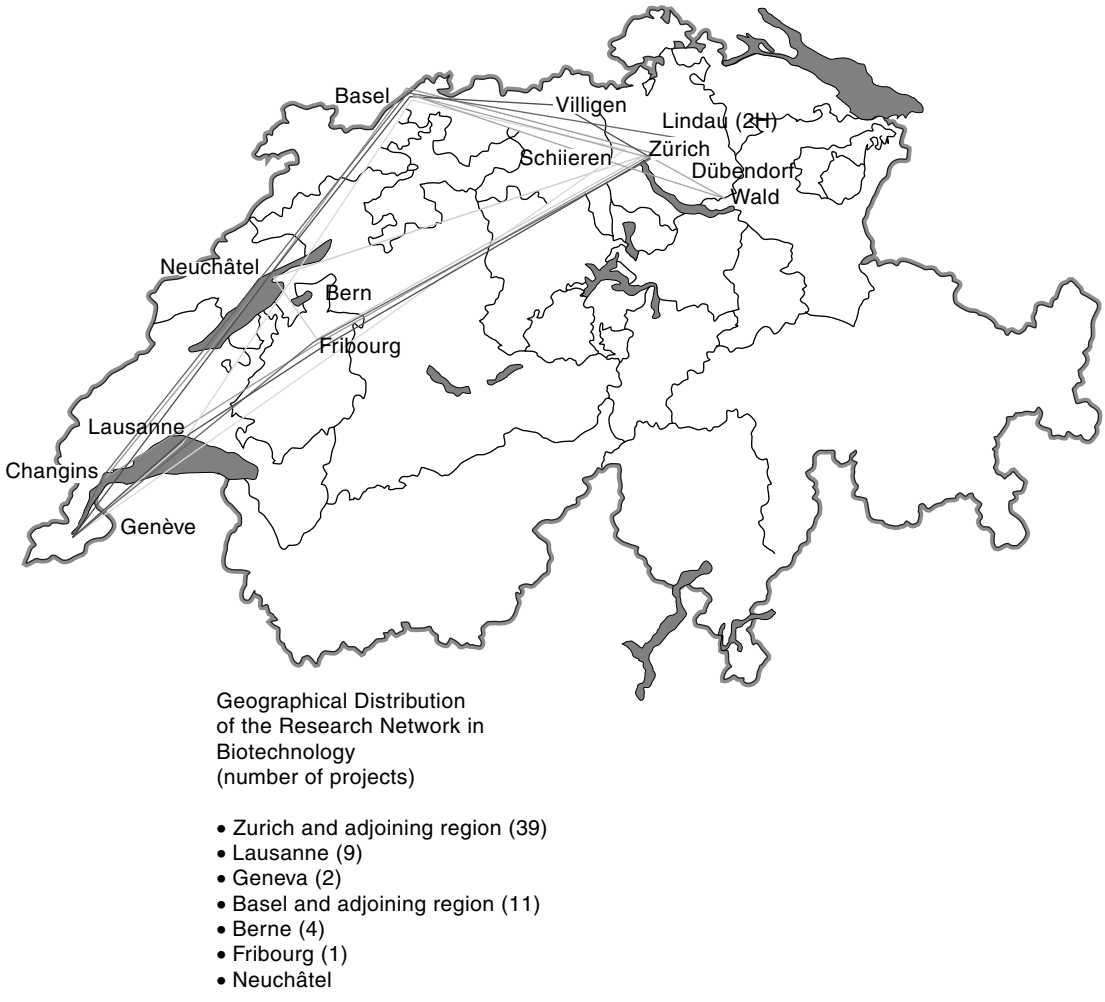

Figure 2. The Swiss Priority Programme. SPP BioTech was launched in 1992 with public funds. Six research areas in biotechnology and complementary activities in continuing education, information, communication, technology assessment, and technology transfer were designated to receive state support over a period of 10 years. The objective of the SPP BioTech is to consolidate strategic, applied biotechnology research in Switzerland.

Diversified and Rapidly Growing Swiss Biotech Industry

With a long tradition of economic strength in chemistry, Switzerland has added considerable expertise to bioscience in the past decades. The leading multinational drug companies Novartis, Roche, and Ares-Serono have, however, rather obscured the view of a very dynamic entrepreneurial bio-industry of small and medium-size enterprises. Unitectra, the technology transfer organization of the universities of Berne and Zurich and of the SPP BioTech, recently conducted the second comprehensive review of modern Swiss industrial biotechnology. This survey was published in September 1999 as *Biotechnology Industry Guide Switzerland* (5). It includes companies that meet the biotechnology definition of the European Federation of Biotechnology (EFB).

> Biotechnology is the integration of natural sciences and engineering sciences in order to achieve the application of organisms, cells, parts thereof, and molecular analogues for products and services.

Overall, the new directory lists 234 companies compared to 177 in the first edition which was published in 1996. Half of the companies (117) are classified as biotech companies, that is their main business focus is on biotechnology. The other half (117) are "other companies," that is, enterprises where biotechnology represents only one segment of their activities.

Forty-five percent of the listed companies are manufacturers of biotech products in Switzerland, 30 percent are suppliers or distributors, and about 20 percent are service companies. The fields of activity of the various companies are listed in Table 3.

The majority of companies can be grouped in three geographical clusters. The Zurich area has 89 companies, the Basel area 74 companies, and the region around Lake Geneva has about 30 companies. The total number of biotechnology-related jobs in these companies is estimated at 6500 to 7000. This is more than three times as many as in the United States on a per capita basis. Behind these figures lies a typical feature of the Swiss biotechnology industry. In Basel companies are based around

Platform technologies	16
Reagents/biochemicals	29
Veterinary	2

Note: Some companies are active in several fields.

the chemical and pharmaceutical multinationals. In the Zurich and the Lake Geneva area academe provides the main impetus.

The new survey reveals a sharp increase in the number of entrepreneurial spin-off and start-up biotech companies created over the past three years. Without considering the numerous consulting firms, more than 40 new biotech companies were created. Two-thirds of these start-ups have a strong R&D focus mainly in the pharmaceutical area; the rest can be divided evenly into engineering and service companies, respectively. About one-third of the newly formed companies are typical university spin-offs, whereas others are spin-offs from large pharmaceutical companies. The high number of university spin-offs, in relation to the population and the number of universities, reflects the new entrepreneurial spirit among young scientists in academe. Moreover it also is the result of the increased support provided by various start-up programs.

Some examples of recent innovative start-up companies are:

Actelion has its focus of research on the endothelium, which constitutes the innermost layer of blood vessels and plays a role in cardiovascular diseases, inflammation, asthma, and many types of cancer. The aim of the company is the discovery and development of innovative drugs.

Biolytix is a young company located close to Basel providing services in the area of molecular biological analyses. It is specialised in the field of real-time quantitative PCR using state-of-the-art technology.

Biospectra develops and manufactures novel on-line analytical equipment and state-of-the-art automation solutions for fast bioprocess development and bioprocess optimisation.

Cytos Biotechnology, a spin-off company of the ETH Zürich, is developing new process solutions in the area of cell culture technology to optimise protein production. It also develops innovative solutions in other areas e.g. vaccines.

Modex Thérapeutiques is a university spin-off company based in Lausanne. Its focus is on new approaches to cell therapy for chronic systemic diseases, such as anaemia or diabetes. It plans to soon start with clinical trials on its first treatment regimen.

Prionics specializes in the detection of prions which cause BSE ("Mad cow disease") in cattle, Traber's disease in sheep, and Creutzfeld–Jakob disease in humans. It markets a bovine spongiform encephalopathy test for slaughtered cattle and sheep. Future R&D efforts also aim at prevention and therapy of prion diseases. Prionics was created as a spin-off company from the University of Zürich.

Zeptosens has its core competencies in the areas of advanced optical sensor and array technologies, bio-interaction analysis and bioassay design and development. It develops analytical platforms for the detection of analytes at extremely low concentrations. Typical applications include gene expression analysis, investigation of drug-receptor interactions, identification of bioactive compounds, and so on.

The rapid growth and development of the industrial biotech sector is confirmed by the annual *European Life Sciences* report of Ernst & Young (6). Although the absolute numbers in this report differ from the Unitectra survey because of slightly different definitions and inclusion criteria, the recently published report lists about more than 90 entrepreneurial life sciences companies (ELISCOs). This corresponds to an increase of 600 percent in a period of only three years (7).

The Association of Swiss Biotech Companies (AESB) established in March 1998 has already more than 100 member companies, mostly small and medium-size enterprises. It promotes biotechnology in the country and actively represent its members' interests in political and other circles. One of the AESB's essential goals is the facilitation of technology transfer between its members and universities. AESB will also advise foreign biotech companies looking for development opportunities in Switzerland.

FINANCE

Over the past decade Swiss industry has attracted considerable media attention through a series of biotechnology acquisitions and partnerships in the United States. This has been particularly true of large chemical/pharmaceutical corporations.

The new drive in Swiss biotechnology is reflected in the country's financial community. The last few years have seen the creation of a number of funds focusing on private equity and venture capital financing. There are currently more than 60 different funds operating in Switzerland and many of them explicitly seek opportunities in the biotech field.

Investments in venture capital in Switzerland reached 215 million Eurodollars in 1998, an increase of almost

300 percent over the previous year. About one-third of the 86 projects supported were in the seminal or early stage phase, another third in the expansion phase. Most of the investments went into the high-tech sector. A number of biotech and life sciences companies are listed on the Swiss stock exchange (Swiss Exchange, SWX). SWX has introduced a new market segment in summer 1999 especially designed to meet the needs of young companies (Table 4). This adds another exit opportunity for investors.

However, the main shortage currently is not in finance but in skilled management with experience in setting up and running high-tech start-up companies. A number of initiatives are set to improve this issue such as the CTI Start-up Program and the recent formation of a Swiss Business Angels Club.

SAFETY AND TRANSPARENCY WHEN INTRODUCING TECHNOLOGICAL INNOVATIONS INTO SOCIETY

Successful Launch of Swiss Biosafety Research Network

The safety of technological applications is a prerequisite to their introduction into society. Swiss policy makers have recognized the importance of a publicly funded program for carrying out biosafety research and technology assessment, and view this as a service to society. A special unit on Biosafety Research and Technology Development was created by the SPP BioTech to address the safety aspects of biotechnological applications. A national agency for biosafety research, the agency BATS, was also created to coordinate research projects on the biosafety of transgenic organisms, as well as hazardous, naturally occurring organisms (Table 5). The safety of transgenic plants has been an area of intense activity, for which there is considerable effort invested in safety research and the development of methodologies for the safety assessment of open biological systems (8–10).

Biosafety Research and Technology Assessment

Though important, safety is not the only criterion that is considered in evaluating technology applications. Decision makers in Switzerland rely on technology assessment (TA) for understanding the interrelationship of a technology or a product and society or its environment. In Switzerland, TA is coordinated by a central TA unit, founded in 1991, which was a time when the Federal Council and the Parliament decided that the Swiss Science Council (SSC) should develop a Swiss model for the assessment of the effects of technologies. In the field of biotechnology, the TA unit of SSC has coordinated several studies and organized a Publiforum, as the consensus conferences are called in this country. They are presently organizing a second Publiforum on xenotransplantation. The agency BATS is one of the partner institution of this federal TA program.

One example of a TA is a study that was carried out on the effects of potential widespread use of transgenic crops in Switzerland. This TA focused on the impact assessment in the ecological, toxicological, and economical dimensions (11,12). The culture of transgenic crops was compared to other agricultural alternatives, such as organic farming and integrated production, for each of the three impact dimensions mentioned. Another example of a TA project is a study of alternative agricultural production strategies for sustainability, based on ecological and economic indicators. From the information generated by this interdisciplinary effort, the existing scientific knowledge could be presented in a format that is useful to decision makers who define policy options related to transgenic crops.

Making Scientific Knowledge Available to Society

Access to reliable information is fundamental to good decision making on the personal and governmental level.

Members of the public require an adequate understanding of the meaning of new discoveries in order to make personal choices. Officials on all administrative levels need easily accessible knowledge and resources for the preparation of new legislation or for regulatory oversight.

The agencies BATS and BICS, granted by the SPP BioTech to provide information on all aspects of biotechnology, are both non profit and non lobby organizations. BICS publishes the unique Swiss quarterly review on Biotechnology, *BioTeCH forum*, available in a bilingual French/German edition. Other publications of BICS include facts sheets and brochures which are also available online and are a source of useful information not found in the media. The home page of the agency BICS allows the visitor an easy access to a vast selection of links covering all aspects of this field (13). The objectives of the Internet site developed by the agencies BATS and BICS are to (*1*) offer value-added knowledge on biotechnology impacts, and (*2*) pool and organize digital information for easy access (14). Contributors of information are research institutions, government agencies, and nongovernmental institutions. At this site the visitor can find information on a range of biotechnological applications. The information for the site is carefully gathered and checked for the quality of the source. In addition the retrieval of information is facilitated through a full-text retrieval system. Links are also given to other relevant sites. These sites are constantly being improved in order to serve the public better. A new feature of the *bioweb* site provides an interactive forum. Visitors to the site can discuss issues related to biotechnology with other citizens and a panel of scientists knowledgeable in the field.

REGULATORY FRAMEWORK AND PUBLIC DEBATE IN BIOTECHNOLOGY

Swiss Citizens Against a Ban on Genetic Engineering

Like their fellow European citizens, the Swiss are ambivalent about modern biotechnology. They have nevertheless acquired the distinction of being the first in the world to call for a national referendum, based on the complex technical and emotional issues surrounding genetic engineering. In June 1998 the Swiss were asked to vote on a constitutional prohibition of genetic engineering, therefore banning the use and patenting of transgenic animals and the deliberate release of transgenic animals, plants, or microorganisms into the environment. The political campaign leading to the vote lasted two and a half years and provided a unique opportunity for public and private organizations to hold informational meetings and public debates on the issues of genetic engineering. There was extensive media coverage of public debates, which helped to improve the overall public understanding of science, and to a significant extent, also the public acceptance for certain applications of genetic engineering. In the heat of the public discussion preceding the referendum, the Swiss Parliament also committed itself, in a motion called Gen-Lex, to enact a strict regulatory framework, in place of an all-out ban. On the day of the referendum, the Swiss people rejected a general ban on genetic engineering by a margin of 2 to 1.

At the time of writing, the Swiss government is still in the process of drafting the legislative framework regarding applications in genetic engineering. Nine existing laws pertaining to the various aspects of the use of genetically modified organisms (GMOs) and modern biotechnology are in the process of revision. Swiss legislation, based on the European Directives 90/219 on contained use of GMOs and 90/220 on deliberate release, has also introduced pioneering regulatory measures (14).

Prior to the drafting of the new legislation, a Federal Commission of Experts on Biosafety was created to oversee the use of GMOs. This was in the early 1980s, and the Commission followed the U.S. National Institutes of Health (NIH) guidelines on the safe use of GMOs. As a result, even in the absence of legislation, there have not been any abuses of GMO in Switzerland. In January 1997 a Swiss Expert Committee for Biosafety was created, as foreseen in the law on the protection of the environment and on epidemics. The role of this Expert Committee is to advise the administration regarding authorizations of field releases of transgenic organisms and on the drafting of the new legislation to encompass the newest knowledge in this field.

On November 1, 1999, three ordinances were enacted to regulate (*1*) the contained use of GMOs and pathogenic organisms, (*2*) safety at the workplace, and (*3*) the deliberate release of GMOs, including experimental field release or commercialization (15). Other aspects of genetic engineering applications are still not covered and are being hotly debated. In human medicine, these are genetic testing and xenotransplantation. Other contentious issues are liability insurance, intellectual property rights, and international trade, which must respect the guidelines of international agreements on trade and safety. The Swiss regulation for the labeling of foods derived from GMOs is similar to that of Europe. Labeling must be clear and unambiguous in Switzerland, with mention of the GMO origin, for example, in the list of ingredients. Chemically defined substances that are purified from GMOs and are free from traces of modified DNA or proteins do not have to be labeled. Switzerland was the first country in Europe to introduce, on July 1, 1999 (15,16), a threshold value of 1 percent for compulsory declaration. This means that any unintentional inclusion of a GMO equivalent during processing or transport of a product does not have to be declared, as long as the threshold is not surpassed. The threshold value of 0.5 percent for animal feed has also been legally accepted.

Although not legally prohibited, food derived from GMOs are deliberately kept off the shelves of department stores and groceries. No GMO-labeled product is currently sold in Switzerland because of the massive rejection by consumers of GMO-containing foods. The major food producers now ensure a sufficient stock from suppliers guaranteeing GMO-free crops. In addition environmental organizations act as watchdogs for the systematic monitoring of products suspected of containing unintended traces of GMOs. When a product tests positive for the presence of GMOs, it is withdrawn immediately from the shelves.

Swiss law does not prohibit deliberate releases, although a de facto moratorium currently exists in

Switzerland on the deliberate release of transgenic animals, plants, or microorganisms into the environment. In the spring of 1999 two experimental field releases were denied authorization by the Federal Administration despite the recommendations of the Commission of Experts on Biosafety to authorize the release, based on a thorough examination of safety. The final decision of the Federal Administration not to grant authorization was swayed by public opinion, which was against any type of deliberate releases of transgenic plants. At the time of writing, there has not been any field releases in Switzerland, experimental or commercial. Independently of this federal decision, the concluding opinion of a Publiforum on gene technology and food (June 1999) called for an official moratorium on the commercial cultivation of transgenic plants but not for experimental field releases. The discussion on how Switzerland will proceed in the future is still ongoing within the Federal Administration.

Ethics of Nonhuman Applications of Biotechnology

In Switzerland, public concern for the dignity of human and nonhuman organisms is taken very seriously. Switzerland is the only country in the world with a Federal Commission of Experts on Bioethics for the Nonhuman Applications of Biotechnology. The members of this Commission represent the various schools of thought in philosophy and ethics rather than lobby groups. This Commission works in conjunction with other Expert Commissions for biosafety, animal experimentation, and human applications of biotechnology (at the time of writing, this commission does not exist yet but is planned). The role of the Federal Commission on Bioethics is to advise the Swiss authorities and to provide them with criteria for a comprehensive evaluation of the ethical dimension of genetic engineering applications on nonhuman organisms. The elaboration of evaluation criteria in this new field is a fascinating and pioneering aspect of the Commission's work and will contribute to the legal recognition of the intrinsic value of animals and the environment.

Regulatory Framework for Biotechnology Applications on Humans

At the time of writing, several biotechnology applications on humans are close to being regulated and are hotly debated. Preimplantation diagnostics will most probably be banned in Switzerland by a law that is presently in preparation. In addition freezing of additional embryos, cloning, or any type of research work with human embryos or embryonic cells will most probably be banned, to avoid any abuse. Genetic testing is currently being debated because of its social implications beyond medical diagnosis. A public hearing has been organized for citizens to assess the various aspects of genetic diagnostics; Swiss legislators are currently consulting the report of the hearing.

Opinion on xenotransplantation is divided in Switzerland, as the biosafety and ethical aspects of xenotransplantation are highly controversial. Some people would like to see a restrictive legal framework, while others prefer a contingent ban. A Publiforum has been planned for citizens to discuss this issue.

The liability concerning transgenic plants or products derived from GMOs is currently under discussion. It is possible that the liability period for adverse effects will be extended from 10 to 30 years for transgenic organisms.

Technology, Law, and Society

The Swiss legislation that is under preparation attempts to accommodate the needs of the commercial sector, as well as public expectations on safety, information, and dialogue. During the years 1995 to 1998, the threat of a ban on genetic engineering applications generated a feeling of uncertainty that hampered business decision making, particularly in small and medium-size companies. Some scientists and entrepreneurs considered leaving Switzerland. Therefore the outcome of the vote in June 1998 has given the development of Swiss biotechnology a definite boost.

In the aftermath of the referendum in 1998, media coverage on bio- and gene technology issues remains passionate in Switzerland and is sustained by public opinion coming from abroad, such as on the Pusztai report of the possible adverse effects on rats after eating transgenic potatoes containing lectins or the adverse effects of Bt treated corn on the monarch butterfly. The experience of the political campaign prior to the referendum in 1998 has also propelled the scientists into the public debate.

Gen-Lex, the proposed legislative framework for biotechnology applications, is now undergoing the final step of approval in Switzerland. Applications such as experimentation with human embryos, xenotransplantation, sociopolitical consequences of gene diagnostics, and liability insurance on agriculture products derived from GMOs are the topics currently being debated in the Parliament and by federal agencies and the public.

Switzerland's first-rate university research and strong position in modern biotechnology have already produced important results in the areas of health, nutrition, environmental protection, raw materials, and specialty chemicals. In building firmly on its existing strengths, Switzerland is in a good position to keep pace internationally with future rapid developments in biotechnology. This will take place, however, with a firm commitment to the needs of society for safety, information, and innovation. The structure is now in place, through government policies, for promoting public dialogue at all stages of technology development.

OUTLINE

INTRODUCTION

The term "biotechnology" covers "any technological application that uses biological systems, living organisms, or derivatives thereof, to make or modify products or processes for specific use." This definition appears in Article 2 of the Convention on Biological Diversity (1). Biotechnology touches our lives in many ways. It is instrumental in health care, food, the environment and agriculture, as well as such diverse fields as waste disposal, biomediation, and the promotion of more energy efficient, less polluting, and cheaper production processes. The diversity of biotechnologies, and their relevance to so many different spheres of human concern, is reflected in the breadth of different kinds of regulatory instrument and the range different administrative responsibilities and structures in place in the United Kingdom of Great Britain and Northern Ireland (UK) at the present time. Similarly the relative novelty of many biotechnological methods, and the ethical uncertainty surrounding many them, is reflected in the mix of statute law, common law, advisory committees, and public policy in the UK at the present time. The British media and public have repeatedly indicated ambivalent concerns about much biotechnology, as is shown by ongoing debates over cloning, genetically modified (GM) foods, various reproductive medicine techniques, hunting and animal experimentation, to name but a few instances.

In order to understand the political and legislative structure of UK biotechnology regulation, we now briefly review UK law and policy making, and the relationship between this and European Community (EC) law and policy making.

UK Law

It is not strictly necessary to provide a detailed overview of the UK's system of law making, particularly as the UK regulatory scheme largely derives from two sources. For a general overview of the English legal system, see Ward (2). Those laws that possess relevance are not derived from the case law. Rather, in the context of biotechnology, various Acts of Parliament (or "statutes") and associated subordinated legislation govern the vast majority of the UK regulation. Essentially an Act of Parliament, once it has passed through Parliament (comprising the House of Commons and House of Lords) to become law, will bind those within the jurisdiction. Such Acts as apply to biotechnology often enable bodies other than Parliament to issue subordinate (or delegated) legislation. An example is the "statutory instrument," which enables a Minister to make a legally binding regulation. As we will witness

below, there is a proliferation of such regulations within the scheme for regulating biotechnology.

UK Law and European Law

Much of the impetus for the regulation in the UK has been provided by European legislation in the area. For a general overview of the European impact on UK law, consult Ward (2). Two sources of European legislation are of particular relevance. First, the UK has been a member state of the Council of Europe since its inception in 1949. The Council of Europe strives to establish Europe-wide standards on a range of issues. Bolstered by various authorities and institutional machinery (e.g., the European Court of Human Rights), the Council of Europe itself comprises the Committee of Ministers and the Parliamentary Assembly. The former is the decision-making body; it may lay down binding legislation such as Conventions, or adopt recommendations to governments. The latter is the deliberative body; it too may make recommendations or resolutions. The Council of Europe has issued a number of legislative documents relating to biotechnology and the most important of these will be noted.

Second, having joined the EC in 1972, EC law is of prime importance to the UK's regulation of biotechnology. Since the Treaty of Maastricht, the EC is but one of three "pillars" of the European Union (EU). For the most part, the following discussion relates to the EC (see Ref. 3). The EC treaties set out broad frameworks that must be fleshed out by more specific measures. This task is performed by the various EC institutions: the Court of Justice (ECJ), the Council, the Commission, and the Parliament. These bodies provide three types of secondary legislation: regulations, directives, and decisions.

Regulations are directly applicable in all member states, and are binding in their entirety. Directives differ because these may be implemented by those means chosen by the member states to which they apply. There are a number of such regulations and directives that relate to biotechnology, either directly or indirectly. Finally, decisions are addressed to a specific person or persons: for example, the decisions of the ECJ. This latter source of EC law does not warrant exhaustive study, as the numerous regulations and directives suffice to provide the EC perspective.

One other, albeit non-statutory, area of European standards-setting warrants mention. The European Committee for Standardisation (CEN) is responsible for the planning, drafting and adoption of European technical standards (with the exception of those pertaining to the electrotechnology and the telecommunications sectors). In Europe, CEN works in partnership with CENELEC — the European Committee for Electrotechnical Standardization and ETSI — the European Telecommunications Standards Institute.

Such technical specifications ensure compatibility between products; guarantee appropriate levels for their safety, quality, or efficiency; and provide the test methods necessary to establish conformity. Once the need for a European standard has been firmly established, and nonduplication of work verified (CEN may also use an international standard), an experts Technical Committee is established. CEN's remit is to promote voluntary technical harmonisation in Europe in conjunction with international bodies and its partners in Europe. This harmonization is designed to diminish trade barriers, promote safety, allow interoperability of products, systems and services, and to promote common technical understanding.

In essence, then, legislation in a particular area of biotechnology is governed through Acts of Parliament, Regulations and the relevant legislation from Europe. By way of example, [this example is discussed in greater detail later in this article (contained use of GMOs and deliberate release of GMOs).], Genetically Modified Organisms (GMOs) are controlled in the UK by a number of regulations, including the GMO (Contained Use) Regulations 1992 and the GMO (Deliberate Release) Regulations 1992. These three pieces of legislation were created under the Health and Safety Act 1974 (contained use) and the Environment Act 1992 (deliberate release). Within Europe there are two major Directives that relate to the use of GMOs and are implemented by the UK regulations: Directive 90/219 (contained use) and Directive 90/220 (deliberate release). To assist in the implementation of these Directives, CEN is drafting appropriate safety standards that will apply to Europe in the use and release of GMOs; these standards should further serve to harmonize work in this area.

UK REGULATION OF BIOTECHNOLOGY

Introduction

In this section we will outline the legislative and regulatory framework that exists at present in relation to biotechnology in the UK. The wide-ranging scope of biotechnology means that the regulatory bodies — which are both governmental and nongovernmental — often have blurred remits. Numerous committees, subcommittees, and groups advise these bodies. Because of the rapid advancement in this field, the existing bodies are often inadequately equipped to deal with specific issues. To compensate for this there is a practice of creating new statutory and ad hoc committees to fill in the gaps that develop in the framework. Additionally, the government is also advised through independent bodies, such as the Royal Society, which periodically produce reports on matters of interest.

The regulatory and advisory framework, according to the UK government, has two distinct functions: to consider whether to grant approvals for individual products or processes (based on ethical, legal, regulatory, and scientific criteria), and to set a strategic framework for development of the technology in the UK (4). The main measures to provide safeguards against any real or hypothetical risks in biotechnological products are rigorous pre-market assessment of safety, research to improve scientific understanding of the particular product, and health surveillance to provide reassurance against any unexpected adverse effects. There is a concentrated effort to ensure that the governmental review of, and

action on, issues relating to biotechnology are sufficiently transparent. Transparency is urged, in order to facilitate input from interested parties (such as the public and concerned industries) on matters of policy.

The regulation of biotechnology in the UK is divided into five areas of responsibility under a lead governmental departmental body. As observed, the scope of these areas is often blurred, with certain issues falling within the jurisdiction of one or more of the responsible organizations. The areas of legislative responsibility are divided among: the Department of Trade and Industry (DTI) (consumer safety, product liability, trading standards, and patents); the Health and Safety Executive (HSE) (health of biotechnology workers, the control of hazardous substances and the contained use of GMOs); the Department of the Environment, Transport and the Regions (DETR) (release and marketing of GMOs into the environment); the Ministry for Agriculture, Fisheries and Food (MAFF) (food safety and labeling, animal feed and veterinary medicines, and plant health and pesticides); and the Department of Health (DOH) (therapeutic medicinal products, medical devices, gene therapy, and medicines licensing). These same groups are responsible for specific guidance and advice, access to funding, and research and expert services. This additionally includes the input of research councils, universities and trade associations.

The various statutory and advisory committees that exist within these five areas regulate and provide advice on the safety and broader impact of biotechnology. In general, the issues fall within the remit of, on the one hand, food and agriculture and, on the other, medicines and therapeutics. Some bodies, however, such as the Advisory Committee on Genetic Modification and the Advisory Committee on Release into the Environment, involve themselves in each of the two areas. There are essentially two types of committee: those that are established (either statutorily or ad hoc) by the government to specifically address issues arising from developments in biotechnology, and those that are not biotechnology specific, but nevertheless undertake significant amounts of biotechnology based work. There are other groups, such as English Nature, that only occasionally touch on biotechnology as part of a much wider area of interest.

Eight of the existing committees have a statutory function to advise Ministers on the exercise of their powers under specific pieces of legislation. These committees are the Animal Procedures Committee (APC), the Veterinary Products Committee (VPC), the Human Fertilisation and Embryology Committee (HFEA), the Advisory Committee on Release into the Environment (ACRE), the Advisory Committee on Pesticides (ACP), the Food Advisory Committee (FAC), the Committee on Safety of Medicines (CSM) (which also advises the Medicines Control Agency, (MCA)), and English Nature (along with its equivalents in Scotland, Wales, and Northern Ireland). The relevant Ministers, and MCA in the case of CSM, are statutorily required to take into account the advice of three of these committees when taking decisions. Thus the relevant Secretary of State consults ACRE; the recommendations of ACP must be taken into account by Ministers at the Ministry of Agriculture, Fisheries, and Food, the Department of the Environment, Transport, and the Regions, the Department of Health, and the Scottish and Welsh Offices; and MCA must consult the CSM.

In addition there are a number of nonstatutory committees. These offer advice on specific matters of interest or concern. These committees are the Advisory Committee on Novel Foods and Processes (ACNFP), the Farm Animal Welfare Council (FAWC), the Advisory Committee on Genetic Modification (ACGM), the Human Genetics Advisory Commission (HGAC), the UK Xenotransplantation Interim Regulatory Authority (UKXIRA), the Genetics and Insurance Committee (GAIC), the Gene Therapy Advisory Committee (GTAC), the Advisory Group on Scientific Advances in Genetics (AGSAG), and the Advisory Committee on Genetic Testing (ACGT).

The Department of Health

DOH is concerned with the health of humans, and it plays an active role in relation to biotechnology and the relevant UK legislation that governs the medical field and public health. DOH's main responsibilities concern the protection of public health from any possible hazards arising from the application of biotechnology. With this overarching objective in mind, DOH acts as a focal point in developing and coordinating policies, both national and international. The Department has legislative responsibility for developments in biotechnology in therapeutic medicinal products, medical devices and gene therapy also plays a role in the active encouragement of inward investment and sponsors the UK's biopharmaceutical industry. Research plays a large part within DOH and is divided into three main areas: the policy research program, NHS research and development strategy, and the research of nondepartmental public bodies. It is also involved in the European Community's Biomedicine and Health Research Programme.

DOH and the Office of Science and Technology (OST) jointly form the secretariat of the Human Genetics Advisory Commission (HGAC) which reports to and advises DOH and OST. HGAC remit is to "keep under review scientific progress at the frontiers of human genetics and related fields; to report on issues arising from new developments in human genetics that can be expected to have wider social, ethical and/or economic consequences, for example in relation to public health, insurance, patents and employment; and to advise on ways to build public confidence in, and understanding of, the new genetics" (5). It works alongside other committees that have an interest in human genetics. DOH also jointly forms the secretariat of the Advisory Committee on Novel Foods and Processes with the Ministry of Agriculture, Fisheries, and Food and provides members for the Inter-department Group on New Food Developments which covers feed intended for animal consumption.

The following discussion examines those various forms of biotechnology regulation which effectively operate under the auspices of DOH. Thus we address research, medicinal products, medical devices, and a variety of measures designed to survey the general field of human genetics. Before commencing the overview, two caveats

must be noted. First, although efforts have been made to distinguish and categorize the areas of interest, in an effort to avoid unnecessary duplication, naturally, such duplication cannot be entirely avoided. Second, and related to this first point, we should note one issue that will not be rehearsed: contained use and deliberate release. Here DOH does not have a statutory responsibility, although it is closely involved with the relevant independent expert advisory committees (ACGM and ACRE) (6).

Research. Research in DOH is divided among the Public Health Laboratory Service (which develops and implements epidemiological typing methods and laboratory diagnostics), the National Institute for Biological Standards, the Centre for Microbiology Research, and the Edward Jenner Institute for Vaccine Research. The Chief Scientist Office in the Scottish Office Department of Health and the Welsh Office Health Department are the overseers of research in Scotland and Wales, respectively.

From the point of view of medical research on humans, the most important bodies are the local and multi-center research ethics committees. The first Local Research Ethics Committees (LRECs) began to be set up in the mid-1960s, in emulation of the U.S. Institutional Review Boards. Initially these LRECs were locally originated, and without official status, although their pattern of constitution and process was defined by the Royal College of Physicians guidance on the Research Ethics Committees in 1967. Gradually the number of committees grew and acquired Department of Health recognition. There are now over 230 LRECs in the UK, regulated since 1991 by official Department of Health guidelines, and responsible to the area health authorities. Since 1997 any research protocol involving five or more centers has been reviewed in the first instance by a Multi-centre Research Ethics Committee (MREC). There are 10 MRECs, one each for Scotland and Wales, and one for each of the eight English health Regions. The MRECs are responsible to the Regional Health Authorities, and to the Department of Health centrally. For information and documentation on RECs in the UK, see Smith (7).

LRECs and MRECs are responsible for any research on (National Health Service) NHS patients, the recently dead in NHS premises, fetal tissue research on NHS premises, access to the medical records of NHS patients, and any other research on human beings that takes place on NHS premises. Their remit is to protect the subjects of such research, and to facilitate useful research; when these two aims conflict, the presumption is supposed to be that protection of individual patients takes priority (as required by the Declaration of Helsinki).

The constitutions of LRECs and MRECs are similar. Such committees must have a chair and a vice-chair, one of whom must be a lay person, together with at least eight members drawn from a range of professional backgrounds and including at least one other lay person. The committees are consensus-forming committees, and are not intended to be voting committees or "representative" in any but the broadest political or social sense.

Research approved by the MREC must also be reviewed by the relevant LRECs, but the LRECs in this situation can only consider four factors: the suitability of the site for the research, the suitability of the local investigator to do this research, the suitability of the local population to take part in this research, and the usability and comprehensibility of the patient information sheet to patients in this locality.

LRECs and MRECs are expected to take their decisions in the light of a fair process of discussion, and in the light of the best available written guidance (including that from government advisory committees such as the ACGT, the medical Royal Colleges, and international agencies such as the World Medical Association, the Council of the International Organisations of Medical Sciences, and the International Committee on Harmonisation of Good Clinical Practice).

Medicinal Products. Therapeutic medicinal products are primarily controlled by the Medicines Control Agency (MCA). MCA acts on behalf of Health Ministers and the UK licensing authority to issue marketing authorizations for medicinal products for human use and other licenses governing manufacture, clinical trials, wholesale dealing and parallel imports. This is based on the product reaching required levels of safety, efficiency, and quality. Independent advisory committees support the MCA in its tasks: of chief importance are the Committee on the Safety of Medicines and the Medicines Commission. The MCA is responsible for enforcing compliance with those authorisation provisions issued under the *Medicines Act 1968* (and its associated legislation, such as the Medicines for Human Use (Marketing Authorisations etc.) Regulations 1994) (8), and is assisted in this by the Royal Society of Great Britain, the DOH and the Social Services in Northern Ireland.

The Committee on Safety of Medicines (CSM) is a statutory body that advises the UK Licensing Authority (part of DOH) and MCA on the quality, efficiency, and safety of medicines in order to ensure that appropriate public health standards are met and maintained. A final important feature of the regulation in this context operates at the international level. The National Institute for Biological Standards and Control (NIBSC) oversees international standards in medicinal products. This is the executive arm of the National Biological Standards Board, which essentially exercises certain controls on the purity and potency of biological substances. Specialist medicines inspectors are responsible for the inspection of biological — including biotechnological — manufacturing sites.

The *Medicines Act 1968* and its associated legislation gives effect to the European medicines legislation, as initially laid down in *Directive 65/65* (9). A subsequent Directive in 1975 began to flesh out this basic framework in, among other matters, providing the data requirements for testing (10). Another Directive from 1975 established the Committee for Proprietary Medicinal Products (CPMP) (11), which now forms part of the European Agency for the Evaluation of Medicinal Products (EMEA). This latter agency controls the European authorisation of UK medicinal products. *Council Regulation 2309/93* set up the EMEA and a centralized procedure for biotechnological, and other "high-tech," medicines (12). This allows an authorization, through the EMEA, which is valid

throughout the Community. There is also a decentralized procedure for member states to mutually recognise each other's authorizations, which is also controlled through the EMEA.

Other Directives provide further amendment to, and elaboration on, the European legislative scheme relating to medicinal products. Those warranting particular mention are the laws governing specific products such as immunological products (13), radiopharmaceutical products (14) and products derived from human blood or human plasma (15), alongside more general measures dealing with good manufacturing practice (16), wholesale distribution (17), the classification of medicinal products (18), labels and leaflets (19), and advertising (20).

Medical Devices. Medical devices "are those diverse and extensive products, other than medicines, which are used in the healthcare field for the prevention, diagnosis, monitoring and treatment of disease and injury" (21). These are controlled by the Medical Devices Agency (MDA). This body is responsible for ensuring that medical devices and equipment for sale or use in the UK meet acceptable standards of safety, quality, and effectiveness and that these standards comply with the relevant EC Directives. At present, there are three directives that regulate the safety and marketing of medical devices throughout the EU. These are Directive 90/385 (governing active implantable medical devices) (22), Directive 93/42 (which covers all medical devices except those covered by Directive 90/385 and medical devices for in vitro diagnostics) (23), and Directive 98/79 (governing in vitro diagnostic medical devices) (24). The first of these Directives, which effectively covers such devices as heart pacemakers and cochlear implants, finds expression in UK law in the Active Implantable Medical Devices Regulations 1992 (25), as amended by the Active Implantable Medical Devices (Amendment and Transitional Provisions) Regulations 1995 (26). The second Directive, which has a broader scope, is implemented by the *Medical Devices Regulations* 1994 (27). It appears that the third of these Directives has yet to be implemented.

A number of aims and themes can be identified in this legislation. Emphasis is placed on the requirements that devices must not compromise the health and safety of the patient, user or any other person, and that the risks associated with the device must remain compatible with the patients health and protection. In order to achieve these aims, a number of specific requirements must be met. Thus clinical investigations are to be carried out, adverse incidents must be reported, devices must be classified and controlled according to the degree of risk inherent in their application, and monitoring must occur in order to ensure compliance with the requirements.

Gene Therapy. The UK's approach to the control of gene therapy has been informed by the 1992 *Clothier Report* (28). The Clothier Committee observed that gene therapy should be regarded as research involving human subjects. It concluded, inter alia, that research in the area should be restricted to disorders that are life threatening or cause serious handicap and for which treatment is either unavailable or unsatisfactory. The Committee decided that, for the time being, no attempt should be made to intervene in germ line cells. Finally, the recommendation a national supervisory body be established to consider and advise on the acceptability of gene therapy protocols resulted in the establishment of the Gene Therapy Advisory Committee (GTAC). GTAC is responsible for both the case-by-case review of individual protocols and an assessment of more general issues relating to such therapy. In addition GTAC provides advice to Health Ministers on developments in this field and on their implications. As well as working closely with LRECs, GTAC works closely with the MCA. As previously noted under the *Medicines Act 1968* and *Directive 65/65* (as modified), the MCA has a responsibility for regulating the quality, safety, and efficiency of medical products and applications for their clinical trials. This possesses relevance for gene therapy. HSE and DETR are similarly involved when the scope of the gene therapy falls within their remit.

Genetic Testing. The Advisory Committee on Genetic Testing (ACGT) is a nonstatutory body that advises UK Health Ministers on developments on genetic testing, taking account of ethical, social, and scientific aspects. Established in 1996, its remit is to provide advice on developments in testing for genetic disorders and to establish requirements, especially in respect of efficiency and product information, to be met by manufactures and suppliers of genetic tests.

Xenotransplantation. The UK Xenotransplantation Interim Regulatory Authority (UKXIRA) is a nonstatutory body that provides the voluntary regulatory framework for biotechnology in the area of human genetics and xenotransplantation. At present there is no domestic legislation, although the need for primary legislation has been realised. Set up through the Advisory Group on the Ethics of Xenotransplantation, UKXIRA, with the assistance of the Committee on Dangerous Pathogens, reviews and assesses the safety and efficiency of xenotransplantation procedures. All treatments for patients in this field have to be approved by the Secretary of State (29). As for specific legislation, some aspects of xenotransplantation are covered by the Human Fertilisation and Embryology Act 1990 (including cell therapies and gene therapies involving viable tissue) (see also the section "Home Office").

Genetically modified (GM) animals created in the course of xenotransplantation research are disposed of (although some GM animals can be used as food) under the assistance of the ACNFP, FAC (for labeling issues) and ACRE. Any live GM animals used in containment will be subject to the GMO (Contained Use) Regulations 1992 (as amended 1996) and the GMO (Risk Assessments) (Records and Exemptions) Regulations 1996 with respect to environment risk assessment (see below). The control of animals under these regulations will be the responsibility of HSE and DETR, as advised by ACGM. Xenotransplantation protocols that involve animals are covered by the Animals (Scientific Procedures) Act 1986,

and UKXIRA works closely with the Home Office in this matter. It is widely accepted that primates should not be used in such procedures, although the possibility has not been entirely ruled out (30). As of yet, no xenotranplantations from animals to human beings have taken place in the UK, although, while being cautious in its policy, the government has by no means excluded the possibility (31).

Infertility Treatment. The Human Fertilisation and Embryology Act 1990 established the Human Fertilisation and Embryology Authority (HFEA). Another important, albeit nonbiotechnology specific, piece of legislation in the field of infertility is the *Surrogacy Arrangements Act 1985* (which essentially prohibits commercial surrogacy arrangements). Its primary function is to licence and monitor centres providing treatment, research and care in this field. The Act and the Authority are therefore concerned with the use of gametes and embryos; as for HFEA's more general functions, advice will be disseminated on issues arising from developments in assisted conception and associated research. Key concerns include the need for safe, efficient, and ethical advances in the field.

The Health and Safety Executive

The Health and Safety Executive (HSE) is responsible for the health and safety of workers (and others) engaged in biotechnology in Great Britain. In Northern Ireland, the Health and Safety Inspectorate of the Department of Economic Development is responsible.

In Great Britain, the Health and Safety Commission (HSC) aids the HSE in its duties. HSC, whose members are appointed by the Secretary of State for the Environment, Transport, and the Regions, therefore considers, and also develops, health and safety policy. HSE advises the HSC on the shaping of policy and is responsible for implementing it. HSE specialist inspectors provide advice on the areas in question, specifically on risk assessment and containment. In relation to biotechnology, HSE's main responsibilities concern the regulation of the contained use of GMOs and the implementation of general health and safety legislation. (HSE works with the DETR with regard to the related issue of deliberate release when the release has implications on the health and safety of individuals. The COSHH regulations deal with certain deliberate releases of GMOs.)

Contained Use of GMOs. The former responsibility derives from those requirements laid down in the Genetic Manipulation Regulations 1989 (32), and the GMO (Contained Use) Regulations 1992 (as amended) (33). These regulations were made under the *Health and Safety at Work Act 1974*. The regulations revoke the regulations from 1989 (32) and replace them insofar as they relate to contained use. The latter contained use legislation assesses risks to humans and the environment, and essentially derives from EC Directive 90/219 (34). The 1996 amendments maintain this dual aim, as well as including various other requirements. These include the need to keep records; the need to establish a local GM safety committee, the need to classify all activities and organisms used; the need to notify the HSE of first an intention to use premises for GM for the first time and second, an intention to engage in certain subsequent individual activities (and, in some cases, work must not begin without the HSE's prior consent); and, finally, the need to adopt adequate controls, including suitable containment measures. Since the amendment, DETR also plays a role — alongside the HSE — in the regulation of this area.

The contained use regulations are thus concerned with the health and safety of both workers involved in the contained use of genetic engineering and those members of the public who may come into contact with such work. HSE and HSC rely on advice from the Advisory Committee on Genetic Modification (ACGM). ACGM advises all relevant government departments on human health and the environmental aspects of the contained use of GMOs, including laboratory and industrial installations. It is not involved in product approval. ACGM is accordingly advised by a technical subcommittee formed to provide specialised technical advice on all aspects of the human and environmental safety of the contained use of GMOs. The Advisory Committee on Dangerous Pathogens (ACDP) and the Department of Health's Health Promotion Division Select Committee on Science and Technology (SCST) also have a role in the control of the contained use of GMOs. SCST is divided into three subcommittees: the Human Genetics Advisory Commission (nonstatutory advisory body that also advises OST), the National Screening Committee, and the Advisory Committee on Genetic Testing (nonstatutory advisory body). Other committees may or may not advise on specific issues of GMO contained use depending on their remit. Finally in relation to contained use, ACRE advises the HSE/HSC and any other bodies appropriate on the possible human consequences of releases into the environment.

General Health and Safety. The legislation focusing upon general health and safety includes the *Health and Safety at Work Act 1974* and the *Control of Substances Hazardous to Health (COSHH) Regulations 1999* (35). Here the risks to be assessed are those risks to humans. The *Health and Safety at Work Act 1974* applies to all persons at work in Great Britain, whether employees or self-employed. Its requirements cover biotechnology, including the application of genetic modification techniques. Under this Act, employers have a duty to ensure the health and safety of the employees and to ensure that the general public is not put at risk by the work. The COSHH regulations apply to biological agents, including those which have been genetically modified, that may cause an infection, allergy, toxicity, or otherwise cause a hazard to human health. The COSHH regulations implement those EC directives relating to the protection of workers from risks associated with biological agents (36). Employers must therefore assess the risk of working with certain biological agents, to adopt appropriate control measures, and to notify the HSE of work involving certain biological agents.

The Department of the Environment, Transport and Regions

The Department of Environment, Transport and the Regions (DETR) is responsible for the regulation of the deliberate release and marketing of GMOs in Great Britain, and in furtherance of its aims, it promotes an extensive research program into associated risks. Before analyzing the various bodies that work with DETR, the (distinct) position in Northern Ireland deserves mention. There the position is virtually identical to that in Great Britain, although the requisite notification must be made to the Department of Economic Development; it is enforced by its Health and Safety Inspectorate. The Department of the Environment for Northern Ireland controls legislation governing the release and marketing of GMOs.

Other bodies, however, also have a role to play in this context. In addition to DETR, the Ministry of Agriculture, Fisheries, and Food, the Scottish Office Agriculture, Environment and Fisheries Department, the Department of the Environment for Northern Ireland, and the Welsh Office Agriculture Department are implicated in regulating specific areas. In addition the Department of Health addresses those releases of GMOs that have an impact on human health. The Ministers are advised primarily by the Advisory Committee on Release to the Environment (ACRE) and the Advisory Committee on Genetic Modification (ACGM). With regard to food and the marketing of GMOs, the Food Advisory Committee (FAC) and the Advisory Committee on Novel Foods and Processes (ACNFP) have particular relevance. FAC advises Ministers on the exercise of powers in the *Food Safety Act* relating to the labeling, composition, and chemical safety of food. It also advises on general matters relating to food safety.

Turning to the particular role of DETR, the regulation of the release of GMOs is primarily covered by the Genetically Modified Organisms (Deliberate Release) Regulations 1992 (37), issued in accordance with the Environmental Protection Act 1990 (Part IV). Other domestic legislation that impacts upon biotechnology and the environment must also be noted (38). The latter Act sets out the offences and penalties which apply in the event of a breach of its requirements. Any release of GMOs, with a few specialized exceptions, into the environment must be approved by the Secretary of State for the Environment, Transport, and Regions (acting jointly with other appropriate Ministers). Its purpose is to minimize any damage to the environment or the public that might arise from the deliberate release or escape of GMOs. The Secretary of State is therefore empowered to revoke a consent and to take enforcement action. The *GMO (Deliberate Release) Regulations* are enforced jointly by DETR and HSC. The HSC, in turn, can direct the HSE inspectors to perform the delegated enforcement functions.

Both of the relevant pieces of legislation (i.e., the Environmental Protection Act 1990 and the GMO (Deliberate Release) Regulations 1992; note that parallel legislation exists in Northern Ireland) implement the EC *Directive 90/220* (39), which specifically addresses the deliberate release of GMOs. This Directive has been amended in the light of progress in relation to the (new, simplified) procedure for applications to release GM crop plants (40), and the technical progress made, for example, regarding the information requirements of GM higher plants (41). These amendments were implemented by the GMO (Deliberate Release) Regulations 1995 (Section 7.40). The EC has passed other legislation dealing with deliberate release, but this may best be dealt with in other contexts. It should also be noted that the Council of Europe is similarly committed to the safety of both humans and the environment, as evinced in a number of legislative documents (42).

Ministry of Agriculture, Fisheries and Food

The policy of the Ministry of Agriculture Fisheries and Food (MAFF) is to support the development and exploitation of biotechnology within the food and agriculture industries, while protecting people, livestock, crops, and the natural environment. Where applicable, MAFF is jointly responsible for regulations governing pesticides, plant health, veterinary medicines, food products and imports. The approach of MAFF is coordinated with other government departments. Thus, for example, it consults with ACNFP to provide guidance on, and to regulate the use of, GM food. ACNFP is also responsible for assessing all applications made under the EC regulations relating to novel food and novel food ingredients. HSE, DETR, and the DOH also consult MAFF on the contained use and deliberate release of GMOs and act jointly, where appropriate. Finally, in Northern Ireland, the Department of Agriculture for Northern Ireland coordinates its work with MAFF with regard to biotechnology as it applies to its jurisdiction.

Novel Foods. In the UK assessment of GM and other novel foods, Ministers are advised by the independent Advisory Committee on Novel Foods and Processes (ACNFP). This committee carries out safety assessments of individual novel foods as part of the pre-market approval scheme controlled by the EC. In carrying out such assessments, the ACNFP is assisted by other governmental advisory committees, such as the Committee on Medical Aspects of Food and Nutrition Policy, the Committee on Toxicity of Chemicals in Food, Consumer Products and the Environment, and the Food Advisory Committee on the labeling of GM foods.

MAFF operates under the Food Safety Act 1990 (which applies to England, Scotland, and Wales and is parallel to the Food Safety Act (NI) 1991), which controls food consumption in Northern Ireland. The legislation makes it an offence to render any food injurious to health by adding or using any article or substance, abstracting any constituent from the food, or by subjecting the food to any other processes or treatment. In the main, local authorities enforce those portions of the Act that relate to hygiene and health. Environmental Health Officers and Trading Standards Officers enforce the requirements governing labeling and composition. In the capital, the London borough and Metropolitan authorities carry out both of these sets of enforcement duties.

Evidently food safety is a key concern. This concern is also detectable at the more general European level, although competing interests have been cited. For

example, Reports from the Council of Europe concede that risks should be assessed and minimised, but observe that advances — specifically in biotechnology — might increase yields and therefore prosperity (43).

Nevertheless, in the specific field of biotechnology, food safety is the pervasive theme. The primary piece of European legislation relating to novel foods and novel food ingredients is EC Regulation 258/97 (44). The Commission has taken many decisions in this context, too numerous to mention. These decisions concern such plants and vegetables as swede, maize, and soya, and an overriding concern is that the products will not adversely affect health. The UK has provided for its enforcement in The Novel Foods and Novel Food Ingredients Regulations 1997 (45). The EC regulation created a comprehensive EU-wide regulatory framework controlling all aspects of GM crops in Europe, from seed to final product. Accordingly, member states cannot introduce their own requirements in this area without the agreement of the other countries of the Commission, who are advised by the EC Scientific Committee for Food (SCF). (The SCF also re-evaluates any additives if they are prepared significantly differently from the original evaluation.) The regulation introduced a statutory pre-market clearance system for all novel foods, including those produced by genetic modification, and it is binding on all member states. Under this regulation the safety of individual GM foods is assessed by all member states, and any differences of scientific opinion are resolved by reference to a number of scientific committees within the EC.

The primary regulation has since been the subject of a recommendation concerning the scientific aspects and the presentation of information relevant to a safety assessment (46). Materials not originally covered by the regulation have also been brought within its procedures. Accordingly Regulation (EC) No 1813/97 (47), which generally concerned labeling requirements, dealt with genetically modified soya and maize, which was originally approved for food use under Directive 90/220 (supra), prior to the novel foods regulation. Detailed rules relating to the labeling stipulations contained in the later regulation have since been laid down in *Council Regulation (EC) No 1139/98* (48). These regulations governing the labeling of GM foods enter UK law via the Food Labelling (Amendment) Regulations 1999 (49).

Animal Feedingstuffs. The Agriculture Act 1970 (as amended) governs the marketing of animal feed in the UK. The Act makes it an offence to sell any material for use as feed that contains any ingredient that is deleterious to animals and, secondly, to human beings, who consume the products of an animal fed with the material. The Feeding Stuffs Regulations 1995 (as amended) (50) implement those EC Directives. The regulations cover a permitted list of single-cell proteins in feedingstuffs (51) (this Directive may be extended to encompass novel feed material; at present, a voluntary scheme for the approval of new feed material is in operation in the UK); assessment of "certain products" used in animal nutrition (52); and assessment of additives used in animal feedingstuffs (53). These Directives set out permitted additives that are allowed to be used or present in animal feed. The Directives also laid down requirements governing the information that must be provided (54).

Veterinary Medicines. The manufacture, distribution, marketing, and administration of veterinary medicines are controlled by the Medicines Act 1968, in conjunction with the secondary legislation issued under it and other UK legislation implementing the apposite EC legislation. Veterinary medicines are also controlled by the Marketing Authorisations for Veterinary Medicinal Products Regulations 1994 (55). These, in implementing parts of Directive 81/851/EEC (as amended) (56) state that only veterinary medicinal products subject to a marketing authorisation valid in the UK may by placed on the UK market. The Agriculture Departments and the Department of Health and Social Security (Northern Ireland) enforce the provisions governing veterinary procedures, acting on behalf of the health and agriculture ministers. The Royal Pharmaceutical Society of Great Britain also undertakes responsibility for the enforcement of provisions relating to certain retail sales. The Veterinary Medicines Directorate (VMD) administers the control of veterinary medicines, on behalf of DOH and MAFF. These bodies are advised by the independent Veterinary Products Committee (VPC) (created under the Medicines Act 1968) on the safety, quality, and efficiency of veterinary medicines covered by the 1968 Act. The VMD monitor and regulate all veterinary products on the market, including postauthorization monitoring.

The Council's Regulation (EEC) 2309/93 establishes a European centralized authorization procedure for high technology products in veterinary medicine (57). Compliance with this procedure is obligatory for certain biotechnological products and for novel growth promoters. Under this regulation initial applications are made to the European Medicines Evaluation Agency. The application is then submitted to the EC Committee for Veterinary Medicinal Products, comprising representatives from all member states, which assesses the application for authorization throughout the Community.

Pesticides and Plant Health. The Control of Pesticides Regulations 1986 (COPR) (as amended) addresses the majority of pesticides (58). The responsibility for regulation in this area is divided between MAFF and HSE. MAFF deals with the approval of products for use in agriculture and horticulture and in food storage practice. HSE is concerned with products for use with regard to mainly nonagricultural and nonfood uses.

COPR, as it relates to the MAFF remit, is progressively being superseded by the body of legislation which implements EC law. MAFF is responsible for the domestic legislation that implements Directive 91/414/EC (59), which covers the placing on the market of plant protection products (broadly, agricultural pesticides) and the import of pesticides. Included within this legislation are the Plant Protection Products Regulations 1995 (as amended in 1996 and 1997) (60), the Plant Protection Products (Fees) Regulations 1995 (as amended in 1997) (61), and the Plant Protection Products (Basic Conditions) Regulations

1997 (62). The legislation also contains powers to control the import of pesticides.

Under this legislation, manufacturers seeking to gain approval for pesticide products must apply to the independent Advisory Committee on Pesticides (ACP), according to the Food and Environment Act 1985. It is expected that this legislation will be superseded by the recent EC Directive on biocidal products (63), which will have a larger scope than that presently under the control of the COPR.

The legislation is enforced by the HSE, local authorities, and agriculture departments. Local authorities are concerned with consumer aspects of the legislation (as overseen by Trading Standards Officers) and issues, including storage, which are not covered by HSE (as overseen by Environmental Health Officers). The agriculture departments enforce provisions relating to wildlife, including the impact of pesticides and of pesticide residues in the environment.

Finally with regard to plant protection measures, following European legislation (64), the Plant Health (Great Britain) Order 1993 (as amended) places restrictions on the import and movement within the EC, and keeping in Great Britain, of particular plant pests, including GM plant pests, plants and products (65). The Order further provides that no unauthorized person may engage in any activity that involves genetic modification of a plant pest without proper authorization. Licences to undertake such work are supplied by the Plant Health Division of MAFF and, in Scotland, by the Scottish Office Agriculture Environment and Fisheries Department.

Plant Breeders and Plant Varieties. Applications for plant breeders' rights and the National Listing of Varieties are governed by the Plant Varieties and Seeds Act 1964 (as amended), the Plant Breeders' Rights Regulations 1998 (66), and the Seeds (National Lists of Varieties) Regulations 1982 (as amended) (67).

Discussions are persisting on the most appropriate manner in which to embody the EC provisions in this context. Although a lengthy discussion of the European law in this context is unnecessary, a few points do warrant mention. Accordingly there are provisions relating to the marketing of GM material that require domestic adoption. The new EC Plant Varieties system (introduced on April 27, 1995) makes specific licensing provisions for essentially derived varieties (i.e., those produced from existing varieties using biotechnological techniques). A recent important Directive allows varieties to be marketed. Thus member states may authorize producers in their own territory to place GM materials on the market (68). Such authorization may be granted only if all appropriate measures have been taken to avoid adverse effects on human health and the environment (as determined in accordance with other Directives) (69). Other stipulations relate to such matters as the need for labels to identify GM products and the need to protect varieties threatened with genetic erosion. (The novel foods legislation is also taken into account.)

Animal Welfare. The Farm Animal Welfare Council (FAWC) advises MAFF Ministers on the welfare of farm animals on agricultural land, at market, in transit, and at place of slaughter. It can freely investigate, advise, and communicate with any outside body, including the European Commission and the public, on any legislative or any other changes that may be necessary in this context.

As for existing legislation in this context, the Animal Health Act 1981 provides for Ministers to control the spread of disease, and the Specified Animal Pathogens Order 1993 (SAPO) (70), prohibits the import of animal pathogens and carriers of pathogens except under licence. It appears that the prohibition essentially relates to Third World countries. Under the latter Order, GMOs require a licence regardless of their origin (i.e., whether or not they are from the Third World). The licence is granted by Agriculture Departments, as advised by the state veterinary service. With specific regard to fish, broadly similar requirements apply, as provided for in the Diseases of Fish Act 1983. (The approaches of the EC and the Council of Europe to animals (and specifically animal welfare), are discussed below.)

Department of Trade and Industry

The Department of Trade and Industry (DTI) is legislatively responsible for product liability, trading standards, and the Patent Office. DTI is also the lead sponsor department for biotechnology. DTI's Chemicals and Biotechnology Directorate works within the DTI and with other government departments on the regulation and general appraisal of issues surrounding competitiveness in biotechnology. DTI thus has the ultimate responsibility for championing the biotechnology industry in all aspects of governmental, European, and international policies that affect its competitiveness. For this reason DTI has strong links with both the industry and the regulatory bodies of the UK government. The Office of Science and Technology, part of DTI, is responsible for managing the science budget and coordinating government policies on science and technology.

Product Liability. The DTI regulates consumer safety through a number of specific Acts and Regulations, depending on the product. Among these are the General Product Safety Regulations 1994 (71), and those other measures that implement the relevant EC Directives. The 1994 regulations impose a general requirement for safety in all consumer products which have not already been comprehensively covered by extant, specific European product Directives, and British and European standards. Local Authority Trading Standards Officers enforce the regulations. There is also the Consumer Protection Act 1987, which implements the EC Directive on product liability.

Patenting. The central piece of legislation in the UK is the *Patents Act 1977*, which succeeded the prior European Patent Convention (72). In the context of biotechnology, it must be emphasized that animal or plant varieties and biological processes for the production of animals or plants not involving significant technical intervention *cannot* be patented. (However, certain interested parties are not left unprotected: for example,

plant breeders; see the discussion below.) Nevertheless, as certain biotechnological innovations do remain subject to patenting, a basic overview of the UK system must be provided.

As with other inventions, the granting of a UK patent for a biotechnological invention depends on satisfying certain criteria, including those of novelty, inventiveness, and industrial applicability. In order to obtain a patent for any invention, an application that clearly and fully discloses the invention must be filed. It has been recognized that in some cases it may not be possible to describe a microorganism in words. In such cases a culture of the microorganism must be deposited in a culture collection not later than the date of the filing of the application. Indeed, the National Culture Collections offer a number of services, including the supply, identification, and safe deposit of cultures for patent purposes. Once the applicant has satisfied certain procedural requirements, a patent may be granted.

In the UK an applicant may deal with the Patent Office or the European Patent Office. The systems are broadly similar, although differences do exist. It should be noted that a UK grant of a patent is effective only in the UK. Patents for other countries generally have to be obtained locally. It is possible under the Patent Co-operation Treaty to obtain patents in a number of countries through a single initial application. It is also possible to obtain patents in up to 18 European countries, including the UK, by a single application to the European Patent Office.

We do not need to further probe the UK system governing patents because, with regard to Europe, the position on patenting is due to undergo some revision. It has been recognized that the biotechnology industries require a secure and effective intellectual property regime. The EC has answered the calls for such a regime in a 1998 Directive (73). This constitutes a significant piece of binding legislation, particularly for biotechnology. Member states will have until July 2000 in which to ensure that their national patent law is consistent with the requirements laid down by the Directive. The Directive maintains the general position with regard to patenting and biotechnology. Notable additional requirements include the denial of patents to inventions whose commercial use would be "immoral" (e.g., where suffering may be caused to a GM animal without particular gains for humans or animals). The Parliament and Council have also issued a regulation that impacts upon patenting biotechnology (74). This regulation enables certification, and strives to overcome some of the difficulties surrounding the granting of patents. Nevertheless, the 1998 Directive is undoubtedly the most important development in the area. Finally, and in contrast to the EC, the Council of Europe has appeared less willing to perceive patents as the panacea for the troublesome issue of rights in biotechnological advances. In that context, intellectual property rights are still being debated (75).

Home Office

In relation to the Home Office, a particular area of interest is the use of animals in scientific procedures (see the discussion below). The Animal Procedures Committee (APC) advises the Home Secretary on this issue, under the Animal (Scientific Procedures) Act 1986. The Committee is bound to have regard for both the legitimate requirements of science and industry and the protection of animals from avoidable suffering and unnecessary use in scientific procedures.

Similar themes are detectable in the relevant European legislative documents (for obvious reasons, not every document will be cited). The Council of Europe has had much to say on the status and treatment of animals (76). A key convention from 1986 regarding animals used in experimentation was, to a large extent inspired, by Directive 86/609 from the EC (77). It is notable that the contents of the two documents are broadly similar in their concern with ethical issues, such as the welfare of animals. Nevertheless, there are some distinctive differences. Thus, for example, whereas the Directive is primarily interested in the harmonization of national laws, in order to avoid any distortions in the internal market, provides better explanations of "alternative methods," and is supported by an Advisory Committee, the convention, by way of contrast, directs increased attention to the ethical issues, such as animal rights and humankind's needs.

In relation to biotechnology, two issues seem to have particular relevance to animals. These are cloning and genetic modification. As to the former issue, the EC has called for strict controls, with a particular view to ensuring that harm — to humans, animals and the environment — is minimized (78). As for the latter issue, both the EC and the Council of Europe have devoted some considerable efforts to assessing the permissibility of transgenesis; it is evident that each the ethical — primarily welfare-related — issues (79).

LOOKING TO THE FUTURE OF BIOTECHNOLOGY REGULATION IN THE UK

It is clear from the developments surveyed below that the regulatory philosophy of the UK government is unlikely to change much in the near future. It is unlikely, for instance, that a single National Bioethics Commission will be set up, partly because of the complexity of existing relationships within the administrative structure of the state (as shown), partly because of some scepticism regarding the merits of "bioethics" as an academic or policy discipline within the UK, partly because the experience of international debates with countries that have such a commission do not lead UK commentators to hope for much from such a commission, partly because of such a commission's enormous work load, and partly because there is no pressure for change at present. Bioethics advice is normally seen as the province of scientific experts, together with individual profession-based insights from key members of religious confessions (especially the established Church of England), the legal professions, and some social scientists and philosophers.

The credibility of some of the recent advice (e.g., on GM foods) has come under attack of late, in the main because many expert advisors have become seen to be out of step with the public mood, and in part also because some advisors have been seen as *parti pris*, in virtue of

the intellectual or commercial links with the activities they regulate. This is a problem in particular for scientific advisors, as has been seen in the GM foods debate.

It is true that the present Blair administration, and the previous Major administration, public commitments have been made to "open government" and to accountability of governmental and quasi-governmental committees. Appointments to all advisory committees must now be opened to applications for membership, and stringent appointment procedures now apply. But many important groups (e.g., commissions of inquiry) remain committees appointed by the minister on advice of his or her civil servants. Accountability is secured by accountability to parliament, and to the press, rather than any more direct method (e.g., public meeting).

Moving on from processual considerations of how committees are set up, structured, and members appointed, it has been noted by some commentators that most UK committees apply some very specific kinds of ethical and regulatory considerations to the legitimation of research and technology. Most committees apply some sort of risk–benefit calculus, modified in the light of broad social or cultural concerns. The initial Warnock report on Human Fertilisation and Embryology was much criticized by philosophers and by members of conservative pressure groups for the way it tried to synthesize analytic philosophical argument with more intuitive ideas about right and wrong. The result was felt to be unsatisfactory both from a consequentialist point of view (which underlies the risk–benefit arguments) and from the mainstream religious viewpoints (because the risk–benefit arguments were felt to miss the point). Nonetheless, the Warnock committees recommendations were broadly taken up in the form of the Human Fertilisation and Embryology Act. The general methodology of Warnock is similar to that of all the chief regulatory committees; what differentiates them is the way they assess risk, the significance attached to particular risks, and the way in which socially expressed concerns are permitted to influence these considerations (80). This point of method has significant consequences for the politics of such decision making (Risk to whom? How much is tolerable and by whom? Which risks are considered?), not least in the essential informality of the way judgments about risk must be made. At least one chair of a major committee has indicated great dissatisfaction with this state of affairs, but it is unlikely that the philosophy of such committee decision making will change significantly unless a different but similarly mechanical means for taking decisions can be found (81).

One major change over the next few years will be the impact of research programs in bioethics and biolaw in the UK; recent funding initiatives by the Wellcome Trust and by the European Commission, among others, are likely to result in major research projects into both the sociology of public discourse on biotechnology, and the incorporation of public attitudes into bioethical decision making. It will be interesting to see how (and if) such research affects policy making in the more formal arena of central government. However, it is likely that the main source of advice will continue to be the scientific and medical communities, whether or not the public credibility of these sources of advice, qua impartial advice, rises or falls.

In the light of these considerations, then, the main structural changes to biotechnology regulation will be constitutional changes in the state, rather than in the organization of regulation, its deliberative processes, or its underlying philosophy. The two main changes in the next few years are increased devolution of power away from the UK government in London "down" toward the national and regional authorities in Scotland, Wales, Northern Ireland, London, and the English regions, and "up" toward the European Commission and the juristic functions of the European Courts.

Recent Changes: The Implications of Devolution

With the devolution to the Scottish, Welsh, and Northern Ireland Parliaments, certain changes will be made to the regulation of biotechnology in the UK and Northern Ireland. Assisted conception, genetics, and health and safety legislation will be reserved to the Westminster Parliament, and therefore, the makeup of the primary and secondary legislation-making process and the advisory structure will generally remain the same. All other biotechnology related fields will become the responsibility of the devolved parliaments. The Northern Ireland and Scotland Parliaments will gain the ability to make primary legislation under the new structure, while the Welsh Assembly will acquire a similar range of functions, including powers to make secondary legislation.

All the devolved administrations will have access to the existing committees, irrespective of whether legislation is devolved or not. Where legislation is devolved, the new administrations, once in place, will be required to decide whether they wish to use the existing committees or create an alternative. They will also possess powers with regard to appointments to existing committees that are effected by devolution. The FSA and the proposed HGC and AEBC will operate on a UK-wide basis, with the devolved administrations having a say in appointments.

Of the statutory committees, those that will remain reserved to Westminster will be HFEA, CSM (which primarily advises the MCA, which will itself have some of its remit devolved; the CSM itself will become a UK-wide committee), ACGM (the environmental aspect of this committee will become devolved), VPC, and APC. The nonstatutory committees will all remain reserved, with no changes to the ACGT, HGAC, AGSAG, and GTAC. The remaining four committees, GAIC, UKXIRA, FAWC, and ACAF, will be altered so as to report to all the UK administrations within a UK-wide remit. Four of the remaining five statutory groups, although operating under devolved legislation, will continue to advise Westminster, and the devolved administration, if requested to do so. English Nature will be replaced in its UK advisory role by the Joint Nature Conservation Committee.

Recent Changes to UK Biotechnology Regulation

In May 1999 a government report was published that reviewed the UK's regulatory and advisory structure in biotechnology (4). In the report the government confirmed its existing policies, which are to protect the health of the public and to protect the environment while ensuring that

the potential benefits of this technology are not denied to the British people. Through consultation with the public, industry and experts, it was decided that there was a need to introduce a new regulatory framework. The new framework is designed to be less complex and more transparent, reflect the broader ethical and environmental questions and views of potential stakeholders, and is sufficiently forward-looking to encompass the rapid developments in this field.

The new comprehensive strategic advisory structure will be headed by the Food Standards Agency (FSA), and two new nondepartmental public bodies, the Human Genetics Commission (HGC) and the Agriculture and Environment Biotechnology Commission (AEBC). The remit of these three bodies is to advise relevant ministers on issues, receptively, on food safety, genetic technologies, and their impact on humans, as well as all other aspects of biotechnology without a direct impact on humans and food safety or food standards. Many of the present advisory committees' work has been taken on by the commissions, while other committees and technical bodies will be involved in cross-boundary issues between the three commissions. The commissions are not be involved in case-by-case review. This is still the responsibility of the remaining specialist technical bodies (84).

The ultimate responsibility in this area will lie with the appropriate Ministers. They will be responsible for giving guidelines to regulatory and technical bodies, changing the regulatory and advisory structure, and granting individual consent decisions. To aid the Ministers, the framework of independent expert regulatory and advisory committees will still exist under the remit of three nondepartmental public commissions. Direct advice to Ministers will come from these three strategic advisory commissions. The commissions will lease with the regulatory and technical bodies to give Ministers an overall picture of issues in biotechnology. In addition they advise on future strategy, changes in the guidelines for advisory/regulatory bodies, broader issues including ethics, and gaps in the framework.

Proposed Changes in to the European Legislation

There are a number of changes being proposed at the European level. Some of these are only entering the earliest debate and report stages, while others have progressed to encompass a draft Directive, which needs only to be debated. Due to the usual constraints, this discussion of potential innovations will have to be restricted. One of the more important proposals relates to those EC Directives governing deliberate release. In 1998 a draft Directive was drawn up (82), which is proposed to amend the central Directive 90/220 in a number of significant ways. These include strengthening the provisions on environmental risk assessment and monitoring, streamlining some procedures, ensuring greater transparency and improved labeling requirements, and providing for the consultation of EU ethics and scientific committees. Advances have also been proposed in the specific of novel foods, specifically in relation to additives (83).

CONCLUSION

The main advantages of the UK regulatory system are that it is flexible and responsive to the rapid changes in the biotechnology world; it is accountable readily to parliament and the courts; and some sort of workable balance is maintained, for the most part, between the politicians, scientists, technologists and industrialists, industrial consumers, and public consumers of biotechnological goods. For the most part the existing system has maintained public credibility, despite such recent disasters as the BSE/CJD affair and the GM foods affair. To some extent, at least, these crises are seen as failures of government rather than failures of advice. But underlying this assignment of responsibility is a growing sense of the politicization of science and the interested nature of scientific advice, and a response to this politicization that has not been seen since the nuclear power debates of the 1960s and 1970s. The weaknesses of the system of regulation are then (perceived to be) vulnerability to regulatory capture and lack of responsiveness to public debate. There is a sense abroad that "public debate" is perceived by government and the scientific community as necessarily ill-informed and misled, and therefore to be ignored or "educated." At the same time, certain kinds of public concern are taken note of (as in the cloning debate). It is not clear which sorts of public concern get to dominate scientific concerns and which are dominated by scientific and policy concerns. What is clear is that the political agenda, if not regulatory practice, will be increasingly shaped by the new single-issue agendas prompted by biotechnological change.

INTERNATIONAL INTELLECTUAL PROPERTY ISSUES FOR BIOTECHNOLOGY

CYNTHIA M. HO
Loyola University of Chicago School of Law
Chicago, Illinois

OUTLINE

OVERVIEW OF INTERNATIONAL INTELLECTUAL PROPERTY

Introduction

International intellectual property issues are becoming increasingly important as biotechnology is used and sold worldwide. This is because intellectual property rights are inextricably linked to the right to exclude others from use. The right to exclude can provide a competitive advantage or a barrier to entry into a commercial market. Several types of intellectual property provide some right to exclude others from an invention in the area of biotechnology — trade secrets, patents, and plant variety rights. Trade secrets enable their holder to prevent others from wrongfully appropriating valuable information for a potentially infinite time period. But they do not protect against independent invention, and they terminate once the information becomes public. A patent provides a right to exclude others, including independent inventors, from using the patented invention without consent, and only for a limited time. Plant variety rights function similarly to patents with respect to the ability to exclude others, but they are only available for plant "varieties."

Types of Protection

Trade Secrets. A trade secret typically consists of any information that is not generally known to others in the same business; it provides a competitive advantage to its owner. This is the easiest type of intellectual property

to acquire, but it also provides the weakest protection. Unlike other types of intellectual property protection, formal procedural requirements are usually unnecessary to "obtain" a trade secret. Rather, the inventor of a trade secret merely needs to keep the information reasonably secret. The trade secret lasts as long as the information remains secret. However, once the information becomes publicly known, the trade secret ceases to exist. One way this can happen is if the information is independently developed and patented by another. Under this scenario, a trade secret would be exterminated because a patent on the same information would reveal the information to the public (since patents are public documents). Moreover, under this scenario, the patent owner could preclude the former trade secret owner from using the now patented invention because patent owners generally have rights to exclude all others from the patented invention. Although some countries soften this approach by providing those who used an invention prior to its patenting by another (prior users) with the right of continued use, there is no uniformity in such protection; for example, while some European countries allow a limited right, no analogous protection exists for biotechnology trade secrets in the United States.

Even without the complications of a superceding patent, trade secret protection offers minimal protection. To begin with trade secret protection does not allow exclusion of those who independently invent the identical "trade secret" therefore, two or more individuals or corporations could theoretically be using the same trade secret without infringing on each other's rights if they all did so independently. A trade secret does not confer any affirmative rights except as to those who misappropriate the information (e.g., an employee who leaves with confidential information). Even then, the "protection" provided is usually inadequate because monetary compensation for the trade secret misappropriation cannot restore information to trade secrecy status if it has been disclosed to the public.

Patents. Patents provide inventors a reward or incentive for publicly disclosing an invention, by providing the inventor with the right to exclude others from the patented invention for a limited term. The exclusivity provided by a patent is considered critical to stimulate ideas and lead to further advances. The requirements established for patentability are aimed at securing the goal of promoting innovation. Although the requirements vary somewhat between various countries, the typical requirements for obtaining a patent are that (*1*) the invention constitute patentable subject matter, namely constitute the type of subject matter that country wants to encourage innovation in, and (*2*) that the invention, as disclosed in a patent application, satisfies technical patentability requirements. The scope of patentable subject matter may include both products and processes in all areas of technology. Technical patentability requirements typically require that the invention be at least "new," "useful" (or have "industrial application"), "nonobvious" (or have an "inventive step"), and fully disclosed in a written document such that someone who was similarly technically competent could reproduce the invention. These requirements are intended to define inventive activity deserving of a patent. A national patent office typically examines patent applications to determine whether the patentability requirements are met. Additionally, in some countries, third parties are allowed to oppose the issuance of a patent or petition to revoke an existing patent for failing to meet the technical requirements.

Patents are generally considered the preferable type of intellectual property to protect biotechnology because they provide the most exclusive rights. Unlike trade secrets, patents protect against independent invention because the owner of a patent can exclude all others from using the patented invention. In addition, because a patent can entitle its owner to exclude others, including competitors, a patent or even a potential patent can justify the often high cost of research and development involved in biotechnology. The potential to exclude all others through patent protection is considered more valuable than attempting to maintain a trade secret indefinitely with no potential to affirmatively exclude others. Thus patents are the principal type of protection that is sought for biotechnology even though disclosure of the invention is required and patent protection is not a certainty.

Plant Variety Rights. A plant variety right also confers some exclusive rights. A plant variety right, which is also referred to as a "breeder's right" (because the right is provided to the breeder of a plant variety), functions analogously to patent rights — a relatively exclusive right is provided to breeders of new plant varieties to further the development of agriculture. As with patents, plant variety rights are not automatic; rather, they must be applied for and examined to determine whether they meet the requisite technical requirements. The requirements for plant variety rights are intended to function similarly to those for patent rights in that both are intended to provide protection to subject matter that is truly innovative. Some of the technical requirements for plant breeder rights parallel those for patent rights — a variety must be "new" (although the definition differs from that for patents, as will be discussed later), "distinct," "uniform," and "stable." These requirements are generally less onerous than those needed to meet patentability requirements. In addition, unlike patents, disclosure of the invention, or at least the method of making the invention, is not always required, which could be seen as an advantage. Although plant variety rights will be addressed in this article, the focus is on patent protection because patents provide coverage for more types of biotechnology and broadest protection.

Examining International Issues

Intellectual property rights are national rights provided by individual countries such that examining international protection requires examining the laws of individual countries. The need to examine what protection is available for biotechnology on an international scale is of obvious importance. However, national laws are currently evolving, particularly in the area of biotechnology. One way in which an international perspective of important issues can be obtained is by examining key international agreements, as well as illustrative national

laws. Although no international agreement creates an international right, or even identical national rights, some agreements mandate minimum levels of protection by member countries, such that examining these agreements establishes what minimum levels of protection are globally available for biotechnology. The most important international agreement for this discussion is the Trade-Related Agreement on Intellectual Property (TRIPS) (1), which mandates minimum levels of protection for patents concerning all technology, as well as other types of intellectual property. In addition the International Convention for the Protection of New Varieties of Plants (UPOV) requires that its members provide minimum levels of protection for plant "varieties" (2,3). Both TRIPS and UPOV provide a useful framework for analyzing international protection as they establish a foundation of protection for all member countries. However, TRIPS and UPOV only provide a framework of minimum protection, rather than binding law. To determine global protection of intellectual property, national and regional laws will be discussed as illustrative of current approaches, as well as anticipated approaches in the near future. The laws applicable to Europe and Japan will be addressed as representative of current law impacting international protection of biotechnology (relevant U.S. law is addressed in a separate article of this encyclopedia). In addition to representing areas that are generally considered important for biotechnology, the laws of Europe and Japan highlight the application of both older and newer laws to biotechnology. Europe will be addressed as a single entity for this discussion because many European countries have adopted similar laws pursuant to international agreements other than TRIPS. The applicable agreements are the European Patent Convention (EPC), which applies to any European nation that signs the agreement and the European Union's Directive on the Legal Protection of Biotechnological Inventions (EU Directive), which applies to any country that is or becomes a member of the European Union (EU) (4,5).

Table 1 highlights membership in relevant international conventions based upon information obtained from the official website for each convention. However, it should be noted that this table only presents some members of these conventions — there are presently over 130 members of TRIPS and over 40 members of the UPOV and Budapest Conventions. For complete and membership regarding all conventions summarized in Table 1 (TRIPS, UPOV, and the Budapest Convention), the Web sites of those specific conventions should be consulted (6–11). In addition, for current membership to any of these agreements, official Web sites should be examined; this is particularly true for both TRIPS and the EU, as the scope of membership is expected to increase. For example, China is applying for membership to the WTO and if accepted, would be bound to comply with TRIPS. In addition countries that may be included within the EU include Hungary, Poland, and the Czech Republic (12).

Table 1 includes all members to EPC, as well as the EU (6–7). This table also includes important areas outside of Europe for which biotechnology protection is often considered important such as Australia, Canada, Japan, and New Zealand. Some areas where biotechnology protection is beginning to develop are also included for comparison such as South Korea and South Africa. For all these countries, Table 1 shows which are bound to the requirements of TRIPS and which provision of UPOV, if any, they comply with (as there are currently two versions of UPOV which govern) (8,9). Also countries that subscribe to the Budapest Convention, which governs deposits of biological material in relation to obtaining patent protection, are noted (10–11).

DEFINING THE PARAMETERS OF PROTECTION

Patents Pursuant to TRIPS

It is important to note that although TRIPS does not create a uniform worldwide patent law, it does establish a minimum floor below which no member may go without subjecting itself to potential retaliation by other countries in the form of trade sanctions. All countries that are members of the World Trade Organization (WTO) — an international organization designed to reduce trade barriers, including barriers to trade based on intellectual property — must comply with TRIPS. TRIPS binds a substantial number of countries — over 130 countries are presently members of WTO; these countries constitute 90 percent of world trade and include countries that utilize or expect to utilize biotechnology (2). Compliance with TRIPS requires complying with provisions of other international agreements that TRIPS incorporates, such as the Paris

Convention for the Protection of Industrial Property (13). TRIPS came into effect on January 1, 1995. However, the TRIPS requirements were not immediately binding; all members were provided time to enact laws to comply with TRIPS, with more time allotted for developing countries (many of which previously provided limited, or even no, patent rights whatsoever). The first date by which any WTO member had to comply with TRIPS was January 1996; at this time all developed countries were supposed to be in compliance with all provisions of TRIPS. In addition, as of January 2000, all developing countries (and those whose economies are in transition from a centrally planned economy into a free-market economy) should be in compliance with most portions of TRIPS. However, "least-developed" countries have until 2005 to provide patents for any subject matter that was previously deemed unpatentable. Moreover less-developed countries (LDCs) do not have to comply with any of the minimum patentability standards until 2005, with the possibility for a further extension of time.

Compliance with TRIPS requirements is aided by the potential of some type of retaliatory behavior by other WTO member nations. In particular, if a member state fails to comply with TRIPS, another member country may challenge the noncompliance. Members must initially try to resolve issues through a dispute resolution process pursuant to the Dispute Settlement Understanding (DSU) (1,14). If members fail to reach a mutually satisfactory resolution regarding any alleged noncompliance with TRIPS, a complaining member may request a WTO panel to examine the issue in an adjudicatory proceeding. The WTO panel must issue a decision within a relatively short timeframe, after which parties must comply or appeal to an appellate body of the WTO and subsequently comply with any decision by the appellate body. If a member fails to comply, sanctions may ultimately be imposed, including retaliatory action that includes withholding benefits under TRIPS or other WTO agreements such as the General Agreement on Tariffs and Trade (GATT). Although additional information on the DSU is beyond the scope of this chapter, the WTO Web site provides a current overview of active disputes; also additional information on dispute settlement is readily available from other sources (14–19). However, it should be noted here that the DSU rules have already been effectively applied to enforce protection of biotechnology. For example, India's compliance with the transitional provisions of TRIPS was challenged by the United States and the EU. After failing to convince both the WTO panel and Appellate Body that its laws were in compliance, India took action to amend its laws (20–21). The India dispute illustrates the effectiveness of TRIPS in effectuating real change to protection of biotechnology, as well as the relative rapidity under which such change occurs.

The TRIPS requirements relating to patents focus on three main issues: what must be patented, the scope of patent protection for issued patents, and the enforcement of patent rights. Although all three of these are important, this section will primarily focus on the first two issues since their impact is more particular to the field of biotechnology; information concerning enforcement of all patent rights under TRIPS, including patent rights for biotechnology patents, is available from other sources (19). The TRIPS requirements are actually minimum standards of protection that must be satisfied by all members. Because of the substantial number of countries that must comply with TRIPS, the TRIPS requirements are very important.

Eligible Subject Matter. The requirements for what must be patented are set forth under Article 27 of TRIPS. In particular, TRIPS first sets forth that:

> 1. Subject to the provisions of paragraphs 2 and 3, [p]atents shall be available for any inventions, whether products or processes, in all fields of technology, provided that they are new, involve an inventive step and are capable of industrial application. Subject to paragraph 4 of Article 65, paragraph 8 of Article 70 and paragraph 3 of this Article, patents shall be available and patent rights enjoyable without discrimination as to the place of invention, the field of technology and whether products are imported or locally produced.

This provision imposes several requirements. First, it states that patents must be available for "inventions" subject to two limitations (in paragraphs 2 and 3) which exist for particular categories of subject matter as well as exceptional situations. Second, it states that a patentable invention must be "new," involve an "inventive step," and be "capable of industrial application." Third, it states that except for countries to whom a transitional period is allowed (under Articles 65 and 70 of TRIPS), patents and patent rights must be provided without discrimination; countries cannot discriminate in issuing patents or providing patent rights based on where the invention was made, the type of invention, and whether products are imported or locally produced. As the last requirement relates to both patentability and scope of patent rights, it will be discussed with respect to both issues separately.

Although these requirements are not presently binding on all WTO members, they must eventually be complied with. The TRIPS requirements of patentability indicate what types of biotechnology are presently patentable or will be in the future. TRIPS requires that patents be granted to all "inventions" that satisfy technical patentability requirements, subject to three specific exceptions. Table 2 summarizes these exceptions. As shown in this table, subject matter may be excluded if it is (*1*) not considered an "invention, or (*2*) specifically delineated within TRIPS as excludable, or (*3*) falls within the unspecified exclusion for inventions contrary to *ordre public* or "morality." Each one of these three requirements allows member states the opportunity to narrow the scope of patentability. The scope of patentable subject matter may be limited based on a narrow interpretation of undefined TRIPS terms; this table indicates such undefined terms by placing them all in quotes.

The requirement that patents be available for all "inventions" without regard to the type of technology involved and whether the invention is a product or a process is important for biotechnology. Prior to TRIPS more than 50 countries did not provide patent protection

Table 2. Permissible Exclusions of Patentable "Inventions" Pursuant to TRIPS[a]

Anything excluded from the definition of an "invention"[b]
Specific subject matter exclusions (Article 27(3))
• Methods of treatment of humans and animals
• Plants[c] and animals (other than microorganisms)
• "Essentially biological processes" for making plants and animals (other than microorganisms)
Unspecified exclusion for "*ordre public*" or "morality" (Article 27(2)) (subject matter may be excluded if preventing commercial exploitation is necessary to protect "*ordre public*" or "morality")[d]
• Protecting human, animal or plant life
• Protecting health
• Avoiding serious prejudice to the environment

[a]TRIPS *permits* members to exclude these categories from patentability, and members are free to provide patent protection for these categories.
[b]The word "invention," as well as other quoted words on this table, are undefined in TRIPS and may be subject to differing interpretations (which can affect the scope of patentable biotechnology).
[c]TRIPS does require that plant "varieties" (also undefined within TRIPS) be protected either under the patent system or a sui generis system.
[d]N/A where commercial exploitation is prohibited by local law.

for pharmaceutical and other products relating to health and medicine (22,23). In fact, the disparate treatment of such products was a prime consideration in enacting this language (24). Still it is unclear whether this provision mandates a general principle of patentability of "inventions" (25). In addition, even if a general presumption of patentability is established, the meaning of the word "invention," as well as the allowable exceptions from patentable "inventions," can substantially narrow what types of biotechnology are patentable (26).

Identifying what is an appropriate "invention" is the first point at which subject matter may be narrowed. TRIPS itself does not define an "invention." Although this is consistent with prior patent law in many countries, it leaves the scope of patentable subject matter particularly uncertain in the biotechnology area where there is not always a marked distinction between unpatentable "discoveries" and patentable "inventions." Countries generally consider discoveries and naturally occurring substances to be unpatentable inventions, but the genetic manipulation of naturally occurring substances has arguably blurred the line between discovery and invention. Some countries take a relatively expansive view of the term "invention" to include products that are found in nature, so long as they are isolated by an unnatural (biotechnological) process; isolated genes and gene sequences may be considered patentable under such a definition of invention. On the other hand, countries may elect to *exclude* isolated products of nature as noninventions (22,24). Because the term is undefined in TRIPS, countries are free to adopt either view. However, even if isolated biological material is considered a patentable invention, problems with other patentability requirements such as "industrial application" may exist (e.g., if there is no known use for the material other than as a general probe, as will be later discussed).

Specific Exclusions. The three types of subject matter that are specifically set forth as excludable subject matter under TRIPS all impact the scope of biotechnology that may be patented. TRIPS allows the following categories of subject matter to be excluded from patentability:

1. Methods of treating and diagnosing humans and animals
2. Plants and animals other than microorganisms
3. "Essentially biological processes" for creating plants and animals

It is important to note that these are *optional* exclusions from patentability. Accordingly, countries may adopt some, all, or none of these exceptions in their patent laws and still be in compliance with TRIPS. In addition, it should be noted that even if a country enables a broad range of subject matter to be considered an "invention," adoption of these exclusions, or a broad interpretation of these exclusions could significantly narrow the field of what is considered patentable subject matter. Moreover, even if none of these exclusions are adopted, what is actually patentable may nonetheless be a narrow range of inventions if the criteria of patentability are applied strictly, as will be explained later.

1. *Methods of Treatment and Diagnosis.* TRIPS allows methods of treating or diagnosing humans or animals to be excluded from patentability under Article 27(3)(a). This prohibition is similar to the language of many European and Latin American countries' patent laws (22). Application of similar prohibitions under national laws have shown that the scope of such an exclusion may be a function of the interpretation of individual terms, such as the meaning of "therapy," "method of treatment," or "diagnosis." (27–32). This exclusion is of great importance for biotechnology as the exclusion of "therapeutic and surgical methods" may exclude patents for gene therapy. In addition the bar on "diagnostic methods" may result in the exclusion of genetic testing or screening kits from patentability. Countries have taken varying stances in applying similar statutory exclusions to gene therapy; for example, some countries only exclude in vivo, but not ex vivo methods of treatment, whereas other countries exclude treatment involving humans but permit patenting of the identical treatment on animals.
2. *Animals, Plants, and Essentially Biological Processes.* TRIPS also states under Article 27(3)(b) that members may exclude from patentability "plants and animals other than micro-organisms, and essentially biological processes for the production of plants or animals other than non-biological and microbiological processes." However, protection of "plant varieties" must be provided either under the patent system or a sui generis system (1). This provision allows countries to disallow patents on transgenic plants and animals, even if they meet the technical requirements of patentability. Although genetically

modified plants may be entitled to some protection if considered a plant "variety" (which is not defined under TRIPS), exactly what protection is uncertain. While TRIPS requires an "effective" sui generis system, there is no definition of what this system requires. This may include one system for protecting plant varieties that existed at the time TRIPS was enacted — UPOV (24); however, not all commentators agree that UPOV is consistent with this provision (33). Moreover, even if applicable, UPOV does not provide the identical scope of protection as that required under TRIPS, as will be noted in the later discussion of UPOV. In addition it is uncertain what other system besides UPOV would be adequate. Moreover, TRIPS does not require any protection for transgenic animals. While there is the possibility that the process of creating a transgenic animal could be patented (assuming the technical patentability requirements are met), this provides less protection than if the animal itself were patentable. In addition patentability of a process for creating a transgenic animal is not certain as members need not protect "essentially biological processes" for the creation of animals. TRIPS does not define "essentially biological" other than to state that it does not include processes that are "nonbiological" or "microbiological." Accordingly member countries could define "essentially biological" to exclude any process that involved at least one biological step (i.e., one that does not involve genetic engineering). This exclusion will likely generate continued debate as it was controversial during the initial TRIPS negotiation and must be reviewed every four years after TRIPS enters into force (1,26,33).

Nonspecific Exclusion. In addition to the foregoing specific exclusions that implicate biotechnology, a potentially major hurdle for biotechnological inventions may be the unspecified exclusion under Article 27(2) that allows "inventions" to be barred from patentability if preventing "commercial exploitation" of the subject matter is necessary to protect "*ordre public* or morality." However, TRIPS also states that this exclusion is not satisfied by the mere fact that exploitation of an invention will be in violation of a national law. TRIPS does not provide additional guidance on the definition of *ordre public* or *morality* other than to indicate that it may involve the following broad categories: protecting human, animal or plant life, protecting health, and avoiding serious prejudice to the environment (1). Further, because this exclusion refers to "inventions" rather than categories of subject matter as in Article 27(3), it appears that it may need to be applied on a case-by-case basis (24).

This provision stands as a potentially large barrier to patenting new types of biotechnology as patenting biotechnology raises issues of morality even in countries where patenting of biotechnology is allowed. Similar provisions have been utilized, or noted as capable of being utilized, to deny patents on transgenic plants and animals as well as isolated gene sequences (27). However, interpretation of what constitutes ordre public or morality in the context of patenting biotechnology has been elusive. This exception requires that the violation of "ordre public" or "morality" be the result of "commercial exploitation." This may pose some interpretative difficulty as commercial use or exploitation is not required to be disclosed in a patent application and may not be known. Accordingly, although a patent office is charged with determining whether commercial exploitation of an invention would violate these undefined terms, the necessary information may not be available at the time of examination to enable an educated decision.

The scope of this exception may be limited by prior interpretations of similar terms, albeit in contexts other than TRIPS, or even patent law. In particular, prior WTO dispute panels have examined and interpreted the meaning of "necessary" and "morality" under the General Agreement of Trade and Tariffs (GATT), which governs trade of goods (24,34–36). In that context, it has been found that the term "necessary" requires objectively justifiable measures and that there be no alternative measure available (24). Although prior WTO panels may be relied on by subsequent panels, it is unclear what weight a panel would give to a previously interpretation made in a different context (37). In addition it has been suggested that the definition of *ordre public* can be derived from case law by the European Court of Justice, the court that arbitrates issues among the EU countries (38). This may however be similarly unhelpful as there are no such cases interpreting *ordre public* in the context of patentability. Finally, countries or the WTO could look to prior interpretation of similar provisions, such as in Europe; although there are no decisions finding that inventions violate such a provision, suggestions as to the parameters of such a provision may be considered. For example, European courts have interpreted a similar provision under EPC article 53(a). The EU Biotechnology Directive also provides explicit examples of types of commercial exploitation that would violate an identically worded provision (5,27).

Illustrations of Patentable Subject Matter. Because TRIPS is a minimum standards framework with terms that are subject to differing interpretations, the scope of patentable subject matter may vary among different countries that comply with TRIPS. The diversity of approaches may be illustrated by a comparative view of specific types of patentable subject matter. A recently compiled report by the Working Party of the Trade Committee of the Organisation for Economic Cooperation and Development (OECD) provides a good source of such information. In response to an OECD questionnaire to individual countries concerning intellectual property practices in the area of biotechnology, information from patent offices of 22 OECD countries was obtained. Although the information was provided in varying degrees of detail and does not necessarily constitute official policy of individual patent offices, it is nonetheless useful for comparison.

Table 3 presents a summary of information submitted by individual patent offices to the OECD concerning the types of inventions in the area of biotechnology that are considered patentable subject matter. This information was submitted roughly in the time period 1998 to 1999. Accordingly, to the extent that laws have been amended

Table 3. Patentable Subject Matter

	Nucleic acid sequences	Amino acid sequences	Isolated materials	Living unicellular organisms	Plants, parts, varieties	Animals, organ varieties	Humans, organ, human-derived products	Methods of treatment	Methods of diagnosis
Australia	Y	Y	Y	Y	Y	Y	N	Y, except essentially biological processes that produce humans	Y except essentially biological processes that produce humans
Canada	Y	Y	Y	Y	N (but PVR exist)	N	Human-derived only	No, except ex vivo	Y, unless surgery or therapy
Japan	Y	Y	Y	Y	Y	Y	Human-derived; human organs if not immoral	Only animals or ex vivo	Animals only
Korea	Y	Y	Y	Y	N, except asexual plants	Y	Human-derived only	Animals only	Animals only
New Zealand	Y	Y	Y	Y	Y	Y	Human organs; human-derived (if process to create not immoral)	Animals only	Y, unless surgery involved
Norway	Y	Y	Y	Y	N, except plant parts that can't differentiate to whole plants	Animal organs only	N, except isolated elements	Ex vivo only	Ex vivo only
EPC/EPO	Y	Y	Y	Y	Y, except "varieties"	Y, except "varieties"	Human-derived only	N	N
EU	Y	Y	Y	Y	Y, if not technically limited to specific variety	Y, unless animal modified to cause suffering without substantial medical benefit	Human-derived if isolated or produced by "technical process"	N/A (national/EPC law to apply)	N/A (national/EPC law to apply)
United States	Y	Y	Y	Y	Y	Y	Human-derived only	Y	Y

since that time, this information would not reflect that. The table includes countries in which patents are often sought such as Japan, Canada, and Australia. In addition, the EPO is included because it issues EP patents that can become transformed into national patents. Information from individual countries of EPC are not included in this table as their laws largely mirror that of the European Patent Office (EPO), the governing office of EPC. However, some of these countries did provide separate information to the OECD survey, and this information is available from the OECD Web site (40). In addition some countries are included for comparison such as South Korea, New Zealand, Norway, and the United States. For information concerning all 22 countries that responded to the OECD questionnaire, the actual report should be consulted, as well as the responses of individual countries (39–41).

As noted on Table 3, there are several categories of biotechnological matter that are universally considered patentable subject matter. In particular, chemical structures composed of nucleic acid sequences and gene sequences are considered patentable subject matter in all responding countries; this is true regardless of whether the sequences correspond in part or whole to information found in living organisms. Material isolated from living organisms, other than such sequences, are all considered patentable subject matter as well as living unicellular organisms. It should be noted, however, that despite the uniform patent eligibility of such inventions, actual patents nonetheless may not issue because of how the technical requirements of patentability are applied.

More variation in patentable subject matter exists with respect to multicellular organisms and subparts of those organisms. The only common denominator among approaches is that patents on humans are universally rejected. However, "human-derived products," including cell lines, genes, and nucleic or amino acid sequences are considered patentable, for example, in Canada, Japan, and the United States. However, even to the extent that multicellular organisms and their parts are not categorically excluded from protection, they may nonetheless be denied protection on grounds similar to TRIPS 27(2)—namely they may violate a provision of the patent act that precludes patents on inventions that are unethical or immoral. Exclusions on the basis of morality could be a factor in the denial of patents for inventions by the EPO as well as by the patent offices of Japan, and Canada as all of them have such a provision.

Similarly there is wide variation with respect to what types of methods of treatment or diagnosis would be considered patentable. For the purposes of comparison, the methods of treatment column in Table 3 represents responses to both whether methods of treatment are patentable and whether methods involving genetic engineering for purposes other than surgery, therapy or diagnosis (e.g., for experimentation or research) are patentable. Some countries appear to take a fairly strict interpretation of statutory provisions against methods of treatment and diagnosis such that gene therapy is excluded. Others will allow methods of treatment or diagnosis only with respect to animals, or with respect to methods occurring outside the body (ex vivo). Finally, just as with patents on multicellular organisms, patentability of biotechnological methods are also impacted by provisions in patent acts that preclude patents that are immoral or contrary to *ordre public*.

Table 4. Technical Patentability Requirements

A patent application must disclose an "invention" (see Table 2) that is: • "new" • "industrial application" or "useful" • "inventive step" or "nonobvious"
Patent application (Article 29) must disclose invention adequately for duplication by one "skilled in the art"

Patentability Criteria. There are two basic requirements for patentability, as shown in Table 4. An application must establish that an invention meets technical requirements of patentability. The application must further sufficiently disclose the invention such that someone who is similarly skilled could replicate the invention. Article 27(1) of TRIPS requires that technical requirements include that an invention be new (novel), nonobvious (or have an inventive step), and be useful (or be industrially applicable) (1). Although these requirements are ones that are common to most patent laws, countries have differed in their definition of these terms, as well as in the application of these terms to biotechnology (22,24). For example, there is no consensus on whether patents on gene sequences (that are considered "inventions") may be denied for lack of "industrial applicability" if the function of gene sequences is unknown other than as a probe. Similarly there is no consensus on whether isolated biological matter is "new." While application of patentability requirements to biotechnology are developing with respect to all the requirements, novelty and adequate description will be focused on here because application of these standards to biotechnology raises unique issues. As was seen with patentable subject matter, the undefined patentability criteria allows wide variation among countries; each requirement is an additional juncture at which the scope of patentable subject matter may be further limited.

Novelty. The requirement that an invention be new is fundamental to the patent system policy of providing an incentive to produce things that would not otherwise be known to the public. An invention is generally new or novel if it was not known or available to others prior to the application of the patent; it is often stated that an invention is new if it is not previously known in the "prior art." Prior art may include descriptions in printed publications (e.g., foreign patents and published patent applications) as well as oral information and actual use. In all cases, to constitute prior art, the information must be such that the invention is essentially known to those in the same field (i.e., the description must be adequate to "teach" the invention to one in the field).

In determining novelty, it is important to note that pursuant to TRIPS, all WTO members must now recognize a "right of priority" for filing of patent applications (1,13,42). This means that if a patent application is filed in a member country, that date of filing may be relied on for subsequent filings of applications for the same invention in

other member countries, so long as subsequent filings are within 12 months of the original application (1,13,42). This right of priority is very important to determining novelty because, without such a right, an applicant's own application could bar a patent in another country unless patent applications were simultaneously filed in every country in which protection were desired. Therefore recognition of priority date is important as it gives an applicant 12 months within which to decide where to file and actually complete the formal filing requirements.

There are different interpretations of the novelty requirement taken by countries to determine whether an invention is sufficiently deserving on patent protection. The different approaches reflect different perspectives of how new something must be before a patent is awarded. Under a "strict" approach to novelty, an invention is not novel if it was known in any way, in any country, prior to the date of the patent application — regardless of whether the applicant was aware of it, or if the applicant could have reasonably been aware of it; this strict approach is often referred to as "absolute novelty." However, another approach is to reward an applicant for bringing some invention to the particular territory in which the patent is sought that likely would not otherwise have been known. Under this "relative novelty" approach, nonwritten knowledge or use of an invention outside the territory is not considered prior art for purposes of novelty; this is the approach taken by the United States. The rationale for this scheme is that a printed publication is accessible to all even if printed in another country, whereas a use of an invention is much more difficult to ascertain and thus a patent should be granted to one who brings the invention to the public's attention.

In the biotechnology area, the distinction between the absolute and relative novelty standards are demonstrated by some biotechnology methods. For example, new uses of previously known products (often referred to as "second use" or "second medical use") may be disallowed under a strict novelty criterion. Although such uses are considered "new" under both United States law as well as the EPC, TRIPS certainly does not mandate such an interpretation. Similarly new products that result from previously known processes may be disallowed under a strict novelty criterion. Again, the United States provides patent protection for such processes.

It is possible to also provide a grace period in terms of novelty. In particular, a grace period may allow an applicant to disclose an invention to the public prior to filing the patent application without sacrificing patent rights. It is common for the grace period to last only six months from the triggering event and to be no longer than a year; for example, the United States has a one-year grace period, while Canada and EPC provide a more limited period of six months. The rationale behind such a system is that it enables speedier public access without removing the incentive of patent protection. Countries vary with respect to what activities are allowable during the grace period. For example, in the United States a grace period is provided for not only publications but also prior use, sale, and offers for sale. However, in other countries, a grace period may only be available for activity of an inventor, and the activity may be limited to disseminating information only at specified conferences; some illustrative subscribers include Canada, Australia, and EPC.

Adequate Description. TRIPS requires that for a patent to issue, an application must first disclose the invention "in a manner sufficiently clear and complete for the invention to be carried out by a person skilled in the art." (1). Once again, the TRIPS agreement has only mandated the result but has not dictated how countries must meet it. Countries vary with respect to whether a deposit of a sample of a biotechnological invention is required, as well as when and where this must be done (4,5,39). The Budapest Convention provides some guidance to its members (many of whom include WTO members) on when deposits are required, and the relevant procedures that must be followed (10).

Patent Rights

Patent Term. TRIPS requires that members provide a minimum patent term of 20 years, calculated from the date of filing of the patent application (1). An applicant generally has no rights during the application process. No extension of the term is required by TRIPS even if the effective term has been substantially reduced by the patent examination process; this is problematic for patents that involve biotechnology as they often take longer to examine than more traditional inventions. In addition no extension of term is provided for delays in the sale of a patented invention that often result from regulatory approval for pharmaceuticals. Accordingly the effective term of pharmaceutical patents may be considerably shorter than that provided to other subject matter. Although many developed countries, including the United States, and more recently Japan, provide an extended term of protection for such patents, TRIPS does not require it. Accordingly, although TRIPS mandates patent protection for all inventions and nondiscrimination in terms of patent rights, it does not mandate an effectively equal patent term.

Scope of Protection. Consistent with prior patent law doctrine, patents granted pursuant to TRIPS do not provide an affirmative right of use to the patent owner. Rather, patents only provide a right to exclude others. To be entitled to use the patented invention, the owner must determine if there are additional laws with which compliance is necessary. For example, a newly patented pharmaceutical typically cannot be sold without governmental approval and separate applications are required to obtain patent rights and the right to sell. Moreover the patent owner may need to determine if permission from another patent owner is required to avoid infringement. For example, the owner of a patent on a new use of a previously known and patented compound would need permission from the owner of the patented compound to actually use the newly patented invention (as the owner of the patented compound has the right to exclude others from making the compound).

TRIPS provides that a patent confers on its owner "exclusive rights" to prevent unauthorized persons from certain activities. The activities that may be excluded differ with regard to whether the subject matter of the

patent is a product or process. If the patented subject matter is a product, the owner can exclude others from "making, selling, offering for sale, selling, or importing, the patented product. On the other hand, if the patented subject matter is a process, the owner is entitled to exclude others from using the patented process as well as offering for sale or selling the process; in addition the owner can exclude others from importing the product obtained "directly" from the patented process. Most of the exclusive rights established under TRIPS have been generally recognized in industrialized countries. It should be noted that many industrial countries also allow rights against persons who contribute or induce these activities, although TRIPS does not require this; the United States, Japan, and certain European countries allow such rights.

Although TRIPS specifies that certain activity is within the patent owner's "exclusive rights," the nature of that exclusivity may be limited pursuant to other articles of TRIPS (as will be discussed in the next section), as well as by a nation's interpretation of these provisions. For example, what constitutes a patented product or process must first be determined in order to determine what may be excluded. Generally, patents include one or more claims, which are sentences at the end of a patent that define the scope of the invention, and accordingly define the scope of patent rights. In addition patents generally can include claims to both products and processes; some countries allow claims to not only chemical structures but also claims to function and products made by certain processes. To determine what constitutes the patented invention, the claims most likely will be examined (often referred to as "claim interpretation"). However, countries differ vastly in their approaches to claim interpretation. Countries may look not only at the patent claims but also the rest of the patent, its history, and other extrinsic evidence to determine the "true meaning" of the claims. Some countries are more liberal in interpreting patent claims, and they find patent infringement even when a defendant is not precisely within the literal scope of patent claims (sometimes referred to as infringement under the "doctrine of equivalents" as the defendant's actions are considered equivalent as a matter of equity, to what is literally stated in the claims). Equivalents are considered either at the time the application is filed or at the time of the infringement. All of the above variations allow member countries substantial leeway in the extent of protection granted.

Regardless of how a country interprets the patent, TRIPS provides a higher threshold of protection for patented processes than was previously recognized in most countries. In particular, TRIPS provides the right to exclude unauthorized persons from products obtained "directly" from a patented process in addition to excluding persons from the patented process itself. The additional protection against products "directly" obtained by a patented process is intended to provide protection in the case where the patented process is used in a country where no protection exists, and the resulting product is imported into the country in which patent protection exists (24). The extension of protection to direct products also aids owners of such patented processes to establish unauthorized use of a patented process as access to an infringing process is often impossible. In addition TRIPS now provides that judicial authorities may require the alleged infringer to rebut a presumption of infringement in the case of patented process if the infringer's product is identical to that produced by the patented process (1). However, it is only required in one of two circumstances: (*1*) where the product obtained by the patented process is "new," or (*2*) when there is a "substantial likelihood that the identical product was made by the process and the owner of the patent has been unable, through reasonable efforts, to determine the process actually used" (1).

Although the scope of the patent owner's exclusive rights is fairly clear, one exception is the scope of the importation right. In particular, TRIPS specifies that for patents on both products and processes, the owner has the right to exclude others from importing the patented product or the product obtained directly from the patented process. The right to preclude importation of a patented product is a right that was not generally recognized in industrialized countries prior to TRIPS. However, TRIPS does not clarify what this new right should include; there is a footnote after the importation right that cross-references an earlier article of TRIPS that states that for purposes of dispute settlement, TRIPS is considered not to address the issue of exhaustion of patent rights. The principle of "exhausting" a patent right is that if a patented product is legitimately sold or otherwise conveyed, no further patent rights exist with regard to that article. To the extent that there is an argument that imports of patented products fail to impinge on a patent owner's exclusive rights because of the principle of international exhaustion, such arguments will not be recognized in official dispute settlement proceedings.

Exceptions. Although the previously discussed provision of TRIPS provides "exclusive rights" to the patent owner, TRIPS also clearly contemplates that the "exclusive right" may be more circumscribed. Two separate articles of TRIPS provide exceptions to the "exclusive right" that is provided in Article 28. In particular, Article 30 provides a "limited exception" to the exclusive right, while Article 31 contemplates that member countries may allow unauthorized "other use" of a patent. As these exceptions are critical to defining the full scope of patent rights — just as possible exclusions to patentable subject matter were important to determining what inventions are patentable — the exceptions to the patent owner's exclusive rights will be discussed here.

"Limited" Exceptions. Although TRIPS provides that members may provide "limited exceptions" to the patent right, it does not clearly define what constitutes a "limited exception." In particular, TRIPS Article 30 states that "[m]embers may provide limited exceptions to the exclusive rights conferred by a patent, provided that such exceptions do not unreasonably conflict with a normal exploitation of the patent and do not unreasonably prejudice the legitimate interests of the patent owner, taking account of the legitimate interests of third parties" (1).

Although the scope of this exception is not explicity clear, some countries have tried to incorporate the exception into national law. Some countries have incorporated

the language of TRIPS Article 30 wholesale into their national laws, without attempting to define any terms. Other countries, while not using the literal language in Article 30, have adopted language that is equally vague. For example, Argentina has amended its patent laws to state that the patent office is permitted to establish limited exceptions in "sectors of vital interest to the socio-economic and technological development of the country" (43). It remains to be seen whether countries with established patent systems, including exceptions to patent rights, are in fact TRIPS-compliant; this cannot be clearly established in the absence of challenge by another country. However, even in the absence of an official challenge, countries are becoming more cognizant of TRIPS requirements and the possibility of a challenge. In fact there has been some discussion in the United States concerning whether a provision of the U.S. patent laws that precludes patent owners from obtaining relief against infringing doctors of medical procedure patents either violates the TRIPS rights or is exempt under this provision (44–46).

The proper interpretation of the "limited exception" provision will probably be a major issue in international patent protection. One panel recently addressed WTO whether Article 30 permits (*1*) the manufacture of patented product for the purpose of obtaining regulatory approval prior to the patent expiration or (*2*) the manufacture and storage ("stockpiling") of generic drugs such that they can be sold the day the patent expires (15). In particular, Canada's patent laws were alleged to infringe on patent rights during the patent term (15,47). Canada argued that Article 30 provides it with an exception to what would otherwise technically be a violation of patent rights mandated by TRIPS (48). In particular, Canada believed that its actions were allowable as a "limited exception" in the case of patented pharmaceuticals where generic drug companies need to infringe a patented drug to obtain regulatory approval prior to the expiry of the patent (48). The rationale for such an exception was that without it, a patent owner would effectively be given an extension of patent term due to the generic manufacturer's need to wait for regulatory approval; allowing limited infringement by the generic manufacturer was considered to be in the public interest because it enables cheaper drugs to be provided to the public sooner. The WTO found that the regulatory approval exception was an allowable exception to the usual patent owner rights pursuant to article 30. However, the WTO panel found that the stockpiling provision was not a "limited exception" in accordance with article 30. Although the decision is not binding on other parties, it is important to the many nations which have regulatory approval exceptions similar to Canada's such as the United States and Japan; these countries are now more assured that their patent law exceptions are TRIPS-compliant. The WTO decision is also important beyond the specific subject matter of regulatory approvals. In particular, the WTO panel decision explained how article 30 should be interpreted in relation to patent rights under article 28 (47). The WTO panel underscored that a patent owner is entitled to the full panoply of patent rights listed under article 28 (and not just the right to sell as Canada had previously asserted) (47). In addition, the WTO panel clarified that to be entitled to an exception under article 30, three requirements must be met:

1. there must be a "limited exception" to the exclusive rights;
2. the exception must not "unreasonably conflict" with the "normal exploitation" of a patent; and
3. the exception must not "unreasonably prejudice" the "legitimate interests" of the patent owner, taking into account the "legitimate interests" of "third parties."

The WTO panel decision itself may be consulted for the detailed explanation of each of these requirements (47). Even without a complete explanation of the panel's opinion, however, it should now be appearent that future disputes concerning exceptions to patent rights will be carefully evaluated by WTO panels in accordance with the specific facts of each case.

In addition, what other exceptions to a patent owner's exclusive rights may exist remains an issue. Some countries and commentators have assumed that certain activity is covered by Article 30 based on prior drafts of Article 30 (22,24). For example, activity that has been assumed to be allowable includes private noncommercial use, use of the invention for research, experimental use to test or improve the invention, use for teaching purposes, preparation of medicine, prior use of the invention by a third party before the date of application of the patent (22,26). However, whether such uses are actually consistent with article 30 is unknown. Although a WTO panel recently had occasion to address this issue, it specifically declined to comment on whether national patent laws providing exceptions for experimental use were consistent with TRIPS ariticle 30 (47).

Compulsory Licensing. Compulsory licenses are an important issue as they substantially limit a patent right. The term "compulsory licensing" refers to a license of the patent owner's invention that is involuntary, or compulsory. Compulsory licensing is important to biotechnology patents because even if patents are appropriately granted, the patent right is substantially diluted if compulsory licensing is allowed. Moreover, prior to TRIPS, it was not uncommon, particularly in developing countries, to require compulsory licensing of pharmaceutical patents, or other patents relating to health on the ground that it was necessary in the interest of public welfare. In addition compulsory licenses have been granted in some countries where the patent owner is not using the invention in the country (usually referred to as not "working" the invention).

Article 27 prohibits certain types of "discrimination"; in particular, it requires that all patents, once issued, be entitled to the same right to exclude without regard to the subject matter of the patented technology; in particular, it states that there should be no discrimination based on whether the invention is "imported or locally produced." The negotiating history of this provision indicates that developed countries intended this to exclude compulsory licenses for nonworking as previously allowed

under the Paris Convention (24,49). Some interpretations of this provision interpret it as eliminating such a requirement (50–51). However, although this may have been the intent of some countries in drafting this provision, the correct interpretation is unclear. For example, Brazil explicitly provides compulsory licenses for failure to exploit an invention locally (52–54).

An important issue under TRIPS is determining what types of compulsory licensing are permissible. Several articles of TRIPS may relate to compulsory licensing. Article 31, which places procedural limitations on licenses, is often presumed to apply to compulsory licenses; indeed, although Article 31 presently refers to "other use" that is unauthorized by the patent owner, prior drafts of Article 31 used the term "compulsory licenses"(24). Two additional articles of TRIPS recognize that intellectual property rights, including patent rights, are not absolute. In particular, Article 7 states that:

> protection and enforcement of intellectual property rights should contribute to the promotion of technological innovation ... to the mutual advantage of producers and users of technological knowledge and in a manner conductive to social and economic welfare, and to the balance of rights and obligations.

Article 8 provides that:

> 1. Members may ... adopt measures necessary to protect public health and nutrition, and to promote the public interest in sectors of vital importance to their socio-economic and technological development, provided that such measures are consistent with the provisions of this agreement.
> 2. Appropriate measures ... may be needed to prevent the abuse of intellectual property rights by right holders or the resort to practices which unreasonably restrain trade or adversely affect the international transfer of technology.

It is unclear whether only situations described in Article 31 are subject to compulsory licensing, or if Article 31 imposes requirements on compulsory licenses of any subject matter. TRIPS implicitly provides certain ground for issuing compulsory licenses; in particular, compulsory licenses are deemed proper for a national emergency, noncommercial use, anticompetitive practice, if a patent owner has refused to license, and where necessary to practice another patented invention (1). However, TRIPS does not indicate what other grounds would be permissible for compulsory licensing, or whether this is the only provision that relates to such licensing. Although all compulsory licenses are an imposition on a patent right, at least those provided under Article 31 provide the owner with reasonable remuneration and are not to be granted for entire classes of inventions. However, if another provision of TRIPS is interpreted as justifying compulsory licensing — such as Article 8 — the protection provided to patent owners under Article 31 would essentially fail to exist. Interpreting Article 8 to establish an independent basis for compulsory licenses has been suggested by commentators, usually in the context of trying to accommodate developing countries who are attempting to comply with TRIPS (55–56).

Determining whether Article 31 is the only applicable provision to compulsory licensing is important because of the many limitations placed on licensing under Article 31. In particular, Article 31 requires that authorization be "considered on its individual merits." This seems to suggest that compulsory licensing of all patents within a certain category would be impermissible. In addition Article 31 requires that compulsory licensing should only be permitted if a patent owner has first denied a request; although the attempt to obtain permission is waived for a national emergency or public noncommercial use, even in these situations, the patent owner must be informed promptly after the use has begun. Also Article 31 places limitations on the scope and duration of the use; it must be nonexclusive, nonassignable, preferably for a domestic market, and subject to termination once the conditions that necessitated the unauthorized use cease. The decision to grant a license must be subject to judicial review, and the holder of the patent right must be entitled to "adequate remuneration," which takes into account the "economic value of the authorization," The holder of such a right is also entitled to judicial review of any decision regarding remuneration.

All of the above requirements raise issues of interpretation. For example, it is unclear whether compulsory licenses must be granted on an individual basis, or if categories of inventions may be considered together. TRIPS also does not specify any criteria to determine whether remuneration is "adequate" other than to state that it must take into account the "economic value of the authorization." Countries could continue to apply the average royalty rate paid in voluntary licenses within a given industry rather than consider the royalty that would have been paid with regard to the particular invention.

Transitioning to the Future. Although developing countries and "economies in transition" should have in compliance been with most TRIPS requirements as of January 2000, they need not provide product patents until the year 2005 in any areas that they had previously not patented. This is important to international biotechnology because many countries do not provide product protection of pharmaceutical and/or agricultural products. However, TRIPS does provide some protection for such products during this intervening period.

For countries that did not provide patents for pharmaceutical and agricultural chemical products on terms consistent with Article 27 as of January 1995, a system for filing what has been referred to as "mailbox" applications must exist as of that date (1,20–21). The mailbox applications consist of patent applications that will not be examined until the country must comply with the remainder of TRIPS provisions; however, the mailbox system provides patent applicants with a "date of application" on the day the application is deposited for purposes of novelty and priority (1,20). Patents will issue based on mailbox applications after the expiration of the transitional period.

For products that are subject to mailbox applications, an exclusive marketing right (EMR) must be granted

to provide patentlike protection in the interim period before mailbox applications are examined. An EMR is available where (*1*) a patent on the same invention was granted in another WTO country as of January, 1995 and (*2*) marketing approval for the invention was granted in the same country (1,20). The EMR must last for the shorter of (*1*) five years after the EMR is granted or (*2*) the grant or rejection of the patent (1,20). Thus an EMR enables exclusion of commercial use even in the absence of a patent. However, an EMR provides no possible recourse to oppose noncommercial use.

Even after the transitional period expires, issues are likely to linger concerning the TRIPS requirements. Not only are some present requirements subject to interpretation, but there are also suggestions to modify the TRIPS requirements. For example, it has been suggested, mostly by developing countries, that the scope of items that may be excluded from patent protection should be broadened to include microorganisms, microbiological processes, gene sequences and essential drugs listed by WHO (55). Similarly African countries and Venezuela have argued that compulsory licensing should be allowed for essential drugs. On the other hand, developed countries want to expand patentable subject matter by eliminating the permissible exclusion of plants and animals. Moreover there is some desire to provide protection for holders of "traditional knowledge" or to disallow patents on items available to the public; this desire derives from the belief that TRIPS is not consistent with the Convention on Biological Diversity and International Undertaking on Plant Genetic Resources (32). However, while this issue continues to be studied, the TRIPS agreement is unlikely to be radically changed in the near future as any actual reconciliation with other international agreements is likely to require substantial time and negotiation. While all these issues will likely be discussed either within the context of TRIPS or some new international agreement, TRIPS is likely to be the relevant framework for the near future, considering its long path to enactment and the difficulty in establishing enough consensus to change the agreement.

Plant Protection Under UPOV

Overview. Intellectual property protection of plants should be examined outside the TRIPS framework because TRIPS expressly allows members to exclude plants from patentability, so long as an effective sui generis system exists to provide protection. Although TRIPS does not specify what such a system would require, patentlike rights have been provided to those who develop new plant varieties. In particular, plant breeders have been provided certain exclusive rights of exploitation when they create new varieties of plants; such rights have been referred to as "plant breeders' rights" (PBR) or "plant variety rights" (PVR). The rationale for such a system is very similar to the rationale for the patent system, albeit limited to one particular area. Namely breeders' rights are justified as providing an incentive to develop new plant varieties that further the development of agriculture; also the PVR enables the breeder to obtain a reasonable return on developing a new variety.

International agreement on the importance of such a right has existed since 1961 when UPOV was first signed. UPOV represents a union of member states that have agreed to provide a breeder's right in accordance with the terms of UPOV. Each member country enacts its own national laws to implement at least the minimum standards stated under UPOV. Accordingly, as with patents, an applicant seeking a PBR must seek protection from each country where protection is desired.

Although UPOV was revised in 1972, 1978, and 1991, there are primarily two versions under which countries are currently operating — the 1978 and 1991 versions of UPOV. Thirty countries operate under the 1978 UPOV, while only 12 countries use the 1991 version, which generally provides greater rights to breeders. Countries who were members of the 1978 UPOV had the option, but were not required, to sign the 1991 Convention. As of May 2000 the following countries had signed the 1991 UPOV: Bulgaria, Denmark, Germany, Israel, Japan, the Netherlands, Republic of Maldive, Russian Federation, Slovenia, Sweden, the United Kingdoms and the United States Although the EU is not a formal member of UPOV, it has enacted legislation consistent with the 1991 UPOV (100–101). As countries are currently operating under both systems, the highlights of both will be discussed here, as well as the critical distinctions; additional information is available elsewhere (57–59). Table 5 provides a summary and comparison of the requirements of the 1978 and 1991 UPOV; the distinctions between the two are noted in italics.

Eligible Subject Matter. The fundamental premise of all versions of UPOV is that breeders should be entitled to some exclusionary right with respect to the varieties they create; however, the different versions of UPOV vary in the type of right that must be provided. Under both the 1978 and 1991 UPOV, members may protect a particular variety through either patent protection or a breeder's right consistent with the provisions of UPOV. However, an important distinction is that under the 1978 UPOV — the version that is most widely followed at present — only one type of protection is available for the same genus or species such that dual protection under the patent system and a UPOV-type system is prohibited (2, Article 2(1)). However, there is a grandfather clause that allows members who had previously provided double protection to continue to do so. This provision was included chiefly to accommodate the United States which provided dual protection prior to the 1978 UPOV and wanted to continue do so (2, Article 37). In contrast, under the 1991 UPOV, dual protection is explicitly allowed, namely members may grant the same plant variety a patent as well as a breeder's right (3, Article 40). Accordingly, whereas dual protection was prohibited under the 1978 UPOV, it is now permissible under the 1991 UPOV but still not mandatory.

The scope of varieties that a member must protect also differs between the 1978 and 1991 versions of UPOV. The 1978 UPOV only requires 24 genera or species to be granted protection, and only after eight years of joining UPOV. On the other hand, the 1991 UPOV requires that *all* genera and species eventually be protected; any

Table 5. Plant Protection Under UPOV (non-patent protection)

	1978 UPOV	1991 UPOV
Available protection	Plant *or* UPOV protection *only*; no concurrent protection allowed except for grandfather clause	Plant *and* UPOV *possible*; members can elect for concurrent protection
Scope of varieties entitled to protection	*Requires* that *24* genera or species be granted protection within 8 years of member joining UPOV; *allows* protection for *all* genera or species	*Requires* protection for *all* genera or species within 5 years of signing 1991 UPOV if already a member, or within 10 years if new member
Technical requirements	• Distinct • Uniform • Stable • Commercially novel; grace period *optional*	• Distinct • Uniform • Stable • Commercially novel; grace period *required*
Excluded activities	• Production of the propagating material for purposes of commercial marketing • Offering the propagating material for sale • Marketing the propagating material • Repeated use of the plant variety to commercially produce another variety • Commercial use of ornamental plants as propagating material in the production of ornamental plans or cut flowers	• Production or reproduction • Conditioning for the purpose of • Offering for sale • Selling or other marketing • Exporting • Importing • Stocking for any of the above purposes
Excluded subject matter	Plant variety and its propogating material	• Protected variety • Varieties that are not "clearly distinguishable • Essentially derived varieties • Variety whose production requires repeated use of a protected variety
Exceptions to UPOV right	• Noncommercial use • Experimental use • Use for further breeding • Farmers saving seed from the harvest of a protected variety (farmer's exception)	• Noncommercial use • Experimental use • Use for further breeding *unless it creates an essentially derived variety* (members *may* provide a farmer's exception subject to the interest of the breeder; otherwise, activity will constitute infringement)
Rights during pendency of application	Members *may* provide provisional protection against the "abusive rights of third parties"	Members *must* provide provisional remedies during this time; at a minimum the breeder must obtain equitable remuneration for any activities within the right to exclude
Term of protection	15 years from grant of breeders right; 18 years from grant for vines, fruit trees, forest trees, and ornamental trees	20 years from grant of breeders right; 25 years for trees and vines
Sample countries operating under the convention	Australia, Austria, Belgium, Canada, Finland, France, Ireland, Italy, New Zealand, Norway, Portugal, South Africa, Spain, Switzerland	Denmark, Germany, Israel, Japan, Netherlands, Sweden, United Kingdom, United States

member who was already a member to the 1978 UPOV must do so within five years of signing the 1991 UPOV whereas those who are joining UPOV for the first time have an additional five years to do so (3, Article 3).

A UPOV right can only be obtained after an examination in a member state that determines whether the application satisfies the UPOV technical criteria. UPOV requires that breeders be entitled to a right of priority similar to that under TRIPS; the breeder may utilize the date of the first application in a UPOV member state in determining novelty of subsequent applications for the same variety in other member states. However, UPOV does not mandate how member states must perform the examination. Nonetheless, it does contemplate that the breeder applicant provide information, including propagating material and seed (2, Article 7). In addition the 1991 UPOV suggests that the examination include growing the actual variety (3, Article 12). Accordingly, some countries compare the grown variety with the closest reference variety in the applicant's submitted description as well as a standard benchmark variety (26). The formalities of the application, including whether a description of the breeding process is necessary and whether it needs to be publicly disclosed, are left to individual member countries to determine.

Requirements for UPOV Protection. UPOV rights are provided to (*1*) a plant "variety" in accordance with the

UPOV definition that (2) meets the technical criteria under UPOV of being distinct, uniform, stable, and commercially novel (2, Article 6; 3, Article 5). Although the technical criteria are essentially the same under the 1978 and 1991 versions, the 1991 UPOV provides a definition of a "variety," whereas the 1978 UPOV did not. In particular, the 1991 UPOV explicitly defines a qualifying variety as "a plant grouping within a single botanical taxon of the lowest known rank which grouping can be defined by features characterizing a given genotype or combination of genotypes, and is distinguished from any other plant grouping by the expression of at least one of the said characteristics." (3, Article 2(i)).

Both Acts require that the variety be sufficiently distinct. They both provide that a variety meets this requirement if it is "clearly distinguishable" from another variety that is "common knowledge" at the time (2, Article 6; 3, Article 7). A variety is likely to be "clearly distinguishable from another" if the variety is different from one or more morphological characteristics (e.g., leaf shape and flower color) or physiological characteristics (e.g., disease resistance and hardiness) of other varieties known at the time of the application (26). The more difficult issue is to determine what was known at the time of the application. What is common knowledge appears similar to the concept of "prior art" under patent laws. Just as TRIPS does not define what should be considered prior art in determining novelty, UPOV does not define "common knowledge." However, both Acts include applications filed in the definition of "common knowledge" although such applications are not publicly available (2, Article 6(1); 3, Article 7). In addition the 1978 UPOV provides that common knowledge may include description in prior publications or commercial sale (2, Article 6(1)(a)).

Besides being distinctive, the new variety must be both "uniform" and "stable." The variety must be uniform with respect to features of its reproduction or propagation (26). The variety must maintain its essential characteristics after repeated reproduction or propagation, or if the breeder has defined a limited cycle or reproduction, it must remain true at the end of each cycle (2, Article 6(d); 3, Article 9). The amount of stability required is a function of the species and variety. However, it is generally assumed that a variety is stable if it exhibits a reasonable level of uniformity in its essential characteristics for a minimum of two successive growing seasons (26).

Finally, the breeder must establish "novelty" of the variety. Under the 1978 UPOV, novelty exists as long as the breeder does not authorize the variety to be offered for sale or market in the state where the breeder seeks protection prior to application. Novelty may also exist even after the breeder authorizes the variety to be offered for sale or marketed in a state where protection is sought if that state provides a one-year grace period after the commercial activity to file an application; states may provide a grace period of up to four years for commercial activity that occurred in other states. In contrast, the 1991 UPOV provides that members must provide a one-year grace period.

Commercial activity that affects novelty differs between the 1978 and 1991 versions of UPOV. Under the 1978 UPOV, the only commercial activity that defeats novelty is activity pursuant to the authority of the breeder (2, Article 6(1)(b)). However, under the 1991 UPOV, protection is barred if the "propagating or harvested material" of the variety was "sold or otherwise disposed of to others ... for the purpose of exploitation of the variety"; as this no longer mentions consent of the breeder, it includes all commercial activity regardless of whether the breeder consents (3, Article 6).

UPOV Right

Scope of Protection. Although member states can always provide additional protection, at a minimum they must enable the breeder to exclude certain activities by others. Under the 1978 UPOV (Article 5(1)), the breeder can exclude others from the following:

1. Production of the propagating material for purposes of commercial marketing,
2. Offering the propagating material for sale,
3. Marketing the propagating material,
4. Repeated use of the plant variety to commercially produce another variety,
5. Commercial use of ornamental plants as propagating material in the production of ornamental plants or cut flowers.

Accordingly, under the 1978 UPOV, the reproductive material of a protected variety may be used to produce another variety as long as it is not for the purpose of selling the protected variety and as long as there is no repeated use of the material of the protected variety for the commercial production of the new variety. Thus a second breeder could generally breed and commercialize a new variety without providing any compensation to the initial breeder of the protected variety.

The activities that the breeder can exclude under the 1991 Act are even broader than those under the 1978 Act. The 1991 Act provides seven acts of exploitation for which authorization from the breeder is required (3, Article 14):

1. Production or reproduction
2. Conditioning for the purpose of propagation
3. Offering for sale
4. Selling or other marketing
5. Exporting
6. Importing
7. Stocking for any of the above purposes

The breeder must authorize these seven activities with respect to propagating material of the protected variety as well as varieties that are not clearly distinguishable from the protected variety (in accordance with the UPOV definition of distinctiveness). In addition the breeder must authorize these activities with regard to harvested material (including entire plants or parts of plants), if the harvested material has been obtained through the unauthorized use of propagating material and the breeder has had no reasonable opportunity to exercise

his right in relation to the propagating material (3, Article 14(1)–(2)). The 1991 UPOV permits, but does not require, that member states provide the breeder with the right to exclude products made directly from harvested material of a protected variety through unauthorized use of harvested material where the breeder has had no reasonable opportunity to exercise his right in relation to the harvested material (3, Article 14(3)); a member state that adopts this provision would preclude farmers from saving harvested seeds. However, member states can instead elect to provide a farmer's right similar to that which is available under the 1978 Act. If the breeder is not provided rights with regard to farm-saved seeds (if a farmer's exception is provided), the breadth of any such farmer's exception is within a member state's discretion as long as it protects the breeder's "legitimate interests" (3, Article 15(2)). For example, the breeder's interests may be safeguarded by only providing a farmer's right to small farmers, or farmers of certain crops.

Under both the 1978 and 1991 UPOV, provisional protection may be granted to the breeder during the pendency of the UPOV application. Under the 1978 UPOV such protection may, but need not, be provided against "abusive rights of third parties" during the pendency of the application (2, Article 7(3)). Under the 1991 UPOV, however, provisional remedies during this time period are required. In particular, members to the 1991 UPOV *must* provide measures to safeguard rights during pendency so that at a minimum the breeder obtains equitable remuneration for any activities within the right to exclude. However, member states can reduce the impact of this provision by only applying it against those who knew of the application (3, Article 13).

Exceptions. A major distinction between the 1978 and 1991 UPOV is that under the 1978 Act the breeder cannot prevent farmers from saving products of their harvest to replant, namely farmers who save seed from the harvest of the protected variety do not infringe when they later replant the seed. However, under the 1991 Act, although a member state *may* provide a farmer's exception subject to the interests of the breeder, it can also allow such activity to constitute infringement — something that was not a possibility under the 1978 Act.

Other than the farmer's privilege, the exceptions to the breeder's right under the 1978 and 1991 Acts are similar. Both provide for three exceptions to the breeder's rights: private noncommercial use, experimental use, and use of the protected variety for further breeding (3, Article 1(i)–(ii)). However, with respect to use for further breeding, the breeder has more rights under the 1991 UPOV. In particular, the breeder has a right against those who use the protected variety to breed additional varieties if the new variety is "essentially derived" from the protected variety (3, Article 15(1)(iii)). A variety is "essentially derived," and subject to the breeder's right to exclude, when it is predominately derived from the initial variety and, except for differences that result from the act of derivation, it displays the same essential characteristics that result from the genotype, yet is clearly distinguishable from the initial variety (3, Article 7(5)(b)). This new requirement is intended to remove the unfairness that operates under the 1978 Act, whereby a genetic modification of a protected variety could enable a second breeder to obtain rights without providing any recognition or compensation to the original breeder. UPOV explicitly provides examples of what should constitute essentially derived varieties: those obtained by selection of a mutant, of a somaclonal variant, or of a variant individual from plants of the initial variety, backcrossing, or transformation by genetic engineering (3, Article 14(5)(c)). Thus, although protected varieties may continue to be used as a source of initial variation, if the resulting variety falls within the definition of an essentially derived variety, authorization from the initial breeder is required.

Two final limitations to the PBR under UPOV are compulsory licensing and exhaustion of the PBR. Compulsory licensing is permissible under both versions of UPOV. However, it is only possible if it is in the public interest and equitable remuneration is provided to the breeder (2, Article 9; 3, Article 17). Only the 1991 UPOV provides for a principle of exhaustion. The UPOV exhaustion principle is analogous to that previously discussed with regard to patent protection; in particular, it provides that the breeder's right will not extend to acts concerning material of the protected variety (or essentially derived variety) if sold or otherwise marketed by the breeder unless further propagation is involved or export of the variety is involved (3, Article 16).

Comparison of UPOV and Patent Protection. It is important to note the distinctions between UPOV and patent protection, particularly for countries where only one type of protection is allowed such that an informed decision on the optimal type of protection may be made. First, it should be noted that whereas patents protect all "inventions" (whether the inventions are products or processes) UPOV seeks to protect one type of product — plant varieties. UPOV can only protect the variety itself, whereas patent protection, if available, can also cover a transformed gene or process of making such a gene. Second, rights against imports are only available under the 1991 UPOV, whereas any country that is a WTO member can prevent imports of patented products. Third, both UPOV Acts explicitly allow use of a protected variety for not only noncommercial purposes but also for the purpose of breeding other varieties. Although there is the possibility that such use could be permissible as a "limited exception," to patent rights under Article 30 of TRIPS, there is at least uncertainty as to whether that is possible, unlike the explicit exception provided under UPOV.

In one respect, the 1991 UPOV may provide more extensive protection than patent rights because of the requirement that states provide protection during the pendency of the UPOV application. Although WTO members may provide similar protection, TRIPS does not require any rights be provided prior to the issuance of a patent. In addition the requirements necessary to obtain UPOV rights potentially require less disclosure than a patent application and potentially no disclosure to the public. Whereas TRIPS mandates disclosure of the invention to obtain patent protection, UPOV does not require a description of the "invention," and does not

require any disclosure that would allow replication by another. There is no requirement of either a deposit or of public access to the deposit. Although a member state may impose such requirements on an applicant, UPOV itself does not.

The term of protection may also be different if patent protection is chosen versus UPOV protection. Notably TRIPS calculates the term of patent from filing date, whereas UPOV calculates it from the date of grant of the right. While TRIPS requires a minimum period of 20 years from the filing of an application, the term is 15 years from the grant of the breeder right under the 78 UPOV (18 for vines, fruit trees, forest trees, and ornamental trees) or 20 years from grant of the breeder right under the 91 UPOV (and 25 years for trees and vines).

PRESENT SYSTEMS OF PROTECTION

Europe

Relevant Laws. Most European patents are sought from the EPO rather than from patent offices of individual countries. EPO law includes (*1*) the EPC, which is an agreement among European countries (24), (*2*) regulations implementing the EPC, and (*3*) judicial interpretation of the EPC by EPO courts (60,61). EPC provides a streamlined process for obtaining patents in Europe — a single application to the EPO may lead to national patents in every member state; EPC thus provides a shortcut to obtaining patent protection in multiple European countries.

Eighteen months after an application to EPO, a European Patent (EP) application is published. Subsequently EPO will determine whether to grant a patent (an EP patent). If EPO decides to grant a patent, the EP patent is published and available for opposition on almost any ground on which EPO could have denied patentability. If the EP patent survives the opposition period (is not revoked in its entirety), it will become transformed into individual national patents once certain procedural requirements are fulfilled. Once those requirements are met, EPC ceases to govern the EP patent, and national laws control how the national patents are enforced in each country (4,27).

In addition to the EPO law on patentability, patentability requirements in the European Union (EU) will be discussed. The EU is a union of presently 15 countries. It was founded to further political, economic, and social cooperation; formerly, the EU was known as the European Community (EC) or the European Economic Community (EEC). Unlike EPC, the EU is an organization that governs many facets of national law through a governmental structure including a Parliament, Council, and Commission that roughly represent branches of an executive government. These EU bodies can require member states to take actions through the issuance of regulations (immediately and directly binding on member states) or directives (binding as to result only and usually not immediately effective). In the area of biotechnology, the EU has enacted a directive concerning patent protection for biotechnology that includes both patentability and enforcement of such inventions (5). Member states are to be in compliance with this by July 20, 2000 (5). It is unlikely that all members will actually be in compliance by this time since the EU directive is presently subject to legal challenge by several member countries (62,63). However, it is perhaps more important to note that the EPO has issued regulations that adopt many of the articles of the EU Biotechnology Directive. Thus, even if EU member states have not yet altered their national laws, that may be of minor import because most patent applicants utilize the EPO's streamlined application system, rather than applying to individual national patent offices. This is particularly true because all of the current EU member states are also members of the EPC. Most importantly, all of the current EU member states are also members of EPC. Accordingly, because the EPO has made its laws consistent with the EU Directive, the laws and policies of the EPO are presently of paramount importance and will be the focus of this section. More information on patent laws of individual European countries is available from other sources (64–67).

Patentable Subject Matter. The first hurdle to patenting biotechnology is to establish that there is a patentable "invention." Natural discoveries are excluded from the scope of patentable inventions under EPC. Accordingly an issue that has been raised is whether certain types of biotechnology, including isolated natural substances, are natural discoveries and thus unpatentable. Under current EPO policy, "biological material," which is defined as "any material containing genetic information and capable of reproducing itself or being reproduced in a biological system" may be patentable regardless of whether it previously occurred in nature if it is "isolated from its natural environment or produced by means of a technical process" (5, art. 2; 40–41). Isolated elements may be patentable even if the elements are isolated from the human body such as gene sequences or partial gene sequences (5, art. 3(2); 29). However, the mere discovery of the elements of the human body, including embryonic stages of the human body is not considered to be patentable (5, art. 5; 40–41,61).

Specific Exclusions

1. Methods of treatment. The patentability of gene therapy and associated technology is an issue due to a provision of EPC that defines methods of treatment and diagnosis of either humans or animals to lack "industrial applicability," therefore making such methods unpatentable. In particular, Gene therapy can be considered a method of treatment; diagnostic kits utilizing genetic engineering can be considered as methods of diagnosis. However, EPO courts could interpret this exclusion narrowly to allow some methods to be patentable. For example, although the EPC excludes diagnostic methods, the EPO has interpreted this exclusion narrowly to only exclude diagnostic methods whose results can be immediately used to decide on a course of medical treatment; if the method provides interim results in the course of making a diagnosis, the method is patentable (67). Methods of diagnoses

are only excluded if actually carried out on the body; accordingly diagnosis of body tissues or fluids removed from the body may be patentable (67).

Even without relying on judicial construction of the method exclusion, some patent protection may be available pursuant to a related part of the EPC statute. In particular, the EPC explicitly states that the medical treatment prohibition "shall not apply to *products*, in particular substances or compositions, for use in any of these [prohibited] methods." (68, Article 52). Therefore, even though patent protection is excluded for the actual method of treatment, products used for such treatment may still be patentable subject matter. Thus, although both somatic and germ-line therapies are considered unpatentable methods of medical treatment, the EPO has indicated that products such as genetically modified cells intended for use in somatic gene therapy are patentable and would not be automatically barred (39). However, patentability may be ultimately precluded pursuant to another provision of the EPC or the EU directive that bars patenting of inventions that are contrary to *ordre public* or morality. Products for use in germ-line gene therapy, in particular, may be found in violation of such a provision (39).

2. Plant and animal varieties. EPC Article 53(b) declares unpatentable "plant or animal varieties or essentially biological processes for the production of plants or animals; this provision does not apply to microbiological processes or the products thereof." This provision does not bar the patenting of transgenic animal (65,80–81). However, other provisions of EPC, in particular, the exclusion of inventions that raise morality concerns could pose a problem even if this provision does not (4, art. 53(a); 80–81). The patentability of plants, on the other hand, is less certain.

   The patentability of plant varieties is presently unclear because of conflicting EPO case law and the yet to be implemented EU Directive. The EU Directive as well as recent amendments to the regulations implementing EPC provide that plants are patentable "if the technical feasibility ... is not confined to the particular plant or animal variety" (7,61). This would suggest that transgenic plants could be patented and patent claims could cover varieties so long as it covered more than a single variety. Not all EPO case law is consistent with this — recent cases have held that so long as a claim to a transgenic plant may cover a plant varieties, it should be precluded from patentability (27,69–73). However, in the most recent EPO case T1054/96, In re Novartis, the Enlarged Board of Appeal declared that a claim to a transgenic plant could be acceptable even though it may include specific plant varieties (74). Although this would appear to make EPO practice consistent with the EU Directive, whether this will continue remains to be seen.

   It should also be noted that article 53(b) states that although processes for creating the ambiguous "varieties" are unpatentable, other types of biotechnological processes may be patentable. In particular, microbiological processes and the resulting products are patentable — so long as they do not include the improper "varieties" and also meet the technical requirements of patentability. A microbiological process consists of "any process involving or performed UPOV or resulting in microbiological material" (7,61). A process for the production of plants or animals is deemed to be "essentially biological" if it "consists entirely of natural phenomena such as crossing or selection" (7,61). Accordingly only traditional breeding of plants and animals are excluded "essentially biological" processes under Article 53(b). Potentially patentable microbiological processes could thus include methods of obtaining, transforming and using microorganisms such as viruses and bacteria.

Nonspecific Statutory Exclusion. Inventions, whose publication or exploitation would be contrary to *ordre public* and morality, are excluded from patentability even if they otherwise constitute an invention and meet the technical patentability requirements. The important query here is the meaning of *ordre public* and morality. One EPO board has considered the term *ordre public* to include the protection of public security and the physical integrity of individuals within the society, including protection of the environment (71). However, there is no single unitary concept of either *ordre public* or morality in all members of EPC. Moreover it is unclear whether the accepted standards of conduct to which the invention is to be compared are those within one member state or all member states. An invention could be deemed to be lacking morality only if it was contrary to the accepted standards for all member countries, or, an invention could be deemed to be lacking morality if it was contrary to any one country. In addition it has been noted by certain EPO courts that there must be an "overwhelming consensus" of opinion before Article 53(a) will bar patentability (76,77). In any event, there have been instances where this has been raised as a ground for denying a patent on genetic engineering inventions. In particular, patents on transgenic animals, plants, and isolated gene sequences have been opposed based on this provision (76,77–78).

Although not an absolute bar to patenting transgenic animals, the *ordre public* and morality exclusion may preclude patents on some animals. To determine whether a transgenic animal is barred by this provision the EPO has previously used a balancing test that takes into account the suffering of animals and possible dangers to the environment, on one hand, with the potential benefits to humans, on the other. Accordingly, in the first and most famous case where this was applied, the Harvard OncoMouse application, it was held that because a mouse genetically engineered to be predisposed to cancer had such substantial utility to humankind, that it outweighed the suffering of the individual animal (81). However, not all transgenic animals have been held to meet this test. For

instance, the EPO has denied applications of transgenic animals whose utility is to study baldness (27).

In the future a modified balancing test may be applied as the EU Directive, as well as the amended EPO regulations, state a differently worded test. In particular, patents on processes for creating transgenic animals as well as the resulting animals are precluded if it is "likely to cause them suffering without any substantial medical benefit to man or animal" (7,61). It literally seems to require some showing of "*substantial* medical benefit" where a process is "likely" to cause animal suffering. However, it is unclear what would constitute a "medical" benefit, let alone a "substantial one." For example, cows that are genetically engineered to produce more milk would appear to be of questionable "medical" benefit. Moreover it is unclear what "suffering" must consist of. Some might even argue that the cow is "suffering" by having its genes altered. On the other hand, unlike the OncoMouse, the altered cow is not programmed to a hastened death.

The appropriate test to apply to plants is unclear. It has been noted that the OncoMouse balancing test is not the only way to evaluate violation of Article 53(a) (71). However, in the absence of a balancing test, the vaguer standard of *ordre public* and morality must be applied. This appears difficult to establish. For example, in a case where a transgenic plant engineered to be pesticide-resistant was opposed as violating Article 53 (a) (among other provisions), the EPO court dismissed alleged danger to the environment on the ground that surveys of the general public showing opposition to genetic engineering were inadequate; actual danger, rather than the "mere possibility" of danger was stated to be necessary and infringement of environmental regulations alone was not considered adequate (71).

Although the interpretation of the morality requirement is still unclear, the EU Directive and the EPO regulations provide a noninclusive list of what will per se violate morality or *ordre public*. Current examples of biotechnology that are unpatentable because of this include processes for cloning humans, processes for germline gene therapy, and use of human embryos for industrial or commercial purposes (7). Processes for modifying the genetic identity of animals which are likely to cause them suffering without any substantial medical benefit to human or animal, and animals resulting from such processes" (7). Because EPO has amended the regulations to EPC to essentially adopt the EU Directive wholesale, the categorical bars to patentability stated in the Directive presumably apply (61). In addition, although EPO has noted that "the provisions of Article 27(2) of TRIPS will be considered" (39), it is presently unclear how that will affect the analysis, if at all, as there are notable similarities in the language, as indicated on Table 6. In fact, it may be that the EPO case law is drawn upon by the TRIPS council and member countries as the most pertinent and largest body of law in interpreting what is otherwise vague language.

Patentability Requirements. As the focus of this article is on issues relating to patenting biotechnology, major issues regarding technical requirements will be noted. However, more detailed information on the specifics of each technical requirement under EPC alone is discussed elsewhere (27,64).

Novelty. EPO takes an "absolute novelty" approach to determining whether an invention is patentable.

Table 6. Exclusions from Patentability

	EPC/EU[a]	TRIPS
Categorical exclusions of specific subject matter	• Methods for treatment or diagnosis of human/animal body • Plant and animal "varieties" • "Essentially biological processes" for the production of plants or animals except "microbiological" or other technical processes • "Human body, at the various stages of its formation and development"	• Diagnostic, therapeutic and surgical methods for the treatment of humans or animals; • Plant and animals other than micro-organisms, • "Essentially biological processes" for the production of plants or animals other than "nonbiological" and "microbiological processes"
Nonspecific exclusions	Inventions whose commercial exploitation would be contrary to "*ordre public* or morality" Listed examples: • Processes for cloning humans • Processes for germ line gene therapy of humans • Commercial uses of human embryos • Methods of genetically modifying animals that are "likely to cause them suffering without any substantial medical benefit to man or animal," and any animals resulting from such methods	Inventions whose commercial exploitation must be prevented to protect "ordre public or morality," including to protect human, animal or plant life or health or to avoid serious prejudice to the environment

[a]Mandatory exclusions.
[b]Permissive exclusions.

Accordingly relevant prior art includes any written publications, abstracts, or drawings; prior use anywhere in the world; and prior, though later published, patent applications (3, Article 54). However, EPO does recognize a very limited grace period of six months before the filing of the application for disclosure made by the applicant at an official, or officially recognized, international exhibition (3, Article 55). In addition there has been some discussion concerning whether a more expansive grace period should be provided.

Novelty may be satisfied for isolated products found in nature so long as it is done through a technical process. Thus a new substance discovered as being produced from a microorganism, or a previously unknown gene or protein, would be considered novel and patentable if the other patentability requirements were satisfied (40).

Novelty may be established in cases of newly discovered uses of previously patented compounds. In particular, a compound may be patented with a use limitation even if the compound itself was previously known as long as its use for treatment or diagnosis was not previously known (first medical use). A second patent can be obtained for the newly discovered use of a previously known compound, even if the compound was previously known to have a use, if it is newly discovered to be useful for additional therapeutic purposes (second medical use). In either event, it should be recalled that only the compound, and not the process of using the compound, can be patented so that the medical treatment prohibition is avoided. This often results in just a technical distinction of how the invention is claimed — a claim reciting a "method of treating X using substance Y" would be considered unpatentable, whereas a first medical use claim reciting "substance Y for use as an active pharmaceutical substance" would be acceptable, as would a second medical use claim stating "use of substance Y for the preparation of a pharmaceutical compound for the treatment of X."

Industrial Applicability and Inventive Step. The invention must also have "industrial applicability," which requires that the invention be useful in "any kind of industry, including agriculture." (3, Article 57). In general, this is a fairly easy requirement to meet. However, industrial applicability may be an issue with some nucleic acid sequences. The EPO has noted that it is "questionable" as to whether sequences that have no known use other than as probes satisfy the industrial applicability requirement (40). Similarly most inventions will be found to have met the "inventive step" requirement unless the invention is "obvious to try" by a person skilled in the art with a reasonable chance of success. However, in the area of biotechnology, the application of the inventive step requirement is uncertain as different tests have been applied by EPO and national courts (82–83).

Description and Deposit. The disclosure requirement merely requires sufficient disclosure such that the invention can be carried out by a skilled person for the claimed subject matter using common general knowledge and the information provided in the application. No specific examples are required in the application if a skilled person could carry out the invention without undue experimentation. In addition, pursuant to the EU Directive, the patent application for a sequenced or partially sequenced gene must be disclosed; however, that alone may not be sufficient — there may be other issues with patentability requirements for expressed sequence tags (ESTs) pursuant to Articles 52(1) and 56 (40).

A deposit is required if necessary to enable reproduction of the invention claimed in an application. A deposit is required, for example, if a specific microorganism cannot be reproduced based on the application alone. However, if a protein or nucleic acid is sufficiently defined in the application such that it may be synthesized by one of skill in the art, it need not be deposited.

If a deposit is required, it must be made no later than the filing date. The deposit may be made to any institution recognized under the Budapest Treaty as well as other institutions as noted in the Official Journal of EPO. The deposit may become available to others after the patent is published. However, if the applicant informs EPO prior to the publication of the application of a preference to limit access, there will be no public access until an EPO patent is granted, or 20 years after the filing date if the application is refused or withdrawn. If public access is not specifically requested to be restricted, the deposit will be available after the application is published to any person who requests it on the condition that the person does not make the material available to a third party and if the person is using the deposited material for experimental uses only.

Patent Rights

Challenging an EP Patent. Even after an EP patent has been issued, there is some uncertainty involved because the patent is subject to a period of opposition during which anyone, including competitors or special interest groups, may file an opposition against the patent. Oppositions may be filed within nine months after the patent grant is published. There are many grounds for contesting a published EPO patent, including lack of novelty (Articles 54–55), lack of inventive step (Article 56), lack of industrial application (Article 57), improper subject matter (Article 53), noninvention (Article 52) and inadequate disclosure (Articles 100(b) and 83). Opposition may result in amendment of the patent scope or complete revocation of the patent.

It should be noted that opposition proceedings are conducted by EPO before the EP patent becomes a collection of individual national patents. Accordingly successful opposition of an EP patent is a much cheaper and more efficient to challenging parallel national patents in different countries. However, even if a patent withstands opposition in EPO, it may still be subject to revocation in national proceedings. An EPO decision in opposition proceedings has no binding effect, even on the same parties in later national proceedings for which national law, rather than EPC, will govern.

There may be inconsistency between the EPO system and national courts as well as inconsistency within courts of same nations. For example, in the recent biotechnology case of *Biogen v. Medeva*, several different courts reached different decisions on whether the Biogen patent was valid, and even courts that reached the same result had

different reasoning (82–87). The Biogen patent was first subject to opposition within EPO, after which the EPO Technical Board of Appeal maintained the patent (84). However, once the Biogen EP patent was transformed into national patents, trouble began. Biogen first sued Medeva for using its patented composition. In its defense, Medeva asserted that Biogen's patent was invalid on a number of grounds. In the initial court, Biogen's patent was considered valid on the same grounds as the EPO had found (85). However, the next court to hear the case, the High Court of Justice, came to the opposition conclusion — namely that Biogen's patent was invalid for all asserted grounds — that it was insufficient, obvious, and possibly not even an "invention" (86). Finally, the House of Lords also declared Biogen's patent invalid, but for different grounds than the High Court of Justice; in particular, the House of Lords declared the critical issue was one that had not been formally raised in any of the decisions of the prior courts (87). The House of Lords determined that the claimed invention was too broad and held that the patent from which priority was claimed could not support the patent at issue (87).

Scope of Protection. Granted EP patents have the same scope of protection within a given country as do patents granted by the individual country's patent office (4, Article 2(2)). EPC generally does not govern activity after the opposition period with two exceptions. EPC provides that there should be uniform protection conferred by European patents pursuant to Article 69. EPC provides that there should be protection for the "direct product" of a patented process under Article 62(2). However, because national courts may interpret identical provisions differently, there is bound to be some inconsistency despite the requirement of "uniform protection."

The scope of protection for biotechnological matter is still under development. Although EPO issued regulations in June 1999 implementing some of the provisions of the EU Directive, it did not include any of the EU Directive provisions concerning the scope of protection of biotechnological inventions (61). However, the EU Directive will be considered here as all EU members are EPC members. The EU Directive provides that patents on biological material provide protection on any biological material derived from the initial patented material through propagation or multiplication; accordingly offspring of a patented transgenic animal would be within the scope of protection (7). In addition, for patented processes that produce biological material with specific characteristics as a result of the invention, protection is extended to any biological material "directly obtained" from the patented process as well as any biological material "derived from the directly obtained" material through propagation or multiplication (7).

The EU Directive provides limitations on the scope of protection for certain biological material. In particular, it is stated that no protection is provided for material obtained from material placed on the market by the holder of the patent with his consent (7). In other words, once the patent owner sells the patented product, rights for subsequent products are extinguished. In addition the Directive provides a farmer's rights similar to the rights provided under UPOV as well as a corollary right for animal breeders (7). Member states have control over how much of an exception to provide with respect to the newly created animal breeder's right (7). Finally, compulsory licensing is also specifically provided for, although most of the specifics of such licensing are left up to individual countries (7).

Another limitation on infringement that has been established in some countries is an exception for experimental use. Many EU and EPC countries exempt from infringement "acts done for experimental purpose relating to the subject matter of the patented invention" (64,88); this is often referred to as an experimental use exception. It is unclear whether experiments for market approval constitute infringement and whether there should be any difference when testing is done by manufacturers in preparation for the sale of generic drugs (89–90). However, the most recent case on this issue in Germany found that clinical trials on a patented compound to determine its properties and effects were protected by the experimental use exception even if conducted with the goal of acquiring marketing approval; the only limit to the exclusion was stated to be if the tests were solely directed at determining commercial facts such as market needs and price acceptance (91). Even if national courts uniformly interpret a broad exception, such an interpretation could be challenged as violating TRIPS and not protected by the "limited exception" provision of Article 30 of TRIPS.

Enforcement Issues. An important enforcement issue in Europe is that in recent years, some courts have issued "cross-border" or "pan-European" injunctions against defendants in patent infringement actions (92,93). An injunction is an order issued by the court; in the context of a patent infringement action, an injunction is often issued against a defendant who is infringing. The injunction orders a defendant to stop infringing or be subject to court sanctions. What is notable about cross-border injunctions is that typically courts only issue injunctions within their territorial boundaries, that is, within the nation in which the court sits. However, cross-border injunctions are injunctions in which the court orders a defendant not to infringe in other states or countries (across its own borders).

The availability of cross-border injunctions are particularly useful to patent owners desirous of relatively inexpensive means of stopping a defendant from infringing in multiple nations. While a patent owner attempting to enforce an EP patent would traditionally have to pursue litigation in multiple jurisdictions with potentially different verdicts, a cross-border injunction enables a single litigation to potentially enjoin a defendant's action in all European countries.

The legal basis for cross-border injunctions is based on a provision of the Treaty of Brussels (94) that allows a case to be brought before the court of any defendant's residence when there are multiple courts. Through a liberal interpretation of this provision, courts, and particularly the district court of the Hague, have found themselves competent to hear cases against defendants in patent cases as long as one defendant was Dutch (92–94,97). Jurisdictions that have issued cross-border injunctions

include the Netherlands, England, Germany, Belgium, and France, although the majority of such injunctions have been issued by Dutch courts (92–94,97). Although subsequent case law has limited application of this principle in cases against foreign defendants (95), the potential for such injunctions still exists in the absence of an effective means to enforce patents issued by EPO. Indeed, commentary on cross-border injunctions has noted that the only long-term solution is a more uniform enforcement mechanism (97). Such a possibility is in fact a potential reality.

Additional Protection

Pharmaceuticals. In addition to patent protection, manufacturers of patents on pharmaceuticals in the EU are entitled to some patentlike exclusionary rights after the term of a patent via a supplementary protection certificate (SPC) (98–99). A SPC allows a limited exclusivity right after the ordinary 20-year patent term expires. The term of SPC is calculated as the time elapsed between the date of filing the application for the patent and the date of the first marketing authorizing minus five years, up to a maximum of five years. There are four requirements that must be met to obtain a SPC: (*1*) The product sought to be protected by an SPC must be protected by a basic patent in force, (*2*) the product must not have been granted marketing authorization, (*3*) the product must not have already been the subject of an SPC, and (*4*) the marketing authorization is the first to place the product on the market (Article 3). Only the patentee, not a licensee, is entitled to apply for a SPC.

A SPC allows its owner the right to exclude others from the commercial sale of covered goods. However, because a SPC is not a patent, the owner of SPC cannot exclude others, such as generic drug manufacturers, from testing the drug that is no longer patented. SPC effectively achieves the same result as an infringement exception provided to manufacturers of generic drugs under the U.S. system.

Plants. Regardless of the status of patenting plant "varieties" under EPC or the EU Directive, an alternative means for protection exists both under the EU and under national laws of individual countries. Plant Variety Rights within the Community are governed by an EU regulation that provides a communitywide right; this right is additional to any rights available under national regimes. This means that for plants, protection is potentially available through EPO (subject to the bar on plant varieties), through national patent systems of EPC or EU countries; in addition PVR may be available either from individual countries or from the EU. The benefit of obtaining rights under the EU system is that the breeder obtains an exclusionary right that applies throughout the entire EU system with only one application. Plant variety protection pursuant to the Community regulation is consistent with protection available under the 1991 UPOV (100–101).

For patented plant-related inventions, additional protection is available in the form of a patentlike right along the same lines as for pharmaceuticals. Since 1996, an SPC has also existed for "plant protection products" that are protected by a patent (102). The term and procedural requirements of an SPC for such products is identical to the one provided for pharmaceuticals. What differs is the product that is protected. In relation to plant products, those that qualify for SPC protection are defined as "active substances and preparations containing one or more active substances ... intended to": (*1*) protect plants against harmful organisms, (*2*) influence the life processes of plants, such as a growth regulator, (*3*) preserve plant products, (*4*) destroy undesirable plants, or (*5*) destroy parts of plants or otherwise minimize undesirable growth (102).

Future Developments. Patent protection for biotechnology in Europe is likely to continue to be in a state of flux in the near future due to the existence of different systems for obtaining and enforcing patents. A uniform system for obtaining as well as enforcing patent rights throughout the EU member states has been previously envisioned, although it has not yet become a reality.

In particular, although the Community Patent Convention (CPC) provides for such a system, it has not been ratified by all EU members. Because of political and constitutional reasons, CPC has not come into force, although it was first signed in 1975 (65). At this point, it is anticipated that the EU will cease efforts toward effectuating CPC, and instead work toward enacting a regulation to create a unitary EU patent (103); the EU Commission is planning to propose such a regulation in the year 2000 but no such regulation has been proposed as of June 2000. The EU has been clear that such a system would be largely consistent with the EPC provisions and at least for a transitional period, coexist with the present two-tiered system of national and EP patents (103). However, even if such a regulation were adopted, the protection of biotechnology is likely to continue to be remain unsettled for quite some time.

Japan

Japanese patent law has changed markedly in the last 10 years, both because of the TRIPS agreement and because of international pressure to conform its laws to those of Europe and the United States. Some doctrines that have been established for decades in the United States have only recently been established in Japan. It is likely that amendments and clarifications to its patent laws will continue. Current Japanese Patent Office (JPO) practice with respect to biotechnology can be determined by examining the JPO Guidelines, as well as the JPO's response to some hypothetical biotechnology patent examples, all of which are publicly accessible through the JPO web site (104,105). Because of the availability of this information, as well as the fact that Japanese patent law will likely continue to evolve, this discussion will provide an overview of recent changes to Japanese patent law that affect biotechnology rather than attempt to provide a comprehensive description of all laws concerning biotechnology.

Patentability. The JPO has clarified that biotechnology inventions are not per se precluded from patentability (39–40,105). Therefore the usual patentability standards

apply to such inventions. However, application of those standards has posed some difficulties in the area of biotechnology. For example, it is sometimes difficult to determine when genetic engineering inventions are novel or have an inventive step. Nonetheless, the JPO has indicated a wide variety of biotechnological innovations to be considered patentable subject matter, so long as they can still meet the technical patentability requirements. In particular, living unicellular organisms, animals and animal parts, plants, and plant parts are all considered patentable subject matter. As a "general rule," human-derived products are said to be eligible for patentability, although humans themselves may be barred under a morality-based exclusion (40). New uses of known compound are also considered patentable (40).

However, "industrially applicable" has been statutorily defined to exclude certain subject matter that narrows the scope of patentable biotechnology. As in EPC certain types of "medical activity" are considered not industrially applicable. Of particular relevance to the pharmaceutical area is that methods of treating humans by surgery or therapy, as well as diagnostic methods practiced on the human body are all excluded as being not industrially applicable; however, pharmaceutical compositions for use in the unpatentable methods can be industrially applicable. In addition methods of treating animals are patentable so long as there is no attempt to patent treatment on the human body. The relevance of these exclusions to biotechnology is that gene therapies are not patentable because they are considered a method of treatment within this exception. However, pharmaceutical products produced by gene therapy techniques may be eligible to be patented (40).

Another bar to patenting biotechnology is that inventions "liable to contravene public order, morality or public health" may be considered unpatentable under Section 32 of the Japanese Patent Laws (106). This language has been the basis for denial of patents on new medical treatments as well as methods of breeding new plants or animals. In addition JPO has indicated that this may also preclude patents on humans as well as human organs (40).

While not a bar to patentability, it is important to be aware of deposit requirements for biotechnology. For inventions concerning microorganisms, the microorganism must generally be deposited with an institution designated by JPO or international depositary authorities. This requirement can be met simultaneously with application but is improper after filing. There are certain situations where microorganisms need not be deposited, for example, if it can be created by a person skilled in the art based on the specification description alone.

Patent Rights

Opposition and Patent Term. Prior to 1996 the JPO published applications for opposition by third parties after examination, but prior to the issuance of an actual patent and tied the patent term to this opposition period. The pre-1996 patent term was 15 years from the date of publication of the postexamination (and pre-grant) application, with a maximum duration of 20 years from filing date (106, Article 67(1)). This scheme has been substituted with an opposition procedure *after* the patent grant, similar to the situation described with regard to EPO (106, Article 113). Now, any third party can file an opposition, and there is a uniform patent term of 20 years from the date of filing of the patent application.

Patent terms of pharmaceutical or agricultural inventions that are subject to pre-marketing administrative approval may be extended for up to an additional five years. However, there are certain limitations to obtaining such an extension in addition to qualifying subject matter. For instance, the request must be submitted within three months of regulatory approval of the patented invention, and no request may be filed within six months from the end of the patent term. The request must show that the patent could not be commercialized for at least two years after issuance due to delay necessitated by regulatory approval (from either the day the patent issues, or the day approval is first sought, whichever is *later*).

Scope of Protection. Infringement of a patent can occur through both direct and indirect means. However, the infringement must be commercial and public, unlike infringement under U.S. law. It should be noted that pursuant to TRIPS requirements, the rights of patent owners were recently extended to also include the ability to exclude unauthorized offers for sale of the patented invention. In particular, literal infringement occurs when an authorized party:

1. commercially makes, uses, sells, offers to sell, or imports a patented product;
2. commercially uses a patented process; or
3. commercially makes, uses sells, offers to sell or imports a product made by a patented process.

Under a recent revision to Japanese patent laws, unless an alleged infringer (the defendant in a patent infringement suit) shows proof to the contrary, if a defendant's product is identical to one obtained by the patented process, it is presumed to be manufactured by such process (107).

Infringement under the doctrine of equivalents (DOE) has been a relatively recent phenomenon in Japan. Although courts had applied the DOE sporadically in recent years, it was not until 1998 that the Supreme Court affirmatively embraced the doctrine and set forth clear standards for its application (108–109). The Supreme Court clarified that the DOE analysis should be considered *at the time of the infringement* (rather than at the time of filing as was previously held by lower courts) (108); this change is consistent with U.S. law and favors patentees and particularly pioneering patents that can now potentially cover related advances that develop after a patent issues. Although courts were initially hesitant to find infringement under DOE, at least one district court has done so as of 1999 (110).

Under the DOE law in Japan, infringement may be found even if the patent has an element that does not cover the accused product, if the accused product is regarded as being equivalent. Equivalence is determined based on a multifactor test. The essential inquiry in finding infringement via DOE is whether the accused product or process contains elements identical or equivalent to each

claimed element of the patented invention; again, this central inquiry echoes current U.S. law requiring that DOE be conducted on an element-by-element analysis. Infringement under DOE may be found where:

1. portions are not essential to the patentability of the patented invention;
2. objectives and effects of the patented invention are still attained after replacing the portions with their counterparts in the accused product;
3. the replacement would have been obvious to those skilled in the art at the time of manufacturing the accused product;
4. the accused product was neither anticipated nor obvious to those skilled in the art as of the filing date of the application for the patented invention; and
5. no special conditions exist, such as the accused product being intentionally excluded from the scope of claims during the prosecution of the application for the patented invention (no prosecution history estoppel).

There are several exceptions to the basic patent right to exclude others from commercial use of the invention that may affect biotechnological inventions. No patent rights are available with respect to products that existed in Japan prior to the filing of the patent application (106). Also no patent rights exist for acts of preparing medicines in accordance with medical prescriptions (106). The Japanese Patent Act has long since established that there is no right to exclude those who use a patented invention for "purposes of experiment or research" (105, Article 69(1)). However, this has been recently interpreted to cover the manufacture of patented products for pre-marketing approval by companies seeking to manufacture generic versions of patented drugs (110). This judicial interpretation brings Japanese patent law in line with practice under U.S. law. However, as noted with the similar provision in the EU, it is unclear whether this interpretation is consistent with TRIPS.

Compulsory licenses of patented inventions are also available in certain circumstances under Japanese law. In particular, one who has independently created a patented invention and has been commercially using it or made preparation to do so, can obtain a nonexclusive license (Article 79). JPO has noted that compulsory licenses are available in the cases of nonworking of a patent for at least three years (Article 83), dependent patents (Article 92), and public interest (Article 93). However, it is unclear whether the provision of such compulsory licenses are entirely compatible with TRIPS.

Enforcement Issues. Finally, damages are important in examining patent protection of biotechnology in Japan because damages enable a patent owner to effectively enforce rights and preclude infringement. An examination of damages under Japanese Patent law is particularly relevant because of recent changes that substantially improve, recovery for prevailing plaintiffs (i.e., patent owners). Previously only limited damage awards were available (at least in comparison to U.S. awards). Plaintiffs generally did not even attempt to seek lost profits as courts rarely granted them; the primary reason for this was that plaintiffs could not establish causation between infringement and damages because plaintiffs had no access to confidential information of the defendant and Japanese patent law did not provide for any inferential causation of lost profits. However, under the present law, which became effective as of January 1, 1999, the types of damages available have been explicitly broadened in the patent statute to include, for the first time, lost profits as a measure of patent infringement damages.

Under the new section, the plaintiff is relieved of the causation burden as the statute provides a presumptory amount that the defendant must then rebut. The presumptory amount of lost profits consists of the infringer's sales volume multiplied by the patentee's profit rate, as long as such amount does not exceed the amount a patentee would be able to obtain based on its own manufacturing capacity. The burden is on the infringer to establish that the presumed damages are incorrect; the infringer would need to show that the actual number of infringing products was lower.

In addition to providing for lost profits, the amended patent law also allows the potential for increased awards based on a reasonable royalty calculation. Previously damage awards were calculated based on industry-standard royalty rates and rates for licensed government-owned patents; this resulted in royalty rates ranging from 2 to 4 percent, which was in stark contrast to a more typical rate of 8 to 10 percent in Europe (112). This stringent calculation was in part derived from the fact that the word "normally" qualified the term "reasonable royalty." The amended law removes the qualification "normally," such that courts should be able to grant higher amounts than previously. The cap for damages available from an infringing corporation has been raised from 5 million yen ($36,500) to 150 million yen ($1.09 million) (106, Article 201).

There are additional provisions in the Japanese patent laws that may assist plaintiffs in patent infringement actions to recover more damages. In the past plaintiffs were forced to extrapolate sales of defendants infringing products based solely on public documents because there was no requirement that parties produce documents other than those that it intends to rely on at trial. However, under a new provision of the patent laws, if a party so requests, a court may order the opposing party to produce documentation necessary to determine damage caused by an infringement (barring some legitimate reasons for failing to produce such documents) (106, Article 105). Moreover a new provision of the Civil Procedure Code, provides judges with discretion to determine the appropriate amount of damages where "it is extremely difficult to prove the amount of damages from the nature of such damage" (114, Article 248). Although this provision was intended to assist in calculating intangible damages such as emotional distress, it has been relied upon to discount a defendant's calculation of lost profits and to instead adopt a calculation closer to the plaintiffs when the defendant's internal documentation was not made available (112,115).

In the future, it is possible that even more monetary compensation may be available for plaintiffs, which would

bring Japanese patent law closer to the situation in the United States In 1998 the JPO proposed to provide punitive damages and partial attorney fees for successful plaintiffs — both of which are available remedies to prevailing patent owners in the United States and serve as a deterrent effect against infringement. Although no such legislation was passed in 1998, JPO, as well as the Ministry of International Trade and Industry, continue to lobby for such changes.

M

MEDIA COVERAGE OF BIOTECHNOLOGY

DOROTHY NELKIN
New York University
New York, New York

OUTLINE

INTRODUCTION

In 1924 Edwin E. Slosson, editor of the first science writing syndicate in America, described his view of science journalism. "The public that we are trying to reach is in the cultural stage when three-headed cows, Siamese twins and bearded ladies draw the crowds to the side shows." That is why, he explained, science is usually reported in short paragraphs ending in "-est." "The fastest or the slowest, the hottest or the coldest, the biggest or the smallest, and in any case, the newest thing in the world" (1).

In some respects little has changed in the world of science reporting. In the 1990s journalists still play up the hottest scientific discoveries, the riskiest technologies, and the latest miracle cures. The media coverage of rapid advances in biotechnology and especially in human genetics illustrates these tendencies: extravagant reports about wonder therapies, genetically engineered pigs, and cloned sheep attract readers and sell magazines. "The gene of the week" is "hot" news even though the significance of particular discoveries has often been questioned. The controversial theories emerging from research in behavioral genetics that purport to explain human behavior and social differences are especially newsworthy though their validity is often in doubt.

The media reporting on biotechnology and genetics is mainly promotional, directly reflecting the influence of scientific sources of information. But it is also polarized, swinging from enthusiastic promises to warnings of peril. Journalists are especially attracted to controversies, and new developments in biotechnology have created many provocative and disputed issues. Biotechnology products, intended to control pests or plant diseases and to increase agricultural yields have been controversial because of potential risks to environmental quality or human health. The bioengineering of animals and the creation of new transgenic foods has raised moral and aesthetic objections as well as concerns about risk.

Media coverage of science and technology provides a useful window on public attitudes, but science reporting also has an important influence on public perceptions. The way people perceive research in human genetics or developments in agricultural biotechnology — the way they interpret their costs and benefits — may be influenced less by the details of scientific evidence than by the repeated messages conveyed in the popular press. These media messages help to create the beliefs and assumptions that underlie personal decisions, social policies, and institutional practices.

Following a brief overview of the history of the media coverage of biotechnology, this article will illustrate its most important characteristics by describing five areas that have received considerable media attention. The first widely reported development in biotechnology was the discovery and synthesis of interferon. The media's presentation of news about this therapeutic product was volatile and polarized, a style that has since characterized many reports about biotechnology events. The coverage of research on gene therapy suggests the important influence of scientific sources in shaping the content and tone of science news. The coverage of cloning demonstrates the appeal of drama, myth, and image to the journalists reporting on science events. The media attraction to behavioral genetics suggests the appeal of scientific theories that conform to popular social stereotypes or support prevailing policy agendas. Finally, reports on biotechnology risks, and the problems that may follow from genetic predictions illustrate the media's attraction to policy disputes. A persistent theme pervades this media coverage of biotechnology issues — a concern about the social implications of the growing ties between science and commercial interests.

HISTORICAL OVERVIEW

"After years of being a dowdy old lady, biology has become belle of the ball." Its revolutionary potential has attracted researchers "in droves," and "bankers [are] in hot pursuit." To the media in the early 1980s, biotechnology was expected to become the next economic miracle. But, ironically, only a few years earlier the reports on biotechnology had been more about risks than revolutions. In the mid-1970s molecular biologists held an international meeting at the Asilomar conference center in California to assess the potential risks of recombinant DNA research (2). This was mainly a technical discussion, but the press evoked images of Frankenstein monsters and Andromedalike strains spreading like an incurable disease. Some reporters worried about "warping the genetic endowment of the human race"; others about "biological holocaust." The message? Runaway science needs to be controlled (3).

Yet, only a few years later, questions of safety ceased to be news. Journalists dropped the subject, turning their attention to promises and applications. The discovery of ways to synthesize interferon brought reports of miracle cures. Techniques of gene splicing, once represented as dangerous, became "a mundane tool," news and headlines began to tout the potential applications of biotechnology research as "miracles," as the key to better health. In the space of only a few years, media attitudes had markedly changed. In 1977, for example, *Time* magazine had run a cover story called "The DNA Furor: Tinkering with Life" Only three years later a *Time* cover story was called "DNA: New Miracle." Similarly in 1976 the *New York Times* magazine section published an article called "New Strains of Life or Death?" Later a 1980 article in the same section of the *New York Times* was called "Gene Splicing: The Race towards Better Human Health" (4).

By the early 1990s the "runaway science of genetic engineering" had become a "technological frontier." Stories welcomed the patenting of genetically engineered products, the implications of these products for resolving medical, agricultural, and industrial problems, and the proliferation of genetics R&D firms. Local papers touted the importance of these firms to the regional economy. Journalists described geneticists as pioneers, "unlocking the basic laws of nature," discovering the "secrets of life," solving the problems of devastating disease. The biotechnologists working on "high tech veggies" will "do wonders" to help meet nutritional requirements and to enhance the economy. Genomic researchers are "riding the DNA trail." Geneticists are "relentless hunters of genes," involved in a "race" to find the markers for disease. Media accounts are reverent — almost religious: A 1994 cover of *Time* depicts a figure on a pedestal, his arms extended in a Christlike pose, his torso inscribed with a double helix. The caption reads: "Genetics — The Future Is Now." The image, of course, is the Ascension.

Encouraged by the enthusiastic response to research in medical genetics, behavioral psychologists in the 1990s began to publish and to publicize their long controversial studies on the genetic basis of behavioral conditions and personality traits. Always seeking provocative copy, journalists reported these claims, focusing especially on the most controversial — those concerning predisposition to antisocial behavior. And, often uncritically, they drew conclusions about the implications of this research for social policy (5).

Despite the general media enthusiasm about biotechnology, media reports are frequently tempered by doubts. Many journalists, for example, have been critical of the growing links between the biotechnology industry and universities for their affect on open research and they have called attention to the conflicts of interest that are endemic to this field where profits and ethics collide. The media have amplified the critical views of activist Jeremy Rifkin, a persistent and media-savvy biotechnology gadfly. They have extensively reported the protests of animal rights groups against the creation of transgenic animals, and the concerns of religious groups about genetic engineering. In response to the rapid development of genetic tests, media attention turned to the issue of genetic discrimination as tests reveal information about individual predispositions that could influence access to insurance or to jobs (6). And the old Frankenstein metaphors have reappeared in reports about genetically modified foods.

Reporting on biotechnology — from the development of interferon to the creation of clones — the press has batted readers back and forth from biotechnology miracles to visions of apocalypse, from celebrations of progress to warnings of peril, from optimism to doubt. These dramatic shifts in media reports take place as journalists respond to the promotional hyperbole of scientists and technical institutions, but also to protestors and changing popular fashions. This fickle and volatile style of reporting serves the interests of the media in their endless quest for newsworthy and dramatic material. The discovery and synthesis of interferon provided the first opportunity for this style of science journalism.

INTERFERON

Interferon, a protein manufactured in the body when a virus invades a cell, was discovered in 1953 as a natural therapeutic agent, a so-called interfering protein that inhibits infection. The possibility of isolating the protein raised hopes for eventually developing a cancer cure, and this caught media attention. However, the scarce supply of the agent at that time limited scientific progress and clinical possibilities and journalists lost interest until 1975 when Mathilde Krim, a politically astute geneticist, organized a conference intended to publicize the potential of interferon and to win public support for research (7).

Krim's persistent efforts and the growing interest of the American Cancer Society (ACS), which began to sponsor clinical trials, brought a deluge of media coverage in the late 1970s. The research articles in scientific journals explicitly qualified the promises of interferon, indicating the tentative nature of existing studies, the high cost of isolating the protein, and its therapeutic limits. In the popular press, however, interferon became a "magic bullet," a miracle cure for everything from cancer to the common cold.

In 1980 Biogen, a new biotechnology firm, developed a DNA clone for this protein, opening the possibility of producing large quantities of the product at low cost. Uncritically accepting promotional information provided by the company at a press conference, journalists welcomed this new technological development as still another miracle. "Like the genie in a fairy tale," the *Detroit Free Press* told its readers, "science came up with the key to the magic potion." *Reader's Digest* wrote about a "wonder therapy," *Newsweek* about "cancer weapons" and "the making of a miracle drug." Business journalists focused on interferon as a profitable commodity, calling attention to the dramatic increase in stock prices of biotechnology firms. *Business Week* described the efforts to synthesize the substance as a "race" to capture the market: "We have just passed the quarter mile pole and all the horses are in a bunch." *Time* wrote described interferon as a "gold mine" for patients and for biotechnology firms.

The *New York Times* science writer Harold Schmeck, however, broke this promotional pattern. Writing cautious

reports, he suggested that while interferon was promising, there was no definitive evidence of its effectiveness. He also reported on possible harmful effects, suggesting that "the seemingly ideal weapon" was less of a panacea than anticipated, and he reported on interferon studies that "put cancer use in doubt" (8). Emphasizing the "modest, controversial, and even negative results of research," Schmeck observed that the promise of a scientific advance was raising research money, but also raising false hopes. In response to this article four scientists from the Sloan Kettering Institute for Cancer Research wrote a letter to the *New York Times*, expressing concern that such qualified reporting could undermine public support of interferon research (9).

The difficulties of using interferon as a therapeutic agent became public in 1982 when four patients in France died after they were treated with the drug. Abruptly, the tone of reporting changed from exaggerated optimism to disillusionment: "From wonder drug to wallflower." The wonder drug was demoted from a magic bullet to a "research tool." Newspapers and magazine articles assessed the situation pessimistically: "Jury's out on interferon as a cancer cure"; "Studies cast doubt on cancer drug"; "It's a hard row to hoe." Research continued, but little more appeared in the press until a series of patent disputes turned media attention to the question of proprietary interests in commercially promising biotechnology products.

These reports on interferon research demonstrate several themes that have since characterized media reports on biotechnology. First, the content is limited. Little appeared in the press coverage of interferon about the actual nature of the research; instead, most articles appealed to public concerns about cancer and the hopes of soon finding a cure for this dread disease. While interferon's short-term usefulness as a therapeutic agent was problematic, the research did yield significant scientific understanding of basic biological concepts (e.g., the control of gene expression in mammalian cells and the regulation of immunity) that in the long term have affected the practice of medicine. But those readers who followed the interferon story learned little about such developments.

Second, the media coverage of interferon placed great emphasis on scientific and technological competition. Scientists and the firms developing interferon were in a "race" for breakthroughs, for solutions to a dread disease. The gradual accumulation of information that is inherent to the research process was not considered news. Whether the goal is to discover a new genetic marker or to clone a sheep, the media are attracted to the competition in science, the race to be the first to get results.

The media reports about interferon were also volatile. Readers were mainly treated to hyperbole — to a promotional coverage designed to raise their expectations and whet their interest. Scientists played an important role in shaping this coverage. Far from being neutral sources of information, they actively sought a favorable press, equating public interest with research support, and journalists for the most part were inclined to accept the claims of scientific sources. However, when predictions about interferon's curative powers failed to materialize, unqualified optimism in the press quickly shifted to the opposite extreme. This pattern of premature promotion followed by a bitter backlash when optimistic promises fail has continued to be a striking characteristic of the media coverage of gene therapy.

PROMISES OF GENE THERAPY

The media have welcomed claims about gene therapy with extravagant headlines and promotional hype as reporters convey — often uncritically — an array of futuristic scenarios presented by enthusiastic scientists. In the future, said a geneticist to *Discover*, "present methods of treating depression will seem as crude as former pneumonia treatments seem now" (10). In the future, said another scientist, food companies will sell infirmity related breakfast cereals targeted to aid those with genetic predispositions to particular diseases. "Computer models in the home will provide consumers with a diet customized to fit their genetic individuality, which will have been predetermined by simple diagnostic tests" (11). In the future, geneticist French Anderson told a *Time* Reporter, "Physicians will simply treat patients by injecting a snippet of DNA and send them home cured" (12).

To the media, the National Institutes of Health (NIH) Human Genome Initiative has replaced the NASA Space program as a new frontier, the cutting edge of high-technology exploration, and just as in the heyday of NASA, journalists are receptive to scientific enthusiasm. On their part, scientists seek media coverage as a form of public relations, regarding public visibility as a means to attract funds for their research. Thus scientists and the press offices of their institutions are inclined to turn precliminary experimental findings into magic bullets. For example, in 1995 the Scripps Research Institute issued a press release announcing that researchers had found a cure for cancer through a small injection of a protein that would cut off the blood supply from tumors and cause them to shrink while leaving normal tissue intact. The announcement about a cancer cure, designed to attract media attention, was, it turned out, only about a laboratory observation; there had been no experimental trials testing the relevance of the observation to human pathology. But as anticipated, the press release was covered as welcome news in the press (13).

Traditionally working in a context where success is measured by the judgment of peers, scientists have long assumed that a record of accomplishment is sufficient to maintain research support. Thus information, the scientist's "stock-in-trade," has been directed primarily toward professional colleagues. Most scientists have not been interested in public visibility; on the contrary, they have feared it could result in external controls on their work. And "visible scientists" — those who seek media attention — have often been marginalized or disdained (14). But attitudes in the scientific community have changed. Dependent on direct congressional appropriations or, increasingly, on corporate support of research, many scientists now believe that scholarly communication is no longer sufficient to maintain their enterprise. They

see gaining national visibility through the mass media as crucial to securing the financial support required to run major research facilities and to assuring favorable public policies toward science and technology.

Geneticists seeking to maintain public support have become skilled in rhetorical strategies designed to attract the media. In media interviews they have described the genes as "master molecules:" We are but "readouts" of our genes. They describe the body in deterministic terms — as a set of instructions, a blueprint, a map, or a program that is transmitted from one generation to another. They suggest that by deciphering the text, classifying the markers on the map, and reading the instructions, they will unlock the key to human ailments and human nature, revealing the secrets of human life. Molecular biologist Walter Gilbert, introduces his public lectures on gene sequencing by pulling a compact disk from his pocket and announcing to his audience: "This is you." Scientists, he claims, will "provide ultimate answers to the commandment, know thyself" (15).

Geneticists also emphasize the predictive powers of their science by calling the gene "a Delphic oracle," "a time machine," "a trip into the future," "a medical crystal ball." James Watson, the first director of the Human Genome Project, has announced in frequent media interviews that "our fate is in our genes." The metaphors scientists use to describe their work convey several messages about the meaning of genetics that have been widely disseminated through a receptive press: a definition of the gene as an essentialist and deterministic entity, and a promise that genetic research will enable the prediction of future behavior and disease and thus lead to therapeutic solutions.

The biotechnology industry has further encouraged media hype about gene therapy. The industry has made a major financial commitment to gene therapy, expecting this will be the basis of future medicine. Over 60 percent of gene therapy studies are directly financed by industry in anticipation of a profitable market in the near future. Corporate advertisements announce "a great leap in the treatment of disease," and promise "a healthy future one gene at a time." Immediately following the discovery of the mutation in the BRCA-1 breast cancer gene, one pharmaceutical company announced in a newspaper advertisement that they had made progress in finding a "breakthrough . . . new treatments and ultimately the cure for breast cancer." Another advertisement appearing in sports magazines, said it all: "'Bad Genetics?' Use Optigenetics — 'The first genetic optimizer.'"

The development of pharmaceutical products and the proliferation of clinical trials on new therapeutic procedures have encouraged the tendency towards technological optimism in the press. For example, the introduction of therapeutic molecules, especially TPA (tissue plasminogen activator) for dissolving clots, and the use of human growth hormone to treat dwarfism became newsworthy issues. Then the first FDA-approved gene therapy experiment in 1990 — the injection of cells containing ADA genes in a child with an immune system malfunction — became a major news event. "The long awaited era of genetic therapy has at last arrived" said a writer in *The Sciences* (16). *Discover* called gene therapy, "The Ultimate Medicine." Writing on gene-transfer techniques, the reporter proclaimed, "Genetic surgeons can now go into your cell and fix those genes with an unlikely scalpel: a virus." Interviewed for this article, molecular biologist Richard Mulligan declared that "We can use gene transfer to make a cell do whatever we want. . . .We can play God in that cell." Similarly *US News* told its readers that gene therapy is the medicine of the future. "No disease has given up more of its secrets to genetic sleuths than cancer." Genetics, promised the writer, will allow doctors to "do something" about the disease. The isolation of the colon cancer gene in 1993 prompted an enthusiastic scientist to tell a *New York Times* reporter of its implications: "Deaths are entirely preventable" (17).

When they report on complex scientific issues, journalists rely heavily on press releases, often responding with uncritical enthusiasm to promotional hype. "Genetic Research Leaves Doctors Hopeful for Cures," "New Hope for Victims of Disease," "Genetics, the war on aging . . . [is] the medical story of the century . . . Genetic technologies will dramatically curtail heart disease, aging, and much more" (18). In a story called "the Age of Genes," *US News* reported that "advances bring closer the day when parents can endow children not only with health but also with genes for height, good balance, or lofty intelligence" (19).

While promises, backed by scientific authority, raise hopes of instant cures, aside from controlling reproduction there is little that can be done to cure genetic disease. The gap between identifying a predisposition to a genetic condition and finding a therapeutic solution is very wide. The problems of clinical application follow in part from the complexity of genetic diseases. Some are caused by the absence of the activity of a gene product, others by altered proteins that disrupt cellular function, and still others by alterations of chromosomal structure. The early expectations about a successful therapy for cystic fibrosis, reported widely in the press, were confounded by the fact that this disease has many more mutations than originally anticipated.

There are also problems in finding safe vectors capable of transporting genes into targeted cells. Most gene therapies use viruses as the carrier mechanism, for this is the most feasible way of targeting appropriate cells. But there are risks. Inserting a gene in the wrong place along a strand of DNA could cause an undesirable effect. And the immune system may attack cells treated with gene therapy, responding to them as foreign or infected. Gene transfer experiments on monkeys were found to cause malignant T-cell Lymphoma. Clinical trials of Genentech's promising drug called Pulmozyme, developed to treat cystic fibrosis, were halted when they found significant mortality rates among treated patients.

Discovering risks and side effects is, of course, the purpose of animal research and clinical trials. But in an area hyped by both scientists and the media as "the medicine of the future," failures become more than routine science; they also become a newspeg for journalists who seldom convey to their readers the fact that a failed clinical trial can itself yield useful information. The death of a gene therapy patient in 1999 brought an abrupt end to the gene therapy hype.

The growing realization of the practical difficulties of extending laboratory studies to clinical applications is puncturing inflated expectations, and this is reflected in skeptical media reports. Describing the research on the unusual frequency of a mutation in the BRCA1 gene among Ashkenazy Jewish women, reporters commented again and again on the absence of effective therapies. "Does it make sense to screen healthy women for the defect given that there is no good therapy to offer those in whom it is found?"

Some media reports associate experiments in gene therapy with genetic engineering or "tampering" with genes. "Lurking behind every genetic dream come true is a possible Brave New World nightmare," says a *Time* reporter. "To unlock the secrets hidden in the chromosomes is to open up the question of who should play God with man's genes." An accompanying image portrayed scientists balancing on a tightrope of coiled DNA (20). And an illustration for a *New York Times* article on gene therapy and the potential of genetic engineering featured a drawing imitative of the famous Edvard Munch painting, "The Scream." A figure stands, horrified, mouth ajar, eyes wide open, her hair a mass of coiled DNA (21). Such images proliferated in the reports about the creation of Dolly, the first cloned sheep.

CLONING

This section "Cloning" has been adapted from Ref. 22. The consequences of cloning have long captured the popular imagination: cloning has been a major theme in horror novels and science fiction films. Genetic engineering research that has been associated with cloning has met a critical press. For example, in 1993 scientists at a George Washington University laboratory conducted a genetic engineering experiment that "twinned" a nonviable human embryo. The purpose was find a way to create additional embryos for in vitro fertilization, but major newspapers, popular magazines and talk shows covered the experiment as if it had actually yielded a cloning technology for the mass production of human beings. The media response was remarkable and diverse. The *Los Angeles Times* announced the glorious news that "infertility, virginity and menopause are no longer bars to pregnancy" (23). But also envisioned were embryo and selective breeding factories, cloning on consumer demand, breeding of children as organ donors, a cloning industry for selling multiples of human beings, and even a "freezer section of the biomarket" (24). *Time*, wrote of the "Brave New World of cookie cutter humans" (25). And repeatedly, scientists in media reports were accused of "playing God."

Then, in February 1997, scientists at the Roslin Institute in Edinburgh cloned Dolly, after 276 attempts, from the genetic material of a six-year-old sheep. The media response to the production of a sheep by cloning a cultured cell line reflected futuristic fantasies and Frankenstein fears about science and especially about genetic engineering. The meaning of Dolly that was conveyed by the media reflected a pervasive assumption of "genetic essentialism" — that human beings in all their complexity are simply readouts of a molecular text, that human identity is contained entirely in the sequences of DNA in the human genome (26). Thus, speculated journalists, why not clone great athletes like Michael Jordan, or great scientists like Albert Einstein, or popular politicians like Tony Blair, or less popular politicians like Newt Gingrich, or wealthy entrepreneurs like Bill Gates. Some reporters lauded cloning as a way to assure immortality. Again and again, media stories predicted that cloning will allow the resurrection of the dead (e.g., bereaved parents might clone a beloved deceased child). Or the technology could provide life everlasting for the deserving (narcissists could arrange to have themselves cloned).

But there were also anxious scenarios developed in the press, including futuristic stories about making new Frankenstein monsters, or creating Adolph Hitler clones, or producing "organ donors" only to harvest their (fully compatible) viscera (27). While cloning could theoretically make both sexes irrelevant to reproduction, the technology appeared as a threat to the male of the species — men would no longer be necessary! It also held a promise of creating perfect cows, sheep, and chickens, or perhaps even perfect people. If sperm banks (as portrayed in some women's magazines) were a place to "shop for Mr. Good genes," why not, asked reporters, use cloning to produce and reproduce perfect babies?

Journalists elicited views from people in various professions about the implications of cloning for their fields. A divorce lawyer predicted the doubling of his business. Historians wondered if the founding fathers could be cloned for display in a "living history" exhibit in a theme park: They suggested that the park might be called "Clonial Williamsburg." Some facetious policy commentators announced that cloning experiments could be developed to solve social problems: The race problem could be resolved by manipulating the balance between melanin and IQ genes. The age-old nature-nurture dispute could be definitively settled by creating clones and raising them systematically in different environments.

News articles covered religious perspectives on cloning (28). One writer quipped that cloning offered a "second chance for the soul." If you sin the first time, try again. But a theologian, Rabbi Mosher Tendler, a professor of medical ethics at Yeshiva University in New York City, warned in a news interview that "whenever man has shown mastery over man, it has always meant the enslavement of man." Other theologians, long concerned about the implications of genetic engineering, worried that the scientists who experimented with cloning were "playing God" and "tampering with God's creation." Articles in evangelical magazines such as *Christianity Today* or *The Plain Truth* have regular articles opposing genetic engineering as "tampering" with genes." Pope John Paul II has taken a position on genetic manipulation, arguing that: "All interference in the genome must be done in a way that absolutely respects the specific nature of the human species, the transcendental vocation of every being and his incomparable dignity. . ." (29).

In his scientific paper itself, Dr. Wilmut called attention to the problem of whether "a differentiated adult nucleus can be fully reprogrammed." He called the lamb in question

6LL3 rather than Dolly, and made it clear, in diagrams and illustrations of gels, that there is some question about the precise genetic relationship between Dolly and the "donor" (30). Somatic DNA, which was the source of Dolly's genes, is constantly mutating. Dolly, in fact, may not be genetically identical in every way to her "mother," a point that is of some importance for the possible agricultural applications of cloning techniques.

For the media, however, such technical details were less important than symbolic associations. The cloning of a lamb was immediately set in a context of other fears about genetics and genetic manipulation, and even in a context of more general fears about science and its applications. One journalist compared cloning to weapons development. Another worried that the shortage of organs for transplantation would be resolved by cloning anencephalic babies (who are born without a brain but are otherwise normal) so that their organs could be harvested for patients in need. And a writer for *Newsweek* related the creation of Dolly to broader concerns about food biotechnology by speculating about "cloned chops" (31).

Dolly also evoked an amazing range of media humor. A *New York Times* journalist interviewed writer Wendy Wasserman who wondered what you would say to your shrink if you are your own mother (32). A cartoonist in the London *Guardian* depicted a women comforting a cab driver who had just run over her husband: "That's alright, I have another one upstairs." A writer predicted a new action movie called "Speed Sheep" in which thousands of cloned sheep clogged Interstate 95. Headlines of cloning stories revelled in puns: "An udder way of making lambs," "Send in the clones," "Little Lamb, who made thee?" "Will there ever be another ewe?" and "Getting stranger in the manger." And inevitably there was the anticipation of "Double Trouble."

More pointed jokes — as well as serious editorial commentaries — expressed the growing tensions over commercial control of biotechnology and its implications for the commodification of the body. Just as the GWU experiment evoked images of a cloning industry and breeding factories, so Dolly evoked cynical references to "test tube capitalists," and sardonic queries about a market for genetic "factory seconds" and "irregulars." Meanwhile *Business Week* anticipated "The Biotech Century" in which cloning animals is just the beginning: "It's all happening faster than anyone expected" (33).

As in the media coverage of gene therapy, the messages evoked by Dolly have ranged from promises of miracles to portents of disaster. Editorial appeals called for regulation and for a moratorium on cloning experiments. As political and social pressures began to grow, scientists responded, defending the importance of the work. Media images were "selling science short." The calls for regulations and restrictions, some argued, ignored the medical benefits that could follow from cloning experiments and their potential contribution to the development of life-saving treatments and the testing of new drugs. We are not interested in playing God, said James Geraghty, president of the biotechnology firm, Genzyme, but in "playing doctor" (34). Mammalian cloning could help to generate tissue for organ transplantation and encourage transgenics experimentation. And certainly research using cloning would enhance scientific knowledge about cell differentiation. The politicians who sought a ban on cloning research, said the scientists, were "shooting from the hip."

But media coverage continued to reflect mistrust of this kind of science, concern that commercial interests would ignore social considerations, and fear that the outrageous possibilities suggested by a cloned sheep will eventually, perhaps inevitably, be realized. News reports and media headlines suggested that "Science fiction has become a social reality." "Whatever's Next?" And, inevitably, "Pandora's Box."

Dolly, for a very brief period had reinforced media myths about science — evoking both euphoric fantasies and horrible nightmares and eliciting a fear of science out-of-control. Yet, only a few months after the media blitz, Dolly and the problems of cloning ceased to be news. By June 1997, when the National Bioethics Advisory Commission appointed by President Clinton reported its recommendations to continue the moratorium on federal research funding in this area, and to consider federal legislation, the media had lost interest and paid little attention to the report. In July 1997 the British scientists who had cloned Dolly cloned Polly and three other lambs, this time from fetal rather than adult cells. Polly, a transgenic lamb, carries a human gene in her cells. But cloning was already old news, and this event was reported as merely one more technical advance — the fusion of a fibroblast cell from a fetus to an egg cell. For the media, cloning, even when it involved a human gene, was accepted as routine.

Dolly in the media had been more than a biological entity; she became, ever so briefly, a cultural icon, a symbol, a way to define the meaning of personhood and to express concerns about the forces shaping our lives. She provided a window on popular beliefs about human nature, on public fears of science and its power in society, and on concerns about the human future in the corporate-driven climate of the biotechnology age. A more lasting preoccupation for the media has been research on the genetics of human behavior, research that purports to explain age-old questions about human differences and offers tantalizing, if problematic, prospects for developing technical solutions to social problems.

GENETICS OF HUMAN BEHAVIOR

The language of biological determinism is pervasive in the press. A media survey found references — some more plausible than others — to the genetic basis of shyness, directional ability, aggressive personality, caring tendencies, exhibitionism, homosexuality, dyslexia, job success, arson, traditionalism, preferred styles of dressing, tendencies to tease, political leanings, religiosity, criminality, intelligence, social potency, and zest for life (26). The media refers to selfish genes, pleasure-seeking genes, criminal genes, celebrity genes, homosexual genes, couch potato genes, depression genes, genes for genius, genes for saving, and even genes for sinning. They are presented

in the media as if they are simple Mendelian disorders, directly inherited like brown hair or blue eyes.

Theories of behavioral genetics seek to explain human differences, and like other theories purporting to explain race or gender differences, they have enjoyed a very active press. The idea of biological determinism had attracted considerable news coverage following the controversy over Jensen's claims about the relationship between race and IQ. It later reappeared as sociobiology in media reports that were less concerned with substance than with provocative images, social implications, and policy applications. In selecting this subject for extensive coverage, journalists in effect have used a controversial theory to legitimize a particular point of view about the importance of biological determinism.

Sociobiology is a field devoted to the systematic study of the biological basis of social behavior. Its premise is that behavior is shaped primarily by genetic factors, selected over thousands of years for their survival value. Its most vocal proponent, E.O. Wilson from Harvard University, contends that genes create predispositions for certain types of behavior and that a full understanding of these genetic constraints is essential to intelligent social policy. He believes that sociobiology is "a new synthesis," offering a unified theory of human behavior. "The genes hold culture on a leash," he wrote in his book *On Human Nature*. "The leash is very long but inevitably values will be constrained in accordance with their effects on the human gene pool" (35).

During the early 1980s Wilson's arguments about human behavior, extrapolated from his research on insect behavior, were attacked by other scientists for their purported justification of racism and sexism, their lack of scientific support, and their simplistic presentation of the complex interaction of biological and social influences on human behavior (36). But the 1980 publication of Wilson's first book on the subject, *Sociobiology, A New Synthesis*, was welcomed in the *New York Times* as a "long awaited definitive book." Subsequently sociobiological concepts appeared in newspaper and magazine articles about the most diverse aspects of human behavior. They were used, for example, to explain:

- Child abuse. "The love of a parent has its roots in the fact that the child will reproduce the parent's genes." (*Family Week*)
- Machismo. "Machismo is biologically based and says in effect: 'I have good genes, let me mate.'" (*Time*)
- Intelligence. "On the towel rack that we call our anatomy, nature appears to have hung his-and-hers brains." (*Boston Globe*)
- Promiscuity. "If you get caught fooling around, don't say the devil made you do it. It's your DNA." (*Playboy*)
- Selfishness. "Built into our genes to insure their individual reproduction." (*Psychology Today*)
- Rape. "Genetically programmed into male behavior." (*Science Digest*)
- Aggression. "Men are more genetically aggressive because they are more indispensable." (*Newsweek*)

The press has been especially attracted to sociobiology's controversial implications for understanding stereotyped sex differences. The theory, we are told, directly challenges women's demands for equal rights, for differences between the sexes are innate. *Time*, for example, tells its readers that "Male displays and bravado, from antlers in deer and feather-ruffling in birds, to chest thumping in apes and humans, evolved as a reproductive strategy to impress females" (37). And a *Cosmopolitan* reporter, citing the "weight of scientific opinion" to legitimize his bias, writes: "Recent research has established beyond a doubt that males and females are born with a different set of instructions built into their genetic code" (38).

The media have readily picked up on every research project suggesting there might be a genetic basis of sex differences. In 1980, for example, two psychologists, Camille Benbow and Julian Stanley, published a research paper in *Science* on the differences between boys and girls in mathematical reasoning (39). Their study, examining the relation between Scholastic Aptitude Test scores and classroom work, found that differences in the classroom preparation of boys and girls were not responsible for differences in their test performance. The *Science* article qualified the implication of male superiority in mathematics: "It is probably an expression of a combination of both endogenous and exogenous variables. We recognize, however, that our data are consistent with numerous alternative hypotheses." But the popular press was less qualified, writing up the research as a strong confirmation of biological differences and a definitive challenge to the idea that differences in mathematical test scores are caused by social and cultural factors. The newspeg was not the research but its implications.

The authors themselves encouraged this perspective in their interviews with reporters, where they were less cautious than in their scientific writing. Indeed, they used the press to push their ideas as a useful basis for public policy. According to the *New York Times*, they "urged educators to accept the possibility that something more than social factors may be responsible. . . .You can't brush the differences under the rug and ignore them" (40). The media were receptive. *Discover* reported that male superiority is so pronounced that "to some extent, it must be inborn" (41). *Time*, writing in 1980 about the "gender factor in math," summarized the findings: "Males might be naturally abler than females" (42).

The most striking feature of the media articles on sociobiology was how easily reporters slid from noting a provocative theory to citing it as fact, even when they knew that the supporting evidence was flimsy. A remarkable article called "A Genetic Defense of the Free Market" that appeared in *Business Week* clearly illustrates this slide. While conceding that "there is no hard evidence to support the theory," the author wrote: "For better or worse, self-interest is a driving force in the economy because it is engrained in each individual's genes. . . .Government programs that force individuals to be less competitive and less selfish than they are genetically programmed to be are preordained to fail." The application of sociobiology that he calls "bio-economics" is controversial, he admitted; nevertheless, it is "a powerful defense of Adam Smith's laissez-faire views" (43).

The journalists who write about the genetics of behavior recognize, indeed rely on, the existence of controversy to enliven their stories. Yet most articles convey a point of view by giving space to advocates and marginalizing critics — often described as "few in number but vociferous," or people who are "unwilling to accept the truth." In 1976, for example, *Newsweek* suggested that Wilson was a victim like Galileo: "The critics are trying to suppress his views because they contradict contemporary orthodoxies" (44). In 1982 *Science Digest* compared the criticism of sociobiology to the attacks by religious fundamentalists on the theory of evolution: "Like the theory of evolution, sociobiology is often attacked and misinterpreted" (45). This a comparison places sociobiology's scientific critics, such as Stephen J. Gould and Richard Lewontin of Harvard University, in the same league as William Jennings Bryan.

In a seamless transition, the sociobiological ideas that appealed in the early 1980s have drifted into genetic explanations of social behavior and human differences. During the 1990s the media have disseminated the ideas about the inherited basis of behavior that were generated by studies of identical twins reared apart. These controversial studies gained both media attention and public credibility as part of the growing popular interest in genetics. Offering a simple explanation of complex behavior and a reinforcement of prevailing stereotypes, these ideas appealed to the media that began to attribute an extraordinary range of behaviors to "the genes." *US News and World Report* published an authoritative-looking table providing precise percentages of how much personality traits were determined by heredity rather than culture: extroversion 61 percent, conformity 60 percent, worry 55 percent, creativity 55 percent, optimism 54 percent, and so on (47). In the same issue, *US News* published an article called "How Genes Shape Personality," claiming that "solid evidence demonstrates that our very character is molded by heredity." It suggested that the future of Baby M, the child in a controversial surrogacy dispute, may not rest on which family got her, but in her genes (46). In 1992 *Time* once again offered an explanation of sex differences: "Nature is more important than nurture" and it is just a matter of time until scientists will prove it (47).

The concept of genetic predisposition has appeared to explain a range of personality characteristics. A 1993 *New York Times* article was called: "Want a room with a view? Idea may be in the genes" (48). But especially attractive to the media are explanations associating aggression and violent behavior with biological predisposition. Throughout the coverage of behavioral genetics are references to "bad seeds," "criminal genes" and "alcohol genes." To a *New York Times* writer "evil is embedded in the coils of chromosomes that our parents pass to us at conception" (49). And in a news report of a murder involving the arrest of a 14-year-old high school boy from a "good home," the *New York Times* interpreted the event as a key piece of evidence in "the debate over whether children misbehave because they had bad childhoods or because they are just bad seeds." The reporter used the power of inheritance to explain the incident: "Raising Children Right Isn't Always Enough" read the headline. The implications? There are simply "bad seeds" (50).

The acceptance, indeed promotion of genetic explanations of behavior, reflects in part the media's idealization of science as an ultimate authority. But it also reflects the tendencies of science to justify social stereotypes and popular policy agendas. By its selection of what theories to champion, the press in effect uses the imprimateur of science to support a particular world view. It does so, however, with little attention to the substance of science, its slow accumulative process, and the limits of these theories as an adequate explanation of complex human behavior, shaped by multiple genetic and environmental influences.

THE REPORTING ON BIOTECHNOLOGY RISK

The media coverage of biotechnology has been, in large part, enthusiastic, optimistic, and, indeed, promotional. Yet there remains a persistent and pervasive ambivalence about the implications of this rapidly developing field. Though journalists raise few questions about the ultimate benefits of genetics research or the credibility of research claims, they frequently question the potential abuses of genetic information. We read of the importance of genetic explanations of disease, and then are warned that the ability to identify genetic predisposition is far ahead of therapeutic possibilities. Stories extol the benefits of genetic research, but then decry the risk of gathering genetic information. We are told that this is the dawn of a new genetic era, and then cautioned about an impending eugenic nightmare.

Journalistic attention has often focused on the risks of biotechnology, especially in the area of agriculture and food production where biotechnology applications have been a target for public demonstrations. Some of this reporting is futuristic — abstract speculations about the possible harm of bioengineered products that are yet to appear. But journalists have mainly reported on existing controversies. One of the earliest biotechnology disputes focused on the field testing of Ice Minus, the genetically altered microbes that were developed to inhibit ice crystallization so as to protect strawberries and other fragile crops from injury from frost. Environmental groups, concerned about health hazards, were strongly opposed to these tests. Attracted to a growing controversy and to public demonstrations, news reports about the Ice Minus field tests included striking and provocative photographs of the workers who were spraying the fields, wearing protective clothing that resembled the moon suits associated with the cleanup of toxic chemicals and nuclear wastes (51).

Opposition to the bioengineered Flavr Savr tomato also gained considerable media attention. As in the case of cloning, the issue appealed to journalists as much for the irresistible potential for puns as for evidence of real risk. The genetically engineered tomato, introduced by the biotechnology firm Calgene in late 1991, was initially welcomed in the press as a fruit that would not rot on the way to the market. The product generated media stories on the "wonders" of high technology foods — leaner meat, celery sticks without strings, crisper and sweeter vegetables — and the press supported Calgene's effort to

classify its product as a food rather than a drug subject to FDA regulations. But then, as critics of biotechnology moved in, skepticism became fashionable, and journalists began to write about the tomato as a "frankenfood," a "killer tomato." There was a "tomato war" and a "tomatogate" (52). The idea of injecting mouse genes into food, the spectacle of restaurant chefs boycotting a tomato, the concern about "safe soup," attracted reporters who covered this product as an example of the risks of biotechnology. The business press responded by denouncing "crackpots and scaremongers" who hold back the "wheels of progress" by playing on public fears.

The bioengineering of transgenic animals was also controversial especially among animal rights activists whose colorful antics have often attracted the attention of reporters (53). The media uncritically followed the antics of animal rights groups who projected images of composite cattle, "geeps" (half goat, half sheep) and grossly oversized, distorted pigs. Reporters also addressed the concerns of small farmers who believed that costly applications of biotechnology advances would give further economic advantage to agribusiness, and the opposition of religious groups who worried about the meaning of scientists tampering with nature and "playing God." Here again, media-savvy Jeremy Rifkin was able to use the press to attract publicity for his antibiotechnology campaign. But, as we saw in the evolution of media coverage of cloning disputes, reporting on transgenic foods and animals is usually focused on the newest or most dramatic events. The media, for example, only briefly mentioned Polly, the ultimate transgenic animal who had been cloned in 1997 with human genes.

In some striking ways the images pervading the media coverage of biotechnology risks are remarkably similar to those that were projected during the nuclear power controversy — Frankenstein monsters, mutant animals, mad scientists, and consumers without choices who are captive to an industry portrayed as out of control. Reporting in both of these areas has suggested that risk in the media is often a surrogate issue. Fears of biotechnology are linked to ethical and religious issues, to concerns about economic inequities, and to deep mistrust of a commercially driven science. And media reporting reflects the sensitive question of consumer choices about food and environmental quality — controversial issues of considerable interest to newspaper readers.

CONCLUSION

The media serve, in effect, as brokers between science and the public, framing social reality for their readers and shaping the public consciousness about science-related events. They are for most people the only accessible source of information about important scientific and technical choices. Through their selection of news about science and technology, the media help set the agenda for public policy. Through the information they convey about biotechnology risks, they may affect stock market prices in a volatile industry and influence product sales. And through their presentation of science news, they shape personal attitudes and public actions.

Thus scientists and the companies involved in biotechnology research have been extremely sensitive to their image in the press. And like advocates in any field, they are prone to overestimate the benefit of their work and minimize its risks. Hoping to shape that image, they have become adept at packaging information for journalists. It was not journalists, but scientists who initially employed attention-seeking metaphors to describe the genome as a "blueprint of life," a "Book of Man," a "medical crystal ball." Geneticists themselves have promoted the "gene of the week" and touted the latest therapeutic possibilities. And agricultural researchers were the first to promote the economic benefits of cloning. Courting media attention, those engaged in biotechnology and genetics research have also helped to evoke premature enthusiasm and optimistic expectations. The media have not created the science news; they have mainly amplified and disseminated the messages conveyed by scientists themselves.

Most journalists have limited knowledge about science, and they are vulnerable to manipulation by their sources of information. But as the above review suggests, the media are conveying mixed messages about the costs and benefits of biotechnology. Journalists seem to welcome the notion of biological determinism — simple, startling, and easy to convey — yet many writers remind their readers of the history of eugenics and place current research in this threatening historical context. While journalists report with enthusiasm and wonder the promises of gene therapy, they also warn about potential abuses of genetic manipulation. The media have welcomed agricultural innovations, but they have also warned about potential health or environmental risks.

Perhaps the most striking feature of the media reporting on biotechnology is a pervasive concern about the social and economic context in which this field is developing. The ties between the science of genetics and its commercial applications have invited widespread media cynicism. Reporters have repeatedly called attention to the nonscientific interests — the investments and profits in an intensely competitive field — that are driving biotechnology and its clinical and agricultural applications. Science journalists have long maintained an image of academic science as a pure and unsullied profession, a neutral source of authority, and an objective judge of truth (4). They are skeptical of corporate driven science. These days, according to some disillusioned journalists, scientists working in biotechnology and genetics are "greedy entrepreneurs" or "molecular millionaires" driven by economic interests that threaten their objectivity and override concerns about abuse. Political cartoons portray geneticists in less than flattering terms as bumbling, naive, and unaware of the social implications of their discoveries. And news reports and editorials repeatedly call attention to troubling aspects of the growing links between science and industry, the conflicts of interest that are inevitable when profits and ethics collide.

The context of science, especially in the fields of biotechnology and genetics, has radically changed in recent years. And media coverage, appropriately, is beginning to reflect the implications of these changes.

The media have retained their history of technological optimism, but they are also expressing a growing concern that the expanding commercial interests in these profitable areas of science will overide important social considerations.

MEDICAL BIOTECHNOLOGY, UNITED STATES POLICIES INFLUENCING ITS DEVELOPMENT

ROBERT MULLAN COOK-DEEGAN
Georgetown University
Annapolis, Maryland

OUTLINE

INTRODUCTION

National policies, including but not restricted to government rules and actions, have profoundly influenced the pace and direction of biotechnology. Medical products and services were among the first and most significant applications of biotechnology. The economic impact of new biotechnologies was felt first in pharmaceuticals, even

before other sectors that saw early applications, such as agriculture and environmental applications. Many nations have pursued policies to cultivate the growth of biotechnology. Many of the first applications were developed in the United States. This was not because the United States had a coherent policy to promote biotechnology. It did not. The United States does, however, have a set of policies to promote health research, and in particular a political structure that has supported the consistent growth of the National Institutes of Health (NIH) since the end of World War II. Those health research policies spawned medical biotechnology.

Development of diagnostic and therapeutic products depends to an unusual extent on government and private funding for research, intellectual property protection, norms governing academic science, product regulation by government, and historical and cultural factors that influence how national governments frame issues arising from medical biotechnology. This entry reviews how national policies influenced the development of medical biotechnology, using the United States as a case example.

DEFINITIONS

Biotechnology is the practical use of living things. At this level of generality, however, agriculture, forestry, fishing, ranching, and many other activities would be included, whereas most intend to refer to the practical applications of molecular biology, and in particular the structural analysis of DNA and proteins. In its most common sense, biotechnology was a term used first by stock analysts to describe a set of companies that began to form late in the 1970s to exploit recombinant DNA, cell fusion, and other methods of molecular biology (1).

One of the first and most influential reports on biotechnology, *Commercial Biotechnology, An International Analysis*, was completed in January 1984 by the Congressional Office of Technology Assessment (OTA) (2). That report distinguished so-called new biotechnology from the old, and focused mainly on "dedicated biotechnology firms," those largely or solely devoted to using the new molecular biological techniques. OTA's definition, modified to accommodate other new techniques of molecular biology, remains useful and formed the basis for another OTA report eight years later, *Biotechnology in a Global Economy* (3).

Technologies to analyze the structure of DNA and proteins have evolved rapidly, so the methods that are new change each year, but the term biotechnology has continued to refer mainly to academic and commercial activities that depend on the structural analysis of DNA and proteins. This definition also includes some activities of major pharmaceutical firms, companies, and research groups that develop instruments used in biology. Activities with direct practical relevance to use of information from cellular and molecular biology have come into being since biotechnology became a widely used term, such as computer analysis of DNA and protein structure and large-scale genetic analysis of organisms (genomics). Medical biotechnology, as used here, refers to the use of molecular biological techniques to develop drugs and diagnostic services in established firms as well as those founded for this purpose. Biological instrumentation and informatics firms (or activities) are also often counted as biotechnology, but their focus is generally on markets to supply research tools. They are generally excluded here, except in a section on patent policies for research tools.

FACTORS AFFECTING THE COMMERCIAL DEVELOPMENT OF BIOTECHNOLOGY

The 1984 and 1992 OTA reports analyzed several industrial sectors for which biotechnology was relevant. Among the areas considered, only the pharmaceutical sector was mainly focused on human medical applications. OTA identified 10 factors that influenced the commercial development of biotechnology (Fig. 1). The first nine are listed in descending importance as judged by OTA. OTA judged the tenth factor, public perception, more variable and unpredictable, at times playing a major role in policy and at other times taking a back seat to the other factors:

1. Financing and tax incentives for firms
2. Government funding of basic and applied research
3. Personnel availability and training
4. Health, safety, and environmental regulation
5. Intellectual property law
6. University-industry relationships
7. Antitrust law
8. International technology transfer, investment, and trade
9. Targeting policies in biotechnology
10. Public perception

All 10 factors are significantly affected by social values and government policies.

CAPITAL AVAILABILITY

The practical applications of molecular biology, especially recombinant DNA techniques, took the form of dedicated biotechnology companies with explicitly commercial aspirations. This was particularly true in the United States. The geographic origins in the United States are best explained by a combination of three factors: availability of capital to form new companies, public funding for biomedical research, and strong university–industry ties.

The availability of capital to form companies to exploit technological opportunities has proved crucial in most high-technology sectors. After World War II several methods of raising capital were developed. The first venture capital firm was established in conjunction with MIT scientists and Boston bankers (4). Eventually the San Francisco Bay Area became an even more active center for venture capital (5). By the 1970s and the dawn of the new biotechology, venture capital firms that had grown up to fund computers, software, and telecommunications were open to help finance the launch of commercial biotechnology. The impetus to found Genentech, for example, came from venture capitalist Robert Swanson

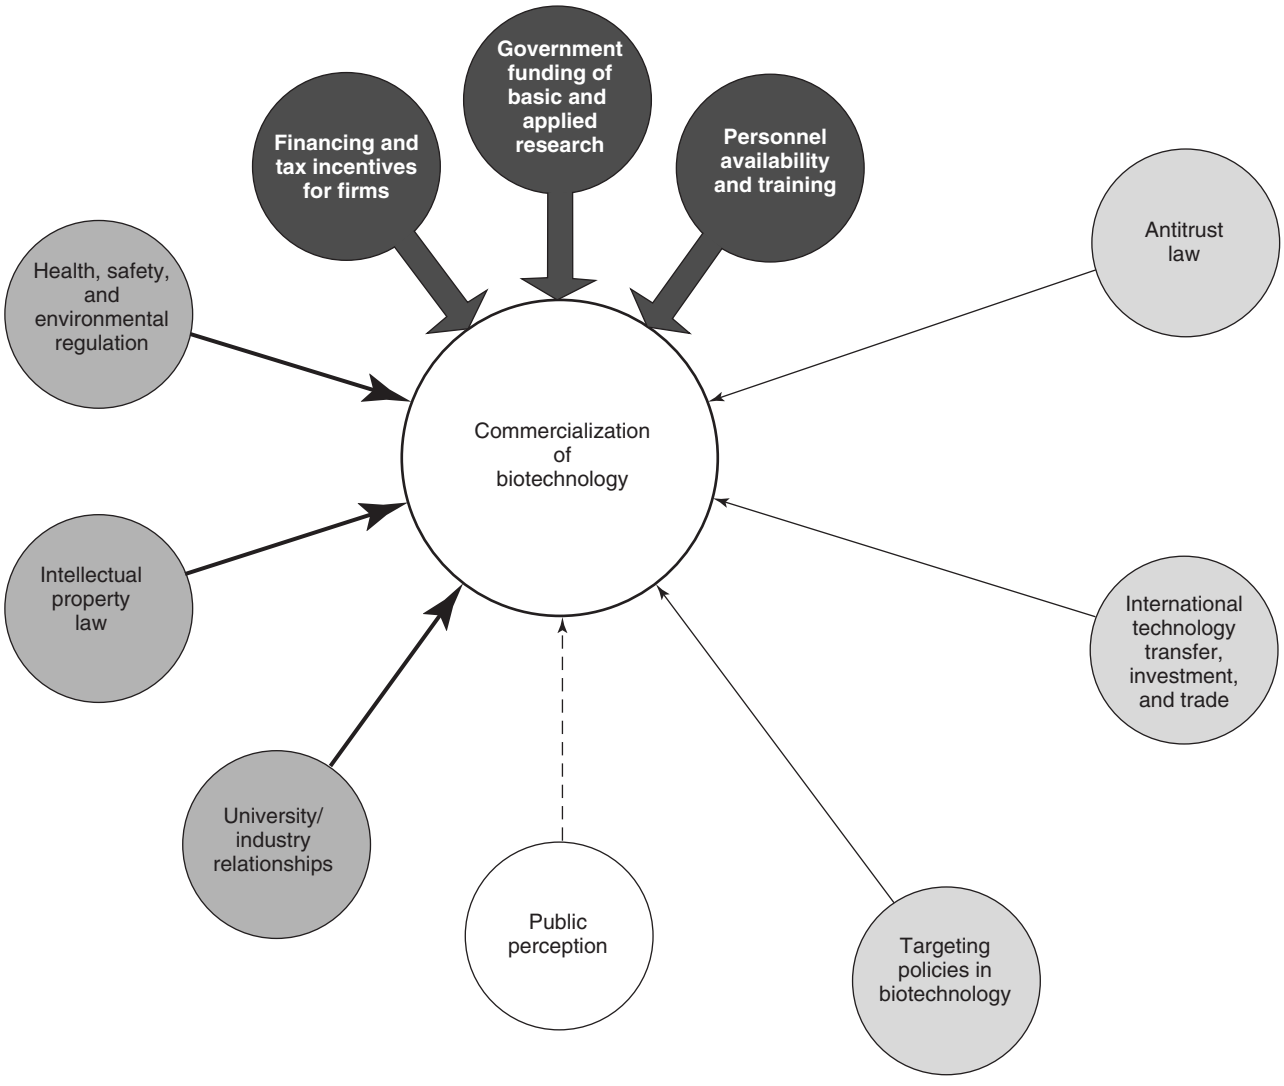

Figure 1. Relative importance of factors affecting the commercialization of biotechnology. *Source: Office of Technology Assessment*.

who approached scientist Howard Boyer of the University of California, San Francisco (6). The financier approached the scientist, and not vice versa. Once the seed was planted and companies had formed, some scientists and university administrators began to approach venture capitalists, rather then the reverse, but the origin of the modern biotechnology sector clearly arose from a member of the investment community. The national and regional environment for capital formation and access to investors willing to fund new technological ventures were critical to the emergence of biotechnology.

The need for early investment to found new companies has attracted attention in Europe and Asia, leading to government incentives and private efforts to create markets along the lines of those started in postwar Boston. Venture capital firms have become a worldwide phenomenon.

In addition to formal venture capital firms, there is another larger but less conspicuous and less easily characterized capital market. Individuals or small groups of wealthy individuals who invest several hundred thousand or millions of dollars in new ventures are often called "angels." They function as an informal market to finance new ventures and often fill gaps in the venture capital markets because they can move more swiftly. They typically close deals with a handshake. The angel market is harder to study, but is comparable in size and at least as important as the formal venture capital market (7).

The angel and venture capital markets enticed university and government scientists to found companies that were privately held, with most equity shared among the investors, scientists, and founding managers. Privately held firms often later become corporations with publicly traded stock. Once a firm's stock was publicly traded, investors could more readily trade their equity for cash.

The availability of venture capital and angel markets depended on a diverse set of government policies, including antitrust, tax (local, state, and national), and other domains of public policy. As a general rule, however, public policy governing individual investments and venture capital was far more subject to private sector actions than deliberate government policy fostering innovation. Indeed,

formal government policies intended to encourage startups and availability of risk capital has tended to be local and late in the game, and sometimes even been impediments, rather than a coherent national policy helpful early in the process of spawning a new industry (4,5). The policies that most influence the availability of startup capital have been in financial institutions and among individual investors rather than the product of deliberate government action. In contrast, government policy has been absolutely crucial in the other most important factor influencing the genesis of medical biotechnology: publicly funded biomedical research.

FUNDING FOR RESEARCH AND DEVELOPMENT

Biotechnology companies were founded to exploit a technological base that grew from substantial and sustained public investment in biomedical research. The term molecular biology first referred to a grants program funded by the private Rockefeller Foundation in the 1930s (6). As Rockefeller Foundation administrator Warren Weaver first used the term, molecular biology addressed scientific problems in the life sciences by importing techniques and scientists from the physical sciences, especially physics and chemistry. Molecular biology, and its spin-offs into commercial biotechnology, is the child of federally funded research but the grandchild of policies first developed in private philanthropy.

Before World War II, government funding for biomedical research was relatively sparse throughout the world. Academic medicine, of which research was a component, had a strong tradition in Germany, France, Great Britain, and other countries in Europe and Asia. Most research was conducted "on the side" in hospitals, or funded through private philanthropy. In the United States, the federal government funded less than private sources — the Rockefeller Foundation, the Foundation for Infantile Paralysis (later the March of Dimes), the Carnegie Corporation, universities and hospitals, and other private philanthropies.

In the years leading up to World War II, Mary Lasker and the American Cancer Foundation (later the American Cancer Society) began to pursue a new strategy for biomedical research funding that focused on inducing federal investment through the political process. After the war, this strategy caused an explosive growth of the NIH budget (9,10). The movement already underway to fund cancer research, and then heart disease research, merged with a consensus favoring federal investment in basic research most conspicuously articulated by President Roosevelt's wartime science advisor, Vannevar Bush (11). This consensus did not become embodied in the form of Bush's proposed National Research Foundation, which would have administered biomedical, military, and general science under a single roof. Instead, the Navy established the Office of Naval Research in 1946, and the other armed services then created their own research and development (R&D) organizations. The Atomic Energy Commission was created to support nuclear physics and to apply it to both military and civilian uses. Most relevant to biotechnology, NIH began to take shape as the nation's foremost patron of biomedical research.

Mary Lasker, then-Senator Claude Pepper, and a succession of NIH directors formed an "iron triangle" to expand federal funding (the vertices of the triangle were nongovernment advocates for medical research, NIH administrators, and congressional champions). They chose to focus resources on university-based research, funded through disease-oriented institutes. Through the late 1960s, Lasker forged strong ties to the chair of the House appropriations subcommittee that funded NIH, Representative John Fogarty, and to his Senate counterpart, Senator Lister Hill. Supported strongly on the inside by NIH Director James Shannon, these congressional patrons boosted biomedical research funding substantially year after year (Fig. 2) (12).

The iron triangle was reconstructed with different players after the death of Fogarty in 1967 and retirement of Hill and Shannon in 1968, and the tactics were replicated by groups wanting "their" institute (for heart disease, for neurological illnesses, for eye diseases, etc.). The direct access that disease advocacy groups had to Congress drove the rise of NIH's budget. Health research grew consistently for five decades, more consistently and more substantially than other federal science programs (Fig. 3).

NIH grew into the world's largest source of support for biomedical research. In a survey of articles from 1973 to 1980, for example, the National Cancer Institute alone accounted for 40 percent of all cancer research publications in 275 medical journals (13). Other U.S. sources — including government (mainly other NIH institutes), private nonprofit, and for-profit firms — accounted for roughly another third, with the remainder unknown or funded by an institution outside the United States. The level of public support for health research in the United States has been a critical factor in biotechnology, and it helps explain biotechnology's geographical origins. Medical applications of new technologies appear likely to remain dependent on science for the foreseeable future, so biomedical research policy will continue to be a decisive factor in the development of medical biotechnology.

The basis for this consistent and substantial growth in health research was not a desire for economic growth but for the conquest of disease. The relevance of medical

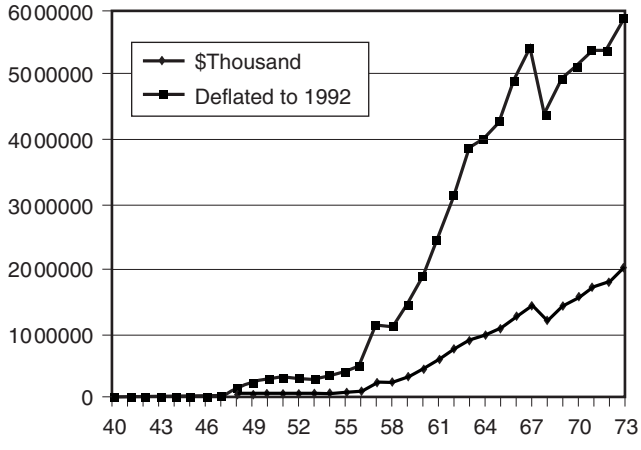

Figure 2. Postwar growth of the NIH budget.

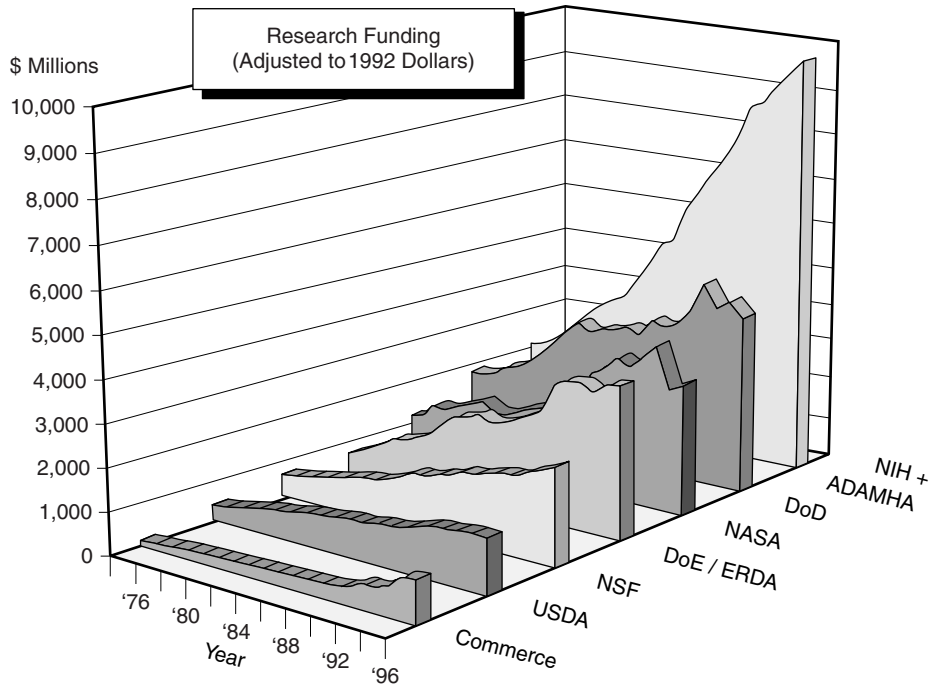

Figure 3. Rise of NIH among U.S. R&D agencies. ADAMHA = Alcohol, Drug Abuse, and Mental Health Administration, DoD = Department of Defense, NASA = National Aeronautics and Space Administration, DOE/ERDA = Department of Energy (and Energy Research and Development Administration for relevant years), NSF = National Science Foundation, USDA = U.S. Department of Agriculture, Commerce = U.S. Department of Commerce.

research to the private commercial development of drugs, devices, and services was foreseeable and foreseen, but promoting such uses was a subsidiary goal, not the primary goal.

The most important two institutions in the birth of biotechnology were universities and start-up firms, with the start-up firms seeded by university scientists. As biomedical research budgets rose and NIH institutes proliferated, the science base grew enormously. It grew most in universities and private research institutes. While Vannevar Bush's vision of one central R&D agency did not become policy, another important feature of his vision did — the emphasis on federal funding for university-based research, as opposed to government owned and operated laboratories more common in other nations and prewar U.S. R&D. (Agricultural research, the grandfather of federal R&D, was typically done by federal employees in government laboratories; military research until World War II waxed and waned with military commitments, and scientists were brought directly into the military in times of war (14).) NIH did conduct some research on its own campus, and in 1953 added a research hospital. During the Vietnam War, the intramural program of NIH grew dramatically in both size and international prestige, in part because working at NIH was a means to avoid induction into the military, but even during this era, most biomedical research dollars flowed to universities and private academic research centers affiliated with them. Those universities were in turn the birthplace of biotechnology.

Coupled with a powerful biomedical research lobby, the decentralized structure of U.S. science enabled a disproportionate growth of the life sciences, particularly medical research. One reason that health research enjoyed growth rates in excess of those in physics, chemistry, engineering, and other fields is the political popularity of health research. Improving health through research is an accepted federal responsibility in both political parties. Boosting health research budgets, moreover, does not mean having to reduce other research budgets because the United States lacks a central research ministry or ministries. With the exception of the National Science Foundation, research budgets are part of budgets for mission agencies, health and defense being the two largest, but also including space, agriculture, energy, and environment. Budgets for research are decided by congressional appropriation subcommittees that do not have to trade off a reduction in defense research that might affect computing, for example, to obtain more dollars for health research. That is, whereas most countries have a research ministry that must set priorities, no unitary science budget exists in the United States. While this is irrational to the degree that research accounts, which are intended as investments to secure future benefits, are mixed with other accounts that focus on current consumption spending, it has enabled different research fields to expand and contract independently, and health research has expanded consistently, in part because of the perceived scientific opportunities, but also because of political popularity and citizen advocacy. In some countries the science and technology ministries are independent, in others, part of a larger body with responsibility for education (e.g., Japan) or industry (e.g., the United Kingdom). The unique separation of powers and the delegation of appropriation authority to Congress under the U.S. system has led to a uniquely rapid growth of health research that would have been far less likely under Bush's unitary National Research Foundation, and it has not been replicated in other developed economies.

The United States funds both a larger total R&D budget and a far higher share devoted to health within that than other countries (see Table 1). If items not directly

Table 1. Share of R&D for Health from NSF S&E Indicators

Objective	United States (1994)	Japan (1994)	Germany (1993)	France (1993)	United Kingdom (1994)	Italy (1993)	Canada (1992)
Total R&D ($U.S. billion, 1995)	68.3	18.1	15.0	13.7	8.7	5.2	3.4
Percent R&D for health	16.5	3.0	3.3	4.5	7.2	6.1	7.8

Sources: From *Science and Engineering Indicators, 1996*, National Science Board (National Science Foundation), table 4–32; Office of Economic Cooperation and Development, Main Science and Technology Indicators database, Paris, June 1995.

related to creation of new knowledge and technology are taken out of the U.S. R&D budget, as recommended by the National Academy of Sciences (NSF), the total U.S. 'federal science and technology' budget is a smaller total, but the fraction devoted to health in 1994 rises to 28 percent (15), more than twice as concentrated on health as the next closest country. Some nations (especially Japan) categorize a substantially higher fraction of science funding as "advancement of knowledge;" there general university funds cover research that in the United States would appear in NIH "health" research accounts. Michaud and Murray have estimated health R&D as a fraction of gross domestic product (GDP), arguably the most pertinent statistic, and by their estimates the United States remains first, but by a far smaller margin (16). The real disparities are therefore not as large as the figures of the Office of Economic Cooperation and Development (OECD) figures suggest, but the U.S. research system clearly tilts much more heavily toward life sciences and health than do other countries.

Anemic public support for research is an important factor explaining Japan's relatively small role in biotechnology (2,3) for example, and the rich base of public and nonprofit support in Europe, especially the United Kingdom, goes a long way to explain Europe's large role in biotechnology. While government funding for R&D has not been generous in the UK compared to other developed countries, the R&D fraction devoted to health is high, and private philanthropies play an unusually large role, funding biomedical research at levels comparable to government (the Wellcome Trust and the Imperial Cancer Research Fund, among others). Countries with a strong pharmaceutical base, such as the U.K., Switzerland, Germany, France, and Denmark are major powers in biotechnology.

In addition to the overall level of support, the responsiveness of the R&D system is also important. Investments in promising new scientific fields and in emerging technologies must be available to sustain innovation. A system that funds specific projects case-by-case through a system of peer review is far more adaptable than one that allocates most funding through institutions (15). Examples at each end of the peer review spectrum are investigator-initiated grants funded by NIH and NSF, on one hand, and the system of institutional funding of the former Soviet Academy of Science, on the other. While institutional funding achieves many notable successes, and peer-reviewed grants can fund poor science, as a general heuristic, systems that channel a substantial fraction of their funds through competitive peer review appear to produce better work and respond better to new opportunities in the long run.

OTA's third crucial factor, the availability of trained experts, is closely tied to academic science, and thence to publicly funded health research. This is especially true in the emergent phase of a science-dependent technological sector, when the only source of training may be university laboratories. In many countries, academic training is funded through educational ministries, and the size and flexibility of those ministries, and their attentiveness to needs of an emerging field such as biotechnology, is highly dependent on policy. In the United States, most academic training in the life sciences is covered by NIH research budgets, and so the growth of NIH has created an ample supply of labor. Indeed, indicators suggest the increase of available graduate students and postdoctoral fellows has exceeded even the growth of NIH research budgets, creating a surfeit of young, trained personnel who may turn to careers in biotechnology (17).

PATENTS

Patents are more important in pharmaceuticals and biotechnology than in most other economic sectors. Patents are grounded in national laws and international treaties, and therefore heavily dependent on government policy. Governments (or organizations delegated authority by governments, e.g., the European Patent Office) convey patent rights to private parties, enabling them to exclude others from making, using, or selling an invention. The period of exclusivity generally extends from the date a patent is issued until 20 years after the patent application is filed, although patent terms can be extended in the United States under certain circumstances. Enforcement of patent rights ultimately falls to the government through administrative procedures and litigation in national court systems.

Several different kinds of patents are relevant to medical biotechnology. The most valuable are patents covering both the composition of matter (that is, the protein or chemical) and its method of manufacture. The path to current biotechnology patents leads through several seminal events. In 1980, the U.S. Supreme Court permitted patenting of a microorganism, in the case of *Diamond v. Chakrabarty* (18). That same year, the U.S.

Patent and Trademark Office issued the first of three landmark patents covering recombinant DNA to Stanford and the University of California (19–21). These Cohen-Boyer patents ultimately produced over $200 million in revenues for the two universities until the patent expired in December 1997 (22). Thus began a succession of patents for genes, DNA fragments, methods of producing useful gene products, and methods for making and characterizing DNA. Between 1980 and 1993 the U.S. Patent and Trademark Office issued over 1000 DNA-based patents, and many thousands more have been issued since (23). The rationale for patenting DNA was that while genes were found in nature, isolating and making those genes into a useful form required substantial inventive activity (24–26). A DNA or other biotechnology patent must meet the same criteria as other inventions. Three principal criteria are used worldwide, with some variation in details of interpretation. An invention must be (*1*) new (or "novel"); (*2*) inventive (or "nonobvious"), and (*3*) useful (or have "utility"). In return for the exclusion rights conferred by the patent, the inventors must describe the invention in sufficient detail to enable others to make it work ("enablement").

Therapeutic pharmaceuticals constitute the largest and most financially rewarding applications for medical biotechnology. There is considerable argument about the cost of discovering and marketing a new therapeutic pharmaceutical. The average cost is estimated in the hundreds of millions of dollars to introduce a new product (27). This average is not meaningful in any particular case because the cost varies tremendously. Through the pharmaceutical sector as whole, however, and hence for policy purposes, it is clear that R&D costs are high, and highest for therapeutics. New therapeutic products thus face the highest costs but also yield the highest payoffs. Patent protection is most important for therapeutic drugs, medical biotechnology's most profitable subsector.

Medical biotechnology encompasses many other products and services with diverse product cycle times. Some biotechnology instruments may resemble short computer or telecommunication device product cycles, measured in years rather than decades, and biotechnology informatics firms face the rapid cycle times of software, with product cycles as short as a year or two. Medical diagnostic products typically reach the market faster than therapeutics because they face a less elaborate regulatory gauntlet. Diagnostics do require FDA approval, and so face regulatory hurdles higher than for most nonmedical goods and services. The capital and time needed to secure market approval for diagnostic products, therefore, are generally lower than for therapeutics but higher than for most nonmedical goods and services. Where product cycle times are short, lead-time advantages, trade secrets, and other factors tend to be more important competitive factors than patents, although patents may still be important in negotiating licensing and technology-sharing arrangements among firms, and in raising capital for new firms. The importance of patents in therapeutic pharmaceuticals builds on a century of industrial history.

Modern biotechnology is the extension of a long trend in which pharmaceutical discovery and development has become increasingly dependent on scientific and technical advance. The modern pharmaceutical industry grew by applying science to medicine (28). Early products were often discovered initially as folk remedies or through clinical observation, but modern pharmaceutical research grew to prominence by making the hunt for new products more systematic. A century ago acetylsalicylic acid (aspirin), was identified as more potent for pain relief than the salicylic acid in bark extract, and then manufactured on a massive scale by Bayer. Companies began to synthesize and screen large numbers of compounds for medical effects. They turned to the emerging methods of organic chemistry to create the compounds and to manufacture them. Firms also used the growing power of microbiology and physiology to discover and screen potential drugs. Antibiotics were first found as products of soil fungi that used them as defenses against bacterial attack, and the industrial innovation was to identify and purify the active agents, and devise ways to produce them cheaply on a grand scale.

In the pharmaceutical business, drug discovery is only one determinant of success. Efficient conduct of clinical testing and manufacture are just as important. Pharmaceutical firms must also manage large and complex distribution systems, manufacturing plants, and they devote enormous sums to marketing. The end markets in health care are financially complex and heavily regulated, requiring expertise and management. At root, however, success follows introduction of new drugs, and innovation through drug discovery where patent protection is paramount.

The time horizon for investment in pharmaceuticals is quite long compared to other industries (29). More than a decade typically passes between discovery of a lead compound and market introduction of a therapeutic pharmaceutical (27). The level of R&D investment is also unusually high in pharmaceuticals, rivaled only by software and a few other high-technology sectors. The pharmaceutical industry invests an estimated 19 percent of revenues in R&D (30). Firms invest heavily in R&D because drug discovery is a major basis for competition. Since the early 1980s private pharmaceutical R&D investment has grown even faster than the NIH budget.

The strength of patent protection in pharmaceuticals is one major reason such substantial, long-term private R&D investments are possible. Patents increase the price that can be charged on drugs that make it all the way through the pipeline, producing revenues to fund drug discovery and development of future products. Gambardella's econometric monograph on pharmaceutical innovation concluded that managing the process of drug discovery was a powerful predictor of financial growth (31). In several other studies of pharmaceutical innovation, economists have used patents as indicators of success among pharmaceutical competitors (32,33), empirically corroborating this message.

The general criteria for patents are shared worldwide, but the criteria can be applied differently in different

countries. The interpretation of patent claims is left to litigation when one party sues another for infringing its patents. Such litigation is costly and takes place long after the R&D results have been disclosed in the patent application. Patent litigation over recombinant DNA-derived insulin cost over $30 million and consumed half a decade (34,35), and the case was decided in 1997, two decades after the crucial events disclosed in the relevant patents. Battles raged over most first generation protein therapeutics — insulin, growth hormone, tissue plasminogen activator, interferons, interleukins, and others. Such litigation is not only costly and slow, but its outcome is uncertain and may differ from country to country. The same drug may be patented in one jurisdiction and not another (e.g., Genentech's tissue plasminogen activator patent is vadid in most countries, but not the United Kingdom). This can occur with traditional drugs as well, but uncertainty is higher in biotechnology because the interpretation of patent criteria is less well settled. Patent policies may differ among countries in three areas relevant to biotechnology: animal patents, gene patents, and research tools.

If patent policies diverge, it is the patent policies in the largest markets or the first markets that will most influence the development of biotechnology. An invention made in a country can be patented in any other country, and the patents that matter most are those that cover inventions in the most lucrative markets, where prices are highest or more units can be sold. While an inventor tends to file the first patent application in his or her home country, this is not necessarily the case, and many biotechnology patents have been filed first in the largest expected markets, rather than in home countries. The largest national pharmaceutical market is the United States, followed by Japan, which has higher per-capita consumption but generally lower prices. Europe is, in aggregate, roughly comparable in size to the United States. Asian and other markets are growing in size, and recent international harmonization of patent law should lead to policies in developing economies coming to resemble those in the developed economies. Because the United States is among the few countries with no pharmaceutical price controls, its drug prices are higher, and for many drugs, the U.S. market alone accounts for most of the global profit.

UNIVERSITY–INDUSTRY RELATIONS

The pharmaceutical sector in general, and biotechnology in particular, is uniquely dependent on academic research. The late Edwin Mansfield queried industrial executives about the degree to which their product stream depended on academic science (36,37). Pharmaceuticals stood out. Executives estimated that twice as many products either would not have been developed at all or would have been substantially delayed without academic research, compared even to other high-tech sectors. The survey results are corroborated by patent data in this unusually patent-dependent sector. Pharmaceutical and biotechnology patents are much more likely to cite academic research than others (38,39). In most patent classes, academic institutions hold only a few percent of patents, but the fraction is much higher for pharmaceuticals and rises to almost one-third of all DNA-based patents in the period 1980 to 1993 (23). The number of academically owned patents has risen steeply in pharmaceuticals, and unlike a drop-off of citations to academic patents in other fields, citation of academic patents in pharmaceutical and medical patent classes has risen over the past two decades (40).

The patent story is but a small part of a larger story of academic-industrial mutualism in biotechnology. The impetus to create biotechnology firms did come first from private investors, as noted above, but it was the commercial potential of academic science that they recognized. To an even greater extent than the already science-dependent pharmaceutical business, biotechnology has emerged as a hybrid academic-industrial enterprise.

The national policies most influencing academic science are public funding decisions for health research, covered above. The policies of universities and private firms, both individually and in aggregate, also influence the development of biotechnology. Biotechnology companies develop around scientists who first use the technologies and take action to apply them commercially (41). Biotechnology companies first appeared close to universities and centers of biomedical research excellence, especially near (*1*) Stanford and the University of California campuses in San Francisco, Berkeley, Los Angeles, and San Diego; (*2*) MIT and Harvard; and (*3*) Johns Hopkins University and the NIH campus. The highest concentrations of biotechnology firms thus arose in California, Massachusetts, and Maryland, not because of a national targeting policy but because that is where the science was based.

The academic research base is necessary, but not sufficient. If federal funding for academic science were the sole determinant, then biotechnology investment would more closely parallel federal spending for health research in specific regions. While California does lead the nation in NIH grant funding, if the intramural program in Maryland is taken into account, California receives less total NIH funding than Maryland. New York is third in NIH funding and Massachusetts fourth, but Massachusetts is second in number of firms, ahead of Maryland and New York. Moreover the fraction of firms based in California and their capitalization is far more heavily weighted to California than the funding would predict. A combination of academic policies conductive to industrial collaboration at Stanford and the University of California, the availability of venture capital, and the history of specific technologies, especially recombinant DNA techniques, led to biotechnology taking root around San Francisco Bay in California.

Policies on the industrial side of the equation are clearly important in addition to factors on the academic side. The formation of small biotechnology companies is in part a signal that established firms in the relevant markets are not fully exploiting an emerging technology. Established firms have been important in introducing many of the first protein therapeutic products, but the initial discoveries generally took place either in academic laboratories or in dedicated biotechnology firms collaborating closely with university scientists. Pharmaceutical firms that adopt the R&D ethos of academic science — encouraging

open publication, forming numerous collaborations with academic groups, and allowing scientists to influence R&D rather than exclusively dictating objectives from the top down — tend to be more innovative (31,32). While it has not been similarly corroborated by empirical studies of biotechnology firms, the "academic ethos" in dedicated biotechnology firms is widely perceived to be even more important than among established pharmaceutical firms.

The importance of federally funded academic research is not unique to biotechnology, but it is more important than for most other sectors. An historical study of computing and software research notes the critical importance of federal funding and academic research in the commercial development of those fields (42). Publicly funded research at academic institutions appears to be important for several reasons. First, it is directly linked to training those who will further develop the science and technology, whether in academic science, industrial R&D, or in management. Second, the results of academic science are generally published openly, and are thus in theory available to all potential beneficiaries. This enables information to flow readily not only among academic scientists, but also among disparate industrial users. Third, the federal government can invest in research that is expected to produce broad social benefit over the long term. Private firms are not similarly motivated, except in unusual cases of monopoly or extensive market dominance (e.g., AT&T in telecommunications until the 1970s or IBM in computing until the 1980s), because no one firm can expect to capture the benefits of its R&D investment. Federally funded academic research is thus a tide that raises all ships in the biotechnology and pharmaceutical sector.

The pattern of geographic clustering is also shared with other high-technology sectors, such as computer manufacture, software engineering, and telecommunications. The region along Route 128 outside Boston and the San Francisco Bay Area have been particularly well studied (4,5,43). The reliance of industrial innovation on academe is similar to other industries whose early history depended critically on science and technical innovation (44), and the academic–industrial nexus is particularly salient in medicine (45).

REGULATION OF PRODUCTS AND SERVICES

The modern pharmaceutical industry started by purifying and manufacturing agents using chemical methods. A century ago, "patent medicines" were as likely to be peddled using grandiose, unsubstantiated medical claims as they were to be legitimate and effective medications. A system of regulation grew up to combat charlatans and quacks, and that system of regulation became most explicit and elaborate where the most money changed hands and where the health stakes of misuse were highest, that is, for products marketed as therapeutic pharmaceuticals.

For therapeutic pharmaceuticals, that is, chemical compounds that are claimed to alter a body function, firms developing the drug must test the compound for safety and efficacy. Clinical testing is the most expensive and prolonged component in the pharmaceutical product development cycle. It entails several phases of clinical trials. The usual development process entails testing the compound for toxicity in a small number of health individual volunteers (phase I), based on evidence from laboratory and animal experiments that suggest the compound might be clinically useful. If the compound proves safe to administer to humans, phase I is followed by use in a larger number of individuals (usually tens or hundreds) to establish dosage and preliminary evidence of efficacy (phase II), and then larger trials (involving hundreds or thousands of individuals) to establish efficacy and to monitor adverse outcomes and side effects (phase III). If a compound proves safe and effective, it is approved for market. A phase IV of clinical trials for new indications or for other reasons (e.g., a requirement for further data by the regulator) may take place once the drug is approved. Approval to market may be withdrawn if concerns about safety come to light.

Drugs and devices are regulated somewhat differently and details of such regulation vary among countries. In general, however, devices that affect essential body functions or raise potential safety concerns, such as heart valves or respirators, face standards of evidence about safety and efficacy similar to therapeutic pharmaceuticals, entailing a series of clinical trials. Products that pose less direct threats to safety or that merely modify well-studied devices, including most diagnostics, face lower regulatory thresholds but still require premarket approval. Some products of biotechnology, such as analytical software or research tools and medical procedures that do not entail introduction of a drug or other product into the body, may not require regulatory approval before entering the market.

The main impact of product regulation on the emergence of medical biotechnology has been to increase the barriers to entry into pharmaceutical markets by substantially increasing both the R&D costs and the time from discovery to market. The need to raise tens to hundreds of millions of dollars to cover clinical testing has deeply affected the development of biotechnology. A few dedicated biotechnology firms that quickly discovered protein therapeutics of substantial value have grown to rival the smaller established pharmaceutical firms. Most biotechnology firms, however, have found the cost of independent development prohibitive, and have forged strategic alliances with larger firms or have been wholly or partially purchased by established firms. Established pharmaceutical firms have created in-house R&D efforts that do molecular biological research quite similar to that done by dedicated biotechnology firms. The relationship between the established firms and dedicated biotechnology firms has become highly complex, and varies so much case-by-case that generalization is perilous.

PUBLIC PERCEPTION AND POLITICAL PROCESS

The economic, R&D, patent, and regulatory policies analyzed above fail to capture some factors that have influenced the speed and direction of biotechnology development in different nations. OTA refers to these, for want of a better term, as "public perception," lumping

together disparate factors that influence industrial development in different ways and to different degrees. Historical and political factors were the most conspicuous elements OTA addressed in this category. Religious views have also played a major role in national debates about select areas of biotechnology policy, such as reproductive technologies, gene transfer, stem cell and embryo research and their applications. Religious demographics of different countries vary so much that the U.S. case may not be suitable grounds for generalization.

The influence of such factors is not surprising or unusual, and is far from unique to biotechnology. Indeed, all areas of policy are influenced by religious, moral, historical, and political factors. It is impossible to capture all the factors that influence public perceptions, but many of them share a common element — they increase or mitigate public fears about biotechnology and its applications. A few factors that have been particularly important in the development of medical biotechnology deserve special mention. Two historical events, the eugenics movement in the first half of the twentieth century and the recombinant DNA debate of the 1970s, had a particularly strong influence on biotechnology policy.

The rise of national bioethics commissions is a new feature of political process in many countries and international organizations. Such commissions have developed as an attempt to grapple with moral and religious pluralism as well as the desire for explicit analysis of ethical implications of rapid scientific and technical advances. Such commissions typically cover more than biotechnology, often addressing topics in health care, end-of-life issues, reproduction, and other areas. The focus here is on bioethics and genetics, where "public bioethics" has an especially rich history.

Eugenics in the first half of the century cast a dark shadow over genetics in the second half. Eugenics as a term refers to many different notions with varying levels of political coercion, having in common directed inheritance intended to improve human populations. Eugenics first became a political movement in England and the United States (46). The ideology of eugenics spread worldwide and took its most extreme expression in association with racial hygiene, part of the ideology underlying the National Socialist Holocaust (47,48). Eugenics and racial hygiene as political movements became associated with senior academics in anthropology and human genetics (49), and this association carried over into postwar German genetics. Applications from molecular genetics were regarded as suspect in the German Green political party, and in German-speaking Europe, public distrust of biotechnology emerged in both agriculture and medicine. The first applications of biotechnology were controversial in many countries, but the controversies were more protracted and pervasive in Europe. The causal association between the history of eugenics and different perceptions of biotechnology is weak and circumstantial. It is historically plausible, but far from demonstrated. At the least, however, the resurgence of scholarship about eugenics, and particularly about the coercive social policies associated with its most florid expressions on both sides of the Atlantic, has contributed to greater vigilance about untoward consequences of social policies that intrude on choices about marriage, immigration, and reproduction, and also about discrimination based on disability or illness.

The recombinant DNA controversy of the mid-1970s also left a legacy for several decades. The recombinant DNA debate began with scientific concerns about biohazards from gene-splicing experiments. The central concern was that bacteria carrying spliced genes could spread uncontrollably and cause harm to individuals subsequently infected. Molecular biologists declared a moratorium on experiments involving recombinant DNA, which was lifted after a famous meeting at Asilomar in California, when the moratorium gave way to federal guidelines for such experiments devised and effected by NIH (50). The debate activated several social activists, who turned their energies to opposing applications that emerged from recombinant DNA and other techniques of molecular biology, and hence biotechnology. Jeremy Rifkin and his Foundation on Economic Trends became the most prominent antibiotechnology activist in the United States; and similar sentiments entered social movements commingled with Green politics in Europe and Asia. At the root of public distrust of biotechnology lay concern that the speedy advance and power of the new technologies were outstripping government and other social mechanisms to ensure they were applied fairly and safely. As with patent policy, capital formation, and public support for academic science, biotechnology emerged first in the most permissive environment, the United States. While this was where the recombinant DNA controversy first arose, it was also where guidelines governing the research were relaxed first and most extensively among developed economies.

National bioethics commissions and biotechnology share a common origin in policies governing the application of molecular biology. The first national bioethics commission, the U.S. National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (National Commission), was the result of almost a decade of congressional debate. The first hearings on such a commission were convened by Senator Walter Mondale in the late 1960s, out of concern that technical advances in biology were proceeding in advance of policies to ensure wise use of the technologies in genetics, reproduction, and medicine. In 1971 attention shifted to human cloning, but there was insufficient congressional support for a bioethics commission until a series of scandals about the conduct of medical research involving human participants led to hearings by Senator Edward Kennedy. The National Commission was established in 1975 and operated until 1978. The legacy of its origins in concern about advances in biomedical research was a single report (51). As the National Commission faded out of existence, it recommended that Congress establish a new national bioethics commission with a mandate beyond protection of human participants in research. Congress did so in the form of the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research

(President's Commission), whose title was admirably self-explanatory if lamentably long. The President's Commission operated from 1980 through March 1983. Two of its reports dealt directly with genetics, on genetic testing and screening and on human uses of recombinant DNA, particularly human gene therapy (52,53). These reports came out just as the term biotechnology was coming into general use. As it neared the end of statutory term, the President's Commission recommended that Congress establish a more permanent body to deliberate and make recommendations about ethical issues in medicine, in particular about rapidly advancing technologies that touched areas of controversy and moral uncertainty, including reproduction and genetics (54). In 1985 Congress acted on this recommendation by establishing a new congressional advisory agency modeled on OTA, the Biomedical Ethics Advisory Commission. That Commission took three years to get underway, largely because of delays in congressional process, and in the end never issued a report. In effect, there was a hiatus from 1983 until 1995, when President Clinton established the National Bioethics Advisory Commission by executive order (55).

During the interregnum of bioethics commissions in the United States, many countries established national bioethics commissions and several international organizations also did so. A November 1992 OTA survey of international bioethics bodies found 31 countries and 5 international organizations had some form of advisory apparatus for bioethics (56). Many countries had more than one body, such as Denmark, France, Australia, and Canada.

The growth of national bioethics initiatives and international organizations with bioethics consultative capacity grew from an effort to link explicit analysis of ethical, social, and legal implications of medical science and technology. In many cases they were an attempt to clarify values and to sample disparate religious and social perspectives on medical practices and emerging medical technologies. Most bioethics bodies included attention to advances in genetics or biotechnology or both within their remit. Several of these bodies, particularly those in Europe and Canada, have proven influential in government policy about biotechnology. In Denmark, Sweden, and Germany, for example, commissions recommended proscribing germ line genetic alterations (introduction of DNA into a person so that genetic changes are inherited), and the national parliaments did so. In many cases bioethics commissions are serving to find common ethical arguments that resonate throughout their respective national cultures, grappling with moral pluralism in the face of advancing technologies and pressing problems arising from practical applications, both immediate and in prospect.

Medical biotechnology differs from other high technologies in that its development directly depends on the participation of people in research, as its applications are intended to influence human physiology. This means that the advance of biotechnology is more immediately relevant to the relief of human suffering than most other technologies, but it also more directly threatens fundamental social values connected to reproduction and inheritance. One response has been an effort to anticipate the social implications of biotechnology through bioethics commissions and other mechanisms. It remains too early to judge the success or failure of these responses.

O

OWNERSHIP OF HUMAN BIOLOGICAL MATERIAL

LISA M. GEHRKE
Nilles & Nilles, S.C.
Milwaukee, Wisconsin

OUTLINE

INTRODUCTION

In recent years biological materials have become increasingly important in biomedical research. These materials, which were once considered waste materials, have become essential to research in many promising areas. As a result the demand and potential commercial value for these materials continues to rise. The legal status of these materials depends primarily on the source of origin of the materials. If the material is obtained from a nonhuman source, the law will generally consider it as property and therefore, a commodity that may be freely bought and sold in the market place. However, if the material is obtained from a human source, the law generally fails to recognize it as property.

OVERVIEW OF THE USE OF HUMAN BIOLOGICAL MATERIALS IN BIOTECHNOLOGICAL RESEARCH

The study of the human body, body parts, and biological materials has traditionally played an important role in the advancement of the biomedical and pharmaceutical sciences. The observation and study of postmortem organs, tumors, and other biological materials obtained during surgery has provided physicians and researchers with an understanding of the nature and function of the human body and human disease processes.

The introduction and refinement of biotechnological tools such as recombinant DNA, cell fusion, cloning, and bioprocessing techniques in the early 1970s dramatically changed the role of human biological materials in biomedical research and development. These techniques enabled researchers to go beyond merely observing tissues and cultivating cell lines to actually incorporating the material into new organisms to create life forms not previously known in nature. Recognizing the tremendous economic potential of these products, researchers and venture capitalists began investing in the development of biotechnologically based products and the private commercial biotech industry was born. As a result, the demand for the raw materials, namely biological materials, dramatically increased.

In 1980 the United States Supreme Court significantly changed the U.S. patent law by expanding the scope of patentable subject matter to include to artificial living organism in the landmark decision *Diamond v. Chakrabarty* (1). Prior to *Chakrabarty*, U.S. patent law considered all plants, animals and microorganisms products of nature and not products of invention. Therefore they did not qualify as patentable subject matter. *Chakrabarty* recognized that a living organism not found in nature and created by the intervention of humans, is a product of invention and not a product of nature. Consequentially artificial living organisms, qualified as patentable subject matter under the U.S. patent law.

In 1988 the United States government allocated three billion dollars to fund the human genome mapping project commonly known as the Human Genome Project (HGP). Concurrently, the Human Genome Organization (HUGO) was formed in Europe to coordinate research and foster collaboration between scientists (2). The information obtained from HGP has been a tremendous source in developing understanding of the genetic basis of human function and the genetic roots of disease. This information serves as a foundation for research and development in biopharmaceuticals and therapeutics around the world.

The biotech industry continues to grow as investors recognize the economic incentive created by the availability of patent protection for artificial living organisms combined with the value of the information obtained from HGP. This growth and increased interest in gene-based therapies has also created a corresponding increase in the demand for both human and nonhuman biological materials.

Human biological materials such as human tissues, cells, and other materials previously viewed as biological waste products are now seen as having significant economic value. As a result some groups support legally recognizing human biological materials as property. Other groups, however, opposed any legal recognition of property rights in human biological material because it commodifies the human body, which is believed to be contrary to the U.S. legal tradition, public policy, and human dignity.

PROPERTY, OWNERSHIP, AND PROPERTY RIGHTS

Ownership is a term arising out of common law that refers to an individual's right to exercise control or dominion over property. Ownership allows an individual to use, control and transfer the owned property to the exclusion of others.

Property is something having recognized value that may be owned by an individual. Property is either real or personal. Real property, such as land and items affixed to the land, is immovable. Personal property, however, is movable property. Personal property may be tangible items, such as cars, jewelry, and furniture, or intangible concepts, such as stocks, annuities, and intellectual property. For example, nonhuman biological materials such as microorganisms are considered personal property because they are tangible materials. A patent claiming a process of making the microorganism, however, is considered intangible property.

A property owner has a bundle of rights known as property rights that are created and recognized by the state. The definition of property and the nature and extent of an owner's rights in that property are determined by the state through either legislation or common law. In addition the state defines the remedies available to a property owner if the property owner's rights are violated.

Many states currently recognize nonhuman biological material as property. For example, the statutes of Illinois (3) and Maryland (4) recognize "samples, cultures, microorganisms and specimens" as property. If it is misused, the owner of the property may sue under a theory such as trespass to chattel, to recover damages for any injury to the property resulting from unauthorized use or misuse of the property. For example, an individual may own a specific bacterial culture. If a culture is misused, harmed, or destroyed by another, the owner has legal standing to sue the third party to obtain restitution for the damage to the property.

Human biological material, unlike biological material from a nonhuman source, is not currently recognized as property by any state within the United States. Several legal theories, however, have been suggested as a basis for recognizing human biological materials as property. The legal recognition of human biological material as property would create a unique situation in which the property owner is also the property subject to ownership. In this situation an injury to the person would not only create standing to sue the harming individual for injury to person but would create standing to sue for injury to property as well. Legal scholars have looked to various theories to support the recognition of human biological materials as property.

HUMAN BIOLOGICAL MATERIAL

The term "human biological material" is used to broadly refer to any replenishable or nonreplenishable substance obtained from a human body. Replenishable or regenerative materials include blood, skin, bone marrow, hair, urine, perspiration, saliva, milk, semen, and tears. Nonreplenishable or nonregenerative substances however, include body parts such as oocytes and organs, whether vital or nonvital (5).

Research facilities generally obtain human biological materials from patients, research subjects, paid donors or repository collections. The individual providing the material may be either identified or unidentified and the material sample may be used directly in research or saved in a repository collection for later use. The laws dealing with the use and transfer of these materials vary greatly depending upon the specific type of human biological material, and the source from which it was obtained.

HUMAN BIOLOGICAL MATERIAL AS PROPERTY

The recognition of human biological material as property would allow an individual to sell or transfer his or her biological material for valuable consideration such as cash. This change would impact society and the tissue recipients and as well as the tissue donors. Therefore all of their interests should be considered in this decision.

Society's Interest

U.S. public policy generally opposes recognizing a property right vested in the donor of human biological material. This position arises out of society's responsibility to ensure the safety and welfare of its citizens, and to promote scientific advancement.

Over the past 40 years, the U.S. government and the global research communities have made great advances in enacting legislation and developing ethical standards to ensure the protection of human subjects in biomedical research. A central principle common to all the laws, codes, and standards is respect for the human dignity of each person. In other words, society is generally prohibited from permitting any treatment or activity involving a patient, research subject or tissue donor that would be contrary to the dignity and integrity of that individual. Opponents of recognizing human biological material as property argue that the commodification of the human body or any of its parts is equivalent to the commodification of the human person. Since society has determined that it is a violation of human dignity to treat human beings as commodities, it is also a violation to treat the human body or any of its parts as commodities. In addition, opponents argue that recognizing a property interest in human biological materials will encourage individuals to take unnecessary risks with their health for a short-term economic gain. For example, an individual in need of money may feel compelled to sell tissues or an organ to obtain compensation even though the donation may seriously compromise his or her health.

Proponents of recognizing human biological material as property argue that any imposition of regulations

restricting the sale and purchase of body parts, tissues, or materials is a paternalistic infringement upon an individual's freedom. Under this approach, if an individual is provided all of the facts surrounding the risks and benefits of the donation, he or she should be able to sell his or her biological material for cash or other valuable consideration. Any law or regulation restricting such a transaction is considered an abuse of the state's authority. Furthermore the sale of human biological material is not equivalent to the sale of a human being.

Material Donor's Interest

It is clear that the value of human biological material has increased within the past 30 years. Research involving the use of human biological materials has produced products with great economic potential. In some cases the discovery or the invention is directly related to a specific trait found only in the biological material of a specific individual or group of individuals. Consequentially proponents of legally recognizing human biological material as property assert that the individual or group of individuals who provided the essential biological material should share in the financial gain generated by the product arising out of their unique trait. For example, if an individual exhibits a specific genetic trait that is essential to the formation of a new pharmaceutical composition, he or she should be entitled to a portion of the profits realized by the sale of that product. Alternatively, since human biological material has a recognized value, proponents argue that an individual should be entitled to sell his or her biological material in the same manner as a farmer sells a crop.

Opponents to recognizing human biological material as property assert that the treatment of human biological material as property is contrary to human dignity and integrity in the same manner as discussed above.

Material Recipient's Interest

Researcher are generally opposed to the recognition of a property interest in human biological material for several reason including fear of increased research costs, fear of future liability for the use of biological material obtained in a wrongful manner. Since a large portion of the research involving human biological materials is directed toward the production of biopharmaceuticals and biotherapeutics, researchers argue that a creating any property interest in human biological materials would only serve to stifle research and should therefore be contrary to public policy. Alternatively, some researchers advocate creating a property interest in human biological materials because they believe the tying an economic incentive to material donation would increase the overall supply of biological materials available for research.

POTENTIAL SOURCES OF PROPERTY RIGHTS

In 1987 the U.S. Office of Technology Assessment issued a report entitled *New Developments in Biotechnology; Ownership of Human Biological Tissues and Cells-Special Report* (5), which addressed the various ethical legal and public policy concerns regarding legally recognizing human biological material as property. The report identified several areas of law that may support creating a property interest in human biological material. The most relevant of these areas are discussed below.

Patent Law

A patent is broadly defined as a grant made by a government to an inventor which conveys and secures in him the exclusive right to exclude others from making, using, selling or offering for sale his invention for a term of years (6) Governments grant patent rights to their citizens as economic and social incentives to publicly disclose scientific and technological innovations. Patent protection is intended to provide economic and social incentives for inventive efforts made in the advancement of sciences and for the benefit of all. The promise of high financial returns provides the economic incentive for inventors to publicly disclose the fruits of their research, rather than concealing it from competitors. Therefore society benefits from the public disclosure of scientific advancements.

Under U.S. patent law, a patentable invention must qualify as patentable subject matter and be novel, useful and nonobvious to one skill in the technology of interest. As discussed in a previous section, in 1980 the United States Supreme Court expanded the scope of patentable subject matter to include artificial living organisms in the case of *Diamond v. Chakrabarty* (1). Since that time, inventions directed to biotechnologically modified organisms are commonly the subject matter of U.S. European, and Japanese patents.

Although biological materials, such as human biological materials, are commonly used in the development of the invention claimed in the patent, the patent is directed only to the invention formed of the human biological materials and not the biological materials themselves.

For example, an inventor may use a tissue expressing a particular genetic trait as raw material for new pharmaceutical. Although the tissue may have been essential to the development of the new pharmaceutical, the actual invention is the new pharmaceutical and not the tissue or raw material used in its creation. Since patentable subject matter must be the product of invention, only the new pharmaceutical and not the tissue used to create the new pharmaceutical would qualify for patent protection.

Although patent law may provide protection for inventions formed out of human biological materials, it does not provide a basis for creating a property right in human biological material.

Laws Relating to the Donation and Transfer of Organs Tissues and Other Biological Materials

The law relating to the donation and transfer of human biological materials looks to see if the biological material is replenishable or nonreplenishable. No federal or state law prohibits the sale of replenishable human biological materials such as blood, plasma, and semen. As a practical matter, however, state laws categorize this type of transfer as a service rather than a sale of a commodity to avoid any potential liability, such as product liability, created by the sale of an imperfect or harmful good. If the transfer

of human biological material were treated as a sale of goods, the implied warranties would be subject to implied warranty of merchantability and the implied warranty of fitness under the Uniform Commercial Code (UCC) (7).

The Implied Warranty of Merchantability would require the human biological material to be of "fair and average quality" as described by the seller. It is unclear how this would apply to the transfer of human biological materials. If the materials, such as blood or semen, were infected with a contagion, it would create significant liability for the merchants who distribute the material obtained from donors (8).

Similarly the Implied Warranty of Fitness requires the human biological material described to be suitable for the buyer's purpose (9). The law dealing with the transfer of nonreplenishable materials generally falls within the Uniform Anatomical Gift Act (UAGA) (10) and the National Organ Transplant Act (NOTA) (11).

The UAGA was finally approved in 1968 and has been adopted by all 50 states and the District of Columbia. The Act allows any competent adult to donate any or all of his or her body to medical education, research and transplantation at the time of death.

The NOTA was enacted by Congress in 1984. It prohibits the sale of any human organs such as kidneys, hearts, livers, eyes, and bone marrow. It does not, however, prohibit the sale of human tissues and cells for research, nontransplantation or commercial purposes.

In summary, neither federal nor state law explicitly prohibits the sale of either replenishable or nonreplenishable human biological material if the sale is for research, commercial or nontransplantation related purposes.

Law Trespass to Chattel and Conversion

Under civil law, any intentional interference with the personal property of another is considered "trespass to chattel." Trespass is a civil action that allows an injured party to seek restitution for any injury done to his or her person or property. A trespass to chattel action refers more specifically to any injury done to one's personal property.

If the personal property has simply been taken, the usual remedy is to have the trespassing party return the personal property and to provide monetary compensation for any diminution of the value of the property. If, however, the personal property is converted into another form rendering it useless to the owner, the law allows the injured party to seek monetary compensation under a conversion action, equivalent to the value of the property that was converted. In determining whether a conversion has taken place, the court considers the following factors: the extent and duration of the actor's exercise of dominion or control over a chattel, the actor's intent to assert a right inconsistent with the owner's right of control, the actor's good faith, the extent and duration of the resulting interference to the owner's right of control, the harm done to the chattel, and the inconvenience and expense caused to the owner.

If human biological material is recognized as property, a material donor could assert a property interest in that material. Therefore any unauthorized use of that material would constitute a misappropriation of the donated material and the donor could bring a conversion action for compensation for the unauthorized use.

The Case of John Moore's Spleen

In 1990 the Supreme Court of California considered the legal theories discussed above in the case of *John Moore v. The Regents of the University of California* (12). In this case, the Court determined whether the plaintiff, John Moore, a patient with hairy cell leukemia, stated a cause of action against his treating physician, David Golde, for using his cells in potentially lucrative medical research without his permission. Moore alleged that Golde failed to disclose his preexisting research and economic interests in the cells before obtaining his consent to extract the cells. The Court determined that Moore did state a cause of action for breach of a physician's disclosure obligations, but the Court did not for a conversion action.

Statement of the Facts. On October 5, 1976, Moore visited the UCLA Medical Center after having learned that he had hairy cell leukemia. Moore was hospitalized and extensive amounts of blood, bone marrow aspirate, and other substances were removed. Golde confirmed the diagnosis. At that time the defendant was allegedly aware that certain blood products and blood components were of great commercial value and that these substances, which were found in Moore's biological materials, would provide certain competitive, commercial, and scientific advantages.

On October 8, 1976, Golde recommended the Moore's spleen be removed. Golde informed Moore that the splenectomy was necessary to slow down the progress of his disease. Moore signed a written consent form authorizing the surgery.

Before the surgery, Golde had made arrangements to obtain a portion of Moore's spleen for a special research project following its removal. Moore was never informed of Golde's plan.

Between November 1976 and September 1983, Moore traveled from his home in Seattle to the UCLA Medical Center for treatment at Golde's direction and based on the representations that the visits were necessary for his health and well-being. On each visit, Golde withdrew samples of blood, blood serum, skin bone marrow aspirate, and sperm. Moore was told that these procedures could only be performed there and under Golde's direction.

During the course of these treatments, Golde was actively involved in research on Moore's cells and planned to benefit financially and competitively from the exclusive access to these cells through the physician–patient relationship.

Prior to August 1979, Golde established a cell line from Moore's T-lymphocytes (Mo Cell line). On January 30, 1981, the Regents applied for a patent on the cell line listing Golde as one of the inventors. The patent, U.S. patent number 4,438,032, was issued on March 20, 1984. The Regents and Golde entered into several agreements intended to commercialize the Mo cell line.

Based on the allegations discussed above, Moore filed suit stating 13 causes of action including conversion, lack of informed consent, and breach of fiduciary duty. The

superior court only recognized the cause of action for conversion.

Majority Opinion

The California Supreme Court addressed the issues of Golde's alleged breach of fiduciary duty to his patient Moore, and Moore's action for conversion of his biological materials. The Court ruled that Moore stated a cause of action for breach of fiduciary duty but did not state a cause of action for conversion.

Breach of Fiduciary Duty. Under the law of California and all U.S. jurisdictions, a physician has a duty to inform a patient of all the information material to a proposed treatment or procedure before the patient consents to the procedure. This allows the patient to make an informed decision about undergoing or proceeding with a treatment or procedure. For example, a physician has a duty to inform a patient of the risks that are believed to be relevant to the patient's decision such as the mortality rate and success rate of the treatment or procedure, and the possible side effects associated it.

The Court ruled that a physician's economic interest in a patient's treatment should be disclosed to the patient because it may be relevant to that patient in his or her decision to proceed with the treatment. Golde therefore had a duty to disclose his economic interest and the research involving Moore's biological materials to Moore before Moore then underwent the splenectomy. In addition Golde has a continuing duty to disclose his financial interest in Moore's follow-up care. Since Golde did not inform Moore of this information, the Court rule that Moore did state a cause of action against Golde for breach of fiduciary duty to a patient for failing to obtain informed consent. The suggestion is that if Moore would have been aware of Golde's financial interest in Moore's biological materials, Moore may not have undergone the treatment. This situation raises a question of fact that would be answered by a jury if the case proceeded to trial.

Conversion. The California Supreme Court did not allow Moore's claim for conversion. To state a cause of action for conversion, a party must show that he or she has a property interest in the material converted. A property interest is only present if the material is legally recognized as property. California law, however, does not recognize human biological materials as property. Therefore Moore cannot have a property interest in his biological materials and his action for conversion could not stand.

The Court discussed the public policy concerns in favor of and in opposition to recognizing human biological materials as property. Ultimately the court determined that human biological material is necessary to the advancement of biomedical research, and any impediments to the advancement of this research, such as any uncertainty of title, would be against public policy. The Court determined that a legal recognition of biological material as property should be done through legislation.

Justice Arabian's Concurrence

Justice Arabian believes the majority's opinion correctly concludes that a tissue donor does not have a property interest in his or her donated tissue. Arabian's opinion, however, stems from moral rather than economic concerns. It is feared that a recognition and enforcement of a property interest in human body parts would have a highly negative effect on human dignity. Arabian notes that the plaintiff is not left without a remedy. Moore may pursue an action under the breach of fiduciary duty theory.

Justice Broussard's Dissent

Contrary to the majority opinion, Justice Broussand believes that Moore does, in fact state a conversion cause of action because he alleged that Golde wrongfully interfered with Moore's right to determine how his spleen would be used. Unlike the majority, justice Broussard asserts that conversion is not only applicable when personal property is taken but also when it is used without authorization. This position may be supported by the Uniform Anatomical Gifts Act.

The UAGA allows a donor to control the express manner in which the biological materials will be used after his or her death. Accordingly Moore arguably had a similar right to determine how his biological materials would or would not have been used after their removal.

Justice Mosk's Dissent

Justice Mosk believes the majority's opinion is incorrect because it fails to recognize a difference between the use of materials used for nonprofit research purposes and commercial use. Mosk believes that Golde's failure to disclose his economic interest in Moore's biological materials amounted to commercial exploitation of Moore. Furthermore Mosk concluded that Moore should have a property interest in his tissues that would allow him to enter into contracts for the exploitation of his tissues if he so desires.

Impact of the Moore Decision

Following the Moore case, both public and private parties having interest in the use of human biological materials began to reevaluate their methods and policies regarding the procurement of these materials. In view of the majority opinion the focus of the discussion shifted from concern over the creation of a property interest to reviewing and revising the standards of informed used in obtaining human biological materials from patients and/ or research subjects.

ROLE OF INFORMED CONSENT IN THE PROCUREMENT OF HUMAN BIOLOGICAL MATERIALS

Since the Moore decision, society has developed a deeper understanding of the value connected to human biological material and the potential harms and benefits that may arise out of its commercialization in research. As a result the ethical principle of respect for persons has expanded to require disclosure of any potential harm or benefit resulting from the intended harvesting or use of the material, to the potential donor.

The ethical principle of *respect for persons* recognizes an individaul as an autonomous person capable of deliberation about personal goals who acts under that deliberation. Therefore, to respect the autonomy of the individual is to give weight to his considered opinions and choices while refraining from obstructing his actions unless they are harmful to others. To show lack of respect for an autonomous person is to repudiate the person's considered judgement when there is no compelling reason to do so (13).

Respect for persons requires that each research subject be given the opportunity to choose what will or will not happen to his or her body or biological materials. This opportunity is provided when adequate standards for informed consent are satisfied (13). To accomplish this, an individual must be given all the information regarding the nature of the procedure, the potential risks and benefits arising out of it and all other factors, such as economic considerations, that may bias the situation.

The requirement of informed consent was originally applied to a traditional biomedical research setting in which the subject received an experimental treatment. The requirement was intended to ensure that the research subject knew the risks involved in the procedure to be performed. Traditionally the doctrine of informed consent was not extended to require a disclosure of any future use of the human biological materials taken from a person. In recent years the informed consent requirement has been extended to apply to the procurement and use of any human biological materials obtained from a known donor as in the Moore case.

On December 13, 1995, the *Journal of the American Medical Association* published the results of an NIH workshop charged with formulating informed consent requirements and their application to the gathering of human biological materials that may be used in genetic studies, and with identifying when further consent for the use of material samples already in the possession of researchers should be obtained (14). The participants concluded informed consent is required for all genetic research using samples that may be linked to an identifiable person (14). The participants further concluded that the disclosure of genetic information could have medical, psychological, and economic implications on the material donor. Therefore individuals have the right to put limits on the use of their biological materials. For example, they may specify that their tissues shall only be used by a noncommercial entity.

In August 1999 the U.S. National Bioethics Advisory Commission (NBAC) issued its report entitled Research Involving *Human Biological Materials: Ethical Issues and Policy Guidance* (15). As in the 1995 NIH report, NBAC discusses the importance of human biological materials in the advancement of medical research and recommend obtaining informed consent from all identifiable tissue donors including disclosure of any economic interests of the parties and all potential physical, social, and psychological harms they may arise from its procurement or use.

PRACTICAL APPLICATIONS RECOMMENDATION

As a practical matter, it is essential that any individual, company or organization that is involved in the procurement and use of human biological materials, obtain full informed consent from all potential material donors. More specifically, the economic interests of the researchers, or procuring organization, the proposed use of the materials, and any physical, social, psychological or economic harms that may arises from the use of the materials, must be disclosed to the potential donor prior to the donation. In addition, it is advisable to have the potential donor explicitly transfer any title or property interest to the procuring individual or organization before the donation occurs. Although a donor's property interests in their human biological materials are not currently recognized by any state in the United States, it is important that the potential donor is fully informed about the implications and potential economic ramifications of the transfer of title before it is granted. The biological material may be transferred to a jurisdiction that recognizes such a property interest in the future. Therefore, it is important to take every precaution to ensure the title to the human biological material in question is clear.

OUTLINE

BACKGROUND

The view, in general, on what biotechnological inventions may be patented is more restrictive in Europe than in the United States, although the differences have diminished over the last few decades. Moreover there have been important variations in the United States, Canada, and the European Union (EU) positions, as well as among their peoples over time, as a brief glimpse at their historical backgrounds will indicate.

The 1961 UPOV Convention (Union internationale pour la protection des obtensions végétables) has continued to be endorsed by many European countries and also by the United States and Japan. It provides protection for new plant varieties in a different way than the patent system does. It means that a plant breeder and plant improver can obtain exclusive right to use a particular brand of plant according to certain conditions that are specified in the convention. This convention was revised in 1978 and later in 1991. The new UPOV convention provides a somewhat stronger protection of the rights of the plant breeders.

A new instrument of International patent cooperation, the Eurasian Patent Convention, was signed in Moscow on September 9, 1994, and entered into force on August 12, 1995.

United States

In biotechnology a number of difficulties have been encountered in the attempts to patent living materials. Products of nature are not patentable under U.S. law. Nevertheless, before the rapid expansion of modern commercial biotechnology, protection by patents had been granted on materials derived from natural sources through human intervention, such as substances obtained by purification of naturally occurring products.

In 1930 the Plant Patent Act made it possible to extend protection to new and distinct asexually propagated plant varieties. To be sure, the protection was subject to certain limitations: a research exemption that allows use of protected varieties to develop new varieties, and a farmer's exemption that allows farmers to save protected seed for use on their farms or for sale to other farmers.

Before 1980 patents could be obtained on processes using bacterial strains for commercially valuable purposes such as in producing antibiotics. But bacterial strains per se could not be patented in the United States. However, the United States Supreme Court decided in 1980 that a genetically modified living single-celled bacterium, transformed to give it the capacity to break down multiple components of crude oil, could be patented. The Patent and Trademark Office (PTO) soon extended the categories eligible for patent protection, to such products as corn plants (1985), polyploid oysters (1987), as well as to "nonnaturally occurring nonhuman, multicellular living organisms, including animals."

The first patent on a transgenic animal was issued in April 1988 to Harvard University for the development of a mouse with a human onco-gene that makes it susceptible to cancer, the OncoMouse. This extension to animals has generated considerable public controversy, however. Restrictive legislation, including a moratorium on animal patenting, has been proposed (1–3).

The present American patent law is the Utility Patent Act, in Title 35 of United States Code, which among many other things states that "whoever invents or discovers any new and useful process, machine, manufacture, or composition of matter, or any new and useful improvement thereof, may obtain a patent therefor" (35 US Code 101).

Canada

In Canada, patent legislation governing drugs evolved through a series of amendments to the Patent Act. From 1923 to 1993 Canada operated a system of "compulsory

licensing," described in some detail by Mathews (4), allowing generic copies of patented medicines to be manufactured within Canada and, by 1969, to be imported.

In 1987 the Act was amended. A compulsory license could be issued on patented medicines only after a fixed period of market protection. Moreover a price review board was created to monitor and control prices charged. Brand-name drug companies promised to invest a growing percentage of sales revenue in research and development in Canada, in exchange for patent protection.

A further amendment to the Patent Act in 1993 fundamentally changed the legislation by abolishing the system of compulsory licensing and applying general patent regulations to medicines. In that way Canadian law was brought into line with that of its trading partners, particularly the United States. It is now illegal to sell a copy of the drug until the patent has expired.

Europe

The European Patent Convention was signed in Munich on October 5, 1973. The European policy on patentability is in general stricter than the one in the United States, even though there have been variations among the national patent offices and the European Patent Office (EPO) in Munich. Before 1998 the existing legal framework did not allow the patentability of living organisms in the European Community countries, notwithstanding some decisions of the European Patent Office (which still are contested).

This changed with the Directive 98/44/EC of the European Parliament and the Council issued on July 6, 1998. This directive grants free circulation of patented biotechnological products, guaranteeing compliance with the European Patent Convention from 1973, the trade-related aspects of Intellectual Property Rights agreement of April 15, 1994, and the Rio de Janeiro Convention on Biological Diversity of June 5, 1992.

The European Patent Convention also states that European patents will not be issued for plant or animal varieties and essentially biological processes for the production of plants or animals, with the exception of microbiological processes or the products thereof. Nevertheless, EPO in 1991 issued a European patent to Harvard University on its transgenic mouse, after having refused this application a few years earlier.

According to Schatz (1998) in Europe, only some 15,000 European patent applications have been filed in biotechnology and over 2000 patents have been filed for DNA sequences isolated from the human genome used to develop therapies and medicines.

CONTROVERSIES

There are controversies within and among countries as to what can be patented, the conditions of patentability, how these conditions have been interpreted and applied, as well as concerning the exceptions to these conditions. There are also conflicting views on the entire system of patenting forms of life, in particular animals and plants. By implication, these controversies have a bearing on the reasons accepted for and against the system of patenting different forms of life. Even though there are variations in views between the developing and developed countries, the latter on the whole take a more negative view of the present system, which they feel has been exploited.

The competition over transgenic technology rights has financial implications. Those individuals who have the intellectual property rights can protect their discoveries by patents and earn money by getting royalties from others or by exploiting the intention themselves. It is then hardly surprising that there are objections to such rights and that they have sometimes resulted in court cases (5–7). But the basic issues concern what can be patented and on what conditions.

Conditions of Patentability

The conditions of patentability include utility, novelty, nonobviousness. Some of the clauses in patent laws and patent conventions contain difficult but important expressions, like "utility," "novelty," and "inventive step" as well as "living organism." Each of these conditions can be interpreted and applied in different ways (8,9). Controversies as to how they are to be interpreted and applied in practice are to be expected.

What Is Excluded? And Why?

What is excluded from patenting, and how are these exclusion clauses to be interpreted? In the European Patent Convention (EPC) a broad concept of invention is being used. There are three express exceptions:

1. Methods for treatment or therapy.
2. Essentially biological processes for producing plants and animals (and the results of these processes).
3. Inventions contrary to public order and morality (in Europe at least).

The terms "plant variety," "animal variety," "essentially biological processes," "invention," and "public order and morality" can be interpreted in different ways, since the praxis of interpretation has evolved over time. The novelty requirement presupposes that there is a distinction between earlier existing plant varieties and a new one. In this context the definition and criteria of identity of "plant variety" becomes relevant.

Klett (10), Moser (11), and Thomsen (12) have discussed the interpretation of various clauses of exemption in the legislation and practice of several different countries (Germany, Switzerland, Denmark). Other legal scholars Kern (13) and Schatz (14) have elucidated the views on patentability and the patenting practice in the United Kingdom and EPO. The various changes in the Belgian attitude toward the patenting of biological material have been described and analyzed by van Overwalle (15).

Lugagnani (16) proposes that in setting practical limits to patentability via ethical considerations, the moral judgment should move from exploitation of the invention to the nature and/or objectives of the research and development (R&D) projects that produced it. In his view, unethical R&D activities should not be rewarded by granting intellectual property rights. The crucial question

then becomes: What is the basis of these moral judgments? And who has the privilege of interpretation?

Lugagnani suggests that ethical guidance be derived from the 1996 Council of Europe Convention on human rights and biomedicine as well as from the Directive 98/44/EC of the European Parliament. According to Article 7 in the directive, the European Commission (EC) states that its European Group on Ethics in Science evaluates all ethical aspects of biotechnology. The group has already discussed several aspects in earlier reports, and several others are on their way.

Several tasks ought to be separated in the discussion of these clauses of conditions and exceptions. Clearly, there is the empirical task of finding out how, in fact, they have been interpreted by particular patent offices. In the literature, this has been discussed extensively. But, since the clauses, like a musical score, are in general open to many interpretations, there is also a question with normative implications: How are they to be interpreted? In a way the question can be understood as a means-end question: How are the clauses to be interpreted if one wants to achieve (or avoid) certain ends? Obviously an author can at the same time be interested in discussing and answering all these questions.

What Can Be Patented?

Today's candidates are microorganisms, plants, animals, and genetic material from humans as well as the methods or processes used in biotechnology to modify them. While attempts to manipulate and patent human life, also before birth (embryo, fetus), is controversial and forbidden in some countries, the situation is different when it comes to microorganisms.

If gene technology and patents only served good purposes, for example, in the production of medicines, vaccines, diagnostic methods, or protection of environment (e.g., producing bacteria that break down crude oil), objections would be more difficult to obtain and sustain. A great deal of criticism has to do with the use of human growth hormone to get salmon to grow quicker, for example, and a range of similar enhancement purposes. With regard to animals, the public generally considers it unethical to produce and patent animals with properties that cause them to suffer. It has been argued that plants, animals, and large organisms should not ever be patentable.

The general idea in the July 1998 Directive 98/44/EC of the European Parliament and the Council is that discoveries per se are not considered patentable, nor are plants and animal varieties per se, nor essentially biological procedures for the production of plants and animals. Also methods of surgical and therapeutic treatment and diagnostic methods applied to animal bodies are not considered to be inventions of the sort that may be patented. But plants and animals with newly introduced genetic traits, like the famous OncoMouse, may be protected by patents. The same goes for biological materials and material isolated from its natural environment and isolated elements of the human body with technical processes.

In Europe, inventions contrary to law and order or public morality may not be patented. This includes processes for human cloning for reproductive purposes — banned by a protocol to the Council of Europe Convention on human rights and biomedicine (17). The same holds for processes for modifying the germ-line identity of human beings and the use of human embryos. Processes for modifying the genetic identity of animals with substantial medical benefit for humans, because they are useful for treating serious diseases such as cancer or AIDS, may be protected by patents. If this is not the case, they are not considered to be patentable.

Computer-aided molecular design techniques have recently been used along with more traditional methods to design new peptides possessing specific properties, such as bactericidal activity. Patel and Colleagues (18) have argued that the ability to protect the intellectual property rights associated with the discovery of the new molecules is a key issue for commercial utilization of such peptides, and the authors have described and proposed an extension of established patenting practice.

Moreover Green (19) argues that combinatorial libraries are patentable as long as the library meets the statutory criteria of utility, novelty, and nonobviousness, and the application meets the standards of enablement, best mode, and written description. Licensing and alternatives to patenting are also considered, along with potential problems unique to combinatorial chemistry agreements. A particularly interesting illustration of the diversity of views on the ethical aspects of gene patents, reflecting deep disagreements as to both conclusions and arguments, concerns patenting of disease genes.

Patenting of Disease Genes?

The possibility and desirability of patenting disease genes is a much-debated area where heated controversies have attracted a great deal of attention around the turn of the twenty-first century. For example, McGee (20) has argued that gene patents can be ethical. He examines some arguments against patents in this area and concludes that patenting on methods for detecting the presence of a genetic correlation with disease-related (and other) phenotypes can be appropriate.

The main reason offered for this position by McGee is that there is a subtle distinction to be made between "observing DNA" and constructing a DNA-based product for diagnosis of some disease or phenotype. He examines two arguments that oppose his view: (*1*) genetic information is part of nature and (*2*) gene patents create a "toll bridge" barring research using patented genes.

Taking the first point, McGee argues that disease gene patents are more an innovation of scientists than a discovery. "Finding DNA is discovery. Correlating it with human life for the purpose of creating a diagnostic process is innovation" (20).

The second position poses a problem: How is one to avoid the issue that genetic research will be hindered, that genetic tests will not be developed, if researchers in the early stages of work are not able to pay the tolls necessary to start the research? McGee claims that this can be prevented by "correctly framed and issued gene patents."

He argues that infringement of the patent occurs not when methods are used for further research but only when the actual innovation is put to use in the same sense that the method of detecting the gene's or allele's correlation with a particular phenotype is applied to a patient.

Kimbrell (21) is an important early work that has played a central role in the debates on engineering and marketing of life. Various positions in the subsequent debate have been advocated by several researchers (22–27).

Caplan and Merz (23) have instructively compared the identification of disease genes to the land rush. They agree that the debate is timely, for a number of reasons, but contend that McGee's position is untenable. Caplan (26) argues laying claim to own what we find in the biological world cannot be done without an arrogance or hubris about our creativity, that patenting genes is profane — it is "commercializing something that ought to remain outside the realm of commerce," and that "allowing patents ignores that it is our common genetic glue that holds us together as a species, and that is something all of humanity has as its common legacy." These metaphysical concerns are especially at the heart of religious-based objections to patents, according to Caplan.

Merz and Cho (27) argue that McGee is wrong and that methods of screening for Alzheimer's disease should not be patentable. Obviously they criticize that a U.S. patent on such methods has been granted by PTO. More specifically, they argue that there are two false premises in McGee's argument:

1. The difficulty and effort involved in making a discovery makes the discovery patentable.
2. Patentability is based on the usefulness of the discovery.

They argue that market potential is not a necessary, much less a satisfactory, condition to determining whether something comprises patentable subject matter. They point out that gold and diamonds, though valuable, are not patentable, regardless of who first discovered gold and diamonds and how difficult this discovery was.

Referring, for example, to Eichenwald (28), they conclude by arguing that broad diagnostic patents may led to the abandonment of methods of prenatal or genetic testing that long have been the standard of care: "This is simply unacceptable. These patents are contrary to good medical practice, and must be prohibited" (27).

Also Tribble (29) argues against exclusive licenses with a single commercial developer for all uses of the invention: "This limits both the potential benefits for human health and the potential for greater financial returns to the academic institution that could stem from their research" (29). Therefore he proposes a kind of compromise position. He argues that scientists could protect their intellectual property rights by granting access to the research tools for research use via nonexclusive licenses to scientists in both academic and industrial laboratories, and simultaneously reap financial returns and realize the commercial potential of the patented technology. He points out that "refusal to grant non-exclusive licenses ... could have a chilling effect on biomedical research and would be contrary to public interest" (29).

Magnus (30) criticizes the approach of PTO in the United States, in particular, the constructivist interpretation of genetic testing to avoid the "product of nature" doctrine. (If something is a product of nature, it does not satisfy the earlier mentioned conditions of novelty and inventive step.) He argues that the strategy of the defenders like McGee will result in an intolerable dilemma for physicians.

ALTERNATIVES AND CONSEQUENCES

Some important questions in this debate are as follows:

1. Which are the available alternatives: protection by patents, with or without specified exemptions, trade secrets, protection of intellectual property rights in other ways, such as by the UPOV-convention, compulsory licensing or no protection at all?
2. What is the range of application, if any, of these methods of protection? Each method could have a different area of application (one for microorganisms, another for plants, still another for animals, etc.), they could be partly overlapping, or totally overlapping.
3. What are the actual or likely consequences of these alternatives for the various stakeholders, including the pharmaceutical and agrobiotechnological industry, farmers and animal breeders, the researchers, the universities, the developing countries, and the entire population of the earth, expected to double in less than 50 years?
4. What ethical considerations should be used in evaluating these consequences: (which) deontological considerations, utilitarian theories, contractualist ethics, and the like? For obvious reasons, it will be impossible to take a stand on the latter issue here. What is important is only to make clear that the choice of ethical framework will have practical consequences; hence transparency and explicitness is important.

The first of these questions deserves some elaboration. Patents provide protection of intellectual property rights. Patents also expire after a number of years and are limited to a geographic area. A patent granted by a national patent office is valid in that country, a patent granted by EPO is valid only in Europe, and so forth. Moreover it takes time and is costly to obtain a patent, and the patentee has to check that no infringements on his or her rights are made. If infringements are made, the patentee has to prove that he or she has suffered damage. Besides, it is always somewhat uncertain what the rulings of the courts will be. What is certain, however, is that the system provides patent lawyers with a great deal of work; it is good for them.

Therefore alternatives to the patenting system have been considered, and the consequences of each alternative, within each particular area (microorganisms, plants, animals, etc.) ought to be evaluated in some detail. An

alternative is to keep the invention secret in order to use and develop trade secrets. This may work (as it has for Coca Cola) if the product is difficult to copy. Further alternatives include inventing other forms of protection, like the UPOV convention for plants, or to carry on without protection of intellectual property rights at all.

REASONS FOR THE PATENTING SYSTEM

The controversies over protection of intellectual property rights via patents also concern the foundations of this protective system and the reasons offered for and against patenting. The main arguments in favor of patenting biotechnological inventions center on justice, economic growth, and openness.

Justice

The standard reasons for patenting include considerations of justice. The idea is simply that the inventor should not be without financial reward while others make a fortune on the basis of his or her invention. The inventor is entitled to economic compensation. The underlying conception of justice in this context is justice according to desert. This means, for instance, that universities can get royalties on biotechnological inventions made by their researchers. For big universities like Harvard or Stanford in the United States these royalties amount to very large sums every year. If these inventions had not been protected by patents, big companies could use these inventions free of charge to increase their own profits.

Economic Growth

The second main line of argument is concern for economic growth — the desire to stimulate the biotechnology industry by the possibility of financial rewards. Society needs research and development, and patent laws are designed to encourage this. Protection of intellectual property rights encourages investments by the private sector in agrobiotechnology simply because it increases the chances of financial reward. For instance, Dompe (31) argues that patents are a useful legal instrument to protect intellectual property rights, allowing society to promote and to support the innovation and development of useful inventions.

Openness

The disclosure requirement in patent laws prevents secrecy and attempts by researchers to preserve exclusivity in access to their discoveries. Thus patent laws work in favor of openness. To obtain a patent, the applicant has to send in a detailed description of what the applicant wants to protect. This description should make it possible for anyone in the field to repeat the process or to manufacture the product in the future. These descriptions can be bought at a very reasonable price from the patent office.

It could be objected that the patent system slow's down scientific publications. But in many countries this problem is taken care of by a clause in the patent laws. In order not to discourage early publication of research results because the inventor is considering to apply for a patent on his discoveries, patent laws in the United States and Canada contain a clause about a "grace period," during which time the author may wait to apply for a patent. In fact this encourages early publication, since the author who publishes first also has the right to (apply for) a patent. But to say this is not to say or suggest that the U.S. patent law requires filing before publication.

REASONS AGAINST THE PATENTING SYSTEM

The standard arguments offered against protection of biotechnological inventions by patenting could be classed into two broad categories: (*1*) objections to the underlying technology itself, rather than to its protection under patent laws and (*2*) objections to the actual or anticipated effects of patenting itself on research and health care, for example (32). Here focus will be on the latter ones. But on a more general note, Hoffmaster (33) has argued that patenting of life forms promotes an irreverent materialistic conception of life. It may affect our attitudes toward life negatively when life forms are treated as commodities to be bought and sold in the market (34), particularly when the organisms to be patented have been modified by gene technology so that they possess human genes (2).

Effects on Research

It has been feared that the patent system will distort the research agenda in favor of potentially lucrative projects rather than the traditional mission of expanding knowledge regardless of potential financial gain. It is clear that there is at least a potential tension between commercial imperatives and traditional scientific norms, such as is evident in Merton's oft-quoted CUDOS norms (35):

- Communism, according to which there is no private ownership of knowledge
- Universalism: hypotheses, objections, and criticism should be treated equally, regardless of the age, sex, race, and nationality of the author
- Disinterestedness: impartiality is essential and researchers should not be influenced by their own economic, religious, political and other ideological interests
- Organized Scepticism: everything may be questioned, and this ought to be done systematically

Heller and Eisenberg (36) take the metaphor of the "tragedy of the commons" as their starting point. This metaphor helps to explain why people overuse shared resources, like water and air. The authors argue that the recent proliferation of intellectual property rights in biomedical research may lead to a different tragedy, a tragedy of the "anticommons," in which people underuse scarce resources because too many owners can block one another. The authors conclude that privatization of biomedical research must be more carefully deployed to sustain both research and product development. Otherwise, more intellectual property rights may lead to

fewer useful products for improving human health. This article has provoked several comments and responses (37).

Along similar lines Merz (38) has argued that the rapidly growing number of disease gene patents — patents protecting all methods for diagnosing a particular genetic condition — will threaten the ability of physicians to provide optimal medical care to their patients. Disease gene tests are being monopolized by a small number of providers. This, according to Mertz, threatens to restrict research activities, creates unacceptable conflicts of interest, may reduce patient access to testing, and may lead to inequitable extensions of patent terms on tests and related discoveries. It will make it possible for patentees to dictate the standard of care for testing, and in that way to interfere with the practice of medicine. In view of these risks, Merz suggests an amendment of the patent law to require compulsory licensing of physicians providing medical services. In the United States, a National Institutes of Health (NIH) proposal, discussed by Flores (39), will restrict the licensing of federally funded biomedical research tools for commercial gain.

Effects on Developing Countries

The development of genetically modified plants, fruits, and animals may undermine the export of products (plants, fruits, sugar, raw material, etc.) from developing countries; the products will no longer be competitive. Since the biotechnological industry is situated in the developed countries, this could increase the gap between rich and poor countries. The rich will be made richer, while the poor will become poorer.

It has been feared that patents can be used as an instrument to exploit the third world. A double exploitation has been evoked. Researchers from rich countries, where advanced biotechnology industries are located would harvest and refine desired biological material from the developing countries. The derived products now protected by patents or the UPOV convention, would be sold back to farmers in the countries from which they originate, and the seeds made sterile so that they can only be used for one crop.

Concern has also been expressed in the *Bulletin* of the World Health Organization (WHO) that recent global developments in the regulation of trade and intellectual property rights threaten to hinder the access of populations in developing countries to essential drugs. Velasquez and Boulet (40) have argued for state intervention in the health and pharmaceutical markets in order to guarantee equitable access to these essential products.

Serageldin (41) has argued that biotechnology can contribute to food security if it benefits sustainable small-farm agriculture in developing countries. The agrobiotechnology focus has been on ethical, safety, and intellectual property rights issues. An effective system of protection of intellectual property rights would encourage investments by the private sector in agrobiotechnology by increasing the chances of financial gain. But, as Serageldin argues, in developing countries the needs of small farmers and environmental conservation are unlikely to attract private funds. Public investment will be needed, and new and imaginative public–private collaboration could make the gene revolution beneficial to developing countries as well.

Thus there is particular cause of concern for the effects of licensing and patents on farming and agriculture in the developing countries. Traditionally these countries have had two important sources of income. The first is cheap labor, which is less important today than it was, because of the rapid development and widespread use of industrial robots and information technology. The second important source of income is their raw material and agricultural products, which the developed countries do not need today to the same extent as before, because of the rapid progress of biotechnology.

Effects on Environment

The major part of the world's collected genetic resources are to be found in tropic or subtropic areas, that is to say, mainly in the developing countries. Will genetically modified plants yielding better crops in the future replace traditional domestic plants? Will this lead to a reduction of biological diversity? And is this to be deplored? For what reasons? Here empirical and value questions are intertwined. There is clearly a risk that biological diversity is threatened by present developments in plant breeding.

Will patenting increase the risk for environmental problems? Will patenting of animals make the situations of animals worse? To view the problems in a proper perspective, however, it is important to realize that environments can be endangered also by release of products that are not protected by patents. This is usually the case in air and water pollution. Thus the pressing problems of preservation of the environment need to be addressed independently of the problems discussed in this article.

A precautionary principle has been launched in the international debate, in the wake of the Bovine Spongiform Encephalopathy (BSE) ("mad cow disease") and various threats to our environment: Irreversible processes in nature should not be started, such as by using genetically modified and patented seed (or salmons) that may spread in nature in uncontrollable ways. Ethical arguments in this area had better be regarded as preliminary and provisional, and if mistaken judgments are made, such mistakes should preferably have been done for a good purpose. This, of course, presupposes that ethical analyses are made both of the research that eventually leads to a patent, in the application for a patent, and in the use of a patented product.

Effects on Industry, Farming, and Agriculture in the Developing Countries

The impact of patents on demographical structure of society may alter the settlement patterns of populations. Sparsely populated regions may become more sparsely populated due to migrations. The direct and indirect impacts of migration on various economic interests is another cause of concern and another reason for criticism of the patent system.

It has been argued, for example, that the higher cost of patented livestock or seed will restructure farming. Small farms will be put out of business, and there will be even more concentration of corporate agriculture. Agricultural patenting also undervalues the contributions of less developed countries to biological diversity (42).

Further, with the increasing globalization of the world economy, the biotechnology industry may be restructured worldwide. Knowledge and economic resources may be concentrated in a few big corporations. Already large corporations have merged, and small companies are finding it difficult to survive in the market place, particularly those in the developing countries.

VALUE CONFLICTS AND FURTHER ETHICAL ASPECTS

What are the possible benefits? Which are the risks? To make this explicit, we must look to identify some of the value conflicts. The possible economic benefits are as follows:

- Consumer values, in terms of better-tasting grapes, firmer tomatoes, bigger oranges
- Producer values, in terms of increased crops for farmers, pigs with faster or increased muscle growth
- Company values, increasing revenue, such as by developing and marketing plants resistant to pests afflicting specific species
- Environmental values, such as in developing plants resistant to herbicides so that fewer herbicides are used by farmers

The monopolies achieved by patents will stimulate technological inventions, but they may clash with ideals of free competition. A patent will give an air of legitimacy to an invention, but this is sometimes what is challenged. Free competition is a value, and so is reward for beneficial work.

These values may clash or be combined, according to each particular case. They have to be compared to other positive and negative values wherever the values clash: increasing unemployment among the population, immiserizing growth in the developing countries, health risks for patients (if patents and royalties change the standard practice of medicine so that tests cannot be performed because of expensive royalties), health risks for large segments of the population (if genetically modified products are not safe to consume), environmental hazards (if genetically modified organisms are released into nature and cause ecological problems).

So what economic, social, psychological, environmental, and medical values are at risk, and whose values are these? Further, which values are favored or promoted by the various alternative methods of protecting, or not protecting, intellectual property rights?

Is it the prosperity of one group against the prosperity of another? The prosperity of one group against the health of another? The prosperity of one group against the welfare or quality of life of another? If two families of values clash, and both are equally legitimate, we are facing an optimization problem. If one is arguably more legitimate than the other, the situation is, of course, different.

A Strategy of Analysis

The questions are difficult, strong economic and other interests are at stake, and the terminology invites talking at crosspurposes. Therefore, it is essential to be explicit and open, try to separate different kinds of disagreements, make clear what we know as well as in what areas there are considerable gaps in our knowledge, and to identify the alternatives, the stakeholders and their interests, and the principles used in assessing these interests.

Consequences for human and animal welfare, broadly defined, are clearly important considerations in this debate. Consequentialists argue that they are the only important reasons. Moral philosophers of other persuasions want to supplement consequentialist arguments with deontological, contractual, egalitarian, and other considerations, to use appeals to human rights as a basis for claims as to what human beings and animals are entitled to, or as negative restrictions for what others may do to them.

Many other ethical problems than those discussed here are raised by recent developments in biotechnology, such as issues of informed consent and remuneration to those from whom genetic material has been collected. The celebrated case Moore case (*Moore vs. University of California*) illustrates this. The court ruled that Moore was not entitled to a share in the profit made by the company that had used tissues he donated, but the court criticized the information Moore had received as inadequate (43). The special problems raised by human tissue banks (collection, preservation, access, purpose, etc) are also relevant but will not be discussed here.

Underlying Assumptions

The controversies described here are important and interesting because they bring to the foreground a number of underlying and culture-dependent assumptions on what the human being is, what the place of humans is in nature, whether there is a radical and sharp distinction between humans and other living organisms and what constitutes this difference. That is to say, what differences, if any, exist between humans and the so-called undignified biomass, between what is considered natural or unnatural? To what extent is everything living an end in itself, or are humans entitled to exploit animals and plants as well as human DNA for their own purposes, and so forth? Views on these matters may vary somewhat among cultures, and also within a culture over time. There are also indications of interesting recent value changes in the relations between humans and nature. Here is an interesting area for research.

Who owns the genetic resources, in particular the human genome? Among the alternative views are the following:

1. They are the common heritage of humankind. This is a position undermining the whole system of protecting intellectual property rights in this area

via patents: It implies no patents on disease genes, no royalties on biotechnological inventions involving the human genome.

2. The genetic resources belong to the country where it is found. This could be taken to mean that royalties for patents of biotechnological inventions based on genetic material found between the borders of a country should go to the country of origin. This is a more general point, and it is applicable outside the field of biotechnology and genetic resources as well.
3. The invention belongs to the company or the researcher who developed it, applied for, and was granted a patent — the inventor is entitled to royalties. As already mentioned, at the base of this position is an argument of justice, but a different one from that used to support the previous position.

Since a large share of the world's collected genetic resources is to be found in tropic or subtropic areas, consisting mainly of the developing countries, the second alternative might favor developing countries, and this has been their line of argument for the most part. Alternatives discussed at the Rio Convention have also been tried, calling for the transfer of technology from developed to developing countries and royalties on patents developed from genetic material found in the country, in return for the right to harvest and refine genetically the desired material from a developing country.

These basic views could be backed up by religious, social, economic, and legal reasons. Like the underlying assumptions mentioned above, they point to the cultural context in which this debate is taking place, and where there are considerable differences as to views and traditions both between and within developing as well as developed countries.

Appel (44) argues in his analysis of the human body and patent law that human life must not be allowed to be reduced to "undignified biomass" and that protection should be guaranteed from the beginning of life, from embryonic stage. Can patent offices be in a position of assessing the risk factor of a genetic engineering invention? Is there justification for excluding therapeutic treatment from European patent law? Appel argues that this has an extremely inhibiting effect on research.

As is often true in difficult cases, there are good arguments on both sides and many difficulties in assessing the relevance and tenability of the reasons given. Often one has to take a close look at each separate case before making a judgment.

CONCLUDING REMARKS

In view of the strong commercial interests, and the rapid development of biotechnology, future trends are hard to predict. But it is essential that the ethical aspects of patenting and licensing are not neglected. Different constructions of licensing and protection of intellectual property rights, whether by patents or in other ways, will create winners and losers. Who will be the winners, and who the losers, in the short and the long run? And who should decide this? For careful consideration of these issues, the many underlying conflicts of interests and value clashes need to be made explicit, as well as the principles used in weighing the conflicting interests.

The ethical issues underlying licensing and patents are relevant from the start of the research that eventually leads to the patent, to the examination of the patent application and the decision whether or not to grant a patent, and to the actual use of the patent. This means that all biotechnological research project should be decided under the aegis of an ethical review board, and not just certain medical projects involving patients.

The various patent offices sometimes express frustration when they have to deal with ethical issues. This is not something they are prepared for. It may not be the role of EPO to engage in ethical debates and take a position (45). Other national and international fora exist for the discussion and analysis of the social, ethical, and other extrajuridical aspects of patenting and patentability. One solution may be to suggest different fora and to make a clear division in the discussion and analysis between legal and ethical aspects of patent applications.

Ideally, then, a patent will not be granted if the application offends public order; the issue of morality will be relevant, and controversial applications will be contested. Lawyers will review each application and provide examples of what they consider to be compatible or not compatible with this or that related clause. An attempt could then be made to interpret the clauses in the light of this praxis or to describe the changing praxis of various patent offices.

Since patent applications are certain to come in an increasing extent from different countries, international cooperation and harmonization of patent laws will be important in the future. Comparative research in the present situation of globalization is obviously essential. What are the similarities and differences between the approaches in Europe and the United States concerning plant protection? Concerning protection of biotechnological inventions in general? With focus both on the current framework and future developments (8,46)? The studies should include countries not mentioned expressly here, such as Japan and China. By noting similarities and differences, problems as well as possibilities can be identified.

OUTLINE

INTRODUCTION

Almost every person who enters a doctor's office for a routine examination can be sure to leave some of their body tissue behind. Typically requests for a blood or a urine sample are a minimally invasive part of the standard routine of clinical practice, enabling physician diagnoses of ailments, and more commonly, of good health. In nonclinical settings, such as research studies, samples of human body tissues may be collected for purposes of assessing disease prevalence or susceptibility. DNA analysis of waste tissue, such as saliva or hair, can reveal very detailed genetic information about a person. Persons may also part with their body tissue with the intent to benefit others: Gametic tissue, for example, may be donated or sold to enhance the prospects of fertility treatment of another person in otherwise good health. In acute crisis settings, donation of an organ or tissue, such as bone marrow, may be a life-saving therapy.

There are, in short, many purposes in clinical medicine and biomedical research that involve retrieval and sampling of human body tissues. The procurement and use of human tissue in diagnostic, therapeutic, research, and educational purposes illustrates how contemporary scientific study understands the human body as a source of medical information. The National Bioethics Advisory Commission recently estimated there are over 282 million body tissue specimens collected throughout the United States, a figure that is increasing by an additional 20 million specimens each year (1). This practice has been

accelerated significantly by research on the human genome and by the advent of genetic technologies in medicine, which can provide valuable diagnostic and prognostic information about a person, family or ethnic community.

This increasing use of body tissue as an information resource in the grand projects of contemporary biomedicine presupposes views about the moral status of the human body, of its parts and tissues individually and in aggregate, and of conceptions of self-identity. These biomedical assumptions may be compatible with, or in conflict with, philosophical and religious perspectives, as well as cultural and personal attitudes. This article will reflect on some major issues regarding the moral status of body tissues, beginning with an examination of the relation between the self, the body, and excised body tissue. Analysis and ethical reflection on the status of body tissue requires attention to prominent metaphorical understandings in scientific and research discourse, and provides a basis for ethical transfers of body tissue from patient to researcher. However, important questions must be addressed regarding the limits of use of body tissue in order to avoid abuse.

BODY AND SELF

Attitudes Toward the Body

Moral reflection on the status of body tissue must first begin by considering tissue in relation to the organic bodily whole and to the self. Bioethicist William F. May has distinguished five philosophical attitudes on the status of the body and its parts that are useful to review in the context of retrieval of human tissue (2):

Dualism — Gnosticism — Holism — Materialism — Idealism

May differentiates these attitudes based on questions regarding whether the body has a phenomenal reality, is ontologically good, and is intrinsic or incidental to personal identity.

Dualism. Dualism affirms the phenomenal reality of the body but denies its goodness because of the body's association with flesh and matter. Dualism portrays the body as "at war" with the self, its literal mortal enemy. Parts of the body, disposal of the body, and persons who come into contact with the corpse are denigrated, stigmatized, and considered taboo and sources of pollution or uncleanness.

Idealism. At the opposite end of the continuum, idealism denies that bodily life has any ultimate significance. The body, disease, and death are constructs of the mind that can be transcended through identification with a separate realm of the spiritual. The self seeks its true home in this noncorporeal realm of spirit. Idealism supports practices of spiritual healing rather than medical ministrations in response to disease. Body parts, or study of the body, are viewed as existentially indifferent within the idealistic worldview.

Gnosticism. The gnostic attitude seeks liberation of the true self from the body through knowledge. The true self resides in a disembodied mind or consciousness, while the body is a prison of the soul. Liberation entails overcoming the burdens of mortality, including finitude, disease and death. Body parts have no significant value, and may even have disvalue, insofar as a preoccupation with bodily life can hinder the quest for liberation.

In contemporary Western thought, May argues that the gnostic attitude has assumed the form of philosophical Cartesianism. Philosophical and moral emphasis is placed on the mind or consciousness, distinct from the body. The body (and body tissue) is a possession and instrument of the rational will, useful as a tool to achieve the self's own goals and aims, but assumes no independent value of its own. Except in those circumstances where the body may impinge on and frustrate the plans and desires of the rational self (e.g., in illness), the body and constituent body tissues can be assessed as morally indifferent.

The Cartesian separation of self (mind) and body (matter) is embedded within the ideology of biomedical research; the body may be perceived merely as a resource for obtaining raw biological materials from which information and knowledge can be retrieved. In turn, this knowledge can be converted into technologies, therapies, and pharmaceutics that enable mastery over nature (3). The separation of self and body would also seem to imply there is no moral necessity for informed consent to the removal of bodily tissue, or subsequent research and manipulation. Even though bodily space is violated by such procedures, since a body is incidental to personal identity, the retrieval of an organ, tissue, or cell cannot be said to violate the person and their integrity. In this regard informed consent appears to be a rule without a rationale. However, the increasing importance of informed consent procedures in the procurement of human tissue for research (4) is a signal of a fundamental inadequacy of the Cartesian/gnostic perspective.

Materialism. In contrast to a knowledge-based quest for philosophic liberation and biomedical mastery of nature, the materialistic attitude to the body is informed by an ideology that human life is subject to, and at the mercy of, powers in nature that are arbitrary, abusive, and destructive. This can lead to two different and conflicting perspectives, avoidance and denial (of aging, death, etc.), or resistance, both of which resonate in contemporary Western cultures, including biomedicine. The perspective of resistance is enacted primarily through the practice of medicine and its war on death and human disease (5). In the medical effort to resist the inevitable natural course of bodily morbidity and mortality, the body assumes the role of primary "battleground." Patient consent to invasive procedures (an "invasion" not only of the body, but against nature) still leaves the patient as principally a passive observer to the battle plan carried out by physicians. A successful war often requires excision of body parts and removal of tissue. This body tissue is not only surplus but also is a valuable diagnostic and prognostic information source.

Holism. Within the typology constructed by May, the dualistic, gnostic, and materialistic attitudes are compatible with the interests of biomedical research in human tissue. The idealistic attitude, by contrast, finds in medical research a misguided attempt at medicalization of the metaphysical. This implies that scientific proposals for using human tissue samples are an *ethical* issue primarily in those traditions — philosophical, religious, and medical — that affirm a holistic attitude of human embodiment. Holism expresses an intrinsic relationship of body and self, in contrast to the instrumental value embedded in Cartesian and materialist thought. Holistic traditions claim for the body an ontological reality of the body (in contrast to idealism) and an intrinsic moral goodness (in contrast to dualism). Moreover the traditions of holism affirm the intrinsic nature of the body to personal identity: Human beings are embodied selves, not simply a soul or a mind housed within a corporeal prison.

The holistic attitude thereby supports a presumption in favor of bodily integrity and intactness (even beyond death in some cultural and religious traditions). However, this presumption can be overridden for purposes of preserving the health of the person or for providing direct therapeutic benefits to others, as in transplantation. The reality and goodness of the body entail the use of medical procedures to restore and heal. The fundamental connection of body and self makes consent of the person a moral mandate with respect to invasive medical procedures and removal of bodily tissue, healthy or diseased. Given the integration of body and self, holism places significant emphasis on accountability for uses of the body and an orientation of uses of excised body tissue toward the common good. Ethical positions and liturgical rituals, for example, justify sharing of the body and its constituent organs and tissues as a form of altruistic service to others. Thus an understanding of body tissues as "gifts" is prominent in discourse with respect to organ transplants or transfusions of vital tissues, such as blood or bone marrow (6,7).

A more circumspect attitude is characteristic of holism toward research or educational uses of body tissue. Until the onset of the era of genetic and molecular medicine in the mid-1980s, holistic discourse largely followed the lead of technological capacities and examined the status of human organs and tissues with respect to donation for therapeutic goals. Despite ongoing collection and analysis of pathological tissue specimens, very little ethical discussion was devoted to nontherapeutic research uses of human tissue, other than questions pertaining to autopsy procedures.

Conflicts: Bodily Integrity and Disintegration

Although these five attitudes about the body are compelling as basic or ideal types, none can fully accommodate the complete range of bodily experience nor the new requests for body tissue precipitated by emerging biomedical technologies. Holism requires modification to accommodate scientific interest in body tissue, particularly those tissues that are not core to the conception of self. Similarly attitudes congruent with scientific interests — dualism, gnosticism, materialism — must be adapted to account for human experience that displays that the self is more than the mind, and that the body, and at least some bodily tissues, are not mere instruments but are morally and symbolically significant.

For example, empirical studies suggest that it is not only the body as a whole but also body parts, organs, and tissues that can be formative of self-identity (8). Visible parts of the body, such as skin, genitals, fingers, hands, legs, and eyes, as well as the heart, have a strong correlation with a sense of self. With the exception of the heart, nonvisible organs and tissues are not as strongly incorporated into a sense of self. Thus not all body parts possess equal ontic status, or are equally important to self-identity. It is possible, as Belk (8,9) suggests, that the less an organ or tissue is connected with a sense of self-identity, the more willing a person will be to donate it for use by others or to have it retrieved for purposes of a scientific research study.

Despite this possible convergence of scientific and nonscientific attitudes on the body regarding the specific question of the status of body tissue, an important question about the starting point for inquiry is still unresolved. Philosophical or religious claims about the ethical significance of bodily integrity can conflict with scientific and research interest in parts of the body, that is, the body as a disintegrated entity.

While the human body as an organic totality has long been the subject of philosophical reflection and a symbol of political (Plato's "Republic") or religious ("the body of Christ") communities, the interest of medical science often begins with a micro unit as its point of inquiry, the "building blocks of life," or DNA. DNA constitutes the fundamental components of life, with stem cells and somatic cells, tissues, organs, bodily systems, and the like, viewed as more complex, functional expressions of basic genetic materials. The scientific value of the body as a totality is thereby a means to the goal of deciphering the codes, messages, and functions of the genetic building blocks that contain valuable information.

In some circumstances these different starting points will generate quite different ethical conclusions about appropriate interventions, manipulations, and excisions of the body and its tissues. Legal philosopher E. Richard Gold cites the "disparate claims of scientific investigation and religious belief" as the exemplary case of incommensurate values regarding the body. According to Gold, "The body, from a scientific viewpoint, is a source of knowledge of physical development, aging, and disease. From a religious perspective, the body is understood as a sacred object, being created in the image of God. . . .The scientist values the body instrumentally, as a means to acquire knowledge; the believer values the body intrinsically, for being an image of God" (10).

The Mechanistic Body

Perhaps the most prominent discursive scientific understanding of the body, which has its roots in the intellectual Enlightenment, the industrial revolution, and Cartesian science, is that of a "machine." Among others of his generation, Thomas Jefferson clearly expressed this understanding toward the end of his life: "But our machines have now been running seventy or eighty years, and we must expect

that, worn as they are, here a pivot, there a wheel, now a pinion, next a spring, will be giving way; and however we may tinker them up for a while, all will at length surcease motion" (10). The role of biomedicine becomes very clear in the mechanistic understanding of the body: to "fix" the worn-out parts through technical acumen and knowledge, perhaps to replace others through transplantation, and to improve on still others through research and engineering. Research on body tissue becomes an important gauge by which to determine the various developmental and functional processes of cells and tissues, as well as providing a means to identify what has gone wrong in case of malfunction.

Clearly, a valuation of the body that is mechanistic and instrumentalist will permit more research interventions and manipulations than will a position that affirms the intrinsic value of the body and its inextricable intertwining with the self. Moreover tissues retrieved from a mechanized body may elicit sentiments of revulsion rather than respect. The distinction between the status of organs, tissues, and fluids when they are incorporated within the body rather than outside and separate from the body is displayed in a memorable illustration by psychologist Gordon Allport: "Think first of swallowing the saliva in your mouth, or do so. Then imagine expectorating it into a tumbler and drinking it! What seemed natural and 'mine' suddenly becomes disgusting and alien. . . .What I perceive as separate from my body becomes, in the twinkling of an eye, cold and foreign" (12).

The emphasis on bodily integrity in the western religious faiths has culminated in the development of stigmas and taboos regarding certain bodily tissues when they are external rather than internal to the body (12). Characteristically the dis-incorporation of bodily tissues is assessed by religious thought with reference to issues of purity and cleanliness. A very prominent historical illustration of purity, which has permeated secular culture and has not been entirely overcome in contemporary religious communities, are stigmas and taboos surrounding menstruation (13).

There are then different ways of assessing the moral status of the body and of body organs and tissues depending on the "place" of the organs or tissues, that is (*1*) intrinsic to self-identity (e.g., heart) or incidental, (*2*) visible (eyes, skin) or hidden (kidney), and (*3*) integrated (circulating blood) or dis-incorporated (bodily excretions). In general, it may be claimed that the more an organ, tissue, or fluid possesses intrinsic connection, visibility, and integration, the more its retrieval and use for biomedical research purposes may present ethical questions. Put another way, philosophical and religious thought on the body begins with a strong presumption that the status of the body as a whole is greater than the sum of its parts. Body organs and tissues contain potent symbolic significance when considered as part of the bodily whole. Yet, when considered in isolation from the rest of the body, organs and tissue may generate revulsion and stigmas. This ambivalence can be heightened or ameliorated by scientific research that seeks to use body tissue for any number of research, therapeutic, or commercial purposes.

These perspectives and conflicts must be faced directly in the face of, and in anticipation of, technological advances in the realms of genetics and reproduction. Such advances have vastly expanded the biomedical gaze and the scope of scientific and medical interest in the body and its tissues. There is now virtually no part of the body that may not be the subject of scientific scrutiny. Genetic analysis in particular offers the prospect of gaining information about human character traits and behaviors, including susceptibilities to illness and bodily responses to disease, through study, analysis, and understanding DNA. Such information is not otherwise possible through an examination of the bodily totality. An assessment of body tissue as it is related to, and separated from, the body is inescapable in the context of biomedicine and biotechnology.

UNDERSTANDINGS OF BODY TISSUE

Metaphors of Body Tissue

Assessing the moral status of disincorporated body tissue can be illuminated by analysis of important metaphors that emerge in scientific and ethical discourse. These metaphors function to provide an understanding of something relatively unfamiliar, such as the significance of DNA or body cells, in terms of something more familiar and concrete.

Library. A central metaphor in discourse about the human genome project, for example, is that of a "book" or "library." This metaphor highlights the "information" stored in genes and cells, which scientists seek to retrieve and interpret through genetic analysis. Although information itself is often said to be value free, the process of determining what counts as information and what is "junk DNA" is clearly value laden. Indeed, as Rosner and Johnson observe, "By the choices [the genome project] makes — the choices of what books to include in the library and in what condition — the Project will determine what is 'correct,' what is 'real.' It will necessarily set standards, defining and cataloging what it means to be human, limiting what range of diversity is acceptable" (14).

The library metaphor highlights the extraction of information as the primary feature in research on body tissue. This implies that bodily tissue has at best instrumental moral status. What is concealed by the metaphor, however, is that unlike the information contained in a library, which is generally publicly accessible, the information that is retrieved from genomic studies is highly personal and sensitive. The information stored in any DNA library can be interpreted in ways that hold out implications for personal identity, including comparisons to a collective group standard or prospects of personal risks of disease susceptibility.

The information itself is of moral significance and should thus be treated in a manner equivalent to other forms of medical information. As with any information that is personally identifiable, there are legitimate concerns about the uses and potential for abuses of genetic information. Thus, in some jurisdictions, regulations

and laws have been passed to ensure privacy and confidentiality of genomic information and to protect persons from discrimination.

For example, the Genetic Privacy Act passed in 1995 in Oregon affirms: "The DNA molecule contains information about an individual's probable medical future. . . .Genetic information is uniquely private and personal information that should not be collected, retained, or disclosed without the individual's authorization." While employers or insurance companies may, with consent, have access to a person's genetic information, the law prohibits the use of such information for purposes of hiring or setting insurance rates (15).

Resource. A second prominent metaphorical understanding of human body tissue is that of a "resource," most commonly, a resource that has been removed from its "natural" integrated state in the body and is thus accessible for a variety of scientific manipulations and purposes. More specifically, body tissue is portrayed in terms of a valuable mineral resource: Genetic analysis is described as a "gold rush," umbilical cords are referred to as "clinical gold," a patient's body as a "gold mine," and the researchers themselves assume the role of "gene prospectors" (16).

Ultimately the image behind these metaphors is that of the body as the "new frontier" encountered by cutting-edge science, a wilderness that biomedical science seeks to map and mine and ultimately to master and domesticate. Exploring the frontier requires and rewards individual initiative, thus it is not surprising that aspects of the resource metaphor move in the direction of commercial and entrepreneurial exploitation of body tissue. As Andrews and Nelkin express it, "Body parts are extracted like a mineral, harvested like a crop, or mined like a resource" (16).

The frontier or wilderness is also a realm beyond moral control; thus, as the frontier begins to be explored, and resources extracted, rules must be developed to facilitate a coordinated discovery effort. If the metaphor follows historical patterns, however, then there is ethical reason for concern: If the human body of the early twenty-first century is treated in terms analogous to the land and mineral rushes of the nineteenth century, short-term benefits may be obtained at the expense of harms that befall future generations. When the bodily frontier is viewed as an exploitable natural resource of immense scientific interest, a question arises about the extent to which researchers will take steps that respect and ensure the integrity of the whole.

The resource metaphor of body tissue is distinct from but certainly compatible with the book or library metaphor. Indeed, body tissue is a resource *precisely* because it contains information. The purpose of procuring tissues for research is to generate generalizable knowledge, for example, advancing researchers' understanding of the genetic dimensions of human diseases. However, this research has yet to yield significant promise of therapeutic benefits to persons afflicted with those diseases. Similarly investors in a biotech company engaged in genetic research may have to stay with their investment over the long haul until the research bears fruit in a commercially marketable product. This distinction between basic research that provides information or enhanced diagnostic capabilities in the short term but defers therapeutic (and entrepreneurial) benefits to the distant future is one point of criticism in ethical assessments of genetics research (17).

Property. Both the library and the resource metaphor are inadequate in at least one morally essential respect: They overlook authorization from the person from whom the body tissues are retrieved. The genetic library is not a public library, but contains very intimate, private information, that can accessed only by a select few, and only then upon consent. Similarly a person's body tissue is not a resource commons. Thus, lest scientific explorations on the frontier of the body become unnecessarily invasive of privacy and trespass integrity, or body tissue be subject to the research equivalent of a public land grab, a third metaphor of body tissue has been promoted to address issues of control and authorization. This is the model of the body and of body tissues as "property" (18,19). The property understanding stems from a claim of self-ownership, and it seeks to authorize the individual person, patient, or research subject, rather than the scientific prospector, with control over the use and disposition of the body and of body parts.

Not unlike some of the scientific attitudes about the body discussed previously, the property metaphor tends to treat the body as incidental rather than intrinsic to personal identity. The philosophical assumption is that the body even as a totality is distinct from the self, and body organs and tissues can therefore be transferred or alienated to others without compromising the integrity of the self. Thus, with the proviso that informed consent is obtained from the person, these assumptions make the property perspective very conducive to scientific interest in body tissue. However, conflict can arise when, for example, a patient and a researcher assert competing claims or "property rights" to excised body tissues, or to cell lines that have been isolated from retrieved tissue.

The Moore Case

The most prominent example of such conflict involved the case of John Moore, who sought treatment for a rare disease, hairy-cell leukemia (20). Moore's physician recommended a splenectomy, which was performed with Moore's consent. However, the physician recognized early into the course of treatment that Moore's body was overproducing lymphokines, an important component of the human immune system. Samples of Moore's blood, skin, bone marrow, and sperm were then retrieved in follow-up visits. Cells from these tissues were cultured and altered to create an immortal cell line, which was patented and commercially developed, without Moore's knowledge. Upon learning of this activity, Moore brought a lawsuit, alleging that he retained ownership of his body tissues and cells and that the research had wrongfully used his "property" to benefit others. Moore's proprietary interests in the removed body tissue and cells were rejected by the Supreme Court of California, although

the court did find he had a compensatory claim if he had not been informed by the physician of the prospective research use and commercial development of the tissue. The majority opinion rejected Moore's claim on the basis that granting Moore property rights would impede scientific progress. A decision in favor of Moore, it was claimed, would open the door to actionable claims by patients any time body tissue was retrieved for research purposes. Moreover pharmaceutical companies would be deterred from investing capital and energy in new product development for fear of litigation.

The Moore case throws into sharp relief many questions about ownership and control embedded in any situation where body tissue is removed from a patient. There is no dispute that, when the tissues and cells are functioning as integrated parts of the intact bodily organism, they are under the authority and control of the patient. However, does the patient relinquish any and all claims and interests to the tissue once it is excised from the body? Do physicians or researchers gain rights of ownership to the tissues that are removed by their labor? Such questions necessitate attention to various modes of transfer and acquisition of body tissue.

TRANSFER AND ACQUISITION

The property, library, and resource metaphors assume the validity of the use of body tissue, so long as consent is voluntary and informed. Consent provides authorization for the transfer of body tissue from a patient or subject to a researcher. However, consent is only a necessary, rather than a sufficient, condition of morally justifiable transfers. Questions must still be addressed concerning the limits to be placed on such transfers and on avoiding abuse in research on acquired tissue.

Modes of Transfer

An analogy can usefully illustrate the moral context of these issues. I will adapt Belk's observation that "the house is a symbolic body for the family" (8,9), and construct an analogy wherein household goods take the place of human tissue samples. The relevant question is the manner of transferring household goods. I want to focus on four modes of transfer, all of which have correlates in methods of transfer of bodily tissue (21).

Donation. One transfer method is to donate certain goods such as clothing to a community goodwill program. This presents an example of a gift or an altruistic action designed to benefit others and to enhance a recipient's quality of life. Similarly various life-saving organs and tissues, such as blood, have been referred to as "gifts of life" in popular discourse.

Contribution. A second form of transfer concerns those household goods whose designed use has been depleted by members of the household, for example, food products that come in plastic or cardboard containers or newspapers. These containers and other materials could still be used for some household functions, such as for storage or for starting a fire; they are not without household utility. It is also possible, however, to contribute these materials for a greater good, the benefit of the community through recycling. An important difference between donation and a contribution is that the donated goods are typically transferred and used in their original form, while a contributed good, be it a household container or body tissue, undergoes some alteration before re-use.

The recycling approach requires communal support of organizations with the knowledge and expertise to convert the recycled materials into valued products. Similarly a biomedical research institution may retrieve certain tissues contributed for the greater good of the advancement of scientific knowledge. Researchers can then subject the tissue to a research process in which cells are isolated to yield a valuable immortal cell line or genes analyzed to provide information.

Abandonment. A different set of household materials are those goods that have been consumed completely, and whose benefits have been exhausted by household members. The packaging protecting these materials is now "waste" and is commonly discarded through a community utility such as a trash collection service. Household refuse has no personal meaning to the discarder, who is typically quite willing to abandon the refuse and even pay a fee to have the items removed. This does not, of course, preclude the possibility that this refuse might have value to someone else who is willing to take the time to sort through the materials. Similarly at least some bodily tissues are referred to as "waste" or "garbage" in biomedical literature (22,23), even though research processes may transform the tissues into a beneficial and profitable product.

Property Sale. A fourth form involves transferring the household goods to others through an informal market transaction, the "garage" or "yard" sale (or through classified advertising). In these situations the original owner hopes to obtain some financial gain through the transfer, although the expectation is that neither the purchase price, nor the quality of the goods, will be as high as if the purchaser had obtained a similar item through an established business. These informal transactions occur parallel to, but outside of, formal and regulated market mechanisms and controls; once the transaction has taken place, there is no expectation of a continued buyer–seller relationship. Procurement of some body tissue does occur through buying and selling, although typically the seller remains anonymous.

It may be the case that all of these modes of transfer, and their biomedical analogies, have a role in considering ethical issues in research acquisition of body tissues. As suggested, there are precedents already for tissue as a donated gift, as a research recyclable, as abandoned refuse, and as a commodity. However, certain tissue may be considered more or less appropriate to a particular form of transfer.

This differentiation may, in part, rely on a sense of connectedness to self-identity delineated above. Some body parts, such as the heart, eyes, or blood, may have such

symbolic significance and connection to personal identity that their donation is the moral equivalent of a gift of self. Donation or contribution imagery may seem more fitting with the transfer of such tissues than abandonment or selling. Other body tissues, for example, urine or hair clippings, may have such minimal value to a sense of self that they are considered "waste" and routinely abandoned. Still other organs and tissues, such as a pancreas, liver, spleen, or marrow, may fall in between these examples, not as central to personal identity as the heart or eyes but not as incidental as urine either. Still other tissue, such as gametes or blood, may be considered so vital to the creation of life or to the maintenance of life that society is willing to permit a limited market to function to procure these tissues.

Of the above modes of transfer, gifts or donations have a prominence in discourse relative to contribution, abandonment, or sales. The discussion below will explain this prominence through examining the features of what may be designated the "donation paradigm," and it then will assess the extent to which methods of contribution, abandonment, and selling retain or violate these features.

The Donation Paradigm

Ethical thought on the body and its use within medicine has presupposed a context within which organs and tissues are donated for therapeutic purposes of healing, restoring, or saving life. This moral ideal is emphasized through the language of "gift," "altruism," "sacrifice," and so on, on the part of the donor and that of "benefits" for recipients. The donation paradigm seems constructed by four principal features:

Altruistic Intent. The intent of the donor of an organ or tissue is structured by gift-giving to beneficiaries or recipients, such as persons on a waiting list for a transplant (although the identity of such persons may be veiled from the donor).

Therapeutic Expectation. The expected outcome of a gift of the body is that it will be used in such a way as to offer a pronounced therapeutic prospect for the recipient. These prospects encompass both enhancing quality of life and preserving life.

Generative Re-incorporation. Body tissue that has been retrieved from the donor, or dis-incorporated, should in most circumstances be re-incorporated within the body of the recipient. As noted above, tissue that is dis-incorporated may evoke sentiments of revulsion and practices of stigma and taboo. Some religious practices and rituals require burial of removed body parts, or re-incorporation in the earth. This is particularly the case with body parts that have an identifiable human form: In Jewish thought body parts such as limbs, composed of "flesh, sinew, and bones," should under most circumstances be buried. Roman Catholic tradition distinguishes major from minor parts of the body in a similar manner. Major parts of the body are those, such as a limb, that retain their "human quality" following excision and should be buried (24). Such concerns reflect in part the importance of these visible body parts for self-identity.

Re-incorporation of body organs or tissues in a human recipient has a generative power in that it offers the prospect of new or renewed life to the recipient. In general, then, the donation paradigm prioritizes practices in which body tissue remains with a body (even if transferred and transplanted to the body of another person) and thus symbolizes the significance of bodily integrity and holism.

Recipient Responsibilities. The gift of body tissue carries with it certain responsibilities on the part of the recipient, which are embedded in everyday practices of sharing and gift-giving (25,26). These responsibilities include a sentiment of gratitude toward the gift-giver, or toward the institutional structure that mediates the gift transfer. Gratitude may also be enacted in the actions and conduct of the recipient by which he or she makes grateful use of the gift. In addition a gift induces a responsibility of reciprocity. Reciprocity does not necessarily mean the continuation of the gift relationship between the initial giver and recipient; rather, a recipient of donated blood, for example, may at some time in the future become a donor for other strangers.

The donation paradigm provides a moral justification for medical use of human body tissue. It is especially prominent in bioethics discourse because it highlights simultaneously moral virtue and altruism, and medical success, the restoration of life to the nearly dead. The paradigm is limited, however, for the most part to medical practices of transplantation or transfusion, that is, those practices that promise some form of therapeutic outcome from the gift. However, different models seem necessary to accommodate biomedical retrieval and use of body tissue in circumstances where nontherapeutic uses of body tissue are contemplated (e.g., tissue contributed for research and educational purposes) or where altruistic intent is absent (e.g., abandonment and sales).

Contributions

The idea of body tissue as a contribution shares with the donation paradigm the intention of gift-giving or altruism. However, the anticipated outcomes are rather different. The goal in research or educational uses of human tissue is to advance scientific learning and to generate knowledge that is generalizable, not to furnish a prospective therapy for an individual recipient (although certainly some research progresses in the direction of therapeutic outcomes). This is not an incidental issue, for some cultural and religious traditions that are generally supportive of donation for therapeutic goals find it much more difficult to provide a justification for biomedical research undertaken without therapeutic intent. In examining the ethical status of tissue contributions, we will rely on the fourfold features of the donation paradigm to illuminate distinctions and comparisons.

Intent. A person who places their recyclable household materials at the curbside is engaging in nonobligatory gift-giving in an important respect because they could well retain the materials for their own purposes, such as

storage, collections, or fire-starters. While they are not making a personalized gift to a specific individual, they do contribute to a cause that is larger than themselves and the benefits they might provide in a direct or mediated relationship with another person in need. The cause in the domestic case may be "environmental preservation"; in the case of body tissue, it may be designated as "scientific discovery" or "medical progress." The contribution in both cases is one of nonspecific generosity; it is "nonspecific" in that a "cause," rather than a person, is the intended beneficiary. The contribution is also a generous act in that a person is participating in the advancement of the larger cause when they could just as easily place the recyclable material in the refuse bin without moral blame, or request abandonment or return of the body tissue.

Contributor Expectation. Unlike the therapeutic expectation embedded in the donation paradigm, a contribution of body tissue for research or educational purposes does not bring direct and immediate benefits to a specific or designated individual. To be sure, there is an expectation of benefits on the part of the contributor but these are much more diffuse in space and remote over time. The recipient of the tissue contribution, a science researcher or medical educator, may develop protocols or pedagogies that over time will accrue benefits to the larger good of society, or at least to those persons with a stake in biomedical research or education. Perhaps the tissue will turn out to have "immortal" features, either through its cell progeny or through laboratory learning that is transferred to clinical practice. Still the objective in contributions is advancing knowledge, not therapy; learning, not curing. The good of the greater cause, not an individual in need, predominates.

This difference in expectation marks a distinction between donations and contributions of body tissue. There are also marked differences between contribution and abandonment or sales. A willingness to contribute does not imply that the contribution has minimal or no value to the contributor. A plastic milk container that can be recycled is equally serviceable as a water jug. Similarly a person may attribute value to many tissue specimens, including blood, reproductive tissues, skin or hair that have been retrieved or excised from the body. The prime difference of contributions lies in the fact that something of value is contributed to a person or organization through whose work the society realizes a benefit that is greater than would have been the case had the contributor decided to retain the material. A contribution thereby intends a benefit for the common good of all.

Symbolic Re-incorporation. The donation paradigm involves re-incorporating removed tissue or organs into another body, whether an organ transplant or blood transfusion into a person, or as is common among some religious rituals, burial in the earth. Re-incorporation practices are not literally possible in contributions, because the research and educational purposes necessitate analysis or study of body tissue in isolation from the body totality. However, a form of symbolic re-incorporation is possible with contributions of body tissue. For example, just as recycling contributes to the good of the larger communal whole, the contribution of body tissues for research can provide information that can then be integrated within, or require revisions to, a larger, symbolic whole, designated as the "body of scientific knowledge."

Recipient Responsibilities. Contributions in general are acknowledged in some form by the recipient, but implementing an acknowledgment is more difficult with respect to contributions of bodily tissue. It is important that those who seek informed consent for nontherapeutic uses of body tissue not presume that a patient or subject will simply "sign off" to any and all uses made of retrieved body tissues.

However, since the moral point of the contribution is to facilitate the achievement of some cause greater than the interests of either tissue source or recipient, the researcher should assume a role of trustee and steward for the community. This entails a research responsibility to use the contribution of body tissue for the common good. At a minimum this requires treating the information generated by tissue research with safeguards that ensure protection of the contributor against discrimination or harm.

The appeal to the "common good" does not preclude recourse to the private sector to carry out research; in some cases, as with domestic recyclables, the good of all can be more efficiently and effectively achieved through private sector initiatives. However, in a contribution approach, profit interests must be subordinated to the common good and the greater cause that the contribution is designed to advance. In short, retrieved body tissue is a source of good, and not merely a resource for financial gain. Body tissue that is contributed for purposes of the general cause of advancing science should not be viewed as merely an economic asset. Such limitations may not apply, however, in situations of acquisition of body tissue through abandonment or sale.

Abandonment

Many of the 282 million specimens of human biological materials stored in labs in the United States have been acquired following abandonment by the patient or research subject. A person who has undergone a surgical procedure during which certain body tissue has been removed is characteristically not interested in retaining the tissue themselves; the removed tissue assumes the status of "surplus" or bodily "refuse" that the patient is quite willing to discard, especially if the tissue is implicated in a disease condition. In some cases (though not all) the person may sign a general consent form permitting research or educational uses of their tissue. This tissue is a resource for scientific study and exploitation, but this permission is an attenuated form of donative or contributory intent.

In other circumstances, as with the placenta or umbilical cord, the removed tissue may not have been a source of disease but a sustainer of life that is no longer biologically needed. Nonetheless, for some persons, as well as cultural traditions such as Native American, these tissues are profound symbols of life and relationships, and the patient may retain them. For many others, however, they are surplus membranes that can be discarded following birth; even if research consent is given, the primary intent is to be rid of the tissue.

This suggests departures in several respects from the features of the moral model that inform the donation paradigm, and with some modifications, contributions of tissue. If a donative intent is present at all, it is relatively insignificant and possesses secondary importance. There is also likely to be no expectation of a therapeutic outcome and minimal interest in any research or educational uses. Are efforts at re-incorporation attempted? As Murray writes, in most cases of the removal of a diseased organ, "the tissue is disposed of, usually by incineration." Yet this does not relieve pathologists or researchers of recipient responsibilities, including respect and dignity appropriate to "the fact that the tissue is from a human" (7). Moreover, since research analysis could establish linkage to the tissue source, considerations of privacy and confidentiality continue to apply.

Sales

Certain body tissues, though not solid organs, are allowed to be bought and sold. These include blood, skin, and reproductive tissue. Financial transactions for body tissue stretch the language of "donor" beyond all reasonable usage. The language of tissue "source," "seller," or "vendor" is more appropriate. In sales of body tissue the altruistic intent of the donation paradigm has been replaced by the commercial prospects of property (27). The property understanding of the body, and its correlate, an understanding that excised or retrieved body tissue is, potentially, a "commodity," recognizes the ownership rights of the person to his or her own body and body tissue. As with any other form of property, these rights can be transferred to, and acquired by others, including researchers or tissue banks through contractual agreement.

A contract that transfers property rights in body tissue means that a person's interests in their body tissue are effectively ended with the transaction. The tissue source may harbor expectations for a successful fertility outcome for the buyer, or some therapeutic developments by researchers, but that is not the primary rationale for the commodity exchange of tissue for money. If it were, then the tissue source should be equally satisfied with a donation or contribution of body tissue. Rather, the point is to use a shared procedure, the market mechanisms that function to transfer goods and services in various social realms, to facilitate mutual self-interest. Once the transaction is completed, the new property holder possesses rights to use and dispose of the commodity at his or her discretion.

Within the transaction, the social identity of the researcher-recipient of body tissue marks a striking contrast to that found in the donation paradigm or in contribution. The latter approaches present the recipient as a trustee and steward of what are communal resources, with a responsibility to use the resources as consonant with the common good. No such strictures apply in a commodity exchange of body tissue. The researcher functions more along the lines of a private entrepreneur, seeking to protect personal property as both a scientific and an economic investment. In some cases this protection is secured through patenting of an innovation, such as an immortal cell line derived from body tissue. For example, in the case of John Moore, the physician entered into contracts with pharmaceutical companies to enable successful exploitation of the estimated $3 billion potential of the cell line. A patent on the cell line and its derived products was secured and transferred to the research university (9).

The property paradigm thus has a very attenuated view of recipient responsibilities; those responsibilities are primarily directed toward advancing the interests of the recipient rather than shared societal interests. The researcher is not bound by responsibilities of gratitude or reciprocity because the work of the scientific community has made possible the retrieval of the tissue in the first place. Were it not for the initial labor of physicians and researchers, there would be neither donations nor sales of body tissue. The main responsibility of the researcher-recipient thus appears to be ensuring that informed consent takes place.

While the donation paradigm has few critics, other than those who may fault it for providing an inadequate supply of organs and body tissue, the property paradigm of the body, and the idea of tissue as a purchasable commodity, has received criticism similar to that directed at (so far, unsuccessful) proposals for a commercial market in solid organs. These criticisms include questions about the impact of financial incentives on voluntary, informed consent; "quality assurance" mechanisms to ensure safety; and the potential for the property paradigm to compete with, and ultimately erode, communal support for donation. Underlying these procedural and consequentialist concerns is a substantive criticism that commodification of body tissue, and understanding the body as personal property, ultimately is an affront to human dignity. Proponents of the property paradigm have argued in response that it provides assurance of personal control over the disposal of body tissue and freedom of choice for the tissue source. A commercial market, it is claimed, can and should supplement gifts of the body; after all, property can be sold as well as donated. Moreover a commercial market could increase supplies of scarce body tissue.

One common concern is that the effort to increase supplies of tissue for either therapy and research through permitting sales risks undue influence and coercion of the decision maker. Thus laws prohibit women from selling tissue from their aborted fetuses, and regulations are currently being discussed that would impose similar restrictions on couples in vitro fertilization (IVF) programs who are informed about the possibility of research on stem cells derived from surplus embryos. In other circumstances, however, such as procurement of gametes, financial incentives are not necessarily deemed as compromising the voluntariness of a choice. With respect to gamete procurement, the voluntary guidelines promulgated by various professional societies that discourage excessive financial inducements seem to have gained general acceptance.

CONCLUSION

Innovative biomedical research, especially in the field of molecular genetics, has heightened scientific interest in tissue samples, and thereby posed new questions

about the moral status of body tissue in research and educational settings. In a diverse and pluralistic culture, wherein many traditions, cultures, and communities vest body tissue with tremendous symbolic significance, the moral burden of proof falls on the scientific community and researchers to justify acquisition of body tissue. Researchers seeking access to body tissue must make a compelling case for its use, ensure that their scientific design will likely generate significant results, determine that there are no other alternatives to achieve the research objectives, facilitate a process of informed consent with tissue sources, and provide guarantees of confidentiality and anonymity as appropriate. In this way body tissue can legitimately be used while minimizing abuses.

Pittsburgh, Pennsylvania

OUTLINE

INTRODUCTION

One might think that the question of the patentablity of DNA and other biological components is narrow and technical, of interest only to lawyers, directors of research, venture capitalists, and a handful of scientists. In fact it is a question of great interest and concern to a wide range of organizations from every continent that for some reason feel compelled to express an opinion on this subject. And while the technical matters of patenting law and trade policy are often lost in the public debate, it is clear from the wide range of organizations with positions and from the intense passion with which they sometimes express their opinions that deeply held convictions are at stake in this question of the ownership and commercial use of biological components. Because patent law and trade policy are created through political processes, the conflict among organizations on biological patenting may have wide significance for the biotechnology industry for years to come.

The organizations with positions on patenting range across the entire spectrum of institutional styles and continuities of identity, from religious organizations, with

thousands of years of unbroken institutional identity, to conferences that meet briefly but leave a lasting impact. What counts as an organization? For the purposes of this summary, transient organizations, such as coalitions and conferences, are included, not only because their impact often outlives their structure but because of their galvanizing effect on their complex constituencies and on public consciousness. Some of these "organizations" are virtual; that is, they exist primarily if not exclusively on the Internet. Internet technology, so important to genome research and sequence publication, and thus partly determinative of what is patentable and what is not, is also used by individuals and communities worldwide to organize their opposition to biotechnology, to commercial use of genetics, and specifically to biological patenting. The impact of such "virtual organizations" and of Internet-based community organization should not be underestimated. Furthermore, precisely because of the fluid boundaries of organizations, "virtual organizations" can be remarkably successful in swaying the position of traditional organizations, such as religious bodies or governments or the United Nations.

The positions of these organizations on biological patenting also span the whole spectrum of possible views. Some of the organizations included here (mostly the environmental and indigenous peoples groups) oppose not only patenting but biotechnology itself and see opposition to patenting as a strategy toward their broader end. Others (mostly the religious organizations) support biotechnology, at least for many purposes, but oppose many if not all forms of biological patenting. Many others (e.g., scientific organizations) support biotechnology and therefore oppose certain forms of patenting on the grounds that they impede progress in the field. Others organizations (largely the industry groups) support broad patenting of genetic and biological discoveries, including (for some) short DNA sequences of unknown function.

The organizations that have take public positions on biological patenting may be grouped into seven categories, namely religious, indigenous peoples, environmentalist, public interest science, scientific, and industrial. Each category will be considered in the sections that follow.

RELIGIOUS ORGANIZATIONS

Of all the public statements made on biological patenting, perhaps the most widely reported is the May 1995 statement, the *Joint Appeal against Human and Animal Patenting*. The text of the statement, which was endorsed by the heads of over 80 religious organizations in nearly all faith traditions, consists of three sentences: "We, the undersigned religious leaders, oppose the patenting of human and animal life forms. We are disturbed by the U.S. Patent Office's recent decision to patent human body parts and several genetically engineered animals. We believe that humans and animals are creations of God, not humans, and as such should not be patented as human inventions" (1).

The Joint Appeal was organized by the General Board of Church and Society of the United Methodist Church and promoted in cooperation with the Foundation for Economic Trends, whose leader, Jeremy Rifkin, is a well-known activist in opposition to genetic technology. In a press statement that accompanied the release of the Appeal, the Rev. Kenneth L. Carder, Resident Bishop of the Nashville, Tennessee, Area, the United Methodist Church, argued for the Appeal on religious grounds: "The issue is the commodification of life and the reduction of life to its commercial value and marketability.... Life is a sacred gift from God the Creator. As a gift from God, life has intrinsic value. The patenting of genes, the building blocks of life, tends to reduce it to its economic worth.... Patenting further identifies life mechanistically and blurs the distinction between the animate and the inanimate.... The conflict is between reverence for life and exploitation of life, life valued for its marketability and life valued as an intrinsic gift. It is a conflict between utilitarianism and transcendent meaning. It is conflict between control based on economic profit and access based upon shared need" (2).

The 1995 Appeal was not the first time that religious leaders had joined to speak publicly on this issue. In 1987 a *Statement of Religious Leaders against Animal Patenting* was signed by seven national leaders of mainstream Protestantism and of Judaism and issued in response to U.S. Patent Office decision to allow patenting of transgenic animals. The statement objected to the decision, saying: "No decisions about the patenting of genetically altered animals should be made without the most careful examination of all possible consequences." The statement urges "support for congressional measures to halt such actions by the Patent Office, and to enable a careful consideration of these questions by the Congress and the public. The gift of life from God, in all its forms and species, should not be regard solely as if it were a chemical product subject to genetic alteration and patentable for economic benefit. Moral, social, and spiritual issues deserve far more serious consideration before binding decision are made in this area" (3). It should be noted that most of the religious leaders who signed the 1987 or the 1995 statements did so without their religious body having discussed a policy on patenting, much less having taken an official stance.

In these two statements, theological opposition to biological patenting is grounded on the belief that life is a gift from God, its creator and (one might say) inventor, who alone should possess any intellectual property rights in biological phenomena. The sheer act of patenting, the claim to possess a property right in the design of a biological organism, is an affront to this theological conviction. Furthermore patenting is an act that reduces an organism to mere matter and denies the special status that living things enjoy in relation to their creator. These two theological principles are the twin pillars upon which religious opposition to patenting is based. The first, that God is the creator, giver, and rightful source and definition of the value of the creation, leads in many of these statements immediately into the second principle, that God has so ordered creation that living things enjoy a special status that must not be violated or ignored. The first of these principles warns against the danger of anthropocentrism or the view that we (or any other creature) can define the value or purpose of creatures. The

second principle warns against reductionism, the view that all creation is nothing but matter, valueless apart from its usefulness to us.

It is the second of these twin principles that comes to the fore in positions taken by the Church of Scotland and found in a report of the European Ecumenical Commission for Church and Society (EECCS), a commission created by the Protestant, Anglican, and some Orthodox Churches to relate to the European Union and the Council of Europe. (It should be noted that the Church of Scotland has been especially strong in supporting the development of the positions taken by the EECCS.) The 1998 EECCS report, entitled "EECCS and Bioethics," holds that, "[c]oncerning patenting, it is a matter of ethical concern that commercial demands are now tending to abuse the normal distinctions between what is alive and what is not, and what is discovery and what is human invention. The mere knowledge of a gene should not be patentable in itself, nor should an entire transgenic organism — animal or plant — when it is only a tiny modified gene sequence that is novel. Moreover, there seems to be a real danger that genetically modified organisms are looked upon only as commodities in a global market place" (4, p. 5). The theological significance of the distinction between the living and the nonliving is also asserted in a major position paper of the World Council of Churches (WCC), whose participants come from every continent and nearly every tradition within Christianity. Among the concerns raised about biological patenting, the report states: "The US Supreme Court decision on patenting of life forms rested upon a specific, highly reductive conception of life, which sought to remove any distinction between living and non-living matter that could serve as an obstacle to the patenting of living but unnatural organisms. It would be easy to underestimate the philosophical, moral and ideological importance of the abolition of such a distinction, precisely because it allows a shift in accepted ideas as to what may be done to living things" (5, p. 18). It must be noted, however, that what is being opposed here is biological patenting, not biotechnology. In fact the statements are clear that they do not intend to prohibit biotechnology, even if they do raise concerns about some of its uses. But it is not clear in the statements why the living/nonliving distinction would prohibit patenting but would permit biotechnology. Nor is it clear just where, in biological phenomena, one should find the distinction between the living and the nonliving, or whether theology can offer any help in locating that distinction.

Religious opposition to some aspects of biological patenting is of course grounded in other theological and ethical concerns beyond the two central principles. Indeed, the WCC 1982 report lists "five causes for concern," of which the living/nonliving distinction is only one and which does not put "life as gift" on the list. Among the other four concerns, the report notes that "some argue that patent protection in this form will allow existing and emergent corporations to make excessive profits out of human suffering, to sustain an unhealthy worldwide dependence on pharmaceutical products, and to ignore real health needs because they offer lesser economic returns." In addition, due to inconsistencies and imprecision in patent law, there is a concern about "extremely costly patent litigation. This prospect is likely to cause major distortions in the process of innovation and to restrict the range of products made and the kinds of organizations making them" (5).

The report notes the concern that the patent system will lead "to a curtailment of communication and greater reluctance to exchange new research materials and to engage in collaborative projects." The final concern noted in the 1982 WCC report is that in view of the fact that "much of the research leading to commercially valuable knowledge was supported by public funds," patents leading to private profit will cheat the public twice. "Not only does this deplete the public exchequer but the needs of the community might be better served by arranging for the commercial exploitation of publicly funded research by publicly owned corporations." In particular, "churches and other institutions should press for alternative ways in which the labours of science are transmuted into the maximum human good." In light of these concerns, however, the report does not call for sweeping opposition to patenting but merely "[t]hat the WCC maintain a watching brief on the issues arising from the patenting of micro-organisms" (5, p. 26). The general thrust of the argument is that excessive patenting will lead to injustices in profits and to social inequities in the progress of research for the benefit of all.

The WCC 1982 report was followed in 1989 with a report from the WCC Subunit on Church and Society, entitled *Biotechnology: Its Challenges to the Churches and the World*. Like the 1982 report, the 1989 document included a major section on intellectual property, specifically on "The Patenting of Life." The report notes the economic impact of biotechnology patents on farmers and on scientific research, where patenting "is leading to a curtailment of communication and sharing of resources in the scientific community." The 1989 report notes, of course, that the alternative to patenting might be "complete research secrecy." But of all the economic impacts of patenting, "perhaps the greatest concern in the patenting of life is that the lure of patenting can cause a misappropriation of Third World genetic resources by corporations looking for patentable, genetic products. Since a significant amount of useful genetic material is found in the tropical and subtropical countries, First World patenting of life could increasingly exploit the collective resources and germplasm of Third World countries and peoples." This is not an insurmountable barrier, however, because already there are examples of "responsible sharing of information and benefits" (6, p. 22).

While the 1989 report observes that patenting may itself contribute to environmental problems, it moves quickly to the "Ethical and Theological Impacts" of patenting, where its strongest concerns are expressed. Here again, we find the living/nonliving distinction clearly articulated as the leading theological concern: "The patenting of life encodes into law a reductionist conception of life which seeks to remove any distinction between living and non-living things.... This mechanistic view directly contradicts the sacramental, interrelated view of life intrinsic to a theology of the integrity of creation. As

expressed by Arie Brouwer, former General Secretary of the National Council of Churches of the USA, 'Reverence for all life ... may be eroded by subtle economic pressures to view life as if it were an industrial product invented and manufactured by humans.... The gift of life from God, in all its forms and species, should not be regarded solely as if it were a chemical product subject to genetic alteration and patentable for economic benefit.' The churches should question all those technologies, whether traditional or modern, whose only stance toward creation is one of exploitation and profit, ignoring the biblical call to 'tend the garden and keep it'" (6, pp. 22–23). The final sentence is instructive in that the target of questioning is not patenting but technology itself; if technology is reductionist and blurs the distinction between the living and the nonliving, it should be challenged and rejected.

The report then enumerates (with cautious endorsement) a list of concerns about patenting: (*1*) First World control of Third World genetic resources by corporations looking for patentable genetic products, (*2*) encoding a reductionist conception of life by removing the distinction between living and nonliving things, (*3*) creating the loss of genetic diversity, (*4*) animal patenting creating the profit incentive for cross-species genetic transfers that leads to great animal suffering, (*5*) threatening environmental destruction by encouraging the deliberate release of genetically engineered organisms, (*6*) severe effects of patenting life on small farmers and producers, and (*7*) continued and growing confusion in the legal community over precise and acceptable definitions of patentable living matter (6). In light of these concerns, the report concludes with the recommendation from the Subunit on Church and Society that "The World Council of Churches believes that animal life-forms should not be patented and calls for further study of the profound moral and social implications of patenting life forms" (6, p. 23). In contrast to the preceding discussion, which is wide-ranging in scope, the final recommendation is limited to opposition to patenting of transgenic animals and leaves aside many other areas of biological and genetic patenting.

Somewhat in structural parallel to WCC, but operating on the national level within the United States, the National Council of the Churches of Christ (NCC) has also engaged in studies of the religious and ethical implications of biotechnology and has specifically addressed biological patents. A 1986 NCC report, entitled *Genetic Science for Human Benefit*, notes that "[s]cientists, investors and managers who provide the knowledge and capital necessary for biotechnological development and marketing deserve fair compensation for their ingenuity, work and willingness to incur economic risks." Patenting, however, can lead to "threats to science itself.... More serious still is the admonition against monopolistic ownership of genetically modified organisms or substances which are known to be essential to human life or for nourishment and health" (7, p. 14).

In contrast to this somewhat "pro-patenting" stance, more recent church positions have tended to view patenting with greater suspicion. For example, one of the largest Protestant denominations in the United States, the United Methodist Church, adopted a resolution at its highest national gathering, the 1992 General Conference. The resolution states that "[t]he position taken by the church ... is consistent with our understanding of the sanctity of God's creation and God's ownership of life. Therefore, exclusive ownership rights of genes as a means of making genetic technologies accessible raises serious theological concerns. While patents on organisms themselves are opposed, process patents, wherein the method for engineering a new organism is patented, provide a means of economic return on investment while avoiding exclusive ownership of the organism and can be supported.... We urge that genes and genetically modified organisms (human, plant, animal) be held as common resources and not be exclusively controlled, or patented. We support improvements in the procedures for granting patents on processes and techniques as a way to reward new developments in this area" (8, pp. 332–333). It was on the basis of this position that United Methodist officials went on to organize the May 1995 Joint Appeal, which was signed by many leaders of other religious bodies.

The largest U.S. Protestant denomination, the Southern Baptist Convention, adopted a resolution "On the Patenting of Animal and Human Genes" at its June 1995 national gathering, declaring that "the scriptures of both the Old and New Testaments plainly teach that God alone is creator and owner of all he has made ... [and] humans legitimately may own individual or groups of animals of a given species, but not an entire species and its progeny ... [Therefore,] we, the messengers of the Southern Baptist Convention ... do hereby affirm our conviction that God alone is Creator and owner of all creation ... we call upon the President, the Congress, the National Institutes of Health, and the United States Patent Office to place an immediate moratorium on the patenting of animal and human tissues and genetic sequences until a full and complete discussion has occurred" (9, pp. 7–8). The United Methodist and the Southern Baptist statements both stress the first theological principle noted earlier, namely, that God is the creator and owner of life. While the living/nonliving distinction is not unimportant, it is less important that the principle that God is creator and therefore owner of all living things.

The principle that God is owner of life and therefore we cannot claim ownership could be understood in a way that makes God appear possessive and petty. On the other hand, it can be interpreted as pointing to something important about the creation and its transcendent (as opposed to anthropocentric) ground of value. In this view, "as Creator, God reserves the right to determine how the knowledge of organic development is to be used. In a way, it is as if God the Creator were the first to patent genes, not to exclude us from using the knowledge, but to exclude us from excluding others.... It is as if anyone who tries to patent a gene should have the application rejected because it encroaches upon a prior patent whose holder, God, has given free license to everyone. As Creator, God has and reserves the right to define how we may use the knowledge of the creation, including the knowledge of DNA sequences. God exercises this right by saying, in effect, that this knowledge is to be used without exclusion, that is, without patent protection" (10, p. 154).

The second key principle, that of the importance of the distinction between the living and the nonliving creation, is more commonly asserted than the first in the theological statements opposing patenting. The fullest development of this distinction is found in the report noted earlier of the EECCS Bioethics Working Group. The report declares: "We object to the patenting of living organisms, to the patenting of human genetic material of any sort, and to non-human genetic material which has not undergone a major change by inventive means" (11, p. 38). This is because there is an important conceptual distinction that must be maintained between what is living and what is not. "Boundaries need to be drawn to make this distinction [between animate and inanimate matter] clear, to avoid reducing life conceptually to being merely an economic commodity, and then treating it as such" (11, p. 43).

It should be noted, however, that alongside the living/nonliving distinction, another boundary, this time between the human and the nonhuman, is also asserted in this report and elsewhere in church statements. For example, the report declares that "[p]atenting any part of the human genome is ethically abhorrent, in principle" (11, p. 44). In this context we should note that Roman Catholic concerns about patenting are not as sweeping or as urgent as those voiced by Protestants, in part because of the relatively greater emphasis Catholics place on the human/nonhuman distinction than do Protestants. For example, in one of the few Catholic statements on the subject, Pope John Paul II said to the Pontifical Academy of Sciences in 1994 that "...we rejoice that numerous researchers have refused to allow discoveries made about the [human] genome to be patented. Since the human body is not an object that can be disposed of at will, the results of research should be made available to the whole scientific community and cannot be the property of a small group" (12, p. 3). The opposition to patenting is both mild and limited to human DNA.

Generally speaking, Protestant statements rely on the living/nonliving distinction more than on the human/nonhuman distinction to define the limits of acceptable use of patenting as the means of intellectual property protection. According to the statement of EECCS, patenting is simply unacceptable for living things, in part because patenting is so firmly associated in the public mind with mechanical inventions that its application to living things conveys the wrong attitude toward life, one that is prejudicial in regarding living things as mere matter, mere mechanisms. In contrast to a mechanistic view, "[a]nimate material presents a radical discontinuity from mechanical and chemical inventions, which requires a different way of thinking about intellectual property.... Living organisms of any kind should not be patentable" (11, p. 42). For jurists or corporations to patent living things is an inappropriate use of governmental and financial power to the rule on a moral and theological question. In the strongest terms, the statement holds that "[w]e deplore the implications of various court decisions regarding patenting of living organisms.... This represents an unacceptable paradigm shift in how life forms are regarded.... This view sees nature entirely in anthropocentric terms of its utility to humans, as tools and products, and has lost the sense of respect for animal or plant as of value in itself. This perception runs contrary to Christian understanding that all of creation owes its existence to God, and its significance is first of all what it is before God, irrespective of any use to which human beings might think of putting it.... An animal, plant or microorganism owes its creation ultimately to God, not human endeavour. It cannot be interpreted as an invention or a process, in the normal sense of either word" (11, p. 43). But this does not necessarily mean that biotechnology should not be given *some form* of intellectual property protection. If "patenting" connotes "mechanism," surely some other legal category could be created that protects inventive value without demeaning natural value. And so the report suggests "that consideration should be given to developing an alternative form of intellectual property for biological material" (11, p. 38). In other words, a new form of intellectual property protection that encourages research but does not contribute to reductionism would be acceptable.

It should be expected that religious organizations, perhaps including those of other major faith traditions beside Christianity, will continue to express opinions on biological patents. The question of patenting can easily become the lightening rod for general concerns about technology, the human role in nature, and the meaning of life itself. "While patent law may seem to be a technical and arcane subject and therefore of little relevance to the religious community, patenting biotechnology raises important questions traditionally within the domain of religious ethics. These include such issues as the nature and status of life, the relationship between the Creator and the creation, and the protection of human dignity. Placing biology within the jurisdiction of intellectual property law also has important symbolic implications relating to whether humanity can or should claim ownership of forms of life" (13, p. 8).

INDIGENOUS PEOPLES AND THEIR COALITIONS

At the 1995 United Nations conference on women in Beijing, women representing indigenous peoples met for extended discussion resulting in the *Declaration of Indigenous Women*, which addressed many concerns, among them attitudes toward nature and the question of biological patenting. The Declaration affirms a view of the earth as "our mother. From her we get our life, and our ability to live. It is our responsibility to care for our mother and in caring for our mother, we care for ourselves. Women, all females, are the manifestation of Mother Earth in human form" (14). From this consciousness arose a concern about technology, global trade, and the right of corporations to patent biological components. Recent global trade agreements are criticized as "new instruments for the appropriation and privatisation of our community intellectual rights through the introduction of the trade-related intellectual property rights (TRIPs). This facilitates and legitimises the piracy of our biological, cultural, and intellectual resources and heritage by transnational corporations." These global agreements threaten traditional social values: "Our indigenous values and practice of sharing knowledge among ourselves,

and mutual exchange will become things of the past because we are being forced to play by the rules of the market." Furthermore global trade agreements legitimize the theft of traditional knowledge by incorporating it into patentable technological knowledge. "Bio-prospecting, which is nothing but the alienation of our invaluable intellectual and cultural heritage through scientific collection missions and ethnobotanical research, is another feature of recolonisation. . . . Their bid for the patenting of life forms is the ultimate colonisation and commodification of everything we hold sacred." The threat envisioned here is threefold: patenting endangers the value of traditional knowledge of plants or animals, cultural values such as sharing, and ultimately the survival of the people as a distinct identity. "It won't matter any more that we will disappear because we will be 'immortalised' as 'isolates of historic interest' by the Human Genetic Diversity Project." In highly passionate language, the Declaration urges resistance: "It is an imperative for us, as Indigenous Peoples, to stand in their way, because it means more ethnocide and genocide for us. It will lead to the disappearance of the diverse biological and cultural resources in this world which we have sustained. It will cause the further erosion and destruction of our indigenous knowledge, spirituality, and culture. It will exacerbate the conflicts occurring on our lands and communities and our displacement from our ancestral territories" (14).

The most immediate and specific form of resistance, according to the Declaration, lies in refusing to accept the universal validity of global trade agreements and their assertion of biological patenting. "We demand that the Western concept and practice of intellectual property rights as defined by the TRIPs in GATT, not be applied to indigenous peoples' communities and territories. We demand that the World Trade Organisation recognise our intellectual and cultural rights and not allow the domain of private intellectual rights and corporate monopolies to violate these. . . . We call for a stop to the patenting of all life forms. This to us, is the ultimate commodification of life which we hold sacred" (14). The Human Genetic Diversity project is particularly offensive, and the idea of any patent applications derived from these samples is especially abhorrent.

An incident that served to galvanize global opposition by indigenous peoples to biological patenting was the attempt by the United States Department of Commerce to file a patent application on a cell line derived from a Guaymi Indian woman from Panama. The Guaymi tribal president was widely quoted as saying, "I never imagined people would patent plants and animals. It's fundamentally immoral, contrary to the Guaymi view of nature, and our place in it. To patent human material . . . to take human DNA and patent its products . . . that violates the integrity of life itself, and our deepest sense of morality" (15, p. B5). Not only did this event and comment inspire opposition among indigenous people; they evoked a response far beyond indigenous peoples and served to mobilize opposition to patenting within Christianity and other religions.

So important is the issue of intellectual property to indigenous peoples that international conferences have been convened on this subject alone. For instance, 150 delegates from as many as 14 countries met in 1993 in New Zealand and issued the *Mataatua Declaration on Cultural and Intellectual Property Rights of Indigenous Peoples*. In the view of those gathered, "[w]e declare that Indigenous Peoples of the world have the right to self determination: and in exercising that right must be recognised as the exclusive owners of their cultural and intellectual property." The conference issued a call to indigenous peoples to develop protection strategies to resist corporations and governments in their unilateral pursuit of traditional knowledge or intellectual property protection. "Commercialisation of any traditional plants and medicines of Indigenous Peoples, must be managed by the indigenous peoples who have inherited such knowledge" (16) In the same year the *Intellectual Property Rights and Biodiversity* statement was developed by the Coordinating Body of Indigenous Organisations of the Amazon Basin (COICA). The COICA statement voices generalized suspicions about international intellectual property accords, which are seen as a new form of colonialist exploitation. The issue then becomes a matter of self-determination and of territorial sovereignty, especially in controlling access to traditional knowledge of plants within the traditional territory. "Biodiversity and the culture and intellectual property of a people are concepts that mean indigenous territoriality. . . . For members of indigenous people, knowledge and determination of the use of resources are collective and intergenerational. No indigenous population, whether of individuals or communities, nor the Government, can sell or transfer ownership of resources which are the property of the people and which each generation has an obligation to safeguard for the next" (17). Here again, the issues of traditional knowledge and of cultural values are both seen as threatened by global trade agreements. In particular, indigenous people are resisting the idea that they lack intellectual property or that they have no system to protect and regulate its value, and that therefore a intellectual property system can be asserted over their heads, so to speak. "Adjusting indigenous systems to the prevailing intellectual property systems (as a world-wide concept and practice) changes the indigenous regulatory systems themselves." Precisely because intellectual property systems are already in place, the assertion of alien Western-style "patents and other intellectual property rights to forms of life are unacceptable to indigenous people" (17).

In part through the assistance of the United Nations, indigenous peoples from around the world have come together to address common concerns, such as intellectual property. A gathering in Geneva in July 1999 resulted in *No to Patenting of Life! Indigenous Peoples' Statement on the Trade-Related Aspects of Intellectual Property Rights (Trips) of the WTO Agreement*, which begins with language that echoes the 1995 Beijing Women's Declaration. "*We, Indigenous Peoples* from around the world, believe that nobody can own what exists in nature except nature herself. A human being cannot own its own mother. Humankind is part of Mother Nature, we have created nothing and so we can in no way claim to be owners of

what does not belong to us" (18). The concern that is raised in the statement is that by asserting a global regime, trade agreements force global and therefore local consensus in favor of a western and modern worldview. What looks to be a conflict of law and economy is ultimately a clash of worldviews, as "western legal property regimes have been imposed on us, contradicting our own cosmologies and values" (18). The idea of owning nature "goes against the very essence of indigenous spirituality which regards all creation as sacred." This concern is remarkably similar to that expressed by EECCS, which protested that courts, by ruling on patenting, were in effect ruling on theology, on worldview, and deciding in favor of a mechanistic reductionism and against traditional theological or spiritual views of nature and life.

In the 1999 No to Patenting of Life! statement, as in the Beijing Declaration, the claim is made that traditional cultures have rich legacies of intellectual property, but that the intellectual value is commonly held because it is the result of common effort. These two systems of intellectual property are bound to clash, and indigenous peoples will inevitably lose in the ensuing struggle. This conviction is clearly asserted in the closing statement of the Consultation on the Protection and Conservation of Indigenous Knowledge, meeting in East Malaysia in 1995, which declared: "The intellectual property rights system is in favour of the industrialized countries of the North who have the resources to claim patent and copyright, resulting in the continuous exploitation and appropriation of genetic resources, indigenous knowledge and culture of the indigenous peoples for commercial purposes" (19). The problem is both structural and conceptual. As relatively weaker partners in political and economic discussions, indigenous peoples are unable to assert claims and to protect them. But the problem is also deeper in that the very concept of intellectual property advanced by the international trade agreements is at odds with the cultural foundations and worldview of many indigenous peoples. "The intellectual property rights system totally ignores the close inter-relationship between indigenous peoples, their knowledge, genetic resources and their environment" (19). Or as stated elsewhere: "The inherent conflict between these two knowledge systems and the manner in which they are protected and used will cause further disintegration of our communal values and practices. It can also lead to infighting between indigenous communities over who has ownership over a particular knowledge or innovation" (19). It must be clearly recognized that in these statements, indigenous peoples are making the claim that they possess intellectual property in the form of their traditional knowledge of nature. But their claim, they believe, is wholly incommensurate with Western legal protections and indefensible within global trade accords. If the accords win, their claims will inevitably lose. This is because the accords reflect one view of nature and ownership, one that favors technical over traditional knowledge. Furthermore it should be understood that it is not the idea of the value of knowledge of biology that is disputed in these statements. At dispute is something far more profound, namely, how *bios,* life itself, is to be regarded and how value is to be owned.

ENVIRONMENTAL GROUPS

Environmental groups have been active in voicing opposition to biological patenting, largely out of the conviction that widespread patenting will likely reinforce certain tendencies in the development of genetics and biotechnology that will have especially detrimental effects on the environment. Groups such as Greenpeace have organized and issued press releases to try to persuade the European Parliament (EP) to pass legislation that prohibits or sharply limits biological patents. In a press release in response to a 1997 vote by the EP, Greenpeace states that "[g]enes, and living organisms are not inventions and therefore they should not be patentable. Patent law was introduced to protect technical inventions. It has been enshrined in law that patents should only be granted if inventions are novel, are not discoveries and can be manufactured. Genes, plants and animals clearly do not fit with patent protection. They exist in nature so are discovered and not novel. Because they reproduce biologically, they are not man made. Allowing patents on life is highly immoral because it would give monopoly control over life to private interests for profit alone" (20). The argument here is based on Greenpeace's view that biological patents fail to meet the technical requirement of novelty. That argument expanded on a press statement issued just two weeks earlier: "Greenpeace believes it is immoral to claim genes, cells and living organisms are inventions of man to be used and controlled by commercial interests.... Greenpeace believes that by allowing patents on animals they will simply be seen as machines to be treated as people wish. Their dignity will be sacrificed for flimsy supposed benefits to humans." Of course, the core conviction for Greenpeace or any broad-based environmental group is that biological patents favor biotechnology, which threatens the environment. "Greenpeace also believes genetically engineered plants bring threats to the environment which are irreversible and unpredictable in nature" (21).

This environmental focus is echoed in a 1997 *Statement on Life and Evolution* drafted during the 1997 State of the World Forum (November 4–9) in San Francisco by environmentalists and posted on the Internet for others to sign. "Life is an intimate web of relations that evolves in its own right, interfacing and integrating its myriad of diverse elements. The complexity and interdependence of all forms of life have the consequence that the process of evolution cannot be controlled, though it can be influenced. It involves an unpredictable creative unfolding that calls for sensitive participation from all the players, particularly from the youngest, most recent arrivals, human beings." The statement makes a broader claim when it asserts that "[l]ife must not be treated as a commodity that can be owned, in whole or in part, by anyone, including those who wish to manipulate it in order to design new life forms for human convenience and profit. There should be no patents on organisms or their parts." The statement then returns to the core theme of threat to the environment, which of course leads not just to opposition to patenting but to a rejection of biotechnology: "We must also recognise the potential dangers of genetic engineering to health and biodiversity, and the ethical problems it poses for

our responsibilities to life. We propose a moratorium on commercial releases of genetically engineered products and a comprehensive public enquiry into the legitimate and safe uses of genetic engineering" (22). In contrast to the statements of religious and indigenous peoples groups, the statements of environmentalist groups about patenting are limited in the depth of their argument.

PUBLIC INTEREST SCIENCE GROUPS

Also limited in depth are the brief but influential statements of organizations like the Council for Responsible Genetics (CRG), which argues that "[n]o individual, institution or corporation should be able to claim ownership over species or varieties of living organisms. Nor should they be able to hold patents on organs, cells, genes or proteins, whether naturally occurring, genetically altered or otherwise modified." Their reasons are largely prudential or consequentialist, namely, that patent protection will restrict the practice of good science. The CRG statement adds that "[p]atenting organisms and their DNA promotes the concept that life is a commodity and the view that living beings are gene machines to be exploited for profit" (23). In an effort to build support for its position, CRG circulates a petition on the Web entitled *No Patents on Life*!

A similar strategy is found in the *World Scientists' Statement Calling for a Moratorium on GM Crops and Ban on Patents* (1999), issued by a group that is largely self-identifying and uses the Internet to recruit supporters. Its statement contains the following call: "Ban patents on living organisms, cell lines and genes." The supporting argument echoes the concerns raised by indigenous peoples: "The patenting of living organisms, cell lines and genes under the Trade Related Intellectual Property Rights agreement are sanctioning acts of piracy of intellectual and genetic resources from Third World nations, and at the same time, increasing corporate monopoly on food production and distribution. Small farmers all over the world are being marginalized, threatening long term food security for all" (24).

Another organization, the Crucible Group, met in 1993 and claims to "represent the widest cross section of sociopolitical perspectives and agricultural experience that may have ever been assembled. . . ." Perhaps because of the diverse perspectives, the gathering produced a report but did not claim that it is a "consensus document." Notably they did not achieve an agreement on biological patenting except to conclude that the matter is urgent, divisive, and requires global attention. "Sensing, on the one hand, a certain uncertainty and lack of understanding related to intellectual property regimes and, on the other hand, the opportunity to create a new covenant in support of wider innovative processes, the Crucible Group recommends that the United Nations convene an international conference on society and innovation. Now, and at this conference, policymakers must bear in mind that some people, countries, and cultures have deep ethical concerns about biotechnology and the concept of life patenting" (25).

SCIENTIFIC ORGANIZATIONS

The Human Genome Organization (HUGO), which is an international association of leading researchers in human genome research, has issued a *Statement on Patenting of DNA Sequences*. While the statement does not oppose gene patenting altogether, it notes that "[i]t would be ironic and unfortunate if the patent system were to reward the routine while discouraging the innovative. Yet that could be the result of offering broad patent rights to those who undertake massive but routine sequencing efforts — whether for ESTs or for full genes — while granting more limited rights or no rights to those who make the far more difficult and significant discoveries of underlying biological functions. A second, equally unfortunate outcome would arise if a partial sequence publication or submission to a database precluded patenting of innovative disease gene discoveries leading to improved medical diagnostics and therapeutics. This could lead to inhibition of contributions to databases and lack of investment protection for the innovative. We hope that the system will find some way to adjust to the changing realities in this field to promote and protect this important and ongoing process of discovery in the public interest" (26, p. 7).

This statement was followed by HUGO in 1997 with a one-page comment that updates and clarifies HUGO's position, namely, that "*reaffirms* . . . that HUGO does not oppose patenting of useful benefits derived from genetic information, but does explicitly oppose the patenting of short sequences from randomly isolated portions of genes encoding proteins of uncertain functions . . . *regrets* the decision of some patent offices, such as the US PTO, to grant patents on ESTs based on their utility 'as probes to identify specific DNA sequences,' urging these offices to rescind these decisions and, pending this, to strictly limit their claims to specified uses, since it would be untenable to make all subsequent innovation in which EST sequence would be involved in one way or other dependent upon such patents . . . [and] *urges* all large-scale sequencing centres and their funding agencies to adopt the policy of immediate release, without privileged access for any party, of all human genome sequence information in order to secure an optimal functioning of the international network, as well as to avoid unfair distortions of the system" (27).

HUGO's position is quite similar to the view put forward by the American Society of Human Genetics (ASHG) in its *Position Paper on Patenting of Expressed Sequence Tags* of November 1991. ASHG states that it has "taken the position that the issuing of patents for ESTs is likely to do far more harm than good. . . ." Once again, this partial objection to patenting is not to be construed as general opposition, for "ASHG has not opposed patenting of genetic information when that information had utility." The fear is that the patenting of short sequences of unknown function will inhibit research in genetic science, and therefore "[t]he ASHG does not support the concept of patenting a short sequence from a randomly isolated portion of a gene encoding a protein of unknown function" (28).

As should be expected, the opposition of science organizations to patenting will be based on and limited to the negative effects of patenting upon scientific research.

Likewise, physicians might be expected to object to patenting that would limit the prompt application of research to medicine, and in fact the American College of Medical Genetics (ACMG) has voiced this concern. In its *Position Statement on Gene Patents and Accessibility of Gene Testing*, ACMG asserts the belief that gene testing "must remain widely accessible and affordable, and that the development and improvement of safe and effective genetic tests should not be hindered. The decision of the Patent and Trademark Office (PTO) to permit the patenting of naturally occurring genes and disease-causing mutations has produced numerous difficulties. While the ACMG disagrees with the PTO over this fundamental issue, we have further concerns over current patterns of enforcement of patents on genes that are important in the diagnosis, management and risk assessment of human disease." It should be noted that the scope of ACMG's objection is broader than that of the genetic science organizations, precisely because ACMG is concerned not merely for research but for the transfer of the benefits of research to the clinical setting. With that in view, ACMG complains of "...exorbitant up-front fees and per-test fees, and licensing agreements that seek proportions of reimbursement from testing services. These limit the accessibility of competitively priced genetic testing services and hinder test-specific development of national programs for quality assurance. They also limit the number of knowledgeable individuals who can assist physicians, laboratory geneticists and counselors in the diagnosis, management and care of at-risk patients." Patent protection and excessive licensing fees unduly restrain the field of clinical genetics, and "restricting the availability of gene testing has long-term implications beyond patient care. It affects the training of the next generation of medical and laboratory geneticists, physicians, and scientists in the area enveloped by the patent or license. It also retards the usually very rapid improvement of a test that occurs through the addition of new mutations or the use of new techniques by numerous laboratories that have accumulated samples from affected individuals over many years" (29).

As a result of this analysis, which is argued entirely on grounds that patenting will inhibit clinical genetics, the statement concludes that "it is the ACMG's position that ... [g]enes and their mutations are naturally occurring substances that should not be patented ... [p]atents on genes with clinical implications must be very broadly licensed ... [and] [l]icensing agreements should not limit access through excessive royalties and other unreasonable terms" (29).

Most scientific organizations draw back from such broad opposition to patenting and limit their concerns to specific misuses of the patenting process, especially the patenting of short sequences of unknown function. In a statement issued by the British Society for Human Genetics (BSHG) in 1997, the general principle of the patentability of genetic knowledge is affirmed: "Patenting is a valuable means of protecting intellectual property and promoting investment in developing products for the diagnosis and treatment of genetic disease." However, "[t]he discovery of gene sequence has for some little time been a well understood process. There is nothing novel or inventive about this in principle, and as such new gene sequences should not be patentable, even where a straightforward utility e.g. diagnostic testing has been specified, unless there has been real progress towards the design of a specific commercial product." Patent offices must address, in greater precision, questions of usefulness or novelty, which "cannot reside in the mere description of a nucleotide sequence. It must rest in either novel methodologies for discovering the sequence or a novel use or application of the sequence. Conventional technology, conventionally applied, should not result in patents on newly isolated sequences." In a similar way, the standard for a claim for usefulness must be clear and fairly high: "A claim for utility must describe a utility specific to the sequence in question, and not simply rehearse those possible applications of any known gene sequence which are part of the general public state of the art." Specifically, claims of utility should be denied if they are based upon "use for isolating the full gene sequence ... use for detecting mutations in the gene ... [or] use for studying expression or function of the gene." Stated positively, the criterion of utility applicable to gene patenting ought to be "some meaningful indication that the sequence being patented has a reasonable prospect of being developed into a marketable product (which may be a diagnostic test) ... [or] a proposed specific use — for example, diagnosis of mutations in people with a specified clinical indication." The BSHG statement concludes with a call to patent offices to limit the scope of gene patents to the "specified applications which meet the novelty and utility criteria" (30).

It was noted earlier that the possible patenting of discoveries linked to the Human Genome Diversity Project is especially offensive in the view of the statements of indigenous peoples. To respond to this concern, the North American Regional Committee of the Human Genome Diversity Project has drafted a model protocol for collecting DNA samples. The model contains this description of the position of the HGDP regarding intellectual property rights: "The HGDP has no position on questions of patentability, although individuals participating in the HGDP hold a variety of positions. The HGDP does, however, hold clear positions about the commercial use of its samples and of the information derived from them." There are two principles to which all HGDP researchers are required to give assent: "First, it [HGDP] has resolved that it will not profit from any commercial uses of samples it gathers or knowledge derived from those samples. Second, it has vowed to ensure that, should commercial products be developed as a result of the HGDP's collections, a fair share of the financial rewards shall return to the sampled populations" (31, p. 1466). Enforcement mechanisms are not specified, nor is it clear that this will satisfy the concerns of indigenous peoples.

INDUSTRY ORGANIZATIONS

In response to the May 18, 1995, Joint Appeal of religious leaders that called for sweeping bans on biological patenting, Gerald J. Mossinghoff of the Pharmaceutical

Research and Manufacturers of America (PhRMA) stated that "PhRMA believes that it would be immoral for the pharmaceutical and biotechnology industries to walk away from new technologies that could stop pain, suffering and hunger. Because patents on animals, cell lines, genes, and their products are necessary to foster such scientific enterprise, PhRMA believes it is a moral imperative that the patenting of these types of inventions be maintained and encouraged" (32). This position is more fully developed in a PhRMA Policy Paper, *Strong Patent Protection Is Essential*, which argues that patent protection is necessary if research is to be funded and new pharmaceutical products brought to market. "Without strong patent protection, there simply would be no research-based pharmaceutical industry, which discovers and develops virtually all new medicines. As a result, few new life-saving, cost-effective medicines would be developed, and improvements in the quality of health care would be sharply curtailed" (33). The view is echoed by the major firms engaged in this area of research, such as SmithKline Beecham, whose 1997 "Patenting Statement" states: "Patent protection offers the only effective incentive for bringing to market the many commercial and industrial applications for which genetic inventions may be used.... SmithKline Beecham supports the patentability of any inventions which meet the federal patentability requirements of subject matter, utility, novelty, and non-obviousness" (34).

Any suggestion that genes or biological components are *living* and therefore inherently unpatentable is of course rejected in industry statements. The position of the Biotechnology Industry Organization (BIO) is expressed by Alan Goldhammer in these words: "BIO supports continuation of the current law to allow patenting of human genes when the applicant meets the necessary criteria for securing any patent: the invention must be novel, nonobvious and useful. When these standard criteria are met, patents should be issued irrespective of the nature of the invention. No exception should be made for patents on genes, life forms, or any other subject matter" (35). Without any doubt, BIO's position is fundamentally at odds with the views put forward by the organizations of indigenous persons and by some of the religious groups.

While the position of industry does not change significantly from country to country, it is interesting to note that regional industry groups advance the additional pro-patenting argument that national opposition to patenting will undermine a nation's biotechnology industry and therefore the nation's (or the region's) entire economy. For example, the Forum for European Bio-Industry Coordination (FEBC), in a Directive on the legal protection of biotechnological inventions, argues that a positive environment on biological patenting will encourage regional reinvestment in research and development. "Without patents there would be less investment in research. Patents are the foundation on which the development of new products like pharmaceuticals ... depend." At a time when Europe was considering a sharp limitation on biological patents, the industry warning was clear: "FEBC believes that any weakening of the draft would put Europe at a further disadvantage and will shift the emphasis of research in biotechnology further towards the USA and Japan." The statement documents the warning with evidence that appeared to show that biotechnology investment in Europe was falling behind that in the United States and Japan, and stated that "[p]art of the reason for this gap is the lack of harmonised patent practice. The message is clear: although European investment has increased, the competitive gap between Europe and the US and Japan is still increasing" (36).

Many in industry and in government recognize the urgency of the problem posed by intellectual property protection for advances in knowledge in genetics and biology. The Human Genome Project, which has established an informal agreement that raw sequence data will be posted daily on the Web rather than patented, finds itself in competition with private efforts to sequence the genome in order to gain proprietary advantage. Speaking of the differences between the publically funded National Human Genome Research Institute (NHGRI) and private efforts such as the joint Perkin-Elmer-TIGR genome project, Francis Collins, the Director of NHGRI, told Congress that the "release of sequence data from the Perkin-Elmer-TIGR effort will occur quarterly, rather than daily. The policy of daily release of DNA sequence data by publicly-funded efforts was arrived at because of the great interest in the scientific community in gaining access to this highly valuable information. Any delay can result in wasted effort in research" (37). Deep differences of opinion and philosophy exist even here between scientists and laboratories that are engaged in essentially the same research.

OUTLINE

INTRODUCTION

Current biotechnology patenting practices raise major ethical, legal, and economic controversies. Patenting "life," including plants, animals, and their genes, has been criticized as unethical and inimical to social justice. The Council for Responsible Genetics circulated "The No Patents on Life! Petition," which argues:

> The plants, animals and microorganisms comprising life on earth are part of the natural world into which we are all born. The conversion of these species, their molecules or parts into corporate property through patent monopolies is counter to the interests of the peoples of this country and of the world. No individual, institution, or corporation should be able to claim ownership over species or varieties of living organisms. Nor should they be able to hold patents on organs, cells, genes or proteins, whether naturally occurring, genetically altered or otherwise modified (1).

Patent advocates retort that of course life cannot be patented — merely genes and genetically modified organisms (GMOs) (2). However, it is unlikely that patent critics actually misunderstand that point, as is evident in No Patents on Life! petition; indeed, many of its supporters are scientists. Life itself, as some élan vitale, surely cannot be patented, although one can patent living organisms and genes; that alone is bad enough according to critics. Let us consider the arguments for and against animal and plant patents. After a brief review of the legal status of life patenting and the relation of patent law to morality, we will look at arguments specifically addressed at animal patenting first, before considering arguments that apply more generally to both animal and plant patents.

PATENT LAW AND MORALITY

Patents grant the right to exclude others from making, using, or selling an invention for a period of 20 years. A patentable invention must be novel, useful, and nonobvious. Ideas, theories, mathematical algorithms, laws of nature, and the like, cannot be patented; processes (e.g., production methods, special techniques, and diagnostic methods), products (e.g., microorganisms, enzymes, plasmids, cell lines, and DNA and RNA sequences), and new uses of an existing product can be patented.

Plants were the first living organisms to receive explicit patentlike protection. The Plant Patent Act of 1930 provided protection of asexually reproduced plants, and it was mainly applied to flowers and certain fruits. The broader 1970 Plant Variety Protection Act (PVPA) provides patentlike protection for new varieties of plants, although it differs from a patent in lacking the utility requirement. Plant breeders use both plant variety protection and patents to protect genetically modified plants and plant genes.

Since the landmark 1980 Supreme Court decision *Diamond v. Chakrabarty*, living organisms — "anything under the sun that is made by man" — can be patented in the United States (3). However, the *Chakrabarty* decision focused on a microorganism, and did not explicitly address higher life forms (4). In 1987 the Commissioner of the U.S. Patent and Trademark Office (PTO) formally affirmed the patentability of "nonnaturally occurring non-human multi-cellular living organisms, including animals." It clarified that "Products found in nature will not be considered to be patentable subject matter . . . unless given a new form, quality, properties or combination not present in the original article existing in nature in accordance with existing law" (5).

In 1988 the first transgenic animal was patented, the "Harvard mouse" or "Oncomouse" (6), genetically modified for hypersensitivity to carcinogens for medical research. Animals are genetically modified for medical research, agriculture, and as pharmaceutical biofactories. Animal, plant, and human genes may be patented, including cloned, unmodified genes. Most animal patents thus far are for mice and rats.

Morality comes into play at various levels in the legal practice of patenting (7). Normally the extension of the patent system to a new technological discipline is automatic and may be assumed. However, unique features of new technologies can result in difficult questions of interpretation for patent law. In modern biotechnology, the distinction between discovery and invention is becoming blurred. Moreover genetically modified organisms (GMOs) are unique as inventions. Not only are some of them alive, but also they are able to reproduce on their own, and are not well standardized, easily described, and so on. If they are released into the environment, they will interact with it unpredictably. These are good reasons to pause, rather than extending or excluding patent protection automatically. Old definitions and criteria must be reconsidered and sometimes redrawn.

Although the legal question of the patentability of life forms has been settled in the United States and Europe, some popular sentiment against it remains in these countries. Moreover it remains a lively issue within the international community, as developed nations pressure less developed countries (LDCs) to adopt Western intellectual property laws. LDCs are rich in genetic resources, and many object to intellectual property laws and alleged "biopiracy" on grounds of morality and social justice. Thus the moral debate over life patenting has become increasingly important to discussions of international trade relations and international justice. Are there any special reasons to believe that animal and plant patents are more or less justified than other types of patents, that they should be subject to special conditions or exclusions, or that they raise special problems of ethics and social justice?

ANIMAL PATENTS

Animal patents are criticized on the grounds that they:

- Encourage increased production of transgenic animals, many of which suffer greatly
- Violate animals' rights
- Encourage the reduction of animals to mere inventions
- Engender additionally most of the criticisms that apply to plant patents (see the discussion below)

Several philosophers and legal scholars, such as Baruch Brody (9), Robert Merges (10), and Rebecca Dresser (11), have considered the arguments against animal and plant patenting in depth. They have argued that the criticisms are without merit or point, to problems that are not fundamentally about patenting. Let us consider the arguments for and against animal patenting in greater detail.

Animal Welfare

Animal welfare advocates warn that animal patents encourage more research that, on balance, tends to increase animal suffering. With animal patents, claims Michael Fox of the U.S. Humane Society, "the wholesale industrialized exploitation of the animal kingdom will be sanctioned, protected, and intensified" (8). Although genetic engineering may sometimes decrease animal suffering, critics are concerned that its record thus far is not good, and that this trend will continue. In fact genetic engineering poses special problems for animal welfare, above and beyond normal concerns about the treatment of farm and research animals. While many traditionally bred animals are routinely subjected to inhumane treatment, transgenic animals may be engineered to inevitably suffer even under the best conditions, for example, cancer-prone or hairless mice (12). The U.S. Animal Welfare Act does not apply to farm animals, birds, or rodents, making critics skeptical that genetic engineers will be subject to limits on cruelty (9). Insofar as genetic engineering is likely to cause more suffering for animals than it prevents, and insofar as patents promote the development and commercialization of genetically engineered animals, animal welfare advocates attack animal patenting as an economic incentive for much morally problematic research.

Patent advocates respond that animal welfare advocates should attack the problem of cruelty to animals directly, rather than through patenting (9,11–13). Banning such patents would discourage even research designed to alleviate animal suffering, and which may help many humans. Even if some transgenic animals suffer more, their suffering might be outweighed if it is possible to use fewer but more efficient animals. Moreover patents are perfectly compatible with strong animal welfare regulations, and in themselves are morally neutral.

A few animal welfare advocates have admitted that if sufficient animal protection regulations were in place, they would have less or no opposition to animal patenting. This makes sense for utilitarian animal welfare advocates, many inspired by utilitarian philosopher Peter Singer's book *Animal Welfare*. Singer argues that animal suffering is morally relevant but may be overridden by the likelihood of greater benefit to others (14). Thus some research on animals could be justified — if there were no adequate alternatives, if the benefit were great enough, and if the suffering were small enough. How much animal research would remain is a matter of debate; many utilitarians argue that it would be very little. Most of animal agriculture is not justified on a utilitarian animal welfare view, since vegetarianism is usually a feasible alternative. Thus utilitarian animal welfare advocates, as critics of most of animal agriculture and research, are natural critics of animal patents, but mostly because and insofar as it is likely to increase the suffering of animals. The key assumption is that patented transgenic animals are likely to suffer in order to more efficiently promote our medical and agricultural ends. While this initially may seem extremely pessimistic, the charge warrants examination. For utilitarian animal welfare advocates, criticisms of animal patenting would naturally be combined with a more direct approach toward alleviating animal suffering and strengthening animal welfare laws — and indeed that is often the case, as with Michael Fox.

Animal Rights

A more radical view of animals and morality, inspired by philosopher Tom Regan, holds that animal suffering is morally relevant but that animals also have moral *rights* and may not be used as a mere means to our medical, agricultural, or recreational ends — regardless of the benefits (15). Animal rights advocates are likely to be categorically opposed to animal patenting, on the ground that it involves the use of animals as property and inventions, mere means to our ends. They are likely to accept genetic engineering of animals only where it might be justified on human infants, done on behalf of the child or animal rather than directly or indirectly in service of adult goals. Thus disease-resistant transgenic chickens would probably not be justified even if the animals suffered less, in the animal rights view. Even where genetic engineering might be justified, animal rights advocates could say that it is unjust to patent the genetically engineered animal, since doing so amounts to treating that variety of animal as mere property rather than as a living entity with rights and its own ends.

Thus, even radical revisions in animal welfare laws are unlikely to move animal *rights* advocates (as opposed to utilitarian animal welfare advocates). Patent defenders sometimes are confused and frustrated by animal rights advocates' criticism of patenting. We treat animals as property all the time. Most people do not consider animals to have rights, so animal welfare concerns could be more directly addressed through animal welfare regulations (10). However, all this makes sense given a certain philosophical grounding for concern for animals, namely an animal rights view. Not only could animal patents work to perpetuate or promote animal suffering, the mere practice of patenting animals violates animal rights by treating them as means to our ends. Patent advocates may respond that public policy should not be molded to accord with one particular minority view of animals and morality. However, for animal rights advocates, the situation is analogous to slavery. If all humans have moral rights, then slavery should be abolished, regardless of whether the majority believes in it and benefits from it. Animal patenting could be compared to patenting of genetically engineered slaves: although slavery is the main practice that should be abolished, the logical implication is that patenting of slaves should be abolished as well, especially if it eases the commercialization of slaves. If the main practice seems unlikely to disappear in the near future, then attacking the newer, more controversial patenting practice makes

sense, particularly if there is a real possibility of banning patenting.

Extending an animal rights view further, biotechnology critics such as Jeremy Rifkin argue that animals have a right to species integrity violated by genetic engineering (16). Defenders reply that genetic material can move between species in nature, and we have been genetically manipulating plants and animals for generations through traditional breeding. Moreover the notion of species' rights is extremely controversial, even compared to the concept of animal rights. (4,10). Finally, this criticism does seem directed more toward genetic engineering than patenting.

Reductionism

Animal and sometimes plant patents are also criticized on grounds that are less directly related to animal welfare. Critics argue that patents are reductionistic and encourage and intensify the commodification and objectification of living organisms, particularly animals. Characterizing GMOs as human "inventions" attaches too much importance to the contribution of scientists and too little importance to what God or nature has given us. It demonstrates an attitude of hubris or arrogance that is also apparent in our release of these organisms into the environment when we cannot fully understand or control the risks. Let us consider these objections, which take both secular and theological forms, in more detail.

Objectification. Patent critics argue that the language used to describe transgenic animals reveals a mechanistic view of them. They are bioreactors, biofactories, disease "models," and so on. While objectification occurs without animal patents, patenting takes the objectification to a new level by reconceptualizing animals as human-made utility inventions and "compositions of matter" (17,18). Critics argue that God or nature creates life, and it is absurd and arrogant to patent living organisms as human inventions. Even GMOs usually have only one or a couple of transgenes, which are merely transferred from another living being rather than being created de novo. At most we are moving around a few parts of God's or nature's creations (19,20).

Patent advocates reply that a patent does not mean that one has created an invention from nothing; patents are allowed for improvements on preexisting things. Of course, humans did not invent the mouse, and they do not patent mice, the entire species. Instead, they patent mice that have been genetically altered in a small but significant way. This does not detract from nature or God's handiwork, it merely adds to it. Scientists would be the first to admit that they are far from being able to create an entirely new animal out of nothing. Moreover genetic engineering, patenting, and the use of terms such as "biofactory," are compatible with proper respect for life in other contexts. Although humans are technically "compositions of matter," they are also much more, and so are other living organisms (21).

Patent critics may be skeptical of this response. It might be compared to the argument that treating people as sex objects is compatible with respecting them in other contexts; feminists are skeptical that compartmentalizing really works that well. Objectifying animals helps us view their plight as morally irrelevant, just as objectifying women helps rationalize violence against them, and objectifying the enemy in war helps soldiers commit acts of violence against them (18,22). While it is not clear that this argument holds merit, it is also not clear that patent advocates are correct that viewing animals and plants as inventions has no larger implications for our treatment of them and our conception of humanity's relationship to the rest of the living world. There may be grounds for making a distinction between the ownership of particular animals, and the ownership of, say, all mammals with a certain gene. There is, one might argue, a difference in attitude (which is simply a fact of our society) between the owner of a cow or dog, and the owner of a technology/invention. This takes the mechanistic view of nature even further than it has previously been extended. We may think that we have finally refuted and rejected Descartes's view that animals are simply machines — but wait! They are, after all, but our own technologies, our own inventions. To say that we own an animal is different than saying that we invented them or that they are a technical solution to a technical problem (7). It is a mistake to completely attribute this debate to a misunderstanding of the practical, patent law distinction between discoveries (unpatentable) and inventions (patentable). Indeed, some molecular biologists agree with the public on this point, hardly out of ignorance of science or patent law. Science and technology, discovery and invention, are becoming increasingly blurred in biotechnology. If a gene, its function, and its structure are scientific discoveries, how can the purified and isolated gene become an invention (23)? The public is perplexed and accuses patent lawyers of playing word games. Critics may charge that patent law has focused too much on technical definitions at the expense of the commonsense "fact" that human, animal, and plant genes are discoveries, not inventions, and that even genetically modified plants and animals still do not qualify as inventions (24,25). We will raise this issue again in the final section.

Commodification. The Council for Responsible Genetics argues that "Patenting organisms and their DNA transforms them into commodities for profit and promotes the view that living beings are little more than 'gene machines'" (26). One may well not be opposed to the research itself but rather to certain forms of its commercialization made possible by patenting. Most people support genetic research that would lead to new forms of human gene therapy. They might even be in favor of commercializing gene therapy, to the extent of making it a private for-profit venture and allowing many aspects of the research (e.g., new processes) to be patented. Opponents of patenting genes argue that genes should and in some sense do belong to everyone and no one. Every researcher should be free to work on them and try to use them to benefit humankind, without having to get a license and pay a royalty. Of course, if companies are able to patent only the process they use but not the gene product, it will be difficult for them to control profits, but to stake a claim on genes themselves is to go too far. Opponents of animal

patents may view the primary problem as patenting itself rather than, or above and beyond, the suffering that occurs. Groups such as Global Action in the Interest of Animals (GAIA) object to the patenting of animals even where the animals do not suffer, or actually benefit, from a genetic modification (17).

Patent advocates reply that we have owned and bred animals for centuries. The fact that a genetically engineered line of mice is patented is unlikely to affect our treatment of those animals, and animal welfare concerns should be separated from patenting (4,9). Moreover patents are needed in order for companies to have an incentive to invest in and commercialize socially useful research. However, critics, including many scientists, are skeptical that this is actually necessary, and argue that it may actually hinder research (27–29).

Why object to patenting genes and GMOs, apart from concerns about genetic engineering itself? This view should not be confused with a criticism of research into a particular area. It is rather an argument for limiting the subjects of product patents, regardless of whether we wish to limit the research itself, and regardless of the fact that patenting genes probably does meet the criteria of current patent law and is explicitly supported by the *Chakrabarty* decision.

HUBRIS AND RISKS

"From an ethical perspective, the patenting of animals reflects a human arrogance toward other living creatures that is contrary to the concept of the inherent sanctity of every unique being and the recognition of the ecological and spiritual interconnectedness of all life" (30). Michael Fox argues that patenting will accelerate the "transformation of life and of the creative process to serve purely human ends, and as many see it, the end of the natural world" (8). Such critics also often question the wisdom of moving genes around. They worry that we do not adequately understand the risks, that we are transgressing natural barriers that might be best respected, and that we often harm transgenic animals. In our hubris we consider GMOs and even unmodified genes to be our inventions, and we further assume that these creations are so under our control that the risks of introducing them are minimal (31). Critics see patenting living organisms and genes as arrogant and unwise. They worry that the upshot of patenting living organisms may be the devaluation of all life, including human life (18,31).

Patent advocates respond that once again, critics should attack the real "culprit," rather than patenting. Concerns about the risks of genetic engineering should be addressed by the U.S. Environmental Protection Agency (EPA), the Food and Drug Administration (FDA), or other regulatory agencies, rather than the patent office. The mere fact that one has patented a genetically engineered organism provides no assurance that one will actually be able to use and market it; it may not receive regulatory approval for release (32). If regulatory processes for genetically engineered organisms are seen as inadequate, then they should be criticized, rather than patenting. If genetic engineering is unwise or unnatural (either in general, or in particular cases), then criticize genetic engineering itself rather than patenting (9).

Rather than being a *symptom of* worries about risks, the hubris objection to patenting "life" is sometimes more accurately classified as *parallel to* concerns about risks. Biotechnology critics hold that our arrogance and greed leads us to engage in risky behavior, and at the same time leads us to consider living organisms and genetic resources as mere inventions to be patented. Another part of the same arrogance and greed is our treatment of animals, which is poor to begin with and often only intensified by genetic engineering. We hold ourselves up as masters and creators of the natural world rather than a humble part of it. This view can take theistic or secular forms, and it may be accompanied by more or less skeptical attitudes toward the possibility of wise, safe genetic engineering. Some critics see genetic engineering as entirely unnatural or immoral, and others do not reject it out of hand but only want it to be done and applied with wisdom and justice.

PATENTING, FARMERS, AND "BIOSERFDOM"

Some farmers' advocates oppose plant and animal patenting. One major concern is that patenting will further encourage factory farms and the consolidation of agribusiness at the expense of small farms and farming communities. Critics charge that agribusiness is becoming an oligopoly. As companies merge and become vertically integrated, they control more of agriculture, and independent animal and plant breeders and dealers can scarcely compete (33). With large multinational corporations heavily invested in genetic engineering, they have to heavily promote their products to recoup research costs. Large corporations are better equipped to handle patent applications and infringement cases. If there are few competitors left, then there will eventually be few affordable, nongenetically engineered varieties available to small farmers, who are so squeezed for profits that they can scarcely afford to make more expensive or less efficient purchasing decisions than their corporate competitors. Practically speaking, they will have little alternative to purchasing expensive patented varieties, both because little else will be offered for sale and because their larger competitors will also be doing it. The genetically engineered varieties are more likely to be well suited to large corporate farms, with their high technology inputs and large economy of scale.

Patents may further mean that farmers are prohibited from breeding animals and seeds for their own use. Patent critics and even sympathizers have argued that at minimum, there must be an exemption for breeding by farmers, particularly small- and medium-sized farmers. Currently U.S. law does not have such an exemption, although European law has an exemption for "small" farmers (33). In the absence of such an exemption, patent advocate Robert Merges argues there are two practical problems. First, considerable record keeping would probably be required of farmers to prove that they did not breed any patented animals without paying the proper royalty. Second, enforcement procedures might be difficult, and might require farmers to open their

farms' animals to inspections to ensure that no patent law violations had taken place (10). Even if farmers are allowed to breed patented varieties without paying royalties, genetic drift assures that in a few generations, most will want to renew their stock from commercial breeders to retain desired traits.

These practical problems also raise moral issues, namely the reduction in the autonomy and privacy of farmers. Critics charge that even Western farmers are becoming poorly paid employees with no applicable minimum wage laws and little autonomy. "As the life industry dictates more and more of the farm-level management decisions, the farmer becomes little more then a 'renter' of proprietary germplasm and information, a step in the food/industrial manufacturing process. Farmers and consumers thus increasingly lose control over what products they grow and consume, and which food production processes they chose to support" (34, p. 5). Some critics have denounced this as bioserfdom. They worry that animal and plant patenting is merely another step on the way to bioserfdom and corporate agriculture, with poor conditions for farmers and animals alike. Let us consider the role of licensing restrictions and the so-called terminator seed in promoting this situation. As we will see, an exemption or derogation for farmers might not be sufficient to prevent it.

Seed Saving and Licensing Restrictions

Farmers traditionally have saved seeds from part of their crop for breeding, trading, and planting the next season. This still occurs to a certain extent in developed countries, particularly for non-hybrid crops such as cotton and rice. The practice is more common among poor farmers in less developed countries (LDCs). "Between 15 and 20 percent of the world's food supply is grown by poor farmers who save their seed. These farmers feed at least 1.4 billion people" (35). Seed companies view seed saving as a problem in expanding their market and protecting their intellectual property, namely proprietary seeds. An analogy may be made to computer software; farmers buy the right to plant the seeds but not to make "pirated copies" by planting second generation seeds. "From an industrial perspective, plant varieties are to be used for growing a crop. All other unauthorized uses of varieties lower returns on investment and therefore must be eliminated" (33, p. 139). Constantly improving seeds is one way to encourage farmers to buy seeds every growing season. However, seed research is expensive and most improvements are small, so this alone may not be sufficient, particularly for nonhybrid crops. So seed companies look to new ways to protect their intellectual property from what they view as the piracy of farmers.

Restrictive licensing agreements attempt to ensure that seeds will not be saved and replanted without payment of royalties. Monsanto has been criticized for its practice of requiring such contracts, which include a rather unpopular provision that Monsanto's agents — sometimes dubbed "gene police" — may enter the farm and test for Monsanto genes for a period of three years following the initial purchase of seeds (36). Monsanto even provides a toll-free number for farmers to report suspected violations and has publicized the names of violators on radio stations, in addition to suing for compensation. Of course, no one is *required* to buy seeds from Monsanto, so if farmers don't like this policy, they may take their business elsewhere, and avoid trading seed with Monsanto customers.

Such a policy of policing intellectual property is criticized as an example of bioserfdom. It is obviously not popular with many farmers and requires considerable expenditures for enforcement and litigation. In LDCs, matters are even more difficult; enforcement costs might be higher, and legal support dubious or lacking. Indeed, proprietary seeds could make it to a developing country without the company's knowledge, and many LDCs are notorious for failing to protect intellectual property. Such licensing agreements may turn out to be an unpopular and not especially effective strategy of protecting intellectual property.

Technology Protection System: "Terminator" Seeds

A further step in protecting seed intellectual property from farmers is to build a technological "fence" around proprietary seeds, comparable to software copy protection schemes (37). Indeed, such a fence is in the development stages: TPS (technology protection system) seed is being developed by the U.S. Department of Agriculture (USDA) and Delta and Pine Land Co., dubbed "the terminator seed," "suicide seeds," or "traitor technology" by Rurual Advancement Foundation International (RAFI) and others. TPS seeds are genetically modified with an extra gene that seed companies can "turn on" before selling the seeds (38) so that second generation seeds are sterile. "The Terminator provides a built-in biological 'patent,' enforced by engineered genes" (35, p. 1). Farmers would buy TPS seeds, which offer farmers no direct benefit in themselves, because the TPS trait would be paired with other valuable traits. They would then have no alternative but to purchase new seeds each growing season, or to buy whatever seed varieties do not include TPS. Of course, critics worry that agribusiness industry is shaping up in such a way that there will be few choices.

The media, developing countries, and several non-governmental organizations (NGOs) have expressed outrage over TPS. NGOs such as RAFI have called for a global ban, claiming that:

> It is a global threat to farmers, biodiversity, and food security. The seed-sterilizing technology threatens to eliminate the age-old right of farmers to save seed from their harvest and it jeopardizes the food security of 1.4 billion people — resource-poor farmers in the South — who depend on farm-saved seed. . . .If the Terminator technology is widely utilized, it will give the multinational seed and agrochemical industry an unprecedented and extremely dangerous capacity to control the world's food supply (39).

Similarly the Center of Education and Technology in Chile warns, "This is an immoral technique that robs farming communities of their age-old right to save seed and their role as plant breeders. Farmers and governments everywhere should declare the use of the technology as contrary to public order and national security. This is the neutron bomb of agriculture" (40). Influential groups such

as CGIAR (Consultive Group on International Agricultural Research) have condemned TPS, and several countries have banned it.

In response to these sorts of criticisms, the USDA released a *Fact Sheet: Why USDA's Technology Protection System (a.k.a. "Terminator") Benefits Agriculture—A Discovery to Spur New Crop Improvement*. The fact sheet claims:

> Because of [farmers'] seed-saving practice, companies are often reluctant to make research investments in many crops because they cannot recoup their multiyear investment in developing improved varieties through sales in one year (38).

The fact sheet goes on to assert that farmers as well as the environment will benefit from new seed varieties that seed companies will be inspired to develop, given the reassurance that their intellectual property will be protected. In particular, "small farmers may benefit greatly if the invention stimulates the extension of biotechnology to 'minor crops' such as tomatoes," since the seed industry will see greater potential for return on their research investment into these minor crops (38). Advocates argue that farmers in developing countries will still be able to save their traditional and public seed varieties. Rather than posing a threat to world food security, it will do the opposite, as seed companies will feel more secure in releasing genetically improved varieties in developing countries with poor intellectual property protection. This will help even the playing field between U.S. farmers who abide by intellectual property laws, and LDC farmers who often do not. In other words, it requires everyone to pay their fair share of the seed research that they benefit from. The market for terminator seeds will not extend beyond its benefits to farmers since no one is forced to buy TPS seeds. Moreover it is a safe technology that poses no risks to the environment, and that may indeed help prevent the unintentional spread of other genetically modified traits. Finally, TPS is part of a larger research program that will allow the controlled expression of many traits in plants, and that has the potential to enormously benefit agriculture.

This is scarcely the place to resolve the controversy, which has received little serious academic attention (41). However, it is clear that TPS is appropriately named Technology Protection System. The debate must be understood as part of the debate over plant patents, especially restrictive licensing agreements. Although TPS is several years away from commercial release and may never prove viable in its current form, expect further attempts at "fencing" plant—and eventually animal—intellectual property.

"Bioserfdom," Western Farmers, and LDCs

In sum, if patents tend to work more to the advantage of large corporations, and if increasing control of agribusiness by large corporations tends to work to the advantage of corporate factory farms, then small farmers view animal and plant patents as another stake being driven through the heart of the Jeffersonian ideal of the yeoman farmer. Critics believe that patents are a government incentive that works mostly in the favor of corporate agribusiness, and contrary to the purposes of preserving the independent family farm. If the government does not want to support family farms, they should at least not provide incentives for the corporate competition that already enjoys many advantages. Again, this is not to say that individual patents might not help small farmers, but on balance the practice of biotech patenting is seen as a tool for agribusiness and corporate farming. Corporate breeders want farmers to keep coming back to them every time rather than breeding their own sometimes, and patents and licensing agreements help ensure that this happens. Many farmers are skeptical that this ultimately will be to their advantage, even if it does encourage more investment in research. The agricultural technology treadmill may help early adopters of new technologies, but given current low prices and overproduction, in the end these new technologies will only drive down food prices further—which might be nice for the consumer but not for most farmers. A strong system of patents in agriculture is, critics say, likely to promote corporate dependence rather than sustainable farming.

If this is true, will patents at least benefit farmers and consumers in countries where overproduction is scarcely a problem? Patent critics argue that these countries are most in need of sustainable solutions rather than increased dependency on Western corporate agriculture. The poorest farmers in those countries are subsistence farmers who cannot afford genetically engineered animals and seeds, plus the capital-intensive farming methods that tend to go with them. Critics worry that like the Green Revolution, new genetic technologies will simply perpetuate or even worsen inequalities of wealth by benefiting large, wealthy farms in those countries (60). Moreover, even if the result is cheaper food, this does not benefit subsistence families. Furthermore many of the crops grown in those countries are actually for export, and do not help feed the poor in that country. Multinational corporations argue that patents are good for American farmers because it is unfair that American farmers pay royalties while farmers in LDCs do not. However, advocates of LDCs argue that they can hardly afford to pay such royalties; how much are U.S. farmers really disadvantaged when compared to farmers in LDCs?

Patent advocates respond that "the economic forces driving a family farm into liquidation, or an academic institution into embracing some corporate suitor, operate quite independently of patents . . . [patenting] is essentially neutral as to oligopolistic trends that may be at work in the present economy. . . .Think twice before turning to the patent system for a means to alter their course" (32, p. 9). "If the government wants to avoid any negative impact of animal patents on the family farm, the appropriate approach is to create mechanisms to enable all farmers to gain access to this new technological development through agricultural extension services and special subsidies" (4). Although other approaches may be necessary to address many of these concerns, patent critics may still be justified in their concern that extending patent law to living organisms is likely to provide incentives that help structure the market in ways that are more favorable to corporate agriculture.

PATENTING AND BIODIVERSITY

If farmers are not allowed to breed plants and animals themselves, biotechnology critics such as Vandana Shiva charge that this increases the centralization of breeding and promotes genetic uniformity rather than biodiversity (19,43). As farmers relinquish their independence and are compelled to forgo most breeding, and as independent breeders go out of business or are bought out, there are fewer options offered and less difference among the options. Monoculture is already a dangerous trend in agriculture, and patenting will just encourage the marketing of varieties with a great deal of genetic uniformity.

Patent advocates respond that monoculture is indeed a worry, however, patents do not contribute to it. Indeed, allowing the patenting of genetically engineered plants and animals may make it more profitable for researchers to innovate to avoid the dangers of genetic uniformity, and to preserve genetic resources for use as raw materials (32). Shiva and others reply that genetic engineering may alter traits or create new ones, but generally this involves only one or a few genes. Thus, even if genetic engineering provides new varieties, they may differ little from other varieties in ways other than the engineered trait (19). Moreover regardless of how new the trait is, if millions of "copies" are sold, there is considerable genetic uniformity. Insofar as patents and licensing agreements limit the ability of farmers to engage in independent breeding, these practices in themselves do contribute to monoculture and the loss of biodiversity.

PATENTING, BIOPIRACY, TRIPS, AND NATIONAL SELF-DETERMINATION

In response to concerns about patenting and bioserfdom, patent advocates assert that "the patent office is not the place to structure a morally appropriate program for the international economic order" (9). However, in the age of information technology, developed countries want and demand strong intellectual property protection worldwide, and consider the absence of such laws to be an unfair trade barrier; developed countries use the patent office to promote their own goals including fairness. Patent advocates often miss the fact that plant and animal patenting raises issues of national self-determination, at least in the era of TRIPS (Trade Related Intellectual Property Rights). "With the advent of TRIPS, virtually all the world's nations have lost their right to determine the balance of private and public benefits designed to meet national goals. Instead, they must comply with a single international standard designed to open their markets to transnational corporate interests" (44, p. 1). Although many LDCs are opposed to plant and animal patenting (if not all patenting), they are being required to adopt patent or patentlike protection for plants and animals, or else suffer serious economic consequences.

According to patent critics, TRIPS are particularly egregious, considering the fact that developed countries have taken or "pirated" the genetic resources of the South for centuries; each side accuses the other of piracy and attempts to take the moral high road. While the North is economically and technologically rich, the less developed South is genetically rich. Plant and animal varieties have been exported from LDCs for centuries, with no compensation to the countries where they were domesticated and made more valuable over many generations of work by indigenous peoples. Indeed, they are treated as and referred to as unimproved genetic resources, rather than the collective property of indigenous communities. International seed banks have been established to save these genetic resources, and many Northern researchers come looking for genetic "gold" to bring back to their laboratories, often with indigenous people as their free "tour guide" (19,45). Recently some researchers have offered compensation to the country of origin if a successful product is created, but much so-called biopiracy occurs without compensation. Moreover compensation is usually small, and often the indigenous community has no control over how the money is used. If it is devoted to preserving the country's genetic resources, this may be rather self-serving on the part of researchers who want to mine further genetic treasures (33).

Many LDCs see genetic resources as the common heritage of humankind which they have no desire to privatize, much less have privatized by others (16,46). They are outraged to discover that medicinals or crops first developed in their country are patented by multinational corporations, or even by the U.S. government. Indeed, the U.S. National Institutes of Health (NIH) has gone so far as to apply for a patent on cultured tissue samples taken by indigenous peoples themselves (which it later dropped). Critics are aghast that not only the country's genetic resources, but also the tissues from its people, are being privatized and commercialized. Patents on some of India's genetic resources have been extremely controversial. India accuses corporations of pirating the sacred neem tree, traditional medicinal uses of turmeric, and basmati rice. While some of these patents have been dropped or overturned, countries such as India continue to worry about biopiracy, and object to international pressure to adopt strong intellectual property protection, particularly over living organisms and genes.

This debate raises issues of international justice, national self-determination, and what should remain in the commons rather than being privatized (47). Many patent critics view genetic resources as a commons, to be shared for the benefit of all (46). Some patent advocates reply that if LDCs are concerned about biopiracy, they should privatize their own genetic resources. If research companies come and find these resources unclaimed, the indigenous peoples have no one to blame but themselves. Simply privatize and fence in the genetic commons, and corporations will have to buy the genetic resources they need from other countries (48). Critics view this response as impractical and beside the point. Even if the practical problems could be surmounted, the moral objections to privatizing the commons would remain. Part of the concern is that developed countries are taking unfair advantage of poor countries, but another part of the concern is that privatizing genetic resources is simply not appropriate; they should belong to no one and everyone, for the mutual good of all.

CONCLUSION

The debate over patenting the products of biotechnology is often polarized. Critics are characterized as being anti-biotechnology, or at least anti-genetic engineering, and quite possibly technophobic. Often the objections to patenting, which to a great degree are interrelated, are characterized as attacking the wrong practice, perhaps to increase public criticism of biotechnology in any way possible, or perhaps because the critics themselves are confused. However, sometimes the attack of patenting is perfectly logical, even if it may rest on the attack of other practices.

Moral Justification of the Patent System

Patenting is characterized by its advocates as morally neutral, and even most critics would agree that we do not want the patent office to act as the arbiter of technology and morality. On the other hand, patenting is supposed to advance morally significant goals. Patents were established to promote useful inventions and thereby benefit society — a form of utilitarian justification. Alternatively, they were established to protect the natural rights of inventors to the fruits of their labors (50). Thus, in a sense, the patent system depends on moral argument. What is the appropriate scope of patent law in biotechnology? It depends on what we take to be the real philosophical justification of the patent system. If patents are justified by the extent to which they encourage research, would this extend to the patenting of living organisms and even human genes? Or if the justification is the protection of the natural rights of inventors to the fruits of their labors, can this be extended to living organisms and especially human genes (27)?

If we choose the former rationale, then it is reasonable to question the extent to which plant and animal patents are likely to benefit society as a whole, particularly in an era when the Western patent system is being imposed internationally against the wishes of numerous countries. Many Westerners simply assume that patents are effective and beneficial. However, it is instructive to examine this assumption, which some argue is unwarranted (27,49). Patents historically were grants of monopoly protection for those who imported, not invented, technologies. Patents initially played a greater role in technology transfer and excluding competitors than in promoting research. They are now being used to keep developing countries from the "piracy" European countries initially designed them to promote when it was in their own interests. In nineteenth-century Europe, many philosophers and economists opposed patents on the ground that they were forms of corporate protectionism that prevented the efficient operation of the free market (50). Now most people assume the opposite, but is the assumption justified? Perhaps not. Patents have played an interesting role in the transformation of agriculture into agribusiness, and it is instructive to study the history of agribusiness opposition to and later support of patents (33,45,51). Indeed, most of the debate over "patenting life" is explicitly tied to larger questions and assumptions about the structure of agriculture and the effects of globalization.

If, on the other hand, the protection of the natural rights of inventors is the primary justification for patents, then it is perfectly reasonable to question the extent of these rights. In particular, it makes sense to consider what belongs in the genetic commons as discoveries and the natural heritage of humankind rather than industrial or government property. Patent defenders, even philosophers, often ignore arguments about the genetic commons. Yet this is the most unique and independent part of the debate. This is a very philosophical issue about the nature of property rights and the commons, and does not rest on larger concerns about animal welfare, family farms, and the like. As such, and given its role in the international debate over TRIPS, this issue deserves greater attention, especially from philosophers.

Novelty, Nonobviousness, Breadth, and Patenting Discoveries

Many responses to criticism of plant and animal patenting ignore problems of the breadth, novelty, and utility of some of the patents being issued. Such problems are not necessarily new or unique, but they may be worse when applied to GMOs. Questions about patenting living organisms have been raised by many scholars who are not necessarily biotechnology critics, such as Louis Guenin (52), Philippe Ducor (53), and Brian Cannon (54). It is instructive to see how the moral arguments against this patenting practice fits within this more academic debate. Moreover some of these scholars have specific proposals that might make patent law more consistent and logical while at the same time addressing some of the moral concerns regarding the patenting of living organisms and genes (although such proposals are beyond the scope of this article). Let us briefly consider some of these criticisms.

Charges of biopiracy may be recast as concerns about the way that the patent law criterion of novelty is being applied. Patent applications must identify any prior art that would be relevant to the patent. The fact that indigenous peoples may have cultivated and improved a variety over generations, or developed a particular use for a plant, is not reflected in prior art, which consists primarily of Western scientific writings. Thus something invented by indigenous peoples could easily be patented as a new invention — even if it had not been modified at all. On appeal, the patent might or might not be rejected — assuming that someone has the knowledge and resources to appeal it. Our Western patent system does very little to acknowledge our transfer of genetic resources and indigenous knowledge. Thus the charge of biopiracy may be seen as at least partially a concern about how the criteria of novelty and nonobviousness can be understood within an international, cross-cultural context.

Plant and animal patents are also criticized for being overly broad (16). Patents are often characterized as a trade-off between the interests of inventors to recoup their costs and the interests of society in having inventions widely and cheaply distributed. Patent advocates argue that this trade-off works to the best interests of society in the long run. However, overly broad patents may strike

the wrong balance in this trade-off, and allow patent holders too much control over the development of further research. Since *Diamond v. Chakrabarty*, "anything under the sun that is made by man" can be patented in the United States. Unfortunately, there is a tendency for patent applications to claim not just anything but rather everything under the sun. Allowing broad patents may not be in the best interests of developing nations, some of which already depend on genetically engineered rice or other crops to feed their growing populations and perhaps produce a small amount for export. Even within one country, very broad patents may benefit one firm at the expense of other firms and often also the public interest (27).

Finally, patenting unmodified genes (human, animal, or plant) is often criticized, even by those engage in biotechnology research. The U.S. PTO allows patenting of cloned, unmodified genes. Cloned genes are not the same as their counterparts in nature, and cloning involves an inventive step. Thus, when scientists discovered and cloned a human breast cancer gene, they patented it. Likewise animal and plant genes can be patented, even if they have not been genetically modified. Patent lawyers explain that GMOs and genes that have been isolated and purified (cloned) are a technical solution to a technical problem, and do not occur naturally. Contrary to the No Patents on Life! petition, they are not "part of the natural world" and do not exist without considerable human innovation.

To patent critics, this is the height of absurdity. Inventions are patentable, but not discoveries. We say that scientists *discover* a gene, not that they *invent* it (49). Patent critics, some of them scientists who understand what goes into cloning a gene, remain unconvinced by the answers of patent lawyers. The general public may not have the knowledge of patenting criteria to express their concern properly, but they are appealing to an intuitive form of the idea that patents must meet the criteria of novelty, utility, and nonobviousness. A cloned gene seems to them to fail the criterion of novelty and/or nonobviousness. To say that scientists *invented* an animal hormone or a breast cancer gene seems inaccurate and arrogant, even though most of these critics would applaud breast cancer research. Although the location and sequence of the gene might be nonobvious, once a gene is discovered, is the process of cloning it nonobvious and the resulting cloned gene novel?

Finally, many critics of plant, animal, and gene patents are perfectly happy to accept process patents. It is a mistake to attribute all of these criticisms to concerns about the research itself, or concerns about animal welfare (7). Rather, they are often genuine concerns about what should constitute a valid patent, what constitutes a criterion such as novelty, and whether it makes sense to say that an entire line or species of animals or plants could be owned (as opposed to owning individual animals and plants). Patent advocates often oversimplify the views of critics, whose spokespersons often are not philosophers or legal scholars and whose arguments are sometimes admittedly not fully developed. However, there are indeed serious issues here. The patenting of animals and plants raises many moral and social issues that have not yet been resolved and that will only become more important in an increasingly globalized information economy.

ACKNOWLEDGMENT

This article was made possible in part by an Iowa State University Science, Technology, and Society grant. Some of the initial research was made possible by a research leave at the Social Philosophy and Policy Center. I would also like to thank my capable and well-organized research assistants, Stacy Bastian and Katherine Dresser, my secretary Janet Krengel, and my husband Richard for playing single dad while I hid in my office.

OUTLINE

INTRODUCTION

Should governments fund scientific research? If so, what types of research, basic or applied? How should taxpayers' money be allocated? What priorities should the government adopt, and how should those priorities be set? If government research yields commercializable products (other than solely for military purposes), how should those developments be moved into the market? Should private parties be permitted to have exclusive rights to publicly funded inventions? And, ultimately, who are, and who ought to be, the beneficiaries of publicly funded research?

To analyze these questions, we look here at the development of research funding policy in the United States. Because of its free-market roots, the United States has approached these questions with trepidation. Over the last 200 years the country has moved incrementally from funding only research having military importance to current policies that provide substantial support for basic biomedical sciences, among many others, and permit private commercialization of and profit from the resulting intellectual property. This intellectual property is heralded as the means to economic prosperity both domestically and in the global marketplace. Though this can be considered standard free-market industrial policy, the public that invests in scientific innovation conceptualizes its benefits in ways other than economic, such as through the development of life-saving medical technology or an increase in general knowledge. Although there are cases where both economic and social benefits of science can be achieved concurrently, technological and industrial growth, particularly in the area of biotechnology, has increased the potential for these goals to compete. Today the government promotes scientific innovation with marketplace incentives which, while serving to promote technological advance and the development of public goods, raises numerous ethical concerns, such as its perpetuation of inaccessible health

care for many individuals and the privatization of basic research knowledge.

EARLY INNOVATION

Although in 1776 there was little tangible evidence of the benefits of scientific advancement, the founding fathers intuitively recognized the importance of innovation for a developing nation. It was argued during the Constitutional Convention that the wording of the constitution ought to reflect the new republic's "duty and ability to encourage progress in the arts and sciences" (1). To this end, some argued the need for constitutional provision for technical schools, societies, seminaries, and a national university. Those who saw pecuniary incentives as the cornerstone of innovation sought constitutional provisions for patenting rights, as well as rewards, prizes, and direct subsidies for citizens who endeavored creatively to promote agriculture, commerce, and other social goods.

Ultimately innovation was afforded very limited constitutional protection for fear that broader commitments would strengthen the central government and thereby increase the potential for later abuse of power. The only explicit constitutional provision for innovation grants Congress the power to:

> . . .promote the Progress of Science and useful Arts, by securing for limited Times to Authors and Inventors the exclusive Right to their respective Writings and Discoveries (2).

A. Hunter Dupree, in his seminal work *Science in the Federal Government*, interprets this clause as sanctifying the creation of national scientific institutions (1). Prior to its first comma, the clause states the intention to promote advancement of the arts and sciences. The intention is qualified by the English practice of affording inventors exclusive ownership of their work as an incentive for further innovation and development. This qualification, Dupree argues, is neither a prohibition of, nor suggestion for, publicly funded research because the Constitution does not address the concept directly. For the century following, however, opponents of government support of research argued that Congress was permitted to do only what the Constitution explicitly authorizes so that the absence of a provision permitting research funding prohibits Congress from doing so.

Although the language of the Constitution falls short of reflecting its framers' high regard for innovation, the government was constructed to rely on scientific expertise. From its inception, the basic operations of the federal government have relied on technical skill, such as surveying new territory and establishing coinage, weights, and measures. However integral to its function, the role of science in the federal government was informal and would remain so for generations.

According to Dupree, the nation's inherent regard for science stems from the invocation of natural law used to deliver its founders from the political and clerical despotism of England (1). With the same rationalist approach used to create the new republic, the founding fathers sought to expand natural history, philosophy, political theory, and science in the New World (1). The widespread dislike of bureaucratic and oppressive rule, however, led the federal government to call on scientists only when needed rather than to expand its organization to employ them full-time. As a result the pursuit of knowledge was slated to occur largely outside of the government domain.

The nation's early scientists were upper-class, professional males who pursued scientific inquiry as a hobby. Though their science was amateurish, their powerful positions in society allowed them to effectively introduce scientific concepts and traditions into American society. Their observations rarely concentrated on one aspect of the natural world, such as chemistry, physics, or botany, and this lack of specialization limited the potential for scientific accomplishment (1). With little distinction between pure and applied research, "science" became the catch-all category for products of systematic investigation that ranged from philosophical theories of electricity to the construction of ornamental clocks. Although it was recognized that science offered potential benefits, the most significant innovations of the era were the results of trial and error by those unacquainted with the scientific method (1).

In 1791 the federal government received its first request to fund scientific research. In seeking a patent for navigational calculations, a surveyor requested that Congress finance an arctic voyage to test his theories. Though there was some question as to whether the matter should be deferred to state legislators, the larger ethical question of whether the government ought to use public funds for such uncertain ends went unasked. Many supported the concept, seeing the issue only in terms of the nation's need to improve geography and navigation. Others, while reluctant to prematurely reject a potentially beneficial enterprise, advised against the hasty support of philosophical patent applications (1). Ultimately the request was refused on account of the poor success rate of arctic voyages.

A federal patenting board had already been instituted in 1790 to process what was fast becoming an overwhelming number of patent applications. Arguments that either a panel of experts or ordinary citizens ought to compose the board were defeated on the belief that a few politicians, under the guidance of Thomas Jefferson, would offer inventors the best protection. Authorized to withhold patent rights for inventions lacking novelty, utility, or importance, the nation's first patent board demonstrated how government regulation could be used to promote the general welfare.

Jefferson understood that the fundamental task of a patenting board is to advance society by delicately balancing two often-competing goals: the desire to encourage innovation versus the need to prevent destructive monopolies. Patents essentially function as a government-endorsed monopoly in that they confer exclusive rights to use, produce, and sell an invention. The provision of exclusivity serves as an incentive for individuals to generate useful, novel, and important inventions and develop them into public goods. By eliminating the threat of competition for a fixed period of time, innovative and enterprising individuals are able to recoup their investment in product development and reap the rewards of their ingenuity.

The patent system benefits society by providing a mechanism for new, technologically advanced goods to enter the marketplace and spur economic growth.

However, if patents were issued indiscriminately, the market could become overrun with monopolies that would impede the competition necessary for promoting technological and economic growth. In the absence of a competition-driven marketplace, the distribution of wealth would be inequitable, the prices of goods would remain artificially inflated, and there would be little incentive to improve existing products. To prevent rampant exclusivity, it is necessary to impose criteria for patentability so that incentives remain for collaborative efforts to expand general knowledge. Otherwise, technology, and in turn society, is unlikely to advance as rapidly. Jefferson sought to protect the public from monopolization that would impede innovation by formalizing the distinction between pure and applied research.

On the belief that exclusive ownership of scientific theories would hinder rather than promote innovation, Jefferson declared theoretical discoveries, or pure science, as ineligible for patent protection. While far from its intention, Jefferson's stipulation transformed the congressional sentiment toward scientific research from one of relative support to complete disinterest in any form of innovation that was not reducible to a "machine of potential cash value" (1). Congress, consistent with its aversion to bureaucratized government, used Jefferson's patent policy to free itself from any formal involvement in scientific research. It contended that the constitutional provision empowering Congress to issue patents limited the congressional role in innovation to that function. The federal government thereby distanced itself from basic science by declaring the subsidization of basic research unconstitutional and its findings ineligible for patent protection.

Jefferson, in contrast, believed Congress ought to exercise its constitutional power to encourage innovation by subsidizing the advancement of pure science. He understood that applied science would prosper in the hands of private enterprise because the potential for profit would attract investors. Pure science, however, would be less likely to prosper through private support because it offers a public good that has little profit potential. It was therefore in the nation's interest to invest pubic funds into pure scientific research because innovation ultimately stems from the progress of both pure and applied sciences.

HISTORICAL MILESTONES

Congress never failed to see the potential benefits of the scientific enterprise. To avert bureaucratization, it was simply preferable to fund science on an "as needed" basis rather than formalize an expensive, open-ended commitment. The occasional research project was conducted within the traditional units of a federal government that was focused almost exclusively on military and industrial needs. As a result federally funded research began through the Departments of Commerce and War.

Jefferson, when he was elected to the presidency in 1801, paved the way for military research by securing congressional support for the Lewis and Clark expedition. While convincing Congress that a technical exploration of the west was essential for military and commercial gain, he disclosed to the Spanish and French, who controlled western trade, that the mission was for scientific discovery only. The explorers, trained by the nation's scholars in topography, botany, zoology, agriculture, geology, astronomy, paleontology, and ethnology, returned with a body of knowledge so great that it was used to establish an American corridor to the Pacific and a trading presence in the northwest. The success of the expedition inspired Congress to fund, under the auspices of the War Department, further expeditions and requisite technical training. Arguably the earliest arm of the federal government receptive to scientific research, the early nineteenth-century American military gave rise to a national weather service, the first accurate observations of digestion, and research studies of diet and nutrition. (It is through the military that the National Academy of the Sciences was established in 1863, during the Civil War, and the National Research Council was formed in 1916, during World War I.) The research, however, was neither explicitly nor entirely publicly funded. While the government provided scientists with materials and laboratory space, direct funding was considered unconstitutional. As a result the processes of data analysis and publication depended on private support.

This mix of publicly and privately supported research did not confront the issue of ownership rights, for the scientists of the time, though increasingly specialized and respected, "had no aptitude for applying their knowledge to a downstream product (1)." Nevertheless, the potential relationship between the science reported in academic journals and the duty of the patent office was recognized. Henry L. Ellsworth, appointed the nation's first Commissioner of Patents in 1836, expanded the patent office into a "central depository" for innovation in the belief that the eventual merger of science and invention would serve the nation's economic interests (1).

Ellsworth collected patent application fees and used the revenue to acquire patented mechanical models as well as unpatented models, specimens, manufactures, minerals, seeds, and scientific findings culled from various collected publications. He drew from his library various solutions to the nation's agricultural crisis, becoming the first to use statistical analysis in large-scale problem assessment. In his promotion of a recently published German study calling for the use of chemistry to remedy soil exhaustion, Ellsworth recognized what was in fact "the first direct application of pure scientific research to agricultural success" (1). As well as devoting his career to promoting the utility of science, his efforts on behalf of the congressionally neglected farming community laid the foundation for the Department of Agriculture. In his striving to develop a great scientific bureau, the first Commissioner of Patents exceeded the traditional scope of both the patent office and the federal government.

Meanwhile, in 1838, S.F.B. Morse had presented Congress with his invention of the electric telegraph, another striking example of the convergence of pure and applied scientific advancement. Without a niche

in the nation's economy and few precedents regarding the development and ownership of his invention, Morse lobbied for four years to receive a $30,000 grant for construction of a telegraph line connecting Baltimore to Washington, DC (Congress justified the expense under the constitutional provisions for commerce and postal service). In 1845 Morse issued a proposal to extend the line to New York City, but it was voted down in Congress because the southern contingency thought it unconstitutional. Eleven years later the same fate was suffered by the electric motor; after an initial research grant, federal support was withdrawn despite extremely successful results.

Congress justified its recoil from research support with the contention that laying any groundwork for a research bureau would open a Pandora's box of new and unwanted federal responsibilities. It was argued that federally subsidized research would inappropriately risk public funds, while it forced the government into the role of examining agent for both the scientific enterprise and any devices it produced. In addition the deluge of research proposals requiring evaluation and, to exclude charlatans, investigation, would be too expensive and expansive to take on. Thus it came to be that the mid-nineteenth century would see Congress neglecting many opportunities to formally engage in the "industrial development of devices born from scientific discovery" (1).

At the same time Congress had stepped up its support of basic science through its technical explorations of the North American continent. Increasingly basic scientists were becoming government employees, but they were hired only for specific tasks and not for the construction or maintenance of a permanent research bureau. In 1834, when the Coast Survey, traditionally overseen by the Secretary of the Treasury, was reassigned to the Navy Department for cost-containment reasons, the scientists revolted by refusing to share their work with nonscientists. Two years later the Coast Survey was returned to the Treasury; the scientists succeeded in securing pay commensurate with their abilities while establishing civilian control of research.

As the power and prestige of the scientific community grew, congressional sentiment toward their research evolved accordingly. By 1842 Congress had even assumed responsibility for publishing the findings of a military expedition. However, the publication process was a fiasco and the finished product ridden with mistakes. It was clear that congressional committees were incapable of effectively administrating the highly technical enterprise that science had become. It is ironic that by the time Congress came to explicitly appreciate the utility of science, a government of nonscientists was no longer intellectually equipped to oversee its advancement (1).

INDUSTRIALIZATION

Despite the federal government's express regard for science, it had no intention of expanding its narrowly conceived administrative interests. By the end of the nineteenth century, industrialization, urbanization, and mobility had imposed vast and unfamiliar problems on a small-town, agrarian nation that had seen its traditional institutional framework erode (3). While Congress saw issues of social welfare as falling outside its sphere of responsibility, the early industrialists acted to address the issues that were a side effect of their success. Beholden to the Protestant work ethic, they developed philanthropic foundations in the belief that as stewards of their wealth they had a moral obligation to manage it in a socially redeeming way. Technology and standardization were the tools of choice for the industrialists-turned-philanthropists who strove to enhance social welfare in a manner that would serve their industrial interests.

Through addressing the educational and medical needs of the masses, the industrialists established a national infrastructure that would, for years to come, foster industrial and technological growth. Private universities, by educating middle class men in science and engineering, were able to equip an emerging professional stratum with the skills necessary to manage the future of industry. To advance the fields of science and engineering, universities and foundations funded the research of pure scientists as a means to further their respective disciplines.

The expansion of the scientific enterprise proved particularly beneficial to the field of medicine. Standardized and cost-effective, the application of science to medicine, called biomedicine, employed a reductionist approach to disease that complemented the political and economic agenda of industrial capitalism. While diverting attention from the environmental and social roots of working class illness, biomedical practitioners were able to restore health to the level of functionality necessary to labor toward capital accumulation (4). Consequently biomedicine was afforded tremendous industrialist support, for while it sustained a productive work force, its approach to research dovetailed nicely with the broader trend of scientific development.

By the 1920s biomedical research conducted throughout the nation's universities and foundations required coordination in order to make significant progress. Leading industrialists, as part of a larger trend of tying the nation's technologically driven "capitalist infrastructure to government function," requested that Congress act to centrally organize the nation's efforts in medical research (3). The government was open to the proposition. Despite its traditional reluctance to expand in organizational structure or function, it had been taking incremental, yet affirmative, steps toward establishing a formal commitment to national health for over a century.

The government's first intervention in public health came in response to the late eighteenth century scourges of Yellow Fever in the nation's port cities, for it had impeded federal revenue collection. The correlation between the presence of trading ships, communicable disease, and the effect on revenue, properly classified the matter as one of interstate commerce and hence one of the principle responsibilities of the federal government. The Department of Commerce enacted quarantine laws and established hospitals initially intended to care only for merchant seamen, and shortly thereafter for the military as well. By the twentieth century the government had organized a national, comprehensive medical research effort intended to investigate "the origin and causes of epidemic diseases" and established the Hygienic

Laboratory for bacteriological research in its Staten Island Marine Hospital (5). In 1912 the nation's Public Health Service was established to coordinate the government's involvement in issues of public health that quickly expanded to include numerous research studies on various facets of communicable and noncommunicable disease.

With the backing of powerful industrialists (who had already committed to large donations upon the success of the effort), scientific societies, the American Medical Association, and the life insurance industry, Louisiana Senator Joseph E. Ransdell, sought to establish out of the Public Health Service a central office to coordinate the nation's medical research. The 1930 enabling act of the National Institute of Health (NIH) changed the name of the Hygienic Laboratory to NIH and relocated it to a new building. Significantly, the act authorized the implementation of a graduate-level fellowship program to train young scientists in biomedical research. The Secretary of the Treasury was permitted to accept the philanthropic donations that would support these newly organized efforts in medical research. The congressional record of the enabling act, filled with rhetoric about doing God's work, is a reflection of the traditional interests and priorities of the federal government and the influence of industry in its decision making (6). In addition to arguing that science and medicine are intrinsic goods worthy of support, the industrialists convinced Congress of the relationship between health status and productivity to explain how health maintenance is in the nation's economic interest. In order to maintain national health, public and private efforts in research and data collection needed to be coordinated on a national scale. Further, with the nation still recovering from World War I, the fact that German progress in biomedical research appeared to be outpacing the United States served as an added incentive to engage more American scientists in government endeavors. Chemists, in particular, were understood as valuable to military and industrial research, but without an expansion in employment opportunities, they would be unable to apply their expertise to biomedicine. Fellowships, instead, would provide opportunities for this specialized graduate training. Last, perhaps the most attractive aspect of the Ransdell Act was that the NIH was expected to advance biomedicine ostensibly through private funds, with periodic support from the public treasury as needed (6).

BUREAUCRATIZATION

By the 1930s the promise of both public and private support of medical innovation made its potential appear boundless. Dupree's observation of the early republic, however, would remain applicable centuries later, for science is "a group activity carried on by limited and fallible men, and much of their effectiveness stems from their organization and the continuity and flexibility of their institutional arrangements" (1). The twentieth century would not only foster the growth of scientific research, but of corresponding organizational structures that would inevitably dilute its social and economic benefits. This process of bureaucratization permeated America's scientific enterprise whether conducted through foundations, the government, universities, industry, or combinations thereof.

While the foundations of the 1920s and 1930s funded scientific research, the scientists themselves were responsible for resource allocation. Over time, however, a stratum of science-administrators developed who, according to Barry Karl, were "not content in the function as mindless vehicles for the products of the academic mind" and so aimed to create their own professional identity (3). This pseudoprofessionalization of the scientific bureaucracy was counterproductive to advancement. Pure science was no longer conceptualized as simply a public good but as a means to enhance the careers and reputation of the administrators and their foundations. By the 1950s the foundation bureaucrats had taken to "reshaping the substance and form" of research proposals and placing undue demands on scientists who, due to a tight university job market, had few alternatives for employment (3).

During this period of the 1920s through the 1950s, the agenda of the federal government evolved to rely on both pure and applied scientific advancement. While an era of progressivism helped to focus congressional attention on public health needs, an effusive international agenda led to massive scientific undertakings, particularly in the areas of aeronautics and atomic physics. Starting with the National Advisory Committee for Aeronautics in 1920 and continuing through the Atomic Energy Commission and the National Aeronautics and Space Administration, new scientific agencies were established to exploit the quasi-military technology that would have remained uncultivated if development were left to the existing federal agencies and the private sector (7). It is clear that this organizational expansion of scientific support was initially justified by the technological needs of both World Wars and the cold war. Beyond assisting the military, however, the new agencies served the nation's economic interests and, in doing so, demonstrated that pure research is a viable investment in the nation's economic future.

The size and complexity of the government's scientific endeavors, particularly since World War II, required it to extend beyond its own laboratories to cull specialized expertise from the nation's universities, foundations, and industries. No longer was there pervasive opposition to such government expansion. Post–World War II organizational theorists heralded bureaucratization as a product of modernization, "a rational management technique that, while striving for effectiveness and efficiency, would leave the sources of intellect and power under popular control" (3).

By the 1960s the federal government became the nation's primary supporter of pure scientific research. A welcome employment alternative to the politicized foundations, scientists were eager to both receive government grants and organize the process of resource allocation. Like the foundations, however, the government produced a stratum of science-administrators whose professional aspirations would come to intrude on the enterprise itself. The function of government bureaucrats was to

reconcile the goals of the scientific community with the "intentions of Congress and sensitivities of its committees" (3). This differentiated them from the foundation bureaucrats who, at the very core, remained guided by the mission to serve humanity. Government bureaucrats had no such moral agenda but instead endeavored to engage in political maneuvering as a means to climb a burgeoning bureaucratic hierarchy. Karl attributes to T.S. Kuhn the observation that science-administrators are essentially "manipulated into producing results that are determined elsewhere; they have no interest in the process beyond its efficient progress toward its stated goal" (3). Karl explains that the role of such administrators is not intended to interfere with knowledge development, for an administrator's knowledge of the discipline he manages may be limited to that which is directly related to his job function.

This concept of isolating the administrator from knowledge development proved problematic for academic institutions whose researchers were the recipients of the government's expanded support of science. A need developed for a "scholar-administrator" to mediate between the university's internal needs and interests and the increasing external demands placed upon it. Karl explains that university faculty members discovered quickly that "even a relatively brief career as an administrator could jeopardize their scholastic careers" (3). Academic research science was faced with the challenge of finding administrators who, in addition to having basic institutional affection and technical skills, had a professional understanding of the discipline to be managed (3). The typical manager of academic research was either a "critical compromise" between the faculty and university administration, a rejected tenure candidate, a doctoral candidate who never completed a dissertation, or a legal or business professional (3).

As the practice of federally funded, privately managed research grew, it introduced an unprecedented level of government intrusion into university matters (e.g., investigations for equal opportunity and audits for accountability in the use of public and private resources). Left with the very nebulous distinction between public and private affairs, the university relied on its bureaucracy to protect the once independent, private academic system from imposition by the government. Similar to the experience of the foundation and the government, the expansion of academic research institutionalized the bureaucrat into intellectual life (3). Over time these bureaucrats became permanent stakeholders in the American scientific enterprise and became the individuals largely responsible for the mechanics of technology transfer.

DEVELOPMENT OF TECHNOLOGY TRANSFER

In his 1968 book *The Government of Science*, Harvey Brooks discusses public concern over the priorities of the federal government (7). During the 1960s the government was perceived to have "deprived the civilian economy of its sources of technological innovation" with its cold-war preoccupation with military and space technology, while neglecting to apply this innovation to the improvement of social welfare (7). Brooks attributes the government's reluctance to resolve social concerns, such as pollution, urban transportation, and disease, in part, to its inability to reach consensus regarding: (*1*) the degrees to which issues are federal responsibility, and (*2*) the means and ends of proposed solutions to civilian problems. He believes that the feasibility of general agreement on the process and goals of research and development determines how the government uses technological progress to address social needs (7).

Brooks argues that direct subsidization of research and development is an effective means for developing highly technical areas, such as defense and space, since, in reality, their advancement rests on the consensus of only a small number of technocrats. In contrast, civilian technology requires numerous parties, often with divergent interests, to strike a compromise on who, where, when, and what is to be sacrificed in the interest of the general good. To illustrate his point, Brooks describes what the installation of an urban rapid transit system would entail if completed exclusively on government subsidy. Test results of the technology and system would constantly have to be weighed against public opinion. Not only would the process be exceedingly time-, labor-, and cost-intensive, it would be wasteful as well if the result was a system people elected not to use. Brooks questions whether "technical-economic analysis is sufficiently refined to justify large gambles with public funds" (7). Ironically a response to this question requires a public consensus that is, for the most part, impossible to reach.

Many believe that the marketplace is the most efficient and effective tool with which to measure mass opinion of a public good. In addition to turning out the most workable solutions to public demand, it produces the incentives necessary for the demand to be satisfied through private investment. It is widely contended therefore that the government need only provide a "framework of information, incentives, and underlying general technology" for an entrepreneur who, by responding to the marketplace, can accomplish the goals of public policy without risking public funds (7). This indirect subsidization of research and development is often heralded as the means through which innovative technology born from public funds ought to return to the public in the form of social goods. In order for it to be an effective method of technology transfer, however, the government must offer sufficient incentives so private developers will invest in bringing federally funded inventions to market.

The federal government's World War II expansion of research support led to an investigation of the ways in which it could promote private development of its discoveries while, at the same time, retaining an unrestricted right to their use. The Roosevelt administration observed that while the practice of publication protects the government's rights to discoveries arising from its research, those rights would be better secured through patent protection. A 1945 advisory report by the National Patent Planning Commission recommended that the government patent its inventions, but retain exclusive ownership of the titles only in

cases where private ownership would be detrimental to national welfare. The commission advised the government to make its titles generally available, on a nonexclusive basis, to anyone wishing to develop inventions into public goods. It recognized, however, that certain circumstances require the government to offer exclusive ownership rights in order to "induce private manufacturers to commercialize an invention" (8). Roosevelt's commission therefore recommended that exclusive licenses be issued in cases where it was reasonable to assume that the invention would otherwise remain idle.

Rebecca Eisenberg, in her review and analysis of the U.S. history of technology transfer policy, explains that the aim of transferring title ownership from the government to the private sector is to promote economic prosperity by "stimulating innovation, new products and new jobs" (8). Many believe that in order to effectively promote industrial growth, the government must have the freedom to grant private developers exclusive ownership of inventions made at public expense. This is controversial, however, for while exclusive private ownership may be an effective method of putting publicly funded technology to practical use, its method of empowering industry for the promotion of large-scale economic growth often entails the sacrifice of other social goods, such as the sharing of scientific knowledge. On the other hand, the absence of a provision for exclusive licensure would sacrifice potential technological and industrial advancement. A technology transfer policy based solely on nonexclusive licensure would dissuade private developers from investing to develop government inventions and discoveries because, in some cases, their competitors could "copy successful inventions without having shared in the initial cost and risk of making them" (8). What would likely happen is that each developer would generate a portfolio of improvement patents covering specific applications of the basic government-funded invention. The threat of competition in the race to develop marketable products, however, increases the risk of development and thus lowers the value of the basic invention. As a result the nation's best firms might refrain from involvement in government innovation and many publicly funded inventions would remain undeveloped.

In 1947 the U.S. Attorney General, Robert H. Jackson, issued a recommendation for technology transfer that underscored the drawbacks of conferring exclusive ownership rights to private parties. His report called for the government to retain, with few exceptions, exclusive ownership rights to all inventions funded in part, or in whole, with public funds. To encourage the development of these inventions, he recommended that rights to government inventions be licensed to private parties on a nonexclusive basis only. In cases where development hinged on the provision of exclusive rights, Jackson contended that the government itself should finance product development rather than endorse the monopolization of a publicly funded invention. He further advised the government against charging royalties for the use of this technology.

The recommendation of the Attorney General was intended to encourage the commercialization of government-held inventions while, at the same time, protecting the public's equitable claim to the technology created at their expense. When a private enterpriser has exclusive rights to a publicly funded invention, the public is required to "pay twice for the same invention — once through taxes to support the research that yielded the invention, and then again through higher monopoly prices and restricted supply when the invention reaches the market" (8). This hurts both consumers and small business because it concentrates innovative technology, and its attending economic power, in the hands of beneficiaries of "government favoritism" (8). The practice of issuing exclusive licenses demands that the government undergo a certain level of bureaucratic expansion in order to orchestrate an application process, "select a licensee, police its operations, and detect and prosecute patent infringement" (8). If the licensees are continually large technology firms, entrepreneurs of limited means are prevented from competing in an increasingly technologically driven global market. As a result the practice of doling out exclusive rights to government inventions may contribute to a progressive concentration and centralization of power. Nonexclusive licensure, on the other hand, would allow publicly funded inventions to be used by many firms, thereby introducing them to a competitive, as opposed to monopolistic, marketplace. This would somewhat level the playing field for small business and benefit consumers through reduced product costs.

The congressional response to the 1945 and 1947 advisory reports for technology transfer policy was to refrain from enacting any governmentwide policy for over 30 years. From the 1940s to the 1980s, the federal agencies involved in research were broadly encouraged to license their inventions to private developers. Actual policies, however, were instituted only in response to particular agency-specific issues. It was believed that the tremendous disparities between federal agency missions, collaborator agendas, and the type and commercializability of federally funded inventions, made a standardized policy both "unfeasible and undesirable" (9). As a result much of the technology transfer legislation during this time was directed toward authorizing federal agency heads to manage collaborative research and development efforts in whatever manner best suited their agency's operations. The perception that disparities in agency needs and practices precluded the institution of a uniform policy was supported by a 1965 study commissioned by the Committee on Government Patent Policy. The study found collaborator decisions regarding whether or not to invest resources in government research and development to rest primarily on the commercial potential of specific research endeavors and inventions, as opposed to the particulars of licensing agreements. In fact, until the 1980s, overall commercial utilization of government-sponsored inventions was "very low, regardless of who held the title" (8). The 1965 study, while reluctant to issue a blanket recommendation, asserted that in some cases the provision of exclusive rights would promote the development of inventions better than acquisition of title by the government.

The Kennedy administration moved to standardize technology transfer policy by issuing a memorandum

outlining those circumstances in which the federal government would retain ownership rights to patent titles, and those where rights should be licensed to private developers. The situations in which the government was to retain title ownership included (*1*) when the products of research were intended for the public's health, welfare, or commercial use; (*2*) when the contractor was coordinating a government owned facility or operation; and (*3*) where the government was the principle developer or leading authority in the field of expertise and granting exclusive rights to a contractor would designate that contractor as the dominant figure in the market. Eisenberg explains that the contractor, in turn, is to acquire ownership rights to an invention when exclusive rights are essential for development, and

> . . .where the contract research is to build upon existing technology to develop information, products or processes for use by the government, and the contractor has acquired technical competence and established a nongovernmental commercial position in the field, the contractor would normally acquire title, subject to a non-exclusive, royalty-free license in the government (8).

Although Kennedy, and later Nixon, took affirmative steps to improve and standardize technology transfer policy, their attempts toward establishing governmentwide uniformity were negated by designating agency heads, with their disparate policies, to administer the practice. Nevertheless, these efforts served to improve government assessment and oversight of federal patenting and licensing practices. Significantly, exclusive owners of publicly funded inventions were required to issue progress reports on their commercialization process. If, after three years, they failed to take reasonable steps to bring their invention to practical application, the government was entitled to terminate the contractor's right to exclusivity.

The tragic flaw of the technology transfer policy from the 1940s to 1980 was not that it varied from agency to agency but that it failed to provide adequate incentives for government contractors and grantees to pursue research with commercial potential. In their paper, *Technology Transfer Laws Governing Federally Funded Research and Development*, James V. Lacy, Bradford C. Brown, and Michael R. Rubin attribute the large numbers of government-owned, unlicensed patents to a "lack of statutory basis for royalty sharing" (9). They argue that the absence of a legal provision that entitled government collaborators to a portion of the profits generated by their invention, denied researchers any incentive to create "commercially viable technology" (9). Whereas private sector researchers were motivated by goal structures and profit-oriented management techniques, government researchers and grantees were motivated by salary alone (9). Consequently one of the key problems with technology transfer during this period was not simply the low commercial potential of many government-held inventions, but the lack of incentive for government employee-inventors to transfer any inventions to the private sector for development.

In the late 1970s Congress, in an attempt to improve the nation's low economic productivity, set out to resolve the deficiencies of technology transfer. A "series of bipartisan initiatives" were enacted to "revise government patent policy, reduce legal and bureaucratic barriers, and create incentives to improve federal technology transfer to the private sector" (9). At last, Congress understood that "it was not enough to fund, invent, and patent inventions. The government had to actually make its way into the market in order [for technology transfer policy] to produce positive economic results" (9).

In passing the 1980 Bayh-Dole Act, Congress sought to improve the practice of technology transfer by aligning federal research policy with the nation's economic needs. The Act entitled small business firms and nonprofit organizations collaborating in government research to retain ownership rights in subsequent inventions. According to Eisenberg, the conspicuous omission of large firms was a reflection of the Carter administration's "strategy for improving the industrial competitiveness of the nation" (8). She explains how many of Carter's supporters believed small business to be "innovative, adaptive, risk-taking, entrepreneurial and competitive, yet [inequitably] burdened by the practice of obtaining case-by-case waivers of title from sponsoring agencies" who were traditionally reluctant to grant research funds and patent rights to small businesses (8). This made it difficult to compete with large firms that during this time period, Eisenberg recounts, were often painted as "short-sighted, risk-averse, and predatory — more likely to suppress new technologies than to adopt them, yet savvy and powerful in their dealings with government agencies" (8). It was a hallmark of the Carter presidency to blame the nation's large firms for the decline in the global position of U.S. industry. Thus a policy for technology transfer that promoted small business growth as a means to enhance the American marketplace was a reflection of the Carter era. By 1984, however, the Reagan administration, with its markedly different economic agenda, extended the provisions of the Bayh-Dole Act. This revision, which remains in effect today, entitles *all* private enterprisers in government collaboration, including large firms, to own any inventions generated in whole or in part with public funds.

Through the Bayh-Dole Act, and related legislation throughout the 1980s, Congress was seeking to improve the competitive position of the United States in world markets. The ideal policy for technology transfer would see to it that every dollar invested in scientific research would, in essence, be a dollar invested in national economic prosperity. In order for the policy to meet this objective, Congress modified the earlier system of technology transfer in three key areas. The first was discussed previously: Policies were instituted so that private parties contributing to publicly funded research would retain the right to develop any subsequent inventions. The second was the establishment of an incentive system to motivate the employees of government-owned, government-operated laboratories to make and license commercializable inventions. Third, a legal basis was provided for favoring American over foreign industry in conferring ownership rights to publicly funded technology.

The policy motivating government agencies and employees to invent and license technology was established as part of the 1986 Federal Technology Transfer Act, which made technology transfer a top priority for agencies involved in research. Employee-inventors are now required to actively seek licensees for their inventions and are evaluated on their ability to do so. In certain cases the inventors are permitted to assume ownership rights and pursue commercialization. A system for royalty-sharing was created that gives the agencies and employees of government-owned, government-operated laboratories a financial stake in the inventions they create. Royalties from commercialized inventions are collected by the sponsoring agency and shared with the employee-inventors. A portion of the remaining revenue is put toward the inventing laboratory's budget for the next year and the rest used for activities that encourage technology transfer within the agency.

Particular provisions of the Bayh-Dole Act ensure that the economic benefits of federally funded research are enjoyed primarily by the United States. Agencies are to favor U.S. industry when a developer (*1*) is not located in the United States, (*2*) does not have a place of business in the United States, or (*3*) is subject to control of a foreign government. Further, in order for a developer to assume exclusive rights to an invention, the "products embodying the subject invention or produced through use of the invention" must be manufactured substantially in the United States (9). Exceptions are made, however, if domestic manufacture is either patently infeasible or not possible at the time. Violation of these terms entitles the government to terminate the licensing agreement.

The Bayh-Dole Act also provides the government with residual rights to all publicly funded inventions to ensure its access to the technology in certain circumstances. The government retains the freedom to employ a licensed invention, royalty-free, for its own use or on behalf of a foreign organization and federal agencies are permitted to retain additional rights. To maintain fairness in the marketplace, the technology transfer policy aims to minimize the monopolization of publicly funded inventions by encouraging the use of nonexclusive licenses. Agencies are only permitted to issue exclusive licenses when they are proved to be in the best interest of the public. Exclusivity is beneficial only when it is a necessary incentive for development, and does not threaten competition or concentrate a particular technology in a specific geographic area. To further protect fair competition, when federal agencies issue licenses, they are required to give first preference to small businesses who have adequate resources for successful commercialization. In addition the government is entitled to exercise "march-in" rights and terminate the exclusivity of a contract if (*1*) The licensee has taken, or is not expected to take in a reasonable amount of time, effective steps toward developing an invention, (*2*) requirements for public use specified by federal regulations are not being reasonably satisfied by the licensee, or (*3*) action is necessary to alleviate health or safety needs that are not reasonably satisfied by the licensee. These march-in rights have never been exercised.

PUBLICLY FUNDED RESEARCH AND BIOTECHNOLOGY

The current policy of technology transfer is a reflection of the federal government's traditional conceptualization of scientific research. Although it offers an array of societal benefits, the primary reason science receives extensive federal support is that its advancement has become vital to national military and economic progress. Thus biotechnology, which is believed to hold great potential for the field of medicine, is primarily conceptualized by the government as a means to promote industrial growth. This is reflected in the 1989 argument by Michael A. Andrews before the House of Representatives in a plea to secure future funding for the Human Genome Project:

> The United States has a soaring trade deficit. We are slowly awakening to a growing weakness in international competition.... The Japanese are developing automated sequencing devices. The English have almost completed the mapping of the roundworm genome. The West Germans and the French have set up international reference data banks to collect the results of genome research. International competition has often spurred the United States into action on major scientific endeavors: Sputnik caused us to put a man on the moon, World War II brought about the Manhattan project.... I believe that international competition will shore up a commitment of the United States to the Human Genome Project more than any other single factor.... One by one, we have watched the pillars of our economy fall: the steel industry, the auto industry, the electronics industry, and the energy industry. Biotechnology is one area where the U.S. can have a clear lead (10).

The government apparently heeded Andrews' advice. Not only was extensive funding secured for the Human Genome Project, but by 1994, federal laboratories were the nation's leading inventors and enablers of new technologies for the biotechnology and pharmaceutical industries (11). The Public Health Service continues to lead the nation as the organization with the largest number of "therapeutics in active development, both in terms of those licensed out and those being developed internally" (11). This vast federal support of biotechnology raises special concerns because discoveries in this field hold value beyond their contribution to industrial growth. Biotechnological innovation carries the potential to improve the lives of the public, who, through their investment of tax money, and by serving as clinical research subjects, make medical research possible. Arguably, because the public is so uniquely invested in the products of medical research, particular aspects of the technology transfer policy ought to be reconsidered.

The absence of price controls, for example, allows private developers to set the price of publicly funded medical technology beyond what portions of the population can afford. In other words, current technology transfer policy confers on private parties the right to ration publicly funded therapies according to what the market is willing to pay. The government refrains from exercising its right to "march-in" and terminate exclusive licenses on behalf of the public health because the ultimate goal of technology transfer is not necessarily to improve social well-being but to serve the nation's economic interests.

The circumstances surrounding the implementation and repeal of the "reasonable price clause" illustrate this point. In 1984, when HIV was identified as the virus that causes AIDS, a screening program was initiated where drug companies submitted shelved drugs to NIH for testing against the retrovirus. Burroughs-Wellcome submitted a drug called AZT that was invented in 1964 by the National Cancer Institute (NCI). In 1985 AZT was deemed effective against HIV in vitro and was therefore worthy of clinical investigation. With NCI supplying the thymidine necessary for AZT production, Burroughs-Wellcome provided NIH with AZT to run the clinical trials necessary for FDA approval. A year later AZT, having successfully prolonged the survival of AIDS sufferers, was approved by FDA. To promote its development, Burroughs-Wellcome was granted a seven-year exclusive marketing privilege and patent rights until 2005 for its use in the treatment of HIV. AZT was introduced to the public in 1987, at the exorbitant price of $10,000 to $12,000 per patient/per year (12).

Outraged, the public demanded to know why the price of AZT was so high when both the initial discovery and later recognition and research of its modern application were publicly sponsored. In his recounting of the AZT controversy, Baruch Brody asks whether "the public's need for the drugs [is] being served by allowing drug companies to charge that much for drugs?" (12). A plausible argument can be made that the needs of the public should take precedence over the promotion of technology transfer. In response, some would argue that technology transfer never actually takes precedence over public needs because it serves those needs in the long term. Allowing companies to set high prices is society's way of rewarding them for transferring the public's scientific research investment into important public goods. The question arises, however, whether a public good is provided when a product is largely inaccessible to its sponsors.

In 1989 the government sought to improve access to products of technology transfer by promulgating a "reasonable price clause" in exclusive licenses arising from Cooperative Research and Development Agreements between government and industry. The clause mandated that the price of inventions must reasonably reflect the health and safety needs of the public and their investment in the product (13). In his explication of the reasonable price clause, Brody outlines its numerous presuppositions. For one, it assumes that the government is entitled to a financial return on the intellectual property rights conferred to private developers. Reducing product prices according to the degree of public subsidization will result in Medicare and Medicaid savings. In addition the clause assumes that access to the products of technology transfer should not be determined by price alone but weighed against public health and safety needs. Last, the reasonable price clause implicitly assumes that its price control measures would not deter private developers from investing in publicly funded inventions. Brody believes that the assumptions contained in the reasonable price clause are problematic in that a pricing policy based on the degree of public funding may yield an entirely different price than a policy focused on accessibility. Furthermore, it is presumptuous to assume that either approach offers the return on investment necessary for private developers to engage in technology transfer (12).

In 1995 the reasonable price clause was repealed, for numerous reasons. NIH claimed that it was not only difficult to enforce but that it had a chilling effect on industry–government research collaboration. The repeal was clearly influenced by the pharmaceutical/biotechnology lobbyists who were vehemently opposed to price controls, by the patient advocacy groups who were incensed over a possible delay of new products, and by a Congress that was quick to abolish regulations without instituting safeguards to secure the public's equitable claim to the products of technology transfer.

The resulting policy omission exemplifies the federal government's prioritization of economic interests over any genuine commitment to improve the fundamental problems of the nation's (and the world's) access to health care. As patients, providers, and payers alike struggle with the burgeoning costs of medicine, the current technology transfer policy propagates the belief that "the proliferation of new technology developed at public expense is an unqualified good" (14). William Sage questions what he has dubbed "the conventional wisdom" of the policy in light of its contribution to health care inflation (14). He points out that most new products introduced by the biotechnology and pharmaceutical companies neither prevent nor immediately cure illness. They tend, rather, to "palliate suffering and prolong life" which, coupled with their high price tags, serves to funnel a significant portion of increasingly scarce health care dollars into industry pocketbooks (14). The government incurs the escalating expense of medical technology through Medicare and Medicaid. To contain costs, it chooses not to question the cost-effectiveness of new technology but rather to reduce provider reimbursement rates and tighten Medicaid eligibility criteria. Whereas it could fund cost-effectiveness studies with the royalties collected from technology transfer, the government has little incentive to do so because any policy that restricts the market for new technology would be detrimental to the pharmaceutical/biotechnology companies that are regarded as key to national economic prosperity. Private insurers, on the other hand, and the employers and individuals who pay insurance premiums, are increasingly reluctant to cover expensive technology when cost-effectiveness has not been demonstrated. At this point, however, programs to evaluate cost-effectiveness are too expensive and controversial to permit their widespread implementation.

For the 44 million Americans without health insurance, the industrialization and bureaucratization of health care has rendered rudimentary care, let alone technologically advanced treatment, virtually inaccessible. Sage argues that to retard the trend of using scarce health care dollars to purchase products that, in the long run, are a cost rather than a benefit to the system, new medical technologies, particularly those arising from public funds, should be brought to market only after determined to be cost-effective (14). Whether an invention's cost-effectiveness is sufficient for it to be brought to market

ought to be based on a societal consensus to purchase the technology for all, regardless of their ability to pay. To increase access, royalties could be used to subsidize the cost of technology for the indigent. Additionally the government could require private patent holders to provide their product to the disadvantaged gratuitously or at a discount. Sage concedes, however, that it is unlikely these suggestions would adequately offset "the incentives for unbridled innovation and consequent cost pressures created by the current technology transfer policy" (14).

Whereas royalties can potentially patch some of the holes in the system, some believe they create more problems than they solve. It is unclear, for example, why the government collects royalties from licensed inventions if the objective of technology transfer is to promote the private development of public inventions. Royalties make publicly funded technology a less desirable investment because they function essentially like a tax on development that reduces the overall profit potential of government-funded technology and increases the risk of the investment. In the end it is the consumer who bears the cost of royalty agreements because product prices must offset royalty expenditure, and higher prices reduce the accessibility of public goods. Again, the public pays twice for inventions.

The Bayh-Dole Act encouraged university ownership as a means to promote academe–industry collaboration. Underlying this decision was the perception that universities are well suited to determine which research results ought to be patented and developed, and which would best serve the interests of science as part of the public domain. University–industry collaboration appeared to optimize the potential for scientific advancement. Industry would provide university researchers with incentives to generate inventions that would benefit society in the form of public goods and economic productivity. However, in order to simplify their administrative burden, universities tend to prefer to grant exclusive rather than nonexclusive licences, which undermines the rights of the public to relatively unrestrained access to publicly sponsored inventions and discoveries (15).

The financial return on commercialized inventions would provide future funding for innovative academic research. The collection of royalties by universities therefore may provide a much-needed source of revenue for sustaining research initiatives and other institutional needs. It would be unwise, however, for all universities to rely on such revenue, since it is only a minority that can generate a sufficient amount of royalty revenue to reliably sustain institutional functions. Further there is some debate over whether the patents to publicly funded inventions should have been transferred to universities in the first place because they offer no advantage over the government in that both are unable to develop inventions into public goods.

The university–industry research collaboration has changed, and it is likely to continue to change the culture of academic science. It is a tradition in academic research to promptly share information with the scientific community with the incentives for doing so largely taking the form of professional accolades for furthering the advancement of knowledge. Commercial sponsorship threatens this tradition by motivating researchers to privatize the knowledge they generate in order to ensure both patent eligibility and gain a competitive edge. This trend is reflected in a study conducted by David Blumenthal that found biotechnology faculty with industry sponsors to be more than four times as likely as colleagues without commercial support to report that they had kept research results a secret in order to protect their proprietary value (16). His study also found these researchers to be five times as likely to report than they had conducted research the results of which were the property of private sponsors and could not be published without the sponsor's consent (16), reflecting a serious sellout of academic freedom. The incentive to patent research results increases the likelihood that researchers will engage in the lengthy patent application process, during which time they may be reluctant, or even contractually forbidden, to share information regarding their inventions. Thus the industrial support of academic research imposes barriers that hinder the sharing of knowledge among colleagues. Yet it is this cooperation that has traditionally advanced science.

In biotechnology patentability is still a gray area, and publicizing information, such as sequence data, may render an invention "obvious" and thus ineligible for patent protection. When patents are granted in young fields like biotechnology, earlier inventions are often granted broader patent coverage than those that follow because "patent claims are drafted to encompass not simply what the inventor has done, but the idea which underlies the specific detail. Sometimes, in the absence of much detail, patent rights may be granted which many regard as excessively broad" (17). The uncertainty that surrounds biotechnology patents is exemplified by the 1988 patenting of the Harvard OncoMouse, a transgenic mouse produced for carcinogenicity testing (18). The OncoMouse patent raises numerous questions, including whether the patent was limited to transgenic mice, or whether it extended to transgenic rodents, or even to transgenic mammals in general (19). When the boundaries of intellectual property are nebulous, the stage is set for complicated turf battles that will likely send potential developers in search of investment opportunities with less potential for complication.

Broad patent claims, when applied to basic research tools like the OncoMouse, may chill entire areas of research. Licenses to use patented research tools may be unaffordable to some institutions, or researchers may be unwilling to purchase licenses that would essentially allow their research to be shaped by the interests of the patent holder. By owning and exploiting the rights to research tools, industry can gain considerable control over the nation's research agenda. This was demonstrated in the controversy over Cre-lox (20), a recombinant technology owned by DuPont that was used freely in NIH genetic research for years (17). In what was thought to be a prudent business maneuver, DuPont began to require researchers to purchase licenses for the use of Cre-lox. Recognizing that these licenses would be unaffordable for some institutions, DuPont permitted researchers to use Cre-lox with the understanding that DuPont would retain

ownership of all their inventions that either incorporated the technology or used it somewhere along the line. Researchers were prohibited from transferring Cre-lox technology to unlicensed colleagues and were required to send all Cre-lox-related papers to DuPont for review prior to publication. Ultimately the research community struck a less restrictive agreement with DuPont for the use of Cre-lox, but the circumstances reflect that the strong presence of industry, and its ownership of technology, can wield such power over research that the government has to intervene, a heretofore unprecedented action.

Companies are involved in the development of products when they are still in the early stages of research. Researchers, including those working under federal grants, often receive private compensation for their ideas in the form of income, equity interest in the developing company, a seat on its board of directors, or a percentage of future sales (14). Admittedly, scientists are entitled to benefit financially from their inventions, and the technology transfer system is constructed to tolerate personal gain at taxpayer expense in order to encourage the development of public goods. However, when universities and individual faculty members have a direct profit motive to invent a product, it "represents a clear departure from past practices, and creates real risks for universities and the functions they are designed to serve in society" (14). When academic research begins to take on market characteristics, competition may tempt scientists "to circulate misinformation about a project's likelihood of success or even to commit outright fraud" (14). In the past it appeared harmless to allow researchers to earn royalties from their inventions because this occurred only in exceptional cases and after a prolonged period of research and development. Today a financial stake has been driven through the lab bench by companies who pay universities and researchers large sums of money up-front for the long-term rights to their inventions. Sage explains that "when the enrichment of scientists is directly related to the success of the scientific endeavor, society runs the risk that researchers will knowingly influence the outcome of neutral scientific inquiries" (14). The compromise of scientific integrity for greater reward violates, particularly in the case of medical research, the scientist's fiduciary duty to the public who entrusts the research community with their health and safety (14).

Royalty incentives, much like researcher equity positions in end products, comprise a facial conflict of interest. The federal government, however, relies on these incentives to drive technology transfer (21) and so excludes them from federal conflict-of-interest regulation. The use of royalty incentives in the absence of safeguards to protect the public from unsound science questions whether the government is using the public's funds responsibly and in the interest of their welfare. The pervasive use of royalty incentives raises the additional concern that if the scientific community is motivated by financial reward, it may cause basic research, because its products lack immediate commercial potential, to become undervalued and underdeveloped. Basic science, however, is essential to societal advancement. It has been understood since the nation's inception that the greatest breakthroughs often occur out of investigations into uncertainty. The information derived from basic research is the foundation for applied research which, in contrast, is defined by certainty in that it usually requires a set of "unambiguous facts" and specific targets toward which to work (22). There is a prevailing fear that as the industrialization of science progresses, the breadth of scientific inquiry may narrow to areas with foreseeable market potential. Thomas Jefferson believed that the government is obliged to promote innovation, and it ought to do so by subsidizing basic science because the goods it produces, and the incentives it requires, cannot be adequately sustained by the private sector. In that case the driving of publicly funded research toward the invention of commercializable goods is not what the government's role in science should be. Without the comprehensive support of basic science, the socioeconomic structure of the nation may suffer as it will be denied the benefit of scientific uncertainty and its resulting discovery. Arguably, the government tilts the nation's research agenda away from basic science through the policy of technology transfer.

If the government funds basic research, then what happens to the results should depend on the commercial potential and usefulness of the results. For example, some space research might hold military importance, some long-term strategic importance (e.g., claiming bases on Mars for future uses), and even some potential commercial utility (e.g., for commercial satellite, communication, or other types of businesses). Other research might be pure science performed in an attempt to understand the universe. Arguably, if the public sponsors the former, then some mechanism should be found to give a commercial preference to domestic companies, which will, in turn, return direct benefits to the country by employing citizens and paying taxes. In the latter case, however, the intellectual contribution of understanding black holes may not and should not be considered property but knowledge. Knowledge should be more freely shared with all. The government, through its policy for technology transfer, promotes the patenting and development of technology that provides society with public goods and economic productivity, but it does so at the expense of the collaboration necessary for overall scientific advancement (23). This is consistent with the federal government's conceptualization of science. Because it is valued as a means to spur economic growth, the measures used to promote this growth may threaten the proliferation of knowledge is not such a pressing concern. This view is rather short-sighted because it is indeed the proliferation of knowledge that ultimately gives rise to overall societal advancement.

Aspects of the technology transfer policy run counter to the ideal of a "more perfect union" where the federal government fulfills its constitutional duty to "establish justice," "ensure domestic tranquility" and "promote the general welfare" (2, preamble). The investment of public funds in the life-enhancing field of medical research, without ensuring the public's equitable claim to resulting therapy, is arguably unjust, despite the aggregate economic benefits. An expensive, bureaucratized, and largely inaccessible health care system is not in the interest of the general welfare, yet aspects of technology transfer perpetuate these systemic flaws.

As this review shows, the evolution of technology transfer policy reflects a difficult balancing between promoting development and use of government-funded inventions and discoveries, and protecting public welfare. One constant throughout this historical account is the military or economic justification for government support of research. A second constant is that as science becomes increasingly complex, it is becoming industrialized and, as a result, bureaucratized. All the while, however, it is not necessarily becoming more accessible to the public. A third constant is the concern about monopoly: Exclusive rights can benefit the powerful at the expense of the public, but exclusive rights sometimes are the best way to move inventions off the shelf and into the market.

PATENTS, ETHICS, HUMAN LIFE FORMS

LOUIS M. GUENIN
Harvard Medical School
Boston, Massachusetts

OUTLINE

INTRODUCTION

It might be supposed that morality operates as a side constraint on patentability. On this view, even though a process or device might meet conceptual and scientific criteria for recognition as an invention, moral considerations might override so as to deny a patent. Or again, it might be held that morality, genetics, and biotechnology so intertwine that whenever we construct criteria of patentability with respect to "genetic inventions," we perforce impose some moral view.

EXPLOITATION AND MONOPOLY OF CLONED DNA SEQUENCES

Whereas U.S. patent authorities formerly declined to issue patents on gambling devices and phony medicines, the U.S. Patent Code of 1952 dissociates law and morality. It leaves to other laws the matter of restraining the use of inventions. Efficiency alone commends this division of labor, since many patents are never exploited. For example, Pasteur obtained a U.S. patent in 1873 on a yeast for making beer. But, so far as we know, he never developed a commercial product (1). If immorality of use does not count as an objection to a patent application in general — even if the proffered device be mischievous — should immorality of use count as an objection to patents on life forms?

We might answer this with another question. If a patent on a gene or other human life form confers ownership over something human, and if, on moral grounds, we reject claims to own humans, are not patents on genes and human substances illegitimate? This question probes not an invention's use but the appropriateness of the patent privilege itself. A patent lawyer will reply, reprovingly, that a patent does not confer ownership, that a patent merely grants for a term of twenty years the privilege to exclude others from making, using, or selling an invention. This reply does not end the discussion. For various circumstantial reasons any policy on biological patents brings moral controversy in its train. In the first instance, allowing commercial entities to wield even limited monopolies on things human will seem morally problematic to many observers. Some will regard such privileges as threats to the autonomy of persons (as discussed below for clinical settings). Others will point to various economic consequences of wielding patents, among them high prices and restricted output of end products. When a DNA sequence patent issues but the patentee fails or declines to introduce a product predicated on the sequence, the only benefit of the patent, if one may call it that, is to prevent the patentee's competitors from exploiting the sequence. It may be granted that for some the welfare loss of squandering an opportunity to improve beer production, especially for a mere scientific career, is cause for lament. But if a patentee shelves a human gene patent and denies society an opportunity to develop beneficial drugs or to perform gene therapy, the cost may be human suffering. As we shall see, good reasons obtain to resist the generalization that biological patents enhance aggregate welfare. In respect of the foregoing concerns, one hears not merely the voices of patent examiners and courts — unlikely arbiters of morality in any event — but a variety of moral views held among citizens to whom accountability for governmental decisions is owed.

Because the decision to award a patent may be publicly perceived as at least implicitly a decision to condone any and all uses of the invention, it may behoove us first to resolve objections concerning morally problematic uses of certain biotechnological innovations before we attempt a consensus on monopoly of the innovations. If prudence commends this two-part agenda in the United States, the European patent system demands it. The European Patent Convention of 1963, whose criteria of patentability are otherwise roughly coincident with the American, proscribes patents on inventions whose commercial exploitation would be "contrary to *l'ordre publique* or morality." This phrase was long considered so vague as to lack teeth. But as adopted in 1998, the Directive on the Legal Protection of Biotechnological Inventions of the European Parliament (the "European Directive," or "ED") declares unpatentable, on the ground that their commercial exploitation would be contrary to *l'ordre publique* or morality, the following: human germ line intervention, "cloning" humans, commercial use of embryos, and both somatic and germ line genetic intervention in animals that is "likely to cause suffering without any substantial medical benefit to man or animal" (2). To this the ED curiously adds, "exploitation shall not be deemed to be so contrary merely because it is prohibited by law or regulation."

Anticipated Benefits of Transgenesis

Mankind has bred plants and animals for millennia. Since Mendel, breeders have exploited knowledge of dominant and recessive alleles. Moral controversy about genetic engineering stems not from manipulation by breeding, but from recombinant DNA. It is not that recombinant techniques clearly violate any moral view in particular. Rather it is the case that recombinant DNA technology poses questions not previously raised within any traditional moral theory.

Transgenesis consists in isolating a gene of one living being and inserting the gene at an early embryonic stage, before somatic and germ cells separate, in such a way that the gene enters the germ line of another living being of a different species. The insertion may be accomplished by introducing the foreign gene into (i) a retrovirus that infects an embryo, (ii) a plasmid microinjected into the pronucleus of a zygote, or (iii) cultured embryonic stem cells injected into the cavity of a blastocyst. The inserted genes are usually few and manifest themselves in only a small subset of an animal's phenotype. Transgenesis enables improvements in the growth, heartiness, and yields of animals and plants as sources of food, vaccines, and other compounds, affords models for study of diseases, the immune system, and gene regulation and expression, holds promise for direct therapeutic use in humans, allows the "pharming" of animal organs so that, upon transplant to humans, they will not be rejected, and allows production of cotton, plastics, and other industrially valuable compounds. A vaccine-enriched transgenic banana holds promise as a vehicle for surmounting economic and practical obstacles to vaccine delivery in many regions of the world.

Reservations Concerning Transgenesis

As encouraging as these prospects may be, they are not without their detractors. Objections to transgenesis include the following. Even if genes insert at a targeted locus, in animals the effect of transgenesis may be suffering, a theme frequently rehearsed in European discussions. The usual defense of animal experimentation (as in the ED) adverts to collective human benefit. A net

increase in aggregate human preference satisfaction is all that need occur to satisfy a utilitarian; the second form of Kant's categorical imperative permits using even humans as means so long as they are not used solely as means. But risk-averse humans worry about their own welfare in eating transgenic plants and animals — even assuming full disclosure in the grocery store. To introduce a vaccine into a banana crop raises questions about imposed risk-taking and paternalism when informed consent may not be feasible. Risk of human suffering is sometimes cited as a consideration against human gene therapy. Risks about where and in how many copies genes insert and whether a procedure will otherwise work are chanced by any single recipient of somatic cell therapy; to this germ line intervention adds the risk that an untoward result may burden future generations who, it may be said, have no voice in what is done to their ancestors' genomes. Even when gene therapy achieves an intended result, the long-term effect may be a population less diverse, a gene pool that is diminished. A suite of controllable genetic characteristics may eventually generate a canon. By reference to that canon, persons lacking certain traits may be treated by others as inferior. Perhaps indeed we shall cavort down a slippery slope from disease-related therapies to frivolous enhancements. To engage in germ line intervention, it is decried, is to "play God."

Defense of Human Germ Line Intervention

A defense of human germ line intervention might run as follows. Genetic engineering may be a way to improve man's contribution as co-creator in God's work (3). One might argue that God would wish caring physicians to use it. Gene therapy will not invent discrimination, a practice already thriving with respect to many traits. We should not count even against enhancement that someone will be born with a trait more desirable than another trait. Instead a temptation to be invidious should remind us, as do Kant and many religions, to recognize the dignity of each person. As for an effect on descendants, that is not a new category of moral responsibility. Future generations are already affected by innumerable influences on one's germ cells of how one lives. One may imagine a complaint of wrongful life by someone born with a genome adversely affected by something that went wrong in a gene therapy procedure, but in another case, the same tort might be committed by failing to attempt gene therapy. It would appear dubious to bar a physician from using an available method of averting disease in a consenting patient's offspring if, for example, the odds of the method's success exceed those of any treatment after birth. It is also difficult to expect a family or society to forgo eradicating a lethal gene if that be possible. A few decades from now, germ line intervention may be considered routine, its provision the duty of a competent physician, its inclusion a requirement of the health care a just society ought to provide.

The slippery slope to enhancement is not fairly ascribed to gene therapy (though perhaps to recombinant DNA). Recombinant human growth hormone, for example, is already dispensed. At least at present, the imagined efficacy of gene therapy is limited to diseases involving single genes, and among those, to diseases mediated by recessive genes, because an inserted gene's locus may not be controllable and any dominant defective gene remains in the patient. On the other hand, someday prospective parents may be speaking of a "designer child" polymath 9′ basketball player. In any event a distinction between "therapy" and "enhancement" may not be sharp or necessary. If a slippery slope connects therapy and enhancement, the transition from first violation of any ban on genetic enhancement to widespread violation thereof may be an avalanche. A treaty presented for adoption by members of the European Union bans enhancement (4). As of this writing, human germ line intervention for enhancement purposes is not feasible, but upon its availability, one may expect the following. Though a government may ban genetic enhancement, as soon as one person manages to procure an enhancement, others acting rationally will likely rush to procure enhancement in order to remain competitive (5). These aspirants will either violate the ban or migrate to a sovereignty that lacks one. Sovereignties will likely behave the same way, rushing to follow the first innovator for fear of being dominated by superiors. Unless one contemplates intrusive "audits" comparing parental and progeny DNA, a ban on enhancement seems unenforceable.

The foregoing brief account reveals moral concerns about uses that insinuate themselves into discussions whether to approve monopolies of uses. We may now turn to moral concerns about a patent privilege itself.

Autonomy and Patent Claims Against Parents and Children

The effect that a patent might exert on individual autonomy may be studied through a dramatic example. This first requires that we explain the rationale for patents on transgenics.

Patented Transgenic Organisms. Although Pasteur's yeast long before gained a patent, modern recognition of a nonplant life form as patentable occurred in a decision with respect to a bacterium into which were introduced plasmids rendering the bacterium capable of decomposing oil (6). Patentability was later confirmed for multicellular organisms (polyploid oysters) (7). A furor ensued over ethical concerns, and for a time, the U.S. Patent and Trademark Office ("PTO") imposed a moratorium on animal patents. Thereafter the PTO issued a patent on the Harvard mouse (8).

Designed for the study of cancer, the Harvard mouse contains DNA sequences, comprising an oncogene such as *myc* and a promoter, that effect a high proclivity to form tumors when the mouse encounters carcinogens. The introduction and expression of the *myc* gene in the mouse was innovationary. One could not have presumed that a zygote acquiring the oncogene would survive its insertion and expression, or if the zygote did survive and a mouse were born, that the offspring would be fertile. The Harvard mouse invention was exhibited for patent purposes by deposit of DNA in a plasmid. But the patent extends not merely to the inserted DNA, not merely to the oncogene's introduction and expression, but to the whole "oncomouse."

Why should a patent embrace an animal? Two arguments might be mustered. First, there has endured throughout the history of patents the notion that patents should not be available on nature's extant treasures — in a phrase attributed to Thomas Jefferson, on any "product of nature" — but should be available only on what humans manufacture. The discovery of uranium garnered no patent, but the PTO issued a patent to Glenn Seaborg on curium and isotopes of americum, transuranic elements believed to exist on earth only in a cyclotron or reactor as a result of human efforts. Of course such elements may be abundant in stars. A precise statement of patent eligibility would not exclude from patentability every naturally occurring thing. Rather we may state patent eligibility by the following proposition, which we may call the "unpatentability of nature": to be eligible for a patent, a thing must be such that there obtains only a very low probability that, without human intervention, the thing exists near the surface of the earth or on other astronomical bodies to which humans travel. What constitutes a "very low" probability requires specification. Since patent lore speaks confidently of things that "exist" or "do not exist," no guidance on probability may be found within it.

It is logically possible for there to evolve an organism whose genome is identical to some modern transgenic organism. Exchange of genes across species occurs and any mutation is possible. Yet the probability may be extremely low that a creature will contain genes of two given organisms that do not mate. In such case a patent examiner may treat a transgenic genome as if it does not naturally occur. An animal possessing such genome is then seen not as an unpatentable product of nature but as a patentable "manufacture" or "composition of matter" (9). With respect to the European Patent Convention, it would be said that such an animal is not an unpatentable "variety" (10). In general, the fruits of breeding programs are considered varieties, but transgenic animals are not considered varieties because transgenesis was unknown in 1973 when the European concept of a variety was introduced.

Second, when introduced into a recipient's germ cells, transgenes pass to descendants. A transgene will not be expressed in all offspring of the first generation, but those in which it is expressed will be selected for further breeding. Were a patent to cover only cells expressing a trait, it would not capture the invention, which, by virtue of being genomic, appears in every cell. Were a patent to cover only an inventor's process of introduction and expression, anyone who purchased one transgenic animal could breed others without infringement; natural reproduction is not the same process as laboratory transgenesis. A purchaser of transgenic agricultural livestock could breed the livestock through unlimited generations. Hence inventors are accorded the protection of a patent on the transgenic genome, which is effectively a patent on the animal. Breeding descendants of a patented transgenic animal without license would just as clearly constitute infringement as would duplicating a patented laboratory process for inserting transgenes into an embryo. The patent system assimilates reproduction, whether natural or artificially aided, to "making" a duplicate.

The Human Qua Infringement. A moment's reflection reveals that if the foregoing two grounds (a claim to originate a manufacture; self-reproducibility of a recipient) entitle an architect of transgenesis to a patent on recipient and progeny, then in the case of human germ line intervention, infringement claims will lie against the birth and existence of humans. To call human birth or life a "patent infringement" seems perverse. But on what principled grounds should we reject such claims? Even in the somatic cell case, as scientists perfect the manufacture of yet more human enzymes and other proteins, as they progress to substantial tissues, should society continue to grant patents on human "parts"? Manufacture of a liver or other major organ, or someday even of a brain, may confound previous thinking.

Abjuring the Human Qua Infringement. To resolve the solecism of the human qua infringement, we may reason as follows. We do not imagine infringement claims against any plant or animal. Instead we recognize claims against people who control breeding. We do so because we recognize a farmer's ownership of plants and animals. When the "designer" of a transgenic organism applies for a patent, the contest concerns only which humans (or corporations they represent) own property in the nonhuman species. When the issue is which of two humans owns a human, we say that humans own themselves. They do not own each other. Human births, we hold, are not analogous to breeding, to manipulation by owners of mating subjects. Hence we may decline to recognize property rights in humans.

The premise that humans do not own each other, that we each enjoy a "bodyright" (11), is not categorically held in all societies, and given that the common law describes an adolescent's maturity as "emancipation," perhaps it is not unequivocally held anywhere. Defense of the premise often comes round to some distinction between humans and animals. According to a Cartesian distinction, man is a singular creature possessed of reason. According to Kant, only man and angels are capable of reason. To say that a human being's existence infringes property rights would seem inconsistent with the second and third forms of the Kantian categorical imperative, which together enjoin that we treat each person not solely as a means but as an end-in-himself in a kingdom of ends. If we allow an ownership claim on a person, we condone treating the person solely as a means. We condone interfering with the person's autonomy. Were someone to assert an ownership claim that purportedly extended to only part of a person, the claim would appear indistinguishable from a claim on the whole. Bodily parts are integrated. For the same reasons, conception and birth, the instantiation of human nature, may be held immune from claims of others. We may also say that conception and birth are private.

Distributive Justice and Patent Claims on Extracorporeal Compounds

Although we may thus deny the permissibility of exerting dominion over, impairing the autonomy of, or disrespecting an individual, a different case, actual in biotechnology, is the following. There is adduced a substance that is human

in the sense of being found in the human species, but which has been made outside the human body and is not ascribable to any individual. Were a patent to issue on that substance, the patent would not appear to interfere with any individual.

To this it must be added that it is not easy to steer clear of the DNA sequences that distinguish an individual or that make any individual akin to another. Only about three million of the three billion base pairs in the human genome account for individual differences, but the genetic code is redundant, the most interesting traits are polygenic and beyond present understanding, and mutation never ceases. For now, individual identity, to the extent it is genetic, is genomic. We have not demarcated a nonindividuating subset of the genome that we may cede. We do know that individuality is greatly affected by a relatively small number of regulatory sequences that control which genes are expressed. Such sequences are indeed used in biotechnology manufacturing unless a bacterium's or other host's regulatory sequences effect expression.

Let us assume for the moment that it is possible to grant monopolies on proteins and DNA sequences without there resulting any interference with the autonomy of any individual. The PTO effectively allowed as much when it began to grant patents on human DNA sequences despite its earlier declaration that a patent on a human would violate the prohibition of slavery in the Thirteenth Amendment to the Constitution of the United States. It contravenes common usage to say that a nonpossessory interest in a protein or gene constitutes slavery.

Were one confident that a system of limited monopolies would lead to advances that prevent or alleviate human suffering, one might decide that the conceptual coherence of the patent system should give way to the promotion of aggregate welfare. If patents on genes contravene the unpatentability of nature, so much the worse for that premise. It seems that one perforce resorts to that stance for the defense of patents on plant antibiotics. One might go so far as to say that there should issue any patent, even if the patenting process is purely piecemeal, that results in net aggregate welfare gains.

Whether compromise with intellectual purity be systematic or piecemeal, and even assuming any contingent results that an advocate of such conceptual indulgence predicts, this talk of welfare effects presupposes a criterion for discerning improvements in welfare. That in turn implicates some version of a social welfare function. A social welfare function is a function that yields or induces a positioning of possible resource allocations on which one may predicate a claim such as "α is a welfare improvement over β." The specification of a social welfare function is the main problem of distributive justice. For this reason, what begins as a moral problem concerning respect for personal autonomy, which arguably is tractable by virtue of the ability to eschew interfering with any individual, endures as a challenging problem of collective morality.

To the extent that patents are distributive mechanisms, this problem arises within an economy in respect of any patent. But concerns abound with respect to the welfare effects of biotechnology patents. Some may espy unacceptable burdens and risks for the human species as a whole from various patents on molecular or structural human life forms. For instance, when a patent owner sets what seems an exorbitant price for a vital drug, one observes an arguably undesirable effect of market power conferred by an unqualified government-created monopoly.

PRODUCT PATENTS ON HUMAN DNA SEQUENCES

Supposing that the prospects of collective benefit or some other morally persuasive consideration have justified the alteration and use of life forms, why confer exclusive control on one party? The orthodox *quid pro quo* of a patent is that, instead of keeping an invention a trade secret, the patent teaches the details. When a patent expires, the invention will be in the public domain, and even during its term, what others learn from its teaching may foster other innovations. Whether the patent's revelations are in fact valuable will depend on whether one may easily infer the invention by reverse engineering (12). An alternative and more familiar rationale asserts that a patent provides an incentive that fosters ingenuity and effort. Or as Bentham put it, "He who has no hope that he shall reap will not take the trouble to sow" (13).

Isolation-Purification Rationale for DNA Product Patents

Organic compounds found in humans are, *ipso facto*, naturally occurring. Suppose that an organic chemist discovers a way to synthesize a protein in a purified form not found in humans. If the protein appears extractable from another organism, then perhaps we should not regard the protein as distinctively human. But in fact the human version of a given protein is unlikely to be identical with that of another organism. Through mutations in duplicate genes, species have evolved a variety of genes coding for different versions of proteins that we call by single generic names. The notion of isolation and purification (a creature of case law, not statute) was popularized by product patents on inorganic chemicals. (In patent parlance, a "product patent" is a patent on a thing as opposed to a patent on a process.) The notion was then borrowed in support of patents on the products of biological processes, including purified human adrenalin, prostaglandins, vitamin B_{12}, and, most recently, human DNA sequences. For the last, investigators' counsel have persuaded patent examiners that investigators have "isolated and purified," which is to say cloned, human genes.

There is reason for scepticism whether a patent must be available in order to induce a given result. "The large amount of research that has already occurred when no researcher had sure knowledge that patent protection would be available," noted the Supreme Court of the United States in affirming the patent on the oil-eating bacterium, "suggests that legislative or judicial fiat as to patentability will not deter the scientific mind from probing into the unknown any more than Canute could command the tides" (6). There arrived for filing a spate of plant patent applications in Europe, many presumably

from European companies, quickly after the first plant patent was allowed there in 1989, which suggests that the research had long before been done. And rivals face effort and expense to follow a first entrant into the market. In the United States the lead time that an imitator of a drug or medical device would need to obtain approval from the Food and Drug Administration ("FDA") for selling the product provides a period of *de facto* exclusivity to the product's originator once the originator obtains approval. There may also be observed a tendency after a favorable experience for physicians to continue prescribing, and consumers to purchase, the first drug of a genre. Assertions about the necessity of incentives can be facile, but evidence is lacking.

Inventions concerning nonliving phenomena make use of materials that mankind has long exploited with an aplomb perhaps attributable to the mistaken belief that we cannot alter earth's vastness. Biological inventions obviously effect alterations of nature. If we approve the engineering of some protein, we might view the circumstance that it is found in humans as a reason against monopoly. Hence the isolation–purification rationale originated for chemistry in general cannot be assumed to carry the day for human compounds. One might add that to adopt such construct for humans would not follow the model of chemistry faithfully enough. Patents have been granted to those first to synthesize chemicals, but courts tend to find evidence that chemical patents have been infringed only insofar as a patentee's process has been copied.

The probable benefits of recombinant innovations may in a given case outweigh the acknowledged detriments. But each wave of innovation evokes a new comparison of risks, costs, and welfare gains.

Unpatentability of Nature and DNA Patents

An enduring challenge for the molecular biologist is to understand a disease or bodily function, to identify a protein related to it, to ascertain the nucleotide sequence of a gene coding for the protein and the protein's amino acid sequence, to locate the gene on a chromosome, and to explain the gene's regulation and expression. Once sequenced, a cloned gene may be preserved as complementary DNA ("cDNA") in a vector. When vectors transform and infect, not only do they multiply an inserted gene, but the gene can integrate into the transformant genome, causing such host to produce the protein for which the gene codes. It is by growing such transformants under suitable conditions that a biotechnology manufacturer may produce a protein in high volume.

A typical patent claims at least three inventions: (a) an isolated and purified DNA sequence encoding some protein, (b) any vector that contains that sequence and any transformed host possessing that sequence, and (c) one or more processes. The patent system indulges the notion that the cloning of genes produces "inventions" that do not naturally occur. By contrast, a detailed examination of what occurs in the laboratory, though providing ample evidence to confirm our admiration for scientific achievements, reveals no *entity* that mankind creates (14).

A gene encoding any human protein exists in nature. It is embodied in a chromosome. Its transcript also exists in mature messenger RNA ("mRNA"), a single strand of DNA-complementary nucleotides. Transcription of DNA into mRNA, followed by splicing that eliminates introns, is nature's own "isolation" of the coding sequence (with uracil in place of the thymine of DNA). This alone seems to tell against the argument that only an inventor has achieved isolation. Is "purification" then the inventor's trump over nature? The process of making cDNA is not thought to occur naturally in humans (though many viruses that infect humans make DNA from RNA). But once a gene is known, the laboratory process of making cDNA can be routine. Perhaps then vector and host deserve credit as the ingenious embodiments of purification? Where a host and a donor of foreign DNA are members of species that do not mate, asserted Stanley N. Cohen and Herbert W. Boyer in teaching the first recombinant process, a recombinant host "could not exist in nature" (15). This imagined impossibility of course is an exaggeration. Any mutation is possible. As Bernard D. Davis observed in debating the hazards of recombinant DNA research, bacteria absorb foreign DNA from lysed cells of their host, including the human gut. The rate of bacterial absorption of foreign DNA is low, but the number of bacteria in the gut is enormous, and bacteria have thrived for millions of years. There is some probability for any given human gene that it has already occurred in a bacterium. We may not observe that gene today, since the gene may have conferred no selective advantage on the bacterium, and the strain vanished (16). On the other hand, what is the likelihood that a plasmid or bacterium naturally contains a given human gene? That probability may approximate that of unicorns existing. Cohen and Boyer evoked a sense of mythological improbability when they called an altered plasmid a "chimera."

When a patent claims a chimera and host, the two are usually notable only in one respect: they contain a DNA sequence that the applicant purports to have invented. The plasmid and host are effectively the sequence's housing and factory. Once an investigator has selected a sequence as described above, the process of cloning it, and hence the "invention" of the sequence in a vector and transformed host, is mechanistic. Advanced techniques for sequencing proteins may make straightforward the selection of probes and primers, and hence the discovery of a known protein's gene. The "invention" of a protein variant may also follow straightforwardly from a variant, experimentally achieved, of a gene sequence. An investigator who finds naturally occurring genes and proteins merits accolades. But it remains to be shown why a patent should issue, and if so, on what.

What Should Suffice for a Biotechnology Product Patent?

As necessary conditions for award of a product patent, consider the following: (*1*) a claimed invention is such that it is highly improbable that we shall find it as such on earth or on any other astronomical body to which human travel is possible, and (*2*) the invention is ingenious. The "as such" phrase in (*1*) would allow some particularly convenient forms (e.g., a vector with a foreign DNA insert) to gain

recognition apart from a natural form. In (*2*), "ingenious," which shares an etymological root with "genetics," is a placeholder for what constitutes an invention, of which more later. Sequences fail (*1*) if they are found in chromosomes and mRNA. Chimeras, transformed hosts, and cDNA meet (*1*) but fail (*2*) when they are mere mechanistic steps from discovery of a sequence. The vectors and hosts of microbiology are not as fastidious as the species united in mythological chimeras: they accept DNA inserts regardless what creature originates them.

An "artificial gene" may satisfy both (*1*) and (*2*). In theory such a gene may be constructed of any codon-containing sequence one likes; in practice the amino acid sequence of a protein may inspire the sequence. Some caution may be needed in characterizing a sequence as "artificial" because if a sequence codes for a human protein, then either that sequence, another differing only by substitution of alternative codons for the same amino acids, or yet another that is insignificantly different exists somewhere in the genome. Because of the phenomenon of overlapping genes, the sequence may also be part of another gene that its discover has not even envisioned. On the other hand, it may be that an "artificial gene" meets (*1*) and that its gene product is in some sense superior. (The artificial gene product might, for example, lack contaminants usually found in the natural gene product.) Not every such sequence will be ingenious. Courts have often declared DNA sequences inferred from protein sequences to be obvious (17, p. 50).

In view of patents on algorithms — a departure from previous conventional wisdom that ideas are not patentable — one might appeal to the notion of patents on information as a defense of DNA patents. But this defense would seem to fail insofar as any information encoded in cDNA is encoded in naturally occurring DNA and mRNA.

Adverse Welfare Effects of DNA Patents

If the autonomy of no one in particular is threatened by a product patent, the autonomy of everyone together might be.

The PTO in 1987 granted a product patent on isolated and purified natural erythropoietin. Merely four months later it granted a second patent to another party relating to a recombinant DNA technique for making the protein. The second patentee had cloned the gene after screening a genomic DNA bank with two sets of probes. It then produced the protein in transformed hamster ovary cells. The first patent blocked the invention of the second. This portended that patients would be deprived of a recombinant method of producing erythropoietin in high volume at low cost. As a group, patients were saddled with the first patentee's production method (extracting extremely low yields of the protein from thousands of gallons of urine). When, four years later, the first patent was invalidated on unrelated procedural grounds, the second became a barrier against any better recombinant process employing the claimed sequence (18). Similarly did a biotechnology firm discover the human gene for factor VIII:C by probing a human cDNA bank, inserting the gene in plasmids, transforming hamster kidney cells with the plasmids, and producing factor VIII:C. This recombinant advance was blocked by an earlier patent on factor VIII:C itself (19). The patentee's process not only required enormous amounts of donated blood plasma for a small yield, but in contrast with the recombinant method, it risked contamination. Contamination was a critical risk because many hemophiliacs who received contaminated factor VIII:C died of AIDS. The recombinant's manufacturer protested unsuccessfully that the patentee had not invented factor VIII:C (though, given the chance, the manufacturer might have argued for its own invention of the recombinant). The erythropoietin and factor VIII:C episodes illustrate how product patents may frustrate society's interest in encouraging, at the same rapid pace at which biomedical research is otherwise moving, helpful innovations in processes for making therapeutically valuable human compounds.

Farmers raise the specter that, burdened by the high cost of patented animals and crops, they may turn to cheap unpatented strains, that crops will become less diverse, and that more crops will succumb to pests. In transgenesis, often an investigator cannot control the place within a genome at which a foreign gene inserts or the number of copies that insert, or in the case of plants, the weeds or other unwanted plants to which a transgene may migrate via airborne pollen. We also have reason to rue "blind promotion of technological innovation" (20). Agriculture, after all, is an industry afflicted with overproduction. A patent granted by the European Patent Office on all manner of genetically engineered soybeans has been criticized on the ground that soybeans are among the world's most important crops and monopoly of soybeans will threaten "world food security." Suppose that a patent on a critical crop, organism, or substance has been conferred on an enterprise that becomes bankrupt. Or suppose that the patent is acquired by some foreign entity that is involved in international intrigue, that uses the patent as leverage for some disreputable purpose, or that otherwise seems to control output contrary to the common good. As exemplified by experience with the anti-AIDS drug zidovudine (or "AZT"), the price of a patented product is a monopolist's price.

Scientists have become acutely aware that availability of patents on DNA sequences may be generating a patent race that misallocates resources and delays publication of results. This would run contrary to the hope underlying the Human Genome Project that disseminating chromosomal mapping and sequence data will foster growth in collective knowledge. It took four years after a gene implicated in breast cancer, *BRCA1*, was mapped to chromosome 17 before one of twelve rival collaborations found the gene, a feat they all recognized as a "discovery" (21). Yet the winner immediately sought a patent on *BRCA1* and related diagnostic processes. About a year later, one of the competing groups contributed to a public database the sequence of a large portion of chromosome 13 where *BRCA2* was thought to repose. "It will not be helpful to medicine," the scientist John Sulston was quoted as saying, "if, by the year 2003, control of every single gene is tied up by one company or another for twenty years. That would be an enormous ball and chain. . . .[F]or

the good of humanity, we should try to keep these things in the publicly exploitable domain" (22). The group contributing the chromosome 13 sequence data urged that DNA sequences be public information. Within a month thereafter, *BRCA2* was found (23). This seemed to exemplify the rapidity of progress when results are shared. Thereupon the discoverers of *BRCA1* filed for a patent on *BRCA2*, launching a dispute over who found *BRCA2* first. Seemingly ignored was the untenability of claiming to invent parts of nature's storehouse.

One cannot dismiss objections to product patents as the outpouring of any single, disputed moral view. Even without an appeal to morality, it may be argued on exclusively scientific and economic grounds that patents on human DNA sequences violate the unpatentability of nature. Many moral views assign significance to the aggregate welfare consequences of that violation. In such case the moral case against human DNA sequence patents reprises the scientific.

ALTERNATIVE INCENTIVES FOR BIOTECHNOLOGICAL INNOVATION

Measures for Holding onto the Availability of Product Patents

The legal criteria for patentability are that a "process," "manufacture," or "composition of matter" be "new," "useful," and "nonobvious" (24). According to a conservative article of faith espoused by patent practitioners, these criteria possess such protean qualities as to suffice for the resolution of all questions that arise from time to time. The criteria need only be interpreted by the courts. In reply to this, it must be said that, under prevailing interpretations, "new" and "useful" erect only minimal thresholds. "New" eliminates from patentability only what has already been published. "Useful" eliminates from patentability only the utterly useless, a rare creature among proffered inventions anyway. (Scientists at the National Institutes of Health, NIH, dramatized the weakness of the "utility" requirement in 1991–1992 when they ostensibly satisfied the criterion by citing a seemingly trivial use for parts, "expressed sequence tags," of cDNA sequences. The applicants conceded ignorance about the feature of usual biological interest, viz., what the sequences encode or regulate, and ventured only that the tags could be useful as genetic markers, primers, or probes in diagnostic kits for unnamed diseases. But any DNA sequence may be a marker in genomic mapping.)

To resolve a question of patentability, two sobriquets, "manufacture" and "nonobviousness," must carry most of the load. In fact nonobviousness must do all the work. For it is considered settled in U.S. patent law that cloned DNA sequences, as fruits of "isolation and purification," constitute a patent eligible genre. Being a "product of nature" is now seen as no impediment to patent eligibility; the question is whether a sequence constitutes a new, useful, and nonobvious manufacture or composition of matter (25). Thus stood on its head is Jefferson's use of "product of nature" for the unpatentable. But the point is only semantic: since every extant thing's ingredients are naturally occurring raw materials, every extant thing may be called a "product of nature" in some sense. The semantic point entails no practical consequence if some other provision insures the unpatentability of nature. (As defined earlier, the unpatentability of nature is the premise that to be eligible for a patent, a thing must be such that there obtains only a very low probability that without human intervention, the thing exists near the surface of the earth or on other astronomical bodies to which humans travel.) We might think that the statutory term "invent" secures the unpatentability of nature. But instead for the domain of biotechnology though not for others, we observe patent examiners and courts effectively either rejecting the unpatentability of nature or exhibiting remarkable restraint as they construe the premise. The DNA sequences that they pronounce patentable are sequences that *chromosomes of living beings contain*. The only apparent way to reconcile this with some version of the unpatentability of nature is to emphasize that a given cDNA sequence corresponding to a chromosomal sequence differs from the chromosomal sequence insofar as the chromosomal sequence is littered with introns. Still it must be said that the chromosomal sequence *includes* the cDNA sequence. That is to say nothing of the chromosomal sequence's uninterrupted transcript in the form of mRNA. Courts and patent examiners keep faith with only a weak version of the unpatentability of nature.

Given that DNA sequences are recognized as a patentable genre, whether a given sequence garners a patent turns on whether the sequence is deemed obvious. When courts first struggled with arguments about recombinant DNA technology, it seemed obvious that what was obvious was not obvious. As courts came to recognize recombinant techniques as commonplace, they bent over backwards to conclude that newly discovered cDNA sequences were nonobvious. If the prior art did not enable a method of finding a proffered sequence "with a reasonable prospect of success," a court would pronounce the sequence nonobvious. (This move vindicated a patent on the sequence encoding erythropoietin, a sequence found by screening a genomic DNA bank with two fully degenerate sets of oligonucleotide probes.) As further reasons to sustain a verdict of nonobviousness, courts have even recognized circumstances extraneous to the intellectual process of discovery and invention, including commercial success, long-felt need, failure of others, unexpected results, and the scepticism of rivals (17, p. 19). As critics would have it, one influential judicial decision saves the day for cDNA patents only by tortuously construing "obvious" so as effectively to declare patentable *per se* any DNA sequence found to encode a protein (26). According to one observer, the obviousness of many purported cDNA inventions is betrayed "in the very attitude of the persons skilled in the field. Today, if a researcher discovers a new protein and its probable properties, he usually does not publicize the information until he has found the corresponding gene. How to explain this in a community whose motto is 'publish or perish' save that it would be obvious to another research team to pick up the information, and clone the gene?" (17, p. 90). In hopes of securing future DNA patents against a tide of progress that may render

ever fewer cDNA sequences nonobvious, it has been suggested that the nonobviousness requirement, to the extent not already emasculated by the aforementioned judicial decision, might be weakened. If the steeplechase jump proves too high for the average contestant, lower the bar. Where a nucleotide sequence is itself a drug, as with anti-sense RNA or the use of a DNA sequence to achieve expression without integration into the genome, it has been suggested that obviousness might be replaced with superiority over prior art in therapeutic efficacy (17, pp. 141–143, 148). Without some such move, it is urged, future application of the obviousness standard may thwart the availability of product patents on the expectation of which the biotechnological industry arose. Here an appeal is made to the biotechnologist's familiar prediction that a world without DNA patents will be a world without therapeutic innovation. But rehearsing that prediction does not provide evidence for it.

The issue remains whether, all things considered, more DNA product patents should issue. By virtue of considerations mentioned earlier, the answer may be in the negative. In such case, what might replace such patents?

Categorical Prohibitions

In the Biotechnology Patent Protection Act of 1995 (27), procured at the behest of the biotechnology industry to allow a biotechnology process claim to piggyback on a product claim, precedent was set for legislation that speaks in biological parlance about patents concerning molecular biology. Despite the supposed protean generality of the patent conceptual scheme, the door has been thrown open to discipline-specific rules. What most commonly seems to flow through that door is a stream of *ad hoc* prohibitions, usually categorical and often embracing uses as well as monopolies on uses. One favorite in the U.S. Congress and the European Parliament is a moratorium on a given sort of patent or research. Sometimes the rationale for a prohibition will appear to assimilate a property interest in an extracorporeal molecule to invasion of personal autonomy, which earlier we found reason to distinguish. As the portion of the human genome claimed by patents expands, motivation arises to prohibit any more such patents. Were a ban imposed, the control experiment of life without patents would run in real time. Biotechnology firms would compete with no intellectual property save for trade secret protection of whatever they managed to keep secret. Such competition might produce salutary results. It might also diminish aggregate welfare unless some mechanism replaces at least some of the incentives fostered by product patents.

Compulsory Publication of DNA Sequence Data to Thwart Patents

When without first filing for a patent, a scientist publishes a DNA sequence, no one may obtain a patent on the sequence. Mere citation of that publication as prior art will spike anyone's claim that the sequence is "new." Mindful of this, some scientists acting of their own volition and other scientists acting in compliance with funding mandates have promptly and systematically released DNA sequence data as discovered. A concerted effort so to publish could thwart most new DNA patent applications. Thereupon it becomes open season for any and all to explore therapies predicated on all unpatented portions of the genome. The benefits of expanding the universe of potential investigators would seem apparent. To the extent that research motivated by profit may contribute applications that might not flow from academic laboratories, incentives must now be sought elsewhere.

Subsidies

When a public good is underprovided, as is familiarly the case in perfect competition (e.g., as to education and national defense), government may step in to provide it. Valuable public ideas are intellectual public goods. Suppose then that no further patents issue on DNA sequences other than artificial sequences. Instead, the government systematically subsidizes biotechnological research. Subsidies are awarded not only to academic institutions but to nonprofit biotechnology research centers. Specifically organized for the pursuit of applied as well as basic research, these centers tackle applications that might not be pursued, or pursued with less zeal, in academic laboratories. This scheme could implement coordinated decisions, reached with benefit of expert extramural advice, concerning which fields of fundamental biomedical and biotechnological research should be pursued and to what extent. The scheme entails substantial expenditures and may importune taxes earmarked for research (20). But the subsidies assure that society gains the benefit of valuable innovations.

Were it widgets that society sought to encourage, subsidies for institutional laboratory research might not succeed in coaxing the same innovations as would market incentives for entrepreneurs experimenting in their shops. When the desired innovations are biotechnological, it happens that academic laboratories constitute society's most fertile source of ideas. What academic laboratories do not pursue by way of applications may be pursued in the research centers. Were a share of sales revenues promised to any laboratory originating an end product, market incentives could also be brought to bear within both academic laboratories and research centers.

In the marketplace, with valuable discoveries being contributed to the public domain and available for exploitation, firms would now compete less on the basis of their discoveries and more on their efficiency in production. As with any subsidy, it may be difficult to ascertain whether the extent of biotechnological innovation induced is optimal. But one could at least compare the extent of technological innovation during the present era of product patent availability with the extent of technological innovation under a new regime.

Exclusive FDA Approval for a Term of Years

A government may also engraft an incentive mechanism upon the process by which, with a view to public safety, the government grants approval for the sale of medical products and devices. The Orphan Drug Act (28) affords a model for such an incentive scheme. According to that statute, if the FDA grants a manufacturer approval to

sell a drug targeted at a disease that affects fewer than 200,000 persons in the United States, or whose likely sales cannot reasonably be expected to recoup the costs of development, the agency must refrain, for seven years after such approval, from approving sale of the drug by anyone else for use against that disease. Routine delay in obtaining FDA approval for any drug affords to the first party who gains FDA approval some period of *de facto* postapproval protection against imitators; in respect of an orphan drug, the first party to gain approval enjoys seven years of *de jure* postapproval exclusivity. The orphan drug scheme is not without its complications. For purposes of identifying which compounds are blocked for seven years by an approved orphan drug, it has been necessary to define what constitutes "the same drug." The FDA defines a new drug to be the same as a previously approved orphan drug if the new drug has the same "principal molecular features" — unless the new drug is "clinically superior" to the approved orphan drug (29). This seems to rehearse, though with variations, a judicial patent doctrine that a claimed invention is obvious if the prior art includes a structurally similar compound — unless the claimed invention possesses an unexpected property (17, pp. 145–148).

This incentive scheme could be extended. From orphan drugs it could be extended to any genre of products that seem likely to serve the public interest — indeed to any and all biotechnology products. To specify the genre of products for exclusive approval, the government could rely on advice from extramural scientific panels. Such a scheme would spare the costs, burdens, and uncertainties of patents. It would reward the development of valuable products without tying up the human genome with property claims. It would respect the unpatentability of nature. The number of years and other terms of the exclusive sale privilege are of course variable. One might also replicate the provison of the Orphan Drug Act that allows the FDA to approve sale of an orphan drug by a second applicant if the original manufacturer "cannot assure the availability of sufficient quantities of the drug to meet the needs of persons with the disease or condition" (30).

Human Methods Patent

Ambivalence between patents on products *vis-à-vis* patents on processes has been evident since recombinant DNA technology began. The Cohen-Boyer patent protects a process. It was followed, as the technology developed, by many process as well as product patents (31). The Cohen-Boyer application also sought claims on recombinants, but no product patents issued until 1984 (on plasmids) and 1988 (on plasmid-transformed hosts). Stanford University's licensing of the process patent thrived beginning in 1981 before Stanford acquired any product patent (32).

A possible resolution of the ambivalence would be to require hereafter that to secure a patent pertaining to a DNA sequence, one must invent some new process that can be performed in respect of the sequence rather than claim to have invented the sequence or its gene product. A new form of patent predicated on this principle has been proposed (14) in the following statutory phrasing:

> There shall be allowed a patent pertaining to a human life form (a "human methods patent" or "*HMP*"), the scope of which patent shall not exceed the least inclusive description of an ingenious process. Such a process may consist in the production, use, alteration, amplification, or attenuation of human life forms outside the human body. An *HMP* may include an additional claim on nonhuman reproduction of any transgenic and its progeny if and only if (a) the ingenious process produces such transgenic, (b) such transgenic produces a human life form, and (c) without reference to such human life form, the process would not be patentable.
>
> No product patent shall be allowed on a human life form or anything in which it is included. The foregoing shall not preclude a patent on a synthesized, fully explicated nucleotide sequence or protein that is not present, consecutively or otherwise, in the human body.
>
> Research in a nonprofit institution for nonprofit purposes shall be exempt from any claim of infringement.

The significance of an *HMP* may be made more clear by the following observations.

(i) Interspecies homology is only similarity to a degree, not identity of nucleotide sequences. Absent evidence of identity with a nonhuman form in a given case, "human life form" may be assumed distinct.

(ii) The confinement of an *HMP* to the least inclusive description of an invention protects against the detriment of overbreadth as illustrated by experience with erythropoietin and factor VIII:C. Such limitation would depart from the law's tendency to allow contributors a claim on a whole — as when a farmer obtains a claim on grain in an elevator with which the farmer's is commingled, or a security interest in a part attaches to a mass in which the part is commingled or assembled. Reasons for parsimony obtain concerning the human genome.

(iii) Suppose that an *HMP* claims "a method for obtaining DNA sequence $b_1, b_2, \ldots b_n$ from genomic DNA as follows: . . . ," and describes the ingenious method by which the sequence was discovered. Without more, such a patent would afford little protection. Everyone may now read the sequence disclosed by the patent. Free of infringement, anyone may then obtain the sequence by employing any process, including the polymerase chain reaction, other than the patented process. To avoid this vulnerability, the discoverer might seek to claim "cloning of the sequence in vector v and transformation by v of host h that results in production of protein p_i as follows: . . . ." Perhaps this investigator has ingeniously devised a way to use a new v to produce p_i in some mammalian h never before used to produce human substances. In general, it will not be ingenious to clone an identified sequence, nor to produce a protein by means of a known gene. The principle of least inclusiveness allows a claim on only so much of the process as is ingenious. The discoverer's successors may find it unnecessary to use the process first used to discover the thing, and may proceed to "event around" the process. This is true about the discovery of any natural thing. Successors may also invent methods by which to use, alter, or promote or attenuate the effect of the thing.

Process patent opportunities still await — in protein chemistry, insertion of foreign DNA, transformation and infection, gene expression, and protein-manufacturing techniques. One process might describe a technique for

making a protein, another how to use it. Or a firm might use knowledge of a gene not to produce but to curtail the effect of a given protein, including a newly discovered protein.

(iv) It may be possible to state certain minimal conditions for work to be ingenious. If a claimed method is predicated on a human life form, it may be unlikely to exhibit an advance over present knowledge unless the life form is fully explicated. "Fully explicated" entails, in the case of DNA, that a specific nucleotide sequence (the "explicated sequence") is identified, including all regulatory sequences necessary for any exons in the explicated sequence to be transcribed into RNA and for a gene to be expressed, that all such sequences have been inserted into a vector or maintained in some stable form, that it is known what the explicated sequence encodes or regulates (or perhaps only that it is implicated in the etiology of a disease), and that the process succeeds in expressing or preventing expression of such gene. For a protein, full explication would embrace biological function, amino acid sequence, and encoding gene sequence.

(v) One could circumvent a patent thus far described if, for example, one were to pay a royalty in order to perform a patented transgenic process of producing a human hormone in a pig, and then, without paying any more royalties, one were to breed a line of pigs. Thereby one could obtain copious amounts of the hormone. Natural breeding of course produces naturally occurring progeny, and, except for plants in the United States, such progeny would seem unpatentable. To prevent the foregoing circumvention, which would defeat an inventor's reasonable property expectations, the *HMP* allows a claim on growing or nonhuman breeding of a transgenic if the transgenic is a result of the invented process and the transgenic produces some human life form without reference to which the process would not be patentable. The additional claim may be defended as a claim on reproduction of an "unnatural" organism, one not likely to be found in nature. Such scheme resolves the predicament to which the self-reproducibility argument for the Harvard mouse patent is directed. It allows no claim on a human life form itself. Nor may the additional claim encompass human reproduction. Should the invented process happen to be one of artificial human reproduction, remedies may be provided (as discussed in the next section) against infringing providers, but never against a parent or child as such.

Whether an "artificial gene" or the protein it encodes will qualify for an *HMP* is contingent on how close a variant or equivalent the gene may be to what is found in the human genome. Will this contingency discourage fruitful research on the genome? Significant disincentives seem unlikely unless firms so greatly prefer product to process patents that they choose to pursue the more difficult task of sequencing proteins rather than finding naturally occurring genes encoding for proteins. Where proteins may be sequenced automatically, a disincentive may occur. But if the therapeutic value of an artificial gene product is not sufficient, it will not be an appealing product no matter what the patent availability. At least the products of naturally occurring genes have known worth.

Objections to the *HMP* and replies thereto include the following. Industrialists preferring product patents often contend that recombinants are more potent and free of contaminants, that recombinants thus differ from natural isolates and from each other, and hence that product patents will not prevent new advances from reaching the market. This conjecture seems belied by the history of erythropoietin and factor VIII:C in particular, and in general by the hegemony of any product patent over improvements. Whichever industrialist happens to be first in time will often hoist another on the petard of contradiction. In scientific publications and in advertising, sellers of recombinants are wont to describe their products as virtually identical to the corresponding natural isolates. But when forced to defend against a claim of patent infringement, the same sellers may be heard invoking the "reverse doctrine of equivalents," which, under U.S. patent law, excuses some literal infringements if the accused product displays differences in specific activity and purity from the patented product. (The doctrine of which this is called the "reverse" sustains a claim of infringement against an accused protein somehow differing from a patented protein if no functional differences obtain between them.)

A more orthodox industrialist objection to the *HMP* would be to say that without product patents, businesses will not invest the millions of dollars needed to find a gene and to produce a protein by recombinant methods. This bluff is handy because it is counterfactual. As earlier indicated, when one looks at the relatively scant evidence of inventive behavior without patents, and then conjectures about what happens if only process and not product patents are available, one may be sceptical about the claim that biotechnology cannot thrive without product patents. The effective protection afforded by process patents depends on how easy it is to design around a process. Large, complex proteins found in humans may be more difficult to design than, say, pharmaceuticals. Biotechnology patents are replete with process claims. It appears that firms have found ways to protect their intellectual property even though patent examiners vary in their view of product *vis-á-vis* process claims, and even though, given how often courts invalidate them, the status of any product patent is contingent. It must be granted that process patents are often less convenient to enforce because a patentee must show what transpired in a rival's plant. Even so, if a patent has been issued on a recombinant process, ordinarily the recombinant result has only a very low probability of naturally occurring. The patent holder may invoke this probability to refute a defendant's claim to have bred transgenics without using a patented process and without using offspring of the patented process.

One previous motivation for a U.S. product patent is now obviated. When the Harvard mouse emerged, anyone could avoid infringement of a U.S. process patent by performing the patented process in a foreign country outside the reach of U.S. law and then importing the end product into the United States; no such move would defeat a product patent. A statutory amendment changed this by declaring that any such importation is

an infringement of the process patent (33). By virtue of the Biotechnology Patent Protection Act, one may obtain a process patent on a recombinant process that uses or makes a patented product, although this piggyback rule will be moot if product patents become unavailable. Instead of this piggyback rule, it might better be declared that a patent is available on an invented process if what the process uses or produces would be patentable but for the fact that the product is a human life form. Such is the effect of the *HMP*. It allows a process claim to be predicated upon a human life form while allowing no claim on the life form itself.

It remains necessary to show an ingenious process. An industrialist may object that there seem to be few new processes to invent, that current biotechnology employs standard processes that differ only by genes expressed. Mere substitution of a different gene in a known process may indeed be perfunctory. It would not seem to state an argument for product patents to say that innovation is difficult. Opportunities for process innovations abound. The Cohen-Boyer patents expired in 1997. It may simply be that the challenge of finding genes commands more attention at present.

The *HMP*, subsidies, and a period of exclusive FDA drug approval could be implemented separately or together.

ANCILLARY MECHANISMS

Compulsory Licensing

A patent subjects society to the vagaries of a monopolist's choices and fortunes. A possible protection against such risk with respect to biological patents is compulsory licensing according to which anyone may use a patented process upon payment of no more than some reasonable royalty. Another protection is ceilings on the prices of goods made by patented processes. As early as the federally supported Cohen-Boyer research, the NIH considered seeking patents on funded innovations. NIH asserted patent rights to AZT based on the research contributions of NIH intramural scientists, all with the declared purpose of restraining prices of products. This prompts the suggestion that a government agency other than the patent office be empowered to determine what events trigger, and the royalty rate of, a compulsory license established as a condition of any biotechnological patent. A further condition might empower the agency to set maximum prices on goods produced and processes performed in the practice of the patent. An ideal scheme would foster commercial incentives and allow a reasonable return on investment while preventing exorbitant prices.

Such a scheme, it may immediately be objected, would interfere with markets. The industrialist might contend that governments should not restrain returns on genetic inventions since they do not restrain prices of patented artificial hearts or organ transplants. One might reply that when a government grants the privilege of selling a drug or medical product, or of enjoying a monopoly on anything importantly related to human health, the public interest may justify conditioning the privilege on end product price restraint. Compulsory licensing would also protect against disasters with respect to things other than price. As earlier noted, the patentee of the sole therapy for a serious disease could become bankrupt or for other reasons decline to practice or license the invention. The common weal may demand that the invention be available. The industrialist's appeal to the case of an organ transplant does not provide a persuasive counterexample against a compulsory license because organs are donated and recipients pay only for services. An artificial organ is not perfectly analogous to a gene since the organ lacks person-defining genetic information. In any case there may be good reasons to interfere concerning any commerce in human parts.

Expert Guidance

A U.S. patent is only presumptively valid. Since courts often invalidate patents, no one knows for sure that a patent is valid until and unless it is upheld in court. Consider how numerous are the courts within the sovereignties that comprise the international biotechnology market. Trial courts decide only questions placed before them by a flow of cases that is nearly stochastic. The same is true for appellate courts on which depend the prospects of resolving conflicts among trial courts. In contrast to scientists for whom dialogue is a way of life, judges of different courts do not, as a matter of decorum, communicate with each other on pending cases. The science on which they rule is also limited to that practiced a few years, if not a decade, before trial. This obtains because time of invention is the reference point for what is obvious. Hence judicial decisions provide uncertain guidance about patentability of today's scientific processes. Moral issues, as we earlier saw, are not even tackled.

It seems improbable that any one word such as "nonobviousness" or "ingenuity" can bear the load of defining what is a sufficient feat to merit a monopoly. For instance, a claimed invention might be a *tour de force* of genetic engineering, even though the investigator knows neither a sequence's chromosomal locus nor the sequence's coding or regulatory function, if the investigator correctly infers that the sequence is involved, by homology or otherwise, in the etiology of a disease. To transform "ingenious" from placeholder to admission ticket, we may have to settle for a notion of family resemblance. For if ingenuity were to admit of precise definition, would anything be ingenious?

To meet the difficulty of recognizing ingenuity as science progresses, to overcome the lag between research and adjudication, and to improve upon the limited expertise brought to bear in patent adjudication, a mechanism could be confirmed for introducing scientific expertise. A government agency, otherwise involved in scientific research, could exercise authority continually to revise published standards for patenting life forms in reliance on recommendations of expert scientific panels. For purposes of judicial review, the law could preserve the practice of judging a patent by the standards in effect at the time of alleged invention. From such expertly framed standards, the biotechnology industry could obtain guidance more

current and systematic than case law or statute is likely ever to be.

IMPLICATIONS OF PATENTS IN THE CLINIC

Introduction of Human Substances Outside the Germ Line

Ex vivo somatic intervention involves removing patient cells (e.g., tissue-infiltrating lymphocytes or bone marrow stem cells), growing them in culture, transferring genes into them using nonvirulent retroviruses or otherwise, and reintroducing the cells into the patient's body, not necessarily at the site of their effect. *In vivo* intervention is exemplified by the introduction of retrovirus vectors containing human genes at the site of the condition to be overcome. The ED, which would allow patents on substances isolated from the human body, would permit, while the *HMP* would deny, a patent on such cultured cells or vectors. They are ineligible for an *HMP* because they are or contain human life forms. Indeed the cultured cells are grown from the patient's. Except for attempted enhancement, the cultured cells would be unlikely candidates for "inventions" anyway. They are not intended to be innovations. The goal of therapy is to insert a normal gene. The ultimate achievement is homologous recombination. Thereby a normal gene replaces a defective one rather than entering the genome at an indeterminate locus.

Somatic interventions involve medical procedures on patients. Medical treatment, surgery, and diagnosis are not patentable in Europe (34). Their eligibility for U.S. patents has been dubious since 1862 when a patent was sought on the use of ether. It has seemed to many that it would be wrong to discourage physicians, on pain of infringement, from deploying in the relief of human suffering the most efficacious procedures they can muster under the exigencies they face. Hence one might conclude that the only processes of somatic intervention that may qualify for an *HMP* are ancillary laboratory processes. Similarly might patents be confined to laboratory processes with respect to tissues or organs grown in cell culture — especially if, as may be typical to avoid rejection, the cultured cells are grown from the patient's. Opportunities for process innovations would appear abundant when one apprises present difficulties in somatic cell therapy and the challenge of growing tissues and organs.

A contrary moral view might be that the foregoing is too generous. Suppose that one opposed patents on reproduction of any sort. One might assimilate the culturing of cells to reproduction, thereby reversing the patent law's assimilation of reproduction to manufacture. One might add that a laboratory process ancillary to a medical treatment is indistinguishable for these purposes from the treatment. The contention that human reproduction cannot be an infringement does not entail any claim about what is human reproduction. One might conclude that a patent on growing cells outside the human body does not threaten any patient's autonomy so long as there is no claim on the cells themselves. The difficulty of developing successful methods of somatic cell therapy, and of cultivating tissues and organs, suggests the benefit of patent incentives. One need not claim that laboratory processes ancillary to medical procedures are in general nonmedical. One need only allow some of them to be patentable.

Human Germ Line Intervention

Germ line intervention affects reproduction in two ways. (a) It alters the genome, an offspring's complement of genes that appear in all cells including the gametes. (b) In order to achieve (a), it is performed before germ and somatic cells of an individual differentiate, i.e., on zygotes and early stage embryos. A moral objection might be lodged against a patent on any such method because of these links to reproduction. As noted, the ED would allow no patent on any method of human germ line intervention. Again a reply may be that collective benefit could result from creating patent incentives on certain laboratory processes. It is also noteworthy that a patent on gene therapy would not be a patent on *in vitro* fertilization. Therapy is subsequent to fertilization. The choice to conceive may be seen as a different choice than the choice whether to intervene genetically for the health of a child whose conception has been chosen, even if the former is contingent on the latter. On the other hand, the opposite may be the case if eggs fertilized *in vitro* are screened for genetic defects or traits, thereby exercising a choice of which shall live. Two *in vivo* methods also merit mention. One consists in altering an embryo *in utero* by retroviral infection. Another consists in causing adult testes or ovaries to produce genetically engineered gametes (35). A requested European patent on the latter technique was criticized as contrary to *l'ordre publique* or morality (36). For these also one may ask whether the prospect of collective benefit suffices to warrant property claims on ancillary laboratory processes of medical procedures.

If government grants patents on any germ line interventionary process, does that comport with the stance that human reproduction cannot be infringement? The answer lies in stipulating that no remedy will lie against a parent or child as such. Damages and preconception injunctive relief could be made available against unlicensed providers of patented processes. If Mr. and Mrs. Thurston, learning of Mendipulate Inc.'s patented technique for germ line manipulation, arrange with their physician for the technique but no one pays the royalty, a damage remedy may lie against the providers. We can scarcely imagine a suit by Mendipulate against Mrs. Thurston, her daughter or granddaughter, or their physicians or hospitals, complaining of the conception of a child, not to mention injunctive relief, i.e., an order for an abortion. Mere pragmatism makes clear that Mendipulate's interests require no remedy against a patient. Drug manufacturers do not sue patients who infringe by "using" an infringing drug. They sue rival manufacturers and distributors who "make" and "sell" the drug in quantity.

Mendipulate may protest that if it cannot obtain a product patent, every Thurston descendant will benefit

from Mendipulate's invention without paying for it. Mendipulate is correct that the *HMP* allows claims on reproducing the progeny of transgenesis only for nonhuman reproduction. But consider that Mendipulate will advertise a patented process of germ line therapy as a method to remedy a genetic defect. It cannot tenably assert that if it had a product patent, many Thurston descendants would become good-paying customers when they inherit the defect! Moreover, whether the process is therapy or enhancement, Mendipulate's twenty years of monopoly will run before any transgenic Thurston reaches adulthood. Mendipulate may still complain that if Mr. or Mrs. Thurston undergoes a patented Mendipulate process that causes them to produce genetically engineered gametes, no more compensation will be gotten by Mendipulate if the Thurstons have a dozen children than if they have one. This of course overlooks the difference between having children and copying a patented contraption for profit. People are not motivated to have children because they can copy a gene for free. Mendipulate may anticipate fecundity when it prices the royalty for its laboratory process.

Since interventions will be performed by physicians, enforcement of a process patent will require showing what happened in the doctor's office. To Mendipulate this will seem inconvenient. It would prefer a product patent whose infringement it could establish by comparison of parental and progeny DNA. Such a comparison would be peculiar, to say the least, as it would be mustered in support of a complaint that a child is healthy or possessed of some enhancement. It should suffice to protect Mendipulate that licensed specialists may generally be expected to pay royalties on patented processes. What would be troublesome would be the enterprising move of a patient who sells gametes that contain altered genes. This concern may be minimized for the moment by realizing that only enhancement genes, not corrected disease-causing genes, would be likely to be marketable.

Society might deem the collective benefit of enhancement to be insufficient for allowing a patent. If concerns about playing God and discrimination prevail, refusing patents on enhancement would be a means to discourage the practice. A contrary view might be that if we demarcate certain interventions to be outside the physician's armamentarium for maintaining health, no public policy will be disserved by a patent.

There remains possible a product patent on a synthetic gene nowhere found in humans. To use such a gene might depart from the present vision of installing normal in lieu of defective genes. The prospect of such departures no doubt explains the habitual mention of Frankenstein when observers discuss germ line intervention. Regardless, the immunity of parents and children as such from claims of infringement would control. The inventor of a human genetic intervention surrenders the product of the process for integration into an unownable being. If a process alters an early stage embryo, integration occurs into a human in gestation. If alterations are made in gametes or the means of their production, integration occurs into the body of the patient.

CONSISTENCY OF POLICY FOR PLANTS AND ANIMALS

Unless policies about forms of life evince a consistent understanding of innovation and reflect generalizable moral principles, a stable consensus seems unattainable. Conditions (*1*) and (*2*) above stated for a biotechnology product patent — low likelihood of finding the claimed invention in nature, and ingenuity — appear applicable to any life form patent. Some transgenic plants and animals may be improbable of natural occurrence and recognizable as the products of ingenuity. Others may possess transgenes from members of their own species for which the odds of acquisition by mutation are better than trivial, or as to which the process of transgenesis is not ingenious. Where a product patent would be unwarranted, a process patent could be available. As may an *HMP*, a process patent could claim a process by reference to an identified plant or animal life form. It could add a claim on the breeding of any plant or animal that the patented process produces and without which the process would not be patentable. Such an additional claim would obviate the self-reproducibility rationale for a transgenic product patent.

One may argue for bounding a patent's enforceability by operation of a "farmers' privilege," a derogation imposed for plants in the United States and often proposed for animals there and in the ED. This permits a farmer to breed patented animals to the extent needed to replenish stocks on the farm, or to plant seeds generated by transgenic plants grown on the farm. A farmers' privilege would avail a typical farmer who does not seek to compete with breeders in selling varieties as such but who wishes to sell what is raised on the farm. The derogation would entail that, as Mendipulate must do concerning the Thurstons, commercial breeders must collect their royalties on the first generation.

OUTLINE

INTRODUCTION

Pharmacogenetics is a new and quickly evolving scientific discipline that studies how genetic differences determine an individual's response to therapeutics. Recent advances have shown that many drug-metabolizing enzymes have genetic variations in expression and regulation. When these genetic variations affect the enzyme's function significantly, different clinical outcomes can occur among people exposed to a particular drug. Pharmacogenetics can help to individualize dosing regimens, thereby maximizing a drug's therapeutic effect and minimizing toxicity. The rapid development of genotyping as a molecular diagnostic tool nevertheless raises ethical, legal and policy issues, as have been the case with other DNA-based testing. Although pharmacogenetics shares concerns with other genetic research in clinical practice, this discipline also has unique objectives

and goals. It therefore is important to address the issues associated with this emerging discipline. The purpose of this article is to describe the concepts and advances in pharmacogenetics, discuss social implications of this field and provide recommendations in this area.

PHARMACOGENETICS

Genetic Variations in Drug Response

Significant variations in drug response exist among both populations and individuals. These variations can be due to genetic and/or environmental factors. Age, gender, body size, diet, alcohol or tobacco consumption, pregnancy, kidney or liver dysfunction, concurrent disease states, and drug interactions can all modify the bioavailability, distribution, protein binding, metabolism and excretion of drugs (1). Interindividual variations in drug response also result from genetically based differences in drug metabolism. Individual differences in the absorption, distribution, metabolism, and excretion of therapeutics can alter the effects of a given dose, leading to a spectrum of responses ranging from clinical benefit to adverse effects or therapeutic failure. When taken up by the human body, foreign compounds typically undergo metabolism via Phase I and II enzyme reactions (2). Phase I reactions involve hydrolysis, reduction, and oxidation. These enzymes introduce a functional group (i.e., hydroxyl, amino, sulfhydrol, or carboxyl) to the compound, usually increasing water solubility. Within the category of Phase I enzymes are the cytochorome P450 multigene family, AND(P)H quinone oxidoreductase, and aldehyde dehydrogenase. Phase II metabolism includes glucuronidation, sulfation, acetylation, methylation, glutathione conjugation, and amino acid conjugations. Most Phase II reactions dramatically increase hydrophilicity, thus greatly enhancing the excretion of foreign compounds. Phase II enzymes include UDP-glucuronosyl transferases, glutathione-*S*-transferases (GSTs), sulfotransferases, catechol-*o*-methyltransferases, phenol-*o*-methyltransferase, and thiol methyltransferases (3). Recent research has identified functionally important variations in most Phase I and II enzymes, which can lead to different metabolic profiles among individuals.

Genetic Polymorphisms of Drug-Metabolizing Enzymes

Genetic polymorphism refers to distinct traits derived from a single gene that exists in more than one form. These polymorphisms are transmitted from generation to generation, sometimes with striking differences in allele distributions among different ethnic groups (4). A majority of the genetic polymorphisms do not affect protein function and therefore have no phenotypic importance. Other polymorphic genes encode drug-metabolizing enzymes with dysfunctional or nonfunctional activity. As a result the subgroup of the population with the genotype(s) will metabolize drugs that are eliminated via this pathway differently from individuals with the normal (wild-type) genotype. A classic example of genetic polymorphism is class 2 aldehyde dehydrogenase (ALDH2). Approximately 50 percent of the Asian population has a single amino acid change of Glu^{487} to Lys^{487} in this enzyme, causing impaired acetaldehyde metabolism (5). These individuals can rapidly convert ethanol to acetaldehyde but only slowly metabolize acetaldehyde to acetic acid. Affected people experience of flushing syndrome after alcohol consumption due to the release of catecholamines triggered by the sustained high blood acetaldehyde levels, which does not normally occur in people with the fully functional form of the enzyme. Pharmacogenetics emerged as a discipline to study genetic variations in drug-metabolizing enzymes that may determine an individual's responsiveness to therapeutic agents (6,7). Advances in this area have important clinical implications and practical values for the design of dosing regimens. It is important to recognize that the genetic variations in drug metabolism can lead to significantly different therapeutic responses, including either low or exaggerated pharmacological effects or side effects.

An increasing number of drug-metabolizing enzyme polymorphisms have been identified in recent years (8). Examples of Phase I and II enzymes with functionally important polymorphisms are listed in Table 1 (9–22). A well-characterized drug metabolizing enzyme with functionally important variants, cytochrome P450 2D6 (CYP2D6, debrisoquine hydroxylase), will be highlighted. The genetic polymorphisms of CYP2D6 are perhaps the most well-established alterations with known clinical significance. This microsomal isozyme is responsible for the oxidative metabolism of approximately 50 clinically important drugs of varying therapeutic classes (2). Its substrates include widely used antiarrhythmics, tricyclic antidepressants, β-adrenergic blocking agents, neuroleptics, and other classes. These drugs frequently have narrow therapeutic windows, meaning that slightly lower than targeted plasma concentrations will not have the desirable therapeutic effect while only somewhat higher concentrations cause toxicity.

CYP2D6 has three clinically distinct phenotypes: (*1*) the normal (or extensive) metabolizers, (*2*) slow (or poor) metabolizers, and (*3*) fast (or ultraextensive) metabolizers. The same dose of a drug metabolized via CYP2D6 will result in plasma concentrations that vary greatly among these individuals. In normal metabolizers, steady-state plasma concentrations will normally fall within the desired therapeutic range and toxic effects will be non-existent or minimal. In fast metabolizer individuals, steady-state drug levels will be below therapeutic concentration and this group of patients is unlikely to respond to standard treatment regimens. It has recently been reported that the cholesterol-lowering drug simvastatin did not reduce plasma lipid levels in CYP2D6 fast metabolizers at standard doses (23). While it may be possible to increase the dose given to these patients and achieve the same therapeutic effect as normal metabolizers, this approach also increases the potential for undesirable side effects, particularly those not related to CYP2D6 metabolism. In slow metabolizing individuals, plasma drug concentrations will be significantly above therapeutic levels when

Table 1. Example Polymorphic Enzymes in Drug Metabolism and/or Disease Susceptibility

Enzymes	Enzyme Reaction	Phenotype
CYP1A1	PAH oxidation	FM associated with lung cancer in smokers (9)
CYP2C9	Tolbutamide hydroxylation	SM for tolbutamide (10)
CYP2C19	S-Mephenytoin hydroxylation	SM for mephenytoin and other drugs (10)
CYP2D6	Debrisoquine hydroxylation	SM and FM for over 50 clinically important drugs (11)
CYP2E1	Chlorzoxazone hydroxylation	Associated with lung cancer (12)
ADH2	Ethanol metabolism	SM for alcohol metabolism (5)
NQO1	Quinone reduction	Associated with urological (13) and lung cancer (14)
GSTM1	Conjugation of epoxide	Gene deletion associated with lung (15) and bladder cancer (16)
NAT2	Acetylation	SM and FM for isoniazid and other drugs (17) associated with bladder and colon cancer (18)
UDPGT1A1	Bilirubin conjugation.	Deficiencies in Crigler-Najjar (19,20) and Gilbert syndrome (21)
TPMT	Methylation	Deficiency associated with mercaptopurine and azathiopurine toxicity (22)

Abbreviations: FM, fast metabolizer; GSTM1, Glutathione S-transferase M1; NAT2, *N*-acetyltransferase 2; NQO1, NADPH-quinone oxidoreductase 1; PAH, polycyclic aromatic hydrocarbons; SM, slow metabolizer; TPMT, Thiopurine S-methyltransferase; UDPGT, UDP-glucuronosyltransferase.

conventional doses are used. In this case undesired toxicity can proceed or mask the desired pharmacological effects, and these individuals are likely to suffer adverse side effects. This is particularly true for many antipsychotic and antidepressant agents (11). In other instances, the parent drug requires biotransformation to an active form. For example, the analgesic effect of codeine largely depends on its conversion to morphine through *o*-demethylation, and so adequate analgesic effect cannot be achieved in CYP2D6 slow metabolizers (24). Therefore clinical practice in the future may benefit from dose individualization to avoid toxicity or achieve optimal therapeutic benefit.

The human CYP2D6 gene consists of nine exons and has been mapped to chromosome 22 (25). After transcription, the premature mRNA undergoes splicing and only the exonal region encodes the protein synthesis. The poor metabolizer phenotype occurs in 7 to 10 percent of the Caucasian population (11) and results from autosomal recessive inheritance of nonfunctional alleles (7). In addition to the wild-type gene (CYP2D6* 1), over 20 different alleles of CYP2D6 are associated with deficient, reduced, or increased enzyme activity (26). The most frequent inactivating mutation among Caucasians is the CYP2D6* 2 genotype, a splice–site mutation involving $G_{1934}A$ transition in the 3′-end of intron 3, leading to a mis-splicing of the premature transcript, and loss of enzyme activity (27,28). The CYP2D6* 3 mutation is a 1-bp A_{2637} deletion in exon 5 leading to a frame–shift change in the translation of CYP2D6 mRNA (29). The CYP2D6* 5 mutation is a deletion of the entire CYP2D6 gene (30). The CYP2D6* 2 mutation constitutes about 75 percent of all mutant alleles, with the CYP2D6* 5 mutation responsible for 14 percent and the CYP2D6* 3 mutation for 5 percent. Together these three polymorphisms account for approximately 95 percent of the slow metabolizer genotypes (29).

Detection of Genetic Polymorphisms

Standard procedure for evaluating metabolic capacity involves administration of a probe compound and measuring the ratio between the parent drug and its metabolite in urine and/or plasma. This procedure involves analytical techniques and often requires a week or more before a conclusion can be drawn. Metabolic phenotyping has additional disadvantages in that results can be influenced by sample stability and that conversion of the drug can be affected by external factors, including age, nutrition, general health, and other medications. Furthermore some poor metabolizers experience unpleasant side effects of the probe drugs (11). Therefore metabolic phenotyping is not widely used in clinical practice. These limitations can be circumvented for many enzymes by genotyping the patient at a centralized laboratory.

Genotyping is relatively easy to perform and generally requires only a sample of peripheral blood from patients. Therefore it is potentially less invasive than phenotyping and is not influenced by drug–drug or drug–food interactions. If a polymorphic site changes the DNA recognition sequence of a restriction enzyme, or if the genetic polymorphism involves a large deletion or insertion, the genetic polymorphism can be identified using polymerase chain reaction (PCR) coupled with restriction fragment length polymorphism (PCR–RFLP) analysis. In this approach, DNA sequences containing the polymorphic site are amplified by PCR, followed by restriction digestion and gel electrophoresis. PCR-RFLP tests have been developed to detect most of the CYP2D6 mutations (26). Other genotyping methods include allele-specific PCR (11), fluorescent dye-based high throughput genotyping (31,32), and the recent gene chip technology (33,34). Genotyping for genetic polymorphisms in drug metabolism can help explain drug toxicity or therapeutic failures, and help predict potential drug interactions. The addition of pharmacogenetic testing will

help clinicians to manage drug therapy, especially for drugs with low therapeutic indices.

Prescriptive Medicine

Interindividual variability in uptake and metabolism of many drugs make clear dose–response relationships for these compounds difficult to predict and toxic side effects a real possibility. A dose that produces the desired therapeutic response in one individual may be toxic or subtherapeutic for another person. Therefore it would be valuable to know in advance the dose of medication to prescribe based on each individual's metabolic capabilities. Pharmacogenetic testing can provide a powerful tool for optimizing therapeutic efficacy and reducing drug toxicity for those compounds known to be metabolized via pathways with functionally important genetic polymorphisms. It has been estimated that a typical marketed drug is efficacious in approximately 20 to 40 percent of patients (35). The same substance is likely to have no therapeutic benefit for 20 to 40 percent of patients, and to cause significant side effects in 20 percent of patients (35). Adverse drug effects negatively impact the health of patients and their quality of life, as well as adding substantial financial burden to society in terms of costs and acceptance of the compound to treat disease. More effectively predicting drug efficacy and toxicity offers significant benefits to society and may be described as "prescriptive medicine." Genotyping for relevant DNA markers may help physicians prescribe the most efficacious drugs for a given individual and disease, while minimizing adverse drug side effects. Patients also could be provided an opportunity to choose among therapeutic agents, both prescribed and over the counter, to obtain suitable medication and avoid undesired side effects. If genotyping and phenotyping can predict which patients are most likely to benefit from a specific treatment, only those people need be exposed, with individuals likely to experience adverse or ineffective responses not administered the drug. In addition health care costs can be reduced, especially for drugs that must be taken for extended periods, such as hypocholesteremic, antihypertensive, and antidiabetic drugs. Once validated scientifically and proved to be cost effective, pharmacogenetics will provide significant benefits to both patients and society. In the future physicians may have the opportunity to prescribe the most effective and safest drug based on the patients' genetic blueprint.

Pharmacogenetics may also help drug makers to design therapeutic agents that specifically target patient subpopulations. A recent study (36) found that a drug given to 400 Alzheimer's patients had no statistically significant effect. However, when patients were stratified according to ApoE subtype, a clinically significant response was demonstrated. Due to the heterogeneity of human populations, genetic stratification can be the difference between a drug's success and failure. Pharmacogenetics thus can assist in identifying safer and more efficacious drugs by targeting subpopulations of optimal responders and predetermining those most at risk of undesirable reactions. It also holds great potential for accelerating the drug discovery process by providing clearer answers, as well as reducing the length and cost of clinical trials.

Ecogenetics and Preventive Toxicology

Ecogenetics is a broader definition of interindividual differences in response to environmental toxic chemicals (37). Just as in the metabolism of therapeutics, some slow metabolizers might detoxify environmental or occupational agents significantly slower than normal populations. By the same token, fast metabolizers may more readily activate some foreign agents to their toxic intermediates. Therefore certain allelic forms of drug-metabolizing enzymes could render an individual either more sensitive or more resistant to the toxic effects of specific classes of foreign compounds. For example, molecular epidemiology studies have identified associations between specific genotypes of CYP1A1, CYP2E1, and GST-M1 with a variety of cancers (9,12,38). By defining these susceptibility genes, those people at increased risk can be advised to avoid certain exposures and safer standards established for workers and the public. An informed decision to avoid exposure to some occupational hazardous materials could be made by individuals whose genotypes had been associated with cancer or diseases. Clearly, there are also uncertainties and controversies in the use of these genotyping and association studies. For example, an association between CYP2E1 DraI genetic polymorphism with increased lung cancer susceptibility was suggested in a Japanese population (12) but was not observed Caucasian populations (39,40). This discrepancy may be due to a significantly low frequency of CYP2E1 Dral polymorphism in Caucasians (41). Clearly, more critical research has to be done to effectively use the research and epidemiological data emerging from this area of study.

ETHICAL, LEGAL, AND POLICY ISSUES ASSOCIATED WITH PHARMACOGENETICS RESEARCH

Most genetic research and tests share similar ethical, legal, and policy issues. The most common concerns involve risks of psychological distress, loss of insurance or employment, as well as confidentiality of genetic information. Since the objectives and goals of pharmacogenetics are different from other genetic research, it is important to discuss these issues separately. Up until now, only a few ethical issues have been briefly touched upon (42). There are potential controversial aspects such as informed consent, confidentiality of genetic information, sample and data ownership, potential discrimination against people identified as genetically "deficient," and access to human genetic materials and information. This section will review the current status in the genetic field and provide some recommendations for pharmacogenetics.

Informed Consent

As pharmacogenetic research requires population-based sampling for genetic variation and gene–environmental interaction studies, it frequently involves collection of large numbers of volunteer and patient samples. In order to obtain the testing materials, researchers need the informed consent of test subjects. Informed consent involves a process of education and counseling that facilitates voluntary, reasoned decision making. The

prospective participants or patients must understand the purpose and the nature of the study or test, understand his/her role in that study, and be cognizant of the benefits and risks that may result from the study. The document should be comprehensive, easily understandable, and serve as the means to protect both patient and care provider.

There is a growing belief that genetic information is particularly sensitive and that some people may not want genetic information about them obtained, even in therapeutic indications. These concerns must be addressed in order to protect individual's rights, pursue important research, fulfill medical ethics, satisfy regulatory requirements, and benefit society. Significant controversy also surrounds the ethical issues associated with archived blood and tissue samples used for molecular genetic testing for either basic research or clinical parameters (43). With PCR technology, even material from archived paraffin-embedded tissue or frozen blood can yield sufficient DNA for genetic analysis. These materials have tremendous value for pharmacogenetic research, particularly when a new genetic polymorphism is identified. Researchers then have the possibility of retrospectively identifing banked samples and conducting genotyping that establishes whether or not a genotype/phenotype correlation exists. This raises concerns about invasion of privacy, loss of individual autonomy, and stigmatization if test results were released. At the same time, however, a balance needs to be achieved that allows researchers access to these human samples for improving disease treatment and test validation. Another compelling reason to use archived DNA is that some historical samples are extremely valuable in that it may not be possible to reconduct the same study or collect new samples. In addition, with the continuing progress in human genetics, these specimens may have significant value in furthering medical discoveries beyond even those currently envisioned. A recent article offers the suggestion to treat the test samples, however obtained, as anonymous by keeping the patient-specific portion of molecular genetic test results confidential from even those scientists conducting the evaluation (44). A general guideline on informed consent for genetic research has been provided by the American Society of Human Genetics (45).

Recommendations. When obtaining informed consent for research and clinical testing, it is imperative to clarify the following:

- Purpose. limitation, and potential outcomes of the research
- Methods for maintaining confidentiality of results
- Anticipated use of testing samples
- Duration of storage and disposal of the materials
- Potential for research to lead to new clinical diagnostic tests
- Final publication or disclosure of study results

When it is not possible to give informed consent to an incomprehensive patient, a legally authorized guardian or appropriate decision maker may be substituted. In addition, a general notification of potential future use of the samples should be included. If the patient does not object and if samples are coded or remain anonymous, the DNA may be used for research not specifically defined in the informed consent statement (46). The collection and storage of DNA used for genotyping should follow established guidelines for DNA databanking (47).

Confidentiality of the Research and Test Results

Confidentiality of test results has been and remains a major focus of the ethical, legal, and policy issues related to genetic testing. Pharmacogenetics provides an opportunity to observe a person's molecular genetic makeup independently of the visible characteristics. The genotyping data may reveal asymptomatic conditions that would only manifest with age, or upon exposure to specific drugs or compounds. Genetic testing therefore may allow better diagnosis for disease risk at earlier stages of life.

Pharmacogenetic testing promises to provide value in making diagnostic decisions and assessing medication risk. As described earlier, recent epidemiological studies and animal models also have identified a strong association between some metabolic enzyme genetic polymorphisms and cancer. Although specific associations exist, these studies identify risks, not certainties. In reality the development of cancer is a complicated process and depends on multiple gene–environmental interactions. Obviously more critical research has to be done to clearly establish the biochemical pathways important in carcinogenesis and the role of genetics in susceptibility. On the positive side, knowing this information may help patients prepare for the risk and adjust their work or lifestyle to minimize potential hazardous occupational or environmental agent exposure that could trigger disease. One major concern in this area revolves around the possibility that insurers and employers might regard an increased genetic risk as the final concrete outcome and use this information to establish policies that discriminate among individuals. For example, employers might propose to identify workers with lower genetic risk for toxicity or malignancy from exposure to particular occupational agents and select only those individuals to perform "high-risk" jobs. Genetic information also could be used by employers to predict health care costs or an employee's productivity. These predictions might influence hiring, retention or promotion decisions.

Similarly genotypic information could be used for insurance purposes to weed out individuals at highest disease risk. This information might be used to justify higher premiums or cancellation of policies. It therefore is very important to establish guidelines that prevent abuse of genotyping information. Researchers and clinicians must carefully consider the risks and benefits and the potential impact of genetic information for participants and others. Protection of patient confidentiality may require further protection through legislation (48).

It is advised that patients or volunteers be informed of pertinent aspects related to acquisition, storage, and use of data, as well as the degree to which third parties can obtain access. Researchers should adhere to the principle of least-intrusive disclosure, in which the data are stored

using identifiers such that patient identity and sensitive personal factors connections are not possible, or where the fewest number of investigators necessary to achieve the research goal is maintained (49). A security infrastructure should be in place to ensure the confidentiality of research information, including access control, audit trails, disaster recovery, and encryption of patient-identifiable data before transmission on networks (48).

Recommendations

- Patients should be informed about storage and access to test results
- Study center should safeguard genetic information
- Disclosure of information and access to DNA samples should respect principles of privacy

CLINICAL APPLICATIONS AND ASSOCIATED ETHICAL, LEGAL, AND POLICY ISSUES

Benefits and Risks of Clinical Pharmacogenetic Testing

Recently genetic testing to predict linkage to late-onset diseases such as ApoE in Alzheimer's disease, or BRCA1 and 2 mutations in breast cancer, have resulted in substantial public debate (50). Genetic testing is complicated by uncertainties in predicting and diagnosing these diseases, and more importantly, by the social, ethical, and legal implications of disclosing genotype results.

Unlike the BRCA and ApoE genotyping, where no current therapeutic intervention is available, pharmacogenetic tests may be more acceptable to the public. The reason for this is that there are intervention strategies available, namely either withdrawal of the drug or switching to another compound belonging to a different chemical class. Based on a patient's drug metabolizing genotype, physicians also may be able to adjust the standard doses, thus achieving therapeutic value and avoiding toxicity. In addition to satisfying patients' physical well-being, substantial financial benefits may be achieved by utilizing the data obtained by pharmacogenetic testing. Incentives from managed care organizations and insurers to control health care costs may strongly support these tests. If a pharmacogenetic test accurately predicts that a commonly prescribed drug will be ineffective, or has serious adverse effects for a relative large percentage of patients, these individuals could be given preselected medications to avoid the lack of efficacy or the severe toxicity.

Predictive Value and Limitations of the Tests

Unlike molecular biology tests for pathogens, definitive or absolute results cannot be easily achieved in current pharmacogenetic testing. For example, CYP2D6 has more than 20 polymorphisms leading to altered enzyme activity. Until testing is performed for all polymorphisms, many of which are extremely rare, it is not possible to have an absolutely accurate prediction about every individual's phenotype. It also must be kept in mind that other functional polymorphisms may exist that have not yet been identified. Since pharmacogenetics is a relatively new area, the prediction of results often must be qualified. There are only a handful of pharmacogenetic markers currently available commercially for genotyping, such as CYP2D6, CYP2C19 and ApoE (8). When used properly, they can be valuable for decisions regarding dosing, counseling and prognosis. Some general principles can be expected for clinical testing in pharmacogenetic testing:

- Testing is useful for detecting functionally important polymorphisms of drug metabolizing enzymes
- Techniques used for genotyping are relative simple and noninvasive
- Testing can be expected to benefit the patient and society
- Pretreatment genotyping might be desirable for drugs with low therapeutic indices and high toxicities
- Positive testing results will be more informative than negative ones

Standards in Clinical Testing

Due to the complexity of interpreting genotyping results and the requirement of expensive and complex laboratory equipment, pharmacogenetics is likely to be conducted primarily through service laboratories. Currently the clinical laboratory is required to establish analytic validity and Clinical Laboratory Improvement Amendments (CLIA) certification (51). Yet the rapid progress in human genome research and development in genetic testing technologies have outpaced the quality assurance and quality control for molecular diagnosis. A major concern is that a complete set of specific standards to assure proficiency for genetic testing in the clinical laboratory has not yet been developed, even though genotyping procedures are classified as being of high complexity. A recent report from the NIH–DOE Task Force on Genetic Testing recommended that clinical validity, such as test sensitivity and the predictive value of a positive test result, as well as institutional review board (IRB) approval of the protocol, should be part of the prerequirement of CLIA certification (52). In addition the Task Force suggested an external review before the genetic test can be commercially offered even after CLIA certification (53).

In the future pharmacogenetic testing is likely to fall within the competency testing currently imposed on clinical pathology laboratories as described under CLIA and Commission on Office Laboratory Accreditation (COLA) regulations. In lieu of the current situation, clinical pharmacogenetic tests should be done by laboratories that meet accepted standards of general laboratory quality assurance, including patient test management, personnel requirements, specimen handling, quality control, test validation, and confidentiality. In addition to CLIA requirements, an inspection of the laboratory's competence in performing the genetic test should be conducted by certification agencies. Interlaboratory comparisons of reference samples might be necessary to assure the quality control mechanism, a system already in place for more routine clinical biochemistry and hematology procedures.

Indications and Demands in Pharmacogenetics Testing

Although pharmacogenetic testing could have predictive value in clinical situations, it is not routinely invoked unless patients have previously had severe toxicity and the primary care providers have a knowledge of pharmacogenetics. Predictive tests, such as the association with cancer risk or late-onset genetic disorders, should not be routinely performed until additional research supports a beneficial outcome and effective treatment.

Several important questions should be asked before initiating pharmacogenetic testing. What are the benefits of conducting these tests? What is the most cost-effective way to do this? Are these tests accurate enough to predict the clinical outcome? At present, it is questionable which variant alleles should be routinely genotyped to allow a sufficiently reliable, but still practical, estimation of a person's metabolic capacity. With rising health care costs and the scarcity of resources, it is not acceptable to adopt expensive testing that does not add any value in patient care or new technologies of which the benefits are still unclear (54).

A genotyping test will only be of value to consumers when it can provide predictive value and a reasonably precise answer regarding individual risk. Currently very few pharmacogenetic tests are available that meet these standards. Although some genotyping tests are commercially available, they primarily provide services for research studies and have not been integrated into routine clinical practice. Another limitation is that pharmacogenetics as a discipline has not been integrated into the medical training curriculum and few physicians are familiar with the underlying concepts, benefits, and applications. Giving the progress in pharmacogenetics, it is easily foreseeable that it will soon become another subspecialty in medicine and pharmacy. One complexity is that there can be many genotypes that produce the same phenotype. Attempting to identify all polymorphisms associated with a defective phenotype will significantly increase testing complexity and expense. The practical approach at this time is to screen for the most common genotypes leading to altered enzyme activities. With the rapid development of modern technology in genetic diagnosis, it will be possible to detect multiple polymorphisms in a single test. For example, there is a report indicating a human P450 DNA chip could identify all the currently known polymorphisms of human CYP2D6 and CYP2C19, but its clinical usefulness has yet to be identified (55). However, these chips only detect those variants specifically programmed onto them and modifications to include new polymorphisms are expensive and time-consuming. The progress in fluorescent-based high throughput genotyping and DNA chip technology will definitely add significant value to pharmacogenetic diagnostics. Genotyping tests for the major drug metabolizing enzyme polymorphisms will soon be as easy as a routine blood test.

Cost Effectiveness of Pharmacogenetic Testing

Pharmacogenetics has the potential to be cost-effective in the managed care community. A simple diagnostic genetic test will enable the drug to be selectively prescribed to those patients for whom a drug would be safe and effective. This would provide cost savings to the health care providers by increasing drug efficacy, reduce follow-up and doctor visits, eliminate costly ineffective drugs, and reduce possible drug toxicity at "normal" doses in slow metabolizers. For example, a patient who metabolizes drugs more rapidly than other patients will not respond to the drug treatment under standard dosing. Identifying these rapid metabolizers of the drug could help these patients to either increase the dose or to use other appropriate drugs without undergoing three or four months' trial and error. This will be cost saving for many expensive prescription drugs for treatment of chronic disease such as dislipidemia, diabetes, and Alzheimer's disease.

Avoiding adverse drug effects alone may bring significant savings to society. It is estimated that approximately 3 to 5 percent of all hospitalizations result from adverse drug reactions, and as many as 30 percent of patients hospitalized for other reasons may have an adverse drug effect during hospitalization (56). The cost of treating drug reactions in the United States alone is estimated at approximately $3 billion annually (57).

Current genotyping generally costs up to two to three hundred dollars per test depending on specific assays. With the rapid development of automated high-throughput genotyping technologies, pharmacogenetic testing will likely become a relatively low-cost/high-volume service, just like a routine blood test. It is reasonable to develop cost-efficient pharmacogenetic tests by using multiplex PCR or non-PCR based genotyping technologies. Therefore pharmacogenetics holds great promise for prescriptive medicine, and it is expected that monitoring of pharmacogenetic markers will be routinely used clinically, especially for patients receiving drugs with low therapeutic indexes.

NEW DIRECTIONS OF PHARMACOGENETICS

Genomic Approach in Pharmacogenetic Studies

Studies of families with disease are informative for identifying highly penetrant gene variants. However, other approaches are needed to study less penetrant alleles, which may not be easily identified in family members. This is particularly true for environmental susceptibility genes and drug response genes. Such alleles may identify those people at risk, but who otherwise would only be observable in an exposed population. While some drug toxicities have been identified, the genetic polymorphisms associated with the effects of most drugs have not been characterized. Targeting these genes will be another goal of pharmacogenetics. The new concept of pharmacogenomics will utilize high-density markers to conduct genome scans to better predict drug efficacy and toxicity. In contrast to the candidate gene method, the strength of this system is the ability to scan the entire genome (58). It is becoming increasingly popular to use single nucleotide polymorphism (SNP) for association and linkage analysis, since they are the most

frequent DNA sequence variations found in the human genome. Researchers will be able to conduct whole genome scans for identification of critical drug–response genes in nonfamilial studies. Creation of high-density SNP maps is feasible using high-throughput DNA sequencing (59) and chip hybridization (60). Cataloging common variants in human genes is moving very rapidly (61). It will be necessary for the scientists to prove the technology can work in the real world and transfer the research to clinical practice. Again, with the progress in this area, and as more genes have been identified, additional and increasingly complicated social, ethical, and policy issues will be encountered. Because of potential social consequences, researchers have been encouraged to pursue anonymous testing whenever possible and to ensure that the results of genetic testing are separated from an individual's record.

Education for Clinical Practitioners

The advances in pharmacogenetics will have a significant impact on the practice of diagnostic and preventive medicine. Currently there are only a limited number of medical practitioners familiar with and conversant in this area. It is important for clinicians to understand the concepts and applications of pharmacogenetics, since they will be explaining genetic tests and implications to their patients, determining when testing is appropriate, selecting specific tests, and interpreting the results. It is therefore necessary to develop training programs, that efficiently transfer a working knowledge of this field. Until such programs are available, physicians and pharmacists are advised to contact specialists or consult with colleagues having expertise in pharmacogenetic testing. As pharmacogenetic testing becomes more commonly offered by clinical pathology and reference laboratories, these facilities also will be called upon to provide expertise and appropriate indications.

Patient Stratification in Clinical Trials

For drugs prescribed on a limited basis due to a high incidence of adverse effects, pharmacogenetics may provide means to identify those most likely to benefit therapeutically without serious side effects. By targeting a specific subpopulation, pharmacogenetics offers the possibility of wider and safer drug use by creating a clear prescription path. The use of patient stratification also offers the potential to rescue an existing drug with great promise but undesirable problems, or to provide the data needed to withdraw a dangerous compound earlier. Pharmacogenetics data similarly could be used to logically design clinical trials and to increase the amount of information obtained from these studies. The greatest, but yet unproved, promise of pharmacogenetics is to alter trial-and-error application of a new medication into prescriptive medicine. Differentiating patient groups to improve the risk–benefit ratio of a new drug is already common practice. Therefore the concept of this predictive medicine approach looks attractive and can build on existing principles. But clearly, any tests associated with drug toxicity must be rigorously reviewed before a conclusion is made.

With the emerging global economy, pharmaceutical companies need to market new drugs in multiple countries. Due to the differential distribution of some drug metabolizing enzyme genetic polymorphisms among populations, a well-developed and extensively tested drug might not be suitable for patients with different ethnic backgrounds. In utilizing data obtained from genotyping both ethnic groups, prediction of drug efficacy and toxicity in a different population group become possible, as well as potentially reducing the need to conduct pivotal clinical trials in multiple countries. The most important step for pharmacogenomics now is proof of principle. It is critical to clearly show that pharmacogenetic concepts will yield improved and more predictive results in clinical trials. This process is actively underway.

CONCLUSIONS

The introduction of pharmacogenetic testing into clinical medicine has great promise for affecting the future of prescriptive and preventive medicine. Physicians may be able to prescribe drugs based on genotype, as well as allowing pharmacists to check for potential drug interactions and side effects. It will be important to educate medical practitioners and patients on both the concepts and clinical practice of pharmacogenetic testing. The up-front discussion of social, legal, and policy issues should not be used to block the collection of genetic data, but should serve as a safeguard to benefit and protect patient rights. With the advances from the Human Genome Project and functional genomics, massive increases are taking place in the information available on individual genes and functionally important polymorphisms. These differences hold the potential to improve effectiveness and limit toxicities of the available drugs while providing an understanding of gene/environmental interactions. Consideration of the ethical, social, legal, and policy aspects of accurate genetic prediction, and the design of more specific and safer drugs to meet individual's needs, will be important considerations as we enter the new millennium.

PROFESSIONAL POWER AND THE CULTURAL MEANINGS OF BIOTECHNOLOGY

OUTLINE

INTRODUCTION

Contemporary bioethics arose in the 1960s in the wake of innovations in dialysis, transplants, artificial organs, and assisted reproduction. These biotechnologies sparked debates about the allocation of scarce resources and the quality and limits of life. In response, ethicists developed a set of abstract normative principles — autonomy, beneficence, and distributive justice — which structure professional debates to this day. These core principles of American bioethics take a generic concept of the person and make it the basis for a universal morality. This is, of course, the autonomous individual of Western liberalism: the sovereign individual who acts freely according to a self-chosen plan. However, the very technologies

that sparked early bioethics unsettle this tacit understanding of the person. They have created new ways of exerting one's will and gauging one's present identity and future fate. For example, predictive genetic testing alters the way people calculate their life prospects — the likely mixture of happiness and suffering they will encounter — and it can erase or intensify certain aspects of their identity. New strategies to assess people's subjective experience are demanded by transplantation and mechanical ventilation. Such technologies set in motion profound transformations in our cultural model of personhood and in the ways we experience and enact moral agency. These transformations, as much as the conflict between abstract principles, motivate our deepest ethical concerns.

This article takes up a vexing tendency in our current use of biotechnologies: the replacement of moral discourse by technical expertise. This tendency is magnified when health care professionals must make educated guesses about the subjectivity of technologically altered individuals. If we regard biotechnology as a simple collection of devices — a morally neutral means to the ultimate good of prolonging life — certain procedures become a standard, unquestionable component of care (1). This, in turn, justifies technical discourse as the sole guide for treatment decisions. It provides certainty for medical workers, but it also rules out other ways to understand the experience of, for example, chronically ventilated children and our ethical obligations toward them. This article examines the conflict of interpretation over the subjective experience of the mechanically ventilated child. Too often, the authority to read it one way or the other remains solely in the hands of medical professionals, illustrating how rational, technical expertise can foreclose genuine moral debate.

PROLONGED VENTILATION FOR CHILDREN WITH NEUROMUSCULAR DISEASE

An infant or young child with a neuromuscular disorder, such as nemaline rod myopathy or spinal muscular atrophy, usually presents with generalized poor muscle tone, which then progresses to respiratory failure and the need for assisted ventilation. Often a muscle biopsy is necessary to make a diagnosis, and the first biopsy may be inconclusive as it takes time for the characteristic pathological findings to develop. Nemaline rod myopathy, selected as an illustration of the issues raised in this entry, is a rare and slowly progressive neuromuscular disease that renders a person immobile (2,3). Unable to move and unable to breath, such an infant may undergo a tracheostomy procedure so that the airway is secure and the infant can be ventilated more easily. A tracheostomy, which is a plastic tube inserted into the windpipe through a surgical incision in the front of the neck, is done when the plan is to provide long-term ventilation, perhaps including sending the patient home on a ventilator. In addition a so-called gastrostomy tube may be placed into the infant's stomach through the abdominal wall so that the infant can be fed without placing a temporary feeding tube through the nose. Once these procedures have been performed, the infant is often transferred from the intensive care unit to a "step-down" unit designed for long-term care and is placed on a simpler breathing machine whose primary purpose is for use in home ventilation.

We do not know what causes nemaline rod myopathy, nor do we have any treatment for it other than putting someone on a ventilator. It only affects the skeletal muscle, so the other muscles of the body such as the heart and gut work fine. In its most severe form, the child cannot move, cannot swallow, cannot breathe, and may not be able to move his eyes or close his eyelids. Eyes open and barely moving, an affected infant or child will stare at you without expression, unable to move the muscles of the face to show pain or pleasure, unable to smile or frown, unable to laugh or cry, unable to communicate at all — the face a frozen, expressionless mask. The disease, however, does not affect the brain. An affected infant or child is alert and aware of everything going on around him.

At times, conflict may arise over the continued use of mechanical ventilation, with a parent insisting on the right to remove the ventilator and let the child die, and the professional staff (both nurses and physicians) resisting or disputing this claim. Usually this conflict is addressed in such terms as the child's quality of life, the "value" of living with a severe disability, the child's "best interest," the authority of the physician/state in determining "medical neglect," the parent's authority to make decisions concerning the child's medical care, and so forth. All of these approaches assume that the technology itself is morally neutral: It sets the stage for ethical conflict but does not influence the outcome. In this article we question that assumption. We suggest that once biotechnology is introduced into patient care, it constrains our subsequent moral choices, and this belies the claim that the technology itself is morally neutral. We examine, in particular, tracheostomy and mechanical ventilation, techniques that undercut parental (or nonprofessional) control over the medical care of children suffering from a neuromuscular disease such as nemaline rod myopathy. Because medical professionals control both how to use these technologies and how to interpret their effects upon individual subjectivity, ethical conflicts become prematurely translated into matters of technical expertise.

To examine these issues in the case of a ventilator dependent child, we need to understand how the technology affects the child, how the ventilator defines and redefines the boundary of body, and how the ventilator produces a subject who is both body and machine. Rather than a neutral technology designed to achieve goals that are selected for non-technical reasons, the ventilator seems to impose its own agenda and values. However, we should not reify this technology in a way that obscures and thus privileges the agency of the medical professionals who control it — as in the Wizard of Oz when we are told "don't pay attention to that man behind the curtain." Moreover, we need to pay attention to the organizational and cultural context within which professionals operate. Only then can we understand how professional power infiltrates both the use of technology and the interpretation of its effects.

MEANING OF TEARS

An infant with nemaline rod myopathy often has tears in his eyes, lending support to the belief (usually by a parent or family member) that this constant tearing indicates emotional and physical distress. The professional staff, however, may interpret these tears as a simple result of an inability to close the eyelids, rather than a reminder of an infant's suffering. Such an infant becomes the locus of a contested interpretation. The parents view the infant as too fragile and unable to tolerate activities such as being propped up in a wheelchair or taken out of the hospital on field trips. The apparent suffering of the infant often motivates their desire to stop the ventilator at some point in the future. The staff regards the infant as able to take pleasure in simple things and to sit contentedly in a chair for hours. On occasion, the staff may blame a parent for the very episodes that the parent interprets as fragility, arguing that the infant would cry when his parent arrived and "suffocated" him during a brief visit. This conjures up the image of an overprotective parent who fails to appreciate the strength and ability of her or his child; however, the use of the metaphor of suffocation takes on a more literal and provocative meaning given the staff's suspicion of the parent's (implicit or explicit) desire to stop the ventilator.

Fundamentally the infant's parent continues to see the ventilator as something other than the infant: as a threat, as an invasion of his body, as something foreign. Removing it in order not to prolong the infant's suffering simply returns the infant to a more natural state. In the eyes of the staff, the threat to the infant is not the ventilator but the parent. The staff often regards such an infant not as a body on a machine, but as both body and machine — that is, a machine-human/ human-machine cyborg (cybernetic organism) whose body and machine components are mutually interdependent (4). Therefore, to ask the staff to participate in turning off the ventilator is to ask them to amputate part of the infant's body. Is there a fact of the matter that could settle this dispute about removing the ventilator? Is there a third point of view, acceptable to both parties, from which the relationship between tears and suffering could be "objectively" determined? Glossing the difference between pain and suffering, the absence of other signs of pain such as sweating and a rapid heart rate may support the staff's argument. This is an argument that a parent can only lose; the best one could hope for is for everyone to agree to disagree.

There often is no apparent disagreement over the moral principle that mechanical ventilation can be stopped if the burden of such treatment outweighs the potential benefit (5). What is in dispute is the description of the child as either suffering or simply unable to close his eyelids. The staff is able to substitute a physiologic argument about the presence of pain for the existential question of whether the child is suffering — in effect, shifting a moral argument about the worth of living life on a ventilator to a technical dispute about the interpretation of a physical sign. In addition the staff has the political power to threaten a parent with a charge of failing to provide necessary medical treatment, that is, "medical neglect," thus throwing the matter into court. Consequently the moral and political questions about what to do are transformed into a rational technical discourse that in the minds of the staff is unambiguous. As such, the dependence of knowledge on subject position or "point of view" is implicitly denied; the power to determine objectivity is invisibly exercised. Rather than moral and political discourse about the conflicting visions of the infant's experience serving as the "paradigm of rational discourse," the professional technical discourse determines the political stakes and reduces moral discourse to the vanishing point (6, p. 194).

KNOWLEDGE AND COMMUNICATION

An appeal by the parent to the shared "sense experience" of the child's tears usually will not persuade the staff that the child is suffering. In addition the staff will probably fail to convince a parent that the child's tears simply mean that he cannot close his eyelids. The staff may additionally dismiss the parent's claim to know that the child is suffering as mere subjective opinion. The staff's insistence that the child is not suffering clearly reinforces their professional interest in continuing treatment.

In answer to the question — "What protects knowledge from being [either] the arbitrary expression of subjective desires [on the part of a parent] or the tool of social and personal interests [on the part of the medical and nursing staff]?" — Helen Longino, a philosopher of science at the University of Minnesota, offers an approach she refers to as "contextual empiricism." Longino, as do other philosophers in the pragmatic tradition, grounds "objectivity" or the truth of a statement concerning a sense experience in an "inter-subjective" or "social" process that should ensure "the inclusion of all socially relevant perspectives in the community engaged in the critical construction of knowledge" (7, pp. 200, 202–203). A necessary part of this communicative process is a critical examination of the implicit assumptions that establish the relevance and interpretation of observational or empirical data. The natural world cannot impose one single interpretation, that is, the empirical observation of the presence of tears does not establish the truth of one or the other interpretation. However, differences of power in this social or communicative process may limit the plurality of interpretations to the one that is consistent with the dominant discourse.

This is the outcome, for example, when a particular powerful group or individual constrains the freedom of expression and diversity of legitimate knowledge, or restricts the community of discourse in such a way as to predetermine which interpretation is accepted. This process involved (fragment) discounting the parent's interpretation of a physical sign such as an infant's tears. Parents may also be isolated from outside family and community supports and effectively alone with the medical staff during conversations in the hospital about the care of their child. In this setting medical professionals fail to establish a meaningful community of inquiry concerning the question of a child's suffering.

In discussing contemporary policy debates about technology in general, Langdon Winner observes that this lack of a coherent community of discourse "contributes to two distinctive features ... (*1*) futile rituals of expert advice and (*2*) interminable disagreements about which choices are morally justified" (8, p. 75). The moral uncertainty involved in the application of ventilator technology to the indefinite support of patients cannot be resolved by an appeal to the technical advice and expertise of the physician. Such a "futile" appeal to expert advice will not achieve a consensus. Moreover the lack of an appropriate community of discourse and the resulting disagreement over what choices are morally justified privileges the physician's technical expertise and thus interpretation of the patient's experience. While this does not avoid a conflict of interpretations, it guarantees that the conflict gets resolved in ways that favor the power and interests of the physician.

KNOWLEDGE AND POWER

In response to this professional prerogative which constrains the available choices, how do we empower a parent to make decisions concerning her child's medical care? The notion of personal autonomy or self-rule has resulted in a significant shift of power from the physician to the patient over the past two decades. However, once we abandoned the concept of the child as property, the notion of parental autonomy as a justification for the right of a parent to direct a child's medical care became problematic. Each one of us may have an absolute right to determine our own medical care. A parent has, at most, a prima facie right that is limited by the child's right to life and freedom from serious bodily injury or disability (9). Within this constraint we expect that a parent will make decisions that benefit the child or, in other words, are in the child's "best interest." Thus the parent's vision of the good is imposed on or becomes the child's vision — an imposition we accept given the diversity and, at times, incompatibility of competing visions of the good within our society. This creates a disturbing paradox. On the one hand, we expect a parent to express a decision concerning his or her child not as "what is good for the parent" but rather as "what is good for the child." On the other hand, the only possible way to give "voice to the voiceless" is by articulating adult values and projecting them upon the child (10). An infant with nemaline rod myopathy cannot speak; so when we speak for such an infant, we ask: "If I (the adult) were in this condition, what I would want?"

If we seek to escape this paradox and avoid this imposition of adult values by supporting the child until he is capable of self-expression, we inadvertently reinforce the physician's tendency for the relentless application of life-sustaining technology. Consequently the concept of a child's "best interest" appears to be the arena for an unavoidable expression of adult power on the part of either the physician or the parent. The stakes are high, for if the parent understands the child's "best interest" in such a way as to refuse what the physician otherwise believes to be necessary medical care, the parent may find him- or herself in court facing a charge of medical neglect.

The past two decades have seen a lively debate in the bioethics literature and the courts concerning the withholding and withdrawal of life-sustaining technology (11). Some have argued that removing a person from a ventilator is to choose death based on the judgment that the anticipated quality of life is not worth living. Others, concerned about the potential abuse of quality-of-life judgments, have argued that such decisions are better understood as the choice of how to live while dying (12) or as simply the decision to remove technology that is no longer medically indicated (11,13). The first argument, that of how to live while dying, makes the decision to remove a ventilator dependent on a prior determination that the patient is dying — a determination that the technology itself makes more difficult. A child with nemaline rod myopathy who is on a ventilator may not die for years in the absence of an intervening complication. Thus, once you put him on the ventilator, you cannot remove it unless he is dying, and he is not dying unless you remove the ventilator. The second argument, that technology can be removed when it is no longer medically indicated, either restricts the removal of technology to those situations where more narrow technical goals cannot be achieved or obscures the physician's own determination of an acceptable quality of life behind the veil of professional technical competence. A ventilator is medically indicated when a patient has respiratory failure; it is not indicated when either the patient recovers or the ventilator fails to correct the respiratory failure. Thus, in most cases, the ventilator for an infant with nemaline rod myopathy is medically indicated. If a physician argues that the ventilator is not medically indicated, since correcting the patient's respiratory failure does not contribute to the overall good of the patient, we necessarily must engage the question of what is or is not in the patient's "best interest" — a discussion that cannot avoid questions of the patient's quality of life. The problem then of trying to avoid an explicit discussion of a child's anticipated quality of life is that the physician's power and authority is inadvertently reinforced.

Physicians impose their power by establishing what counts as legitimate and credible knowledge, rather than by forcing a choice for one of either two credible options. In asking whether a child on a ventilator is suffering, a parent and the health care team may disagree over the description of the child's life, not over the moral evaluation of an agreed upon description (14). It is simply not credible to the medical staff that the child is suffering. In discussing the problem of technology as ideology, Robert Pippin asks whether we have "been so influenced by technical instruments ... that our basic sense of the natural world has changed ... so fundamentally that ... possibilities for social existence are seen only ... in terms of such technical imperatives." The physician's reliance on technology "reaches a point where what ought to be understood as contingent, an option among others, open to political discussion, is instead falsely understood as necessary; what serves particular interests is seen, without reflection, as of universal interest; what is a contingent, historical experience is regarded as natural" (15, p. 46). Physicians appear to have lost any sense of the natural or the contingent as a moral category. Rather the natural

serves to mark that domain that resists the physician's intervention, as in "let nature take its course." The natural becomes that which cannot be technically overcome, rather than that which should not be overcome. The natural is subservient to the technical, which in turn resists the explicit introduction of moral and political questions.

DIFFERENCE BETWEEN STARTING AND STOPPING

The belief that technology is a neutral means to whatever ends are selected on moral, political, or more narrow physiologic grounds is a fundamental conviction and ideology of medical practice. For example, the decision to perform a tracheostomy may not be intended as a decision for long-term home ventilation but may be seen as consistent with a desire to defer any decision to limit or withdraw support given any remaining uncertainty about a child's diagnosis and prognosis. A parent may be told that a decision to perform a tracheostomy does not preclude a decision at some point in the future to remove a child from the ventilator—"what is done can be undone." Such a statement is consistent with the widely endorsed bioethical teaching that there is no significant moral or legal difference between withholding and withdrawing treatment (11).

There are a number of important assumptions behind the use of this bioethical maxim. First, it assumes a symmetry in the application and removal of medical technology consistent with the prejudice that technological means are value-neutral. It also assumes a symmetry between an endotracheal tube and a tracheostomy by reducing each to its essential function of establishing an airway for the purpose of mechanical ventilation. However, as an endotracheal tube is inserted either through the mouth or nose, the tape required to hold it in place covers a major portion of the face. A tracheostomy surgically inserted through the front of the neck results in the entire face being visible and thus capable of expression. Second, the maxim appears to ignore any relevant differences that may occur between the moments of application and removal of the technology, apart from any changes in the medical indications. Third, and related to this historically naive stance, is the view that the organizational context in which these decisions are being made is apparently unimportant. After a tracheostomy a child may be transferred out of the intensive care unit and to the ward that houses patients in the home ventilation program. One wonders whether the use of this bioethical maxim that there exists no significant moral or legal difference between withholding and withdrawing treatment is based on a reasoned ethical stance, or used as a rhetorical device to postpone the discussion of more difficult ethical issues to a later date. The latter interpretation is confirmed, for example, when a receiving physician in conflict with a parent over the removal of a ventilator is unable to find any other physician willing to assume the child's ongoing medical care (and thus agree to withdraw support), including any of the physicians who have previously cared for the child prior to the tracheostomy. An appreciation of the value-laden nature of a tracheostomy, along with the importance of time and context, counsel against a premature surgical procedure and then transfer to a home ventilation program.

IS TECHNOLOGY VALUE-NEUTRAL?

The bias that our medical technology is simply a "collection of devices" emphasizes the functional aspects of technology and obscures its social context. As a result of this dichotomy between function and context, our technology appears value-neutral, while only the application of that technology becomes morally problematic. Andrew Feenberg, in an article reflecting on the relationship between technology and power, points out that this "dichotomy of goal [function] and meaning [context] is a [contingent] product of functionalist professional culture" rather than a necessary component of technology (16, p. 9). Echoing criticisms of the common view of science as value-free, Feenberg asserts that this ideology of technology as value-neutral reinforces the dominant forms of power that compose the cultural horizon and social meaning of technology. Feenberg refers to this as the "bias of technology" by which "apparently neutral, functional rationality is enlisted in support of a hegemony," that is, the professional dominance of those who control the technology. The professional claims to exclusive control of technology are strengthened insofar as its associated values and presuppositions drop out of sight (16, p. 12).

This professional control is also reinforced by the perception that technology should always be used when it can be used: the so-called technological imperative. Barbara Koenig suggests that the technological imperative acquires a certain moral force as the technology becomes habitual or routine (1). Her field research focused on therapeutic plasma exchange, a procedure that involves the removal and then replacement of blood plasma. Koenig identified three steps in the process by which plasma exchange became a routine therapy for certain conditions. The first step was a transformation in roles and responsibilities. The physician–nurse relationship shifted from egalitarian to hierarchical while, at the same time, the physicians moved from being closely involved to delegating many of the routine tasks to nurses (1). Similarly the physicians involved in a home ventilation program maintain close control while shifting many of the routine tasks from in-hospital nurses and respiratory therapists to parents and visiting home nurses. The second step was the use of treatment rituals that appeared to reduce uncertainty, anxiety, and disorder and thus established the meaning of the technology as standard therapy for both patients and staff (1). When a patient is placed on a home ventilator after a tracheostomy, there is an orderly and nearly invariable process of parental training, arranging for nursing services, equipment purchase, and so forth, that must take place prior to discharge from the hospital. Any deviation from this process generally results in uncertainty, inefficiency, omissions, and the like. The third step that Koenig identified was the generation of research data. Noting the enthusiasm with which the physicians engaged in plasma exchange collected clinical data as part of their ongoing research, she speculated that the machine's capability

of producing research data supported the physician's tendency to use the technology (1). Although this may be true with therapeutic plasma exchange, it does not appear that the development of home ventilation programs was driven by a research imperative. The physician's use of home ventilator technology is more likely driven by such factors as the need to find alternative placements for children who otherwise would survive intensive care but remain dependent on ventilator technology. Also the immediate efficacy of the ventilator when compared to plasma exchange is obvious, for otherwise the child would die. Despite these differences Koenig's conclusion remains essentially correct. The technological imperative is transformed into a moral imperative through the development of a "sense of social certainty experienced by health professionals" (1, pp. 485–486). The technology simply begins to feel routine, and hence both appropriate and necessary.

The decision to perform a tracheostomy and then to transfer a child to a unit where the use of chronic home ventilation is considered routine is governed by a similar moral imperative. The unit is organized so that home ventilator technology is accepted as standard therapy. Within this social context, it becomes difficult, if not impossible, to question whether this technical standard of care ought to be used for any particular child. The moral question of what is in a particular child's "best interest" thus receives an axiomatic answer applicable to all children: "Given these circumstances, we should provide the standard technology." The moral meaning of our medical technology is thus created and sustained by the professional culture of the hospital. Since the statutory definition of medical neglect in Wisconsin, for example, is simply failure to provide necessary medical care, the technological and moral imperative experienced by medical and nursing professionals clearly has "the potential to wrest control of decisions about the use of technology" from parents and patients (1, p. 489).

Andrew Feenberg proposes that one of the assumptions behind our modern image of technology is that social institutions must adapt to the technological imperative. Noting that "the economic significance of technical change often pales besides its wider human implications in framing a way of life," Feenberg encourages us to study the "social role of the technical object and the lifestyles it makes possible" through defining "major portions of the social environment, such as ... medical activities and expectations" (16, p. 9, 16). This assumption that we must adapt to technology is readily apparent over the past two decades with the development of home care programs for so-called technology-dependent children (17). The family is explicitly expected to change in response to the demands of caring for a child who is to be discharged from the hospital on a home ventilator. The only other available option is foster care, which is problematic for two reasons. While the child is in foster care, a parent may lose control over any decisions to either withhold additional medical treatment or withdraw existing medical treatment. In addition there is often an unspoken assumption that to choose foster care reflects poorly on the ability of a parent to provide for his or her child. Although many parents choose to take their ventilator-dependent child home out of a sincere concern for their continued life and well-being, the normative pressures against choosing otherwise are enormous once the child is within the context of the home ventilation program. This assumption then that social institutions such as the family must adapt to the technological imperative is another manifestation of the extension of professional power implicit in the ideology of value-free technology.

The apparent inevitability of the technological imperative is rejected by both Koenig and Feenberg. Consistent with Koenig's thesis, Feenberg asserts that "technology is just another dependent social variable" and the "scene of social struggle" (16, p. 8). Contrary to the claim that technology itself requires professional control, Feenberg argues that technology has been used to block the extension of public or democratic control to "technically mediated domains of social life" (16, p. 20). Thus the professional medical culture seeks to reinforce the image of technology as both value-neutral and complex in order to maintain control despite the "routinization" process of placing that same technology into the home.

CONTESTING POWER OVER TECHNOLOGY

To insist that technology is "socially constructed" may give the impression that people ultimately hold complete power over its meanings and uses. The typical circumstance of one group having more control and another group having less control over technology results, in this view, solely from social and political considerations independent of the constraints of particular devices. To deny that technology is "socially constructed" may imply the opposite extreme: that we have no power over technology and that our moral and cultural response is determined by its concrete and independent reality. We argue against both extremes. To assume that technology is neutral — the core of the anticonstructionist position — reinforces the professional dominance of physicians. By failing to recognize the extent to which technical knowledge is constructed by and for the interests of a particular community, we are likely to ratify this group's power and authority. At the same time the strong constructionist position ignores the material effects of this technology and the way it constrains moral deliberation. By use of this technology, a child's breathing becomes, ineradicably and by definition, assisted breathing. As a result the object of clinical decision making has become altered. It is no longer the child as such but the hybrid object of the ventilator/child. Once this massive technological intervention has taken place, it is not clear who gives life to whom: the ventilator to the child, or the child to the ventilator? In the face of this ambiguity, medical workers substitute technical rationales for action (algorithms and expertise about ventilator use) for the search for mutual understanding about the child's experience and, possibly, suffering. In the end this process makes humans subservient to things (18). However, this result is produced by both the social power of the profession and the particular way this technology transforms the very objects of clinical decision-making.

Cleaving to either the strong constructionist or the strong anticonstructionist position misses this complex result.

Controlling the technical mediation of social activities such as medical care is a major source of public power within our society. The ability to manage or expand this technical mediation results in the concentration of power in an elite group of experts, the narrowing of acceptable options for public discussion, and an increase in the extent of administrative or professional control over aspects of daily life (15). Changes in the way medical technology is delivered or applied to a particular problem will require a shift in this expert control of technology. As Feenberg writes: "If authoritarian social hierarchy is truly a contingent dimension of technical progress, . . . and not a technical necessity, then there must be an alternative way of rationalizing society that democratizes rather then centralizes control" (16, p. 5). Is the link between the physician's social role and the control of medical technology necessary or contingent? For example, one approach to the issue of physician-assisted suicide is to allow for assisted suicide while preserving the traditional social role of the physician by making available to the general public the technical tools that to-date remain under the physician's prescriptive authority.

If we move the control of medical technology into the public domain, we will need to create an appropriate community of discourse to monitor development and application. Such a task may be difficult given the diversity of our current communities. Although the reform of technology is a better option than simply resistance, it is not clear that those (e.g., nurses and physicians) who have been socialized in the modern medical ethos could resist attempting to impose new forms of professional control (15). The creation of a community for the reform of medical technology should include those who anticipate needing or who may resist medical technology and thus will require abandoning the notion of professional expertise. In addition such a community of discourse must begin by questioning the assumption that technology is a value-free instrument — an assumption that serves to reinforce professional control and hinder rational debate. Or should we simply recognize the legitimate existence of disparate communities and thus reframe the question of the appropriate application of medical technology as a choice of which community to belong to?

BOUNDARY OF BODY

Let us now return to the question of whether the medical and nursing staff simply see a mechanically ventilated child with a tracheostomy differently than he is seen by his parent(s). As the disease progresses, a child with nemaline rod myopathy cannot move, cannot breath, cannot express emotion, indeed cannot make any facial expressions; communication at best may occur through the movement of an eye in response to a question. Consequently it may be difficult if not impossible to get any indication of what a physical sign such as "tearing" meant to the child. As the passive object of our application of ventilator technology, the child is reduced to either a resource for our instrumentalist projects or a mask for our dominant interest in maintaining control (6). Modern medical technology, as we have seen, clearly includes the feature of the technical control of some human beings by others. Donna Haraway attributes this modern tendency towards technical domination to the dualism between objective nature and subjective culture so that the projects or interests that shape our determination of natural objects are hidden from view. As an alternative, she offers us a view of "objectivity as positioned rationality" (6). To capture a notion of the object as active and not passive, Haraway asserts that "bodies as objects of knowledge . . . materialize in social interaction. Boundaries are drawn by mapping practices; 'objects' do not pre-exist as such" (6, p. 200–201). The issue then is the various positions from which each one of us, including the child's parents, view the ventilated child — a question that necessarily draws us back into an explicit discussion of the power of professional "mapping practices" in determining the boundaries of the ventilated child as the object of our attention.

How then are we to understand who the ventilated child is, this body attached to a ventilator? Through an exploration of the "semiotic use of the body" among the Kayapo of the Brazilian Amazon, Terence Turner illustrates how "the body is at once a material object and a living and acting organism possessing rudimentary forms of subjectivity that becomes, through a process of social appropriation, both a social identity and a cultural subject" (19, p. 145). For example, the Kayapo use various modifications of their body surface to define and redefine their social identity, as in the use of ear piercing to indicate age cohort, marital status, and other social identities. The individual Kayapo, as both a social body and an embodied subject, assumes the dual role as product and producer (19). In our case the body of the ventilated child as a material object of our technical interventions takes on the social identity of a patient in the home ventilation program. Although his parent(s) may try to resist this medical appropriation of the child's body, the tracheostomy and attached ventilator tubing are key modifications of his body that produce the child's social identity as a patient in the home ventilation program (19). The ventilator-infant as embodied subject appears to be the socially patterned product of our technical activity, rather than the producer of its own activity. Similar to the ideological consequences of the view of technology as value-neutral, the misrepresentation of the "cultural subject" of the ventilator-infant as an "objective (natural) feature existing independently" of our social production further reinforces the dominant power of the physician (19). In infancy, it is unclear that there is any content to the notion of the subject existing prior to and independently of the social production of the embodied subject by others. In other words, what meaning can we give to the notion of the "best interest" of the child apart from the specific interests of a particular embodied social subject? Once a child undergoes a tracheostomy and is placed on a chronic home ventilator, he is and will remain a patient in the home ventilation program. This much is visibly announced on his body. Thus we come full circle to the notion of the ventilator-infant as cyborg, the machine-human as "embodied subjectivity" rather than the machine as external to the body. The

social identity of the ventilator-infant/infant-ventilator is a product of being a machine-human hybrid, that is, the ventilator gives life to the body and the body gives life to the ventilator. To contemplate taking the patient off of the ventilator would be to contemplate amputation — a request that the medical and nursing staff cannot and will not honor.

CONCLUDING REMARKS

What have we learned from this story of the social production of the ventilator-infant as a patient in a home ventilation program? We have come to doubt the universality of the classic teaching of the symmetry between withholding and withdrawing technology. We have a renewed understanding of the insight that our medical technology is not value-neutral, and that it often serves to reinforce the professional dominance of physicians. While we acknowledge that specific hospital units have different cultures, the general impact of the organizational context on the ability of patients and parents to control the application of medical technology is greater, on reflection, than previously appreciated. This impact occurs not primarily through the imposition of a different set of moral values, but through fundamental shifts in our point of view, and thus how we see and come to know our patients. The fundamental conflict between medical staff and the parents of young, chronically ventilated children does not turn on a choice between competing ethical principles. As we have seen, medical staff often do not advance any explicit ethical principle in support of their action (i.e., refusing to withdraw the ventilator). The conflict turns rather on what counts as the proper object of concern: the child, the ventilated child, or the hybrid "ventilator-child." In this conflict, medical workers enjoy enormous power to make authoritative readings of the child's subjective experience and, more generally, what is admitted as knowledge in the medical setting.

Using the example of ventilator technology, this article demonstrates how the use of biotechnology constrains our subsequent moral choices concerning the application of that technology in a manner that belies the claim that the technology itself is morally neutral. Physicians and other medical staff are thus "technicians" in the following sense: They translate moral and political issues surrounding the application of biotechnology into the dominant technical discourse. To accomplish this, these technicians may constrain the freedom of expression and diversity of legitimate knowledge, or they may structure the community of discourse in such a way as to reinforce their own power and interests. Whatever strategy they ultimately follow, the ideology of technology as value-neutral reinforces their dominance in the clinical encounter and their authority to establish the local meanings of technology. The belief that biotechnology is a value-neutral means to certain ends selected according to entirely different criteria (moral, political, or physiological) thus perpetuates professional dominance over patients and their families. Moreover this belief obscures that the process is happening at all. Clinical actions, such as withdrawing or continuing ventilation, as well as knowledge claims about the child at the center of attention, are always underdetermined by available physiological evidence. Ethics and politics, even if hidden, play the crucial role in the outcome of conflicts between medical staff and parents. Elucidating that role, and restoring moral discourse where it has been banished, demands that we abandon the model of morally neutral biotechnology.

PUBLIC PERCEPTIONS: SURVEYS OF ATTITUDES TOWARD BIOTECHNOLOGY

DOROTHY C. WERTZ
The Shriver Center
Waltham, Massachusetts

OUTLINE

INTRODUCTION

Surveys can provide a useful baseline for policy planning, educational development, marketing, and ethical discussions. Surveys may include the general public or may seek to identify the views of various stakeholders, such as researchers, physicians, genetic counselors, or patients. Surveys also have limitations. This article will present the rationale for doing surveys, outline major types of survey methods, and describe some results of major national and international surveys of public and stakeholder views on biotechnology, including genetic testing, screening in the workplace, gene therapy (including germ-line gene therapy), and enhancement of average human characteristics.

RATIONALE FOR CONDUCTING SURVEYS

Uses of Surveys

Surveys can be useful in providing a baseline for public policy debates or ethical discussions, devising educational programs, marketing genetic services, and identifying existing or potential abuses of genetics. In the public policy arena, for example, it makes little sense to outlaw a test or procedure that most people would either use themselves or think others should have a right to use. Policies related to abortion for fetal "defects" are one example. The General Social Surveys (GSS) conducted by the University of Chicago's National Opinion Research Center on a random sample of the United States adult public have indicated that about 80 percent believe a woman should be able to get an abortion if there is a "serious defect" in the fetus. This percentage has varied by only a few points between 1971 (two years before *Roe v. Wade*, the Supreme Court decision legalizing abortion) and 1998 (1). Reports such as this can be useful to lawmakers, courts, advocacy organizations, and lobbyists. Surveys have the advantage of allowing a wide variety of people to express their views, including many who would not otherwise come forward to comment on proposed policies, regulations, or ethical guidelines.

In the arena of education, surveys can identify areas of ignorance that may require special educational programs. For example, a 1986–87 survey of 1473 physicians conducted by the U.S. Congress Office of Technology Assessment (OTA) found that 63 percent would reject a sperm donor with a family history of Huntington's disease (an autosomal dominant disorder with severe effects on the nervous system, transmitted to 50 percent of the offspring and not presymptomatically diagnosable in the donor at the time), while 61 and 49 percent respectively would reject a healthy donor with a family history of Duchenne muscular dystrophy or hemophilia A, both of which are transmissible only by females (2). The survey results indicated need for better education of physicians, greater oversight by sperm banks, and new guidelines from professional societies. A 1995 survey of 499 U.S. primary care physicians found that substantial percents held inaccurate knowledge about the life expectancy and functioning of people with common genetic disorders such as cystic fibrosis or Down syndrome (3).

Surveys also inform ethical discussion. A 1985 survey of 683 geneticists reported that 62 percent in the United States would either perform prenatal diagnosis at parental request solely to select the sex of the fetus (34 percent) or would offer a referral (28 percent) (4). Subsequent discussions among bioethicists and medical practitioners led to various international ethics guidelines rejecting this practice, notably those of the World Health Organization (WHO) (5). These discussions appear to have had little effect on attitudes of professionals in the United States; a 1995 survey of 1085 genetics professionals found 72 percent willing to do prenatal diagnosis for sex selection or refer (5).

Market researchers have always used surveys to identify markets for new tests and treatments. Many of these researchers work for nonprofit institutions or health departments, trying to predict demand for new tests or treatments. Surveys of potential uptake of presymptomatic tests for Huntington's disease (7) and carrier status for cystic fibrosis (8) were conducted before such tests become available, and results (indicating that most people at risk would take such tests) affected allocation of government and institutional funds. More recently, studies of willingness to take tests for mutations in BRCA1 and BRCA2 genes (partially predictive of breast cancer) have led to commercial outlays of plant and equipment (9). More general studies of public attitudes toward genetic testing in general and gene therapy (10,11) have enabled researchers, companies, and policy makers to identify trends toward increased public acceptance of genetic technologies, at least for some purposes. Surveys can also identify the extent of possible abuses of new technologies, such as "genetic discrimination" by insurers or employers (12–14), the testing of asymptomatic children for genetic mutations for adult-onset disorders (15), or perceptions of minority populations that they are being used as guinea pigs (16).

In sum, surveys of the public or stakeholders, including patients, professionals, or others (e.g., religious organizations) can help to prevent making policy decisions or ethical guidelines in a vacuum. Surveys provide a window on the opinions of those who will ultimately benefit or lose from research or policy. Surveys also identify differences among the various stakeholders. The public may think differently from the members of bioethics commissions; patients may (and do) think differently from the majority group (18); women may think differently from men (19). Surveys provide a means — albeit imperfect — for gauging some of these differences.

Limitations of Surveys

Most surveys involve hypothetical questions ("What would you do if. . .?"). In genetics, many surveys involve tests, treatments, or products not yet available. The reliability and validity of responses to hypothetical questions are always debatable. Reliability means that the respondent would answer the question the same way if given the survey instrument a second time. In other words, the survey measures the attitudes or intentions it was designed to measure. In real life it is almost impossible to go back to the same respondents and re-ask the questions, especially if a survey was anonymous. In ethics, particularly, the reliability of surveys is always in doubt. The more difficult the ethical, social, or emotional implications of a question, the more likely it is that respondents themselves will report that they might answer the same question differently another time. One possible response to the reliability problem is to present analogous situations (perhaps in different case vignettes) in different portions of a questionnaire and to measure whether there is a meaningful cluster of responses pointing to a possibly stable underlying attitude (one statistical procedure used is called *factor analysis*). Another response is to conduct longitudinal surveys on the same population (e.g., the public) and to look for wide swings of opinion in the short term. Underlying opinions on most ethical issues do not change rapidly unless there is some well-publicized new discovery or other precipitating event, so a major change in 6 to 12 months suggests that the initial survey may have been unreliable.

The problem of validity (predictive value) is perhaps more important. Validity means that a respondent will actually do what he or she says, if presented with the "real" situation. One limitation of surveys is that the questions posed usually cannot describe accurately the complex characteristics of a hypothetical genetic test or predict whether it will actually provide benefits once it becomes available. Time and again research has predicted an active uptake of new genetic tests, yet when such tests actually became available, few used them (9). There are two major reasons for this lower-than-predicted uptake: (*1*) the uncertainty inherent in many of the tests, and (*2*) the absence of proven or acceptable prevention or treatment (20). For example, BRCA mutation testing provides only a "risk" of breast cancer (about 80 percent for women with a family history of BRCA-related cancer, somewhat lower for women without such a history), not a certainty. "Treatment" involves removal of breasts and ovaries and even then does not provide absolute certainty of freedom from the disease. For Huntington's disease there is no prevention or treatment. For autosomal recessive disorders, such as sickle cell anemia or cystic fibrosis, carrier testing may lead to difficult reproductive decisions, including decisions about prenatal diagnosis and abortion, but does not lead to treatment. People who say in surveys that they will take future genetic tests perhaps implicitly believe that treatment will become available at the same time as testing (11). When no treatment materializes, they do not take the tests. Although the validity of surveys may be improved by detailed explanations of what is and is not possible, lengthy explanations tend to reduce response rates and are difficult to apply to technologies still under development. Future technologies often turn out differently than presented in surveys. For example, no one could have predicted that there would be over 800 different mutations for cystic fibrosis or that a few individuals could have two mutations without the classical symptoms (21). The most controversial future technologies — germ-line gene therapy, genetic enhancement, and human cloning — will

undoubtedly present as-yet-unforeseen scientific and technical possibilities posing new ethical problems.

SURVEY METHODS

Sampling

Most large-scale surveys use one of two methods to select samples: random probability sampling or quota sampling (22). Random probability sampling selects a proportion of the population to be sampled at random, to avoid researcher bias, and requires a comprehensive, accurate list of the elements to be sampled (census tracts, blocks, house numbers in the case of door-to-door or mail samples, telephone numbers in the case of random digit dialing). Usually a table of random numbers is used to select the first element in the survey, and interviewers count down the list and select elements at regular intervals, depending on the proportion of the population to be sampled. (For a 1 in 10 sample, every tenth telephone or house number is selected.) Interviewers continue to make visits or calls to the numbers selected until they contact someone. In budgeting for surveys, researchers usually allow for at least three or four visits or calls per selected household in order to obtain a response.

Stratified sampling is a modification of random probability sampling. It is used when researchers are especially interested in comparing several groups, for example, African-American and white women with and without a family history of breast cancer, in regard to their attitudes toward BRCA testing. In a stratified sample, the population would be organized into four groups (African-American women without a family history, African-American women with a family history, etc.) and an appropriate number selected at random from each group. Stratification ensures that each group of interest is included but limits the numbers in each group, thereby reducing the statistical "power" of finding real differences between groups, especially if these differences are small. Power always depends on the smallest group in a comparison. Usually this group must include at least 200 in order to provide an 80 percent likelihood of identifying a difference of 10 percent between groups.

Quota sampling differs from probability sampling. Quota sampling begins with a matrix based on relevant characteristics of the population to be sampled. Researchers first need to know the overall characteristics of the population, for example, sex, age, race, geographical area, income, or education. The population is divided into cells (e.g., white women aged 25–30, living in southern suburban areas, of Catholic background, with a college education and income of $30,000–40,000), and each cell is given a weight according to its percentage in the overall population. Interviewers seek to fill an assigned "quota" of respondents for each cell. They do not attempt repeated visits or calls to randomly preassigned addresses or telephone numbers.

The random probability sample is the "gold standard" of survey research, and is the method preferred by U.S. government agencies and used by the University of Chicago National Opinion Research Center's General Social Surveys (1), the U.S. Congress Office of Technology Assessment (10), and a 1995 survey of primary care physicians (3). The method is expensive, however, since a sampling frame (list of "units" — persons, house numbers, telephone numbers — to be sampled) must be assembled and interviewers have to make repeated attempts at contact. Quota sampling usually costs less than one-quarter the price of random probability sampling and can be completed much more quickly. Most political campaign polls use quota sampling. Some survey firms combine probability and quota sampling. Households are selected randomly, but individuals within each household are selected by quota. This is called *modified probability sampling*. At least one public survey of ethical views in genetics has also used modified probability sampling (23).

Other sampling methods include so-called convenience sampling (e.g., stopping people on a street corner or giving out questionnaires in a college cafeteria) and "snowball sampling" (letting the initial interviewees direct the researcher to other possible interviewees, who in turn suggest further interviewees). For precise statistical reporting of population views, neither method is adequate, though college students frequently use both. These methods can, however, be useful in anthropological studies of communities and in identifying questions for further large-scale research. The snowball method, by providing access to a cross section of willing interviewees sharing particular social characteristics, has enabled researchers to sample in depth the emotional lives of particular groups, for example working-class women (24). The convenience sample is sometimes the only sample readily available, and the researcher faces the choice of using this or not doing the research at all. Scholarly journals have published results of surveys using these methods, providing that authors acknowledge their limitations.

Survey Approaches: Interview, Telephone, Mailed Questionnaire

The various approaches are approximately equal in terms of reaching study populations. Most people now have telephones (although in some of the poorest rural or innercity areas, about 5 percent do not). People with unlisted telephones can be included in surveys by dialing from random number tables instead of phone books. People appear willing to answer phone questionnaires up to about 15 minutes in length (about the same length as in-person interviews) though some surveys have lasted up to half an hour. Mailed questionnaires have the advantage of allowing for greater length and complexity, but they require more tasks from the respondents and must be accompanied by stamped return envelopes. Sometimes written questionnaires are delivered by in-person interviewers, who wait while the respondent completes them. Many people feel more comfortable with methods that promise anonymity, such as mailed questionnaires or randomly dialed calls, especially if questions touch on deeply held personal beliefs (25). In-person and telephone methods now provide similar response rates. Questionnaires may produce lower response rates, but they can convey more complex questions and can use case vignettes.

Requirements for Consent

Participation in anonymous surveys does not require written informed consent of the type usually required in medical research. Anonymous studies usually fall under the educational exemption of the Federal Office for Protection from Research Risks (OPRR) rules, though researchers funded by the federal government or at institutions that receive federal funds must request this exemption from their Institutional Review Board. Answering the survey constitutes consent. Political pollsters and market researchers usually give a very brief description of the survey ("I'm going to ask you a few questions about. . ., which will take about . . . minutes") and ask if the person is willing to participate. Questionnaires usually have a brief introduction describing the purpose of the survey, naming the individual researchers and institution conducting the research and stating that participation is voluntary. If sensitive questions are involved, the introduction gives a warning to this effect (sometimes repeated at intervals in the questionnaire) and tells people that they do not have to answer questions that make them feel uncomfortable. (Similar warnings can be given in voice interviews.) The most sensitive question of all — even in ethics questionnaires — is usually about income. Many people are reluctant to disclose how much money they make. Repeating the word "optional" before this question is advisable.

Anonymity can be preserved even in "before-and-after" surveys by placing matching numbers on sets of questionnaires. In studies where respondents receive payments after completing sets of questionnaires, anonymity can still be preserved by preventing names from reaching researchers and by destroying code numbers once payment is made. Surveys where researchers can match individuals' names to questionnaires or interviews require a signed informed consent document, provided that the survey is sponsored by an agency of the U.S. government or conducted at an institution receiving federal funds. Most medical and educational institutions receive federal funds.

Developing Survey Instruments

Focus Groups. Focus groups are frequently used to help develop questionnaires or interviews. A focus group is somewhat like a group interview focused on a certain topic (26). Focus groups usually consist of 6 to 12 people, often selected by research companies specializing in focus groups. There is no attempt at random selection. Focus groups are not surveys. Ideally participants will be as different from each other as possible. Over an approximately two-hour period, a facilitator gently leads the group through a list of areas that the organizers wish covered and also coaxes out the quieter members of the group. Comments by one member may reverberate in others, leading to a fuller range of responses than would occur in a one-on-one interview. The group is tape-recorded and transcribed. Researchers continue to conduct new focus groups until new viewpoints cease to arise. Focus groups are not "town meetings" of people with special agendas, nor are they neighborhood gatherings. Participants are selected so as not to know others in the group, and usually do not include the most vocal activists. The transcripts help identify concerns and wordings that should be included in the survey instruments. Focus groups are also widely used by market researchers (to develop advertising) and politicians (to develop campaign strategies).

Wording. In developing the survey instruments, researchers will need to consult with some of the major interest groups, whether or not they have used focus groups. For example, in developing questions on relationships between biotechnology and people with disabilities, persons from groups in the disability community should be consulted. It is important to try to avoid language that some people may regard as insulting, such as "burden," "affected child," "defect," or phrases that put diseases ahead of persons, such as "Tay-Sachs baby" or Down syndrome case." The disability community prefers "person-first" language, such as "persons with mental retardation."

Choice of words can have strong effects on responses. For example, most people do not want to be "genetically engineered" or to eat food that is "genetically engineered." People are more receptive to "biotechnology" than to "genetic engineering" (27). Technical terms such as "germ-line gene therapy" are confusing to most people. An explanation, such as "correcting genes that would carry the disease to future generations" (11) may be better. Even "enhancement" is a questionable word for inclusion in a public survey. It is usually better to give an example, such as "increase athletic abilities" or "improve performance in school."

Sometimes researchers skew questions toward a particular type of response that they hope to find. For example, a researcher who hopes that people will agree to participate in biomedical research may say "Do you agree or disagree with the following statements: A. The benefits of the proposed research outweigh the risks. B. This study may lead to an important treatment. I would want to participate in this research myself." Both statements emphasize the benefits and ignore the risks of the research. The vast majority of people will agree with them. In most cases the surveyor constructs skewed questions inadvertently, rather than by design. Even bioethicists construct skewed questions. The usual methodological approach to counteract this is to construct an equal number of questions that may elicit the opposite response. For every question that may produce a positive response to biomedical research, a question phrased in a negative light (stressing risks or uncertainties) should be included. A balanced set of questions not only contributes to internal reliability of responses but is also useful in the data analysis.

Ideally surveys should be short. Exploring complex issues can require more lengthy instruments, however. Projects should not be rejected on the ground that "the public will never understand the issues." Researchers in developing nations have found that most people, including those with no formal education, understand complex concepts (including risk and the placebo effect) if these are explained adequately (28). Simplistic global questions,

such as "Do you think the Human Genome Project poses greater risks than benefits?" tend to produce answers of limited usefulness. Questions about self-perceived knowledge may measure self-confidence rather than actual knowledge, unless accompanied by actual knowledge tests.

Cross-Cultural Surveys. Survey research can be conducted crossculturally (29). Biotechnology will affect populations differently, but human beings face similar issues. For federally funded surveys requiring translation, two steps are ordinarily required. First, the survey is translated and tested on several members of the population who will receive it. Second, the translation is "back translated" into English by an independent translator who has never seen the original and compared with the original English version so that mistakes and nuances of language can be corrected.

Pilot Testing. All survey instruments are ordinarily field-tested on several people, revised for clarity, and then pilot-tested on a larger group. Observers watch people completing questionnaires or interviews and then debrief them regarding comprehensiveness, emphasis, and clarity. Usually an instrument undergoes several rounds of pilot testing.

Response Rates

Some authorities consider 50 percent an acceptable response rate (22). Some journals, such as the *American Journal of Public Health*, have preferred 60 percent but are willing to publish surveys with lower response rates if they include an especially hard-to-reach group, such as physicians. A 70 percent response rate is good by anybody's standards (22). In-person quota surveys usually have very high (over 95 percent) response rates. Questionnaire surveys usually have low response rates (about 30 percent) on the initial mailing, but these are increased by successive mailings and telephone reminders. Most responses to the initial mailing arrive within two weeks. At that time, a second mailing, sometimes in the form of a postcard reminder, is sent, followed by a third and final mailing (sometimes a complete questionnaire in case the first one has been lost) in a week or two. Usually successive mailings produce about half the number of responses received in the previous mailing.

Physicians are a notoriously difficult group to survey and are difficult to reach even for a telephone reminder. Some survey firms specialize in physicians, charging approximately $100 per completed interview. A small payment of $25 for completing a questionnaire or interview can increase response rates dramatically, even for physicians.

Including Members of Minority Groups

Members of minority groups may hold considerably different views from those of the majority with regard to the ethical conduct of medicine and research, in view of past experiences where they were used as guinea pigs without their knowledge (31,32). Unfortunately, most survey research on ethical, legal, and social issues in genetics, like most medical research (33), does not adequately reflect the views of minorities. Two possible reasons are (*1*) underrepresentation of minorities in some groups, notably service providers, and (*2*) extra costs of including adequate numbers of minorities in public and patient surveys, costs that may exceed a funding agency's customary limits.

According to the American Society of Human Genetics, of 4810 members based in the United States, 4031 (84 percent) are white, 604 (13 percent) are Asian, 57 (1 percent) are African-American, 34 (0.7 percent) are Hispanic, 30 (0.6 percent) are Native American, and 54 (1 percent) are "other." These percentages apply to the entire membership, which includes researchers as well as service providers and also includes many people who are not board certified. An examination of names (where sex can be attributed) suggests that about half of board-certified members in the United States may be women. The National Society of Genetic Counselors (the professional association for Master's level counselors) reports that 96 percent of its members are women, 93 percent are white, 4 percent are Asian, 1 percent are Hispanic, 1 percent are African-American, and 1 percent are "other" (34). Women are better represented in genetics than in some other medical specialties; according to American Medical Association data, 44 percent of pediatricians, 29 percent of obstetricians, and 23 percent of family practitioners are women (35). According to U.S. Census Bureau data, 21 percent of all physicians were women in 1990 (36). Some minorities, however, are underrepresented in genetics when compared with other medical specialties and with their proportions of the U.S. population. According to 1990 U.S. Census data on 587,675 physicians, 80 percent were non-Hispanic white, 11 percent were Asian, 5 percent were Hispanic, 4 percent were African-American, and 0.1 percent were Native American (37). In the 1990 census, African-Americans constituted 12 percent of the U.S. population, and Hispanics constituted 9 percent. Today Hispanics are almost 12 percent of the population, excluding Puerto Rico (38). These groups are underrepresented in medicine generally, but especially underrepresented in genetics. There are no national data on race, ethnicity, or sex of individuals or families receiving genetics services.

Surveys of minority groups may cost several times the fee for surveys of the general population. For example, because African-Americans represent only 12 percent of the adult U.S. population, it is necessary to contact successfully and to screen more than 4000 households in order to locate 500 that include an eligible African-American respondent for a door-to-door or telephone survey. Surveying Hispanic populations requires translation and use of bilingual interviewers. Spanish-speaking groups originating from different areas (e.g., Puerto Rico, Mexico, Cuba, Peru) hold different views and their responses cannot be lumped together under the general label "Hispanic" or "Latino." Each group must be surveyed separately. Reaching members of "low-incidence" groups such as Southeast Asians or Native Americans requires construction of special sampling frames, something that most

survey research organizations are unable or unwilling to do.

It is not sufficient simply to conduct a general population survey and hope that minorities will be adequately represented. According to Roper Starch Worldwide, a survey research firm, the average English-speaking population sample achieved is 80 percent white, 10 percent African American, and 10 percent other or unknown. Telephone surveys may result in inclusion of even fewer African-Americans than door-to-door surveys, since fewer households have phones. In order to represent minority views, each group must be "oversampled." In survey research language, "oversampling" means that to get an adequate sample of a minority group, which represents its proportion of the population, it is necessary to solicit participation from proportionately more members of the minority group then are represented in the population as a whole. The low incidence and difficulty of reaching minority groups may quadruple the cost of a survey. For example, a survey of 1000 members of the U.S. public may cost around $25,000, while a comparable survey of only 500 African-Americans may cost a minimum of $50,000. A survey of Native Americans or Asians will probably be unobtainable from most survey research firms. Some researchers consider a survey of 500 persons inadequate to represent the views of an entire minority. The sampling error is plus or minus four percentage points, and many persons will never be reached, either door-to-door or by telephone. To represent all of America's various minorities in adequate numbers for analysis could be economically prohibitive by the usual funding standards for survey research.

Data Analysis and Presentation of Survey Results

Survey data are usually coded (put into numeric form) and entered into statistical programs in computers. The most common statistical packages are SAS (Statistical Analysis System) and SPSS (Statistical Package for the Social Sciences). Qualitative data (people's "write-in comments" on questionnaires or verbal responses to open-ended interviews that ask them to reply in their own words) can be quantified for purposes of statistical analysis. This requires development of categories to organize the responses. Each piece of numerical data is entered by two independent operators, whose work is compared for corrections, a procedure known as "punch and verify."

Survey results are usually expressed as one figure. However, if another randomly selected group of similar size were to be sampled, another figure might emerge. The results of separate surveys would fall on a bell curve, with 95 percent of these results falling within a certain range. Thus, if 80 percent of 1000 people surveyed give answer A, a statistician would say that the true figure is in the range of 77 to 83 percent with 95 percent confidence. In other words, we are likely to be right that the true value falls in this range 95 percent of the time, but there is a 1 in 20 chance that the answer is outside this range. The range is sometimes reported in tables as a "confidence interval"; the 95 percent is the "confidence level" for this interval.

VIEWS ON BIOTECHNOLOGY

Major Surveys

The most careful and comprehensive surveys were conducted for the U.S. Congress Office of Technology Assessment, which is no longer extant. These include a mail survey of the 500 largest U.S. Corporations and 11 labor unions, reported in *The Role of Genetic Testing in the Prevention of Occupational Disease* (1983); a survey of surrogate mother matching services, reported in *Infertility: The Medical and Social Choices* (1988) (40); a survey of 1575 physicians, 1213 fertility specialists, and 30 commercial sperm banks, reported in *Artificial Insemination: Practice in the United States* (1988) (2), and, most important, a 1000-member telephone Survey of Public Attitudes toward Biotechnology, Science, and Engineering, conducted in 1986 and reported in *Public Perceptions of Biotechnology* (1987) (10). The National Center for Human Genome Resources (NCGR), a private, nonprofit research organization in Santa Fe, New Mexico, commissioned a partial repeat of the OTA Survey of Public Attitudes in 1996, by the same survey researchers, in order to examine possible trends (11). In addition, the NCGR study surveyed 521 primary care physicians, 100 leaders of patient organizations, 102 research and development directors from the biotechnology industry, 76 genetic researchers, 50 science journalists, 50 religious leaders, 70 medical directors of insurance companies, and 79 federal and state policy makers. In the United States, Singer (41) has conducted public surveys on the ethics of utilizing prenatal diagnosis, including complex issues such as sex selection, and has examined the views of labor unions and religious groups.

In Canada, the Royal Commission on New Reproductive Technologies surveyed over 9000 people by mail questionnaire and telephone, regarding opinions about use of fetal tissue and treatments for infertility (42).

In Europe, the Eurobarometer surveys in 1991, 1993, and 1996, commissioned by the European Union (EU) and conducted by INRA, a European network of market and public opinion research agencies, are the most comprehensive (27). In the most recent, Eurobarometer 46.1 (1996) public surveys were conducted in all 15 member states of the EU, plus Norway and Switzerland, using random probability sampling, for a total of 16,246 face-to-face interviews about public perceptions of risks and benefits of various aspects of biotechnology.

A series of large-scale surveys of portions of the Japanese public by Macer also looks at global attitudes, but response rates were about 24 percent, well below standards of acceptability in the West, although Macer claims it is average for Japan.

Two worldwide surveys of genetics professionals by Wertz and Fletcher, a 19-nation survey of 683 in 1985 (4) and a 36-nation survey of 2901 in 1995 (44) together with surveys of 499 primary care physicians, 476 genetics patients, and 988 members of the general public in the United States, concentrate largely on ethical issues in genetics services, rather than research, but some questions touch on new technologies.

Overall Views on Biotechnology

In the United States, the public's self-perceptions of adequacy of knowledge increased between 1986 and 1996 (11). The percent who thought they knew what a gene is increased from 85 to 91 percent; those who thought they understood the meaning of "human gene therapy" increased from 29 to 49 percent. In 1996, 68 percent knew that scientists were trying to map the human genome, 48 percent thought this effort would have at least a moderate effect on themselves or their families, and 53 percent knew that genetic tests were available. About 7 in 10 approved of gene mapping. Among the various leadership groups, 87 percent approved mapping the human genome, and 92 percent expected improvement in the early diagnosis of disease in the next ten years; 88 percent of patient group leaders, 78 percent of industry representatives, and 68 percent of scientists thought there would be at least moderate improvement in treatment of chronic diseases, though notably fewer scientists (13 percent) thought there would be "a lot" of improvement, as compared to 42 percent of patient organizations and 39 percent of policy makers. A majority of all leaders (62 percent) said they followed the scientific literature fairly closely, but only 17 percent followed it very closely, including 17 percent of patient organizations, 8 percent of policy makers, 7 percent of insurers, and 0 percent of the media. All groups thought that funding would present the biggest frustration for scientists in biotechnology, though 27 percent of the biotech industry also cited government regulations. Overall, few leaders saw research confidentiality (3 percent), patient confidentiality (2 percent), or discrimination (1 percent) as the biggest source of frustration. Four out of five (81 percent) in the leadership sample expected current efforts to identify markers of genetic disease to have at least a moderate effect on society. Nine out of 10 (92 percent) expected society to benefit from medical applications of biotechnology in the next 10 years, including 51 percent who expected "a lot" of benefit. Notably fewer religious leaders (20 percent) expected a lot of benefit than patient organizations, scientists, and industry (65–67 percent). About two-thirds (65 percent) thought that medical applications of biotechnology would pose some risk to society, ranging from 86 percent of religious leaders and 80 percent of policy makers to 49 percent of scientists and 53 percent of industry. Only 15 percent thought there would be "a lot" of risk. Most (85 percent) thought the benefits of biotechnology would outweigh the risks, while 8 percent thought risks would outweigh benefits. Leadership groups were divided with regard to government regulation. About 40 percent would like to see regulations left as they are now, including 57 percent of scientists, 47 percent of industry, and 27 percent of insurers; 27 percent would like more stringent regulation, including 44 percent of religious leaders, 37 percent of policy makers, 30 percent of insurers, and 17 percent of scientists and industry; 18 percent would like less stringent regulation, including 32 percent of industry but only 5 percent of policy makers.

In the 1996 Eurobarometer survey (27), 50 percent thought that biotechnology would improve life, with Finland the most optimistic and Greece, Norway, and Germany the least optimistic; 15 percent thought it would make things worse, with Austria, Norway, and the Netherlands the most pessimistic. When questions used "genetic engineering" instead of biotechnology, optimism fell to 39 percent and pessimism rose to 27 percent. Although 54 percent thought biotechnology would lead to cures for most genetic diseases in the next 20 years, 70 percent thought it would create dangerous new diseases. Overall optimism about telecommunications, computers, solar energy, and new materials exceeded optimism about biotechnology. Optimism about biotechnology decreased slightly, but significantly, between 1991 and 1996, from 51 to 48 percent. About half of respondents had heard about and talked with someone about biotechnology in the three months preceding the survey. "Textbook knowledge" did not increase significantly between 1993 and 1996; there was wide variation among countries, and generally greater pessimism in countries with lower levels of textbook knowledge, such as Austria. There was great national variation in beliefs about heritability of human characteristics. In all, 62 percent, ranging from 78 percent in Ireland and 77 percent in the Netherlands to 39 percent in France, thought that human intelligence was mainly inherited; 17 percent, ranging from 32 percent in Ireland to 9 percent in Switzerland, believed that attitudes toward work were mainly inherited; 15 percent, ranging from 24 percent in Italy, and 23 percent in Austria, to 10 percent in Denmark and 9 percent in Sweden, thought criminality was mainly inherited; 25 percent, ranging from 39 percent in the Netherlands and 34 percent in Germany to 13 percent in France and 17 percent in Portugal, thought homosexual tendencies were mainly inherited. There are no simple cultural explanations for these findings.

Europeans thought that international organizations such as the WHO (35 percent), or scientific organizations (22 percent) were better able to regulate biotechnology than national governments (17 percent) or the EU (6 percent) (27). Only 24 percent thought that existing regulations were sufficient. Respondents placed the greatest confidence in consumer organizations to tell the truth about biotechnology, followed by schools and universities. Public authorities were way down the list. Over half of respondents (54 percent) thought that "irrespective of regulations, biotechnologists will do what they like" especially in Denmark (71 percent), Switzerland (65 percent), France, Germany, and the United Kingdom (all 60 percent). The Japanese surveys, which were also distributed in New Zealand for comparison, used the words "genetic engineering," "genetic manipulation," and "genetically modified organisms," and the framing of questions makes comparison with European and U.S. surveys difficult. Nevertheless, they suggest a considerable amount of fear about and concern over new developments in biotechnology, as well as need for more education (43).

Views on Genetic Testing

In 1996, 53 percent of the United States public said that they were aware that genetic tests were available,

including 42 percent of high school graduates and 68 percent of college graduates (11). More than 9 out of 10 (93 percent) approved of the use of genetic information for early diagnosis of disease; 85 percent approved of presymptomatic genetic testing for diseases that occur later in life, including 43 percent who approved strongly. About three-quarters (73 percent) thought it was "a good thing for a healthy person to be able to find out how likely they are to get a serious disease in the future," while 17 percent thought it was "bad" to know. More women (21 percent) than men (13 percent) thought it was bad to know. Those who thought knowledge was good cited the possibility of prevention (57 percent), changing lifestyles (11 percent), finding a cure (10 percent), making decisions about having children (7 percent), or early treatment (6 percent), but 23 percent simply said they wanted to know in advance. Those who thought foreknowledge was bad cited worry (34 percent), negative influence on life plans (27 percent), depression (11 percent), fatalism (no need to know) (13 percent), negative self-image, or emotional effects (12 percent). Perspectives on why knowledge is good or bad may explain one of the most persistent problems in survey research on genetics: why the majority of people say that they would take a test and then do not take it once it becomes available. People who think foreknowledge is good implicitly associate the knowledge gained through testing with prevention or eventual cure. If a test becomes available without acceptable means of prevention or cure, most people are not interested (20).

Nine out of 10 (88 percent) approved the use of genetic tests to find out whether future children are likely to have a serious genetic disease. The 1996 NCGR survey did not specify what kind of testing this meant (prenatal diagnostic or parental carrier testing). A 1995 survey of 476 genetics patients (44) (mostly working-class Catholic white women bringing children in for evaluation) found that 64 percent agreed that "before marriage, responsible people should find out whether they could pass on serious diseases or disabilities to their children" (64 percent also agreed in a 1994 public survey); 81 percent thought that "a woman should have tests on the unborn baby if she is at risk of having a child with a serious disease or disability" (62 percent agreed in the public survey); and 80 percent thought that "tests on unborn babies should be available to all women who request them." Fewer patients (21 percent) thought that "a woman should have an abortion if tests say the unborn baby has a serious disease or disability"; 43 percent were neutral on this question.

In Europe, 81 percent thought it was "useful for society to use genetic testing to detect diseases that we might have inherited from our parents," and 72 percent thought that people should be encouraged to take such tests (11). In Japan, most thought prenatal testing (76 percent) and presymptomatic testing (73 percent) should be available under national health insurance (43).

The level of certainty provided by a test might be expected to affect public acceptance of it (20). This was not the case in the 1996 NCGR survey. Most people were willing to accept some uncertainty (11). Only 27 percent said tests should be made available only if they predicted with certainty that someone would develop a disease. Most of the rest were willing to settle for tests that could indicate "a high risk." ("High" was not defined in the survey.) Treatability of the condition had less effect than might be expected on the degree of risk that people would tolerate. For serious, untreatable conditions 27 percent thought tests should be available even if they indicate only a slightly increased risk, 20 percent would require a moderately increased risk, and 40 percent thought tests should be available only if they indicate highly increased risk. Slightly higher percents would approve tests for slightly (36 percent) or moderately (26 percent) increased risk if a condition were treatable. Most (94 percent) thought doctors should "advise" people with a family history of cancer to take a genetic test for cancer, and 48 percent thought doctors should advise everybody to take such a test.

Reports of personal willingness to take genetic tests are of dubious validity, tending to exaggerate greatly the numbers who would take such tests. In 1996, 65 percent in the NCGR survey (11) said they would take a test indicating whether they would develop a fatal disease later in life, almost the same percent as in 1986. There was a statistically significant decline between 1986 and 1996 from (83 to 76 percent) in the number who said they would take a genetic test, before having children, that would indicate whether their children would inherit a fatal genetic disease. Nevertheless, the percent who would be tested on behalf of future children exceeds those who would be tested on their own behalf. A review of recent similar studies of willingness to be tested indicated high percentages of acceptance of BRCA testing, as in earlier surveys, but little evidence that people were actually requesting tests (45).

In Japan, 63 percent of the public, when asked the same question, said they would have tests before conceiving children; 53 percent would have presymptomatic tests for themselves, and 76 percent would have prenatal diagnosis (43). Percents were not substantially different among students, general public, university staff, and scientists.

Prenatal Testing

A survey of labor unions and Protestant religious groups found that most either supported genetic testing and prenatal diagnosis or (in the case of unions) had no position (41). A survey of public attitudes toward using prenatal diagnosis to select the sex of the child found that only 5 percent approved this use; however, when presented with the "hard-luck case" of a couple with four children of the same sex, a substantial minority (38 percent) supported sex selection (41). In a 1995 survey, 72 percent of U.S. genetics professionals, 68 percent of U.S. primary care physicians, 59 percent of patients, and 38 percent of the general public thought the doctor should do prenatal diagnosis in this case (percentages for professionals include those who would offer a referral) (44). This points to another potential weakness of surveys: People may answer one way on a general question and another way in response to a more concrete situation. In medical practice the exigencies of the concrete situation

usually win. This is why some ethics surveys employ case vignettes.

Surveys of women having prenatal diagnosis for genetic disorders generally document increased anxiety, need for sympathetic and accurate counseling, reduction in anxiety after receiving favorable results, and willingness to undergo the procedure in a future pregnancy (46). For women whose tests indicate presence of a genetic condition, studies document the difficulty of decisions (46). Women who already have a child with a genetic condition are often reluctant to abort a fetus with the same condition (47). Most women who choose abortion recover psychologically within months, but a small minority continue to have strongly negative emotions (48). In general, Americans appear reluctant to use selective abortion. In a 1994 public survey describing eight fetal conditions, the majority would not abort for any condition listed, including severe mental retardation, with the child "unable to speak or understand" combined with death in the first few months of life; 48 percent would abort in this situation, 47 percent would abort for severe mental retardation accompanied by a nearly normal lifespan, and 41 percent would abort for paralysis from the neck down, with no retardation and a normal lifespan. Smaller percents would abort for mild retardation ("child could live independently") (17 percent), severe incurable mental disease appearing at age 40 (21 percent), moderate retardation ("could communicate but not live independently") (22 percent), "gross overweight" (16 percent), and "child not of the sex desired" (7 percent). For all of these conditions, except sex selection, majorities believed that abortion should be legal for others.

Testing Children

The genetic testing of asymptomatic children for disorders that occur later in life has occasioned much discussion. A survey of U.S. laboratories found that most had no comprehensive policies and many had performed such tests (15). Other surveys found that geneticists in English-speaking nations and Northern/Western Europe rejected the practice, but majorities of those in other parts of the world would test children for mutations for Huntington's disease or Alzheimer's disease at parents' request (49).

Perspectives on Confidentiality

Access to an individual's genetic information by spouses and genetically related family members is one of the most controversial areas in bioethics. Although surveys of genetics professionals indicate that most believe that spouses should not have access to information without the individual's consent (44), surveys suggest patients and the public think otherwise. In one set of surveys, 20 percent of the public thought spouses should have general access without consent; among patients, substantial minorities thought spouses should have access to their partner's genetic information without consent if there were a risk that a child could inherit mental retardation (43 percent), if the spouse/partner had mutations predisposing to mental illness (31 percent), or alcoholism (23 percent), or if the spouse/partner was a carrier of cystic fibrosis (30 percent). In the NCGR Survey, 75 percent thought spouses should have access, but the question did not specify whether this was with or without consent (11). There was far less support (9 to 12 percent) in any group for access for blood relatives, at least in general questions. When the situation was presented as a case vignette describing Huntington's disease, however, 75 percent of patients and 38 percent of U.S. genetics professionals thought the doctor should tell the relatives, against the patient's wishes (50). These results point to divisions within the professional community and differences among professionals, patients, and the public. Beliefs about privacy are different outside English-speaking nations and Northern/Western Europe, where the unit of privacy is the individual. In most of the world, the unit of privacy is the family (50–52). Surveys point to an overwhelming consensus against access for employers and insurers without a person's consent; many respondents believed that these institutions should have no access at all, even with consent.

Eugenics

An international survey of geneticists found little support anywhere for state-mandated testing or sterilization (53). However, substantial percents of geneticists in developing nations (especially China and India) and Eastern Europe believed that "reducing the number of deleterious genes in the population" was "an important goal of genetics." Except in the English-speaking world, majorities would offer purposely pessimistically slanted information after prenatal diagnosis, so that people would abort without the professional suggesting it directly. Overall, genetics professionals held a pessimistic view about disability (53).

Gene Therapy

The NCGR survey suggests a trend toward public acceptance of gene therapy. In 1996, 87 percent approved of "correcting genes that cause serious illness" (11). The percentage who believed that "changing the genetic makeup of human cells is morally wrong" decreased from 42 percent in 1986 to 22 percent in 1996. In 1986, 83 percent approved of "changing the makeup of human cells to cure a usually fatal genetic disease"; in 1996, 85 percent approved (not a statistically significant increase). There was a significant increase (77 to 84 percent) in those who approved changing human cells "to reduce the risk of developing a fatal disease later in life." There has been a significant decline in approval of gene therapy for enhancement ("to improve the physical characteristics children would inherit.") In 1986, 44 percent approved this use; in 1996, 35 percent approved this use. Approval was highest among those with less than a high school degree (61 percent), lowest among college graduates (28 percent). Among leadership groups, 25 percent of patient organizations but only 12 percent of scientists approved this use.

The majority of the public approved both somatic cell and germ-line gene therapy. In 1996, 68 percent thought doctors should be allowed to correct both the gene affecting the disease in the patient, *and* the gene

that would carry the disease to future generations, an increase from 62 percent who approved in 1986. Four of five (83 percent) primary care physicians thought that doctors should be allowed to correct genes carrying disease to future generations. Majorities in all leadership groups, including 79 percent of patient organizations, 74 percent of religious leaders, 79 percent of insurers, 72 percent of policy makers, 66 percent of industry, and 55 percent of scientists (who may be more aware of the risks) approved of both somatic cell and germ-line gene therapy.

Genetics in the Workplace

The OTA survey of industry suggested that most companies were not using genetic testing, though some had used it in the past (mainly for sickle cell trait, which is irrelevant to occupationally-related disease) and some expected to use it in the future (39). One study found that while employers supported genetic testing to identify presumably susceptible workers and move them to less hazardous jobs before damage occurs, unions preferred genetic monitoring, which means testing to see whether cellular or molecular damage is actually occurring (54). The unions' argument was that genetic testing could have low predictive value for disease and would lead to unfair discrimination against many workers. In a 1995 international survey there was agreement among genetics professionals everywhere that testing should be voluntary, the worker should have access to the results, and no one else should have access without the worker's consent (44). Half of U.S. patients, however, thought that testing should be required, apparently because they thought testing would protect the worker. In the United States, the Americans with Disabilities Act (ADA) now prevents employers from refusing to hire because of family history or presymptomatic tests, provided that the person is able to do the job.

Genetic Discrimination

Although many people believe firmly that insurers and employers are using genetic information to deny insurance or employment, surveys have found little evidence that companies are singling out genetic information for special treatment. What surveys have found is considerable fear of discrimination. A survey of educated members of genetic consumer groups found that most were afraid that information would be used against them (12). The majority of Americans thought that health insurers (85 percent) and employers (59 percent) will probably ask applicants in the future to take genetic tests (11). In Europe, 41 percent of the public thought insurance companies would use genetic tests to set premiums within the next 20 years (43). In the United States, surveys of medical directors of insurance companies and state insurance commissioners suggest that insurance companies intend to rely primarily on family histories, as they have always done (55–57). In an attempt to assess the prevalence of genetic discrimination, one group of researchers sent out over 30,000 questionnaires to members of support groups for families with Huntington's disease, hemochromatosis, and sickle cell anemia in anticipation of identifying asymptomatic people who had been discriminated against solely on the basis of genotype (13). The response rate was about 3 percent, of whom about half reported some form of discrimination. In another set of surveys (14), 1084 genetics services providers reported 76 clients refused employment and 474 refused life insurance because of genetic predisposition or carrier status, for a total of 550 persons refused employment or insurance. The 499 primary care physicians in the survey, with a median of 14 years in practice and 100 to 150 patients per week, reported 29 patients refused health insurance on the basis of genetic predisposition. Patients were asked "because of a genetic disability or disease, have you or a member of your family been refused employment or health or life insurance?" Two percent reported being denied or let go from a job, 3 percent were refused health insurance, 7 percent were refused coverage for some services, 5 percent were refused life insurance, and 1 percent were refused school admission. Most patient descriptions fell within the scope of employment and insurance practice generally and were only indirectly related to genetics and not at all to genetic testing.

Views of Minority Groups

A recent two-wave survey of 500 African-Americans and 500 members of the public before and after President Clinton's May 16, 1998, apology for the unethical treatment of African-Americans in the Tuskegee Syphilis Study (31) showed dramatic differences between African-Americans and the general public on many questions related to medical research in general (16). For example, almost three-quarters of African-Americans thought they were very likely (36 percent) or somewhat likely (38 percent) "to be used as guinea pigs without their consent," as compared with 16 and 34 percent of the general public (16). A 1995 survey on ethics and genetics, while reaching too few African-Americans for proper analysis, found significant differences in responses to half the ethical questions (18).

Forensics

Survey responses have shown overwhelming approval of DNA identification, especially for law enforcement agencies. Over 90 percent of genetics professionals and 95 percent of patients believed that persons convicted of serious crimes (not only sex crimes) should be required to have DNA fingerprinting and that the DNA should be kept on permanent file, like regular fingerprinting (44). Majorities of both professionals (59 percent) and patients (72 percent) would also require DNA fingerprinting for persons charged with, but not convicted of, serious crimes. Most professionals (80 percent) and patients (86 percent) favored DNA fingerprinting of members of the armed forces, to identify casualties. Most patients (73 percent), but fewer professionals (37 percent), would DNA fingerprint newborns to prevent mixups in the nursery. Half the patients, but only 20 percent of professionals, would require DNA fingerprinting for passport applicants. Almost half the patients (47 percent) would require it for people receiving welfare, to prevent fraud, and 34 percent

would require it for credit applicants. In the Eurobarometer surveys, 70 percent thought that genetic fingerprinting would lead to solving more crimes in the next 20 years (27).

Genetically Modified Organisms

The largest surveys of public attitudes have been done in Europe (27). In all, there is greater support for introducing human genes into bacteria to produce medicines or vaccines and for introducing genes into crop plants to make them more resistant to insect pests than there is for using modern biotechnology in food production, for developing genetically modified animals for cancer research, or for xenotransplantation (27). Majorities regarded all these technologies as useful for society, but majorities also found food production (60 percent), genetically modified animals for laboratory research (52 percent), and xenotransplantation (60 percent) risky. Only minorities of respondents believed it morally acceptable to develop genetically modified animals for laboratory research (44 percent), to use biotechnology in food production (48 percent), or to produce animals for xenotransplantation (35 percent). Japanese surveys indicated considerable public concern about the health effects of eating genetically modified foods (43).

CONCLUSION

Surveys are useful in gauging public optimism or pessimism about biotechnology, identifying sources of concern, and pointing to differences of opinion among stakeholder groups. Most surveys have shown that publics, especially in the United States, are generally optimistic about biotechnology and believe that benefits outweigh risks. Majorities support genetic research, testing and gene therapy, including germ-line gene therapy. In the United States, fears center on possible misuses of information by insurers and employers. There appear to be some substantial differences among views of professionals, patients, and the general public. The views of minority groups on issues specific to biotechnology remain largely unknown. In some areas of ethical concern, such as views on research uses of biological samples, potentially useful surveys are still lacking.

RECOMBINANT DNA, POLICY, ASILOMAR CONFERENCE

CHARLES WEINER
Massachusetts Institute of Technology
Cambridge, Massachusetts

OUTLINE

INTRODUCTION

The development and laboratory use of recombinant DNA research techniques in the early 1970s made it possible to manipulate genes, opening the path to genetic engineering. The research and its potential applications were embroiled in controversy from the beginning and became one of the major ethical and public policy issues in the 1970s and 1980s. Unresolved questions persist through the present and the earlier experiences of scientists, citizens and policy makers continue to influence perceptions and actions today. In the 1970s the concern was about the potential health and environmental hazards of laboratory use of these novel research techniques. The researchers, their institutions, and their funding agencies developed a system of self-regulation to avoid hazards and to forestall legislative control. They focused on the means not the ends, on the tools of genetic engineering rather than on the moral limits. Rapid and pervasive commercialization of academic research in the field in the 1980s provoked continuing controversies on the role and nature of universities, the effects of corporate ties on education and on research goals and communication processes, and the threat of potential conflicts of interest of commercially involved academic researchers whose expert advice was sought on ethical and public policy issues. Commercial applications of recombinant DNA and related genetic engineering techniques continue to raise public concern about environmental and health hazards in agriculture and medicine. And the moral limits to applications of human genetic engineering are deeply controversial (1,2).

SCIENTISTS' ORIGINAL CONCERN ABOUT HAZARDS

At the Gordon Research Conference on Nucleic Acids in July 1973, invited specialists on DNA research heard fascinating reports of new techniques for manipulating and moving genetic material. The use of the newly discovered restriction enzymes made it possible to cut strands of DNA at specified precise points and to insert them into the DNA of other organisms, combining the hereditary material of animals and bacteria. These recombinant organisms could be replicated in billions of copies through cloning. It was apparent to the involved scientists that they now had a tool for studying the structure and functions of genes and to probe the details of DNA and its transcription in cells of higher organisms. Biologists recognized that this would open up a new field of work, enabling the posing of fundamental research questions that would not have been feasible before. They expected that the answers to these questions would help solve problems at the forefront of knowledge with important applications.

Amid the excitement about the potential of the new recombinant DNA technique some of the conference participants were alarmed over its possible immediate hazards in their own laboratories. They were concerned that using some of these hybrid DNA molecules might cause unforeseen hazards to human health and the environment. There was a possibility that harmless microbes could be unintentionally changed into human pathogens through introduction of antibiotic resistance, which was part of the technique; through the production of dangerous toxins, which was a possible outcome; or through the transformation into cancer-causing agents of materials that previously were benign. In this relatively new field there was a great deal of uncertainty and little information about the hazards.

The Gordon Conference participants asked for a special discussion of these larger questions. At that brief special session, they decided to write a letter to ask the National Academy of Sciences to study the potential hazards and to devise a plan to do something about them. They voted by a large majority to compose the letter and they approved the content of it. They also voted, this time by a slim majority, to send a copy of the letter to be published in *Science*. The reluctance of many of the participating scientists to call public attention to the problem was an indication of a continuing conflict. They were concerned about a possible public health problem, and yet they feared that talking about it publicly might bring intrusion, as they saw it, into the scientific process. The Gordon Conference letter, replete with technical language, was intended for other scientists (1, pp. 70–80). It was published in *Science* in 1973 and did not generate much public attention (3).

THE BERG COMMITTEE LETTER

The National Academy asked Paul Berg, a distinguished biochemist and a principal researcher in the field, to

organize a group of scientists to consider the issues. They met at MIT on April 17, 1974, and planned a conference for February 1975 to evaluate the hazards of the research and ways of dealing with them. Feeling a sense of urgency, they also drafted a letter to alert the larger community of biologists. Two months after the MIT meeting, Berg described these actions and the group's motivations in a letter to a colleague in England:

> We met at MIT for a day and settled on the idea of calling a conference next February of those scientists working on methods of joining DNA molecules and particularly those involved in constructing hybrid DNAs. It was our plan that one of the major purposes of the Conference, besides a report on the scientific progress, would be a wide ranging discussion of potential hazards growing out of these types of experiments. Were there any experiments that should not be done? How could such a moratorium be proposed or enforced? In short, we expected a frank and searching review of what people were doing or wanted to do, particularly from the point of view of whether they should be done. But as we talked we realized that the pace of events might not wait for February and that some of the experiments many people would agree could be hazardous would be done by then (e.g., attempts to fuse portions of Herpes DNA to appropriate plasmids for cloning in *E. coli* were imminent). Since the technology for constructing hybrids has become ridiculously simple, that fear was well founded.
>
> Consequently we decided to devise a letter to be submitted to *Science* and *Nature* calling on scientists to defer certain kinds of experiments until these potential hazards could be better evaluated and certainly until there was an opportunity to discuss the issues at the February meeting (4).

Drafts of the Berg committee letter were circulated privately among the relevant scientists, and in July 1974 the final version was published in *Science* and in *Nature* (5). Why did the letter go public? Because the committee felt it was the quickest way to bring the potential hazards to the attention of the community of researchers who would be likely to use the new recombinant DNA techniques. They felt that the situation was urgent, because of pending experiments and because the power and fruitfulness of these research tools rapidly would attract many scientists to the field who were not experienced in handling pathogenic organisms. The letter called for a voluntary moratorium, a temporary deferral of those experiments which at the time were thought to be potentially hazardous. This appeal for self-restraint was linked to an end point, the conference scheduled for February 1975.

The response to the letter by the relevant scientific community was generally favorable. When the draft was read at the Cold Spring Harbor meeting in June, 12 of the European scientists in attendance immediately drafted a letter to John Kendrew, director of the European Molecular Biology Organization, requesting urgent consideration of the matter. They felt that it was essential that research utilizing the new recombinant DNA techniques be made possible in Europe by providing appropriate special risk laboratories.

When the Berg et al. "moratorium letter" was published in *Nature*, it was followed by responses from leading British biologists. Michael Stoker, head of the Imperial Cancer Research Fund wrote:

> No doubt a good many dirty tricks have been attempted and discarded by nature in the course of evolution, but the disquiet arises from the utterly novel associations of genetic material which are now possible. The potential benefits should, therefore, be delayed, not for ever, but until consequences can be assessed, and preliminary experiments carried out under conditions of maximum security. . . .[I]t is encouraging that the very leaders in the field have taken the initiative and have been supported by the [National Academy of Sciences]. It is now to be hoped that academics and learned societies in other countries will add their weight, and that international organizations such as the European Molecular Biology Organization will lend support. . . .For many it will be a test of self denial and social responsibility in the face of strong intellectual temptation (6, p. 278).

Kenneth Murray of the University of Edinburgh stated:

> The NAS request is both reasonable and responsible and deserves to be universally respected. It recognizes both the difficulty in evaluating real or potential hazards that may be involved in such work, as well as the obvious criticism that these will remain obscure in the absence of experimental study; urgent consideration of the latter is explicitly recommended. Fears that the proposed limitations to experiments will seriously obstruct research in vital areas of biology seem unfounded. The NAS initiative, by focusing attention on the hazards involved, could well promote rather than hinder work on in vitro recombination in animal viral systems, an area believed by many to hold the key to gene therapy in its broadest terms. . . .[I]f we follow the moderate tone set by the NAS we shall be careful not to oversell the social benefits devolving from recent experiments (7, p. 279).

THE 1975 ASILOMAR CONFERENCE

The February 1975 meeting at the Asilomar Conference Center in California evaluated knowledge in the field and its potential for research. It was the equivalent of an international review conference which ordinarily would be held well into the development of a research field and not at such a very early stage. The detailed review enabled the conference participants, who were the researchers and the potential researchers in the field, to consider the potential risks and ways to control them. The motive from the start was to avoid public interference and to demonstrate that scientists on their own could protect laboratory workers, the public, and the environment. Of course, there is that contradiction again: They were dealing with a public health issue and simultaneously attempting to keep the public out of it.

Initially it was not clear whether any media representatives would be allowed to attend the publically funded conference, but later the organizers decided to limit press attendance to eight invited reporters. A deal was struck with 16 journalists, most of whom were invited, that they would not report on the conference until it was over, because things would be too much in flux. That pleased the reporters because they did not have to call in stories to their editors every day. Instead, the telephone booths were jammed with scientists calling their laboratories in Europe and the United States about the need to tool up for this very exciting new research. The conference

gave them an opportunity to learn as much as possible about the recombinant DNA techniques, and it stimulated the growth of the field while producing a framework for pursuing it safely.

Several technical working groups met independently over a period of months in preparation for the conference. The most active was the Plasmid Working Group, focusing on the circular pieces of DNA which were the main tools for this new technique. They scoured the literature and their own knowledge, talked with other people in the field, and produced a detailed technical document (8). Reports of the working groups were presented and discussed at the meeting and one session was devoted to presentations of lawyers on policy and liability issues. Participants paid special attention to their legal responsibility for damage resulting from their laboratory work.

The narrow technical focus of the conference was evident in the opening remarks of David Baltimore, one of the organizers. He first acknowledged that the techniques that were developed could have applications in a number of areas, including biological warfare, and that it had larger societal implications, but that such issues would be excluded, since there was a full agenda of technical issues:

> The issue that ... [brings] us here is that a new technique of molecular biology appears to have allowed us to outdo the standard events of evolution by making combinations of genes which could be immediate natural history. These pose special potential hazards while they offer enormous benefits. We are here in a sense to balance the benefits and hazards right now and to design a strategy which will maximize the benefits and minimize the hazards for the future (9).

What happened at Asilomar? The recombinant DNA issue was defined as a technical problem to be solved by technical means, a technical fix. Larger ethical issues regarding the purposes and the long-term goals of the research were excluded, despite the rich discussions that had occurred among geneticists and other biologists in the 1960s about where to draw the line when it became possible to do genetic engineering. The 1960s discussions led to congressional proposals for anticipatory study of the ethical limits of genetic engineering, which were resisted as premature by several leading biologists (10). Instead of those longer-term issues, the focus at Asilomar in 1975 was on safety of the newly developed technical tools for genetic engineering, on the means not the ends.

The Asilomar participants adopted provisional safety guidelines based on a two-part system of physical and biological containment of potentially hazardous recombinant organisms (11). The extent of physical containment was graded according to the anticipated level of hazard an organism might present if it escaped the laboratory, ranging from good laboratory technique for those experiments deemed to be of low hazard, to hooded glove boxes, negative pressure, showers and clothes changes for laboratory workers dealing with organisms thought to be especially dangerous. Biological containment would introduce mutations in the organisms that were to be used in the experiments so that if they escaped they could not survive in the environment beyond the laboratory.

RECOMBINANT DNA ADVISORY COMMITTEE

In November 1974 the NIH had established the Recombinant DNA Advisory Committee (RAC), advisory to the director of NIH. The first meeting was held immediately after the Asilomar conference at the end of February 1975. RAC appointees were knowledgable researchers in the field, who were asked to develop and extend the Asilomar provisional safety guidelines to control all recombinant DNA work at institutions receiving NIH funding of any kind. They were designing safety protocols that had the potential for restricting their own work. These controls were to be administered by the NIH, which funded and encouraged the research and therefore was itself in a position of conflict of interest. NIH officials acknowledged the potential conflict, and maintained that although NIH was not a regulatory agency, it had the best expertise in the field and needed to act in the absence of any other government group playing a role. Similar efforts were also underway in other countries.

During 1975 and 1976 scientists on the RAC argued about whether the proposed guidelines were too strict or too permissive, and the document went through many drafts (12). All of this occurred in the absence of risk assessment experiments. At the same time scientists at laboratories throughout the country were tooling up to use the new technique and were impatiently waiting for the green light that would allow them to proceed as rapidly as possible. They exerted a great deal of pressure on RAC and NIH. The process of establishing safety rules involved a series of compromises aimed at achieving a consensus within that portion of the scientific community affected by the guidelines while providing assurances to the public that they would be protected from possible hazards.

LOCAL AND NATIONAL POLITICAL RESPONSES

The long expected NIH safety guidelines for recombinant DNA were approved by the director of NIH on June 23, 1976. On that day when the green light flashed, an extraordinary event took place in Cambridge, Massachusetts. Scientists from MIT and Harvard and representatives of NIH appeared at a special City Council hearing. They had been invited to explain to the citizens of Cambridge why the scientists themselves had been arguing about the safety of recombinant DNA and whether the guidelines were adequate to protect the communities in which the research was to be done. Was there any danger to citizens? Who was going to monitor and enforce the safety standards? Could the scientists and their universities be trusted to regulate themselves? Testimony by several biologists that recombinant DNA techniques posed few risks and that they could be contained by the new guidelines was countered by testimony from other biologists who argued that the guidelines were inadequate and that they were formulated by self-interested advocates of the research. After a second hearing in July 1976 the City Council established a citizens' review board to examine the problem and, pending the outcome of the board's deliberations, placed a temporary ban on experiments classified in the guidelines as posing moderate to major hazards.

The nine member Cambridge Experimentation Review Board met twice weekly for a total of more than 100 hours over a four month period. About one half of the time was used for testimony by scientists on both sides of the issue. The board presented its report to the city council on January 5, 1977, recommending the creation of a city biohazards committee to oversee adherence to the NIH guidelines for all recombinant DNA work in the city whether funded by NIH or not, and several additional safeguards on experimental procedures, containment and testing of organisms (1, pp. 302–307; 13). These community confidence building measures were incorporated in a city council ordinance passed in February 1977, which was the first recombinant DNA legislation in the United States and was interpreted as a qualified public endorsement of the NIH guidelines (14).

A major fear of the recombinant DNA scientists was that their own early concern about laboratory safety had initiated public scrutiny of the new research. This was emphasized by the events in Cambridge and in other communities such as Ann Arbor, Cambridge, San Diego, New Haven, and Princeton where academic biologists were tooling up to use recombinant DNA techniques. By 1978, 16 separate bills had been introduced in Congress to regulate recombinant DNA safety standards by making the NIH guidelines mandatory for both publically and privately funded research and providing enforcement and punishment provisions for any violations. Research universities and scientific organizations saw this local and national activity as public "overreaction" threatening their control of laboratory safety procedures and their research funding. They vigorously lobbied to oppose or influence legislation. Several prominent biologists who had shared the early concern about possible safety hazards of the research publicly recanted, and a resolution to Congress signed by most of the participants in a 1977 Gordon Conference stated that they previously had overstated the risks and now could provide reassurance that the work was safe (15). In the end no legislation was passed by Congress.

EVOLUTION OF RESEARCH GUIDELINES

By 1979 the NIH Recombinant DNA Guidelines had been made far more permissive than the original 1976 version. More than 90 percent of U.S. research in the field was either no longer covered by the guidelines or was subject to only minimal controls equivalent to standard laboratory practice. By 1982 most experiments subject to the guidelines were controlled at the local level through institutional biosafety committees and RAC reviewed only research that had the potential for special safety problems. No demonstrated harm had been caused by the research as conducted under the guidelines. A limited amount of risk assessment research had been done during that period, and several small consensus workshops of scientists in the field were held to review existing knowledge and to refute the earlier concerns (1,2). NIH's approach to the guidelines was that they would be flexible enough to respond to new scientific knowledge. That also opened them up to flexible response to pressures from researchers and their interests, pressures from industry, and pressures from national policy priorities and political interests.

BEGINNINGS OF COMMERCIALIZATION

Downgrading of the guidelines coincided with rapid commercialization of the field and the involvement of academic scientists in biotechnology companies. In November 1974 during the moratorium period, a patent for the recombinant DNA technique was filed by Stanford University and the University of California on behalf of two of the scientists who developed the technique. The patent was granted in 1980 after the Supreme Court decision allowing patenting of human-made organisms (16). Biologists and their universities became involved in what soon became almost a complete commercialization of the work. In the 1980s political climate of deregulation the U.S. biotechnology industry was promoted as a national priority. Emphasis was on government, industry, and media claims of medical, practical, and economic benefits of the research and the need to develop the industry. Critical questions about the health and environmental safety of research techniques and products were met by arguments that if the United States did not move forward rapidly in biotechnology, the country would lose out in international competition. The "gene gap" argument was deployed to resist special regulation of the field.

ENVIRONMENTAL RELEASE OF MODIFIED ORGANISMS

As the guidelines faded away for most laboratory work, attention shifted from the accidental escape of genetically engineered microorganisms to the intentional release of these organisms into the environment for agricultural purposes. The U.S. Department of Agriculture (USDA) and the U.S. Environmental Protection Agency (EPA), the agencies who would ordinarily become involved, initially claimed that they did not yet have the expertise to evaluate the possible hazards and they urged NIH to provide safety oversight for these applications through the RAC. Evaluation by the RAC seemed like a very comfortable approach for scientists and companies who had been working with it. In the absence of federal legislation for recombinant DNA, industry had been in voluntary compliance with the NIH guidelines. It was not until 1984 that EPA issued an interim policy statement on field testing of genetically engineered microbial pesticides. By that time NIH had approved proposals for small scale field testing of a genetically modified organism that was to be sprayed on strawberry and potato plants to prevent frost damage. The "ice-minus" controversy of the mid-1980s involved approvals by NIH, EPA, and California agencies, legal challenges by genetic engineering critic Jeremy Rifkin, congressional hearings, and protests and demonstrations by citizens in the community where field testing was to occur. As in Cambridge several years earlier the citizens asked, "Why are we the last to know?" The test plot was definitely in their backyard, but they were not informed of its exact location. They were also concerned

about unresolved safety questions raised by ecologists. By the time the tests were finally conducted in 1987, RAC's role in approval of environmental release of genetically modified organisms had been superceded by EPA (17).

HUMAN GENE TRANSFER EXPERIMENTS

The RAC also played a transitional role in the oversight of experiments in human gene transfer, generally referred to as gene "therapy" to reflect the as yet unrealized hopes of its advocates. In 1983 the RAC responded to the report of the President's Commission on Bioethics' study of genetic engineering which considered several approaches to the oversight of future human genetic engineering. The commission's study was initiated after the leaders of the three major U.S. religious groups wrote a letter to the President stimulated by the 1980 Supreme Court decision permitting patenting of genetically engineered organisms. They called for study of the ethical issues associated with genetic engineering and observed that "no government agency or committee was currently exercising adequate oversight or control, nor addressing the fundamental ethical issues in a major way" (18). RAC's response to the Commission's report was to establish a Working Group to consider whether it would review proposals for human gene transfer. In 1985 RAC's "Points to Consider in the Design and Submission of Human Somatic Cell Therapy Protocols" was issued by NIH. The RAC said it would be willing to review proposals for human gene transfer protocols for somatic cells but would not "at present entertain proposals for germ line alterations" (19,20). When pressed by a public interest group, the Council for Responsible Genetics, to specifically ban human germ-line engineering, the committee refused. Leroy Walters, the bioethicist who had been for many years a member of RAC and was the head of its human gene therapy subcommittee, subsequently argued that in his view voluntary programs of germ-line genetic intervention were "ethically acceptable in principle" (19).

Gene therapy became the primary task of the group in the late 1980s, and since then it has dealt with the scientific validity of proposals as well as risks for human subjects, the adequacy of informed consent, the role of local institutional review boards, and the liability of researchers. RAC nurtured the development of human gene therapy by applying the clinical standards of biomedical ethics, but bypassed the larger ethical issue of whether it should be done at all. The role of RAC remained as advisory to the director of NIH. In 1995 the Food and Drug Administration (FDA) became the regulatory oversight agency for human genetic engineering, with RAC playing an advisory role in reviewing proposals involving novel techniques or applications (21–24). The adequacy of this approach was questioned by Congress and government agencies when revelations and allegations about violations of regulations were reported in the media in September 1999. These included abuses of informed consent procedures, failure to report adverse effects and harm to human subjects, and possible commercial conflicts of interest. Several clinical trials were shut down by FDA and the situation was under intense review in 2000.

LIMITATIONS OF SELF-REGULATION

Throughout RAC's history — from its creation in 1974 to deal with initial concerns about laboratory safety to its current role in human gene transfer experiments — it has been friendly to researchers and dominated by their interests. At the same time the work of the committee has been relatively open and visible. NIH made efforts to create a full public record of RAC deliberations and documents in addition to the announcements of meetings, proposed changes in the guidelines and decisions required to be published in the *Federal Register*. However, very few citizens read that relatively inaccessible, small print publication. Nor do many people have the opportunity to travel to Bethesda, Maryland, to sit in on committee meetings. The RAC minutes list the noncommittee members who attended the meetings. As the commercialization of genetic engineering increased from 1980 on, the record shows that representatives of companies were consistently present to follow the deliberations and look after their interests.

Public participation on the RAC was broadened in 1978 in response to complaints that it was dominated by self-interested researchers. Yet there were built-in limits and constraints to this participation because most of the issues placed before the committee were technical and often beyond the expertise of the nonscientists. Another problem was that RAC was increasingly asked to review industry proposals. Biotechnology companies were in voluntary compliance with the guidelines and sought NIH approval for their recombinant DNA work with the condition that proprietary information would be kept confidential, as was the practice with federal regulatory agencies, even though NIH was a research-supporting agency. As a result, public representatives on the committee frequently were not able to report to the public about information relevant to environmental and public health.

The development of genetic engineering clearly involves more than the safety issues that have been the major focus of RAC's mandate and activities. The larger ethical concerns about where to draw the line in applications of genetic engineering were occasionally discussed when raised by some members of the committee or at the request of outside groups. RAC, however, resisted taking a stand against the use of recombinant DNA techniques for biological warfare and refused to recommend an unambiguous ban on the review of proposals for human germ line intervention (25). Instead, RAC's emphasis was to develop safe procedures for the research, focusing on *how* to do it rather than *whether* it should be done. As Leon Kass observed in 1997, "the piecemeal formation of public policy tends to grind down large questions of morals into small questions of procedure" (26). Recombinant DNA research was safer as a result of the NIH guidelines developed by RAC. The biologists at Asilomar in 1975 and the subsequent generations of RAC members raised important safety issues and set standards for good laboratory practice.

Despite the success in improving the safety of research, the quasi self-regulation model developed in the recombinant DNA controversy is not adequate for expressing and enforcing societal and moral limits for

potential genetic engineering applications such as human cloning or human germ-line interventions. These potential applications are not inevitable, and they raise profound issues beyond laboratory and environmental safety and patients' rights. They occur in a context of increasing genetic determinism, pervasive commercialization, and aggressive efforts to sell genetic intervention as a cure-all for medical and even social problems. Separation of the technical issues from the ethical issues, and the narrowing of ethical concerns to clinical biomedical ethics, limits meaningful public involvement and obscures the larger picture.

ACKNOWLEDGMENT

This historical summary draws on my observations and documentation of the recombinant DNA controversy from 1975 to the present, utilizing archival materials and interviews collected from 1975 to 1979 in a project under my direction and deposited in the Recombinant DNA History Collection available for study at the Institute Archives and Special Collections, Massachusetts Institute of Technology. Portions of this account are included in C. Cranor, ed., *Are Genes Us? The Social Consequences of the New Genetics*, 1994, pp. 31–51 and C. Weiner, *Health Matrix* **9**, 289–302 (1999).

RELIGIOUS VIEWS ON BIOTECHNOLOGY, BUDDHISM

RONALD Y. NAKASONE
Graduate Theological Union
Berkeley, California

OUTLINE

INTRODUCTION

The modifications and improvements of living organisms, including human beings, and the development of microorganisms through biotechnology to produce or modify products to improve plants or animals challenge Buddhists to reexamine their doctrines, sharpen their interpretative insights, and expand their moral imagination. Buddhist views on biotechnology require an understanding of the spiritual goals that govern the Buddhist life, its doctrines, and the practical demonstration of its ideals. This article begins with a review of Buddhism's origins and spread, continues with a description of the major doctrines, and surveys selected Buddhist responses to biotechnology. Since modern science and technology and population increases have resulted in problems neither confronted nor anticipated by the Buddha and, until very recently, by Buddhist thinkers, this article also describes the Buddhist attitude toward change and new knowledge. Buddhist attitudes toward scientific and technological manipulation of human beings and nature, however, are often tempered by indigenous traditions such as Confucianism and Shinto, by modernization, and by Western culture.

Buddhist interest in biotechnology is relatively recent, and its impact has been felt most keenly in technically advanced countries, such as Japan, and technologically advanced regions of China and other countries. Buddhist thinkers of Third World countries and their devotees who struggle to survive from day to day are concerned with agricultural yields, clean water, political stability, and basic medical care. The dearth of reflections on biotechnology from developing countries such as Cambodia, Laos, and Vietnam indicate their preoccupation with meeting basic survival needs. For these Buddhists exotic high tech innovations, such as mapping of the human DNA or organ transplants, are inconceivable luxuries. While Buddhist thinkers in Japan are reflecting on biotechnology, their thinking is dominated by modern Western bioethical paradigms. They are, however, beginning to reshape questions into Buddhist categories and envisioning Buddhist solutions. The speeds at which change is taking place and new possibilities are emerging, outpace, at least for the moment, religious and moral thinking.

ORIGIN AND SPREAD

Siddhārtha Gautama (563–483 B.C.E.) (1) founded the Buddhist faith and community in what is now northeast India and Nepal. The community remained a single unit until about a hundred years after the founder's death. Disagreements centering on the status of the *arhat*, the archetype personality, the status of Śākyamuni, the historical Buddha, and the *vinaya*, the monastic rules of conduct, split the early community into the Sthavira and the more liberal Mahāsaṅghika. The Sthavira argued for the perfectibility of human-nature in the guise of the *arhat*, the humanity of the historical Buddha, and strict observance of the *vinaya* outlined by the Buddha. Present-day Theravāda, an offshoot of the Sthavira, claims to observe the faith established by its founder. The Mahāsaṅghika, on the other hand, believed that the *arhat* is not completely free from impurities. Its devotees understood Śākyamuni to be a manifestation of a transcendental Buddha who is pure, infinite, and eternal. The tradition stressed the spirit of the *vinaya*, not its letter. These initial disagreements led to further splintering. Buddhist documents mention the existence of as many as 34 monastic sects between the second and fourth centuries after the Buddha's passing.

The origins of Mahāyāna (great vehicle) Buddhism is obscure. Many scholars believe that Mahāyāna (2) emerged during the two centuries between 100 B.C.E. and 100 C.E. from ideas advanced by the Mahāsaṅgika and related sects, and as a reaction against the aloofness of the monastic sects. Others, notably Akira Hirakawa, a Japanese Buddhologist, argue that Mahāyāna began as a lay movement that appeared immediately after the death of the historical Buddha. These devotees who honored the memory of the Buddha at the *stūpas*, memorials that housed his relics, evolved over time their own liturgies, doctrines, and institutions (3). Still others argue that Buddhism's encounter with non-Indian peoples and ideas and the increased influence of the laity stimulated the monastic tradition to redefine their goals, iconography, and doctrines to be more inclusive. These early Mahāyānists referred to themselves as *bodhisattvas*, "beings who aspire for wisdom." The bodhisattva, an outgrowth of the idealization of the historical Buddha, vows to save all beings before he or she achieves full enlightenment.

After subduing his adversaries, the Gupta king, Aśoka (circa 274–236 B.C.E.) embraced the Buddhist faith and sent missions throughout India, Sri Lanka, North Africa, Macedonia, and Central and South Asia. These missions initiated the gradual spread of Buddhist and Indian culture. Sri Lankan chronicles report the establishment of Theravāda Buddhism in the later half of the third century B.C.E. By the eighth century C.E. Indian culture, including Buddhism, stretched from the east coast of the Indian subcontinent all the way to Vietnam, and Bali in the Indonesian archipelago. Theravāda eclipsed Mahāyāna and remains dominant today. Buddhist missions did not leave a lasting impact in North Africa and the Near East. Meanwhile, to the north, Buddhism fared better. It had a well-established presence in Central Asia by the second century B.C.E. Among the many schools, Mahāyāna and the Sarvāstivāda, an influential branch of the Sthavira linage, were the most strongly represented. Buddhist culture established itself in Khotan, Kucha, Turfan, and other city states that straddled the caravan routes to China. Buddhism entered China sometime during the first century B.C.E. and the beginning of the common era (4), and gradually became an integral part of the national life. Distinct Chinese forms of Buddhism emerged between 500 and 800, its most prosperous and creative period. Buddhism continued its eastward advance into Manchuria, Korea, and Japan. It officially entered Korea in 372, and by about 525 had penetrated the entire peninsula. Buddhism arrived in Japan in 552. After six hundred years, the Japanese evolved forms of Buddhism that suited and reflected their temperament.

Mahāyāna in the form of Vajrayāna, later called Tantric Buddhism, traveled to Tibet in the seventh century.

It conceived the Buddha as a cosmic body and as the substance of all things and all beings. By harnessing the forces that pervade the universe, the devotee can achieve Buddhahood in this very life and this very body. Tibetan monks carried their faith to Mongolia in 1261 and again in 1577. The fourteenth Dalai Lama (1935–), the spiritual and secular leader of Tibet, fled his occupied country in 1959 with tens of thousands of other Tibetans. The Chinese claim that Tibet has always been part of China.

Since the mid-nineteenth century when Chinese laborers joined the California gold rush, Asian immigrants have carried their Buddhist faith to Hawaii, North and South America, and other parts of the globe. The 1893 World's Parliament of Religions in Chicago introduced Buddhism and other non-Christian faith traditions to the West. The United States and other Western nations today have sizable ethnic Buddhist communities. D.T. Suzuki (1870–1966) and Alan Watts (1915–1973) popularized Zen Buddhism at midcentury and spawned a still small, but vital American–Buddhist community. Political refugees from Southeast Asia introduced Theravāda Buddhism during the latter half of the century. At present, Theravāda Buddhism is dominant in Sri Lanka and the Southeast Asian countries of Burma, Kampuchea, Laos, and Thailand. Mahāyāna exists in North and East Asia. Tibet, Mongolia, China, and Japan have substantial Buddhist populations. In a once Buddhist country, South Korean Buddhists constitute about one-fourth of the current population of 50 million. The social reformer and former Minister of Law, Bhimrao Ramji Ambedkar's (1891–1956) conversion to Buddhism in 1956 generated a Buddhist rival in India after 700 years of its disappearance from the land of its origin.

BELIEFS AND DOCTRINES

Siddhārtha Gautama began his spiritual journey with the question of human suffering that accompanies old age, sickness, and death. After six years of spiritual exercises Gautama realized the Dharma, the truth of *pratītyasamutpāda* (dependent co-arising or interdependence) and became the Buddha, "the Enlightened One." The Buddha awakened to the truth that all things and all beings are mutually related and mutually dependent. *Pratītyasamutpāda* represents the ideological content of the enlightenment and is the common theme throughout Buddhist thought and practice (5). The history of Buddhist thought can be understood to be simply an unfolding of the implications inherent in this central idea.

This overview begins with a discussion of the temporal and relational aspects intrinsic to *pratītyasamutpāda*. It proceeds to explain the notions of *karma*, *samsara*, *nirvana*, *anātman*, and other key Buddhist ideas, and the Four Noble Truths within the context of *pratītyasamutpāda*. The following section, The Buddhist Posture, discusses the implications for our interest in biotechnology.

Pratītyasamutpāda can be understood to be an extension of karma, the law of cause and effect. The idea of karma, literally "action," appeared approximately two or three centuries before the birth of Siddhārtha Gautama and is closely associated with the notions of samsara, literally "passage," and personal responsibility. There are three classes of karma: good, bad, or morally neutral. An individual's present station in life has been determined by the moral quality of action, or karma, generated in the past. Deeds committed in the present life affects one's status in the next. Buddhists divide karma into three categories: mental, verbal, and physical. Early Buddhists exerted considerable effort debating whether the essential nature of karma is mental or physical. Theravāda concluded that the mental is the essence of karma. Volition, which is mental activity, generates verbal and physical action. It is thus essential, if one wishes to realize nirvana or spiritual peace, to quicken thoughts that generate behavior that lead to that end. The notion that it is not possible to escape the consequences of one's deeds is intrenched in present day Theravāda Buddhist cultures. Sri Lankan Buddhists, for example, explain the death of an impaired infant as the result of the working of karma (6). Present-day Thai women considering abortion of a HIV-afflicted fetus or an unwanted pregnancy from rape or forced prostitution weigh the consequences of an unfavorable rebirth from their poverty as they struggle to be faithful to Buddhist teachings (7). While the idea of karmic retribution is also very strong among Mahāyāna devotees, the inexorable consequence of karmic action is mitigated by the compassion of Buddhas and Bodhisattvas.

The ideas of personal karmic retribution and successive lives are part of the fabric of popular Indian thought and played a key role in the development of Indian Buddhist doctrine. Rebirth, however, is not a necessary tenet of the Buddha's teaching and was not central to the development of East Asian Buddhist thought. Chinese, Korean, and Japanese beliefs in spirits and soul were not based on rebirth (8). Moreover the Buddha maintained that claims of rebirth, like questions of whether life continues after death, are not empirically verifiable and cautioned against such speculations. Does the Enlightened One exist after death? Or not exist? are two of 10 questions that the Buddha refused edification. Hakuin, (1685–1768), the Japanese cleric, offered a similar response when a wealthy parishioner queried about the nature of death: "Why ask me?" The parishioner replied, "Because you are a Buddhist monk." Hakuin retorted, "But not a dead one." Rather than engaging in endless speculation, the Buddha proposed that we deal directly with those problems that will ease human suffering and lead to spiritual ease.

In addition to the temporal understanding of karma, *pratītyasamutpāda* also describes the simultaneous presence of cause and effect. The individual threads of the warp and woof of a piece of fabric illustrate this expanded notion of karma. Individual threads constitute the entire fabric; the fabric in turn defines each thread in relation to all other threads. The metaphor illustrates the mutual dependency of cause and result and, by extension, the mutuality of all things. In a mutually dependent universe each individual does not simply exist in the world. By being involved in the world, he or she helps to create the world through the manner in which he or she thinks, speaks, and lives. This understanding of *pratītyasamutpāda* provides a vision of identity and responsibility to all beings and all things, and

quickens a sense of gratitude for all things and beings. *pratītyasamutpāda* dissolves the preoccupation with the self and gives rise to sentiments of compassion and service to others.

Mahāyāna documents that appeared during the first century of the common era interpret *pratītyasamutpāda* to be compassionate and morally purposeful. The *Larger Sukhāvatīvyūha sūtra* casts the doctrine of *pratītyasamutpāda* in the myth of the Bodhisattva Dharmākara, a spiritual hero who vows to forgo supreme enlightenment until all beings enter the Pure Land, the realm of spiritual ease. Dharmākara and other spiritual heroes accomplish this monumental task by transferring the vast store of merits they have accumulated over innumerable eons to the spiritually impoverished. *Pariṇāma*, or the transference of merit, is a soteriological idea based on the belief that an individual's life is irrevocably linked with all beings and things. Bodhisattvas and Buddhas do not literally withdraw merits from their merit repositories and deposit them in another's. Merits are "transferred" in the sense that we benefit from their spiritual exercises. *Pariṇāma* softens the harsh and uncompromising individualism of karma. In contrast, the rigidly individualistic view of karma dissolved society into isolated individuals, and it fails to acknowledge the mutuality among all beings and the complexity of the human experience. Also in an interdependent world, countless karmic forces intersect to often thwart our noblest intentions and propel us to violate our deepest instincts.

Though Theravāda and Mahāyāna Buddhism emphasize differing aspects of *pratītyasamutpāda*, they agree that change is the nature of reality, that suffering is endemic to the human condition, and that *nirvana* or spiritual bliss is a transcendent reality. For Theravāda, *nirvana* means the transcendence of *samsara*, the realm of suffering that is associated with change. Mahāyāna, on the other hand, identifies *nirvana* with *samsara* and thus speaks of spiritual release in the world of change. Both traditions assert the doctrine of *anātman* (non-self) which allows a person to identify and empathize with others. Early Buddhists explained *anātman* by analyzing the body and mind through five aggregates: form, sensation, perception, mental formations, and consciousness. A person, composed of these five constantly changing and mutually dependent aggregates, is devoid of a substantial and abiding self. Further investigation by the early Buddhist thinkers expanded these 5 categories into 75 dharmas or elements of existence. Eventually form was interpreted to include all material things. Mahāyāna accepted the view of the non-self but advocated a more radical view that dharmas themselves are without substantial and enduring reality. The Mahāyāna view is supported by the *prajñapāramitā hṛdaya sūtra* or Heart Sutra which proclaims: "Form is emptiness [*śūnyatā*] and emptiness [*śūnyatā*] form." Later Nāgārjuna (circa 150–250), a Mahāyāna thinker, asserted "*Pratītyasamutpāda* is *śūnyatā* [emptiness]." The empirical person, the result of the coming together of countless dharmic elements and conditions correlates with "form." "Emptiness" of the self in early Buddhism evolved to designate the intrinsic reality of an individual devoid of all accidental characteristics or *śūnyatā*. *Śūnyatā* thus refers to the "suchness" or "thusness" of the person.

The Buddhist notion of *anātman* came under stiff attack. Critics asked: "If there is no-self, how does one account for the need for rebirth? Who is the agent responsible for action and change? Who becomes enlightened?" These questions arose from a misunderstanding of *anātman*. While the Buddha spoke against the psychological and nonrelational reality of an independent self, he never denied the ontological self (9). The *anātman* doctrine describes a relationship whereby any given person or thing derives its being and meaning, not from itself but from its relations with others. Simply, each individual is defined by his or her role in society and is affirmed by his or her interactions with others. Partly as a reaction against its critics and to affirm the great reverence for the "empty" and ontological self, Buddhists postulated such notions as Buddha-nature, *ālayavijñana* (storehouse consciousness), and *tathāgathagarbha* (womb of the *Tathāgata*, one who has touched the shore of *nirvana*) that posit an underlying reality on which the affectations occur. The significance of an ontological self is further emphasized by the observation in the prologue to the *Tri-śarana-gamana* or Threefold Refugees recited daily by Buddhists, that the appearance of an individual in the world is a rare event. The Japanese cleric, Dōgen (1200–1253), and the aesthetician and art critic, Yanagi Sōetsu (1898–1961) expanded the notion of the intrinsic value sentient beings to include things. Dōgen asserted that even inanimate objects are Buddha-nature (10). Yanagi spoke of enlightened things (11).

While the doctrine of *pratītyasamutpāda* describes the Buddhist understanding of reality and is the rationale for karmic interaction, the Four Noble Truths crystallize this doctrine's existential import. According to Buddhist lore, the lesson of the Four Noble Truths is the first the Buddha shared after the enlightenment. It relates directly to the doctrine of *pratītyasamutpāda* as a moral principle based on a reworking of the law of karma. The Four Noble Truths, an empirical–rational methodology that is closely associated with ancient Aryadevic medicine, parallels the steps — diagnosis, etiology, recovery, and therapeutics — that summarize the medical treatment of a disease. The Four Truths profile the condition of our lives, explain the cause of suffering, and the means by which we, residing in a samsaric world, can extract ourselves and realize an abiding spiritual reality. The Four Truths are (*1*) the Noble Truth of Suffering, (*2*) the Noble Truth of the cause of suffering is illusion and desire, (*3*) the Noble Truth of Nirvana, a realm free from suffering, and (*4*) the Truth of the Noble Eightfold Path is the way to enlightenment or nirvana. The Eightfold Path consists of Right View, Right Thought, Right Speech, Right Action, Right Livelihood, Right Effort, Right Mindfulness, and Right Meditation. In the First Truth, the Buddha acknowledges that spiritual suffering, though the most serious, was just one of many ills. The cause or etiology of this suffering, the Second Truth, stems from illusion and desire. Illusion is the belief in a substantial self and an unchanging world, and desire refers to wishing for unattainable things. The Fourth Truth is the Eightfold Noble Path that releases the individual from ignorance and delusion. The Eightfold

Path is the medicine or spiritual therapy that leads to the Third Truth, wisdom or nirvana.

The Four Noble Truths outlines a method to transcend, not escape suffering through understanding. In the *Vissudhimagga*, Buddhaghosa (circa 400 C.E.), the great Theravāda commentator, correlated the four phased method, for spiritual health systematized in the Four Noble Truths, with the treatment of a disease. "The truth of suffering is like a disease, the truth of origin is like the cause of the disease, the truth of cessation is like the cure of the disease, the truth of the path is like the medicine" (12). Modern Buddhists have applied the four-step method outlined in the Four Truths to remedy social and economic problems. The Sarvodaya Shramadana Movement, a rural self-help program initiated by Ahangamage Tutor Ariyaratnes of Sri Lanka, is the most celebrated example. Since the 1960s Ariyaratnes and his method have empowered poor villages to recognize their problems, discern their causes, envision solutions, and devise remedies.

THE BUDDHIST POSTURE

A vision of an interdependent world affirms the reality that we live in a complex, ever-changing web of interrelationships. This vision allows for important implications when thinking about ethical, legal, and policy issues concerning biotechnology. This brief section begins with a sketch of the ideal relationship between the whole and part explicated by *pratttyasamutpāda*, proceeds to discuss some of its inherent difficulties, and concludes with a some thoughts of the virtues of deliberation in the context of an interdependent world.

Ethical, legal, and policy deliberation and exercise that posit an interdependent world consider a microscopic view along side a macroscopic one. The symphony offers an analogy. To grasp the beauty in a Beethoven symphony, for example, it is not enough to listen to the individual instruments sequentially. One must hear the instruments together, as each musician modulates his or her instrument and timing in response to the other instruments. Each instrument participates in creating a greater whole. The whole in turn gives value to the sounds from each instrument. The microscopic and the macroscopic resonate together.

Like a symphonic composition, in the Buddhist vision of the world, we are parts of a larger whole. The whole in turn gives each individual value and worth. The idea of interdependence links our individual lives to each thing and each being in the universe. To act according to this vision is to work to nurture the lives and relationships that enrich and sustain the life of individuals and the whole universe (13). Such an interpretation of life dictates the various virtues and ends that Buddhists should consider when reflecting on ethical questions, legal issues, and formulating policies. A sense of fair play, compassion, gratitude, humility, and patience are some virtues to nurture and consider when reflecting on such questions as health care, allocation of resources, relating to the most vulnerable in our society, the environment, biodiversity, and the manipulation of life.

This harmonious ideal is difficult and almost always impossible to realize. In a world where lives are inexorably intertwined, like ice and water, our concern should be extended to all beings. In a practical sense, our energies should focus where we can make a difference, before extending our energies to embrace all lives and relationships. The Japanese cleric, Shinran (1173–1262) reiterates this attitude in his fourteenth letter of the *Mattōshō*, "the one who first attains nirvana vows without fail to save those who were close to him first and leads those with whom he is karmically bound, his relatives, and his friends" (14). Additionally our life experiences we are often beset by conflicting demands and responsibilities. Our wishes are continually frustrated by the demands of others and by events beyond our control. While some forces nurture our lives, others demean. In the Thirteenth Chapter of the *Tan'nishō*, Shinran underscores the reality that we are often swept up in events that thwart our best intentions. In his conversation with Yuienbō, a fellow devotee, Shinran says, "It is not that you keep from killing because you are good. A person may wish not to harm anyone and yet end up killing a hundred or even a thousand people" (15). Since our lives are intimately linked with the karmic tide of others, to society, and even the whims of nature, we may be propelled to violate our deepest moral instincts. Under those circumstances we yield — mournfully and perhaps, even justifiably — to the dictates of more powerful karmic forces. In such a world the best that we can hope for, according to Thich Nhat Hahn, the Vietnamese monk, is to be determined to go in the direction of compassion and try to reduce suffering to a minimum (16). The exercise of compassionate aspirations, no matter how insignificant, is based on the belief that an act of kindness resonates throughout the farthest reaches of the universe.

A vision of an interdependent world recognizes the complexity of even the most common event. The quiet unfolding of the morning glory is supported by the entire universe. Fa tsang (643–712) articulates the complexity of this singular event in his Ten Subtle Principles of the Unobstructed Fusion of *Pratttyasmutpāda* (Shih-hsüan-yüan-ch'i-mu-ai-fa-mên). He reasoned that in an interdependent world no dharma (thing or event) is independently established and thus all dharmas are mutually supportive and mutually dependent within the *dharmadhātu*, the realm of dharmas; each dharma is thus of equal importance. However, when a dharma is arbitrarily singled out for consideration, that particular dharma becomes the principal dharma and the remaining dharmas take on a secondary role. Each dharma has the potential of alternately assuming the principal role or a secondary role. The role a dharma assumes is determined by what is weighed to be important at any given moment. Moreover each cause and condition offers a different perspective of how a thing or event arises. No thing or event is ever the locus of attention for everyone. The construction of a much needed new bridge, for example, requires the approval of many public agencies and private interests. The necessity of efficient and reliable thoroughfares must balance commercial, environmental, engineering, aesthetic, and other needs

of the community. The environmentalists concern for biodiversity relegates commercial interests to a secondary concern. The engineer is concerned first with structural integrity, rather than aesthetics. Knowing that we live in an interdependent world means that we may never resolve issues to everyone's satisfaction.

Predicaments also arise from competing interests as well as conflicting perspectives. We may never know for certain how a specific event transpired, as Akira Kurosawa (1910–1998) dramatizes in *Rashamon*. In this murder mystery we hear the testimonies of the bandit, the police agent, the woman who was raped, and through a shaman, the murdered husband. Each individual relates a slightly different version of the circumstances that surround the murder. The film ends without a resolution. Often we must deliberate, make decisions, and act knowing we are unable to reconcile or understand completely differing perspectives. Appreciating the complexity of an issue permits us to see many points of view and is perhaps the most productive way of ethical deliberation and action. We nurture humility and patience knowing that others may not approve or follow our example. Living with and appreciating alternative points of view is reminiscent of a Cubist painter who renders an object from different viewpoints. In contrast, perspective, a visual rendering technique perfected during the European Renaissance, renders an object from a single-fixed point.

Acknowledging the validity of other points of view, the Buddha urged his would be followers not to accept any of his teachings without first critically examining them. Only if any of his teachings lead to spiritual ease, should they be observed and accepted (17). Other paths may be more suitable for one's particular temperament. The Buddha insisted that he was a guide, not an authority. The Buddha's critical attitude toward religious authority, even his own, is seen in Thich Nhat Hahn, a Vietnamese monk whose experiences of the Vietnam War forced him to reinterpret and condense the traditional Buddhist precepts into Fourteen Precepts for Engaged Buddhism. The first Precept reads: Do not be idolatrous about our bound to any doctrine, theory, or ideology, even Buddhist ones. Buddhist systems of thought are guiding means; they are not absolute truth. Explaining this precept, Thich Nhat Hanh writes that clinging to our views can cause us to lose the opportunity to a higher and more profound view of reality. By being open to other points of view, we expand the frontiers of our knowledge and our understanding of the world (16).

BUDDHIST MEDICINE AND HEALTH CARE

Health and health care are metaphors common to Buddhist thought and practice. The Buddha, the great physician, dispenses the Dharma, the medicine that heals humanity's suffering and brings spiritual ease. To the terminally ill he administers the teaching of impermanence and to others meditative exercises. Though spiritual suffering was of paramount concern, the Buddha understood that spiritual well-being necessarily involved physical health, which in turn, is dependent on a wholesome community and its sound management of economic and other resources. The Buddha and his devotees attended to their spiritual ills through self-cultivation, and served as nurses to the sick by dispensing medicine and compassionate deeds. While illness testifies to the frailness and transiency of the human condition, caring for the sick is also an opportunity for spiritual quickening. The sick, in turn, have an opportunity for abundant giving. Spiritual health means to realize and to live with gratitude and responsibility to all things and beings. This section begins with an overview of health and health care within the context of the early Buddhist theory of medicine. It then proceeds to discuss caregiving and the relationship between the caregiver and the patient.

Medical Theory

Grounded in the belief of an interdependent world, Buddhist medical theory understands mind and body to be a single unit. Illness of the body is illness of the mind, and mental illness is directly related to the illness of the body. Health requires balance and reciprocity among all the four elements: earth or the solid element, water or the wet element, fire or the hot element, and wind or the mobile element, and the three peccant humors of wind, phlegm, and bile that constitute the human body. Illness arises when one or more of these elements experience an abnormal augmentation or diminution. Medicine and medical therapies provide the means to restore and maintain a healthy physical balance. By contrast, present biomedical diagnostics understand the body to be made up of distinct divisible parts, whose organs and functions can be isolated and treated. Modern etiology seeks the sources of disorder from external pathogens, rather than internal disorders. While Buddhist physicians traced the etiology of disease to empirical causes, karma or past action is also a category of medical etiology. Past deeds relate to present mental suffering caused by greed, hatred, and doubt.

In addition to the disequilibrium among the four elements and the three humors, Buddhist medical theorists understood that external and societal conditions affected the internal working of the body and cause of disease. Diet, daily regimens, alteration of the seasons, stress from unusual physical activities, and past actions affect one's physical and mental well-being. In keeping with the belief that prevention is the best guarantee against illness and disease, the Buddha urged moderation in spiritual exercises and in all life activities. His monastic rules emphasized personal hygiene and public health. Straining water served to purify it and to prevent consuming water-dwelling organisms. Living quarters and privies were to be kept clean. Even today in Zen monasteries in Japan, certain days are set aside for washing and mending.

The Buddha traced much of human illnesses to poverty. The poor, he reasoned, had limited access to material and nonmaterial resources that ensured basic necessities: food, clothing, shelter, medicine, and education (i.e., spiritual development). A Buddhist state would have the responsibility to provide a wholesome living environment by safeguarding the natural environment, by ensuring

the equitable distribution of resources, and protecting the poor and dispossessed against exploitation. These measures would optimize psychological and physical well-being, the basis on which to nurture spiritual development. The Buddha placed a high value on physical fitness and freedom from illness as a basis for mental and spiritual development. "When sentient beings have sick bodies, their minds cannot be at peace ... the bodhisattva who would cultivate awakening should first minister to the illness of the body" (18). This holistic approach to health and healing resonated within Taoist- and Confucian-based Chinese medicine. Both Buddhist and Chinese medicine do not distinguish between mind and body. In addition to the yin and yang theory which is based on harmony of the universe, the Chinese included the connections between a well-functioning social system and a healthy body.

Caregiving

Medicine and caregiving were integral parts of the early Buddhist community. The model for caregiving is the Buddha himself. On an occasion, the Buddha chanced on an unattended sick monk wallowing in his own excrement. He said, "O monks, if you do not nurse one another, whoever will nurse you?" Thereupon the Buddha bathed the monk, changed his garments, and laid a bed for his ailing comrade. This experience led the Buddha to declare, "Anyone who wishes to make offerings to me, let him make offerings to the sick." Initially the early community focused medical treatment and nursing activity on the care of monks and nuns by fellow cenobites or by pious lay devotees. Caring for their compatriots became part of the monastic code. From around the mid-third century B.C.E. medical care was extended to the population at large. Later the medical arts became part of the curriculum at Nalanda and other monastic universities.

Buddhist documents abound with medical injunctions and prohibitions. The *Aṅguttara Nikāya* lists the five qualities of those who tend to the sick. It also lists the five faults of a patient that impede his or her recovery. The competent caregiver (*1*) possesses knowledge of medicaments and their application, (*2*) tends to the sick with amity of mind and without thought of personal nourishment and profit, (*3*) is not lazy, (*4*) or prone to annoyances and does not loathe removing excrement, urine, sweat, or vomit, and (*5*) since the early Buddhists linked illness with mental states gone awry, the competent caregiver should delight in sharing the Buddha's Dharma and conversing with the sick (19). Conversing requires the art of listening which is personified in Avalokiteśvara, the Bodhisattva of Compassion. "Avalokiteśvara" or "Kanzeon," the Japanese rendering, clearly captures the Bodhisattva's special talent. "Kan" means "to hear," "ze" means "world," and "on" means "sound." Avalokiteśvara who hears the pleas of the world, is the ideal caregiver. Listening to the outbursts of anger, despair, and hurt, the Bodhisattva attends to the journeying spirit, not the momentary stammer. When we engage in conversation and allow another to speak, we act as a midwife who helps to bring new life into the world. By listening, we allow for self-discovery that gives birth to a new being.

Patient Responsibility

The vision of an interdependent world requires a patient's involvement in his or her care. The *Aṅguttara Nikāya* lists five faults of the patient that discourage healing. The patient impedes his or her healing (*1*) by not being selective of what he or she eats or drink, (*2*) fails to take nourishment at the proper times, (*3*) refuses to take medicaments, (*4*) abandons him or herself to melancholy, merriment, and annoyance, and (*5*) is pitiless toward the sick nurse (20). In addition to cooperating with nurses to hasten health, one can use his or her illness as the occasion for spiritual exploration and abundant giving. Vimalakīrti, the most famous invalid in the Buddhist canon, describes the responsibility of the sick:

> Through one's own experience, a Bodhisattva should have sympathy with the sick person. Let them know of the pains they suffered from the infinite past, but encourage them by advising them to endeavor and become the Buddha, the Great King of Medicine and cure the illness of all people ... (21).
>
> Though the body may be in the world of delusion and diseased, if one gives abundantly and tirelessly, that is called expedient means. The body may not be freed from the disease and the disease may not be freed from the body, but if the disease and body are seen neither as new nor old, that is called wisdom. Though the body may be diseased, if one does not forsake this world and does not intend to enter Nirvana, that is called expedient means (22).

Should we choose to heed Vimalakīrti's injunction, illness is an occasion for service and spiritual quickening. Through their experience of illness, caregivers can sympathize with others who are ill. They can urge the sick not to succumb to their pains, but encourage them to relieve the suffering of all beings. Even if one is ill, one can give abundantly. "Expedient means," a rendering of *upāya*, ordinarily refers to the wisdom to convey the Dharma according to the needs and capacities of the listener. But here, Vimalakīrti defines *upāya* to mean the efforts the devotees of the Dharma should expend to relieve suffering.

Abundant giving takes on many forms. The invalid and sick often inspire and instill faith in the human experience to those who attend to them. "*Dana*" or selfless giving is the first of the Six Paramitas or Perfections a Bodhisattva observes. The selfless gift is "*Dana* ... most profound among all joys ... that which is found through witnessing and experiencing the joy of others [so that] ... the joy of others becomes one's own joy" (23).

In an interdependent and ever-changing world, health and healing are possible with the advent of new knowledge and with new relationships. Change assures that illusion can be transformed into enlightenment, illness can be cured, and social decay arrested.

MANIPULATION OF LIFE

The discussion of the manipulation of life includes the environment and attended concerns of ecology, biodiversity, and agriculture, and modifications of living organisms that include human beings, microorganism, and animals. While Buddhist documents offer insight into

dealing with the environment, we can only extrapolate what might be the Buddha's attitude toward the manipulation of life, organ transplants, and cloning.

Environmental Issues

Buddhist responses to ecological issues, biodiversity, and agricultural development are rooted in the sense of responsibility and gratitude, intrinsic to the doctrine of *pratītyasmutpāda*. As it was noted above, for the Buddha, personal health is established within the context of a wholesome society and environment. The *Abhidharmakośa śāstra*, an influential primer composed by Vasubandhu (circa 400 C.E.), defines the world to include both sentient beings and the container world, the realm that supports sentient life (24). Just as mind and body are considered to be a single unit, Buddhism understands the individual, society, and the natural world to constitute a single whole. The idea of "one is all and all is one" articulated in the *Avataṃsaka sūtra*, and the elaboration of this idea in such doctrines as the Ten Subtle Principles of Unobstructed Fusion of *Pratītyasmutpāda* and the Six Principles of the Causal Aspects of *Pratītyasmutpāda* (Yüan-ch'i-yin-mên-lu-i-fa) by Fa-tsang and other Hua-yen masters, articulate the ideological rationale for environmental concerns. These doctrines explain that human, plants, animals, and material entities do not simply exist in and by themselves. Their individual and separate existences are affirmed by and made possible through their relationship with others (25). Our individual well-being is dependent on the health of the world we live in. Our activities should thus be conducted with a sense of respect and reverence for all life. Conservation, harmonious coexistence, the need to care for and to restore the land (26), not exploitation, should be the hallmark of a Buddhist devotee. The destruction of the Amazon rain forests affects my well-being and the very life of the world. The Buddhist devotee should quicken feelings of gratitude to animals and plant life to whom he or she must depend on for life. Donald Swearer sums the modern Thai monk Buddhadasa's (1906–1993) rationale toward the environment:

> One cares for the forest because one empathizes with the forest, just as one cares for people ... [Empathy] is fundamentally linked with non-attachment or liberation from preoccupation with self, which is so central to Buddhasada's thought ... Caring in this deeper sense ... goes beyond the well-publicized strategies of the conservation monks to protect and conserve the forests ... [Empathy] translates as having at the very core of one's being the quality of caring for all things in the world and their natural conditions; that is to say, caring for them as they are in themselves rather than as I might benefit from them or as I might like them to be (27).

The modern environmental ethic that advocates minimum exploitation of and optimum utilization of natural resources and maximizes recycling finds much in common with the Buddhist idea of *pratītyasmutpāda*. Modern Buddhists actively work to preserve the environment and promote biodiversity. The Buddhist Peace Fellowship founded in 1978 under the leadership of Robert Aitken and others in Hawaii have galvanized Buddhists worldwide to work to protect the environment and issues of justice. In November 1997 villagers, Buddhist monks, and environmentalists gathered in Sai Yok National Park to protest the Thai government's decision to allow a pipeline to run through the park. To protest the deforestation and its animal inhabitants, and displacement of people, Buddhist monks ordained the trees (28). The voices of Buddhists thinkers and activists appeared in *Buddhism and Ecology, the Interconnection of Dharma and Deeds*, a collection of papers presented at the 1996 proceedings of Earth Charter, a project that set forth a vision of ethical principles for the twentyfirst century (29).

In the Buddhist countries of Asia, modernized agriculture resulted in increased yields, but it also brought about the large-scale depletion of natural resources. Deforestation for agricultural uses has destroyed much of the wild life, and use of chemical fertilizers and insecticides has killed off mudfishes and edible frogs that once thrived in the rice fields and served as a rich source of food (30). In response to the "destruction of human communities and nature in the name of globalization, of multinational corporations, governments, and local allies" more than 400 social activists and leaders from the Asia–Pacific region gathered in Kathmandu in 1996. The international gathering, "People's Convergence, Shaping Our Future" was the third event of the People's Plan for the twenty-first Century that began in 1989 in Japan to bring attention to environmental pollution. The Minamata Declaration called for a grassroots transborder participatory democracy to change the global structure (31). These grassroots nongovernmental organizations, including Buddhists and Buddhist organizations, attempt to live out the Buddha's insistence that material and environmental needs of the people be respected.

Brain Death and Organ Transplants

The question of brain death and the appropriateness of organ transplants generated great concern and a range of opinions in the Buddhist community. The controversy lies in part in the meaning of life and death, personal identity, and the belief in the inseparability of mind and body. In the United States and other countries where transplants are routine, death is defined as the absence of brain activity, which often occurs before a heart stops beating. Legally defining a patient, whose brain has ceased to function, dead is crucial in harvesting organs. Organs quickly deteriorate once the heart stops beating. Brain death is not satisfactory for Buddhists who subscribe to the traditional cardiopulmonary definition of death. More substantially, others object to the brain-death criterion of death because Buddhists have always associated life with sentience (32), which in its broadest sense includes feeling. Though the brain may have ceased to function, the individual with a beating heart may be pained by being cut, and having his or her organs removed. Doctrinally, death is defined as the dissolution of mind and body. Death dissolves the fortuitous interactions of karmic events that gave birth to and nurtured an individual. The separation of the mind from the body, however, is not death of the person, as we will presently see. Curiously, even with death defined as cessation of higher-brain functions, we commonly begin funeral preparations when the heart has

been removed or has stopped beating, and not when the brain is dead. The medical and legal definitions of brain death often conflict with social notions of death.

Another pervasive attitude against organ transplants is the assumption that life is impermanent. Since life is transient and death inevitable, there is no meaning to artificially extend life by receiving the organs of another. The extension of life by organ transplant disrupts the natural karmic life span. Rather than extending life through heroic measures, humane end-of-life care would be more in keeping with the spirit of the Dharma. Further, organ transplants are possible only at the expense of another's life, a violation of the precept to abstain from taking life. Consequently some Buddhists advocate the development and use of artificial organs. However, those who favor transplants argue that the gift of life is the greatest gift an individual can give. The body is, after all, transient and ultimately worthless (33). Buddhist lore is replete with legends that relate the sacrifice of limb and life by the Buddha. In Sri Lanka, Hudson Silva has used a legend of the Buddha with great success to persuade people to donate their eyes for corneal transplants (34). The legend even makes mention of an eye transplant.

The Buddhist misgiving toward defining death as the cessation of brain activity may be another reason for the ambivalence of the Japanese toward organ, especially heart transplants. After more than 30 years of debate, the Japanese Parliament on June 17, 1997, passed a law that allows a person, whose brain has stopped functioning, to be defined as dead; in cases where a patient has agreed to this definition of death, he or she can request that his or her heart and lungs be donated for transplants. The bill does not provide a legal definition of death; it does nonetheless allow the brain-death standard to be used for donors of hearts and lungs. Current Japanese law defines death as the moment the heart stops beating. The bill does not give the donor an absolute right to ask physicians to decide whether he or she is considered brain-dead. The donor's family has the ultimate right to veto the doctors' diagnosis of brain death and the patient's wishes. A patient's rights, as noted above, are not absolute. Ironically the new Japanese law allows for a greater measure of individual autonomy. Physicians are given permission by the prospective donor to declare himself or herself brain-dead for the purposes of organ donation. In contrast, in the United States brain death is defined by law, and physicians do not need the patient's permission to declare an individual brain-dead.

On February 28, 1999, 21 months after the approval of the new law, Japanese doctors performed their first heart transplant since Dr. Juro Wada attempted a heart transplant 32 years ago. Dr. Wada's patient died and his operation and motives are clouded with legal controversy.

The difference in the importance of individual autonomy differentiates the U.S. and Japanese approach to organ transplants. As we noted, in Japan an individual does not have an absolute right to self-determination; the Japanese Parliament allowed the family to void any prior directive a brain-dead individual may have made concerning the disposition of his organs. The Japanese approach to brain death reflects the manner in which a Buddhist would approach the problem. In an interdependent world where lives are intertwined with countless others, individuals do not have exclusive claim on their lives. We may have separate lives, but we live in resonance with others.

The hesitation of organ transplants among East Asian Buddhists can also be traced in part to the Chinese Confucian notion of filial piety. The opening lines of the *Hsiao Ching*, or Classic on Filial Piety, states, "Filial piety is the basis of virtue and the source of our teachings. We receive our body, our hair, and skin from our parents, and we dare not destroy them" (35). When Buddhism first entered China, the Chinese appealed to this passage to argue against their sons and daughters shaving their hair when entering the Buddhist order. A person should be buried with every part of his or her body. The donation of one's organs would thus constitute a most unfilial act. This attitude has prevented wide acceptance of organ transplants. While the Chinese value keeping the body intact after death, there is a countervailing attitude that the use of organs from executed prisoners can benefit social and public good (36). This attitude toward the asocial elements has its roots in imperial China when social order and individual health were closely linked (37). Korean Buddhists' wariness of organ transplants stems from a strong Confucian imprint. The indigenous shamanic belief that a person who is not buried with all of his or her body will suffer in the next phase of life also contributes to their hesitation.

The importance of family lineage and the reciprocity between the living and dead account for the reluctance of organ transplants among the Chinese, Koreans, and Japanese. In traditional East Asia, death of the physical body is not the death of the person. Incorporating this belief, Buddhist mortuary rites mark the transformation of the person from a physical to a spiritual being. The person matures or proceeds to ancestorhood with the aid of memorial observances sponsored by the living descendants. In return, the ancestor ensures health and prosperity for the family. This accounts for the complex and lengthy memorial cycle. The Japanese Buddhist mortuary rites are especially long. The memorial cycle begins immediately after death and continues for at least 33 years. The 49th day, 100th day, 1st year, and the 3rd, 7th, 13th, 17th, 25th, 33rd year observances are especially important. On the island of Okinawa, a living repository of Japanese culture and language, the 33rd year memorial service marks the complete transition of the individual to an ancestral spirit. After the completion of the service, the individual's memorial tablet is burned. Services are no longer dedicated to the memory of the deceased and the individual is honored collectively as an ancestor with all other ancestors. While the long memorial cycle ritualistically marks the transformation of a person's identity, it in fact reveals something of the nature of our memories. As years pass, our recollections of the deceased become less and less distinct and he or she gradually loses his or her individuality. Korean Buddhist mortuary rituals continue for up until three years, and thereafter the deceased is honored at an annual memorial service for ancestors. Thai and Burmese Buddhists' memorial rituals are seven years (38). In accordance with Confucian sentiments, Chinese Buddhists mourn for three years.

Cloning

In late February 1997, when Ian Wilmut, a scientific researcher, announced the first successful cloning of a sheep named "Dolly," the prospect of cloning a human being prompted celebration, caution, and concern. Buddhists have not raised objections to this scientific breakthrough, but they are concerned with the ends of and motivations for human cloning. The creation of new life should not be seen as a product but an end or value in itself. Such reverence appeals to the idea of Buddha-nature and that the appearance of a clone is a rare event. Cloning a human being to produce organs for use in transplantation, however, would be repugnant (39). In contrast, some appeal to the principles inherent in the doctrine of *pratītyasmutpāda* to celebrate the reality of change. The technique of cloning is a tool that further expands human scientific and technological promises (40) and new moral possibilities (41). Since change is the nature of reality, the present challenge of the cloning question is how to accommodate change, expand our notions of humanity, and our moral parameters.

Organ transplants and genetic manipulation raise questions of family continuity in those East Asian cultures where family lineage is valued. If a person is considered to be the unique repository of prior generations, receiving an organ from another person raises the question of identity. If genes are manipulated what is the relationship between ancestor and descendent?

The manipulation of life through genetic engineering, like other human-generated innovations, is consistent with the Buddhist belief in change. Countless causes and conditions propel us to this present moment, providing for new achievements. Our present thinking and activities interact with current concerns and with the natural order. As active participants and an integral part of the process of interdependence in the life of the world, human beings have the capacity to affect the subsequent course of events. This should give us pause to reflect on our responsibilities and present and future action. Often we are unaware of the consequences of our achievements. For example, an August 1998 article in *Nature* reports that climatologists have linked pollution emitted by factories and automobiles with rainy weekends (42).

CONCLUDING REMARKS

Buddhists, caught up in rapid scientific and technological changes, have been slow to reflect on the ethical, legal, and policy issues generated by recent advances in biotechnology. Since much of these changes occurred in the United States and Europe, technically the most advanced countries, and where the issues surrounding modern biotechnology initially appeared, Christian theologians have reflected on and activists voiced concerns over these advances. By contrast, Buddhism, which is dominant in the countries of South and East Asia where biotechnology has begun to have an impact, has only recently confronted these problems. Japan is the most notable exception. Since the successful cloning of twin calves in July 1998 by Japanese scientists under the direction of Yukio Tsunoda of Kinki University, the Japanese Ministry of Agriculture and Forestry reported that as of March 31, 1999, 57 calves have been cloned from somatic cells and another 461 from nuclear embryo transplantation (43). Buddhist thinkers in that country have been reflecting on cloning.

The notion of *pratītyasmutpāda* holds the key to the Buddhist approach to implications of biotechnological advances. *Pratītyasmutpāda* offers an understanding of change, humanity's place in the process of change, and a vision of human responsibility to all things and all beings and to the world. Nothing in the Buddhist documents suggests halting changes that new knowledge generates. Change is a cardinal Buddhist presupposition. While change may be the opportunity for expanding Buddhists' moral imagination, the idea that all things and all beings are mutually and irrevocably interdependent instills a sense of humility that is necessary for ensuring that all species and all things are accorded respect. Further the vision of an interdependent world quickens concerns for the safety of food from cloned animals and plants, and the long-term consequences of gene manipulation on the environment and all sentient life. These and other ramifications of biotechnological advances and policy decisions must carefully consider all aspects of suffering that change generates. The karmic energies of a single individual have wide repercussions. "A wise man should do things that are beneficial to living-beings" (44).

BIBLIOGRAPHY

1. The most widely accepted dates, 563–483 B.C.E., are based on the Sri Lankan historical chronicles, *Dīpavaṃsa* and *Mahāvaṃsa*. Hakuju Ui (1882–1963), a prominent Japanese scholar, disputed these dates based on Northern or Mahāyāna sources. Thus, according to Ui, the Buddha's dates are 466–386 B.C.E.
2. Followers of Mahāyāna (great vehicle) Buddhism coined the expression, "Hīnayāna" (lesser vehicle) as a pejorative for those who did not accept their documents and their doctrines. Mahāyānists accused Hīnayānists and their *arhat* ideal that was reserved for the select few. The Mahāyāna ferries all beings across the sea of samsara to nirvana, while the Hīnayāna transports only a few. No Buddhist group referred to itself as Hīnayāna. The devotees of Theravāda, a non-Mahāyāna tradition, object to being labeled "Hīnayānaists."

OUTLINE

INTRODUCTION

Judaism, a religion tracing its roots to Abraham close to 4000 years ago and continuing through the Bible and rabbinic interpretations to our own day, has sought since its inception to use the world productively while yet preserving it, both seen as God's commands. This article describes

the theological foundations for Judaism's activist, and yet respectful, stance toward the world. It then describes how this stance is articulated in issues at the beginning and end of life and in environmental matters.

OVERALL CONTEXT OF JEWISH BELIEFS AND PRACTICES RELEVANT TO TECHNOLOGY

Adam and Eve are told in the Garden of Eden "to work it and to preserve it" (Genesis 2:15). Judaism has ever since tried to strike a *balance* between using the world for human purposes while still safeguarding and sustaining it. We are not supposed to desist from changing the world altogether: "Six days shall you do your work" is as much a commandment as "and on the seventh day you shall rest [literally, desist]" (Exodus 23:12).

In changing the world to accomplish our ends, though, we must take care to preserve the environment, whether we are practicing medicine, farming, traveling, or doing anything else. This balance is demanded because, in the end, we do not own the world; God does (1). We are but tenants in God's world, with a lease on life and on the world.

During the duration of that lease, we may and should act as God's agents to improve it. God, in fact, intended that we function in that way. This is probably most starkly stated in a rabbinic comment about, of all things, circumcision. If God wanted all Jewish boys circumcised, the rabbis ask, why did He not create them that way? The answer, according to the rabbis, is that God deliberately created the world in need of fixing so that human beings would have a divinely ordained task in life, thus giving human life purpose and meaning (2). We are, then, not only permitted but mandated to find ways to bend God's world to our purposes — as long, again, as we preserve God's world in the process.

Thus technology, in and of itself, is not good or bad: it depends on how we use it. If we employ it to assist us in bending the world to our ends while yet preserving the world, our use of technology is theologically approved and morally good; if we disregard our duty to preserve the world when using technological tools, we are engaged in a theologically and morally bad act.

FUNDAMENTAL BELIEFS RELATING TO HEALTH CARE

Three underlying principles regarding Judaism's positions on issues in health care emerge from Jewish sources:

1. *The body belongs to God*. Since God owns everything in the world (3), our bodies do not belong to us. Rather, God loans our bodies to us for the duration of our lives, and they are returned to God when we die.

The immediate implication of this principle is that neither men nor women have the right to govern their bodies as they will. Since God created our bodies and owns them, God can and does assert the right to govern the care and use of our bodies. Thus Jewish law requires us to safeguard our health and life (4), and, conversely, to avoid danger and injury (5). So, for example, Conservative, Reform, and some Orthodox authorities have prohibited smoking as an unacceptable risk to our God-owned bodies (6). Ultimately human beings do not, according to Judaism, have the right to dispose of their bodies at will (i.e., commit suicide), for that would be a total obliteration of that which does not belong to them but rather belongs to God (7).

2. *The body is morally neutral and potentially good*. For Judaism the body is as much the creation of God as the mind, the will, and the emotions are. Its energies, like those of our other faculties, are morally neutral, but they can and should be used for divine purposes as defined by Jewish law and tradition. Within that structure, the body's pleasures are God-given and are not to be shunned, for that would be an act of ingratitude toward our Creator (8). The body, in other words, can and should give us pleasure to the extent that that fits within its overriding purpose of enabling us to live a life of holiness.

The Jewish mode for attaining holiness is to use all of our faculties, including our bodily energies, to perform God's commandments. Maimonides states this well:

> He who regulates his life in accordance with the laws of medicine with the sole motive of maintaining a sound and vigorous physique and begetting children to do his work and labor for his benefit is not following the right course. A man should aim to maintain physical health and vigor in order that his soul may be upright, in a condition to know God. . . . Whoever throughout his life follows this course will be continually serving God, even while engaged in business and even during cohabitation, because his purpose in all that he does will be to satisfy his needs so as to have a sound body with which to serve God. Even when he sleeps and seeks repose to calm his mind and rest his body so as not to fall sick and be incapacitated from serving God, his sleep is service of the Almighty (9).

The medical and technological implications of this are clear. Jews have the obligation to maintain health not only to care for God's property but also so that they can accomplish their purpose in life, namely to live a life of holiness. Moreover, since pain is not perceived as a method of attaining holiness but is rather an impediment to acting according to God's law, it is our duty to relieve it. Thus perhaps the most pervasive corollary of Judaism's insistence on the divine source of our bodies is its positive attitude toward the body and medicine.

3. *Human beings are not only permitted but obliged to try to heal*. God's ownership of our bodies is also behind our obligation to help other people escape sickness, injury, and death (10). God is our ultimate healer, as the Bible asserts in many places (11), but God both authorizes us and commands us to aid in that process (12). In fact the duty of saving a life (*pikkuah nefesh*) takes precedence over all but three of the commandments in the Torah (13).

The Talmud reflects some ambivalence about the level of expertise of physicians of its time (most explicitly

in comments like "The best of physicians deserves to go to Hell!"), and some later Jewish authorities were particularly wary of physicians' abilities to practice internal medicine (in contrast to surgery and healing external wounds and diseases). In the end, though, the Talmud prohibits Jews from living in a community in which there is no physician (14). Here this third principle wraps back into the first, for if we were not within easy reach of a doctor, we could not as effectively carry out our fiduciary obligation to God to take care of our bodies.

Medical experts, in turn, have special obligations because of their expertise. Thus Rabbi Joseph Caro (1488–1575), the author of one of the most important Jewish codes, says this:

> The Torah gave permission to the physician to heal; moreover, this is a religious precept and is included in the category of saving life, and if the physician withholds his services, it is considered as shedding blood (15).

The following rabbinic story indicates that the rabbis recognized the theological issue involved in medical care and in the use of technology generally, but it also indicates the clear assertion of the Jewish tradition that the use of technology to assist in good purposes like producing food and preserving health is legitimate and, in fact, obligatory:

> It once happened that Rabbi Ishmael and Rabbi Akiva were strolling in the streets of Jerusalem accompanied by another person. They were met by a sick person. He said to them, "My masters, tell me by what means I may be cured." They told him, "Do thus and so until you are cured." The sick man asked them, "And who afflicted me?" They replied, "The Holy One, blessed be He." The sick man responded, "You have entered into a matter which does not pertain to you. God has afflicted, and you seek to cure! Are you not transgressing His will?"
>
> Rabbi Akiva and Rabbi Ishmael asked him, "What is your occupation?" The sick man answered, "I am a tiller of the soil, and here is the sickle in my hand." They asked him, "Who created the vineyard?" "The Holy One, blessed be He," he answered. Rabbi Akiva and Rabbi Ishmael said to him, "You enter into a matter which does not pertain to you! God created the vineyard, and you cut fruits from it."
>
> He said to them, "Do you not see the sickle in my hand? If I did not plow, sow, fertilize, and weed, nothing would sprout."
>
> Rabbi Akiva and Rabbi Ishmael said to him, "Foolish man!... Just as if one does not weed, fertilize, and plow, the trees will not produce fruit, and if fruit is produced but is not watered or fertilized, it will not live but die, so with regard to the body. Drugs and medicaments are the fertilizer, and the physician is the tiller of the soil (16).

The rabbis quite explicitly, then, understand God to depend upon us to aid in the process of healing. We are, in the talmudic phrase, God's partners in the ongoing act of creation (17).

TECHNOLOGY AFFECTING THE BEGINNING OF LIFE

Underlying Principles Regarding Family, Sexuality, and Procreation (18)

Marriage and children are the epitome of blessing in the Jewish view. "It is not good for man to live alone," the Torah declares, and so one goal of marriage is companionship, sexual and otherwise (19).

The second goal of marriage is procreation. Children figure prominently in the Bible's descriptions of life's chief goods (20), and so God's blessings of the Patriarchs promise numerous children (21). Procreation is not only a blessing; it is a commandment. Indeed, the very first commandment in the Bible is "Be fruitful and multiply" (Genesis 1:28). In rabbinic interpretation, for exegetical and probably economic reasons, it is the man who bears the responsibility to propagate, even though men obviously cannot do so without women. A man, then, fulfills the obligation to propagate when he fathers two children, and since we are supposed to model ourselves after God, the ideal is to have both a boy and a girl, thus creating both male and female, just as God did (Genesis 1:27) (22).

The family is important in Judaism not only because it is in that context that adults gain sexual fulfillment and the next generation is produced; it is also important because it is in the family that the tradition is passed on. Parents have a biblical obligation to teach the tradition to their children (23), and even after schools were established in the first century, parents remained ultimately responsible for the education of their children.

Preventing Conception

Contraception. With the importance of marriage and children in mind, one can understand that traditional Judaism looked askance at interruptions in the process of conception and birth. Normally one was supposed to marry and have children. Birth control, sterilization, and abortion were, both physically and ideologically, counterproductive.

Until very recently the use of birth control or even abortion for family planning purposes, so common in our day, was simply unknown to the tradition. Methods of birth control — either a cloth inserted in the vaginal cavity or a "cup of roots" taken orally — were unreliable, and abortion posed a major threat to the life of the woman. Moreover, if a couple wanted to have two or three children survive to adulthood, they had to produce six or seven. We must keep in mind this major distinction in context and purpose, then, when we examine and evaluate traditional Jewish sources on methods of preventing conception.

The rabbis state that the methods of contraception they had are permitted and even required under certain circumstances. Because the tradition understands the command to propagate to be the obligation of the male, male forms of contraception are generally forbidden. The specific conditions under which female contraception is permitted (and, in some cases, even required) depend on one's interpretation of a second-century rabbinic ruling describing three classes of women who "use" contraceptives — namely a minor (less than 12 years of age), a pregnant woman, and a nursing woman. The present tense of the verb is ambiguous in Hebrew, as it is in English. If it means that these women *must* use contraceptives to protect their life or health or that of their nursing infant, women in other circumstances then *may* use contraceptives. On the other hand, if these three categories of women may use contraceptives only to preserve life and health, then when that

is not a factor, women *may not* use contraceptives (24). In any case, because Judaism restricts the legitimacy of abortion to cases where the life or health of the mother is at stake, modern forms of contraception that prevent conception in the first place (e.g., the pill, the diaphragm) are preferred over those that abort the fertilized egg cell after the fact (e.g., RU486).

Sterilization. The same concerns govern the issue of sterilization, but there another issue arises, namely the prohibition against a person mutilating his or her body in light of the fact that the body is really God's property. Although the procedures are rather new, there are a few rabbinic rulings (responsa) available on the issues of vasectomies and tubal ligations. Both traditional and liberal respondents forbid male sterilization on the basis of the rabbinic interpretation and extension of Deuteronomy 23:2 ("No one whose testes are crushed ... shall be admitted into the congregation of the Lord") (25), or Leviticus 22:24 ("That which is mauled or crushed or torn or cut you shall not offer unto the Lord; nor shall you do this in your land") (26). They are more permissive about female sterilization, both because a woman does not come under those prohibitions and also because she is not legally obligated to procreate (27).

All sources agree, however, that even male sterilization is permitted and perhaps even required if the man's life or health makes it necessary as, for example, if he contracts testicular cancer. Moreover, even though I am not aware of any written opinion that would allow a vasectomy, I could imagine an argument consistent with Jewish law and principles that would permit a vasectomy when pregnancy would entail a severe risk to the man's wife. After all, that procedure is far easier and safer than tying a woman's tubes, and saving a person's life takes precedence over both the commandment to procreate and the prohibition of injuring oneself. Moreover, a vasectomy does not amount to castration or to crushing the testes, and so the biblical verses cited above are not directly violated by the operation. The question, though, would be whether pregnancy could be effectively prevented by other means that would not endanger the woman and would not even possibly violate the verses cited. If so, then such means would undoubtedly be preferable.

Most often, though, men contemplate vasectomies simply because they do not want to father any more children. In light of the strong bias of the Jewish tradition for having children, and in light of the major demographic crisis facing the Jewish community that I will describe below, rabbis have not endorsed vasectomies for family planning purposes, seeing it as a violation of Jewish law and values and a threat to the continuity of the Jewish people.

Abortion. There is a clear bias for life within the Jewish tradition. Indeed, it is considered sacred. Consequently, although abortion is permitted in some circumstances and actually required in others, it is not viewed as a morally neutral matter of individual desire or an acceptable form of *post facto* birth control. Contrary to what many contemporary Jews think, Judaism restricts the legitimacy of abortion to a narrow range of cases; it does not permit abortion at will.

Judaism does not see all abortion as murder, as Catholicism does, because biblical and rabbinic sources understand the process of gestation developmentally. Thus Exodus 21:22–25 makes a clear distinction between an assailant who causes miscarriage of a fetus, when only monetary fines are imposed, as opposed to one who causes the death of the mother, when the rule is "life for life." According to the Talmud, within the first 40 days after conception the zygote is "simply water" (28). Another talmudic source distinguishes the first trimester from the remainder of gestation (29). It is not a theory of ensoulment that determines these marking points; it is rather the physical development of the fetus.

The effect of these demarcations is to make abortion during the early periods permitted for more reasons than during the rest of pregnancy (30). Classifying the first 40 days of gestation as "simply water," though, does not amount to a blanket permission to abort. Thus the RU486 pill, advertised as a "morning after pill" for those couples who simply do not want to have a baby, would be forbidden as a *post facto* contraceptive. On the other hand, if the woman's life or health would be threatened by pregnancy, then use of the RU486 pill would be preferable to a later-term abortion, both because it poses less risk for the woman and because the fetus is further from becoming a full human being.

The fetus does not attain the full rights and protections of a human being until birth, specifically when the forehead emerges or, if it is a breech birth, when most of the body emerges (31). The mother, of course, has full human status. Consequently, if the fetus threatens the life or health of the mother, then it may and in some cases must be aborted, as the following Mishnah graphically stipulates:

> If a woman has (life-threatening) difficulty in childbirth, one dismembers the embryo in her, limb by limb, because her life takes precedence over its life. Once its head (or its "greater part") has emerged, it may not be touched, for we do not set aside one life for another (32).

While all Jewish sources would permit and even require abortion in order to preserve the life or organs of the mother (33), authorities differ widely on how much of a threat to a woman's health the fetus must pose to justify or require an abortion. Based on a responsum by Rabbi Israel Meir Mizrahi in the late seventeenth century, many modern authorities also permit an abortion to preserve the mother's mental health, and this has been variously construed in narrow or lenient terms in modern times (34). To the extent that Jewish law makes special provision for an unusually young or old mother, an unmarried mother, the victim of a rape, or the participant in an adulterous union, abortion is construed to preserve the mother's mental health (35).

There is no justification in the traditional sources for aborting a fetus for reasons having to do with the health of the fetus; only the mother's health is a consideration. As a result some people object to performing an amniocentesis at all, even when the intent is to determine whether to abort a malformed fetus (36). Others reason in precisely the opposite direction. They point out that the sources

could not have contemplated abortions due to the condition of the fetus because nobody could know anything about that until very recently through technologies like amniocentesis and sonograms. Now that we have those tools, most rabbis justify using them to aid in the delivery of a healthy baby. Moreover, when those technologies reveal fetal abnormalities, many rabbis justify abortion on the basis of preserving the mother's mental health where it is clear that the mother is not able to cope with the prospect of bearing or raising such a child (37).

Many Conservative and Reform rabbis, and even a few contemporary Orthodox rabbis, have handled the matter in a completely different way. Our new medical knowledge of the status of the fetus, they say, ought to establish the fetus' health as an independent consideration in determining when abortion is justified (38).

In practice much of this discussion is moot, for Jews engage in abortion as if it were a matter of individual choice. That is a particularly problematic phenomenon for the contemporary Jewish community because Jews constitute only 0.2 percent of the world's population (while Christians make up a full 33 percent). To make matters worse, Jews are barely reproducing themselves in Israel and are falling far short of that in North America, where the Jewish reproductive rate is approximately 1.6 or 1.7 children per couple. Consequently, even those rabbis who are liberal in their interpretation of Jewish abortion law are also calling for Jews to marry and to have children so that the Jewish people and Judaism can survive.

Generating Conception

Artificial Insemination. Since Judaism prizes children so much, it is no wonder that rabbinic authorities have permitted unusual ways of having them for couples who cannot have them otherwise. Nevertheless, there are objections, or at least precautions, connected to some of the procedures.

Rabbis have not objected to uniting a man's sperm with his wife's ovum artificially, whether through artificial insemination or through in vitro fertilization (IVF) (39). Because of Judaism's appreciation of medicine as an aid to God, there is no abhorrence of such means merely because they are artificial.

The matter becomes more complicated when the donor is not the husband. Some rabbis object to such procedures on grounds of adultery. For many, however, adultery takes place only when the penis of the man enters the vaginal cavity of the woman, and that is clearly not the case when insemination takes place artificially. Not only is the physical contact missing; the intent to have an illicit relationship is also absent (40).

More commonly the objection to donor insemination is based on the possibility of unintentional incest in the next generation — specifically, if the product of the artificial insemination later happens to fall in love with a person of the opposite sex who is the child of the semen donor conceived with his wife. Since their biological father is the same man, these two people would be each other's natural half-brother or half-sister. That is problematic for some because it represents a violation of the Torah's laws against incest. Even for those who would invoke the lack of intent to excuse the couple from those laws, there still remains a critical health concern — namely the increased likelihood among consanguineous unions of genetic diseases transferring from one generation to the next.

This issue dissolves if the semen donor is known or if the donor would not likely be a marital partner for someone in the Jewish community. It was on the latter basis that a prominent Orthodox rabbi, Rabbi Moshe Feinstein, ruled that donor insemination would be permissible if the donor were not Jewish, for in his community intermarriage between Jews and non-Jews was rare. Those Orthodox Jews who will use donor insemination will therefore often require that the donor be a non-Jew.

The Conservative Movement's Committee on Jewish Law and Standards has approved by rabbinic ruling, according to which donor insemination is permissible if either the identity of the donor is known or, lacking that, that enough is known about him so that the child can avoid unintentional incest in his or her sexual partners (married or not) and so that the child can know as much as possible about his or her family traits, both medically and characterologically. In view, however, of the psychological problems that may ensue for the child, the donor, and/or the parents who raise the child (the "social parents"), all parties to the insemination should seek and receive appropriate counseling (41).

Egg Donation. The considerations described above with regard to donor insemination apply as well to egg donation. If the identity of the egg donor remains confidential, the same problems arise with regard to possible unintentional incest in the next generation, and the same solutions by the various rabbinic authorities apply. Specifically, either the egg donor's identity should be shared with the couple who will raise the child and ultimately with the child him/herself, or the woman should be a non-Jew, or enough about the biological mother must be shared with the couple and child to enable the child to avoid such unintentional incest. The donor, in my view, must also share enough information about her talents and traits to help the child understand him/herself. Finally, psychological counseling is appropriate for all concerned both before the procedure and afterward.

Egg donation, though, raises some additional problems. Semen donors incur virtually no medical risks, but that is not true of egg donors. In order to procure as many eggs as possible during each attempt, the donor must be hyperovulated with drugs, and there is some evidence that repeated hyperovulation increases the risk of ovarian cancer (42). This is especially troubling since the donor herself will not, by hypothesis, be gaining a child of her own but will rather be helping another couple have a child. For all that Jewish law prizes procreation, it values the life and health of those already born even more. Consequently, while healthy women may undergo the procedure to donate eggs once or twice, they may not do so much more than that, unless new studies allay the fear of increased cancer risk.

Normally, a child is defined as Jewish in traditional Jewish law if born to a Jewish woman. In cases of egg donation, however, some rabbis have maintained that it

is the donor of the gametes who is the legal mother. Most, though, have ruled that even if the egg comes from some other woman, as it does in egg donation, it is the bearing mother whose religion determines whether the child is Jewish or not, and the Conservative Movement's Committee on Jewish Law and Standards has adopted that view (43).

In vitro Fertilization (IVF), Gamete Intrauterine Fallopian Transfer (GIFT), Zygote Intrauterine Fallopian Transfer (ZIFT), etc. When a couple cannot conceive a fetus through sexual intercourse, even when assisted by timing their intercourse, by stimulating ovulation, or by surgery to correct a problem in either the man or the woman, and when the couple prefers to use their own gametes rather than those of donors, they may try any of a number of new techniques, some of which are listed in the title of this subsection. Since the Jewish tradition does not frown upon the use of artificial means to enable people to attain permissible ends, much less sanctified ones like having a child, the mechanical nature of these techniques is not an issue. On the contrary, the important thing to note in recent Jewish rulings is that infertile couples are *not obligated* to use these means to fulfill the man's duty to procreate, even though they *may* (44).

When a woman is impregnated with more than three fetuses, either naturally or artificially, an abortion may be indicated in order to preserve both the life of the mother and the viability and health of the remaining fetuses. For that purpose, such abortions are permitted (and possibly even required). When it can be determined through genetic testing that some of the fetuses have a greater chance to survive and to be healthy than others do, then it is permissible selectively to abort those less likely to survive. This is the same criterion to be used for triage decisions made at the end of life. If all of the fetuses are equally viable, the abortions must be done on a random basis. To avoid the necessity of selective abortion as much as possible, the Conservative Movement's Committee on Jewish Law and Standards has ruled that only three zygotes should be implanted at one time (45).

Surrogate Motherhood. This is really two different forms of overcoming infertility: "traditional surrogacy" or "ovum-surrogacy," in which the surrogate mother's own egg is fertilized by the sperm of the man in the couple who are trying to have a baby (presumably not the husband of the surrogate), and "gestational surrogacy," in which both the egg and the sperm are those of the couple, and the surrogate mother's womb is used to carry and deliver the baby.

From a Jewish perspective, this method of overcoming infertility, or at least something much akin to it, is among the oldest ways recorded in the Jewish tradition. Sarai (later, Sarah), after all, gives her handmaid, Hagar, to Abram (later, Abraham) specifically to conceive a son who would be attributed to Sarai, and Rachel and Leah likewise have their handmaids conceive children with their husband, Jacob. Leah, in fact, had already borne four sons by the time that she uses a surrogate mother because "she stopped bearing"—although she herself was later to bear him two more sons and a daughter (46). These are all, in modern terminology, ovum-surrogates, and even so, because the handmaid belonged to the man's wife, the Bible attributes the child to the wife rather than the surrogate.

These precedents notwithstanding, though, surrogate motherhood raises difficult emotional and legal problems—although not technological problems beyond those of artificial insemination (in ovum surrogacy) or IVF (in gestational surrogacy). Thus rabbis raise some concerns about the way in which a surrogacy arrangement should be handled, but they do not ultimately prohibit it. Specifically, the couple must abide by civil law in their region and, in light of the recency of this matter in most systems of law, the couple must be informed of the possibility of legal challenges. Furthermore Jewish law would require that steps be taken to ensure that the surrogate mother has full and informed intent to abide by the agreement—perhaps, in ovum-surrogacy, at least, by giving her a period of time (usually 30 days) after birth to cancel the agreement. The surrogate mother must not have physical or other conditions that would make pregnancy dangerous for her beyond the risks normally associated with pregnancy. In ovum-surrogacy the child must either be told the identity of the woman whose gametes he or she inherited or at least be given enough information to be able to avoid incest in his or her own sexual relations and to know about his or her physical and characterological background. Within these parameters, the few rabbis who have written about this have generally permitted surrogacy (47).

Prenatal Diagnosis and Treatment. Both for their own good and for that of their fetuses, pregnant women should seek and get prenatal care. They should also take the preventive measures that modern medicine prescribes to ensure a healthy baby, including restrictions on alcohol, smoking, and some prescription drugs; avoidance of toxins (e.g., in paints) and people with diseases which have been shown to cause fetal damage (e.g., German measles); and adoption of generally health-promoting habits of eating, hygiene, exercise, and sleep.

If the age or genetic background of a couple puts the child at risk for a degenerative, fatal genetic disease (e.g., Tay-Sachs) or for being seriously malformed, the mother may—but not must—undergo prenatal testing, even though that puts the fetus at some risk. Moreover, if the tests reveal that the fetus suffers from such maladies, the mother may choose to abort it. If, however, techniques exist that can cure the child in utero or once born, she may, and probably should, choose to employ those techniques rather than abort the fetus.

According to all interpreters of Jewish law, it is generally not permissible to screen specifically for gender just because one wants a boy or a girl or to screen for any characteristic other than disease (e.g., height, intelligence). Similarly the new sperm-splitting machine (a flow cytometer) to enable couples to choose either a boy or girl would generally violate Judaism's appreciation of people of both genders as equally created by God in the divine image (48). At the same time, Jewish law, as noted earlier, requires a man to father at least two children, specifically a boy and a girl. While that could not be used

to justify aborting a fetus of the same gender as those already born, it might justify using the flow cytometer in families who have produced three or more children of one gender and none of the other.

Gene Therapy, Genetic Engineering, and Cloning. Gene therapy is very new and only available in limited areas, and genetic engineering is still only a theoretical possibility. For example, techniques of genetic therapy are already being used to cure hydrocephalus while the fetus is still within the womb of the mother. The Human Genome Project has already discovered the genetic roots of many diseases, and that holds out the hope that someday soon those diseases may be cured. Indeed, on April 27, 2000, scientists in France reported the first success of gene therapy, using it to save three babies with severe combined immune deficiency (SCID) (48a).

There is already general agreement among rabbis that the legitimacy of human intervention to effect cure extends to procedures within the womb as well (49). When used in this therapeutic way, genetic engineering is an unmitigated blessing. Some rabbis have reservations about changing the stem cells themselves and thus all future generations, claiming that our divine mandate is to heal individuals who are ill but not to alter the nature of future human beings. That, in their view, would be to arrogate too much power to ourselves. Thus for them only therapeutic changes in the somatic cells of a diseased individuals would be permitted. Others, though, maintain that if we can root out a genetic disease not only from those who now have it but from descendants of such people as well, we should definitely do so, for our religious mandate is not only to cure diseases but to prevent them, if possible. With respect to degenerative genetic diseases like Tay-Sachs, I myself fall within the latter group.

Genetic engineering also, though, holds out the possibility that someday we will be able to change the nature of the human being so as to avoid the diseases that kill most of us today—heart disease, cancer, and the like. That already raises the question of whether we are effectively trying to reverse God's decision in the Garden of Eden to prohibit us from becoming immortal. Presumably, even if the currently deadly diseases are cured, we will eventually die of something else. So the Jewish justification for human beings to engage in curing may also be applied to genetically engineering ourselves to resist heart disease and cancer.

When we gain the ability to do these arguably permissible (and maybe even mandatory) things, we will also have the ability to change other things about ourselves. In fact, once we can change not only the genes of a particular fetus but even its germ line, we will be able to screen out traits that are not manifestations of a disease at all but merely characteristics that are deemed undesirable by certain individuals or groups. Abortion to eliminate defective fetuses poses the danger of the slippery slope where the definition of "defective" is broadened to the point of allowing only "perfect" children to be born, thus creating a master race. For example, we might change the genetic traits of shortness, merely average intelligence, a particular skin color, a propensity to alcoholism, and, perhaps, homosexuality. Moreover genetic engineering will create a new organism, and that poses real risks to human beings and to the environment.

There are thus some uses of genetic engineering that are clearly legitimate or illegitimate, but there are many where it is, and will be, difficult to tell. How do we determine when we are using genetic engineering appropriately to aid God in ongoing, divine acts of cure and creation and when, on the other hand, we are usurping the proper prerogatives of God to determine the nature of creation? More bluntly, when do we cease to act as the servants of God and pretend instead to be God?

Although cloning has been much more thoroughly discussed in the media, it actually presents fewer moral problems for Jews than genetic engineering does. Cloning, after all, does not introduce into the environment any new organism; it just replicates an organism that already exists, thus posing lesser risks. If cloning is used to overcome infertility, to aid in the research of diseases, or, in plants and animals, to produce food for starving people, it will be a very positive thing. On the other hand, cloning to avoid the intimacy of sexual intercourse, to gain immortality (as if that were possible through this technique), or to replicate oneself without any admixture of someone else's genes would be illegitimate uses of the technique. They smack of self-idolization and of the denial of human mortality; they thus make the moral and theological error of confusing human beings for God.

Our moral doubts about genetic engineering and cloning do not mean that research into these techniques should stop; the potential benefits to our life and health are enormous. They should prompt us, however, to exercise care in how we use our new capabilities. The problems are not just medical and technological; they are moral and theological, requiring us to reexamine the very ways we understand ourselves as human beings, our relationships to others and to God, and the limits inherent in being human.

Care of Severely Handicapped Newborns. Once a child is born, the child is a full-fledged human being and is to be treated in its health care like all other human beings. That is true for disabled newborns (or adults, for that matter) just as much as it is for those with no disabilities. The image of God in each one of us does not depend on one's abilities or skills; in this way the Jewish way of evaluating life is distinctly at odds with the utilitarian view common in Western societies.

If the child is born with severe disabilities that threaten his or her life, however, heroic measures need not be employed to keep the child alive. Here the same rules that govern the withholding and removal of life-support systems of any human being apply to newborns, with all of the diversity of opinion among rabbis noted in that section below. Some rabbis, however, are more lenient with respect to the treatment of newborns than they are regarding people dying later on in life because of the possibility, noted in Jewish law, that the child was born prematurely. Specifically, until the child is 30 days old, he or she is not considered to be a person whose life is confirmed (a *bar kayyma*). Therefore, while we may not

do anything actively to hasten the child's death, we may, according to these authorities, do less to sustain it than we would be called upon to do with regard to people who had lived beyond 30 days. Thus some who would insist on artificial nutrition and hydration for most dying people would not require it for life-imperiled infants less than 30 days old — except of course if the intervention holds out significant promise of curing the infant of the disease or condition. Some would require incubators, but most would not require surgery or medications beyond those necessary to relieve the child of pain (50).

Stem Cell Research

Jewish Views of Genetic Materials. Since human embryonic stem cells can be procured from aborted fetuses, the status of abortion within Judaism immediately arises. As we have seen, sometimes abortion is required by Jewish law and sometimes it is permitted, but mostly it is forbidden. The upshot of the Jewish stance on abortion, then, is that *if* a fetus was aborted for legitimate reasons under Jewish law, the aborted fetus may be used to advance our efforts to preserve the life and health of others.

In general, when a person dies, we must show honor to God's body by burying it as soon after death as possible. To benefit the lives of others, though, autopsies may be performed when the cause of death is not fully understood, and organ transplants are allowed to enable other people to live (51). The fetus, though, does not have the status of a full-fledged human being. Therefore, if we can use the bodies of human beings to enable others to live, how much the more so may we use a part of a body — in this case, the "water" or "thigh" that constitutes the fetus — for that purpose. This all presumes, though, that the fetus was aborted for good and sufficient reason within the parameters of Jewish law.

Stem cells for research purposes can also be procured from donated sperm and eggs mixed together in a petri dish and cultured there. Genetic materials outside the uterus have no legal status in Jewish law, for they are not even a part of a human being until implanted in a woman's womb, and even then, as we have noted, during the first 40 days of gestation their status is "as if they were simply water" (52). Abortion is still prohibited during that time except for therapeutic purposes, for in the uterus such gametes have the potential of growing into a human being, but outside the womb, at least as of now, they have no such potential. As a result frozen embryos may be discarded or used for reasonable purposes, and so may stem cells procured from them.

Other Factors in Stem Cell Research. Given that the materials for stem cell research can be procured in permissible ways, the technology itself is morally neutral. It gains its moral valence on the basis of what we do with it. The question, then, reduces to a risk-benefit analysis of stem cell research. The articles in a recent *Hastings Center Report* (53) raise some questions to be considered in such an analysis, and I will not rehearse them here. I want to note only two things about them from a Jewish perspective.

First, the Jewish tradition sees the provision of health care as a communal responsibility, and so the justice arguments in the *Hastings Center Report* have a special resonance for me as a Jew. Especially since much of the basic science in this area was funded by the government, the government has the right to require private companies to provide their applications of that science to those who cannot afford them at reduced rates or, if necessary, even for free. At the same time, the Jewish tradition does not demand socialism, and for many good reasons we, in the United States, have adopted a modified, capitalistic system of economics. The trick, then, will be to balance access to applications of the new technology with the legitimate right of a private company to make a profit on its efforts to develop and market applications of stem cell research.

Second, the potential of stem cell research for creating organs for transplant and cures for diseases is, at least in theory, both awesome and hopeful. Indeed, in light of our divine mandate to seek to maintain life and health, one might even argue that from a Jewish perspective we have a *duty* to proceed with that research. As difficult as it may be, though, we must draw a clear line between uses of this or any other technology for cure, which are to be applauded, as against uses of this technology for enhancement, which must be approached with extreme caution. Jews have been the brunt of campaigns of positive eugenics both here, in the United States, and in Nazi Germany (54), and so we are especially sensitive to creating a model human being that is to be replicated through the genetic engineering that stem cell applications will involve. Moreover, when Jews see a disabled human being, we are not to recoil from the *disability* or count our blessings for not being disabled in that way; we are rather commanded to recite a blessing thanking God for making people different (55). In light, then, of the Jewish view that all human beings are created in the image of God, regardless of their levels of ability or disability, it is imperative from a Jewish perspective that the applications of stem cell research be used for cure and not for enhancement.

We thus should take the steps necessary to advance stem cell research and its applications in an effort to take advantage of its great potential for good. We should do so, though, with restrictions to enable access to its applications to all Americans who need it and to prohibit applications intended to make all human beings into any particular model of human excellence. Instead, through this technology and all others, we should seek to cure diseases while simultaneously retaining our appreciation for the variety of God's creatures.

TECHNOLOGY AT THE END OF LIFE

Care of the Dying

General Concepts and Categories. Judaism prohibits murder, and it views all forms of active euthanasia as the equivalent of murder (56). That is true even if the patient asks to be killed. Because each person's body belongs to God, the patient does not have the right either to commit suicide or to enlist the aid of others in the act. Those who assist someone in a suicide violate Jewish law; the specific

nature and severity of the violation depend on how the aid is proffered. No human being has the right to destroy or even damage God's property (57).

The patient does have the right, however, to pray to God to permit death to come (58), for God, unlike human beings, has the right to destroy His own property. Moreover Judaism does permit passive euthanasia in specific circumstances.

Point When Passive Euthanasia Is Permissible. When does the Jewish obligation to cure end, and when does the permission (or, according to some, the obligation) to let nature take its course begin?

Authorities differ. All agree that one may allow nature to take its course once the person becomes a *goses*, a moribund person. But when does that state begin? The most restrictive position is that of Rabbi J. David Bleich, who limits it to situations when all possible medical means are being used in an effort to save the patient and the physicians assume that he or she will nevertheless die within 72 hours (59). Others define the state of *goses* more flexibly and therefore apply the permission to withhold or withdraw machines and medications during that time more broadly, in some cases up to a year or more (60).

In a rabbinic ruling approved by the Conservative Movement's Committee on Jewish Law and Standards (61), I noted that classical Jewish sources describe a *goses* as if the person were "a flickering candle," so that he or she may not even be moved for fear of inducing death. That description and that medical therapy only apply to people within the last hours of life (not even the last three days). Consequently, I argued, the appropriate Jewish legal category to describe people with terminal, incurable diseases, who may live for months and even years, is, instead, *terefah*. Permission to withhold or withdraw medications and machines would then apply to people as soon as they are in the state of being a *terefah*, that is, as soon as they are diagnosed with a terminal, incurable illness. In judging a disease to be incurable, we are not responsible for knowing whether a cure is imminent, for we are not God; the attending physicians must just use their best judgment.

Artificial Nutrition and Hydration. While intravenous cannulation to provide nutrition and fluids is appropriately used in people where there is reasonable hope for recovery, where no such hope exists, may one remove such tubes? Some rabbis have said no, reasoning that since artificial nutrition and hydration supply the liquids and nutrients that all of us need to survive, they cannot be classified as medications, which are used only when specific people need them (62). Others, however, noting that the Talmud specifically defines "food" as that which is ingested through the mouth and swallowed, classify artificial nutrition and hydration as medicine and permit removing or withholding them when recovery is not anticipated. Those attending the patient, though, must still go through the motions of bringing in a normal food tray at regular meal times in fulfillment of our duty to feed the starving (63).

Curing the Patient, Not the Disease. The important thing to note, however, is that there is general agreement that a Jew need not use heroic measures to maintain his or her life but only those medicines and procedures that are commonly available in the person's time and place. We are, after all, commanded to *cure* based on the verse in Exodus 21:19, "and he shall surely cure him." We are not commanded to sustain life *per se* (64). Thus, on the one hand, as long as there is some hope of cure, heroic measures and untested drugs *may* be employed, even though this involves an elevated level of risk. On the other hand, physicians, patients, and families who are making such critical care decisions are *not* duty-bound by Jewish law to invoke such therapies and may instead follow a course of hospice care. Indeed, because hospice care involves the support of family and friends and subjects the patient to the least amount of physical invasion possible, it often is preferable to more technologically sophisticated forms of treatment.

Pain medication may be administered as needed. Even in the last stages of life, when the dosage needed may actually hasten the patient's death, it may be used so long as the intent is not to kill the person but rather to alleviate his or her pain (65).

Moreover our duty to cure the patient rather than any specific disease means that if a person who is suffering from multiple, incurable, terminal illnesses develops pneumonia, doctors may refrain from treating the pneumonia if that will enable the patient to die less painfully. This would be in line with the strain in Jewish law that does not automatically and mechanically assume that preservation of life trumps all other considerations but rather judges according to the best interests of the patient (66). That principle does not extend so far as to permit mercy killing (active euthanasia), but it does make it permissible to refrain from administering the antibiotic so that the patient can die of his or her other diseases.

A person may volunteer to undergo an experimental procedure that holds out no hope to improve his/her own health but may increase medical knowledge and thereby help others only if it subjects the person to minimal or no risk. One's duty to preserve one's own life takes precedence over one's obligation to help other people preserve theirs.

Care of the Deceased: Autopsies and Organ Transplants

General Principles. The treatment of these topics in Jewish law depends on two primary principles. The general tenet that governs treatment of the body after death is *kavod ha'met*, namely, that we should render honor to the dead body as a sign of respect for both the deceased person and for God's property. Honor of the corpse, then, underlies Jewish burial customs.

The other principle that affects the topics of this section is that of *pikkuah nefesh*. When interpreting Leviticus 18:5, which says that we should obey God's commands "and live by them," the rabbis deduce that this means that we should not die as a result of observing them. The tenet that emerges is *pikkuah nefesh*, the obligation to save people's lives. This tenet is so deeply embedded in Jewish law that, according to the rabbis, it takes precedence over all other commandments except murder, idolatry, and incestuous or adulterous sexual intercourse (67).

Jews are commanded not only to do virtually anything necessary to save their own lives; they are also bound by the positive obligation to take steps to save the lives of others. The imperative to do so is derived from the biblical command, "Do not stand idly by the blood of your neighbor" (Leviticus 19:16). This means, for example, that if you see someone drowning, you may not ignore him or her but must do what you can to save that person's life (68).

What happens, when you can only save your life or someone else's? Whose life takes precedence? Since the Torah says that one should not exact interest from a fellow Jew "so that your brother may live *with you*" (Leviticus 25:36), and since you must therefore be alive at the time that you care for your brother, "your life takes precedence (*hayyekha kodemim*)" (69).

Autopsies. The two procedures that may interrupt the normal Jewish burial process are autopsies and organ transplants. Even though autopsies require invading the body of the deceased, in 1949 Israeli Chief Rabbi Isaac Herzog enunciated what has come to be the generally accepted position among Jews — namely, that while autopsies may not be done routinely, they are permissible if required by civil law, if the cause of death cannot otherwise be ascertained, if three physicians attest that the autopsy might help save the lives of others suffering from an illness similar to that from which the patient had died, or if a hereditary illness was involved so that performing the autopsy might safeguard surviving relatives. In all these cases we honor the dead by using the body to save lives.

Organ Transplantation. The overriding principles of honoring the dead (*kavod ha-met*) and saving people's lives (*pikkuah nefesh*) also work in tandem in organ transplantation. So the default assumption is that a person would be honored to help another live through organ donation.

Living Donors. Because one's own life takes precedence over helping someone else live, contemporary rabbis have generally permitted, but not required, donations from living donors when their life or health is not thereby subjected to major risk (70). If a family member suffers from leukemia and no appropriate bone marrow match is available, a married couple may seek to have another child in an attempt to find such a match, but only if they will not abort the child even if it becomes clear that the child is not the match they seek.

Cadaveric Donors. Since a dead person incurs no health risk, cadaveric donations are not only generally held to be permissible but, according to a responsum approved by the Conservative Movement's Committee on Jewish Law and Standards, actually a positive obligation so as to prevent the need of living persons incurring such risks while also saving the recipient's life. While traditional Jewish sources define the moment of death as the cessation of heartbeat and breath (71), even the chief rabbinate of the State of Israel in 1987 approved heart transplants, thereby accepting evidence of full brain death (including the brain stem) as fulfilling those requirements (72).

If a fetus has been aborted for reasons approved by Jewish law — namely to save the life or health of the mother or because the fetus suffers from Tay-Sachs or some similar fatal illness — the fetus may be used for purposes of transplant or experimentation.

Use of Animal or Artificial Organs; Animal Experimentation. While Judaism seeks to minimize pain to animals (73), it permits their use for food, for work, and, certainly, for saving a life. This would include medical research based on animal trials and the use of animal parts for transplantation, if that proves successful.

ENVIRONMENTAL USES OF TECHNOLOGY

The Jewish tradition, from the Torah on, was concerned with preserving God's world, leading to a series of ecological laws (74). Although classical Jewish law could not contemplate all the opportunities and problems produced by modern technology, it already prohibits wasting natural resources, even if one owns them, and it makes people responsible for the air and water pollution they cause. Judaism's appreciation of the world as belonging to God would additionally require us, in modern times, to create less waste than we moderns do, especially in technologically sophisticated societies, to recycle, and to use our new technology to reduce and, if possible, prevent pollution.

One application of biotechnology that, on the face of it, might cause special problems for Jews is the use of technology to produce new foods. Jewish dietary laws (*kashrut*, or "keeping kosher") restrict the fish, fowl, and animals that Jews may eat and the way that they are killed and their meat prepared and served. The Torah also forbids mixing seeds (*kilayim*) (75), but if non-Jews, who are not subject to this law, create hybrids, Jews may use them. An established principle in Jewish law, though, is that if a substance is chemically changed so that it cannot be reconstituted in its original form, it is "a new thing" (*davar hadash*) and, as such, loses any characteristics of its origins (76). Therefore bioengineered foods, such as cloned tomatoes, may certainly be eaten in accordance with Jewish dietary laws if the original substances are kosher and, if there is sufficient chemical change, even if the original substances are not kosher. Similarly Jews may engage in bioengineering new foods without violating the laws against mixing seeds if all (or all but one of) the materials to be combined are already so chemically changed as to constitute a new substance.

BIBLIOGRAPHY

1. See, for example, Deuteronomy 10:14; Psalms 24:1. See also Genesis 14:19, 22 (where the Hebrew word for "Creator" [*koneh*] also means "Possessor," and where "heaven and earth" is a merism for those and everything in between); Exodus 20:11; Leviticus 25:23, 42, 55; Deuteronomy 4:35, 39; 32:6.
2. *Genesis Rabbah* 11:6; *Pesikta Rabbati* 22:4.
3. See, for example, Deuteronomy 10:14; Psalms 24:1. See also Genesis 14:19, 22; Exodus 20:11; Leviticus 25:23, 42, 55; Deuteronomy 4:35, 39; 32:6. For these three and four other foundational principles of Jewish medical ethics, see E.N. Dorff, *Matters of Life and Death: A Jewish Approach to Modern Medical Ethics*, Jewish Publication Society, Philadelphia, PA, 1998, Ch. Two.

4. Thus, for example, bathing is a commandment, according to Hillel: *Leviticus Rabbah* 34:3. Maimonides includes rules requiring proper care of the body in his code of Jewish law as *a positive obligation* (not just advice for feeling good or living a long life), parallel to the positive duty to aid the poor: Maimonides' *Mishneh Torah* (1177 C.E.) *Laws of Ethics (De'ot)*, Chs. 3–5.

11. E.g., Exodus 15:26; Deuteronomy 32:39; Isaiah 19:22; 57:18–19; Jeremiah 30:17; 33:6; Hosea 6:1; Psalms 103:2–3; 107:20; Job 5:18.
12. The permission and duty to heal: Babylonian Talmud (edited circa 500 C.E.) *Bava Kamma* 85a, 81b; Babylonian Talmud (edited circa 500 C.E.) *Sanhedrin* 73a, 84b (with Rashi's commentary there). See also *Sifrei Deuteronomy* on Deuteronomy 22:2 and *Leviticus Rabbah* 34:3. Nahmanides, *Kitvei Haramban*, Bernard Chavel, ed., (Jerusalem: Mosad Harav Kook, 1963 [Hebrew]), vol. 2, p. 43, bases the duty for the community to provide health care on Leviticus 19:18, "You shall love your neighbor as yourself"; this passage comes from Nahmanides' *Torat Ha'adam (The Instruction of Man), Sh'ar Sakkanah (Section on Danger)* on Babylonian Talmud (edited circa 500 C.E.) *Bava Kamma*, Ch. 8, and is cited by Joseph Karo in his commentary to the *Tur, Bet Yosef, Yoreh De'ah* 336. Nahmanides bases himself on similar reasoning in Babylonian Talmud (edited circa 500 C.E.) *Sanhedrin* 84b.
13. Babylonian Talmud (edited circa 500 C.E.) *Sanhedrin* 74a.
14. The best of physicians deserves to go to Hell: Babylonian Talmud (edited circa 500 C.E.) *Kiddushin* 82a. Abraham ibn Ezra, Bahya ibn Pakuda, and Jonathan Eybeschuetz all restricted the physician's mandate to external injuries: See Ibn Ezra's commentary on Exodus 21:19 and cf. his comments on Exodus 15:26 and 23:25, where he cites Job 5:18 and II Chronicles 16:12 in support of his view; Bahya's commentary on Exodus 21:19; and Eybeschuetz, *Kereti U'pleti* on Joseph Karo's *Shulhan Arukh* (1565 C.E.) with the glosses of Moses Isserles. *Yoreh De'ah* 188:5. See I. Jakobovits, *Jewish Medical Ethics*, Bloch, New York, 1959, 1975, 5–6. That a Jew may not live in a city without a physician: Jerusalem Talmud (edited circa 400 C.E.) *Kiddushin* 66d; see also Babylonian Talmud (edited circa 500 C.E.) *Sanhedrin* 17b, where this requirement is applied only to "the students of the Sages."
15. Joseph Karo's *Shulhan Arukh* (1565 C.E.) with the glosses of Moses Isserles. *Yoreh De'ah* 336:1.
16. *Midrash Temurrah* as cited in J.D. Eisenstein, ed., *Otzar Midrashim*, vol. 2, New York, 1915, pp. 580–581. Cf. also Babylonian Talmud (edited circa 500 C.E.) *Avodah Zarah* 40b, a story in which rabbi expresses appreciation for foods that can cure. Although circumcision is not justified in the Jewish tradition in medical terms, it is instructive that the rabbis maintained that Jewish boys were not born circumcised specifically because God created the world such that it would need human fixing, a similar idea to the one articulated here on behalf of physicians' activity despite God's rule; see note 2 above.
17. Babylonian Talmud (edited circa 500 C.E.) *Shabbat* 10a, 119b. In the first of those passages, it is the judge who judges justly who is called God's partner; in the second, it is anyone who recites Genesis 2:1–3 (about God resting on the seventh day) on Friday night who thereby participates in God's ongoing act of creation. The Talmud in Babylonian Talmud (edited circa 500 C.E.) *Sanhedrin* 38a specifically wanted the Sadducees *not* to be able to say that angels or any being other than humans participate with God in creation.
18. On this entire matter, the Rabbinical Assembly, the rabbinic body of the Conservative Movement within Judaism, has created a rabbinic letter designed for use with adults and with teenagers discussing the concepts, values, and laws of Judaism governing intimate relations, marriage, nonmarital sex, and homosexuality. See E.N. Dorff, *This Is My Beloved, This Is My Friend: A Rabbinic Letter on Intimate Relations*, Rabbinical Assembly, New York, 1996. See also E.N. Dorff, *Matters of Life and Death*, Jewish Publication Society, Philadelphia, PA, 1998, Ch. 3–6.
19. Genesis 2:18; cf. *Midrash Psalms* on Psalms 59:2. Exodus 21:10 prescribes that a woman has conjugal rights in marriage, just as a man does, and the rabbis then spell out exactly how often a man must offer to have sex with his wife and how long she can refuse his advances without losing part of her settlement in a divorce; see Mishnah (edited circa 200 C.E.); *Ketubbot* 5:6–7. Note that he may never force himself upon her.
20. For example, Deuteronomy 7:13–14; 28:4, 11; Psalms 128:6.
21. Genesis 15:5; 17:3–6, 15–21; 18:18; 28:14; 32:13.

22. Mishnah (edited circa 200 C.E.); *Yevamot* 6:6 (61b); Babylonian Talmud (edited circa 500 C.E.) *Yevamot* 65b–66a; Maimonides' *Mishneh Torah* (1177 C.E.) *Laws of Marriage* 15:2; Joseph Karo's *Shulhan Arukh* (1565 C.E.) with the glosses of Moses Isserles. *Even Ha'ezer* 1:1, 13.
23. Deuteronomy 6:5.
24. Babylonian Talmud (edited circa 500 C.E.) *Yevamot* 12b. For a thorough discussion of this, see D.M. Feldman, *Birth Control in Jewish Law*, New York University Press, New York, 1968; reprinted as *Marital Relations, Abortion, and Birth Control in Jewish Law*, Schocken, New York, 1973.
25. Cf. Maimonides' *Mishneh Torah* (1177 C.E.) *Laws of Forbidden Intercourse* 16:2, 6; Joseph Karo's *Shulhan Arukh* (1565 C.E.) with the glosses of Moses Isserles. *Even Ha'ezer* 5:2.
26. Babylonian Talmud (edited circa 500 C.E.) *Shabbat* 110b.
27. Cf. J.D. Bleich, *Judaism and Healing*, Ktav, New York, 1981, p. 65.

    D. Feldman and F. Rosner, eds., *Compendium on Medical Ethics*, New York, 1984, pp. 46–47.

    S. Freehof, *Reform Responsa*, Hebrew Union College Press, Cincinnati, OH, 1960, pp. 206–208.
28. Babylonian Talmud (edited circa 500 C.E.) *Yevamot* 69b. Rabbi I. Jakobovits [*Jewish Medical Ethics*, Bloch, New York, 1959, 1975, p. 275] notes that "40 days" in talmudic terms may mean just under two months in our modern way of calculating gestation due to improved methods of determining the date of conception.
29. Babylonian Talmud (edited circa 500 C.E.) *Niddah* 17a.
30. Cf. D.M. Feldman, *Birth Control in Jewish Law*, New York University Press, New York, 1968, pp. 265–266 and Ch. 15.
31. Mishnah (edited circa 200 C.E.) *Niddah* 3:5.
32. Mishnah (edited circa 200 C.E.) *Oholot* 7:6. There are variant versions of this. Like our Mishnah, Jerusalem Talmud (edited circa 400 C.E.) *Shabbat* 14:4 reads "its greater part;" Tosefta (edited circa 200 C.E.) *Yevamot* 9:9 and Babylonian Talmud (edited circa 500 C.E.) *Sanhedrin* 72b have "its head;" and Jerusalem Talmud (edited circa 400 C.E.) *Sanhedrin* 8, end, has "its head or its greater part."
33. Cf. I. Jakobovits, *Jewish Medical Ethics*, Bloch, New York, 1975, pp. 186–187 and No. 173 on pp. 378–379.
34. Cf. D.M. Feldman, *Birth Control in Jewish Law*, New York University Press, New York, 1968, pp. 284–294.

    M.H. Spero, *Judaism and Psychology: Halakhic Perspectives*, Ktav, New York, 1980, Ch. 12.
35. I. Jakobovits, *Jewish Medical Ethics*, Bloch, New York, pp. 189–190.

    J.D. Bleich, in F. Rosner and J.D. Bleich, eds., *Jewish Bioethics*, Sanhedrin Press, New York, 1979, Ch. 9, esp. pp. 161 and 175, No. 97.
37. Cf. D.M. Feldman, *Birth Control in Jewish Law*, New York University Press, New York, 1968, pp. 284–294.
38. E. Waldenberg, *Responsa Tzitz Eliezer*, 9:51 (1967) and 13:102 (1978) [Hebrew]; S. Israeli, *Amud Hayemini*, No. 35 cited in *No'am*,16 (K.H.) 27 (note) [Hebrew]; L. Grossnass, *Responsa Lev Aryeh* 2:205 [Hebrew]; A.J. Goldman, *Judaism Confronts Contemporary Issues*, Ktav, New York, 1978, Ch. 3, esp. pp. 52–62.
39. I. Jakobovits, *Jewish Medical Ethics*, Bloch, New York, 1975, p. 264.

    J.D. Bleich, *Judaism and Healing: Halakhic Perspectives*, Ktav, New York, 1981, pp. 82–84.
40. J.D. Bleich [*Judaism and Healing*, Ktav, New York, 1981, pp. 80–84] cites all of the following authorities (all of whom wrote in Hebrew) as requiring physical contact of the genital organs for adultery to occur: R. Shalom Mordecai Schwadron, *Teshuvot Zekan Aharon*, II, No. 97; R. Yehoshua Baumol, *Teshuvot Emek Halakhah*, No. 68; R. Ben Zion Uziel, *Mishpetei Uziel, Even Ha-Ezer*, I, No. 19; R. Moshe Feinstein, *Iggrot Moshe, Even Ha-Ezer*, I, No. 10; and R. Eliyahu Meir Bloch, *Ha-Pardes*, Sivan 5713. Nevertheless, as he points out, these Orthodox rabbis would prohibit donor insemination on the grounds of potential incest in the next generation, as discussed in the next paragraph. Moreover some Orthodox rabbis Bleich cites (R. Yehudah Leib Zirelson, R. Ovadiah Hadaya, R. Eliezer Waldenberg) maintain that violating the prohibition against adultery does not require genital contact, and so they would object to donor insemination on that ground as well.
41. E.N. Dorff, Artificial insemination, egg donation, and adoption, *Conservative Judaism* **49**(1), 3–60 (1996). This rabbinic ruling, approved in 1994 by the Conservative Movement's Committee on Jewish Law and Standards, also discusses several ancillary concerns, such as the identity of the father for various purposes in Jewish law; the psychological issues raised by the asymmetry in the situation — namely that the child will be the biological product of the woman but not the man who will be raising him/her; and the psychological need of the child to know his/her genetic roots. This ruling was reprinted in E.N. Dorff, *Matters of Life and Death*, Jewish Publication Society, Philadelphia, PA, 1998, pp. 66–115.
42. R. Spirtas, S.C. Kaufman, and N.J. Alexander, *Fertility and Sterility* [J. Am. Fertil. Soc.] **59**(2), 291–292 (1993). I want to thank my friend, Dr. Michael Grodin, for sharing this article with me. The 1988 Congressional report also reported a number of other possible complications caused by commonly used drugs to stimulate the ovaries, including early pregnancy loss, multiple gestations (fetuses), ectopic pregnancies, headache, hair loss, pleuropulmonary fibrosis, increased blood viscosity, and hypertension, stroke, and myocardial infarction; see U.S. Congress, Office of Technology Assessment, *Infertility: Medical and Social Choices*, OTA-BA-358, U.S. Government Printing Office, (Washington, DC, 1988), pp. 128–129. Once again, the demonstrated risks are not so great as to make stimulation of the ovaries for egg donation prohibited as a violation of the Jewish command to guard our health, but they are sufficient to demand that caution be taken and that the number of times a woman donates eggs be limited.
43. Rabbi Aaron Mackler, *In vitro Fertilization*, Draft No. 3, November, 1995, adopted by the Committee on Jewish Law and Standards in December, 1995, (unpublished); see p. 12 of the typescript.
44. See, for example, J.D. Bleich, *Judaism and Healing: Halakhic Perspectives*, Ktav, New York, 1981, pp. 85–91.

    E.N. Dorff, *Conservative Judaism* **49**(1), 17–18, 47–48 (1996), with regard to donor insemination and egg donation, but the same considerations, although sometimes in different forms, apply to IVF, GIFT, and ZIFT. See also E.N. Dorff, *Matters of Life and Death*, Jewish Publication Society, Philadelphia, PA, 1998, Ch. 3 and 4.
45. E.N. Dorff, Artificial insemination, *Conservative Judaism* **49**(1), 47 (1996); *Matters of Life and Death*, Jewish Publication Society, Philadelphia, PA, 1998, pp. 56–57, 101–102, 129–130.

46. Genesis 16:2 uses a play on words in Hebrew when Sarai says to Abram, "Look, the Lord has kept me from bearing. Consort with my maid [Hagar]; perhaps I shall have a son [also, I shall be built up] through her." This indicates that Ishmael, the son that resulted from this union, was not only to be considered Abram's son, but Sarai's as well. Similarly Rachel tells Jacob, "Here is my maid Bilhah. Consort with her, that she may bear on my knees and that through her I too may have children" (Genesis 30:3). At that time, Rachel was infertile (she gave birth to Joseph and Benjamin only later), but Leah, who had already had four sons, also gave her handmaid, Zilpah, to Jacob, and when Zilpah bore two sons to Jacob, Leah says " 'What fortune!' meaning, 'Women will deem me fortunate' " (Genesis 30:13) — indicating that those two sons were ascribed to Leah as well. That Leah had stopped bearing and therefore resorts to the use of her handmaid Zilpah: Genesis 30:9. That she later bears three more children: Genesis 30:14–21.
47. See, for example, J.D. Bleich, *Judaism and Healing*, Ktav, New York, 1981, pp. 92–95. While Rabbi Bleich generally prohibits or limits the use of new medical procedures, here he specifically argues against Rabbi Jakobovits' claim that surrogacy is inherently immoral and spends most of his discussion on the question of the Jewish identity of the child. See also M. Gold, *And Hannah Wept: Infertility, Adoption, and the Jewish Couple*, Jewish Publication Society, Philadelphia, PA, 1988, pp. 120–127; and E. Spitz, Through her I too shall bear a child: Birth surrogates in Jewish law. *J. Religious Ethics* **24**(1), 65–97 (1996), a slightly different version of which was approved by the Conservative Movement's Committee on Jewish Law and Standards in September, 1997. At that same meeting the Committee also approved a rabbinic ruling, as yet unpublished, by Rabbi Aaron Mackler that ultimately permits surrogacy but with more disclaimers and restrictions.
48. For a good, popular article describing some of the issues involved, see L. Belkin, Getting the girl. *N.Y. Times Mag.*, July 25, 1999, pp. 26–31, 38, 54–55.

48a. *N.Y. Times*, April 28, pp. A1–A16 (2000).

49. E.g., Bleich, *Judaism and Healing*, Bloch, New York, 1981, p. 106.
50. Rabbi Avram Reisner reasons this way in a responsum entitled *Peri- and Neo-Natology*, approved by the Conservative Movement's Committee on Jewish Law and Standards in Fall, 1995 (unpublished). That a child's life is not confirmed until 30 days of age: Babylonian Talmud (edited circa 500 C.E.) *Shabbat* 135b.
51. For classical sources on this, see E.N. Dorff, *Matters of Life and Death*, Jewish Publication Society, Philadelphia, PA, 1998, Ch. 9.
52. Babylonian Talmud (edited circa 500 C.E.) *Yevamot* 69b. Rabbi Immanuel Jakobovits notes that "40 days" in talmudic terms may mean just under two months in our modern way of calculating gestation, since the Rabbis counted from the time of the first missed menstrual flow while we count from the time of conception, approximately two weeks earlier. See I. Jakobovits, *Jewish Medical Ethics*, Bloch, New York, 1959, 1975, p. 275.
53. *Hastings Center Report*, March–April, 1999, pp. 30–48.
54. See S.J. Gould, *The Mismeasure of Man*, Norton, New York, 1996, and G.J. Annas and M.A. Grodin, *The Nazi Doctors and the Nuremberg Code: Human Rights in Human Experimentation*, Oxford University Press, New York, 1992.
55. For a thorough discussion of this blessing and concept in Jewish tradition, see C. Astor, "... *Who makes people different*": *Jewish Perspectives on the Disabled*, United Synagogue of America, New York, 1985.
56. Mishnah (edited circa 200 C.E.); *Semahot* 1:1–2; Mishnah (edited circa 200 C.E.); *Shabbat* 23:5 and Babylonian Talmud (edited circa 500 C.E.) *Shabbat* 151b; Babylonian Talmud (edited circa 500 C.E.) *Sanhedrin* 78a; Maimonides' *Mishneh Torah* (1177 C.E.) *Laws of Murder* 2:7; Joseph Karo's *Shulhan Arukh* (1565 C.E.) with the glosses of Moses Isserles. *Yoreh De'ah* 339:2 and the comments of the Shakh and Rama there.
57. This includes even inanimate property that "belongs" to us, for God is the ultimate owner. Cf. Deuteronomy 20:19; Babylonian Talmud (edited circa 500 C.E.) *Bava Kamma* 8:6, 7; Babylonian Talmud (edited circa 500 C.E.) *Bava Kamma* 92a, 93a; Joseph Karo's *Shulhan Arukh* (1565 C.E.) with the glosses of Moses Isserles. *Hoshen Mishpat* 420:1, 31.
58. Cf. RaN, Babylonian Talmud (edited circa 500 C.E.) *Nedarim* 40a. The Talmud records such prayers: Babylonian Talmud (edited circa 500 C.E.) *Ketubbot* 104a, Babylonian Talmud (edited circa 500 C.E.) *Bava Mezia* 84a, and Babylonian Talmud (edited circa 500 C.E.) *Ta'anit* 23a. Note that this is not a form of passive euthanasia: in that, people refrain from acting, but here God is asked to act.
59. J.D. Bleich, *Judaism and Healing*, Ktav, New York, 1981, pp. 141–142.
60. E.g., I. Jakobovits, *Jewish Medical Ethics*, Bloch, New York, 1975, p. 124 and No. 46.

61. E.N. Dorff, *Conservative Judaism* **43**(3), 3–51, esp. pp. 19–26 (1991); *United Synagogue Rev.* **44**(1, Fall), 21–22 (1991).
62. E.g., Rabbi Avram Israel Reisner, holds this view; see *Conservative Judaism* **43**(3), 62–64 (1991).
63. E.N. Dorff, *Conservative Judaism* **43**(3), 34–39 (1991).
64. Thus the Talmud specifically says, "We do not worry about mere hours of life" (Babylonian Talmud (edited circa 500 C.E.) *Avodah Zarah* 27b). The Talmud also says, however, that we may desecrate the Sabbath even if the chances are that it will only save mere hours of life (Babylonian Talmud (edited circa 500 C.E.) *Yoma* 85a). The latter source has led some Orthodox rabbis to insist in medical situations that every moment of life is holy and that therefore every medical therapy must be used to save even moments of life; e.g., see J.D. Bleich, *Judaism and Healing*, Ktav, New York, 1981, pp. 118–119, 134–145. The only exception is when a person is a *goses*, which Rabbi Bleich defines as within 72 hours of death, at which time passive, but not active, euthanasia may be practiced. He then uses the source in *Avodah Zarah* only to permit hazardous therapies that may hasten death if they do not succeed in lengthening life. Rabbi Bleich's position is *not*, however, necessitated by the sources. On the contrary, they specifically allow us (or, on some readings, command us) not to inhibit the process of dying when we can no longer cure, even long before 72 hours before death (however that is predicted).
65. Rabbi Reisner does not accept this "double-effect" argument, but he would agree that pain should be alleviated as much as possible up to, but not including, the dosage that would have the inevitable effect of hastening the person's death, even if not intended for that purpose. See A.I. Reisner, *Conservative Judaism* **43**(3), 66, 83–85, Notes 50–52 (1991); and see, in contrast, E.N. Dorff, *Conservative Judaism* **43**(3), 17–19, 43–45, Notes 24–27 (1991). See also Rabbi Reisner's summary of the differences between the Dorff and Reisner positions, *Conservative Judaism* **43**(3), 91 (1991).

66. Tosafot, Babylonian Talmud (edited circa 500 C.E.) *Avodah Zarah* 27b, s.v., *lehayyei sha'ah lo hyyshenan*. See E.N. Dorff, *Conservative Judaism* **43**(3), 15–17, 43, No. 22 (1991). For a contrasting interpretation of this source, see A.I. Reisner, *Conservative Judaism* **43**(3), 56–57, 72, No. 21.
67. Babylonian Talmud (edited circa 500 C.E.) *Yoma* 85a–b (with Rashi there); Babylonian Talmud (edited circa 500 C.E.) *Sanhedrin* 74a–b; *Mekhilta on Exodus* 31:13; and for a general discussion of this topic, see I. Jakobovits, *Jewish Medical Ethics*, Bloch, New York, 1975, pp. 45–98.
68. Babylonian Talmud (edited circa 500 C.E.) *Sanhedrin* 73a.
69. Babylonian Talmud (edited circa 500 C.E.) *Bava Metzia* 62a.
70. I. Jakobovits, *Jewish Medical Ethics*, Bloch, New York, 1975, p. 291; cf. also pp. 96–98. That this is the generally held opinion regarding living donors is true not only for Orthodox rabbis, some of whom he cites but also for Conservative and Reform rabbis. For Orthodox opinions, see Moshe Feinstein, *Igrot Moshe*, Yoreh De'ah 229 and 230 [Hebrew]; E. Waldenberg, *Tzitz Eliezer*, vol. 9, No. 45; vol. 10, No. 25 [Hebrew]; Obadiah Yosef, *Dinei Yisrael*, vol. 7 [Hebrew]. For a Conservative position (the only one I know of to date on living donors), see E.N. Dorff, *Choose Life: A Jewish Perspective on Medical Ethics*, University of Judaism, Los Angeles, CA, 1985, p. 23. For Reform positions, see S.B. Freehof, *New Reform Responsa*, Hebrew Union College, Cincinnati, OH, 1980, p. 62ff.

OUTLINE

INTRODUCTION

Protestant thought has played a critical and ironic role in the development of the ethical justifications and practices of biotechnology. The influential theologians of the Protestant Reformation, such as Martin Luther (1483–1546) and John Calvin (1509–1564), made a sharp distinction between God and nature (including human nature). All value is derivative of the divine being; nature and human beings, having experienced the dramatic and enduring consequences of the human fall from divine grace, have been divested of ultimate value and stand in need of redemption and reconciliation. One result of these profound theological claims was, to borrow from Max Weber's memorable phrase, the "disenchantment of the world" (1), that is, nature loses its reverential hold on human attitudes and actions, and comes to be seen as a realm open to the many manipulations of science and technology. Ironically, these manipulations over time would culminate in skepticism over the existence of the God that Protestant theology wanted to bring to the forefront of human consciousness. For some contemporary Protestants, this unanticipated result of a basic theological claim leads to religious and moral criticism of biotechnology.

It is nonetheless the case that Protestant perspectives on biotechnology are multiple and complex, and connected with deeply rooted theological claims about God, human beings, and nature. This article will provide an overview of these perspectives, beginning with attention to some of the formative views that characterize a position as "Protestant."

PROTESTANT DISTINCTIVENESS

Protestantism is first of all a "religion," rather than an "ethic," in which the primary questions concern the nature of God, God's relationship to humanity, and human nature and salvation. Nonetheless, themes that are embedded in these fundamentally theological issues have implications for ethical actions in the world and for perspectives on biotechnology.

Authority of Scripture

Protestant reformers and theologians are united in affirming the primary authority of the Bible as revealing the word of God to human beings about God, our relationship to God, and our prospects for redemption and reconciliation. God is revealed as Creator, Sustainer, and Redeemer. Human beings are mirrors or "images" of God in the world but have, through participation in sin and evil, fallen short of divine glory. Human reconciliation with God is made possible through the suffering of Jesus Christ for the sins of the world.

The authority of Scripture in the realm of salvation carries over, with some qualifications, in the realm of ethics. In Protestant thought, salvation is a matter of grace and mercy, which means the ethical life expresses salvation rather than being an instrument to salvation, as it is formulated in those religious traditions that emphasize salvation primarily by works or actions. Therefore the question of why human beings should be moral is for Protestants placed within a context of gratitude and gracious response to the divine gift of salvation, and a recognition of humility and human dependency upon powers beyond our control. One issue

for Protestants in examining the ethical questions of biotechnology is whether scientific research and its application retains this motivational sense of gratitude and humility or effaces it by emphasizing human accomplishment.

There is debate within the various Protestant traditions as to the sufficiency of Scripture for moral conduct. While the Bible has moral authority within Protestantism, it may not be *the only* authority. Theologian James M. Gustafson has argued that four resources are required for a comprehensive and adequate Christian (including Protestant) ethics:

1. Scripture and its interpretation through the historical tradition of Christianity
2. Philosophical insights, methods, and principles
3. Scientific methods and information
4. Interpretations of human experience (2)

In this understanding, Scripture illuminates the context of ethical issues, but it is not possible to move directly from a biblical passage to a moral conclusion about a current controversy in an area such as biotechnology. While such a position has been very influential among prominent Protestant theologians, it is not necessarily shared by evangelical and fundamentalist Protestants and their communities (3).

One implication of the moral authority of Scripture for Protestants is a corresponding non-normativeness of nature or the natural order. Indeed, some Protestant thought affirms the ongoing "ordering" of creation, rather than the created "order," precisely to emphasize the fluidity and dynamic interactions of nature, including those changes introduced by human beings. Nature is created good but is now currently disordered and no less in need of redemption. According to Protestant theology, Scripture reveals Jesus as healer of the disorder in nature, and provides a pattern for human beings to emulate. This model of scriptural interpretation is invoked by one influential scholar, Ronald Cole-Turner, to support the genetic alteration of plants in order to enhance their disease resistance. By enhancing the usefulness of plants, and diminishing environmental damage, human beings participate in the divine workings of redemption (4).

Thus, even though Protestant perspectives on biotechnology are profoundly influenced by interpretations of nature and the non-normativeness of the natural world, this does not imply that nature is without normative significance. Under the governance of divine providence, nature is susceptible to human intervention; indeed, human labor and ingenuity can use nature in the service of preserving and enhancing human (and animal) life. In some views, moreover, human beings are called to restore fallen nature to an original, properly ordered condition, given constraints of human finitude and fallibility. Given that Scripture does not speak directly to concrete issues in biotechnology, and that nature does not possess normative status but does possess normative significance for human action, it is possible to establish a Protestant theological presumption in favor of biotechnology. Biotechnology should be directed and constrained by norms of love, freedom, and stewardship.

Christian Freedom

As illustrated by the preceding discussion, dissent or "protest" is itself a characteristic Protestant theological perspective. This internal disagreement is manifested in many areas in Protestant thought, including the nature of ecclesiastical authority and its relation to biblical authority and the authority of personal conscience, as well as the role of sacraments mediated by the Church and their relation to saving grace. Given these disputes on matters of profound ecclesiastical importance, it comes as little surprise that Protestant history has been marked by continual reformations and the founding of new and diverse churches. In addition to these ecclesiastical implications, important ethical issues are embedded within the principle of "Christian freedom."

Freedom and Choice. Protestantism expresses a pronounced commitment to the primary of personal freedom and choice. Christian freedom should not be conflated with the secular norm of autonomy, for freedom is directed and constrained by love and ultimate accountability before God. However, this emphasis does give Protestants significant personal discretion in moral action without necessary reliance on a structure of specific moral rules.

Moral Pluralism. These theological and ethical commitments inevitably give rise to moral pluralism within Protestantism, as different interpretations are offered of the requirements of love and freedom. On virtually any moral question of consequence, a range of Protestant perspectives can be identified, without any ecclesiastical teaching authority available to provide a definitive conclusion. This is no less true of approaches to biotechnology, where assessments span the spectrum from hostility to biotechnology as an arrogant intrusion upon God's created order to a celebration of biotechnology as a beneficial means of partnership with God in continuing creation. These models will be discussed more fully below.

The Image of God. The primary Protestant claim about human nature is derived from the biblical account of the earth's creation; in this narrative, human beings are created in "the image of God," a theological description with profound normative implications. By this designation, human beings are given a status that distinguishes them from both God and nature. First, human beings are not God; the creator is sovereign over the created being. In particular, human beings lack the abilities to predict the results of action, control actions once they are initiated, or to adequately evaluate outcomes. Human distinctness from God is manifest in limitations such as finitude and fallibility. Persons do not have the capacities of omniscience and omnipotence attributed to the divine. When human aspirations exceed human capabilities, the created being runs the risk of the sin of pride or hubris, and of "playing God." This theological anthropology means for Protestant thought that the general theological presumption supporting biotechnological interventions characteristically will be constrained by concern with unforeseen consequences, slippery slopes, and admonitions of caution.

Notwithstanding these limitations, human beings "image" God in the world, a status that distinguishes them from animals, plants, and other manifestations of creation. Human beings are given a mandate of dominion to (*1*) care for and (*2*) cultivate creation, a mandate that within Protestant thought has been subject to numerous interpretations, including models discussed below such as passivity, anthropocentric domination, stewardship, and co-creatorship. These various interpretations, however, all affirm a common theme that responsible dominion involves a covenant with God that the human person will exercise freedom and love toward others — these "others" include human beings, the earth, and its creatures — in a way that benefits the common good. Responsible dominion also entails a recognition that ultimate accountability must be rendered to God for one's actions.

Much of the ambivalence and caution in Protestant thought concerning biotechnology is generated from the intrinsic tensions of the dual mandates of dominion, those of care and of cultivation. The principle of "caring" implies practices of conservation and preservation of our current conditions; the principle of "cultivation" implies reliance on human creative potential in using natural resources to bring about improvements and progress. Theologies of human dominion will tend to give greater emphasis to one or the other of these basic principles, or hold them in some kind of balance or tension, which in turn shapes perspectives on biotechnology.

Since nature does not have normative status within Protestant thought, the use of living organisms in biotechnological methods for making or modifying products, such as pharmaceuticals, enhancing strains of plants and animals, or manipulating genes to provide therapies for humans does not seem intrinsically wrong on the grounds that, for example, such practices "violate nature" or constitute "playing God." This is significant since a study of public attitudes to biotechnology indicates opposition to biotechnology is frequently grounded in claims that it is "not natural," or is "against God's will" (5). Although such claims are frequently presented as religious arguments, it is not clear they are well-ground in Protestant theological discussion: While human beings are not God in Protestant views, humans are responsible to and accountable before God in bringing about the full fruition of creation and in redeeming it from its current disordered condition. This supports the normative theological presumption in favor of biotechnology, unless it can be shown that a particular application of the technology will violate norms of love, freedom, or responsibility. The following section develops a general typology of Protestant perspectives that seek to negate, limit, or enact this presumption.

TYPOLOGY OF PROTESTANT THEOLOGICAL PERSPECTIVES

Nonintervention

One strand of Protestant thought emphasizes a noninterventionist or passive posture regarding the use of biotechnology. This perspective gives primacy to the principle of "caring," while attributing diminished importance to the principle of "cultivating." The noninterventionist understanding does not claim that nature is intrinsically good, and should therefore be left alone. Like all creation, nature has fallen from its pristine paradisiacal state. Rather, the problem is that human beings, because of their finitude and fallibility, are through technological interventions likely to make matters worse rather than better. Thus one Protestant writer urges caution and warns of the potential dangers from genetic manipulations because of the limited understanding and knowledge of human beings regarding the genome (6).

Within this understanding, moral priority is given to a norm of nonharm (as derived from love) rather than seeking to provide benefits through technological progress. Nonetheless, it is open to criticism on several grounds. It must first address what is particularly distinctive about biotechnology relative to other forms of human interventions. In many cases the position of nonintervention does not portray anything intrinsically wrong or misguided about biotechnology but expresses instead concern, rooted in the anthropology of finitude, about human prospects for control of biotechnological applications. This minimized capacity for control increases the risks of harm from biotechnology, both in terms of probability of occurrence and severity of the harm, to substantial and even unacceptable levels. Since it is impossible to empirically establish a risk assessment without proceeding ahead with biotechnology, and since prevention of harms have moral primacy over promotion of possible benefits, the course of ethical wisdom on this view lies in forgoing biotechnology.

The noninterventionist or passive perspective may also be challenged on the grounds that by forgoing benefits, harm is inevitably caused. It is possible to engage in a thought experiment and readily determine what benefits humanity currently enjoys from medical and biotechnological interventions that would have been forgone had the noninterventionist perspective prevailed throughout history. Thus this strand of Protestant thinking appears to convey a "free-rider" approach, willing to receive and make use of the benefits bestowed from the scientific legacy of prior generations but unwilling to develop these capabilities still further to benefit future generations.

Finally, nonintervention seems theologically suspect because of its neglect of the mandate of "cultivation." Responsible dominion involves a judicious balancing of cultivation and care, for cultivation provides justification for human intervention, through biotechnology or other means, in the natural world, while care sets limits on the scope and extent of that intervention. That is, both are necessary principles of dominion, and neither is by itself sufficient. It is part of Christian freedom and responsibility to work out the practical implications of these principles when, as in some instances of biotechnology, they come into conflict.

Anthropocentric Domination

If nonintervention presents one pole of a continuum in which caring assumes primacy over cultivation, the

other end of the role is represented by perspective of anthropocentric domination, which emphasizes the mandate of cultivation to the neglect of caring. Moreover the distinctive status of "image of God" of humans means that human beings should be the primary beneficiaries of cultivation of nature. In this understanding, ontology implies moral superiority: Humans are not only the culmination of creation but also its measure and purpose. Thus human beings are held to receive divine permission to use the resources at their disposal, including the natural resources of the earth and their own intellectual and creative potential to improve human welfare.

The position of anthropocentric domination shares with that of nonintervention the view of a fallen world and nature, but it differs in two important respects. A fallen world invites improvement, which in some views may support efforts of biotechnology and medicine to restore conditions similar to those of an Edenic paradise; in other interpretations, while paradise may be ineradicably lost, there nonetheless is a mandate for cultivating more humane and beneficial conditions for living. Nor is human finitude and fallibility as paralyzing on the domination account as it is within noninterventionist accounts. Indeed, the record of human history, particularly within medicine over the past century, shows dramatic improvements in health and welfare through sustained investigation, understanding, and manipulation of nature. Thus there is confidence that human interventions will culminate in greater benefits than harms, and that the risks of subsequent interventions, such as through biotechnological methods, can be controlled and minimized.

This position has been very influential in Protestant thought, particularly since the dawn of the scientific and industrial revolutions, and it is no surprise that it has also been the recipient of the most sustained philosophical criticism. In a very significant essay, Lynn White, Jr. laid the blame for the current "ecological crisis" precisely at the door of anthropocentric domination. This version of Christianity, in White's view, "not only established a dualism of man and nature but also insisted that it is God's will that man exploit nature for his proper ends" (7). And, such attitudes can easily be reflected in and perpetuated by contemporary biotechnology.

While White's thesis has been very controversial, and has been challenged on several grounds, it is important to differentiate descriptive and normative implications. Descriptively it is the case that (*1*) anthropocentric domination has been present in some Protestant understandings of nature and technology and (*2*) it can be rendered as compatible with at least part of the mandate of human dominion, that of cultivation. Normatively, however, cultivation is not unlimited; it should be directed and constrained by the principle of care, with its emphasis on protection, preservation, and conservation. Moreover cultivation is also limited by responsibility and accountability before God. This is to say that an anthropocentric account of dominion — which is the primary focus of White's critique — may not possess the fidelity to Protestant Scripture and teaching as other interpretations (8).

Stewardship

A third perspective that seeks a balanced response to the mandates of care and cultivation has historically been designated as *stewardship* or *trusteeship*. An ethic of stewardship can itself be articulated in terms of the Protestant themes of authority, agency, and accountability. Human beings have been given divine authority over nature, as well as the moral freedom to make choices regarding the use of natural resources. However, the content of such choices should reflect a concern for the common good (which is not limited to what is good for human beings) and persons are held to assume accountability before God for their choices. In short, the "dominion" of human beings is much more inclusive of other creatures than implied by the anthropocentric interpretation, and as stewards of the earth, human beings are in the service of God to render service to others, with "others" defined holistically rather than anthropocentrically.

Neither care nor cultivation receives moral primacy in this ethic. Rather, the stewardship ethic tries to maintain a responsible balance that both justifies human interventions on the grounds of improving the world and human welfare and limiting those interventions when they overreach these goals. Thus there is recognition that both benefits and harms can occur through human technologies, and making decisions about their use under the human conditions of finitude and fallibility is complex and permeated by genuine ethical uncertainties and dilemmas. Thus, while biotechnology can be justified, good reasons must be offered in its support, and constraints must be acknowledged and adhered to.

There is a depth of kinship between humans and the earth and its creatures present in the stewardship ethic. Human beings are "earth creatures," created by God, to be sure, but of the dust of the earth. Indeed, "human" and "earth" share a common etymological root, "humus." This commonality brings awareness of a sense of interdependence, mutuality, and humility that precludes the attitude of anthropocentric conquest present in the domination perspective.

While certainly very influential in the history of Christian and Protestant thought, to the point that some interpreters have conflated anthropocentrism with stewardship, the stewardship perspective is also not immune from moral critique. Since it tries to hold two principles in some kind of equitable balance, it often is found limited with respect to practical issues and controversies, where some choice about whether to give priority to care or to cultivate is not a theological abstraction but a practical necessity. In addition it has been argued that stewardship is an abstract ideal that is not embedded in cultural practices, which historically have reflected a domination perspective. Thus, on both counts, the practical relevance of this perspective may be much less compelling than its theoretical appeal.

Partnership

While the stewardship perspective affirms that human beings are authorized agents of God in the world, the

purposes for which the earth should be cared for and cultivated are by and large given by divine design. The partnership perspective emphasizes by contrast a much more interactive and engaged role of human beings in shaping these ultimate purposes. It presumes that creation did not end at some prehistorical period, but that creation is a dynamic, ongoing process that human beings participate in as created co-creators with God, with human and bioecological destiny not predetermined but to be shaped contextually. Thus "human work, especially our technology, may be seen as a partnership with God in the continuing work of creation. "[O]ur genetic engineering has the potential for being an extension of the work of God" (4).

This perspective has emerged fairly recently within Protestant thought; it has been given thoughtful exposition in the context of genetics and ecology by such prominent writers as Ronald Cole-Turner, Philip Hefner (9), and Ted Peters (10), and will certainly be increasingly influential in attempts to facilitate dialogue between religious, scientific, and biotechnological interests. Partnership, or created co-creator, models rely more heavily on scientific understandings of cosmology that do their Protestant predecessors, which are largely formulated within biblical cosmologies. The analogical and substantive features of partnership, and by inference its differences from stewardship, are eloquently articulated by British theologian Arthur Peacocke:

> It is as if man has the possibility of acting as a participant in creation, as it were the leader of the orchestra in the performance which is God's continuing composition. . . . [M]an now has, at his present stage of intellectual, cultural, and social evolution, the opportunity of consciously becoming *co-creator* and *co-worker* with God in his work on Earth, and perhaps even a little beyond Earth (11).

Indeed, Peacocke places human beings within a cosmos whose designs and purposes are known neither by human beings or by God; thus persons are even "*co-explorers*" with God. Such an understanding is certainly very compatible with, and gives theological justification for, biotechnology as, to continue the orchestral metaphor, the lead violin in the creative and explorative composition; technology is a metaphor and symbol for divine creative activity.

Certainly the partnership perspective is not without its theological detractors and these objections seem twofold. First, the position presumes that "the future of creation is uncertain, because God has not guaranteed its outcome" (4). Yet, precisely because the future is indefinite, and to be partly shaped and directed by human creativity, the perspective does not seem capable of generating clear limits or constraints. The necessity for some purpose or goal is an issue of acute importance in ethical evaluations of biotechnology, lest the technology create its own justificatory role. Second, the position seems to overstate human capacities to the point of pretension to playing God. While Peters has argued that the theological anthropology embedded in partnership is to "play human" fully and authentically, the long-standing concerns of Protestant thought about sin, human finitude, and fallibility are not as prominent in expositions of partnership. And, as illustrated above, it is precisely those concerns that stand behind many of the limits or cautions some strands in Protestant ethics wish to impose on biotechnology.

LIMIT CIRCUMSTANCES

Certainly many of the innovations of biotechnology, particularly with respect to products that bring about improvements in human health (eg, genetically engineered human insulin) have been welcomed by Protestant thinkers and communities. In this respect, the efforts of biotechnology to alleviate or cure disease are commonly set within a context of divine creativity and redemption, working through the imaginative instrumentality of human beings. Thus, with very few exceptions, biotechnology per se seems to not be theologically suspect; especially on the partnership perspective, biotechnology can be theologically praiseworthy and even morally required. Nonetheless, given the background theological commitments delineated above, Protestant thinkers do raise questions about the purposes and the procedural controls of biotechnology. Some scholars have raised the possibility that "control" itself is fundamental to the enterprise of biotechnology, by seeking to diminish human vulnerabilities to the capriciousness of the natural world. Thus the theme of human control is an issue that cuts across both substantive and procedural questions. These two questions can be more carefully examined by considering selected innovations in biotechnology that have raised concern among a range of Protestant thinkers and traditions.

Gene Therapy

One of the most significant innovations in biotechnology is the possibility to alter the genetic makeup of a person. Protestant denominations, under the auspices of the National Council of Churches in Christ, joined in the late 1970s with Roman Catholic and Jewish ecclesiastical bodies to raise questions about the risks of genetic manipulations, as well as a perceived arrogance of human control and mastery presupposed by such manipulations. In 1982 theologian Roger L. Shinn articulated in congressional hearings five base points for Protestant reflection on genetic interventions:

1. A bias for the sacredness of human life requires minimization of risk to the patient or subject.
2. A sense of "human inviolability" both permits interventions and limits their scope.
3. Efforts to eliminate genetic-based diseases are justifiable.
4. Genetic enhancements cross the boundary of inviolability and are dangerous.
5. Equity and justice should guide the distribution of benefits and burdens in genetics research (12).

In the intervening years, Protestant thought on human gene therapy has tended to reflect the considerations delineated by Shinn, and skepticism has gradually given way to a cautious endorsement of gene therapy in some

circumstances. Some questions have been amenable to resolution through increasing knowledge of scientific and technical issues, as well as through procedural safeguards of public oversight and monitoring. And Protestant commentators have characteristically insisted upon a specific moral rationale for genetic manipulations, that is, that the designed intervention have therapeutic potential for alleviating disease.

These concerns have tended to direct Protestant thought into ethical positions that some times converge and some times diverge with other ethical traditions, religious or secular. As one point of convergence, the Protestant commitment to human equality and the dignity of individual persons has required respect for genetic diversity and correlative opposition to efforts at genetic enhancements and positive eugenics. However, an issue of controversy has occurred over the validity of the line drawn in many bioethics discussions between somatic cell therapy and germ-line therapy. Protestant thought has argued for a greater continuity between somatic cell and germ line therapy insofar as the rationale for either form of genetic intervention is disease-based. A policy document of the National Council of Churches developed in 1986, even before attempts at somatic cell therapy had been conducted, asserted that while germ-line therapy needed "stringent control," it could not be precluded because of prospects of substantial benefits in alleviating disease (13). This view has evolved into a "wait-and-see" position presented in a document of the United Methodist Church: "We oppose therapy that results in changes that can be passed to offspring (germ-line therapy) until its safety and the certainty of its effects can be demonstrated and until risks to human life can be demonstrated to be minimal" (14). Such conditional opposition, or what Shinn describes as "cautious openness" (15), suggests that there is nothing intrinsically theologically objectionable with germ-line therapy, but it does place the burden of proof on those who wish to proceed with such interventions, in the sense that safety and efficacy must be demonstrated, rather than those who wish to prohibit germ-line therapy because of possible risks.

However, there are Protestant dissenters to cautious openness to germ-line therapy, and they are instead characterized by Shinn as adopting a position of "emphatic rejection." Some conservative Protestants have argued that as germ-line therapy will likely involve manipulation of the cells of human embryos, this method constitutes unethical experimentation on the unborn, and ultimately erodes the sanctity of human life. Indeed, some Protestants are concerned about somatic cell therapy, not on its own merits but because the underlying rationale of cure of disease raises a new set of concerns about responsibility to the vulnerable who cannot consent when considered in the context of germ-line manipulations.

A distinguished group of Protestant scholars has, while generally supporting development of gene therapies, raised some additional questions that revolve around the risk of humans losing control of the technology. One concern focuses on the relativity and elasticity of the concept of "disease." It may be difficult to uphold a firm line distinguishing legitimate uses of genetic therapies on the basis of whether they are directed to healing diseases or not because the very concept of disease is so fluid. In addition successes with gene therapy may encourage society and medical researchers to develop innovative uses for genetic manipulation that depart from the disease-based rationale. "[P]roper therapy also directs control to the goods of life and health, to the goal of healing genetic disease. If people simply celebrate genetic control itself, ... we fear that they will lose the capacity to direct and limit this new power to therapeutic uses" (16). An attitude of celebrate without caution, or a practice of cultivation without caring, may open the door to designing human descendants after our own preferred image and characteristics. Thus the slippery slope of most concern to Protestants may not be that of somatic to germ-line therapy but from therapy to enhancement, for enhancement is considered a response to "cosmetic purposes or social advantage" (14). In each case of concern about genetic manipulations — germ-line therapy, the concept of disease, and genetic enhancements — some common ethical perspectives are reinforced in Protestant thought by convictions about human finitude, fallibility, and pretensions to arrogance and pride.

Transgenic Research

For some Protestants, manipulation of the genome of human beings is not the only theologically problematic dimension of biotechnology. While animals do not generally have the theological and moral status of human beings within Protestantism, as creatures, animals do fall under the domain of responsible human stewardship or partnership. Thus, on some accounts, the insertion of genes from one species into another species to produce a transgenic organism or animal raises questions and objections. One kind of argument stems in part from an imperative rooted in the biblical creation narratives to plant and animal species to "reproduce after their own kind" (6). Transgenic biotechnological research may thus be understood to use genetic information for purposes not intended in the origins of plant, animal, or human life. Even though scientific research possesses the power and capability to bring about such genetic alterations, use of that power violates a normative ideal of species integrity and perpetuation.

A second argument regarding transgenic research is that it may compromise human distinctiveness. The claim in this instance is that by eroding distinctions between species, including animal and human species, through the creation of transgenic organisms, it then seems arbitrary to draw a line that would allow for such research on animals but not on humans. Protestant opposition to transgenic animal research in the 1980s led one researcher to reply, "I don't know what they [Protestant opposition] mean when they talk about the integrity of species. ... Much of all genetic material is the same, from worms to humans." This appeal to the commonality of genetic information between species leads Protestant theologian Andrew Linzey to question whether, if researchers are really convinced of this point, what grounds they would then have for opposing transgenic and eugenic research with humans (17).

Theological arguments against transgenic research do not always invoke abstract possibilities; they commonly cite examples of actual research projects that have culminated in harms rather than benefits. The creation of transgenic pigs in the 1980s through insertion of the human growth hormone gene has been cited by Protestant writers as a case in point of the risks and moral mistakes implicit in transgenic research. The point of the research, which was sponsored by the U.S. Department of Research, was to develop pigs that had greater muscle mass and leaner fat content, thus making the animals more commercially desirable. However, the pigs turned out to be excessively hairy, arthritic, impotent, and lethargic.

Significantly, theological critiques of this project argued that transgenic research was proceeding without ethical sensitivity to the harms experienced by the animals, rather than, as would be expected within a framework of anthropocentric domination, to human beings. It is important to note, however, that theological evaluations that assess biotechnology relative to its benefits and harms primarily focus on scientific and technical considerations, rather than on intrinsic theological issues. Such arguments may not be so compelling when the harms are uncertain and unforeseen, as in more recent projects that have created a chicken-quail hybrid as a prelude to understanding brain disorders in human. And, as noted above, other Protestant scholars have supported transgenic plant research on the grounds of increased productivity and diminished harms.

Of particular concern for some evangelical Protestants is maintaining the integrity or purity of the human genome. This follows from the special status of human beings in contrast to animals. Thus, on one account, "genetic information from any other organism which does or did not exist in the human genome should not be placed within humans" (6). However, this position raises questions over which Protestants would differ. First, a prohibition of mixing genetic information from other species with humans seems to suggest that human distinctiveness is constituted by genetic differences, rather than, for example, all that is embedded in the concept of the "image of God." The preservation of human genetic integrity seems bought at a price of genetic essentialism and theological reductionism, or what one theologian criticizes as the "gene myth" (10). Second, such a position presumes that there is something distinct or unique about genetic information, even though there are many other ways by which human beings might absorb or consume animals or plants or their products. While it is clear that not all Protestants hold similar views on transgenic research and organisms, it is clear that this form of biotechnology raises some widely shared questions (18).

Issues of Ownership: Patenting and Distributive Justice

The tools of biotechnology have raised important questions of ownership, particularly with regard to human cells that have been retrieved, modified, and immortalized, or of genetically engineered animals and plants. One issue of debate has focused on the legitimacy of patenting genetically modified life forms, while another has concentrated on ownership of the economic gains from commercial development of biotechnological products. Protestant scholars have engaged both of these debates within their own faith communities and in public discourse.

Scholars and clergy from both conservative and mainstream wings of Protestantism have been in the forefront of challenging efforts to patent genetic material, derived either from animals or (of greater concern) from human beings. A report on biotechnology issued by the World Council of Churches in 1989 opposed patenting of genetically altered animal life forms, asserting that "the patenting of life encodes into law a reductionist conception of life which seeks to remove any distinction between living and non-living things" (19). More recently, in 1995, a group of 186 religious leaders, primarily from Protestant churches, issued a "Joint Appeal against Human and Animal Patenting": "We . . . oppose the patenting of human and animal life forms. We are disturbed by the U.S. Patent Office's recent decision to patent human body parts and several genetically engineered animals. We believe that humans and animals are creations of God, not humans, and as such should not be patented as human inventions" (20,21). The "Joint Appeal" provoked a storm of controversy, not only between religious and scientific communities but within the Protestant community itself, with some theologians arguing that it was misguided and reactionary. However, gene patenting may simply be the issue that crystallizes concerns of many religious communities about biotechnology and the new genetics, concerns that have a deeper and broader significance. Indeed, religious objections to patenting the results of biotechnology appear to stem from a diversity of rationales, including (*1*) symbolism about life, (*2*) scientific reductionism, (*3*) human artifice, and (*4*) anthropocentrism.

As a statement about biology, one would be mistaken to infer from approval of a patent for a gene that "life" is thereby under the realm of the patent office, as is suggested by the language of the WCC report and by comments of individual religious clergy who supported the 1995 "Joint Appeal." However, critics who dismiss this objection as misinformed about science or naive as to the patenting process and public policy may overlook the theological symbolism at stake. The claim is best understood as seeking to resonate at a symbolic rather than literal level of interpretation. In a very probing study, Dorothy Nelkin and Susan Lindee have illustrated how a gene sequence, or the double-helix structure, is invariably used in scientific, academic, and popular literature as a symbol for life as a whole; the gene has become invested with a spiritual or sacral significance historically attributed to the soul (22). Thus a gene is not simply an object for scientific study and manipulation, it has become embedded with a complex matrix of cultural, ethical, and religious meanings. In this respect the willingness to proceed with gene patenting signifies an effort to extricate science from these embedded social meanings, and thereby is interpreted by some opponents as diminishing the value of life.

The value of life is underscored by a second rationale for objections to genetic patenting, a concern about scientific reductionism, an ideology embedded in contemporary

biomedicine that is viewed as blurring the boundaries between life and nonlife. If patenting is an instance of such a reductionist ideology, then some theological questions assume a greater legitimacy. In particular, scientific research and technological applications of parts of the body, such as tissues, cells, or genes, can conflict with religious values about bodily integrity that are central to the Protestant understanding of the "image of God" present in human beings. E. Richard Gold draws on these themes to contrast scientific instrumentalism with theological intrinsicalism: "The body, from a scientific viewpoint, is a source of knowledge of physical development, aging, and disease. From a religious perspective, the body is understood as a sacred object, being created in the image of God. . . . The scientist values the body instrumentally, as a means to acquire knowledge; the believer values the body intrinsically, for being an image of God" (23).

Put another way, Protestant (and Western) religious thought begins with a strong presumption that the status of the body as a whole is greater than the sum of its parts. The interest of medical science in the body stems from the prospect of gaining information about human character traits and behaviors, including susceptibilities to illness and bodily responses to disease, through study and understanding of the basic components of life, such as genes. The scientific value of the body as a totality is instrumental to the goal of deciphering the codes, messages, and functions of the fundamental components of the body that contain valuable genetic information. In this respect, gene patenting may reflect scientific reductionism in that (*1*) genes are viewed as scientifically more significant than the organic body totality and (*2*) the value of a cell or gene resides primarily in the information it provides researchers rather than as a symbol of life's dynamism and processes.

The third Protestant objection raised to gene patenting seeks to maintain a distinction between the realm of divine creation and the realm of human invention. The argument suggests that "creation" is the work of God, and within the Protestant Christian context, God creates *ex nihilo*, or "out of nothing." This is then differentiated from "invention" as a human affair, in which human beings re-organize, or more to the point with genetics, re-combine, already existing material elements to produce a new life form, such as the Harvard OncoMouse.

Given this distinction, however, it is difficult to see just how a patent application is any more an encroachment on divine creativity than the original research that inserted the human gene into the mouse. The latter might be objectionable with regard to the issues delineated concerning transgenic organisms, but it would then seem that the theological line needs to be drawn on that issue, not over the legal rights and restrictions granted by a patent. As with the objection that equates patenting DNA with patenting life, the creativity–inventiveness objection also seems to function as a symbol for objections that are important but not fully articulated.

Perhaps the strongest argument presented against biotechnology and patenting has been put forward by theologian Andrew Linzey who, in a broad-ranging theological critique of human use of animals more generally, sees in patenting the culmination of a departure from Christian stewardship and an embrace of anthropocentric domination. Linzey contends that "biotechnology in animal farming represents the apotheosis of human domination" (17). This development is the technological, if not logical, end point of the anthropocentric perspective that animals (despite also being created by God) belong to and exist for the benefit of human beings, and have no intrinsic value. While Linzey is aware that the human species has always made use of animal species, he nonetheless claims something distinctive is present in the application of biotechnology and genetic engineering to animals, namely it employs "the technological means of absolutely subjugating the nature of animals so that they become totally and completely human property" (17). In this interpretation, genetic engineering and patenting of animals is the moral equivalent of human slavery.

The Christian theology of responsible stewardship entails for Linzey maintenance and promotion of the good that already exists. The "artificial creation" of animals with disease-bearing characteristics, such as the OncoMouse, simply violates the integrity and design of creation. Moreover acceptance of patenting of genetically engineered animals, by which legal recognition is given to human property claims over animals, symbolizes biotechnological enslavement. The granting of patents over animals will "reduce their status to no more than human inventions, and signifies the effective abdication of that special God-given responsibility that all humans have towards the well-being and autonomy of sentient species" (17). Thus, on Linzey's account, animal patenting is a form of "idolatry" because it supplants God with human beings as owners of creation and "represents an attempt to perpetuate, to institutionalize, and to commercialize, suffering to animals" (17).

In explicating these Protestant reservations about genetic and animal patenting, it is important to acknowledge that other Protestant scholars have not found these reservations at all compelling. Ronald Cole-Turner, one of the most influential Protestant scholars at the intersection of theology and genetics, has maintained that because "there is no metaphysical difference between DNA and other complex chemicals, . . . there is no distinctly religious ground for objecting to patenting DNA" (21). Cole-Turner does not contend that there cannot be legitimate objections to patenting, but only that there are no specifically religious grounds for those objections. This claim enables Cole-Turner to encourage the initiation of dialogue between religious communities and scientific researchers, for "religion gives science its purpose, and science gives religion its eyes and its hands." It also provides Cole-Turner a basis for interpreting genetic engineering not in terms of anthropocentric domination, but rather as participation in divine creative activity.

One feature of the Protestant debate over gene patenting raises a more general concern in Protestant discourse about biotechnology, the issue of "commodification." This question may take two different but related forms. First, objections may be raised against biotechnology on the grounds that it transforms what is found in the world, such as genetic material, into commodities for commercial

development in accord with market values. This implies an understanding and valuation of genetic material that may be considered theologically objectionable (24). Thus, in its generally cautious but favorable appraisal of biotechnology, the World Council of Church admonishes, "the integrity of creation is damaged if biotechnology is utilized by commercial pressures to manufacture new life forms that are valued only as economic commodities" (19). Part of the concern embedded in this claim reiterates the Protestant concern with authoritarian control (i.e., commercial pressures) over biotechnology.

A second kind of argument may accept that certain things are legitimately classified as commodities, but protests against biotechnology on the ground that certain peoples and nations are better-positioned to participation in the biomarket and gain access to the benefits of biotechnology, while other peoples and nations will be excluded for economic reasons. In particular, the fruits of the biotechnological revolution are likely to be harvested by first-world peoples, while third-world countries may find themselves on the margins of the technologies. This runs contrary to the norm of distributive justice and the example of the ministry of Jesus, wherein Christians are encouraged to pay special attention to lifting the burdens and meeting the needs of the poor, the vulnerable, and the outcast. Some Protestant scholars believe the community of the vulnerable, and the moral primacy of responding to their needs, must be broadened from the "near" neighbor to the "stranger." Even though Protestant discussion about patenting of genetically engineered life forms is still in its embryonic stages, it seems clear that it will engage Protestants in dialogue and criticism with each other, and with the scientific and biotechnological communities.

Human Cloning

Recent scientific reports on successful mammalian cloning through the process of somatic cell nuclear transfer, which have in turn raised the prospects of human cloning in the near future, have revealed the pluralism of Protestant ethics perhaps more than any other question in biotechnology. Protestant theologians were invited to testify before the National Bioethics Advisory Commission established by President Clinton to recommend public policy on human cloning, and Protestant scholars have begun to contribute to the emerging ethics literature on this question (25). Yet this biotechnological development of the late 1990s is not a new question within Protestantism. Protestant theologians Joseph Fletcher and Paul Ramsey participated in influential academic and scientific forums in the 1960s and 1970s when cloning was first proposed as a scientific solution to many of the ills of the world. Fletcher and Ramsey staked out diametrically opposed positions and envisioned a world of human cloning that is remarkably prescient given the state of current discussion.

Fletcher advocated expansion of human freedom (self-determination) and control over human reproduction. He portrayed human cloning as one among a variety of present and prospective reproductive options that could be ethically justified under circumstances of overriding societal benefit. Indeed, for Fletcher, human cloning was a preferable method of reproduction relative to the "genetic roulette" of sexual reproduction: laboratory reproduction was "radically human" because it was deliberate, designed, chosen, and willed (26).

By contrast, Paul Ramsey portrayed cloning as a "borderline" or moral boundary for medicine and society that could be crossed only at risk of compromise to humanity and to procreation. He identified three "horizontal" (person–person) and two "vertical" (person–God) border-crossings of cloning. (*1*) Clonal reproduction would require dictated or managed breeding to serve the scientific ends of a controlled gene pool. (*2*) Cloning would involve non-therapeutic experimentation on the unborn. (*3*) Cloning would assault the meaning of parenthood by transforming "procreation" into "reproduction" and by severing the unitive and the procreative ends of human sexual expression. Theologically, cloning represented (*4*) the sins of pride or hubris, and (*5*) of self-creation in which human beings aspire to become a man-God (27). The legacy of the themes identified by Fletcher and Ramsey concerning human cloning have been perpetuated in both recent religious and secular reflection on cloning. Within the Protestant religious communities, these debates have revolved around several contested themes.

Sanctity of Life. Protestant evangelicals have appealed to the sanctity of human life to argue against human cloning. The process of somatic cell nuclear transfer for the purpose of making a new human being, at least as illustrated in the current animal studies, would inevitably result in loss of human embryonic life. In addition evangelical positions claim that contemporary societal disregard for the sanctity of human life could possibly lead to a re-definition of humanity, such that the clone may be treated as a repository for spare organs and tissues (28).

Parenthood. Conservative and evangelical Protestants also object to human cloning on the basis of an intrinsic connection between the unitive and procreative purposes of sexuality as embedded in the *Genesis* creation story. Sexuality is understood to be a divine gift with the twin purposes of uniting the partners through a physical expression of their love and for bringing offspring into the world. In this context human cloning runs contrary to critical biological, emotional, and symbolic connections between spouses and between parent and child. In particular, the idea of a child as a "gift" is effaced as the child becomes both a project and a projection of the self (29). This argument interprets human cloning to diminish humanity to "raw material" out of which an artifice can be designed and constructed in our image, rather than the "image of God," thus leading to power over other humans rather than enhanced choices.

The Image of God. Conservative and evangelical Protestant scholars maintain that as bearers of God's image, human beings gain insight into self-understanding and human uniqueness and receive a distinctive status relative to the rest of creation. Cloning risks devaluing this image of the person by suggesting genetics is the essence of personhood, or by valuing the clone because of its replication of valued characteristics of another person.

Some mainstream Protestant theologians have argued, by contrast, that human cloning can express the creative dimensions of the *imago Dei* insofar as the new genetics promotes human dignity and welfare (30). Moreover the Christian vocation of freedom warrants the pursuit of scientific knowledge, when coupled with the obligation of accountability delineated above. Even though the reality of sin will manifest itself in an ongoing disparity between a designed future and its reality, this position holds that Christians are given permission to "sin bravely" in the pursuit of progress. Thus, if further research on human cloning can establish a reasonable expectation of benefits, and ensure human dignity, then both research and eventually human cloning seem warranted.

CONCLUSION

Protestant thought can celebrate biotechnology because of the prospects of revealing more about God's creation and applying that knowledge for human betterment, and the betterment of life on this planet. Simultaneously Protestant thought characteristically urges caution about the biotechnological revolution, lest use be transformed into abuse. The powers that human beings can wield through biotechnology must be acknowledged as limited and beyond our capacity to fully control, but Protestant thought has historically been concerned not simply with the external action but what such action reflects or expresses about a person's moral character. In this regard Protestant theological ethics forces the question of what kind of persons we need to be in order to wield such powers for good rather than ill.

REPRODUCTION, ETHICS, MORAL STATUS OF THE FETUS

BONNIE STEINBOCK
SUNY Albany
Albany, New York

OUTLINE

INTRODUCTION

The moral status of the fetus is not only central to the abortion debate but is also relevant to reflection on such issues as assisted reproductive technology (ART), the moral status of extracorporeal and frozen embryos, prenatal genetic testing, fetal and embryo research, and fetal therapy. This article discusses the meaning of moral status, and its relation to moral value and moral rights. It goes on to discuss the moral status of the fetus in the context of the abortion debate, outlining the main positions that have been taken. These include genetic humanity, brain birth, viability, personhood, potential personhood, the possession of a "future like ours," sentience, and a multi-criterial approach.

WHAT IS MORAL STATUS?

Mary Anne Warren succinctly explains the concept of moral status:

> To have moral status is to be morally considerable, or to have moral standing. It is to be an entity towards which moral agents have, or can have, moral obligations. If an entity has moral status, then we may not treat it in just any way we please; we are morally obliged to give weight in our deliberations to its needs, interests, or well-being. Furthermore, we are morally obliged to do this not merely because protecting it may benefit ourselves or other persons, but because its needs have moral importance in their own right (1).

Some entities clearly have moral status: for example, people. It is difficult even to imagine a moral view that did not require us to consider the interests and well-being of people. Indeed, this requirement may define "the moral point of view" (2). Just as clearly, some entities do not have moral status: for example, ordinary rocks. They are just things, of no particular value or importance. The hard questions fall in between people and more things. What about nonhuman animals, permanently unconscious humans, plants, species, and the environment? A coherent, nonarbitrary answer to the question of whether these beings have moral status requires a general theory of moral status.

Moral Status and Moral Value

While some "mere things" have little or no value, others are valuable in various ways. Some things have commercial value, some aesthetic value, some scientific value, and so on. All of these ways of being valuable can be distinguished from being morally valuable or having moral value. What, then, is it for something to have moral value? A plausible suggestion is that something has moral value if there are moral reasons for valuing it. Consider, for example, the flag of the United States. Viewed solely as a piece of material, the flag has relatively little value. But it is more than that. It is the emblem of our country. School children pledge allegiance to the flag, it is flown over government buildings, lowered to half-mast when important people die, and so forth. Many people have strong feelings about the flag: They respect it, revere it, even love it. Of course it is not the flag itself that inspires these feelings, but what it stands for. This explains why it is held to be wrong to fly the flag in tattered condition or to allow it to touch the ground. It also explains the outrage felt by many patriots when the flag is burned in a political protest. The point is not that flag burning is necessarily wrong. In fact burning is the recommended way of disposing of a worn-out flag. In addition flag-burning could be a legitimate form of political protest. The point is rather that it is a not a matter of moral indifference what one does to a flag. There are moral reasons to treat flags in certain ways. This suggests that the flag, because of its symbolic significance, has moral value.

Bonnie Steinbock has suggested that moral status be distinguished from moral value (3). The difference lies in the reasons why certain treatment is regarded as morally wrong. In the case of the flag, the reason why it is held to be wrong to burn a flag in protest is that this shows disrespect for the flag and the country for which it stands. The reason is not a "golden rule" type reason, along the lines of "how would you like it if you were a flag and someone burned you?" In making this distinction, we recognize that it does not matter to a flag what is done with it, and this differentiates flags from, say, people or animals. To accord something moral status is not merely to consider it important or valuable, and worthy of protection; it is to take its perspective into account when making moral decisions. In this view, flags might have moral value, but they lack moral status. This is because flags do not have a point of view. They cannot have a point of view because they lack awareness of any kind. Mere things can be destroyed, but whatever is done to them cannot matter to them. They do not have a stake in their preservation or well-being (if mere things can be said to *have* a well-being). They have no interests because only beings who can care about how they are treated or what is done to them can have interests of their own. Lacking interests, mere things lack moral status, but it does not follow that it is morally permissible to treat them any way you like.

Many environmentalists object to the view that only sentiment beings can have moral status: the "sentience only" view. For "deep ecologists," like Aldo Leopold, moral status is not limited to sentient beings. Natural plant and animal species, populations, and habitats can all have moral status, just as much as sentient beings. As Mary Anne Warren expresses the point, "To many environmentalists, a theory which allows us to have moral obligations *regarding* the nonsentient elements of the

natural world but never *to* them, seems just as inadequate as the Kantian theory, which allows us to have duties regarding animals, but never to them" (1, p. 72). While this debate is important for environmental ethics, it is not directly relevant to the moral status of the fetus, as those who maintain that the fetus has moral status do not usually base its status on its being an element of the natural world but rather on such features as its being genetically human, potentially a person, or the kind of future it will have.

Moral Status and Moral Rights

All beings that have moral rights have moral status. Indeed, if someone has a right to something, this imposes obligations on others to behave in certain ways. Your moral rights limit my freedom with respect to how I am permitted morally to treat you. This implies that from a moral point of view, someone who has a right counts or matters, which is the same as ascribing to it moral status. However, the reverse does not hold. It does not follow that every being that has moral status has moral rights. It is even possible that there are no moral rights, as some utilitarians maintain. There can be an account of morality that does not include moral rights, but there cannot be an account of morality that does not include a theory of moral status.

MORAL STATUS AND ABORTION

We start with the problem of abortion, where the moral status of the fetus has been a central and contentious issue. First, a word about terminology. During the first week of its existence, the fertilized egg is known as a conceptus. The term "embryo" refers to the entity between the second and eighth weeks. From the eighth week until birth, it is a fetus. However, the term "fetus" is often used to refer generally to the unborn throughout pregnancy. This article follows that usage, except where the different phases of gestation have a bearing on moral status and need to be distinguished. Those who are "pro-life" (often referred to as "conservatives" on abortion) argue that fetuses, throughout gestation, have the same moral status as born human beings, and therefore killing fetuses is seriously wrong, as wrong as killing born human beings. Those who are "pro-choice" (often referred to as "liberals" on abortion) usually argue that fetuses differ in morally important ways from born human beings, and for this reason, lack full moral status and in particular a right to life. Abortion, while not desirable, is not seriously wrong, in this view, and is certainly not equivalent to killing a born human being.

A number of writers have pointed out that the abortion issue does not turn solely on the moral status of the fetus. For example, Thomas Murray argues that "Fetal personhood is only one strand in the web holding our moral judgments about abortion" (4, p. 146). Sociologist Kristin Luker argues that it is a mistake to think that the views of pro-choice and pro-life activists about abortion are determined by their philosophical or religious views on the moral status of the fetus (5). Rather, their views on the morality of abortion stem from their differing views on the meaning and value of sexuality, motherhood, and the proper role of women. How they view the fetus is determined by how they regard abortion, not the reverse. Legal philosopher Ronald Dworkin argues that the abortion debate is not really about the moral status of the fetus, despite the rhetoric on both sides. According to Dworkin, even those vehemently opposed to abortion do not actually believe that a fetus is from the moment of its conception a full moral person with rights and interests equal in importance to those of any other member of the moral community. Nor do those committed to protecting a woman's "right to choose" think of the developing fetus as just a part of the pregnant woman's body. "The disagreement that actually divides people is a markedly less polar disagreement about how best to respect a fundamental idea we almost all share in some form: That individual human life is sacred" (6, p. 13). Judith Thomson maintains that it is a mistake to think that the abortion debate is over if the premise that the fetus is a person, with a right to life, is accepted. For the abortion debate also raises the question of whether the fetus has a right to the use of the pregnant woman's body, and how much of a sacrifice to sustain its life she is required to make. Thomson thinks that even if fetuses are persons, at least some abortions could be justified (7). Finally, some feminists regard the inquiry into the status of the fetus as irrelevant to the problem of abortion (8). They view abstract inquiries into the moral status of the fetus as distracting from the real issues, which have to do with creating the social conditions that permit women to make genuine reproductive choices.

All of these voices have deepened the abortion debate, but it is doubtful that any has proved the irrelevance of moral status. Even if Luker is right about the origin of people's views about the moral status of the fetus, that does not address the correctness or plausibility of their views. Feminists who focus solely on the interests of women can be fairly charged with simply avoiding the question of fetal moral status. Even if sexism, racism, poverty, and other bad social conditions were eliminated, there would undoubtedly still be unwanted pregnancies, and women would still want abortions. The question is whether abortion is a morally permissible choice. It is hard to see how this question can be answered without considering the arguments of those who claim that killing fetuses is seriously wrong. Finally, while Dworkin's view is ingenious, it is doubtful that most pro-lifers at least would accept his reconceptualization. For them, it is not a matter of how best to respect the sanctity of life, but rather a matter of preventing the murder of innocents. Their opposition to abortion cannot be taken seriously if this claim is not addressed.

THEORIES OF MORAL STATUS

Genetic Humanity

According to Roman Catholic teaching, abortion is murder. It is murder because it is "the deliberate and direct killing ... of a human being in the initial phase of his or her

existence . . .” (9,10). In other words, there can be no doubt that a human fetus has the moral status of any other human being, because “from the time that the ovum is fertilized, a life is begun which is neither that of the father nor the mother; it is rather the life of a new human being with his own growth. *It would never be made human if it were not human already*” (9, p. 22, emphasis added). Despite the fact that a fertilized egg does not look like the human beings we know, and has none of the characteristic attributes of born human beings, its possession of its own genetic code makes it a separate, unique, and individual human person. It is worth noting that this argument, though religious in origin, is not religious in nature. It makes no appeal to religious notions, like God or the soul. Rather, the humanity of the fetus is based on its being biologically or genetically human. John Noonan makes the same point when he says, “The positive argument for conception as the decisive moment of humanization is that at conception the new being receives the genetic code. . . . A being with a human genetic code is man” (11, p. 264). All and only genetic human beings have full moral status, and this full or human moral status begins at conception.

Birth

Conception as the point at which a human being acquires moral status is often defended by showing the arbitrariness of any other stage. Consider, for example, birth. Live birth is often taken to be a significant landmark both in Anglo-American law and in religious traditions, such as Judaism. At birth, the fetus becomes an infant, separate from its mother and no longer physiologically dependent on her. Moreover, birth is a precise moment, noted on birth certificates. However, conservatives argue that the difference between a newborn moments after birth and a fetus moments before birth is insignificant. How can location alone determine moral status?

Viability

Moving back into gestation, some regard viability — the stage at which the fetus can survive outside the womb, albeit with artificial aid — as having moral significance. In *Roe* v. *Wade*, the Supreme Court chose viability as the point at which there was no longer a constitutional right to an abortion:

> With respect to the State’s important and legitimate interest in potential life, the “compelling” point is at viability . . . State regulation protective of fetal life after viability thus has both logical and biological justifications. If the State is interested in protecting fetal life after viability, it may go so far as to proscribe abortion during that period except when it is necessary to preserve the life or health of the mother . . . (12).

Of course, the Court’s decision was not intended to mark the point at which the fetus acquires *moral* status, since that is not a legal issue. Nor did the Court stipulate that a fetus undergoes a change in *legal* status at viability. *Roe* v. *Wade* did not hold that a fetus becomes a legal person, with a right to life, at viability. Rather, viability marks the point at which the *state’s* interest in protecting fetal life becomes “compelling,” namely the point at which the state can outweigh the woman’s privacy right to make the abortion decision. However, unless viability has moral significance, it would be a completely arbitrary point at which to allow states to ban abortion. It is clear that the Court did not regard it as an arbitrary point, but rather considered viability as a dividing line with “logical and biological” justification. But what exactly is this justification, and what does it have to do with fetal moral status?

The Court noted that at viability the fetus has the capacity for meaningful life outside the mother’s womb. However, as several commentators have noted, this is not a justification for extending protection to it, but rather an explanation of what viability means. The question is why the capacity for meaningful, independent existence bears on moral status. Nancy Rhoden has suggested that the Court focused on viability because, especially in 1973, the capacity for independent existence was connected with late gestation and fetal development (13). In other words, by the time a fetus becomes viable, it shares many characteristics with infants, who are entitled to the law’s protection. A late-gestation fetus looks like a baby, it can probably feel and hear, it sucks its thumb. It is sufficiently like a newborn that all of our protective feelings for babies “kick in” and incline us to extend the same protection to viable fetuses.

None of this is persuasive to the conservative, who asks, “Why should the dependence of the nonviable fetus on its mother deprive it of human moral status?” Moreover, a viable fetus has a chance at survival if removed from the uterus. The fact that a nonviable fetus cannot survive outside the womb is all the more reason not to eject it. Thus the “logical and biological justification” for permitting abortion of previable fetuses is puzzling. In any event, the conservative does not regard any part of fetal development as having special moral significance. If allowed to grow and develop, the fetus will acquire a nervous system, organs, a brain. It will begin to move and look like a born human being. Eventually it will have sensations and hear sounds. None of these stages makes the fetus a human being. It is already human, and each landmark is nothing more than a stage in its development.

Brain Birth

Most conservatives on abortion base moral status on being human, but not all believe that human life begins at conception. For example, Baruch Brody argues that a functioning brain is essential for being human (14). His position is based on a parallel with the end of human life. If a human being dies and goes out of existence when the brain irrevocably and completely stops functioning, then human life can be said to start when the fetal brain begins to function, or when brain waves can be detected, somewhere around six weeks after fertilization. It is not simply the parallel with the current criteria for death that motivates Brody’s focus on brain birth. In addition brain function is the biological basis for consciousness, thought, and feeling. The importance of this for Brody is indicated when he says, “One of the characteristics essential to a human being is the capacity for conscious experience, at least at a primitive level. Before the sixth week, as far as we know, the fetus does not have

this capacity. Thereafter, as the electroencephalographic evidence indicates, it does. Consequently, that is the time at which the fetus becomes a human being" (14, p. 83). However, from the fact that brain waves can be detected in a six-week old fetus, it does not follow that it can feel. While there is some disagreement on this point (15), and it is difficult to pinpoint the exact time at which the fetus becomes aware of its surroundings, most scientists believe that more than brain waves are necessary before the fetus has the capacity for conscious experience. It seems likely that sentience does not occur until well into the second trimester (probably between 22 and 24 weeks) as prior to that time the neural pathways are not sufficiently developed to be able to transmit pain (or any experiential) messages to the fetal cortex (16,17). So, if it is conscious experience that marks the beginning of human life, then this very likely does not occur until the second trimester of pregnancy. The occurrence of brain waves is certainly a necessary part of this development, but it is not clear why the beginning of brain function should have particular moral significance. Certainly most pro-lifers do not view "brain birth" as having any more significance than any other developmental stage in the life of the fetus.

Personhood

A different approach to the moral status of the fetus focuses on the fact that fetuses, while certainly genetically human, are not persons. Persons are essentially defined or recognized, not by their biology, but by certain psychological features, such as consciousness or an awareness of their surroundings, sentience, self-consciousness, thought, and the use of language. Fetuses, especially at the beginning of pregnancy, when 90 percent of abortions occur, have none of these characteristics. How, proponents of a personhood view ask, can a clump of cells be compared to an individual who feels, thinks, worries, enjoys, and so forth? It is persons who have a special moral status and a right to life. The mistake conservatives make is to equate being human with being a person.

This is a natural enough mistake, since all the persons we know are human beings. In contrast, personhood proponents argue that the two concepts are distinct in theory, however much they coincide in our experience. To see this, think about encountering an intelligent alien like *E.T.* in the movie of that name. Certainly E.T. is not human in a genetic or biological sense. He is not a member of the species *Homo sapiens*. Nevertheless, if we should meet someone like E.T., we would have no hesitation in according him the moral status of a person because, whatever his species membership, he resembles us in morally significant ways. That is, he is conscious, sentient, rational (indeed, far more advanced than human beings), self-conscious, uses language, and is a moral agent. Mary Anne Warren (18) claims that it is these features that have moral significance, not membership in a particular species. Why should a merely biological category make a moral difference? Or, as Don Marquis (an opponent of abortion who nevertheless criticizes the species criterion of moral status) puts the point, "Why ... is it any more reasonable to base a moral conclusion on the number of chromosomes in one's cells than on the color of one's skin?" (19, pp. 26–27). On the other hand, if "human being" is taken to be a *moral* category, then the fetus's claim to be a human being cannot be a *premise* in the antiabortion argument, for that is precisely what is to be proved. The conservative argument appears either to be based on an arbitary, morally irrelevant category (species membership) or to beg the question. To say this is not to say that the genetic humanity criterion has been shown to be wrong, only that it has not been adequately defended. Perhaps membership in the human species can be shown to have moral significance so that the conservative argument can be rendered noncircular.

What are the implications of a personhood view of moral status for the fetus? Warren does not claim that possession of *all* the person-making characteristics is necessary to be a person. Her point is rather that a being who possessed *none* of the relevant characteristics would not be a person. Indeed, she thinks that anyone who claimed that a being who possessed none of the person-making traits was a person all the same "would thereby demonstrate that he had no notion at all of what a person is — perhaps because he had confused the concept of a person with that of genetic humanity" (18, p. 68). On Warren's view, early-gestation fetuses are certainly not persons, as they lack all of the characteristics of persons. But what are we to say about more developed fetuses, who have some of the characteristics of persons, such as sentience and a rudimentary form of consciousness? Warren notes that even late-gestation fetuses are not fully conscious, in the way that an infant of a few months is, and that it cannot reason or use language, and so forth. "Thus, in the *relevant respects*, a fetus, even a fully developed one, is considerably less personlike than is the average mature mammal, indeed the average fish" (18, p. 69). Warren concludes that a fetus at any stage cannot have more of a right to life than a newborn guppy "and that a right of that magnitude could never override a woman's right to obtain an abortion, at any stage of her pregnancy" (18, p. 69).

There are two central problems with a personhood criterion of moral status. The first is that it applies not only to fetuses but to other human beings, notably, newborns. If abortion is not seriously morally wrong, is infanticide equally morally neutral, something best left to parents to decide? Warren's response to this is to offer consequentialist reasons for keeping infanticide illegal and to acknowledge that infanticide need not be seriously wrong in a society that cannot care for all the infants who are born. Whatever the merits of this argument, the personhood criterion seems to leave out many individuals most of us thought were full-fledged members of the moral community: elderly senile people, for example, and people with severe mental disabilities. Are we to say that their deficits in rationality, language usage, and so forth, deprive them of "human moral status" and that therefore killing them is not seriously morally wrong? One way to avoid this unpleasant conclusion is to set the requirements for personhood relatively low. Perhaps consciousness and sentience will do. However, that will mean that a great many animals will qualify as persons whom it is presumably wrong to kill. This is a possible moral view, but one that requires radical revision

of ordinary moral thought and practice. On the other hand, if the requirements for personhood are set relatively high, and rationality and language use are necessary conditions, that will keep out the animals, but at the cost of denying full moral status to many human beings, and not just fetuses.

The other problem with Warren's personhood view is that it suffers from the same defect she criticized in the conservative argument (20). According to Warren, the conservative confuses genetic humanity with moral humanity (or moral personhood). This confusion leads the conservative to think, wrongly, that just because the fetus is genetically human, it must be morally human, that is, have the moral status that human persons have, including a right to life. What is missing in the conservative's argument is an explanation of why species membership should endow a being with a particular moral status. However, Warren can be criticized for making the same mistake, for she does not explain what it is about personhood that endows a being with moral status. As Marquis explains the criticism:

> The principle "Only persons have the right to life" also suffers from an ambiguity. The term 'person' is typically defined in terms of psychological characteristics, although there will certainly be disagreement concerning which characteristics are most important. Supposing that this matter can be settled, the pro-choicer is left with the problem of explaining why *psychological* characteristics should make a *moral* difference (19, p. 27).

Warren says that it is "self-evident" that descriptive persons are moral persons, but that equation is no more self-evident than the conservative's claim that genetic humans are moral humans (i.e., entitled to be treated in certain ways). This is not to say that Warren's claim cannot be defended, but rather to say that it is not self-evident, and an argument connecting the psychological properties of personhood and moral status is needed. Even if such an argument can be given, it does not follow that moral personhood is limited to descriptive persons. The possibility remains open that it is justifiable to confer *normative personhood* (including a right to life) on human beings, such as babies and those with severe mental deficits, who lack the psychological properties of descriptive persons.

Being a Person and Having a Right to Life

Like Warren, Michael Tooley thinks that personhood is essential to moral status, but unlike Warren, he provides an argument to show why only descriptive persons can have a right to life (21). Tooley starts with Joel Feinberg's analysis of right-bearers as beings who can have interests (22). Interests are necessary for rights because the function of rights is to protect interests; if a being had no interests, there would be nothing to protect and the ascription of a right meaningless. Tooley then takes Feinberg's view one step further, arguing that particular rights are connected with specific sorts of interests. According to the "particular-interests principle," an individual cannot have a right to R unless it is capable of having an interest in R. The question then is what is required for a being to have an interest in R. This depends, Tooley maintains, on the sort of thing that R is. Consider the interest in not being subjected to painful stimuli. To have an interest in that requires only that the being be capable of experiencing pain as a disagreeable sensation. Thus we could intelligibly ascribe a right not to be subjected to painful stimuli to any sentient being. Other rights require more conceptual abilities. It would be absurd to ascribe a right of freedom of expression to a cow, because cows have no interests that can be furthered by such a right. Now what about life? It might be argued that life is in the interest of all living things, but this is just what Tooley wants to deny. He maintains that the right to life protects the interest in one's own continued existence, and that therefore only beings who can have a concept of their own continued existence can have a meaningful right to life. Tooley's view is much more stringent than Warren's. It limits a right to life to those who, first, are able to think of themselves as continuing to exist into the future and, second, have desires about that future, in particular, that it exist. This rules out not only human fetuses and most animals, but also babies and young children. It is not clear when children obtain a conception of themselves as existing in the future. It is probably not before they become language users, somewhere around the age of two.

The practical implications of Tooley's view (that it makes infanticide morally permissible) are not the only objection to it. In addition it can be objected that a right to life can be meaningfully ascribed to any being whose life is a good to it now, even if it lacks the capacity to envisage, and have desires about, a future existence. Animals, babies, and severely retarded adult human beings can enjoy their lives; why then cannot we preserve their lives *for their own sake?* If the reason for not killing them is that their lives are a good *to them*, this suggests that they have an interest in living, which can be the basis for ascribing to them a right to life.

Potential Personhood

Some pro-lifers do not regard genetic humanity as intrinsically significant, but rather as an indication that the being will become a descriptive person. An embryo does not now have any of the properties of a person. It is not even sentient or conscious, much less capable of communicating or relating to other persons. However, even an embryo is potentially just like us. If left alone (i.e., not aborted), it will grow and develop into a human person. Therefore we ought not to thwart its natural development. "On its strongest interpretation," Stephen Buckle explains, "the argument is thought to establish that we should treat a potential human subject as if it were already an actual human subject" (23, p. 227).

Is it in fact true that embryos, if not deliberately aborted, will develop into persons? A great deal has been learned about the rate of miscarriage in the last 20 years. When John Noonan was writing in 1970, he claimed that only 20 percent of pregnancies ended in spontaneous abortion. This figure still holds for pregnancies that are physiologically recognized. However, it is now thought that up to 75 percent of all human conceptions are aborted

spontaneously (24). Many of these spontaneous abortions occur before the woman realizes she is pregnant. With such a high rate of pregnancy loss, can it be maintained that every embryo is a potential person? The vast majority do not develop into persons, and would not develop into persons, even if allowed to develop naturally. This is one reason why implantation might be chosen by potentiality theorists as the moment at which the conceptus attains full moral status. After implantation, the prospects for live birth improve considerably.

There are other problems with arguments based on potentiality. The first is known as "the logical problem with potentiality." It is directed at the strongest version of the potentiality argument, which claims that the potential of the fetus to become a person gives it now the rights of a person. But, it may be objected, why should mere potential convey actual rights? As Stanley Benn has put it, "A potential president of the United States is not on that account Commander-in-Chief" (25, p. 143).

The logical problem can be avoided if the claim is weakened. It is not that the embryo or fetus *now* has the right to life. Rather, the claim is that because we think that the lives of persons are valuable and deserving of protection, so too we ought to recognize the value of entities that have the potential to become persons. While this might not accord to fetuses a full-fledged right to life, it would at least require that the reasons for killing a fetus be substantial ones.

A serious problem for potentiality arguments is that they seem vulnerable to a *reductio ad absurdum*. If the objection to abortion is that it kills potential person, why cannot the same complaint be made of contraceptive techniques that kill sperm, or prevent sperm and egg from joining? Why isn't an unfertilized ovum also a potential person? John Harris makes the point this way (although he refers to "human being" rather than "person"):

> To say that a fertilized egg is potentially a human being is just to say that if certain things happen to it (like implantation) and certain other things do not (like spontaneous abortion), it will eventually become a human being. But the same is true of the unfertilized egg and the sperm. If certain things happen to the egg (like meeting a sperm) and certain things happen to the sperm (like meeting an egg) and thereafter certain other things do not (like meeting a contraceptive), then they will eventually become a new human being (26, pp. 11–12).

If abortion is seriously wrong because it kills a potential person, then using Delfen foam (a spermicide) is mass murder! Indeed, even abstinence would have to be justified, since failing to have intercourse, at least during a woman's fertile period, would prevent the development of a new human being. Since virtually all potentiality theorists wish to differentiate between contraception (which they regard as morally neutral) and abortion (which they regard as seriously wrong), they must explain why an embryo is a potential person in a way that a gamete is not.

Some theorists look to probability to defend the claim that an embryo is a potential person, but a gamete is not. Even if a fertilized egg has only a 25 percent chance of becoming a person, this does not compare with a sperm's chance: about one in 200 million. A given ovum has a better chance to become a person than a given sperm, but still much less chance than that of a fertilized egg. However, it is not clear that potential should be understood in terms of probability. As Steinbock points out, "Is not every entrant in a lottery a potential winner, even if the odds of winning are extremely low?" (3, p. 63)

Others regard potentiality not in terms of the odds of success but rather in terms of natural development. Many fertilized eggs do grow and develop into embryos, fetuses, and babies. A gamete, on the other hand, is not growing or developing into anything (27,28). However, basing potential personhood on what fertilized eggs become in the natural course of events has notable consequences for extracorporeal embryos. Since they cannot develop into persons without human intervention (i.e., being placed in a uterus), extracorporeal embryos are not potential persons, and presumably, it is not seriously wrong to kill them. This conflicts with the opinion of many pro-lifers and the Catholic Church that extracorporeal embryos have the same moral status as embryos in a uterus. Indeed, some have regarded frozen embryos as "pre-born children" (29).

Some defenders of a potentiality principle try to distinguish between a gamete and a zygote by saying that prior to fertilization, no particular individual exists. Once the complete human genome is present, there is a new human being, the same individual that will be born, grow up, and die. However, as Mary Anne Warren notes, this claim can be disputed on empirical grounds:

> It is not clear that the zygote is the same organism or proto-organism as the embryo that will later develop from it. During the first few days of its existence, the conceptus subdivides into a set of virtually identical cells, each of which is "totipotent"—capable of giving rise to an embryo. Spontaneous division of the conceptus during this period can lead to the birth of genetically identical twins or triplets. Moreover, it is thought that two originally distinct zygotes sometimes merge, giving rise to a single and otherwise normal embryo. These facts lead some bioethicists to conclude that there is no individuated human organism prior to about fourteen days after fertilization, when the 'primitive streak' that will become the spinal cord of the embryo begins to form (1, pp. 203–204).

In this view, an implanted embryo is a potential person, while neither a gamete nor a newly fertilized ovum is. But some theorists argue that while the implanted embryo may be identified with some *particular* person, in a way that neither the zygote nor the constituent gametes are, nevertheless gametes and zygotes are potential persons. Potentiality is one thing; uniqueness or identity another (30).

A Future Like Ours

A variation on the potentiality principle is offered by Don Marquis in "Why Abortion Is Immoral" (19). According to Marquis, the reason why killing people is generally wrong is that killing deprives the individual of a valuable future, a future like ours (FLO). Killing a fetus by having an abortion deprives the fetus of its valuable future, and therefore abortion is (usually) seriously morally wrong. Marquis notes two ways in which his view differs from

traditional accounts. First, it is not "species-ist." Moral status does not depend on being genetically human but rather on having a valuable future like ours. If there are members of other species elsewhere in the universe who have valuable futures like ours, then it would be seriously wrong to kill them. For that matter, it is possible that some nonhuman animals have FLO, and that killing them is seriously morally wrong. Marquis leaves indeterminate precisely what FLO consists in, but presumably he has in mind the kinds of capacities that make us persons: rationality, self-consciousness, the ability to have relationships with others, and so forth. Therefore, although his account does not refer explicitly to the wrongness of killing persons or potential persons, this is implicit in his account, since the beings it is seriously wrong to kill (i.e., those who have FLO) are persons or potential persons. If a being is neither a person, nor capable of developing into a descriptive person, then presumably it does not have a valuable future like ours. Second, Marquis's view differs from a sanctity of life approach that holds that killing people is always wrong. According to Marquis, killing someone who does not have a valuable future is not necessarily wrong. Thus Marquis's account is compatible with voluntary euthanasia and even nonvoluntary euthanasia of infants and fetuses whose lives will be filled with suffering or empty of the things that make life worth living.

An objection to Marquis's view is that it is vulnerable to the same *reductio* as other potentiality views. If it is wrong to kill a fetus because of its FLO, why is it not equally wrong to kill gametes? Why do not gametes have a valuable future? Of course, it is true that most gametes do not have much of a future at all. They pass out of or are reabsorbed into the body. However, use of a contraceptive prevents those few gametes that might develop into persons from doing so. It would seem that contraception should be somewhat morally problematic, in Marquis's view. He, however, denies this. We can ascribe a valuable future to a fetus because the fetus is identified with the person it becomes. It has the *same* future as the born individual. However, the born individual does not share a future with the egg and sperm that conjoined to form it. Neither the egg nor the sperm is the person; therefore neither has his or her future. As Marquis expresses it:

> If I were the same individual as a sperm and also the same individual as an ovum, then a particular sperm and a particular ovum were the same individual. This is obviously false. It follows that any argument that I was once a sperm (or an unfertilized ovum) is unsatisfactory. Therefore, the contraception objection fails (30).

However, why should the fact that I am not identical with either the sperm or the egg entail that they do not have valuable futures, of which they would be denied if they were killed or otherwise prevented from conjoining? Marquis thinks that neither gamete can have a future because it is only when the two conjoin that there is anything that has a valuable future. The valuable future is that of the new being, and it is not identical with either of its two components. However, it is not clear why only the new being can be said to have a valuable future. To be sure, neither gamete can have a valuable future all by itself, but why does that matter? It might be objected that Marquis has confused identity with having a valuable future.

One of the interesting implications of Marquis's account is the possibility that pre-implantation embryos lack FLO, and therefore lack moral status. Since a pre-implantation embryo might turn out to be two or three people, it cannot be identified with any particular individual. If having FLO depends on identification with a particular future person, then pre-implantation embryos do not have FLO. This means that killing a pre-embryo using a very early abortifacient, such as the morning-after pill, is not seriously wrong. In addition Marquis presumably would not oppose creating embryos either for research or possible implantation, and then discarding them. Only implanted embryos, which have the primitive streak and can no longer become twins, can be identified with the subsequent person, have FLO and are seriously wrong to kill. The fact that most conservatives would be unwilling to accept these implications is not an argument against the FLO theory. However, it remains an open question whether it, like potentiality theories generally, are vulnerable to the contraception objection.

Sentience-Based Views

Sentience is the ability to experience pain or pleasure. It is relevant to moral status because we normally assume that it is wrong to inflict pain without a good reason. Many pro-lifers seem to base their objection to abortion on the premise that abortion causes the fetus to suffer. One pro-lifer was quoted as saying that abortion is "mean." Since most methods of abortion require the embryo or fetus to be ripped from the uterine wall, and often cause it to be torn apart, the idea that abortion hurts the fetus is not surprising. However, as we have seen, it is extremely unlikely that a fetus in the first trimester can experience pain or anything else.

Rejection of unnecessary infliction of pain suggests that sentience is a sufficient condition of moral status. However, the infliction of pain is not the only kind of action with moral importance. Killing is also something that often requires justification, even when done painlessly. We need a deeper reason for thinking that sentience is a necessary, as well as sufficient, condition of moral status. The deeper reason comes from the connection between moral status and interests, and the connection between interests and sentience.

To say that a being has moral status is to say that it has moral claims against us. This in turn suggests that we should do, or forbear from doing, certain things for its sake. We are required to consider its welfare in deciding what to do. The next question is what kinds of beings can have a sake or a welfare. For some philosophers, anything that can be protected or preserved can have a welfare. Others limit a welfare to beings to whom it can matter how they are treated. In this view, it may be morally

wrong to destroy the environment, but it is not a wrong *to* the environment because the environment does not, indeed, cannot, care what is done to it. The environment has no stake in what happens to it. Because nothing can matter to it, it has no interests. If it has no interests, then its interests cannot be considered, and therefore it lacks moral status.

The conceptual connection between moral status and the possession of interests seems self-evident. To accord something moral status is to require that its interests be considered. If a being has no interests, no sake, and no welfare, it is hard to see how it could have moral claims on us. More controversial is the claim that sentience is necessary for a being to have interests. What is it about the ability to experience pain and pleasure that enables a being to have interests? The intuitive idea is that sentient beings care about what happens to them, while nonsentient beings do not. However, perhaps it is not sentience that enables beings to have interests but rather simply consciousness: the ability to have experiences. Mary Anne Warren suggests this when she writes:

> One can imagine a being that has conscious experiences of many sorts, but that never experiences pleasure or pain, or any other positive or negative feeling, mood, or emotion. Such a being would be conscious, but it would not be sentient. Data, the brilliant and personable android of the television series *Star Trek: The Next Generation*, is described by himself and other characters as such a being. Although he is conscious, rational, morally responsible, and highly self-aware, his programming includes no capacity to experience pain, pleasure, or emotion . . . such a being would have strong moral status by virtue of its moral agency; but it could not have any moral status that is contingent upon sentience (3, p. 56).

The ability to experience physical pain or pleasure does not seem essential to having interests. There are human beings who lack the ability to feel pain; they still have all kinds of interests, including an interest in continuing to live. Sentience, understood in purely physical terms, does not seem to be necessary for moral status. However, Data is alleged to have no feelings or emotions at all. This being the case, does it matter to him what happens to him? Does he care if he is destroyed or protected? And if he is indifferent to what happens to him, can preserving him be said to be in *his* interest? It might be argued that the connection between sentience (broadly understood to include emotions and feelings) and interests is not so easily broken.

Tom Regan argues that the belief that sentience is necessary for the possession of interests stems from a failure to distinguish between two senses of "interest." One sense of "interest" refers to what individuals *take* an interest in; what they are interested in or care about, what matters to them. It seems clear that nonconscious, nonsentient beings cannot have interests in this sense. However, there is another sense of "interest" that refers to what is *in* a being's interest. That these are not the same is easily shown. It can be *in* someone's interest to give up smoking, exercise regularly, and eat moderately, and yet the person in question might have no interest in doing so. Conversely, people often have an interest in things that are not, on balance, in their interest. The question is whether it makes sense to talk about what is *in* the interest of beings that do not *take* an interest in anything. Certainly we do sometimes talk this way, recommending that certain actions be taken "in the interest of preserving the environment." But it does not follow that the interests in question are those of the environment, nor that an inanimate object can have a good or welfare of its own in the same sense as a being that cares, if only in the most rudimentary sense, about what is done to it.

Some sentience-based theorists regard sentience alone as having moral significance. For example, Peter Singer is a "sentience-only" proponent, whose theory of moral status is inspired by that of Bentham and Sidgwick. According to Singer, the comparable interests of all sentient beings should be given equal weight in our moral deliberations (31). This does not entail treating all sentient beings alike, since their needs and interests will differ. It does not even mean valuing the lives of all sentient beings equally. Singer acknowledges that the life of a human — that is, a rational, self-conscious, morally autonomous agent — may properly be considered more important than the life of a mouse. However, he thinks that there is no justification for valuing the pain experienced by a person over the (comparable) pain experienced by a mouse. Pain is pain, no matter who feels it.

Not all sentience-based theorists accept the principle of equal consideration of interests. For example, L.W. Sumner, who thinks that sentience is a necessary and sufficient condition of moral status, argues that both sentience and moral status come in degrees (32). The moral status of a being is proportional to its degree of sentience. This is supposed to explain the intuitive view that the interests of people count for more than the interests of mice. However, it is not clear why rationality, self-consciousness, and moral agency should be conceived of as degrees of sentience. Nor does it seem impossible that a being lacking in those morally relevant features could nevertheless be intensely sensitive to pain and pleasure. Bonnie Steinbock does not accept the degrees of sentience view advocated by Sumner; she thinks that there can be features aside from sentience that are relevant to moral status. Thus she argues that while the possession of interests is a necessary condition of moral status, and potential personhood by itself does not endow beings who lack interests with moral status, the potential of a sentient being to become a person must be regarded as enhancing its moral status. Both human infants and nonhuman animals have minimal moral status as sentient beings, but the degree of moral status possessed by human infants is greater than that of nonhuman animals because the infants are potential persons. Another factor is relationships with others. Some humans, due to brain defects, will not develop into descriptive persons, capable of language, reasoning, and moral responsibility. Nevertheless, they remain normative persons. In part, this is because of the place they occupy in a network of affections. A retarded child does not cease to be someone's son or daughter, or loved the less because

of that. Their moral status does not change because they will not fulfill normal human potential. And even if the parents reject the child, society should take on this caring role, out of kindness and compassion for the helpless child who needs our care.

The Multi-Criterial View

Steinbock's suggestion that there might be features besides sentience relevant to the degree of moral status is taken up explicitly by Mary Anne Warren, who argues for a "multi-criterial" view (1). She rejects uni-criterial views, whether based on life, sentience, or personhood, as simplistic and inconsistent with elements of commonsense morality that we cannot reasonably be expected to jettison. Her multi-criterial approach consists of seven principles that she regards as implicit elements of commonsense morality. The principles that might be thought relevant to fetal moral status are respect for life and the transitivity of respect. (The anticruelty principle applies only to beings who can be treated cruelly, that is, sentient beings. It does not apply to early-gestation fetuses.) The respect for life principle accords some moral status to fetuses, but not enough for full moral status. Moreover, the reasons why women seek abortions are sufficiently compelling to justify the destruction of a living thing that is not yet sentient and not yet a member of a human social community. The transitivity of respect principle requires us, within the limits of the other principles and to the extent that it is morally feasible, to respect other people's attributions of moral status. Since some people do regard fetuses as having full moral status, this justifies regarding fetuses as having some moral status. However, the transitivity of respect principle is limited by the basic moral rights of moral agents. Warren concludes that "although the fetus gains in moral status as it becomes increasingly likely to be capable of sentience, until it has been born it cannot be accorded a fully equal moral and legal status without endangering women's basic rights to life and liberty" (1, p. 222).

OUTLINE

TECHNOLOGICAL CONTEXT

History of Prenatal Testing

The oldest reference of prenatal diagnosis is for anencephaly (absent skull and brain) diagnosed by X rays in 1917 by James T. Case. The first amniocentesis is attributed to Schatz in 1883 for the purpose of treating hydramnios (excessive amniotic fluid) (1). Amniocentesis to detect erythroblastosis fetalis (complication of Rh incompatibility) began in the 1950s. Prenatal testing with amniocentesis for genetic disorders began in 1955 when it was discovered that the sex of a human fetus could be predicted by analysis of fetal cells in amniotic fluid (2–5). Initially the testing was used to determine fetal sex when a woman was at risk for having a child with an X-linked condition such as hemophilia (6). In this situation she would have a fifty percent risk of having an affected male infant. If the baby were female, she would have a fifty percent risk of carrying the gene, but would be clinically unaffected. The sex chromatin body (Barr body) could be identified in nondividing amniotic fluid cells. A male fetus (absent Barr body) could be identified and the pregnancy terminated despite a 50 percent probability that it would be unaffected. The first report of the procedure being done for this purpose was from Denmark (7).

It was reported in 1959 that Down syndrome is due to an extra chromosome 21 and use of amniocentesis to detect fetal chromosome abnormalities began in the 1960s (8–11). Widespread use of amniocentesis for increased maternal age in the United States is partly attributed to lawsuit settlements in the late 1970s in cases where the patients had not been referred for testing and gave birth to children with disabilities. In 1983 the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists recommended that all women over the age of 35 be offered amniocentesis; thus amniocentesis became a routine part of obstetric care (12). Other contributing factors to the rapid increase in demand for prenatal diagnostic services include the liberalization of abortion statutes, changes in cultural attitudes toward family size, and extensive media coverage and publicity given to prenatal diagnosis (13).

Chorionic villus sampling (CVS), aspiration of tissue that will become the placenta, was first done in Copenhagen in the late 1960s (14,15). Because of various technical problems it did not come into common use until the 1980s (16). This test has the advantage of being performed in the first trimester of pregnancy (9–13 weeks) as compared to amniocentesis, which is done in the second trimester (15–18 weeks). However, the spontaneous abortion rate following the procedure is approximately 1 percent, which is higher than for amniocentesis (1 in 300–400). There is also a higher rate of mosaicism (two or more cell lines with different chromosomal constitution) with CVS as compared to amniocentesis (0.5–1 percent for cultured CVS cells vs. 0.2–0.3 percent for amniocytes) (17). In most cases the abnormal cell line is confined to the placenta, so a follow-up amniocentesis is often needed to look for the possibility of true mosaicism in the fetus. CVS performed earlier than nine weeks may be associated with an increased risk of limb and facial malformations. And different from amniocentesis, it is not possible to measure alpha-fetoprotein levels with CVS; as a result CVS cannot be used to detect neural tube impairments. Moreover, because CVS is a technically more difficult procedure than is amniocentesis, fewer obstetricians offer CVS in their office. Not all tertiary care facilities or major medical centers offer it.

Screening for neural tube impairments was first demonstrated in 1972 by determining amniotic fluid concentrations of alpha-fetoprotein (AFP). Elevated levels were associated with spina bifida and anencephaly in the fetus (18). Elevated levels of AFP were also found in maternal blood serum when the fetus had an open neural tube (19). By the 1980s most women were being offered serum AFP screening during pregnancy. Maternal serum AFP (MSAFP) screening, ultrasound and amniocentesis are capable of detecting 100 percent of cases of anencephaly and 80 to 90 percent of cases of spina bifida (20).

In 1984 it was reported that AFP values in maternal serum were lower than expected when the fetus had Down syndrome or trisomy 18 (21). AFP measurement along with age of the mother were used to detect pregnancies with an increased likelihood of a chromosome abnormality in women under the age of 35. This technique could detect 20 percent of cases of Down syndrome in this population

who otherwise would not be identified as having an increased risk. Other biochemical markers were identified which varied from normal when a woman was carrying a fetus with Down syndrome or trisomy 18. These include unconjugated estriol and human chorionic gonadotropin. Use of these three markers to screen pregnancies is commonly referred to as the "triple screen" and is generally done at the sixteenth to eighteenth week of pregnancy. Abnormal values are followed by ultrasound to confirm dating. If dating is correct, amniocentesis is offered for definitive testing for chromosome abnormalities. Detection rates with use of the triple screen have been reported as 67 to 75 percent, with a false positive rate of 4 to 5 percent (22).

Ultrasound was first developed in World War I as sonar, to look for underwater submarines. Using it to look at fetuses began in the 1960s (23). Ultrasound is used for determining gestational age, locating structures prior to invasive testing procedures, and identifying structural abnormalities in the fetus. Conditions such as anencephaly, spina bifida, congenital heart defects, hydrocephalus, and kidney abnormalities are detectable with ultrasound. Most women in this country have at least one ultrasound during their pregnancy. Studies have not shown a risk to the fetus as a result of ultrasound, but pregnancy outcomes have not been shown to improve through routine ultrasound use.

Fetoscopy, the direct visualization of the fetus by using an optical instrument, was first used in 1954 but is now rarely done except for fetal skin biopsy. Fetoscopy was used in the past to obtain fetal blood samples, but percutaneous umbilical blood sampling (PUBS) — also known as cordocentesis is currently the method of choice. In this procedure ultrasound guides placement of a needle inserted through the maternal abdomen into the umbilical vein. PUBS is used for diagnosis of chromosome abnormalities, fetal infections, coagulation defects, hemoglobin and red cell disorders, metabolic and immunologic diseases.

The first reported prenatal diagnosis established by molecular genetic techniques was for alpha-thalassemia by means of linkage analysis in 1976, and for sickle cell anemia by analysis of gene mutation in 1978.

Today's Prenatal Tests

Prenatal diagnosis is available for hundreds of genetic conditions including chromosome abnormalities, inborn errors of metabolism, neural tube impairments, and single gene disorders. Ultrasound detects many different structural defects including hydrocephalus, congenital heart impairments, limb anomalies, skeletal dysplasias, and diaphragmatic hernias. In the most recent edition of Catalog of Prenatally Diagnosed Conditions there are 940 conditions listed that have been diagnosed prenatally. These include chromosome abnormalities, congenital malformations, dermatologic disorders, fetal infections, hematologic disorders, inborn errors of metabolism, tumors and cysts, and multiple congenital anomalies of unknown etiology.

Methods of prenatal diagnosis include maternal serum screening for biochemical markers to look for neural tube impairments as well as chromosomal aneuploidies (i.e., abnormal numbers of chromosomes). The triple screen detects up to 75 percent of fetuses with Down syndrome. However, these are screening tests and must be followed by additional procedures such as ultrasound in the case of neural tube impairments and amniocentesis or chorionic villus sampling for chromosome abnormalities.

Data from the Council of Regional Networks for Genetic Services (CORN) for 1989 estimated that 50 percent of pregnancies were being screened for MSAFP, this number is most likely now increased. The 1989 data from this group showed that increased maternal age was the most common indication for prenatal tests (62 percent), with abnormal MSAFP accounting for 14 percent, positive family history in 7 percent, previous spontaneous abortion or stillbirth 1 percent, abnormal ultrasound 1 percent, parental concern or anxiety 1 percent. "Other" and "unknown or unrecorded" accounted for an additional 11 percent (24). In a survey of a university-based cytogenetics laboratory over a five month period in 1997, of 476 amniotic fluid samples, 52 percent were obtained for increased maternal age, 34 percent were for abnormal triple screen, 7 percent were for abnormal ultrasound, 3 percent were for a family history of a genetic disorder, 1 percent were for DNA testing, and the remaining 3 percent were for elevated MSAFP, multiple miscarriages, and maternal anxiety. The DNA diagnostic testing included testing for achondroplasia, Rh, Kell antibody, sickle cell, and X-linked hydrocephalus.

Who Is Offering Tests

Most prenatal genetic testing is obtained through obstetricians in private practices or public health clinics. The remainder is obtained through tertiary referral centers such as university medical centers or private genetic centers. In a U.S. study that looked at discussions between obstetricians or nurse-midwives and their patients during their first prenatal visit, it was found that time devoted to discussion of genetic testing averaged 3.7 minutes $\pm$3.9 minutes (range 0–25.3 minutes). A comprehensive family history was not taken in any of the visits. Discussion of topics such as abortion or continuation of pregnancy if an anomaly were detected, or a description of the disorders for which testing was offered occurred in a minority of visits (24). Guidelines for Perinatal Care (1997) from the American Academy of Pediatrics and American College of Obstetrics and Gynecology does not recommend referral for genetic counseling for women of advanced maternal age because it states that the primary care physicians can explain the risks (25).

When an abnormality is detected through prenatal testing, information and counseling usually comes from an obstetrician, a genetic counselor, or a nurse. The information given varies depending upon the knowledge and experience the professional has of the specific condition. Many health professionals who offer prenatal genetic counseling have not had direct contact with children and adults with developmental disabilities and genetic disorders. Obstetricians often have had little contact with such patients since their medical school training, and even then this contact may have been

minimal. Few genetic counselors work in both prenatal and pediatric genetics. Few genetic counseling training programs give students an opportunity to work with developmentally disabled children and adults. Therefore, most women who receive information about a specific chromosome abnormality or genetic impairment in their fetus receive this information from health care providers without personal knowledge of the natural history and outcomes of the condition.

SOCIAL CONTEXT OF THE DISABILITY RIGHTS CRITIQUE

Outright Discrimination Against and Unexamined Attitudes About People With Disabilities

The history of discrimination against people with disabilities, including episodes of infanticide and compulsory sterilization, is long, ugly, and well documented (26–28). Even with such important steps as the passage of the Americans with Disabilities Act (ADA) and the Individuals with Disabilities Education Act (IDEA), discrimination is far from over. People with disabilities are still often treated as inferior to nondisabled people. As disability studies scholar Lennard Davis has observed, even the most educated of Americans, professors who make a living by writing about the nature of discriminatory practices and who decry discrimination against women, people of color, and other minorities, leave their attitudes toward people with disabilities largely unexamined. According to Davis, in the writings of these literary theorists, while "others" whose bodies are normal become vivid, others whose bodies are abnormal remain invisible (29).

It is not just practitioners of fashionable literary theory who sometimes harbor unexamined and discriminatory attitudes toward people with disabilities. The bioethics and medical literatures of the last decade too reveal misinformation and stereotypic thinking about what disability means for individuals, families, and society. Many clinicians and bioethicists take it for granted that health status is mostly responsible for the reduced life chances of people with a disability, largely ignoring the role of societal factors such as educational and employment discrimination. Furthermore, these clinicians and bioethicists often discount data indicating that people with disabilities and their families do not view their lives in solely or even predominantly negative terms (30); instead, they may insist that such data reflect a denial of reality or an exceptional ability to cope with problems (31–32).

People who make policy concerning the dissemination of genetic information have reached a consensus that the purpose of prenatal testing is to enhance reproductive choice for women and families — not to decrease the number of children with disabilities who are born. Some have acknowledged, however, that there is a tension between the goals of enhancing reproductive choice and preventing the births of children who would have disabilities. Writing about screening programs for cystic fibrosis in the pages of the *American Journal of Human Genetics*, medical geneticist A.L. Beaudet observed: "Although some would argue that the success of the program should be judged solely by the effectiveness of the educational programs (that is, whether screenees understood the information), it is clear that prevention of CF is also, at some level, a measure of a screening program, since few would advocate expanding the substantial resources involved if very few families wish to avoid the disease (33, p. 603). Beaudet acknowledges that, in tension with the genetic professional's stated goal of educating individuals (without any investment in the particular decision those individuals might reach), those who pay for such education do so in part with a view to reducing the number of — and costs associated with — children born with cystic fibrosis.

The profession of genetic counseling is based on a deep commitment to helping clients discover what course of action, upon reflection, is best for them. Some evidence suggests, however, that when disabilities are involved, both trained genetic counselors and others who deliver genetic information do not always live up to that commitment. A recent study designed to understand the experience of mothers who received a prenatal diagnosis of Down syndrome and chose to continue the pregnancy found problematic attitudes toward people with disabilities, evidenced in the way that medical professionals spoke to those prospective mothers. According to David T. Helm, one of the mothers who received a diagnosis of Down syndrome reported the following exchange:

> Obstetrician: *You have to move quickly. There is a doctor at [Hospital X] who does late-term abortions*. Mother: *No, I told you I'm not going to have an abortion*. Obstetrician: *Talk to your husband. You might want to think about it* (34, p. 57).

Because Helm only provides this portion of a longer exchange, the reader cannot confidently interpret the exchange he reports. Advising a patient to discuss a major life decision with her spouse is not prima facie problematic, much less discriminatory. According to Helm's interpretation (and the interpretation of the Disability Rights Community), however, these words reveal the physician's unwillingness or inability to respect this woman's already stated decision to continue the pregnancy with the fetus carrying a disabling trait. The reported exchange provides no evidence that this obstetrician understands the ways in which many families welcome and nourish — and are nourished by — children with Down syndrome.

Research has shown that obstetricians may be more likely than genetic counselors to urge particular actions upon their patients (35,36). Helm's study also reports, however, that some genetic counselors reacted negatively to women who intended to bear and raise children with Down syndrome. A woman who was told that the fetus she was carrying would have Down syndrome reported the following: "[The genetic counselor] treated me as though I couldn't accept this news, although I told her I could. She asked, 'What are you going to say to people when they ask you how you could bring a child like this into the world?'" (34, p. 57) Those words suggest that this counselor has not thought deeply about what disabilities mean for individuals who live with them and for their families. At least from what we learn of her from Helm, she does not seem to appreciate that

welcoming a child with Down syndrome into a family is not a decision that needs to be defended; she does not seem to appreciate that parental attitudes differ, that traits that matter a great deal to one couple may seem inconsequential to another. Such exchanges are probably not rare exceptions; similar examples can be found in other discussions of genetic counseling practices in the prenatal testing situation (37,38).

Nonetheless, many genetic counselors and physicians work extremely hard to live up to the central genetic counseling values of informed consent and nondirectiveness, and many of them are not only aware of but share the concerns voiced by the disability rights community. For example, at the New England Medical Center, women whose fetuses are diagnosed with Down syndrome are routinely scheduled to meet with a pediatric medical geneticist and a nurse clinician who specializes in the care of pediatric genetic patients. These women are scheduled to meet with pediatricians who specialize in genetics rather than obstetricians because pediatric geneticists understand better how Down syndrome influences the lives of children and their families. According to Dr. Diana Bianchi, who practices at the New England Medical Center, every attempt is made to introduce the pregnant woman and her partner to families who are raising infants, children, and/or young adults with Down syndrome. She reports that in her practice, only 62 percent of women who discover they are carrying a fetus with Down syndrome decide to have abortions. That rate of abortion upon a positive finding is believed to be relatively low. Disability critics point to such facts to suggest that when prospective parents obtain more accurate information about what life with disability is like, many realize that parenting a child who has a disability can be as gratifying as parenting a child who does not.

The disability critique proceeds from the view that discrimination results when people in one group fail to imagine that people in some "other" group lead lives as rich and complex as their own. The disability rights critics believe that everyone from literary theorists to bioethicists to obstetricians and genetic counselors are susceptible to such failures of imagination. Moreover they think that the desire of prospective parents to avoid raising children with disabilities may depend on that same failure.

Plurality of Disabling Traits and Plurality of Attitudes Toward Prenatal Diagnosis

In thinking about the meaning of using prenatal diagnosis to detect disabling traits, it is important to notice that the class of "disabling traits" is exceedingly heterogeneous. Prenatal diagnosis can now detect conditions as different as Lesch-Nyhan syndrome and ectrodactyly (a trait involving a partial fusion of the bones of the fingers and toes). Further, not only are the traits heterogeneous, but so are perceptions of their significance and/or seriousness. Nancy Press's research reveals that some generalizations can be made about what people take to be "serious": for example, mothers considering prenatal testing are most fearful of conditions like Lesch-Nyhan, which results in early and painful death (39). But as the infamous Bree Walker Lampley case indicates, there is debate about the seriousness of ectrodactyly. In 1991 Bree Walker Lampley, a television news woman in Los Angeles who had ectrodactyly, discovered that the fetus she was carrying had the trait and, when asked, made it known that she had no interest in terminating for such a trait; some suggested that it was "irresponsible" to bring a child into the world with such a serious trait (40). Indeed, the research of Dorothy Wertz and colleagues suggests that even genetics professionals have very different ideas of what is and what is not "serious" (41). In one of Wertz's surveys, cleft lip/palate, neurofibromatosis, hereditary deafness, insulin-dependent diabetes, Huntington's disease, cystic fibrosis, sickle cell anemia, Down syndrome, and manic depression were deemed serious by some professionals and not serious by others (42).

A similar plurality of views exists within the disability community. Many groups representing people with disabilities, such as the National Down Syndrome Congress and Little People of America, have position statements affirming the value of life with disability for individuals and families (43,44). However, there is nuance and disagreement among groups, and in fact within some groups. This complexity is suggested by attitudes within the membership of Little People of America. Many of those who live with achondroplasia are concerned that prenatal testing, which can identify heterozygotes (i.e., fetuses that will develop into long-lived people with achondroplasia) will be used to obliterate the Little People of America community. In fact some members of that community might use the technology to select for the trait. Nevertheless, many couples who are heterozygous for achondroplasia would like to use prenatal testing to identify fetuses that are homozygous for the allele associated with achondroplasia. Homozygous achondroplasia is a uniformly fatal condition, and they would like to spare themselves the experience of bearing a child who will soon die. Adding to the complexity, some people with disabilities would use prenatal testing to selectively abort a fetus with the trait they themselves carry — and some people who would not abort a fetus carrying their own disability might abort a fetus if it carried a trait incompatible with their own understanding of a life they want for themselves and their child.

A similar diversity of views toward prenatal testing and abortion can be found among parents raising a child with a disability. Many such parents do not use prenatal diagnosis to determine whether their present fetus is affected (45). The reasons for this are many; to some, the trait has come to be unimportant or irrelevant. Some may refuse it on the ground that using the technology would say something hurtful to or about their existing child. Other parents of children with disabilities decide to use these technologies.

The point about the plurality of traits and attitudes toward testing is not to suggest that the terrain is too complex to be amenable to policy response. The point is simply that people committed to ending discrimination and improving life for people who have disabilities are not monolithic on the prenatal testing issue, any more than all feminists are monolithic on a host of "women's issues" or than members of racial minorities are monolithic in

their stance toward affirmative action or other practices that affect them. Comprehensive evaluations of prenatal genetic testing will have to take such complexities into account.

Reproductive Liberty Premise

The proliferation of prenatal genetic testing occurs against the background of the controversy about abortion. Prenatal testing for genetic disability elicits unexpected responses from both sides of the abortion debate: Many of those who are uneasy with abortion based on a prenatal finding of a disabling trait are pro-choice. And many who, in general, are against the right to abortion nonetheless approve of abortions performed on a fetus carrying a disabling trait.

Virtually all the major work in the disability critique of prenatal testing emerges from those who are also committed to a prochoice, feminist agenda: Adrienne Asch, Marsha Saxton, Anne Finger, and Deborah Kaplan, for example (46–49). Other pro-choice feminists, including Ruth Hubbard, Abby Lippman, Carole Browner, and Nancy Press, draw on the disability critique to question the impact of prenatal testing (50–53). The shared premise of these scholars is that women (and men) have the right to determine when and how many children they will have; within the first two trimesters of pregnancy, abortion is a legally and morally defensible means of exercising that right.

What is new about prenatal testing is that it enables prospective parents to some extent to determine not only when and how many but also what kind of children they will have. With the exception of revealing the sex of the fetus, current prenatal testing is used to detect traits considered medically disabling — characteristics deemed undesirable or departures from species-typical functioning. In the future it may be increasingly possible to select for traits that we do value. That, however, is not the possibility that has motivated the disability critique; the motivation for the disability critique is the reality of using prenatal testing and selective abortion to avoid bringing to term fetuses that carry disabling traits.

ETHICAL ARGUMENTS OF THE DISABILITY RIGHTS CRITIQUE

As mentioned above, the number and variety of conditions for which prenatal genetic tests are available grows almost daily (54). Today we test for one trait at a time. In the future, however, with advances in diagnostic technology, it will be possible to test simultaneously for as many traits as one would like. In principle, it will be able to test for any trait one wishes that has been associated with any given allele. Not only will the cost of such testing likely decrease as the diagnostic technology advances, but advances in the technology will make it possible to do the testing earlier in the pregnancy. As mentioned earlier, one such technology will isolate the very small number of fetal cells that circulate in the maternal blood. Insofar as these earlier tests will be performed on fetal cells obtained from the mother's blood (rather than from the amniotic sac or chorionic villi) they will be minimally invasive. Thus it will be possible to do many more tests, at once, and with less cost to the pregnant woman in time, inconvenience, risk, or dollars, than is now the case (55).

As the ease of testing increases, so does the perception within both the medical and broader communities that prenatal testing is a logical extension of good prenatal care: The idea is that prenatal testing helps prospective parents have healthy babies. On the one hand, this perception is quite reasonable. Although no researcher has yet even attempted to correct a genetic impairment with in utero gene therapy, increasingly there are nongenetic approaches to such impairments. At the time of this writing, more than 50 fetuses have undergone in utero surgery to repair neural tube impairments (myleomeningoceles) (56). Moreover, negative (or reassuring) prenatal test results will reduce the anxiety felt by many prospective parents, and this in itself can be construed as part of good prenatal care. On the other hand, as long as in utero interventions remain relatively rare, and as long as the number of people seeking prenatal genetic information to prepare for the birth of a child with a disability remains small, prospective parents will use positive prenatal test results primarily as the basis of a decision to abort fetuses that carry mutations associated with disease and/or disability. Thus there is a sense in which prenatal testing is not simply a logical extension of the idea of good prenatal care.

Logical extension or no, using prenatal tests to prevent the birth of babies with disabilities seems to be self-evidently good to many people. Even if the testing will not help bring a healthy baby to term this time, it gives prospective parents a chance to try again to conceive. To others, however, prenatal testing looks rather different. A moment's reflection about the history of our society's treatment of people with disabilities makes it easy to appreciate why people identified with the disability rights movement might regard such testing as dangerous. Critics contend that prenatal diagnosis reinforces the medical model that disability itself, not societal discrimination against people with disabilities, is the problem to be solved. The charge that such testing is dangerous is supported by two, broad lines of argument. The first is that prenatal testing followed by selective abortion is *morally problematic*. The second line of argument is that the desire to undertake prenatal testing is based on *misinformation* about what disability is like for people with disabilities and for their families.

Prenatal Testing Is Morally Problematic

The disability critique holds that selective abortion after prenatal diagnosis is morally problematic, and for two reasons. First, selective abortion expresses negative or discriminatory attitudes not merely about a disabling trait, but about those who carry it. Second, it signals an intolerance of diversity not merely in the society but in the family, and ultimately it could harm parental attitudes toward children.

The Expressivist Argument. The argument that selective abortion expresses discriminatory attitudes has been called the *expressivist* argument (57). Its central claim

is that prenatal tests to select against disabling traits express a hurtful attitude about and send a hurtful message to people who live with those same traits. In the late 1980s Adrienne Asch put the concern this way: "Do not disparage the lives of existing and future disabled people by trying to screen for and prevent the birth of babies with their characteristics" (58, p. 81). More recently, she has clarified what the hurtful or disparaging message is:

> As with discrimination more generally, with prenatal diagnosis, a single trait stands in for the whole, the trait obliterates the whole. With both discrimination and prenatal diagnosis, nobody finds out about the rest. The tests send the message that there's no need to find out about the rest (59).

Indeed, many people with disabilities, who daily experience being seen past because of some single trait they bear, worry that prenatal testing repeats and reinforces that same tendency toward letting the part stand in for the whole. Prenatal testing seems to be more of the discriminatory same: a single trait stands in for the whole (potential) person. Knowledge of the single trait is enough to warrant the abortion of an otherwise wanted fetus. On Asch's more recent formulation, the test sends the hurtful message that people are reducible to a single, perceived-to-be-undesirable trait.

This observation about letting the part stand in for the whole is surely enormously important. In everyday life, traits do often stand in for the whole, people do get looked past because of them. Indeed, one form of the expressivist argument has been regarded rather highly in another context. Many people who are concerned to support women's rights, have argued that prenatal sex selection is morally problematic because it embodies and reinforces discriminatory attitudes toward women (60). The sex trait is allowed to obliterate the whole, as if the parents were saying, "We don't want to find out about 'the rest' of this fetus; we don't want a girl."

Marsha Saxton has put the expressivist argument this way:

> The message at the heart of widespread selective abortion on the basis of prenatal diagnosis is the greatest insult: some of us are "too flawed" in our very DNA to exists; we are unworthy of being born. . . .[F]ighting for this issue, our right and worthiness to be born, is the fundamental challenge to disability oppression; it underpins our most basic claim to justice and equality—we are indeed worthy of being born, worth the help and expense, and we know it (61).

And as Nancy Press has argued, by developing and offering tests to detect some characteristics and not others, the professional community is expressing the view that some characteristics, but not all, warrant the attention of prospective parents (62).

For several reasons, however, there is disagreement about the merit of the expressivist argument as a basis for any public policy regarding prenatal diagnosis of disability. Individual women and families have a host of motives and reasons for seeking out genetic information, and as James Lindemann Nelson and Eva Feder Kittay argue, it is impossible to conclude just what "message" is being sent by any one decision to obtain prenatal testing (63,64). Acts (and the messages they convey) rarely have either a single motivation or meaning.

Some prospective parents no doubt have wholly negative attitudes toward what they imagine a life with a disability would be like for them and their child; others may believe that life could be rich for the child, but suspect that their own lives would be compromised. Others who have disabilities perhaps see passing on their disabling trait as passing on a part of life that for them has been negative. Parents of one child with a disability may believe that they don't have the emotional or financial resources for another. The point is that the meaning of prenatal testing for would-be parents is not clear or singular. In any case, those sympathetic to at least some forms of prenatal testing point out that prospective parents do not decide about testing to hurt existing disabled people but to implement their own familial goals. In that sense, there is no "message" being sent at all.

To many in the disability rights movement, however, regardless of the parental motive to avoid the birth of a child who will have a disability, the parent may still be letting a part stand in for the whole. That prospective parents do not intend to send a hurtful message does not speak to the fact that many people with disabilities receive such a message and are pained by it.

A second criticism of the expressivist argument is that it calls into question the morality of virtually all abortions. The argument presumes that we can distinguish between aborting "any" fetus and a "particular" fetus that has a disability—what Adrienne Asch has called the *any-particular distinction*. According to Asch, most abortions reflect a decision not to bring any fetus to term at this time; selective abortions involve a decision not to bring this particular fetus to term because of its traits. Pro-choice individuals within and outside the disability community agree that it is morally defensible for a woman to decide, for example, that she doesn't want any child at a given time because she thinks she's too young to mother well, or because it would thwart her life plan, or because she has all the children she wants to raise. The question is whether that decision is morally different from a decision to abort an otherwise-wanted fetus.

But it is not clear that the distinction is adequate. Sometimes the decision to abort "any" fetus can be recast as a decision to abort a "particular" fetus. James Lindemann Nelson, for example, argues that if parents of three children chose to end a pregnancy that would have produced a fourth child, such parents would not be making a statement about the worthwhileness of other families with four children, or about the worth of fourth-born children as human beings (64). Rather, they would be deciding what would be right for their particular situation. If, as Asch and others have argued, prenatal testing is morally suspect because it lets a trait stand in for the whole potential person, precisely the same argument would apply to aborting a fetus because it was the fourth child. The trait of being fourth-born makes the prospective parents ignore every other respect in which that fetus could become a child that would be a blessing to its family and community. Nelson's example of the potential fourth-born child suggests one reason to doubt the merit of the

any-particular distinction; he thinks that the disability critics have failed to explain why traits like being fourth-born could be a legitimate basis for an abortion while disabling traits could not.

A third criticism of the expressivist argument is that it presumes that selective abortion based on prenatal testing is morally problematic in a way that other means of preventing disability are not. Such other means include, for example, taking folic acid to reduce the likelihood of spina bifida, or eschewing medication that is known to stunt the growth or harm the organs or limbs of a developing fetus. Such acts (or refraining from such acts) on the part of the pregnant woman are designed to protect the health of the developing fetus.

Disability critics hold, however, that abortion does not protect the developing fetus from anything. It prevents disability by simply killing the fetus. Proponents of this disability critique hold a strong prochoice position. Their objection is only to a certain way of using abortion.

But those from the mainstream prochoice community think of selective abortion in different terms. They do not see an important moral difference between selective abortion and other modes of preventing disability in large part because they do see an important moral distinction between a born child with a disabling trait and an embryo or fetus with a disabling trait. They argue that parents of all born children have an obligation to love and care for those children — regardless of their traits. They also argue, however, that the pregnant woman (and her partner) are not "parents" before the child is born. Just as a woman or couple may decide during the first two trimesters of any pregnancy that becoming a parent to a first child, or to any child, is not in accord with their life plans, so may they make the same decision on the grounds that the fetus has disabling traits. The woman may terminate the pregnancy and try again to become pregnant with a fetus that has not been identified as carrying a disabling trait. On this view, if it is reasonable to prevent disability in a developing child by adhering to a particular lifestyle, taking specified medications or refraining from taking others, it is equally acceptable to opt for abortion to prevent the birth of a child with a significant disability (65).

Even if expressivist arguments will not dissuade all people from using tests in making reproductive decisions for their own lives, there is widespread agreement that policies that would in any way penalize those who continue pregnancies despite knowing that their child will live with a disabling trait must be avoided. That is, there is widespread agreement that prospective parents who either forgo prenatal testing or decide that they want to continue a pregnancy despite the detection of a disabling trait should not have to contend with losing medical services or benefits for their child, nor feel obliged to justify their decisions.

The Parental Attitude Argument. The second argument that prenatal testing is morally problematic may be called the *parental attitude* argument. According to it, using prenatal tests to select against some traits indicates a problematic conception of and attitude toward parenthood. Part of the argument is that prenatal testing is rooted in a "fantasy and fallacy" that "parents can guarantee or create perfection" for their children (58). If parents were to understand what they really should seek in parenting, then they would see how relatively unimportant are the particular traits of their children.

The parental attitude argument also involves the thought that in the context of prenatal testing, a part, a disability, stands in for the whole, a person. The prospective parent who wants to avoid raising a child with a diagnosable disability forgets that along with the disabling trait come other traits, many of which are likely to be as enjoyable, pride-giving, positive (and as problematic, annoying, and complicated), as any other child's traits. If prospective parents imagine that disability precludes everything else that could be wonderful about the child, they are likely acting on misinformation and stereotype.

According to the parental attitude argument, prospective parents should keep in mind that the disabling trait is only one of a fetus' characteristics. The activity of appreciating and nurturing the particular child one has is what the critics of selection view as the essence of good parenting. Loving and nurturing a child entails appreciating, enjoying, and developing as best one can the characteristics of the child one has, not turning the child into someone she is not or lamenting what she is not. If we were to notice that it is a fantasy and fallacy to think that parents can guarantee or create perfection for their child, if we were to recognize what is really important about the experience of parenting, we would see that we should be concerned with certain attitudes toward parenting, not with "disabling" traits in our children. Good parents will care about raising whatever child they receive and about the relationship they will develop, not about the traits the child bears. In short, what bothers those wary of prenatal diagnosis is what might be called "the selective mentality." The attention to particular traits indicates a morally troubling conception of parenthood, a preoccupation with what is trivial and an ignorance of what is profound.

Those who connect acceptance of disability to what is desirable in any parent–child relationship worry that our attitudes toward parenthood and ultimately toward each other are changing as a result of technologies like prenatal diagnosis (66,67). Do these technologies lead us, one might ask, toward the commodification of children, toward thinking about them and treating them as products rather than as "gifts" or "ends in themselves"? Is it making us as a society less resilient in the face of the inevitable risks that our children face, and less willing to acknowledge the essential fragility of our species? When members of our society are confronted with, for example, sex selection or with the possibility of selecting for non-health-related traits like sexual orientation, they often raise concerns about the selective mentality. Indeed, those who want to reject the parental attitude argument in the context of disabling traits should recognize that they are criticizing an argument that they themselves may sometimes use in the context of non-health-related traits. Certainly many worry about the cumulative effect of individual choices, about the technologization of reproduction, and about a decreasing cultural ability or willingness to accept the

reality of uncontrollable events. These concerns trouble even those who profess to be comfortable with genetic testing and selective abortion.

Nonetheless, many find significant problems with the parental attitude argument. One of the most important is that it makes what William Ruddick has called the "maternalist assumption," namely that "a woman who wants a child should want any child she gets" (68). Ruddick acknowledges that many women do hold "maternalist" conceptions of pregnancy and motherhood, out of which that assumption grows. But he argues that there are other legitimate conceptions of pregnancy and motherhood that do not depend on or give rise to the same assumption. He suggests that some prospective parents may legitimately adopt a "projectivist" or "familial" conception of parenthood, and that either of these views is compatible with trying to ensure that any child they raise has characteristics that accord with these parental goals. In the projectivist parent's understanding of child rearing, the child is a part of her parental projects, and within limits, parents may legitimately undertake to ensure that a child starts out with the requisites for fulfilling these parental hopes and aims. Ruddick is not claiming that projectivist parents could ignore a child's manifested commitments to things beyond the parents' life plans, but he is saying, for example, that, the parent passionate about music may legitimately select against a future child whose deafness would make a love of some forms of music impossible. If a hearing child turns out to be tone deaf and enthusiastic about rock collecting and bird watching but not music, and if the parent views these activities as inimical to her parental values or projects, she need not support them, or (within limits) allow other people to do so.

According to Ruddick, the "familial" conception of parenthood highlights a parent's vision of her child as herself a parent, sibling — a participant in a nuclear and extended family that gives central meaning to life. For example, parents whose dreams of child rearing include envisioning their own child as a parent would be acting consistently with their conception of parenthood if they decided not to raise a boy with cystic fibrosis, whose sterility and shortened life span might preclude either biological or adoptive parenthood. A child of such a parent might, of course, reject family life in favor of solitude or communal adult companionship, but in using available technology to avoid raising a child who would never be able to fulfill a deeply cherished parental dream, the parent is acting in accordance with a legitimate conception of parenthood.

Though many share the disability community's concern that prenatal testing may threaten our attitudes toward children, parenthood, and ultimately ourselves, arguments such as Ruddick's and the others mentioned above make it unlikely that such concerns can undergird specific policies regarding prenatal testing for disabling traits.

Prenatal Testing Is Based on Misinformation

The second major claim of the disability critique is that prenatal testing depends on a misunderstanding of what life with disability is like for children with disabilities and their families. Connected with this claim is the question whether disability is one more form of "neutral" human variation, or whether it is different from variations usually thought of as nondisabling traits, such as eye color, skin color, or musicality.

There are many widely accepted beliefs about what life with disability is like for children and their families. Most of these beliefs are not based on data. They include assumptions that people with disabilities lead lives of relentless agony and frustration and that most marriages break up under the strain of having a child with a disability. Recent studies suggest, for example, that many members of the health professions view childhood disability as predominantly negative for children and their families, in contrast to what research on the life satisfaction of people with disabilities and their families has actually shown (69–70). For example, disability researchers Philip Ferguson, Alan Gartner, and Dorothy Lipsky have reviewed empirical data on the impact of children with disabilities on families (71), and have concluded that the adaptational profiles of families that have a child with a disability basically resemble those of families that do not.

According to Ferguson, Gartner, and Lipsky's reading of the data, families that include disabled children fare on average no better or worse than families in general. Some families founder, others flourish. Ferguson, Gartner, and Lipsky do not deny that families are often distressed upon first learning that their child has a disability. And they acknowledge that families with children who evince significantly challenging behavior experience more disruption than do other families. But recent research on raising a child with a disability offers happier news for families than many in our society have been led to expect. The Ferguson, Gartner, and Lipsky review of scores of studies about family life where children have significant cognitive, physical, and sensory disabilities, behavioral and health problems, suggests that on average, families with and without disabled children fare about the same on such measures as parental stress, marital satisfaction, and family functioning.

Although families of children with a variety of conditions have been studied, families of children with Down syndrome have received the most extensive examination. Nonetheless, all of those studies concerned children whose conditions are incontrovertibly disabilities of some consequence. The findings indicate that challenging behavior of a child is much more likely to disrupt families and cause negative consequences than significant intellectual disability or health problems. While studies differ in methodology, population studied, questions pursued, and types of conclusions, according to Ferguson, Gartner, and Lipsky's interpretation, what most reviewers find is that the mild-severe continuum is not the important one in terms of family outcomes. Behavior of the child is a much stronger predictor of negative consequences than is intellectual or physical impairment.

Studies of family adaptation, too, have begun to recognize the prevalence of positive outcomes in many families (72,73). Indeed, one recent study found that parents

of disabled adolescents reported more positive perceptions of their children than do parents of nondisabled adolescents (74).

In a 1995 study intended to learn how a child's disability affected the work lives of dual career families, the authors found that the needs and concerns of families with and without children with disabilities were "strikingly similar." They did, however, observe:

> What seems to distinguish families of children with disabilities from other working families is the intensity and complexity of the arrangements required to balance work and home responsibilities successfully. For example, parents of children with disabilities, particularly those with serious medical or behavioral problems, find it more difficult to locate appropriate, affordable child care. . . .Similarly, these families are more dependent upon health insurance policies with comprehensive coverage (75, p. 511).

This same study also suggests, however, that a child's disability may sometimes alter the customary parent–child life cycle, in which parents gradually relinquish daily guidance and caretaking and — if they are fortunate — see their children take on adult productive and caretaking roles. Depending on the impairment and on the social arrangements that parents help a growing child construct, some people with disabilities may require their parents' help through adulthood in securing shelter, social support, and safety. Increasingly, adults with disabilities such as muscular dystrophy, spina bifida, cystic fibrosis, Down syndrome, and other conditions do not stay "eternal children," as they were once thought to do. Nonetheless, some, albeit small, portion of the population of disabled people will be more vulnerable for longer than others, and more in need of what Kittay (borrowing from Sara Ruddick) describes as "attentive, protective love" (76).

While it is important to demolish the myth that disability entails relentless agony for the child and family, there is still considerable disagreement about what conclusions to draw from the literature on the family impact of a child with disability. In the view of the disability community, this literature suggests that prenatal testing to select against disabling traits is misguided in the sense that it is based on misinformation. That is, if prospective parents could see that families with children who have disabilities fare much better than the myth would have it, then parents would be less enthusiastic about the technology.

However, recognizing that there are erroneous beliefs that need to be dispelled may not show that the desire for prenatal testing stems from misinformation alone. The first problem with the argument from misinformation has to do with the difference between retrospective and prospective judgments. It is one thing to look back on a stressful but ultimately rewarding experience and say, I'm glad I did that. It is another to look forward to the possibility of a stressful and perhaps ultimately rewarding experience and say, I'm glad to give it a try. To appreciate that many families respond well to stress does not commit one to thinking that it would be a mistake for families to try to avoid it. It may be true that, as one of the studies of working families points out, the concerns of working parents with disabled children very much resemble the concerns of any working parent — ensuring that children are safe, happy, stimulated, and well cared for at home, at school, and in after-school activities. But that study also acknowledges that working parents of children with special medical or behavioral needs find that meeting those needs takes more time, ingenuity, and energy than they think would have to be spent on the needs of nondisabled children. To appreciate that many families emerge stronger, wiser, and even better as a result of such an experience may not suggest that it is unreasonable or morally problematic to try to avert it.

Disability in Society. One of the most difficult issues that emerges in the argument from misinformation concerns what having a disability is "really" like for people themselves and for their families. Just how much of the problem of disability is socially constructed? Is it reasonable to say that in a differently constructed social environment, what are now disabling traits would become "neutral" characteristics?

Undoubtedly, more of the problem of disability is socially constructed than many people generally believe. But does that imply that having a characteristic like cystic fibrosis or spina bifida is of no more consequence than being left-handed or being a man who is five feet, three inches tall? According to the disability rights critique of prenatal testing, if people with disabilities were fully integrated into society, then there would be no need for the testing. In the world they seek to create, if a given health status turned out to be a handicap, that would be because of societal, not personal, characteristics; the appropriate response would be to change society so that the person could live a full life with a range of talents, capacities, and difficulties that exist for everyone. In a society that welcomed the disabled as well as the nondisabled, there would be no reason to prevent the births of people with traits now called disabling.

Those sympathetic to at least some forms of prenatal testing are struck by the fact that, for reasons that seem to be complex, members of the disability community speak at different times in different modes about the nature of disability. Sometimes, members of that community are clear about the fact that disabling traits have a "biological reality" or are not neutral. Adrienne Asch writes, "The inability to move without mechanical aid, to see, to hear, or to learn is not inherently neutral. Disability itself limits some options" (58, p. 73). At other times, however, and this is the mode usually emphasized in critiques of prenatal testing, those in the disability rights movement speak as if those traits indeed are inherently neutral. Thus Deborah Kent writes: "I premised my life on the conviction that blindness was a neutral characteristic (77). In this other mode, the disability community argument often is that, different from what prospective parents imagine, these so-called disabling traits are not, to coin a term, "disvaluable" in themselves; they are disvaluable because of the way they are socially constructed.

Nora Groce's work illustrates the point about how social arrangements shape whether a characteristic is disabling (78). In Martha's Vineyard in the nineteenth

century, Groce argues, being unable to hear was not disabling because everyone spoke sign language. Groce's work establishes that much of what is difficult about having a disability stems from manifold facets of society, from architecture to education to aesthetic preferences. In choosing how to construct our societies, we do, as Allen Buchanan puts it, "choose who will be disabled" (79). We could choose differently than we have, and if we were to choose differently, what's disabling about what we now call disabilities would be largely eliminated. Plainly, then, the social constructionist argument is powerful. The objection concerns, rather, what appears to be a correlative claim of the disability position: that so-called disabling traits are neither disabling nor "disvaluable," but neutral.

Again, adherents of the disability critique acknowledge that some characteristics now labeled disabilities are easier to incorporate into today's society, or into a reconstructed society, than are others. Thus no one would deny that disabling traits — departures from species-typical functioning — foreclose some options, or that some disabilities foreclose more options than others. A child with Down syndrome may never climb Mount Rainier because his strength, agility, and stamina may preclude it; he may also never read philosophy because he does not have the skills to decipher abstract material. Granting that people who can climb mountains and read abstract papers derive enjoyment and meaning from such activities, then being foreclosed from them, not by one's own choice, is regrettable. The lack of possibility is widely seen as disvaluable. In addition these lacks of capacity stem from the characteristics of the individual who is not strong enough or agile enough to climb, or who is unable by any teaching now known to us to grasp complex abstract discourse. In that sense, disability community critics acknowledge that these facets of some disabilities are "real," inherent in the characteristic itself and not an artifact of any interaction with the environment. Even if all traits are to some extent "socially constructed," that is irrelevant to the fact that the existence of these traits forecloses for those who have them the opportunity to engage in some highly desirable and valuable activities; not being able to engage in those activities is disvaluable. To the extent that spina bifida, Down syndrome, blindness, or cystic fibrosis currently preclude people from undertaking some parts of life that people who do not have those traits might experience, the disability critique acknowledges that disability puts some limits on the "open future" (80,81) people seek for themselves and their children.

As Bonnie Steinbock argues, if we really thought disability "neutral," we would not work as we do to maintain, restore, and promote health in ourselves and others. We use medicine in the hope that it will cure or ameliorate illness and disability. We urge pregnant women to refrain from activities that risk harming the fetus. If we thought that disabilities were "neutral," then we could tell women who smoke or drink during pregnancy to rest easy, for developmental delay, low birth weight, and fetal alcohol syndrome would all be just "neutral variations," of no consequence to the future child (82).

While disability community critics acknowledge that some disabilities foreclose some opportunities, they also hold that calling attention to the foreclosure obscures two important points. The first is that rather than dwell on the extent to which opportunities to engage in some activities are truncated, we should concentrate on finding ways for people with disabilities to enjoy alternative modes of those same activities. Philip Ferguson puts it this way:

> The point is not so much whether ... a blind person cannot enjoy a Rembrandt ... but whether social arrangements can be imagined that allow blind people to have intense aesthetic experiences. ...People in wheelchairs may not be able to climb mountains, but how hard is it to create a society where the barriers are removed to their experiences of physical exhilaration? ...Someone with Down syndrome may not be able to experience the exquisite joy of reading bioethics papers and debating ethical theory, but ... that person can experience the joy of thinking hard about something and reflecting on what he or she really believes. ...The challenge is to create the society that will allow as many different paths as possible to the qualities of life that make us all part of the human community (83).

The second fundamental point is that rather than concentrate on the truncation or loss of some opportunities, our society generally — and prospective parents in particular — should concentrate on the nearly infinite range of remaining opportunities. Every life course necessarily closes off some opportunities in the pursuit of others. Thus, while the disability critics of prenatal diagnosis acknowledge that disability is likely to entail some amount of physical, psychological, social, and economic hardship, they hold that when viewed alongside any other life, on balance, life is no worse for people who have disabilities than it is for people who do not. No parent should assume that disability assures a worse life for a child, one with more suffering and less quality, than will be had by those children with whom she or he will grow up.

The claim then is that overall, there is no more stress in raising a child with a disability than in raising any other child, even if at some times there is more stress, or different stress. In that sense the disability community claims that disability is on balance neutral. Even here, however, many find that the terms "neutral" and "normal" are either inaccurate characterizations of disability or are being used in confusing ways. Specifically some worry that these terms are used sometimes only to describe or evaluate traits and at other times to describe or evaluate persons.

Evaluations of Traits Versus Evaluations of Persons. As already mentioned, the disability community itself sometimes speaks about the descriptive and evaluative senses in which disabling traits are not neutral, not normal. Legislation like the ADA could not exist without a recognition that in some sense disabling traits are neither neutral nor normal. Indeed, the societal provision of special resources and services to people with disabilities depends on noticing the descriptive and evaluative senses in which disabling traits are not neutral, and how the needs of the people who live with them are, descriptively speaking, not normal. Yet the recognition of the obligation to provide those special resources is rooted in a commitment to the fundamental idea that the people living with those traits are,

morally speaking, "normal"; the people bearing the traits are evaluatively normal in the sense of deserving the normal respect due equally to all persons. Unequal or special funding expresses a commitment to moral equality. Recognizing the nonneutrality of the trait and the "abnormality" of the person's needs is necessary for expressing the commitment to moral equality and equal opportunity. There is nothing paradoxical about appreciating the descriptive sense in which people with disabling traits are abnormal while also appreciating the evaluative or moral sense in which they are normal.

Some who are sympathetic to prenatal testing worry that people in the disability community (as well as others) often conflate descriptive claims about traits and evaluative or moral claims about persons. For example, Deborah Kent, who is blind, writes:

> When I was growing up people called my parents "wonderful." They were praised for raising me "like a normal child." As far as I could tell, they were like most of the other parents in my neighborhood, sometimes wonderful and sometimes very annoying. And from my point of view I wasn't like a normal child — I was normal (77).

What does Kent mean when she says that she "was normal"? As a descriptive claim, it is not reasonable to say that the trait of blindness is normal. Statistically speaking, it is not. Also, as an evaluative claim, insofar as the trait can make it impossible to enjoy some wonderful opportunities, it does not seem reasonable to say that the trait is neutral. The trait may indeed seem neutral and insignificant when viewed in the context of the whole person, but that is a claim about the person, not the trait. On the view of those sympathetic to testing, the descriptive and evaluative claims about the trait do not bear a necessary logical relation to evaluative claims about the person who bears it. As an evaluative or moral claim about the person, it makes perfect sense to say that a person who is blind is normal; she is normal in the sense that she deserves the normal, usual, equal respect that all human beings deserve.

But if it is easy to notice the difference between the descriptive and evaluative claims about traits and the evaluative claims about persons, why do people in the disability community (and others) keep slipping between the two? Erik Parens has suggested that there may be an important reason for this seemingly imprecise slipping (84). Discrimination against people with disabilities often involves a tendency to allow the part to stand in for the whole; perhaps members of the disability community sometimes succumb to a similar, equally problematic error. It could be that as the majority community sometimes uses the trait to deny the moral significance of the person, the disability community sometimes uses the moral significance of the person to deny the significance of the trait. The majority community slips from an observation about a trait to a claim about a person; the disability community slips from an observation about a person to a claim about a trait. At important moments, both groups fail to distinguish evaluations of traits from evaluations of persons. While such slippage may be easily committed in both communities, and particularly understandable on the part of the disability community, it may be equally counterproductive in both.

Regardless of whether one is or is not persuaded by the disability community arguments regarding prenatal testing, it is important to remember that the disability community arguments are not intended to justify wholesale restrictions on prenatal testing for genetic disability. Rather, they are intended to make prospective parents pause and think about what they are doing, and to challenge professionals to help parents better examine their decisions. They are intended to help make the decisions of prospective parents thoughtful and informed, as opposed to thoughtless and automatic. As the prenatal testing technology marches forward, the need for thoughtful private and public conversations about its uses will become increasingly great. The disability rights arguments will be an invaluable resource in the promotion of those conversations.

OUTLINE

INTRODUCTION

There are basically two ways to approach the issue of sex selection. The first includes an assortment of methods with variable results that can be used to enhance the odds of achieving a conception of one sex over the other. None of these methods ensure that a pregnancy will result in the desired sex, rather they are thought to increase the chances. This approach is often referred to as *sex preselection* as the methods concerned are employed prior to conception. The second approach involves techniques used to determine the sex of an embryo or fetus by directly analyzing the genetic material. Both approaches elicit considerable ethical controversy, but the second is more controversial since a conception has already been achieved. The following discussion will first review the history of sex selection and then examine present and possible future technologies. We will summarize a variety of attitudes regarding sex selection, present a case study, and finally, consider a number of ethical arguments that have been advanced toward this subject.

BACKGROUND

Myriad arguments have been extended in support of and in opposition to sex selection. Prior to discussing the issues surrounding sex selection, it is important to look at the history and understand present and possible future technological interventions. Attempts to influence the conception of a desired sex extend far back in our history. Gledhill, in one paper, and Reubinoff and Schenker, in another publication, present useful portrayals of the early history of this practice (1,2). In early Greece one theory held that males developed on the right side of the uterus while females developed on the left. This led to the belief that the sex of an offspring could be controlled by the position of the woman during intercourse. Another belief was that the right testis produced male sperm while the left produced female sperm. This theory sustained for quite some time and in the eighteenth century led to the procedure of removing the left testicle so that one supposedly would be guaranteed a boy. Even Aristotle also had an opinion on this subject. He argued that the partner who was most active during intercourse would determine the sex of a child.

The Talmud suggests that one can influence the sex of offspring by one partner having an orgasm before the other. If a woman has an orgasm first, the child was said to be a male and if a man was first to have an orgasm, the child would be female. Diet was also, at times, thought to play a role. In the Middle Ages, wine and lion's blood and later in the early twentieth century, bitter and sour foods and a diet rich in red meat consumed by the mother were thought to enhance conception of a male. In 1917 it was reported that the right ovary contained male eggs and the left contained female eggs. Also it was thought that ovulation occurred in an alternate fashion, releasing a male egg from the right ovary one month and a female from the left the next. Therefore it was believed to be possible to predict the sex of a conception by counting the months since the last child.

In the 1950s reports began to emerge that supported a belief that one could influence the conception of a child of the desired sex with the timing of intercourse. This theory maintains that the male determining sperm swim faster but have a shorter survival time than the female determining sperm. Therefore intercourse close to the time of ovulation would result in a male, while intercourse days prior to ovulation would more likely result in a female. Many researchers later followed with reports on the effects that timing of conception had on controlling the determination of sex. Some research also included enhancement techniques such as variations in vaginal penetration and douching with an alkaline solution prior to intercourse. Most of these methods have been alternatively

supported and disputed with many attempts to reproduce the results.

Although today much skepticism surrounds these methods, it is clear from this history that considerable effort has been expended over centuries in the attempt to gain the ability to control the sex of offspring. This history provides some insight into the substantial role that sex of our offspring plays in reproductive issues and the personal identity of parents today.

Current technology involves three distinct approaches: the separation of a sperm sample prior to insemination, evaluation of the genetic material of an early embryo prior to implantation in the uterus, and evaluation of the sex of a fetus in an established pregnancy. Each approach will be discussed in the following text. Before examining the methods, it necessary to know that sex in humans is determined by the genetic constitution of the sperm cell that fertilizes the egg. Females normally have two chromosomes designated as Xs and males normally have one X chromosome and one Y. The combination of a normal X chromosome and a normal Y chromosome in a fertilized egg will result in the development of a male fetus and the presence of two normal X chromosomes will result in the development of a female. Females contribute an X chromosome in each oocyte while males produce sperm with either an X chromosome or a Y. A sample of sperm will normally, on average, be composed of equal numbers of X and Y bearing sperm. Given no abnormalities in the genetic material, the odds of conceiving a male versus a female are equal.

SPERM SEPARATION

Efforts to separate X from Y bearing sperm prior to insemination have revolved around various methods that utilize differences such as size, shape, density, charge, swimming characteristics, and DNA content (1–3). Most of these methods fail to produce consistent results and the research conclusions reported conflict with one another (4–6). Some researchers claim success rates of over 80 percent, while others are unable to replicate these results (7–10). However, some recent research appears to hold promise. Investigators using flow cytometry, a method utilizing the 2.9 percent difference in DNA content between an X bearing sperm and a Y bearing sperm, assert to be able to produce a sperm separation of 80 to 90 percent for X enriched samples and 65 to 70 percent for Y enriched samples (2,11,12). Because this method greatly reduces the number of sperm in the sample, it is necessary to couple it with in vitro fertilization (IVF) technology to achieve pregnancy. This makes the procedure complicated, time-consuming and expensive. As investigators become more proficient with this and other methods in the near future, it will likely be possible to effectively separate X from Y bearing sperm.

PREIMPLANTATION DIAGNOSIS

A second technique is preimplantation diagnosis, which is the evaluation of genetic material in an early embryo prior to implantation in the uterus (2,13). Eggs are harvested from the mother and IVF is performed. One or two cells are then taken from the early developing embryo for genetic analysis. This analysis can include chromosome studies to evaluate the number and structure of all of the chromosomes including those determining sex. In addition direct gene analysis can be performed for a limited number of genetic diseases. This technique is also complicated and expensive. Current use focuses mostly on the determination of the sex of an embryo to prevent a pregnancy with a sex-linked genetic disease, or to detect a known single gene disorder (14).

FETAL SEX DETERMINATION

The final group of techniques that can be used for sex selection involves the determination of fetal sex in an established pregnancy (15). Chorionic villus sampling (CVS) entails harvesting a small amount of early placental tissue containing fetal cells at about 10 weeks into the pregnancy. Chromosome analysis, as well as other biochemical and genetic tests, can be performed on these cells, and the sex of the fetus can be determined. Genetic amniocentesis is a procedure that has been used for quite some time to diagnose a pregnancy affected with a chromosomal or inherited disorder. Amniotic fluid is collected at about 15 to 16 weeks into a pregnancy, and this fluid contains fetal cells that can be analyzed. As in CVS, the sex of a fetus can be learned through chromosomal analysis from fetal cells present in the amniotic fluid.

Since CVS and amniocentesis directly analyze the genetic material that, among other things, determines the sex of the fetus, the accuracy of the testing is extremely high. In addition current prenatal ultrasonographic equipment provides the resolution to ascertain fetal sex with a high degree of precision. Ultrasound uses sound waves to provide a picture of the developing fetus. CVS, amniocentesis, and ultrasound are the most widely used procedures to determine the sex of a fetus, since they currently provide the greatest testing accuracy at the least cost.

ATTITUDES TOWARD SEX SELECTION

A number of studies describe the attitudes of specific groups toward sex selection by examining views of a number of diverse cultures, religions, and professional providers. Most studies separated the use of sex selection for prevention of the birth of a child with a sex-linked genetic disease, from sex selection for the sole purpose of choosing the desired sex. A majority of groups surveyed were supportive of sex preselection and sex determination followed by abortion as options for the prevention of a sex-linked genetic disease in offspring. The following discussion will describe attitudes toward sex selection for nonmedical reasons, that is, for the sole purpose of choosing the desired sex in offspring.

In exploring preferences for a child of one sex over another, reports describe a decided cultural difference between Western views and those of Asia, India, and

some other less industrialized societies. In the United States, studies showed that couples preferred a son as their firstborn and a daughter for their second child. The inclination was clearly toward a balanced sex composition in the family, although the majority of women in the United States do not approve of controlling the sex of their offspring (16). In the early 1960s unmarried college students were asked about sex preference if they were to have only one child. At that time, 91 percent of men and 66 percent of women stated that they would prefer a boy (16). In 1972 and 1987 similar surveys showed that the preference for boys had dropped. In 1972, 55 percent of all students would prefer their only child to be a male, and in 1987 that number was down to 52 percent in favor of males (17). In Great Britain one study asked over two thousand pregnant women if they preferred one sex to the other for their child. The majority, 58 percent, stated no preference while only 18 percent leaned toward a boy and 25 percent toward a girl. When asked if they wanted to know the sex of their baby before birth, 62 percent said no and 20 percent said they were unsure. In a small number of Afro-Caribbean and Asian respondents, there was a slight bias toward wanting boys (18). Another study in Great Britain looked at academic and nonacademic men and women between the ages of 18 and 20 years and found that over 75 percent of all respondents did not support the idea of choosing a baby's sex. No differences were found in the responses based either on sex or between the academic and nonacademic populations (19).

In 1993 the London Gender Clinic opened in London, England. Data gathered on couples who attended the clinic during the first 18 months of service provides some insight into those who would use this technology (20). The ethnic distribution among clients was 57.8 percent East Indian, 32 percent European, 3.6 percent Chinese, and 6.8 percent designated as other. Of all the couples participating in the clinic, 80.6 percent stated that they would have had another baby even if sex preselection were not an option. As expected, Asian and East Indian couples overwhelmingly wanted a boy, while European couples stated a slight preference (62.9 percent) for girls. The main reason given for wanting a girl was the desire of the mother to have a daughter. Couples from the Indian community repeatedly stated the need for a boy to carry on the family name for religious and social reasons. Most interestingly, a major reason for seeking these services involved wanting to avoid having a large family in order to get a son. This was important since 54 percent of the Indian couples in the clinic population already had 3 or more girls in their family and 94 percent had not yet had a son. The authors concluded from their experience that those interested in sex selection are mostly couples with two to three children of the same sex who want one last child of the opposite sex to complete their families. A study based in New York City considered which populations were using sex preselection technology and why. Out of 178 couples studied, 58 were from other countries. All non-American couples in the study wanted a boy, while the American couples wanted boys and girls with equal frequency depending on the sex of the children they already had. They expressed a desire to balance their family. In the non-American couples, reasons for wanting a boy included the custom in their country for a son to support their parents at old age, the belief that it was essential for a male to run a family business, for inheritance purposes, the belief that males are more intelligent, and cultural pressures where males are preferred (21).

Canada assembled the Royal Commission on New Reproductive Technologies to make recommendations to the Canadian federal government by the end of 1993 (22). Before making their recommendations, they held public hearings and conducted random surveys involving more than 40,000 people. Decisions were made in light of research findings, public input, and a set of guiding principles including autonomy, equality, and noncommercialization of reproduction. In addressing the issue of sex selection for nonmedical reasons, they concluded, "The commission viewed sex selection for preference as contrary to its guiding principles, and to generally held Canadian values. Policies are needed to ensure that the values of citizens are respected." In Japan a similar national commission, the Japanese Medical Ethics Advisory Board, set guidelines limiting the availability of sex selection due to the concern that couples would overwhelmingly choose boys if reliable methods of sex preselection were available. However, it was noted that physicians are not legally bound by these guidelines (16). In the Netherlands in 1995, attempts to open the first private clinic to offer sex selection for nonmedical reasons failed due to opposition from doctors and politicians (23). The Dutch health secretary stated that he would take legal measures to ban it because, "the clinic's claims are ethically unjust." Physicians were mostly said to be opposed because, "it crosses the border of what is ethically acceptable in the Netherlands." The Royal Dutch Medical Association said that doctors should not cooperate with the clinic.

In India, son preference is so strong that the use of sex selection technologies followed by abortion is widely accepted. Between the years of 1978 and 1983, about 78,000 female fetuses were aborted following the use of sex selection technologies in India (24). Khanna published a study about the practice of sex selection in Shahargaon, a small village in north India (24). It dramatically demonstrates the effects of wide usage of sex selection procedures on a society. The sex composition of the children in this community for ages 0 to 5 years was found to be 691 females to 1000 males. Khanna, the author of this study, reports, "In this society, the birth of a son is considered an economic and political asset associated with the honor of a family, whereas a daughter is born as an expense and as a moral burden." Lobbying groups brought their concerns surrounding this practice to the Indian government and in response the government has attempted to regulate the use of prenatal diagnostic technologies. The results of these regulations has been an increase in cost for services by the clinics to offset the risks of practice, and an increase in the number of illegal "unregistered" clinics. One of many concerns in India is that a sex-selection industry is rapidly developing because of the great potential for profit.

Attitudes toward sex selection vary among different religions as well. Grazi, Wolowelsky, and Jewelewicz

compared the position of traditional Jewish law with that of Roman Catholicism on the subject of assisted reproduction that included sex selection as one of the issues (25). In the Roman Catholic document *The Instruction on Respect for Human Life and the Dignity of Procreation*, reproductive technologies and IVF specifically are considered to be morally and absolutely illicit practices. This position includes the attempt to conceive a baby of a desired sex for any reason. The Catholic church's position articulates a belief held by many that a fetus has a right to life from the moment of conception. Termination for sex selection would be a most egregious violation of that right.

In Jewish law, gametes and unimplanted embryos have no standing. This would suggest that IVF, if used in treatment of infertility followed by implantation of some of the embryos, the selection for a characteristic such as sex may be allowed. However, the position on IVF for the sole purpose of sex selection is not at all clear. Rabbinic authorities who allow IVF, and presumably other technologies, are doing so in support of the religious obligation to procreate. Some authorities forbid IVF completely, and others preserve the halakhic imperative, which is to maintain natural marital relations. The attempt to conceive a child of the desired sex has been described as, "simply too frivolous a halakhic concern" (25). Neither religion supports sex selection for the sole purpose of choosing the sex of offspring.

Several studies have focused on the perspectives of professional care providers, especially on those who provide clinical genetics services. One study evaluated the attitudes toward sex selection of members of the American Society of Human Genetics, the International Fetal Medicine and Surgery Society, the Society of Perinatal Obstetricians, and selected ethicists and clergy with experience in biomedical issues (26). The majority of respondents in all groups considered sex selection ethically unacceptable. Agreement on this position was stronger regarding the use of sex selection in the second and third trimesters than in the first. The authors of this study indicate that one reason for opposition is a belief that gender is not a disease, and therefore this practice is a form of eugenics and ought not to be a part of health care.

Wertz and Fletcher used hypothetical cases to assess ethical decision making by medical geneticists (27). One case involved a choice about whether to perform prenatal diagnosis for sex selection. The responses were fairly equally split three ways among those who would offer the procedure, those who would refuse the procedure, and those who would refer the patient to another facility that does offer the procedure. Respect for patient autonomy was the reason given by 68 percent of those who stated they would offer the procedure. One interesting finding was that women were twice as likely as men to state that they would perform the procedure in respect for patient autonomy. Burke interviewed genetic counselors to determine attitudes towards fetal sex identification and abortion (28). All but one of the 32 genetic counselors who responded strongly opposed the use of prenatal diagnosis for sex selection. Burke noted that this position imposes stress upon the genetic counselors who also support patient autonomy through the ideal of nondirective counseling and almost universally uphold a patient's right to an abortion. In a similar study of genetic counselor attitudes, Pencarinha, Bell, Edwards, and Best found comparable results (29). When presented with a hypothetical case, 38.3 percent of genetic counselors responding would perform genetic counseling for sex selection while 18.3 percent would refuse to be involved in a such a case and 43.4 percent would refer the couple to another center. Many of the respondents who would refuse the request for these services defended their position, "it is not a medical indication for testing and because prenatal diagnostic services are a limited resource." Genetic counselors who would offer the procedure maintain that the patient has the right to choose and support the patient's decision out of their duty to respect patient autonomy.

Wertz compared the views of geneticists in the United States with those in other European countries (30). As a group, geneticists in the United States were more willing to perform prenatal diagnosis for sex selection, or offer a referral for such services, than geneticists from any other country. Only 4 percent of the participants saw sex selection as having social consequences. Wertz reported that the participants focused on the particular family involved in the case, not on society as a whole. In an extension of this study using the same hypothetical cases, attitudes of genetics service providers from 30 provinces in China were studied (31). The majority, 89 percent, of the participants supported the Chinese laws on termination of pregnancy for genetic abnormalities and for population control and family planning considerations. However, more than half opposed the use of prenatal diagnosis for sex selection.

In summary, most cultural and religious groups surveyed, as well as health care professionals, opposed the use of reproductive technologies for the sole purposes of selecting the desired sex. The opposition was most strong when the result was the abortion of a fetus of the undesired sex.

CASE STUDY

It is sometimes helpful to use a real case to begin to think about how to develop an ethical position involved in a particular issue. The following is a true case that occurred at the University of Minnesota perinatal clinic in the mid-1980s.

AJ was a 35-year-old woman 15 weeks into her fourth pregnancy. She came to clinic with her husband seeking prenatal testing. They were both East Indian and had resided in the United States for about three years. An ultrasound study performed previous to this visit revealed that this was a twin pregnancy. AJ and her husband stated that they have had three previous pregnancies resulting in two normal healthy girls and one son, born in India, who died of a heart defect and many other birth defects. The cause of the anomalies was reported to be unknown and medical records were not available. The couple expressed the concern that if they had another son, he would also be affected because their girls were born healthy. They were also concerned about their age-related risk for having

a child with a chromosome abnormality such as Down syndrome.

The genetic counseling session involved a discussion of age-related risks for chromosome abnormalities, the amniocentesis procedure, and the risks and limitations of the testing. Also discussed was the possibility that their son may have had a chromosome abnormality which, if it were to recur, would be detected with the amniocentesis. He also could have had an undefined genetic birth defect that could recur, but the ability to make a prenatal diagnosis would be limited to what could be seen by a level II ultrasound study.

The couple expressed a strong interest in the amniocentesis and the level II ultrasound study. The results of these studies were normal for both fetuses. When results were called to the couple, they stated that they wanted to know the sex of the fetuses. Both fetuses were female. These results were given to the couple at about 18 weeks gestation. Although they both previously expressed concern if one or both babies were male, they did not appear to be relieved with the test results, and the conversation was short.

About three weeks following the results discussion, AJ called the genetic counselor again. She was calling from a local abortion clinic. She was clearly distressed, and she wanted to know if the results of the chromosome studies could possibly incorrect. We discussed the fact that it was possible but very unlikely. Laboratory errors are rare, and the ultrasound study at the time of the amniocentesis agreed with the chromosome analysis regarding the sex of the fetuses and no abnormalities were seen.

AJ then revealed that she had no real choice in her decision to terminate the pregnancy. Although she very much wanted these babies, she had to terminate this pregnancy. She feared that her husband would leave her and her two daughters if she decided to continue the pregnancy. She had no formal education, no money, and no skills necessary for making a living. She had no way to support herself or her children without her husband. She had struggled with the possibility of having to make this decision since the time she learned of her pregnancy. She then confessed that there had never been a son with birth defects. They had invented this story to explain their interest in the sex of the fetuses, fearing that the clinic would not supply them with this information. Her role in the family was to provide a son and so far she had failed. In reviewing this case we wondered, had she and her husband come to clinic requesting prenatal diagnosis solely for sex selection, what would be the ethical arguments that would help to make a choice for or against providing this service?

ETHICAL ARGUMENTS FOR AND AGAINST SEX SELECTION

Many arguments have been offered in opposition to the use of reproductive technologies for the sole purpose of having a child of a desired sex. A majority point to the injustice of sex discrimination and the value of women. Other arguments in opposition include, but are not limited to, treating children as commodities, inappropriate use of medical technology, setting gender in the same category as disease, the unbalancing of the sex ratio, and lack of respect for human life.

A few organizations have taken a position on this subject. In 1996 the committee on ethics of the American College of Obstetricians and Gynecologists published a position paper specifically on sex selection (32). The committee approved of the use of sex selection for the prevention of sex-linked genetic disorders but strongly rejected the practice of sex selection on demand for the sole purpose of having a child of the desired sex. The main argument given in defense of this position was that they felt this practice, "may reflect and encourage sex discrimination." The committee was concerned that physicians meeting these requests, "may ultimately support sexist practices." The Council on Ethical and Judicial Affairs of the American Medical Association in their position paper on ethical issues related to prenatal genetic testing also opposed the use of sex selection except when it is employed to prevent or treat genetic disease (33). The Council considered selection for sex as, "the most evident example of the discriminatory potential of selection for benign genetic traits." They go on to say that this procedure encourages the value of one sex over the other and places sex in the same category as disease. They argue that the practice of sex selection may result in harms to society including discrimination and the view that children are products. They view sex selection as a form of eugenics. The Turkish General Directorate of Mother and Child Health and Family Planning, analyzed the technical and ethical issues of sex selection (34). This report was explicit in that it emphasized that a baby should never be considered as a technological product. It stated that, "parents should not or any other authorities should not have a right to choose any physical or behavioural features of the baby unless an associated medical problem exists." The Ethical Committee of the Turkish Medical Association agreed that gender should never be treated as a disorder.

In 1985 H.B. Holmes wrote an extensive review of the available technology and ethical arguments and came to the conclusion that sex selection is the practice of eugenics (35). She is careful to acknowledge that for women in countries where females are not valued, the decision to have male children may be a correct moral choice. Given the present social practices, women in these countries are attempting to, "maximize their own and their family's happiness and minimize the suffering of little girls." What is needed, she argues, is social change so that women are valued. She concludes that when people design their children through choosing particular characteristics, they practice eugenics. She states that, "No human is wise enough to choose the kinds of people who ought to perpetuate our species."

Grazi and Wolowelsky examine the issue of sex selection in relation to contemporary Jewish law and ethics (36). They conclude that although new reproductive technology represents an opportunity for alleviating pain and suffering, it should not be used for "frivolous considerations." Rabbinic authorities, not the couple, reserve the right to decide under which situations these technologies can be used. Choosing the desired sex would likely be considered frivolous by most authorities.

Shrivastav writes on this subject from the perspective of the United Arab Emirates (37). It is noted that most citizens of the United Arab Emirates are of the Muslim faith, and since abortions are unacceptable to Muslims, sex selection followed by abortion would not be allowed according to the faith. However, gender preselection may be acceptable to followers of Islam as it would not contravene the Sharia law where IVF and embryo biopsy to rule out disorders are permitted. Despite this, Shirvastav considers that the fact that male offspring are preferred and writes that, "as far as society in the United Arab Emirates is concerned, potential availability of techniques for selecting the gender of offspring will encourage couples to alter the sex ratio of their offspring in favour of boys. Without these techniques, they would probably accept whatever nature has in store for them!"

The issue of unbalancing the normal gender distribution in society by allowing couples to choose the desired sex is a major concern. Seibel, Seibel, and Zilberberstein address this issue and offer a unique solution (38). They first state that they consider using prenatal diagnosis followed by abortion on the basis of sex to be morally unacceptable and that this practice could ultimately lead to an unbalanced sex ratio in society. They go on to say that preimplantation diagnosis for the sole purpose of sex selection, where the unused embryos are destroyed, appears to be an inappropriate use of technology. However, they feel that this practice could be used in an ethically acceptable manner by taking the embryos of the undesired sex and donating them to infertile couples. They argue that if couples were synchronized, this would result in gender distribution. Shenfield, in another letter to the same journal, refutes a previously held position that nature will soon redress the balance of the sex ratio (39). The problem with this position, Shenfield contends, is that it implies the acceptance of the superiority of one sex over the other. Shenfield goes on to assert that the practice of sex selection, "would be detrimental to both sexes to be brought up in a society which acknowledged, by a selective practice, that personal freedom may be obtained at the cost of one's gender identity being constantly assaulted by the implicit disapproval entailed when it becomes a serious handicap worthy of termination."

Steinbacher (40) describes the advantages of the firstborn as being more intelligent, achievement oriented, and successful than second born. Since those who are already privileged will be the ones to utilize sex-selection techniques, supporting selection means enhancing the disparity between men and women globally. "Fewer firstborn females, a higher [male] sex ratio at birth, more poor women in developed countries and elimination of women in the third world are indeed devastating outcomes of sex preselection for women" (40, p. 190). To prevent women's lives from being controlled by technologies, she says that women must first have "voice and vote" when policies are made about all methods of preselection.

Baird's ethical evaluation separates the three approaches: sex-selective abortion, sex-selective implantation, and sex-selective insemination (41). Baird submits that all of these approaches raise ethical concerns about the values of a society of our choice. The concern about sex-selective abortion is lack of respect for human life and dignity. Sex-selective implantation is an invasive and expensive procedure posing risk to women and using medical resources to prevent something that is not a disease. This too, she says, demonstrates a lack of respect for human life. Baird argues that sex-selective insemination does not violate the respect for human life as a life does not yet exist. However, she reasons that this practice reinforces the belief that the sex of the child is important and that families with children of only one sex are less than ideal. Additional concerns about all of these technologies are the possibility that lack of regulation may lead to commercialization of reproduction, the exploitation of the public, and the transformation of children into commodities. Baird argues for regulations and policies to address these concerns.

Botkin examined the broad subject of prenatal screening with respect to policies that would limit parental choice and included the subject of sex selection in his analysis (42). Botkin argues that it would not be justifiable to require that a patient defend her reason for abortion after prenatal screening when abortion is available on demand. However, he does not suggest that parents should have the right to request the use of prenatal screening for any and all purposes, nor that all physicians are obliged to provide all services that patients request. Botkin argues that broad policies limiting parental choice are not workable without a social consensus on the relative values involved, but rather, "physicians should be strongly encouraged to establish and uphold personal moral standards with respect to prenatal screening," thereby respecting the autonomy of both patients and physicians. He believes that, "limits to parental choice may be more appropriately applied through the moral values of individual physicians in their provision of diagnostic services."

Arguments supporting the use of sex selection mostly address parental rights and freedom of choice. Other arguments in support include, but are not limited to, sex selection is merely an extension of other assisted reproductive technologies, it is the least harmful option in some countries, preselection would reduce the number of gender-based abortions and the incidence of infanticide, it would slow population growth, it would eventually result in increased value of women, and it would reduce the number of unwanted children.

In a chapter in *Biomedical Ethics Reviews*, Warren writes in support of the practice of sex selection by refuting the position of Holmes in the same reference (43). She disputes the position that sex selection is a sexist practice. She notes that although some people will only want a child of one sex, many would choose to have a child who is the sex opposite of the child(ren) they already have. Also, in societies where the preference for a son is strong, Warren believes that accusing women of sexism is commensurate with blaming the victim. She reasons that it is not considered wrong to condemn a couple who do not want a child because they are unable to afford to care for it, and so it is also wrong to condemn women in certain societies who decide not to have daughters. She also maintains that many of the arguments made in opposition are based on speculation about the possible

long-term consequences or about how people might behave if this practice was widely accepted. She says that it is wrong to condemn something based on such speculation. In a later publication, she states that sex selection is not always a form of gendercide in that, "if it were inherently wrong to alter sex ratios, then it would be wrong to seek cures for heart disease, breast cancer, and other lethal illnesses which afflict primarily members of one sex" (44). She also holds that, "sexism and its potential for harm are very much a function of how it is done, why it is done , and the social context."Warren argues it would be wrong to condemn a practice outside of its social context.

Anand Kumar offers this social context from the perspective of the culture in India (45). In India, sons are considered an asset, while daughters are considered a great burden. The son preference is so strong that female infanticide is a prevalent occurrence, and although abortion and infanticide are illegal, legislative measures have failed to produce any change. Kumar submits that the real ethical choice lies between the prevention and the perpetuation of feticide, infanticide, and homicide of females. Kumar notes that social change is a long process and asks the question, "Can we afford to wait until these social changes occur and in the meantime silently witness female deaths at all stages of life?" In light of what is now taking place, one argument is that reliable methods of sex preselection would offer the least harm to this society.

In response to the position that that sex selection will lead to an altered sex ratio, Lilford points out that in many countries there is no real preference for one sex over the other but rather a preference for a balanced family (46). He then goes on to say that in countries where there is a strong preference for boys, sex selection may slow the population growth, and ultimately, the demand for girls would increase thereby eventually changing the direction of preference. In the same publication, Lilford refutes the claim that sex selection is a form of discrimination against women but rather a preference for a particular sex may be the result of discrimination. He states that, "peoples' choice for a particular sex is a mirror of their society."

Mahoney separates sex selection followed by abortion from sex preselection. He rationalizes that availability of sex preselection would decrease the number of gender-based abortions performed and the incidence of infanticide (47). Mahoney points out that in Great Britain abortion is legal due to serious social pressure, so it is reasonable that people have access to it for any reason including selecting the sex of the child. This argument has been used by others including Egozcue who wrote, "Sex selection: why not?" in the journal, *Human Reproduction* (48). He discusses the use of sex selection on embryos where those embryos of the unwanted sex are discarded. Egozcue submits that this should not be a problem in those countries where abortion is available on demand as this would be an extension of other assisted reproductive technologies. Also Egozcue states that planned parenthood organizations have always supported the view that every child should be a wanted child, and therefore a child of the desired sex very much is a wanted child. Smith, in a letter to the *British Medical Journal*, also discusses the issue of wanted children (49). He points out that in many families unwanted children are abused. Smith argues that even if sex selection results in an altered sex ratio, the scarcer sex would be valued over time, and since fewer children would be born, it would slow the population growth. In the same letter, Smith discusses the justice problems in attempting to regulate the practice of sex selection. He says, "the rich and connected can usually gain access to any technological innovation that they want."

Pennings addressed sex selection for balancing families and proposed ethical guidelines (50). He proposed that sex selection should not be allowed for the first child nor when there is already a balance in a family. In response to the Pennings proposal, Dawson and Trounson ask the question, "Who will enforce these guidelines?" Although they do not support sex selection, they do point out that the United Nations Declaration of Human Rights states that each individual has the right and freedom to form a family. The application of this declaration to the issue of sex selection is not clear. However, they feel that the Pennings proposal represents, "a violation of the right to freely form a family given in the Declaration of Human rights and, given that the appropriate technology is available." In the end, however, they argue that sex selection is not a responsible use of technology (51).

Lilford challenges the argument that technology should only be used for medical purposes (46). He submits that it is difficult to determine the difference between a medical and a nonmedical mission. He states that, "the important factors in human life are those of suffering and happiness, and the eradication of disease is merely a means towards these ends. If medical technology can produce these ends without eradicating a disease, then it is equally worthwhile."

One final major argument in support of sex selection is that of respect for individual autonomy. Kaye and LaPuma emphasize this position from the perspective of the clinical geneticist (52). They assert that although clinical geneticists are not themselves ethically neutral on this subject, "the best interests of the patient, not of society or the human race, should determine diagnosis and treatment." They strongly maintain that the overriding ethical principle is that of beneficence for the individual patient. Shulman, of the Genetics and IVF Institute in Fairfax Virginia, concludes that it is fundamental to free societies for responsible individuals to have the freedom to differ and to make personal choices based on their own convictions (53). Stephens demonstrates the strong belief that patient autonomy must be the guiding principle when he writes, "It is my opinion that the only issue that is the sole responsibility of physicians really is support of the patient's (and it is usually women who are burdened with this responsibility) right to exercise her (or, in the instance of a couple in a counseling situation, their) reproductive options, regardless of the indication, regardless of the personal moral or ethics standpoint held by the practicing physician" (54). Such wholehearted support of patient autonomy is most prevalent among geneticists in the United States (27).

Finally, an examination of the arguments surrounding sex selection would be incomplete without looking at the

work of John C. Fletcher who has written extensively on this topic and revised his ethical position over time. His initial arguments opposed sex selection because (*1*) sex is not a disease, (*2*) abortion for sex choice could contribute to social inequality between the sexes because of a preference for male offspring, (*3*) sex choice is a "frivolous" and indefensible reason for abortion, and (*4*) amniocentesis is a scarce resource in light of the total number of at-risk pregnancies (55). In reviewing his writings over the years, it is interesting to see how he has re-evaluated his position and his reasons behind his position many times. This speaks to the extreme complexity of this issue.

In this 1980 essay, Fletcher assumes that the main reason for discouraging sex selection is the belief of physicians that performing prenatal diagnosis that such abortions are morally unjustifiable (55). Although this is still his personal view, he believes that the legal rules on abortion defined by the U.S. Supreme Court supersede the clinician's personal moral views. Since a woman need not state reasons for abortion under any circumstances, sex selection ought not be subjected to public scrutiny. He concludes that, "it is inconsistent to support an abortion law that protects the absolute right of women to decide, and at the same time to block access to information about the fetus because one thinks that an abortion may be foolishly sought on the basis of that information" (55, p. 16). Fletcher continues to believe that physicians have a right to state their own moral views and to describe risk factors of prenatal testing, including "an unknown risk of insult to other numbers of the family and to wider society." However, if a couple continues to request the information for sex selection, Fletcher stated that the physician may not legally or morally refuse to provide it if he or she wants to "keep faith" with the moral intent of the law.

In a later re-evaluation of this issue, Fletcher, along with Wertz, considered all of the arguments given in support of sex selection and came to the conclusion that the medical profession as a whole has not demonstrated any responsibility in this arena. They state, "We hold that a very strong normative case exists against sex selection that transcends cultural boundaries, especially based on claims of equal worth of both sexes and justice in social life" (56). They strongly suggest that the medical community take a stand against sex selection. Fletcher and Wertz believe that by doing this, the medical community will ultimately be protecting important reproductive choices by demonstrating that they are able to set the standards for practice. With these standards in place, government intervention would not be necessary and reproductive choices involving medical decisions would not be lost (56). In a more recent study, Fletcher, along with Wertz, evaluated the attitudes of medical geneticists about sex selection in 19 nations. They found that in many nations women do not have access to prenatal testing to detect birth defects either because of the cost or because of the scarcity of such medical technology. They conclude that it is unfair to use these limited resources for nonmedical reasons. They state a concern that sex selection could be, "the first step on a 'slippery slope' toward cosmetic choices for height, weight, eye or hair color." Again, they call for the medical profession to abandon its nonjudgmental stance and set a standard of care with regard to sex selection (57).

SUMMARY

With few exceptions, positions of professional societies and governmental agencies oppose the practice of sex selection. Yet, sex selection continues to occur in practice, and the debate about the morality of the practice continues among ethicists and practitioners. Why is that?

There are two major reasons. One is that sex selection is only one of the possible traits that one can select prenatally. Most prenatal testing is accepted today because it serves the interests of people who want to make decisions based on health information. Even for many who are comfortable with prenatal testing and autonomous choice, however, there is concern about the intrinsic value of human life as it is created. Choosing the sex of their offspring represents the first real and available choice for parents who want to select a child with traits that fit their vision of an ideal family. The specter of sex selection could be the first step down a slippery slope to the "brave new world" of designer children. We worry about whether allowing choice of the sex of the child will open the door to the use of genetic technologies to select other traits for more "trivial" reasons than avoiding disease (55).

Second, sex selection also is a paradigm case for considering what values really ought to guide health care policy. The same tensions, between issues of justice for many and respect for individual autonomy, exist in determining the appropriate use and distribution of health care technologies more generally. A majority of those opposing sex selection address broad societal justice concerns. Some say that using such measures will continue, and even enhance, gender discrimination. Others believe that health technologies ought to serve the needs of improving health, and ought not be squandered in support of individual or societal determination of what human traits are valuable and worthy.

On the other side of the argument, are those who strongly support the individual's right to self-governance and the professionals' obligation to respect that autonomy. Individual (or couple) autonomy undergirds most arguments for allowing sex selection, since prohibiting the practice would be limiting autonomy in reproductive decision making. Genetic and reproductive technologies, particularly sex selection, make the professional obligation to respect autonomy more complex, however. Because decisions about how to use them are intrinsically about families they raise the question of who is the patient, and thus whose interests ought to be served by clinicians and policy makers. Is the primary obligation to the mother, the father, both parents, the child or potential child, existing children, or to the societies in which reproductive and genetic applications are made available?

Both clinicians and policy makers must ponder the right and appropriate use of health care technologies and from the framework that guide how these decisions are made. Sex selection is but one example of this challenge. Examining how positions on sex selection are cast may provide some insight into how other ethical challenges in health care will be addressed as well.

REPRODUCTION, ETHICS, THE ETHICS OF REPRODUCTIVE GENETIC COUNSELING: NONDIRECTIVENESS

BARBARA BOWLES BIESECKER
National Human Genome Research Institute
Bethesda, Maryland

OUTLINE

INTRODUCTION

In reproductive genetic counseling, nondirectiveness may refer to an ethic of practice or to the process itself. Different aspects of genetic counseling have been described as nondirective; the communication style, the offering of genetic testing, or the counseling interaction. These various interpretations of the term *nondirectiveness* have lead to confusion about the goals and practice of reproductive genetic counseling. As well, it has diluted conversation about important issues surrounding the personal nature of reproductive choice involving genetic risk. As an ethical principle, nondirectiveness suggests that pregnant women and their partners ought to be supported to make autonomous decisions about prenatal testing and their reproductive outcomes without the direct influence of the counselor. The personal autonomy of the client facing the genetic reproductive decision is paramount. Nondirectiveness should be used exclusively to describe an ethical principle in reproductive genetic counseling. Although it is not evident always how this principle translates into the practice of genetic counseling, the process may be discussed as a dialogue of client-centered counseling that is guided by nondirectiveness.

NONDIRECTIVENESS IN GENETIC COUNSELING

Nondirectiveness describes components of a young medically related professional service, called *genetic counseling*. This psychoeducational practice assists people who have concerns about birth defects, genetic conditions, or genetic risk (1–3). Throughout its short history, genetic counseling has been consistently described as nondirective, as opposed to advice giving. Genetic counseling may be the only medically related practice intended to be nondirective. The term has been used to describe not only the ethic of practice but also the goal of genetic counseling, the process, and an outcome. The literature discusses nondirectiveness assuming one of these practice components but frequently fails to distinguish its meaning. For those who strive to understand, to investigate, or to use genetic counseling services, it is unfortunate that the concept is inconsistently portrayed. Even those who practice genetic counseling have confused the meaning and interpretations (4,5).

Several scholarly articles have appeared to address the confusion in the meaning of nondirectiveness (4,6,7). The literature has begun to distinguish the various uses of the term in an effort to achieve some consensus on the goals and process of genetic counseling. Since the literature on nondirectiveness is discrepant, this chapter will delineate uses of the term and compare their implications. The success of the practice of genetic counseling depends on continued efforts to define and strive towards nondirectiveness assuming the profession can agree on what it is, that it is central to the process and that it can be achieved.

HISTORY OF NONDIRECTIVENESS

The original introduction of nondirectiveness into the genetic counseling literature remains elusive. Sheldon Reed, a medical geneticist who coined the phrase "genetic counseling" in 1947, spoke of a nondirectivelike practice but only used the term later in his writings after it had appeared in the literature (8). Reed described a genetic social worklike practice of explaining genetic concepts and supporting clients who use the information to make reproductive decisions. In this case the concept of nondirectiveness describes the process of genetic counseling more so than the overarching ethical principle. Some authors claim that nondirectiveness in genetic counseling arose in opposition to the eugenics movement. Resta points out that many of the medical geneticists writing about the process of genetic counseling in the 1950s used the term nondirective but then also described eugenic ideas about the practice (9,10). It is evident from the literature that certain supporters of nondirectiveness were not opposed to eugenic practices. Thus, such claims about nondirectiveness may be unfounded (4,11).

The general source of the term nondirectiveness predated genetic counseling by about two decades. Dr. Carl Rogers, a prominent psychologist, used the word to describe his theory of psychotherapy (12). By 1951, however, Rogers had come to describe his theory and practice as client-centered. This clarification in his terminology acknowledged the presence of directive components to the therapeutic relationship, yet emphasized the focus on the client's expressed needs rather than the explicit direction of the counselor. Rogerian psychotherapy developed prior to the existence of genetic counseling and in parallel to, not in reaction against, the eugenics movement in the United States. It is intriguing to consider why the profession of genetic counseling adopted as its mantra a term that was rejected early on by the field of psychotherapy. Since its introduction into genetic counseling, nondirectiveness has lead researchers, academics, and practitioners astray.

Genetic counseling has sustained the use of the term nondirectiveness despite its ambiguity. Client-centered theory and practice have offered one useful framework (within limits) of thinking about and practicing genetic counseling. Nondirectiveness has been used effectively to describe a client-centered counseling style not unlike a Rogerian approach. Since genetic counseling has evolved as a clinical and atheoretical practice, it has borrowed ideas from its theoretical neighbors. In a different sense, genetic counseling has long recognized the lack of desire or ability to make reproductive decisions for others. It has emphasized autonomy and voluntariness (13,14). Genetic counseling embraces a certain hands-off approach to sensitive issues of life and death that are entwined in reproductive decision making. This has proved to be

a more comfortable stance for genetic counselors than entering into the difficult and sticky terrain of directing people in their childbearing decisions that involve genetic risk. Rather than as a reaction against eugenics, perhaps nondirectiveness has been sustained by an abhorrence of eugenic practices. Some would argue that it might also serve to shield practitioners from confronting difficult aspects of reproductive genetic counseling.

INTERPRETATIONS AND IMPLICATIONS OF NONDIRECTIVENESS

Nondirectiveness as a Guiding Ethical Principle

There have been at least four different, yet overlapping, meanings of nondirectiveness expressed in the literature. Most often, nondirectiveness has been used to mean a desire to uphold the personal nature of reproductive decision making. Nondirectiveness in this sense represents an underlying value or ethical principle of the profession. Genetic counselors in the United States have emphasized the principle of nondirectiveness conceptionally in their code of ethics: "Genetic counselors strive to enable their clients to make informed independent decisions, free of coercion, by providing or illuminating the necessary facts and clarifying the alternatives and anticipated consequences (15, p. 41). Yet as a value it does not readily translate into a way of practice or a specific goal. It is difficult to assess whether an individual or couple has made a "good" personal decision. How does a genetic counselor promote the decision-making process within an ethical framework of nondirectiveness? Clients experience many influences on their reproductive decisions. Exclusively personal or autonomous decision making is difficult, and not necessarily uniformly desirable, to achieve. Yet it is important that providers not assert undue influence on the reproductive outcomes of their clients. This is a blatantly eugenic goal and contradicts the desires of most geneticists and genetic counselors internationally (16). Kessler points out that even when there is an explicit goal to discourage certain reproductive outcomes (e.g., in a country that supports such practice), a significant number of clients ignore the advice (17). It is unclear that it is necessary for professionals to completely withhold advice from clients. Yet much of the international genetics community, and in particular, genetic counselors in the United States, Canada, and the United Kingdom, finds the notion of advising people directly on their reproductive choices to be loathsome. It is difficult to know or to appreciate the values, resources, thought-processes, and ideas of another person sufficiently to provide advice about having or not having children who may be affected with a certain genetic condition. The truth is, most people struggle to understand what choices they would make for themselves, let alone know better for another.

Genetic counselors need to be exquisitely self-aware and not harbor personal opinions of what constitutes a life worth living. If they do, they must be honest with themselves and disclose to clients that they may hold beliefs that children affected with certain genetic conditions should not be born. This differs from stated goals to enhance personal choice for clients. Yet it is more honest than undisclosed potential agendas. Most counselors, who also work with children and families affected with genetic conditions, serve as advocates for those with special needs as children or who are disabled as adults. As a profession they value diversity and often enter the field of genetic counseling concerned about genetic conditions and how society views disability.

Medical genetics services, such as triple screening for neural tube defects and carrier screening for recessive or sex-linked genetic conditions, may have the more or less explicit goal of reducing the number of individuals affected with genetic conditions (18–20). Cost–benefit analyses to justify such programs may be based on an assumption that a significant number of affected pregnancies will be aborted. In this case the genetic counseling that accompanies such practices may have values that are in conflict with the intention to reduce the incidence of genetic conditions. Genetic counseling may strive to help the individual make the best personal decision, yet the goal of the program may be to abort affected fetuses. Genetic counselors may find themselves caught in a dilemma between professional values that emphasize personal autonomy and programs that are justified by social policy to improve the health or well-being of the populace. If counselors uphold a nondirective ethic, then they should not paradoxically endorse genetics services that have a goal of preventing the birth of individuals who will be affected with a genetic condition. Genetic counselors should and do endorse services that emphasize informed and autonomous choice in reproductive decision making. An example is the choice about whether to undergo amniocentesis to determine the chromosomal status of a fetus. Nevertheless, aspects of service provision (e.g., assuming the outcome of the decision to undergo testing by scheduling the amniocentesis to follow the counseling session) do not always promote the genetic counselor's role to ensure personal choice about testing.

A challenging aspect of an ethic of nondirectiveness is not so much the goal to refrain from explicit influence on reproductive decisions, as it is the potential for more subtle and unintended (even unconscious) influence. Such practice may occur when a genetic counselor harbors a belief that a certain reproductive outcome is most desirable for a person or couple. But rather than state the bias outright, the counselor's approach is influenced by her or his beliefs. This would be an ethically directive approach even if the counselor did not intend to provide direction to the client.

When counselors successfully manage to facilitate the client's decision making without influencing the outcome, the process is flexible and difficult to operationalize. Counseling is inherently directive, as is providing education to ensure understanding about the options. Genetic counselors have no standard of practice to consistently uphold an ethic of nondirectiveness. Counselors recognize that the type of information they provide and how they present it may influence decisions (21,22). An ethical principle should translate into an effective mode of practice. White has proposed a counselor–client dialogue as a working description of the process (7). The practice is to facilitate client centered reproductive decision making, within

an ethical framework of nondirectiveness. As a guiding principle this ethic would suggest a process of genetic counseling that emphasizes the values and beliefs of the client, but that tolerates the direction offered by a competent counselor who does not preconceive a decision for the client. In order to further clarify the underlying ethical principles of genetic counseling, the field may need to differentiate itself from other genetic services whose goals (such as abortion of affected pregnancies) are inconsistent with the values of the profession.

Nondirectiveness as a Guiding Policy on Genetic Testing

Nondirectiveness also has been used to describe the concept of not denying access to genetic testing. This definition relates to genetics health policy and access to services. It is a practical one, although it has overlap with the previous definition in its intention to uphold reproductive freedoms. In this case genetic counselors are reticent to deny access to any genetic test that an individual or couple may request (even one that puts a pregnancy at risk) provided that there is understanding about the risks and benefits of the test and its potential outcomes.

Historically much of genetic counseling has addressed risk for serious conditions, with the exception of certain mild birth differences (such as a cleft lip) and sex chromosome "anomalies" (such as Turner syndrome). Counselors offer genetic testing to determine whether a fetus will be affected (prenatal) or whether a couple may be at increased risk for having an affected child (carrier). One survey has suggested that the majority of genetic counselors, internationally, offer prenatal diagnosis (or a direct referral) for sex selection (23). This is worrisome when one considers that genetic counseling originated from a desire to help people grapple with difficult dilemmas about serious genetic conditions or birth defects. Genetic counselors, as represented by the U.S. professional society (NSGC), uphold a moral right to reproductive freedom (24). The majority of practitioners believe that if a woman (or couple) has consented to prenatal testing by considering the relative balance of risks and benefits, she should be offered the opportunity to determine the sex of the fetus, even if she desires to abort a fetus of undesired sex. Such a finding bodes poorly for the future of genetic testing, when prenatal tests may be offered for physical or personality traits. Will genetic counselors, in the name of nondirectiveness, offer prenatal testing for anything a couple desires as long as they are informed?

In this regard, the meaning of nondirectiveness has caused the profession of genetic counselors to be passive about taking a stand on what tests ought to be offered. There have not yet been professional guidelines written by U.S. genetic counselors discouraging certain prenatal testing. Within NSGC there are position statements and a resolution on genetic testing or screening, for instance, one exists on prenatal and childhood testing for adult-onset disorders (25). It states that while such testing is discouraged, each case should be considered individually and counselors should decide whether to offer parents testing of their children on a case by case basis. This leaves the judgment of reasons, fitness, and values of the client up to the counselor. While inherently flexible and accounting for individual differences, it neglects to take a clear stand and puts counselors in the position of practicing inconsistently. It leads to confusion for the profession. In response, members of the genetic counseling community published a substantial position statement on the genetic testing of children for adult onset conditions to more clearly state a testing policy (26). While it is unlikely that there are many moral absolutes in reproductive decision making, an insistence on nondirectiveness has stymied the process of policy making in prenatal genetic testing. With the promised onslaught of new genetic tests, reproductive counselors seem to be prepared to offer testing for any indication. In the name of nondirectiveness, genetic counselors have avoided their professional and moral obligations to take a stand on the appropriateness of certain types of prenatal testing.

The approach to reproductive genetic testing, "anything goes as long as the individual has had pre-test counseling," predicts that counselors will play less of a role in establishing genetics health policy. Yet genetic counselors may be one of the most important groups of professionals to be involved in helping to establish guidelines or polices about what testing may not be an appropriate use of resources or may be morally reprehensible (27). Do genetic counselors advocate for the use of prenatal testing to potentially abort fetuses found to be at somewhat increased risk for adult-onset cancer, for instance? Worse yet, for a slightly lower projected adult height? The role of testing gatekeeper may be an important one for genetic counselors in the future. Yet nondirectiveness has been misinterpreted to imply that any genetic tests that are technically feasible should be offered. In the name of nondirectiveness, counselors refrain from judging the choices of their clients. In doing so, genetic counselors may be washing their hands of the responsibility to offer morally, not to mention economically, responsible reproductive testing options.

Rather than interpreting that nondirectiveness holds no opinion on genetic testing, reproductive genetic counselors ought to offer genetic testing only for serious conditions that may significantly impede an individual's ability to achieve quality of life. While there is no consensus on what constitutes a serious genetic condition (28), this should not dissuade genetic counselors and other providers from establishing responsible genetic testing services and genetics health policy (29,30). This misunderstanding of nondirectiveness has led to a significant lost opportunity and an ongoing need for the professional practice of reproductive counseling.

Nondirectiveness as a Style of Communication

In contrast, nondirectiveness has been construed as a style of communication within the practice of genetic counseling (31,32). Genetic counseling has been described as a value-neutral encounter despite awareness that any human relationship is value laden. The mis-notion of value neutrality has further confused the issue of nondirectiveness (33). In communicating genetic information within genetic counseling, there are many directive components. In an educational relationship, the person with

the information has more power and there is an inequality to the relationship (1). The way the information is conveyed and the amount of information given may be quite directive. Genetic counselors lead, guide, and even advise their clients. Each of these is a directive process. Genetic counselors strive to give complete and balanced information, but it is human nature to be inconsistent and influenced by individual experiences. This might be described as directive practice as well.

This interpretation of nondirectiveness implies information should be conveyed in a nonleading way. Studies that have been conducted to assess use of directive language have concluded that the process is directive (30). While such outcome studies are necessary and valuable for determining what happens in genetic counseling, they seek to document a nondirective psychoeducational practice. It is an unattainable paradox.

In a desire to use nondirective language to communicate, genetic counselors may seek to use words that are ambiguous. Such avoidance of direct language may not be useful to clients who are often seeking not only information but also advice on how to use it or how to make meaning of it. The irony of the use of vague language is that expert communication of complex genetics information is often heralded as a prominent goal of genetic counseling. A nondirective intent has guided counselors into inexplicit use of language that could otherwise make genetic concepts and their implications more obvious to clients. This use of nondirective communication has lead to process studies that have shed light on this perplexing notion of genetic counseling (31,34). Conclusions have been drawn that counselors are directive in a manner that implies they are undermining a guiding ethical principle. In fact they are merely communicating as professionals do, using language that is often directive and in a manner that may be directive. While there is merit in research toward understanding how an ethical principle such as nondirectiveness translates into practice, the mode of communication is only one component of a complex dialogue within a relationship of influence.

Without guidance on the adaptation of an ethic of nondirectiveness into practice, counselors have assumed a nonjudgmental approach that also involves noncommittal or evasive communication around difficult issues. This minimization of an ethical principle has led to one outcome counselors seek: clients who have not been explicitly directed in their reproductive decisions. But it has also lead to not providing clear messages about the implications of the information, and perhaps even not facilitating "good" reproductive decisions. For instance, Wertz and her colleagues found that in the majority of prenatal genetic counseling sessions they studied, abortion was not mentioned (35). Since it is the only intervention a couple could choose to take for the vast majority of conditions tested for, it should be prominent in discussion about the potential usefulness of prenatal testing. If nondirectiveness had been uniformly adopted as an ethical principle that supports a client-centered counseling process, rather than a communication style, word choice and tone would be considered less significant than the components of dialogue within a therapeutic relationship.

Nondirectiveness as a Theoretical Basis of Counseling Practice

This point segues into a further interpretation of nondirectiveness, the intent to provide client-centered counseling. This definition is not dissimilar to that of Rogers's theory of psychotherapy. In this regard, nondirectiveness represents a reasonable and responsible goal for genetic counseling. It heralds the role of the client as central and as a goal, can be achieved (1,36). In this venue nondirectiveness provides a model for genetic counseling that can uphold an ethic of personal reproductive decision making. But nondirectiveness should not be used to describe both the process of counseling as well as the underlying ethical framework or the existing confusion will pervade.

In describing genetic counseling as a psychoeducational process, the psychological or therapeutic goal is to explore the meaning that the genetic information has for clients. This is a client-centered approach that focuses on client values, beliefs, ideas, and desires. The process by which it is achieved varies but the client's agenda and needs are paramount. As Rogers previously discovered, the term nondirectiveness in this case compounds the confusion, since many strategies used by the counselor might be described as directive. Yet they are executed with the client in mind. For instance, the counselor may help the client to set an agenda to explore implications of the information in a way that is personal, useful, and lends itself to decision making. The counselor may be directive in helping a client determine what may be reasonable to try and accomplish in one or two sessions. While these behaviors are directive, they do not override the needs of the client. Rather, they represent the counselor's expertise that may be used to enhance the effectiveness of genetic counseling. The client's needs are the ones addressed, but the client is not left to talk randomly without focus on the problem or issue at hand. Without such structure, a session would never become therapeutic. This is only one example of directive practices of counselors that do not undermine a client-centered approach.

In this more appropriate use of nondirectiveness the term remains problematic and should be replaced with client-centered genetic counseling. In much the same way nondirectiveness did not accurately depict the therapeutic approach proposed by Rogers, it has lead genetic counselors to largely ignore the need to engage actively with clients in order to address their concerns. Transcripts of genetic counseling sessions indicate that counselors practice inadequate counseling skills to accomplish even a minimally client-centered approach (1,5,31). The mantra of nondirectiveness may have caused counselors to hesitate over using their own best judgment about people's ability to make good decisions for themselves, to grow from difficult experiences, and to cope and adjust. In the name of nondirectiveness, many counseling opportunities have been lost in genetic counseling. An active dialogue about options, alternatives, resources, strengths, and outcomes within a therapeutic relationship may best help clients (3,6,7). Such a dialogue is likely to have many directive statements in it but does not direct the client toward a certain outcome in a coercive or even persuasive way.

Although the various uses of the term nondirectiveness have been problematic for the profession of genetic counseling, the pervasiveness of the concept of personal autonomy in genetic reproductive decision making sets the practice apart from the majority of medical services. The ethical principles of autonomy and beneficence in reproductive decision making, the need for thorough informed consent for genetic testing, and the value of human diversity and the lives of those affected with disabilities are crucial to reproductive genetic counseling. And the few outcome studies that have been conducted suggest that reproductive genetic counseling clients are satisfied with the service. They like their genetic counselor and are grateful for the time spent teaching them genetic principles (37). From a process and outcomes perspective, clients are likely to be best served by a psychoeducational approach that includes a client-centered or cognitive, theoretically based practice. This therapeutic process and its desired outcomes of self-determination, feelings of personal control, and restored self-esteem have yet to be studied (38). To achieve them, a counselor may be directive and to conduct process studies that investigate how directive she or he is seems counterproductive. Studies are needed on the most effective therapeutic approaches in genetic counseling, to observe how successful they are in achieving desired outcomes. Research would be facilitated if genetic counselors embraced such a therapeutic approach, and if consensus could be achieved on the goal of restoring feelings of personal power to clients and on outcomes of the process that can be systematically measured.

NONDIRECTIVENESS IN PRACTICE

In the most common reproductive genetic counseling example of a couple learning that their fetus is affected with Down syndrome (due to an extra chromosome 21), genetic counseling is the process through which the couple can determine what the condition may mean for their lives. Down syndrome cannot be "repaired," although some of the symptoms can be treated. The child will be mentally retarded, although to what degree is unknown. The couple may continue the pregnancy as planned or have an abortion. This is an agonizing decision even for couples who initially feel confident about what they would do in such circumstances. In facing the situation couples often take into account their expectations of parenthood, family life, economic resources, previous experiences with persons who have Down syndrome, opinions of family and friends, spiritual beliefs, social influence and expectations, and so on. Decisions about a pregnancy are complex, deeply personal, and irreversible. Important aspects of the decision may even be intangible or elusive to the couple themselves.

A genetic counselor in this situation seeks to establish an empathic connection or a therapeutic bond with the couple in order to help them make personal meaning of the information about Down syndrome. The counselor may strive to identify resources useful to the couple in making the decision so that they can live with their decision (one way or the other) in the years to come. A therapeutic approach focuses on enhancing self-determination and perceived personal control. Couples are helped to recognize that they have the strength to make such a difficult decision and that they have made other decisions successfully in the past. The counselor works toward facilitating the decision-making power of the couple in addressing their needs and concerns. This process may be described by some as nondirective counseling. Yet it is more appropriately described as client-centered and personally empowering.

The example of a client or couple asking the counselor what he or she would do in the same circumstances is often used to illustrate nondirectiveness in genetic counseling. Common responses by genetic counselors may be:

- "I am not in your situation so I couldn't possibly know what I would do."
- "Other people in your situation have chosen to continue the pregnancy, while others have had an abortion."
- "There are no right answers, I am here to help you make the best decision for yourself."
- "I will support any decision you make."

Evasive answers such as these do not address the concerns of the client. The client is asking for advice because she has not received the help she needs to make her decision. It is unlikely that she is literally handing over responsibility for the decision to the counselor (although a minority of clients may do so). Nor is she likely to mimic the choice of the counselor in order to solve her dilemma. However, all too often counselors neglect to work toward exploring and understanding where the client's anxiety and concerns come from in an effort to best help her with the decision. Kessler reminds genetic counselors that if the clients are frequently asking this question, there is something fundamentally flawed about the process (4). There are many respectful and considerate ways to address this question without abandoning the client in a time of great need. They challenge genetic counselors to fully experience with clients some of the hardest decisions of their lives. It takes a lot of hard work and *direction* on behalf of the counselor. A nondirective mode of practice misinterpreted is a missed counseling opportunity and at its worse an abandonment of a client in need of help.

SUMMARY

Nondirectiveness is a term to be reserved for an ethical principle of practice in reproductive genetic counseling. It emphasizes the importance of autonomy in genetic reproductive decision making. As a guiding principle, nondirectiveness provides a moral framework for providing client-centered counseling. Reduced to merely how a counselor communicates or to a lack of health policy on the use of genetic tests, nondirectiveness is an ineffectual concept. Its counterpart, direction, is an essential aspect of effective client centered counseling that supports informed reproductive choices involving genetic risk.

REPRODUCTION, LAW, IS INFERTILITY A DISABILITY?

LAURA F. ROTHSTEIN
Louis D. Brandeis School of Law
University of Louisville
Louisville, Kentucky

OUTLINE

INTRODUCTION

Infertility is defined as the inability to conceive a child within a period of one year. There are many causes of infertility, and it may be attributable to either partner or a combination of factors related to both partners. Infertility can be costly and time-consuming to treat, and success is not guaranteed or even probable in many cases. The costs to infertile individuals and couples can involve money, time, and physical and mental health.

Working women and men who are infertile want to keep their jobs, even if they require leave time or scheduling changes for fertility treatment. The spouses of infertile partners also may require workplace accommodations to participate in fertility treatment. Both individuals want to have health insurance coverage that provides reimbursement for costly fertility treatments. For these reasons it is important whether infertility is considered a disability under federal or state disability discrimination law.

The Americans with Disabilities Act (ADA) of 1990 (1), the Rehabilitation Act of 1973 (2), and many state laws prohibit discrimination against individuals with disabilities by employers and providers of services, which may include health insurance. It is essential to

determine whether a particular condition is a disability before applying the nondiscrimination and reasonable accommodation mandates of various statutes. It has yet to be determined whether infertility is considered a disability.

THE AMERICANS WITH DISABILITIES ACT

Major Statutory Provisions

Employment and Health Insurance Providers. Most employers are subject to one or more federal laws protecting individuals with disabilities from discrimination on the basis of their disabilities. The Americans with Disabilities Act of 1990 applies to private employers with 15 or more employees and to employees of state and local governmental agencies. The Rehabilitation Act of 1973 protects employees of federal agencies, most federal contractors, and recipients of federal financial assistance. Virtually all states have statutes covering public and private employers, although they vary in the number of employees necessary for an employer to be covered.

The application of disability discrimination law to health insurance providers is less clear. Title III of the Americans with Disabilities Act prohibits discrimination by 12 categories of private providers of programs and services to the public. While the weight of opinion is that Title III applies to health insurance providers, this has not been definitively decided. In addition, where health insurance is a benefit of employment, discriminatory treatment in an employer-provided health insurance program would be subject to the employment discrimination prohibitions.

Even if health insurance is covered by disability discrimination laws, insurance companies may be permitted to limit or exclude coverage for certain treatments in appropriate circumstances. The legality of such limitations and exclusions has yet to be clearly defined in the context of infertility treatment (3–6).

Nondiscrimination and Reasonable Accommodation. The major mandate of disability discrimination law is to prohibit discrimination against individuals with disabilities who are otherwise qualified. Lawmakers have recognized that most discrimination is not intentional, particularly in the context of disabilities. For that reason, facially neutral policies and practices that have a disparate impact on individuals with disabilities are subject to challenge as well, although not all will be found to be impermissible. For example, requiring that an employee have a drivers' license could have a disparate impact, and this might be challenged if driving is not an essential function of the position.

In addition to prohibiting discrimination, these laws also require employers to provide reasonable accommodations to known disabilities. Employers are not required to provide accommodation if it would constitute an undue hardship to do so. Undue hardship means significant difficulty or expense. Neither are employers required to lower performance standards or to make fundamental alterations to the program. Employees must be able to perform essential functions of the job if reasonable accommodations are provided, although the employer generally has the burden of showing that a particular function is essential.

Reasonable accommodations in the employment context might be the removal of architectural barriers, acquisition or modification of equipment, and other accommodations such as interpreters or readers. For an employee with fertility problems, the accommodations that might be sought would include job restructuring, part-time or modified work schedules, and reassignment to a vacant position.

Definition of Who Is Protected

Substantial Impairment, Regarded as, Record of. When most people think of disability discrimination laws, they think of individuals who are wheelchair users or those with visual or hearing impairments. Nevertheless, these laws cover a broad range of conditions and require not only nondiscrimination but reasonable accommodation. Whether infertility is to be included in statutory coverage is not clear on the face of the statutory language or the regulations.

Federal discrimination laws and many state discrimination laws define those to be protected similarly (7). Although some have urged that the definition be categorical and that specific impairments be listed to determine coverage, Congress specifically declined to do so. Instead individuals with disabilities are those who have a physical or mental impairment that substantially limits or more major life activities, those who have a record of such an impairment, or those who are regarded as having such an impairment.

The ADA regulations (1630.2 h) define a physical or mental impairment as "any physiological disorder, or condition, cosmetic disfigurement, or anatomical loss affecting one or more of [listed body systems]." These listed body systems include the reproductive system.

Major life activities are defined in the regulations as functions such as caring for oneself, performing manual tasks, walking, seeing, hearing, speaking, breathing, learning, and working. These listed activities are not intended to be all inclusive.

Substantially limited refers to being "unable to perform a major life activity that the average person in the general population can perform" or being "significantly restricted as to the condition, manner or duration under which an individual can perform a particular major life activity as compared to the condition, manner, or duration under which the average person in the general population can perform that same major life activity."

The requirement that the impairment be one that is substantially limiting is an important issue when considering infertility. This is because of the natural physiological changes that occur during the aging process which affect fertility, without an impact from disease, injury, or other condition that would affect fertility during the normal life cycle. This raises the question whether a woman who is in the average menopausal or postmenopausal age range would be considered disabled because she is no longer fertile or whether the definition

only covers women in their twenties or thirties who have substantial difficulty conceiving.

Statutory language and the regulations adopted pursuant to statutes are essential starting points for determining what is prohibited and what definitions apply in a particular policy context. Consideration is also generally given to interpretations provided by federal and state agencies charged with enforcement or implementation of statutes. In the case of employment discrimination, the primary agency is the Equal Employment Opportunity Commission (EEOC).

The EEOC was the agency that promulgated the regulations for the employment portion of the ADA, Title I. These regulations include an interpretive appendix. In addition the EEOC has issued a number of separate interpretive guidelines on various aspects of Title I. Not all of the EEOC interpretations have received complete acceptance by the courts and commentators.

The EEOC has published a memorandum providing guidance as to the definition of disability (8). In that memorandum the EEOC did not clarify specifically whether fertility is a disability. It has been argued, however, that the EEOC memorandum indicates an intent that procreation is a major life activity. In this regard, since infertility substantially limits the ability to procreate, infertility thus should be considered a disability under the ADA (9). EEOC does indicate that the ADA should be read broadly. The EEOC's discussion of human immunodeficiency virus (HIV) has been argued to support a determination that infertility is a disability. The EEOC has indicated that even someone with HIV who is asymptomatic would be covered because of the impact of the virus on procreation. Although not all courts initially accepted this interpretation (10), this interpretation was applied by the Supreme Court in 1998 in *Bragdon v. Abbott*, which is discussed later in the section on judicial interpretations (10).

The Department of Justice (DOJ), an agency with major implementation responsibility for the Rehabilitation Act, similarly supports protection for individuals with HIV, even those who are asymptomatic (11). The DOJ position is that a person with HIV cannot procreate without significant fears about the impact of the virus on the child. Again, this reasoning was adopted by the Supreme Court in *Bragdon*.

It has been argued that the DOJ logic on application to individuals with HIV should extend to infertility. The argument is:

> If an asymptomatic HIV-infected individual is protected under the Act because the potential to pass the virus onto a biological child constitutes a substantial limitation of the major life activity of procreation, then an infertile person, whose physical impairment substantially limits his or her ability to procreate in the first instance, likewise should be afforded the protection of the Act (12).

Courts have reached a wide range of conclusions about the coverage of various conditions. In cases involving sensory or mobility impairments, the decisions generally turn on the severity of the condition and the nature of the employment. Cases that are more problematic involve medical conditions, such as cancer, diabetes, obesity, and heart disease. Infertility is one of these problematic conditions.

Associational Disability. In addition to protecting individuals who are themselves impaired, the ADA (and arguably the Rehabilitation Act) also protects individuals from discrimination based on their association with someone with a disability. For example, it would be impermissible for an employer to refuse to hire someone because he or she had a child who is mentally retarded.

While the individual associated with someone with a disability is protected from discrimination, federal law does not require that reasonable accommodations be provided based on "associational disability." For example, while it would be impermissible to fire an employee because it was learned that the employee's daughter had suffered severe brain damage in an automobile accident, the employer is not required under the ADA or the Rehabilitation Act to provide an accommodation of allowing the employee time off to take the daughter for medical treatment or rehabilitation (14). The Family and Medical Leave Act (15), however, may provide relief to the employee in such a case, but nondiscrimination statutes will not.

This is significant with respect to infertility. Even if it were decided that infertility is a disability, accommodations would only be required for the partner with the medical condition, not for the other partner, whose presence may be necessary for certain infertility treatments.

OTHER APPLICABLE STATUTES

The importance of finding protection under disability discrimination statutes is highlighted when viewed in the context of other laws that might provide some protection for individuals and couples with fertility problems. As noted below, while these statutes are of some help, they do not provide the same level of substantive protection that would be available under the ADA or the Rehabilitation Act.

Pregnancy Discrimination Act of 1978

The Pregnancy Discrimination Act (PDA) of 1978 is a amendment to Title VII of the Civil Rights Act of 1964 (16). This statute prohibits employers from discrimination on the basis of "pregnancy, childbirth, or related medical conditions." The PDA does not require reasonable accommodation, so even if it were applied to an individual who is infertile, it is unlikely to be an avenue for the type of remedy being sought, namely accommodations in the work schedule and coverage of fertility treatment by an health insurance provider. It would only provide protection against an employer terminating employment or otherwise adversely treating an employee because of such a condition.

Several courts have found that infertility is a pregnancy-related condition under the PDA. One case involved an employee whose employment was allegedly

terminated because of her use of sick leave and vacation days to undergo fertility treatment. The court held that such action was subject to review under both the PDA (because infertility is a pregnancy-related condition) and the ADA (because infertility was determined to be a disability) (17).

Family and Medical Leave Act of 1993

While the PDA is unlikely to be a statutory basis for a leave of absence, the Family and Medical Leave Act (FMLA) of 1993 (18) does provide for such a leave in appropriate circumstances. The FMLA applies to employers with 50 or more employees, and it requires employers to provide up to 12 weeks of unpaid leave in a 12-month period of time. The leave is required only for the birth, adoption, or placement for foster care of a child; for care of a child, spouse, or parent with a *serious* health condition; or for the employee's own *serious* health condition that results in the employee's inability to perform the job. The term *serious health condition* is defined as one that involves inpatient care or continuing treatment by a health care provider. Neither the statute nor interpretations of the statute have discussed the potential applicability of the FMLA to infertility.

Health Insurance Portability and Accountability Act of 1996

The Health Insurance Portability and Accountability Act (HIPAA) of 1996, also known as Kennedy-Kassebaum (19), applies to employer-provided group health plans and group health insurance issued by private providers. HIPAA was intended to allow individuals to change group health insurance coverage without being unduly penalized. After initial eligibility with the first group health insurance plan, a transfer to subsequent plans should not adversely affect the individual. The covered employers and insurers may not deny coverage, or discriminate in eligibility, enrollment, or premium rates based on preexisting conditions. For the individual with infertility, the only benefit would be that if the individual is covered for fertility treatments by a health insurance plan subject to HIPAA, and the individual changes jobs, there would be no preexisting condition exclusion and no waiting period for coverage if fertility treatment is covered by the new employer's health insurance plan.

State Laws

Many states have statutes that are similar to PDA, FMLA, and the ADA. In general, state law interpretation often mirrors federal statutory applicability and interpretation, although there are a few notable exceptions. No state law clearly protects individuals with infertility problems.

JUDICIAL INTERPRETATION

The courts have addressed whether infertility is a disability in several cases. Two early cases have been subject to substantial commentary. Unfortunately, they have reached opposite conclusions, and there is not yet a definitive resolution of this issue as a result.

Both cases involved individuals who had been employed for some time. In *Pacourek v. Inland Steel Co., Inc.* (20) an employee with 10 years of service was dismissed because of her absences related to fertility treatments. The court determined that unexplained fertility is a physical impairment under the ADA. It further decided that reproduction is a major life activity, based on inference from EEOC interpretation and other judicial decisions, and that infertility is substantially limiting to this major life activity. Therefore infertility is a disability under the ADA.

The court relied on an earlier federal appellate court decision, *McWright v. Alexander* (21) in which the court had indicated that the Rehabilitation Act protected individuals with physiological disorders affecting the reproductive system. In *McWright*, the individual was seeking leave time to care for an adopted baby. Ms. McWright was unable to bear children as a result of childhood polio.

Zatarain v. WDSU-Television, Inc. (22) also involved a long-time employee. Ms. Zatarain was a television news anchor whose fertility treatments were initially accommodated. Eventually, however, her contract was not renewed after negotiations involving accommodations to her treatment. The court rejected her ADA claim, deciding that reproduction is not a major life activity. The court's reasoning was that other examples of major life activities in ADA regulations (e.g., walking, seeing, speaking, breathing, learning, and working) are done throughout the day, every day. Because one does not reproduce throughout the day, every day, this is not a major life activity. Neither is she substantially limited in working because she is not "significantly restricted in the ability to perform either a class of jobs or a broad range of jobs in various classes" because of her condition (23). The reasoning in *Zatarain* has been criticized as not being an appropriate interpretation of EEOC guidance (24).

It is noteworthy that these two cases addressing infertility as a disability, cases that result in conflicting definitions, had been decided at the time EEOC issued its 1995 interpretive guidance. The failure of the EEOC to specifically clarify its position on infertility is therefore troubling.

While *Pacourek* and *Zatarain* are the first major cases addressing infertility as a disability, a case decided after these cases is the first to reach a federal appellate court level. In *Krauel v. Iowa Methodist Medical Center* (25), the court considered the denial of health insurance coverage for a surgical procedure for a woman with endometriosis, a condition affecting her fertility. The court held that infertility is not a disability because it does not interfere with performing her job duties as a respiratory therapist, and that it would be a "considerable stretch of federal law" to treat it as a disability (25).

In one of the few cases involving health insurance coverage, rather than termination of employment, a court in the same jurisdiction as the *Pacourek* decision decided that a police officer with an ovarian dysfunction and infertility was protected as disabled under the ADA (26). The claim was that the employer had violated the ADA in denying health insurance coverage for fertility treatments.

The same court also determined that an employee with an incompetent cervix, which compromised her ability to carry a fetus to term, was protected as disabled under the ADA (27).

In 1998 the Supreme Court, in *Bragdon v. Abbott*, answered some of the questions about whether infertility should be treated as a disability under federal discrimination laws (28). The case involved a plaintiff who was a woman of child-bearing age who was HIV positive but asymptomatic. When she sought treatment from a dentist, he examined her in his office but indicated that he would only fill her cavity in a hospital because of her HIV status, and that she would have to bear the additional costs of hospital treatment. She brought suit under Title III of the ADA, claiming discrimination on the basis of disability by a private provider of a public accommodation. The Supreme Court addressed the issue of whether being HIV positive, but asymptomatic, is a disability under the ADA. The Court held that for this plaintiff it is.

The Court first determined that reproduction is a major life activity, by relying on the plain meaning of the statute and congressional intent to construe the statute to be consistent with regulations under the Rehabilitation Act. The second part of the test is whether one is "substantially limited" in that major life activity. Again, the Court held that Ms. Abbott is substantially limited because it affected her decision to conceive because of the significant risk to the partner as well as to the child, and this plaintiff had provided unchallenged testimony that her HIV infection controlled her decision not to have a child. So for Sidney Abbott, her HIV status was a substantial limitation to a major life activity.

Applying this analysis to infertility, it would seem clear that just as in the case of HIV, reproduction would be a major life activity for purposes of determining whether someone who is infertile is protected. The resolution of the question becomes more difficult, however, in applying the second part of the test, that is, whether for a particular individual, infertility is a substantial limitation to a major life activity. At first the answer might seem to be that it clearly is. It is not entirely clear, however, that all individuals who are infertile will be protected, just as the *Bragdon* Court did not hold that all individuals with HIV are automatically protected. Similarly it is not entirely clear that all individuals who are infertile will be automatically covered under the definition.

PROBABLE FUTURE DIRECTIONS

The initial split of opinion by the courts has been reinforced by other subsequent decisions. At the time of this writing, there have been several cases in which the court have determined that infertility is a disability. Most of these decisions, however, have been made by the same federal court in Illinois, so the number of decisions does not necessarily indicate the weight of authority.

The Supreme Court has, however, seemingly resolved the split to some degree in the *Bragdon* decision. The Court has at least decided that reproduction is a major life activity. This decision could certainly be extended to determine that infertility is a substantial impairment to a major life activity. What is unresolved is whether all individuals who are infertile will be covered.

As was previously noted, substantially limited means being "unable to perform a major life activity that the average person in the general population can perform" or being "significantly restricted as to the condition, manner or duration under which an individual can perform a major life activity as compared to the condition, manner, or duration under which the average person in the general population can perform that same major life activity." This may be interpreted to apply only to individuals who are in the normal age range for child bearing or fertility. This will thus be different for males and females.

Courts applying this analysis to cases involving infertility may examine whether the individual who is infertile is within the normal age range for fertility. Thus the 63-year-old may not be protected as disabled, while a 25-year-old woman would be. The fact that men are generally considered to be fertile under normal conditions throughout their adult lives raises some interesting disparate treatment issues. Would the 63-year-old man be considered disabled if he became impotent as a result of prostate cancer treatment?

Even if it is definitively decided that infertility is a disability under discrimination statutes, that is only the first step in receiving statutory protection. The individual must also be able to carry out the essential functions of the position with or without reasonable accommodations. The employer will generally have the burden of demonstrating what the essential functions of the job are and proving that accommodations such as schedule changes are unduly burdensome or fundamentally alter the program or lower standards. This will necessarily involve an individualized determination. And even if it is reasonable to accommodate an employee who is infertile, employers will not be required to make accommodations for employees where it is the partner with the infertility problem requiring the employee's presence for fertility treatment.

Finally, assuming that infertility is considered a disability and assuming that the accommodations sought are reasonable, there remain unresolved policy questions as to whether employers should be required to accommodate, and insurance companies to provide, health insurance coverage for an individual on an indefinite or undefined basis. Should the protections be extended to the 63-year-old woman who is seeking to conceive a child or to the woman who has already given birth to septuplets and seeks additional pregnancies? How will the application of disability discrimination law apply to individuals seeking access to health insurance coverage for drugs such as Viagra? These questions remain for the policy makers regardless of the direction taken by the courts and regulatory agencies in interpreting existing law.

REPRODUCTION, LAW, REGULATION OF REPRODUCTIVE TECHNOLOGIES

KAYHAN P. PARSI
Institute for Ethics, American Medical Association
Chicago, Illinois

OUTLINE

INTRODUCTION

Almost as fascinating as the reproductive technologies are the cultural responses to the new methods of controlling, enhancing, or limiting individuals' abilities to procreate. Writers have often invoked Aldous Huxley's *Brave New World* as a predictor of things to come, as if a single novel can faithfully capture the complexity and richness of reproductive technology. In reality, reproductive technologies vary a great deal, from the low tech, such as surrogacy and artificial insemination, to more highly sophisticated methods, such as intracytoplasmic sperm injection (ICSI). Regulation of these technologies by professional associations, states, and countries also varies considerably. While these reproductive technologies have created interesting and complicated abstract ethical issues, this article will only examine the regulatory responses to such technologies. Although regulation is often associated with the prohibition of specific activities, it is also enabling by allowing key parties to execute particular agreements in the area of reproductive technologies. This enabling aspect of regulation is in accordance with a liberal notion of procreative rights.

Commentators such as John Robertson generally support an individual's ability to choose a procreation method. Robertson believes that Americans have a procreative liberty interest. The very title of his book, *Children of Choice*, reflects a very American attitude: Choice is an inherently good thing, and this applies to reproductive technologies as well (1). Robertson's perspective epitomizes the viewpoint that reproductive technologies enhance and expand an individual's ability to make choices regarding procreation. Robertson acknowledges that although the technologies may produce ambivalence about their use, limiting persons' reproductive freedoms would curtail one of the most fundamental aspects of our lives. Other commentators, such as Dorothy Roberts, observe a darker side to certain kinds of reproductive technologies. Instead of focusing on the standard set of reproductive technologies, such as in vitro fertilization (IVF) or cryopreservation, Roberts concentrates on technologies that limit the ability to procreate (2). Roberts's concerns focus on utilization of drugs, such as Depo-Provera and Norplant, and sterilization of poor people. She is critical of the general acceptance of reproductive technologies to

enhance wealthy people's ability to procreate, while governments employ the aforementioned methods to curtail poor — especially black — women's ability to procreate. As exemplified by Robertson's and Roberts's viewpoints, goals of reproductive technology are quite diverse.

U.S. CASE LAW

In the United States, a number of cases provide a basis for Robertson's notion of procreative liberty. One of the earliest cases to assert a constitutional right to procreate was *Skinner v. Oklahoma* (3). This case overturned the now infamous sterilization case *Buck v. Bell* (4). In *Skinner*, the Supreme Court declared unconstitutional the Oklahoma Habitual Criminal Sterilization Act, which allowed for the sterilization of habitual criminals (2). The Court's language accorded reproductive freedom a high level of deference: "Oklahoma deprives certain individuals of a right which is basic to the perpetuation of a race-the right to have offspring ... we are dealing here with legislation which involves one of the basic civil rights of man." *Griswold v. Connecticut* (6) was another landmark case where the Supreme Court further expanded the notion of procreative liberty. The Court struck down a Connecticut statute that prohibited the distribution of contraceptives to married couples. This statute, the Court held, violated married couples' constitutional privacy rights. Justice Douglas wrote that "the First Amendment has a penumbra where privacy is protected from governmental intrusion. ...We deal with a right of privacy older than the [Bill of Rights]. Marriage ... is an association for as noble a purpose as any involved in our prior decisions" (5). In *Eisenstadt v. Baird* (6), the Court expanded the privacy right beyond *Griswold's* realm of marriage. In his opinion, Justice Brennan wrote:

> If the right of privacy means anything, it is the right of the individual, married or single, to be free from unwarranted governmental intrusion into matters so fundamentally affecting a person as the decision whether to bear or beget a child (7).

The Court again addressed the issue of contraception in *Carey v. Population Services International* (7), by striking down a New York statute that criminalized distribution of contraceptives to minors under 16, prohibited nonpharmacists from distributing contraceptives to people over 16, and banned any advertising or displaying of contraceptives. The *Carey* Court held that:

> [I]t is clear that among the decisions that an individual may make without unjustified government interference are personal decisions relating to marriage...; procreation...; family relationships...; and child rearing and education. The decision whether or not to beget or bear a child is at the very heart of the cluster of constitutionally protected choices (7).

After Carey, procreative liberty rights continued to grow. The now-famous Supreme Court case of *Roe v. Wade* (8) expanded privacy rights to permit women in collaboration with their physician to have an abortion. In *Planned Parenthood v. Casey* (9), the Supreme Court, based on its "liberty" rights reasoning, argued that abortion is an essential liberty. The liberty argument in *Planned Parenthood* focused more on control of one's own body, as opposed to limiting the government's ability to control reproduction, which was the language used in the aforementioned privacy cases (10).

The foregoing cases strongly suggest a basic negative right to procreative decision making and influence a variety of reproductive technologies — such as surrogacy, IVF, artificial insemination, and contraception. The remainder of this article will explain how different entities regulate various reproductive technologies; however, the discussion does not evaluate an exhaustive list of all possible reproductive technologies. First, a description of the guidelines promulgated by certain professional groups, such as the American Medical Association's (AMA) Council on Ethical and Judicial Affairs (CEJA) and the American Society of Reproductive Medicine (ASRM), will be given. The article will then examine state responses in the form of case law and legislation. It will then look at different approaches by countries and then finally different approaches by international bodies (e.g., the Council of Europe) to these technologies. A variety of approaches are represented, from the U.S. free-market approach to the more heavily regulated and centralized UK approach.

PROFESSIONAL GROUP GUIDELINES

Professional guidelines are a useful place to start when examining regulatory aspects of reproductive technologies. Although they do not have the force of law, they often do inform legal cases. Moreover, in the absence of any national legal or ethical consensus regarding these technologies in the United States, professional guidelines provide physicians, researchers, and ethicists with some guidance. The AMA's Code of Medical Ethics addresses the following reproductive technology issues: artificial insemination, IVF, freezing pre-embryos, pre-embryo splitting, and surrogacy.

Artificial Insemination

The AMA Code (11) makes the following requirements for recipients of artificial insemination: counseling, informed consent (e.g., risks, benefits, and alternative treatments), and information regarding the conceived child's legal status. The Code stipulates that sex selection is only allowed to avoid an inheritable sex-linked disease. Posthumous use of frozen sperm, according to the instructions of the decedent, is allowed (see the later California case *Hecht*). The Code also requires rigorous screening of potential donors for infectious or inheritable diseases, recommends the use of frozen semen (to ensure freedom of HIV infection), and advises physicians to use the professional guidelines set out by the ASRM, the Centers for Disease Control and Prevention (CDC), and the Food and Drug Administration (FDA). Physicians are also required to maintain permanent records of the sperm donors, reflecting health and genetic information that is both identifying and nonidentifying. The Code recommends obtaining the consent of the husband if he

will become the father through artificial insemination by anonymous donor. Unlike certain European guidelines, the Code does not prohibit single or lesbian women from obtaining artificial insemination by anonymous donor. Last, the Code admonishes compensating donors beyond incidental expenses such as time.

Regarding IVF, the Code prohibits using fertilized ova that will later be implanted to be used for laboratory research. Those fertilized ova that will not be implanted may be used for research purposes, but only in accordance with the Code's fetal research guidelines. The following guidelines are offered as aids to physicians when they are engaged in fetal research:

1. Physicians may participate in fetal research when their activities are part of a competently designed program, under accepted standards of scientific research, to produce data that are scientifically valid and significant.
2. If appropriate, properly performed clinical studies on animals and nongravid humans should precede any particular fetal research project.
3. In fetal research projects, the investigator should demonstrate the same care and concern for the fetus as a physician providing fetal care or treatment in a nonresearch setting.
4. All valid federal or state legal requirements should be followed.
5. There should be no monetary payment to obtain any fetal material for fetal research projects.
6. Competent peer review committees, review boards, or advisory boards should be available, when appropriate, to protect against the possible abuses that could arise in such research.
7. Research on "dead fetus," macerated fetal material, fetal cells, fetal tissue, or fetal organs should be in accord with state laws on autopsy and state laws on organ transplantation or anatomical gifts.
8. In fetal research primarily for treatment of the fetus:
   a. Voluntary and informed consent, in writing, should be given by the gravid woman, acting in the best interest of the fetus.
   b. Alternative treatment or methods of care, if any, should be carefully evaluated and fully explained. If simpler and safer treatment is available, it should be pursued.
9. In research primarily for treatment of the gravid female:
   a. Voluntary and informed consent, in writing, should be given by the patient.
   b. Alternative treatment or methods of care should be carefully evaluated and fully explained to the patient. If simpler and safer treatment is available, it should be pursued.
   c. If possible, the risk to the fetus should be the least possible, consistent with the gravid female's need for treatment.
10. In fetal research involving a fetus in utero, primarily for the accumulation of scientific knowledge:
    a. Voluntary and informed consent, in writing, should be given by the gravid woman under circumstances in which a prudent and informed adult would reasonably be expected to give such consent.
    b. The risk to the fetus imposed by the research should be the least possible.
    c. The purpose of research is the production of data and knowledge that are scientifically significant and that cannot otherwise be obtained.
    d. In this area of research, it is especially important to emphasize that care and concern for the fetus should be demonstrated (12).

The Code makes the gamete providers the primary decision makers when exerting control over a frozen pre-embryo. The providers are prohibited from selling their gametes, but they are allowed to donate them to others. Research is also prohibited on a pre-embryo if it will later be implanted in a woman. Interestingly, however, the Code allows pre-embryos to thaw and deteriorate. With regard to use of pre-embryos, the Code requires consent of both providers and encourages the use of agreements between providers in case the couple divorces. The Code permits pre-embryo splitting with the agreement of both gamete providers. Pre-embryo splitting allows a greater chance for conception while diminishing the number of potentially painful procedures to procure eggs (13).

Surrogacy

Surrogacy is one of the oldest forms of reproductive technologies. It is referred to in the Bible when Abraham's servant Hagar bears Abraham's child to be raised by him and his wife Sarah (14). It is the focus of such recent dystopian novels as *The Handmaid's Tale* by Margaret Atwood. And it has raised a number of ethical and legal concerns in recent years. Accordingly the AMA Code cites certain concerns regarding surrogacy agreements: commodification of children, exploitation of poor women, and interference with the natural maternal–child bond. It also raises potential psychological problems and the possibility that the mother may want to have an abortion or even refuse giving up the child. The intended parents may not even want the child if it happens to be born with disabilities. Despite major criticisms of surrogacy contracts, the Code permits them with certain safeguards. For instance, the birth mother should have:

> the right to void the contract within a reasonable period of time after the birth of the child. If the contract is voided, custody of the child should be determined according to the child's best interests. In gestational surrogacy, in which the surrogate mother has no genetic tie to the fetus, the justification for allowing the surrogate mother to void the contract becomes less clear. Gestational surrogacy contracts should be strictly enforceable (i.e., not voidable by either party) (15).

Cryopreservation

ASRM outlines a number of concerns with regard to cryopreservation. For instance, it encourage couples who are considering storage to put into writing what they wish to happen to their stored embryos in the following instances: death, divorce, separation, failure to pay storage charges, inability to agree on disposition in the future, or lack of contact with the program. ASRM requires that the consent form allow disposal of embryos if the couple lose contact with the program after some period of time and if they do not provide the program with key contact information, such as addresses and phone numbers. The ASRM guidelines allow a couple to revise their initial directions for embryo disposition by drafting a new set of written directions. Moreover, ASRM does not make rigid requirements with regards to embryos that lack written directions for disposal. In the absence of clear legal guidelines, programs may want to store indefinitely or accept the risk of liability by disposing of embryos after attempts to contact the couple have failed and a lengthy period of time has elapsed. ASRM approaches the issue of embryo preservation and storage pragmatically, in that a couple cannot claim an injury if they have failed to provide written directions, have lost contact with the program, and have not provided current address and phone information. Simply put, ASRM does not believe that programs have the ethical obligation to store embryos indefinitely. ASRM does state, however, that a period of five years should elapse and that "diligent effort" by phone and registered mail to contact the couple should be made by the program. Last, ASRM does not allow abandoned embryos to be used for research or donation to another couple without appropriate consent. The embryos must be thawed and allowed to deteriorate (16).

Embryo Splitting

Neither AMA nor ASRM prohibits embryo splitting (a technique whereby in vitro fertilized pre-embryos are split to create genetically identical siblings). Both organizations argue that splitting provides certain benefits: splitting provides a greater number of embryos, increasing the chances of a successful pregnancy and may prevent additional invasive procedures to retrieve more embryos, which are painful and costly. Neither AMA nor ASRM finds persuasive ethical concerns about using split embryos as a source of organs or tissues for an existing child, or the sale of stored embryos with desirable genomes based on the appearance of characteristics of existing children. For instance, the AMA Code recommends a complete prohibition of the sale of pre-embryos. Both the Code and ASRM acknowledge that offspring with identical genomes may be born at different times. ASRM raises the issue of "personal identity and the meaning of being a twin that require further investigation before it can be determined that such transfers are ethical." It recommends that such scenarios can be avoided "by transferring all genetically identical embryos in the same cycle." The Code permits couples to transplant genetically identical siblings in order to harvest their tissue for a needy sibling. The Code discounts any accrual of psychological harm and argues that the sibling may indeed gain psychological benefits by saving his or her sibling. In sum, both the ASRM and the Code take a consequentialist approach in that they believe that the benefits outweigh any costs in allowing embryo splitting (13,18).

Use of Fetal Oocytes in Assisted Reproduction

ASRM sees a number of problems with fetal oocyte donation: emotional harms to children, informed consent dilemmas, and an impersonalizing influence in assisted reproduction. Because of these concerns ASRM does not believe this technology should be pursued (18).

Posthumous Reproduction

Similar to surrogacy, posthumous births have an ancient lineage. These kinds of births routinely occurred when a woman conceived and her husband or partner died before she delivered the child. This child was commonly considered the legal heir of the father. ASRM, however, recognizes that posthumous reproduction became an issue when semen could be frozen and later implanted after the death of the donor. Although the AMA Code only makes a fleeting commentary regarding posthumous reproduction, ASRM has extensive commentary. ASRM cites a variety of scenarios where such reproduction may take place: A widow may retrieve a dead husband's sperm to procreate, sperm may be retrieved from terminally ill spouses or partners (employing techniques such as stimulated ejaculation, microsurgical epididymal sperm aspiration, MESA, or testicular sperm extraction, TSE), or sperm from a dead anonymous donor may be used. Moreover, a man facing radiation therapy or chemotherapy may want to store his semen for later (possibly posthumous) use.

Cryopreserving ova for posthumous procreation also poses certain concerns, but the inability to successfully freeze ova (as compared to semen and pre-embryos) has limited this particular technology. ASRM permits the designation of frozen gametes or embryos to be used in posthumous procreation as long as the key parties involved are fully informed. However, the absence of clear and written instructions would preclude posthumous reproduction. Moreover, ASRM believes that the requests of a living spouse should not override the express wishes of the deceased spouse.

ASRM also permits a husband to use his deceased wife's ova for implantation in a surrogate. Although the surrogate would not be considered a traditional surrogate, the ASRM requires that the surrogate be made aware of the circumstances and informed that she would be involved in a posthumous pregnancy. The rearing parents may lack genetic ties to the dead donor and may not be involved in the gestating pregnancy. They should, however, be made aware of the deceased status of the donors of gametes and embryos. Although the ASRM guidelines are supportive of posthumous reproduction, they do cite some reservations:

> . . .when reproduction takes place as a consequence of a loving relationship in which both partners were desirous of children, but a pregnancy is frustrated by the death of one partner, posthumous reproduction would ordinarily be well accepted both socially and culturally. . .. There is less certainty of the

impact on the child and more caution should be exercised for posthumous reproduction that occurs with the use of donated gametes from unrelated individuals who are not living and may have been deceased for several years, as may occur with the use of commercial banks as a source for sperm, frozen embryos, or ova (19).

STATE LAW AND REGULATIONS

Reflecting its organization, American state law that regulates reproductive technologies is a hodgepodge of case law, statutes, and administrative regulations. Certain issues, however, have been addressed extensively. One of them is surrogacy. One of the early surrogacy cases was *In The Matter of Baby M* (20). In this case, William Stern entered into a surrogacy contract with Mary Beth Whitehead. Elizabeth, Stern's wife, was infertile, and the Sterns were hoping to be able to have a baby with the assistance of Whitehead. The contract was for the sum of $10,000. In early 1985, Mr. Stern and the Whiteheads executed a surrogacy agreement. To avoid revealing the nature of the agreement, the child's birth certificate listed the Whiteheads as parents. It became clear very quickly that Mrs. Whitehead did not wish to part with her baby. Despite initial misgivings, Mrs. Whitehead gave the baby up to the Sterns. Whitehead underwent a depression and threatened suicide. The Sterns, therefore, returned the baby to Whitehead for a short visit. Thereupon, Whitehead left with the baby to Florida for four months. The Sterns's complaint, in addition to seeking possession and ultimately custody of the child, sought enforcement of the surrogacy contract. Pursuant to the contract, the Stern's asked that the child be permanently placed in their custody, that Mrs. Whitehead's parental rights be terminated, and that Mrs. Stern be allowed to adopt the child.

The Supreme Court of New Jersey invalidated the agreement and named Whitehead the mother of the child. The judge in this case noted certain ethical problems, such as commodification, with regard to surrogacy.

Because of commodification concerns, a number of states do prohibit enforcement of surrogacy agreements. For instance, Arizona, the District of Columbia, Michigan, and Utah prohibit all surrogacy agreements, whereas Kentucky and Louisiana prohibit commercial surrogacy agreements. Some states permit unpaid surrogacy agreements: Florida, Nevada, New Hampshire and Virginia. Florida, New Hampshire and Virginia require that the intended mother be infertile (21).

Another important surrogacy case was *Johnson v. Calvert* (22). In this case Mark and Crispina Calvert entered into a contract with Anna Johnson for Johnson to carry the Calverts's fertilized embryo (Crispina Calvert had underwent a hysterectomy but was able to produce ova). The Calverts agreed to pay Johnson $10,000; in return, Johnson would relinquish her parental rights to the child in favor of the Calverts. Near the end of the pregnancy, Johnson demanded immediate payment or she would not deliver the child after birth to the Calverts. The Johnsons sued, seeking a declaration that they were the legal parents of the child. Calvert countersued. The case wound its way through the California judicial system, until the Supreme Court of California heard it in 1993. The California court took a very different approach than the New Jersey court in *Baby M*. Here, the court was not concerned about potential exploitation or commodification. Moreover it found such concerns to be paternalistic and condescending toward women. The court held that the woman who intended the birth of a child that she intended to rear was the natural mother under California law.

Another issue that has been addressed by state case law is embryo storage and disposal. Perhaps the most famous case involving frozen embryos is the Tennessee case *Davis v. Davis* (23). In this case, a couple undergoing a divorce were arguing over the disposition of their frozen pre-embryos. The Davises never executed a disposition agreement regarding their embryos. Mary Sue Davis wished to achieve a pregnancy after their divorce, whereas Junior Davis wanted to avoid becoming a father entirely. In the absence of any statutory authority, the Tennessee Supreme Court stated that the pre-embryos occupy an intermediate status between property and persons. The court ruled that the fate of the frozen pre-embryos should be decided by "the party wishing to avoid procreation" if the other party has a reasonable possibility of achieving parenthood by other means and the parties have not made an agreement regarding their disposition. A later New York case, *Kass v. Kass* recognized the legal enforceability of a disposition agreement regarding frozen embryos. The court ruled that the couples' agreement controlled the fate of their embryos (24). Last, a couple of state statutes provide some guidance: Florida law requires that couples execute disposition agreements when undergoing a reproductive technology procedure (25) and Louisiana law defines the embryo as a "juridical person," limiting the ability of progenitors to dispose of their embryos (26).

Finally a case that raised the issue of posthumous use of sperm is *Hecht v. Superior Court of LA County* (27). In this case William Kane "willed" a vial of his own sperm to his girlfriend Deborah Hecht. He thereupon took his own life. Despite the fact that Kane's intent was clear, his ex-wife and children challenged his bequeathal. The probate judge initially ordered that the sperm be divided according to the original property settlement. The Court of Appeals later ruled that the remaining vials of sperm, which were in the custody of the administrator, be delivered to Hecht. The court argued that Kane had a legitimate property interest in his own sperm. Analogous to the Davis court, the Hecht court argued that the sperm occupied an interim category of property because of its potential for life. The court's reasoning in this regard was not dissimilar from the policy guidelines of ASRM.

FEDERAL GUIDELINES

Although federal regulation of assisted reproductive technologies is very weak in the United States, Congress has made some attempts to impose some regulation in this area. For instance, in the early 1990s, Congress passed the Fertility Clinic Success Rate and Certification Act of 1992: A Model Program for the Certification of Embryo Laboratories (28). This act required the Secretary

of the Department of Health and Human Services, through CDC, to develop a model program for the certification of embryo laboratories. This program was to be carried out voluntarily by interested states (28).

INTERNATIONAL APPROACHES

In addition to the United States, other countries, such as Canada, the UK and Australia, have all addressed the legal and regulatory aspects of reproductive technologies. Despite Canada's tradition of strong social solidarity reflected in its national health insurance system, no federal guidelines have been created to govern the practice of IVF, artificial insemination, as well as egg and sperm donation. Similarly, although no specific law prohibits surrogacy contracts, they would not stand up in court because they violate Canadian contract and family law principles. Recommendations do exist, however, for storage of gametes and embryos — 10 years and 5 years, respectively (29). The Law Reform Commission's 1992 Working Paper recommends that "[t]he commercialization of donated gametes and embryos must be prohibited outright. Allowing gametes and embryos in the consumer market would constitute a direct assault on human dignity" (30). After many years and millions of dollars, Canada's Royal Commission on New Reproductive Technologies issued its voluminous report *Proceed with Care*. The report's recommendations were essentially prohibitive in nature. In the aftermath of the Commission's issuance of *Proceed with Care*, a liberal government bill, C-47 (The Reproductive and Genetic Technologies Act), was on its way to passage in 1996 but died because a federal election was called (31). This bill would have prohibited the following practices and procedures: commercially exchanging sperm and eggs, cloning, fusing animal and human zygotes, implanting a human embryo into an animal (and vice versa), altering the genetic structure of the germ line, retrieving an ovum or sperm from a cadaver with the intention of using it in a live recipient, maintaining a human embryo outside of a human body, fertilizing an ovum for purposes of research, and commercial surrogacy (32).

In England, the focus shifted from the status of the fetus to the status of the embryo in the aftermath of the birth of Louise Brown, the first "test tube" baby. Public alarm about the untrammeled growth of reproductive technologies motivated Parliament to explore legislative measures (33). The Committee of Inquiry into Human Fertilization and Embryology (the Warnock Committee) took its charge into examining these issues seriously. The Warnock Committee's work in the reproductive health arena left an indelible stamp. The Committee recognized a special status for the embryo but permitted embryonic research up to the fourteenth day after fertilization. The committee permitted research on excess embryos, whether or not the embryos were intentionally developed for research. Britain enacted legislation concerning the reproductive technologies in 1990 with the Human Fertilization and Embryology Act 1990. The Act defines an embryo as "a live human embryo where fertilisation is complete." Moreover, the Act states that "fertilisation is not complete until the appearance of a two cell zygote." The Act also outlines a number of prohibited practices, as outlined below:

> (1) No person shall —
> (a) bring about the creation of an embryo, or
> (b) keep or use an embryo, except in pursuance of a licence.
> (2) No person shall place in a woman —
> (a) a live embryo other than a human embryo, or
> (b) any live gametes other than human gametes.
> (3) A licence cannot authorise —
> (a) keeping or using an embryo after appearance of the primitive streak,
> (b) placing an embryo in any animal,
> (c) keeping or using an embryo in any circumstances in which regulations prohibit its keeping or use, or
> (d) replacing a nucleus of a cell of an embryo with a nucleus taken from a cell of any person, embryo or subsequent development of an embryo.
> (4) For the purposes of subsection (3)(a) above, the primitive streak is to be taken to have appeared in an embryo not later than the end of the period of 14 days beginning with the day when the gametes are mixed, not counting any time during which the embryo is stored (34).

The Act addressed four of the treatments available: artificial insemination using donated gametes, egg donation, embryo donation, and IVF. The act also contained explicit statutory regulations of embryo research, which is permitted until the appearance of the primitive streak ("taken to have appeared in the embryo not later than the end of the period of 14 days beginning with the day when the gametes are mixed") (35). The Act prohibits the creation of hybrids using human gametes, the cloning of embryos by nucleus substitution to produce genetically identical individuals, and genetic engineering to change the structure of an embryo. Despite these regulations commentators have called the Act a "'radical laissez faire' approach; a system of regulated private ordering" (36). Hence sex selection is not explicitly prohibited, as evidenced by an Essex woman who selected her child's sex in 1994 at the London Gender Clinic (36). Moreover, the National Health Service announced in 1994 that it would offer fertility treatment to lesbian couples, a departure from the heterosexual requirements seen in other countries (37).

The Human Fertilisation and Embryology Act of 1990 also amended the Abortion Act of 1967 by reducing the limit for legal abortion to 24 weeks. One commentator noted that the 1988 Alton bill sought to reduce the legal limit for an abortion even further, to 18 weeks (38). Despite the fact that English abortion law was codified in the Abortion Act of 1967, judges were still left with some amount of discretion in their rulings. Moreover certain judges would interpret English legal tradition as affording the fetus a fairly high level of protection. Judge Denning in *Royal College of Nursing* compared the fetus in utero to a child and argued that English law recognized a criminal cause of action if a fetus was intentionally killed. These mixed views toward the status of the fetus, however, did not undermine the United Kingdom's effort in passing the

Human Fertilisation and Embryology Authority. Among the countries surveyed here, the Authority is a rare instance where the government has enough consensus to regulate reproductive technologies on a national level.

In Australia, the Rios case in the early 1980s triggered an interest in the status of embryos ex utero. In this case the Rioses had participated in IVF procedures in Melbourne. They produced three embryos from Ms. Rios's eggs and the sperm of an anonymous donor. One was implanted and the other two were frozen for storage. The Rioses both died in a plane crash, prompting a son from Ms. Rios's previous marriage to declare his share of his stepfather's estate. The embryos were left frozen, following the Australian Waller Committee's declaration that the embryos had no status of their own to be independently unfrozen and implanted in another surrogate mother.

The first official Australian pronouncements on the legality of IVF were issued by the National Health and Medical Research Council in 1982. The Council's guidelines permitted IVF, but with certain constraints: The recipient had to be in an "accepted family relationship," embryos could not be kept beyond the normal implantation time schedule, and cryopreservation could be maintained no longer than usual reproductive need. Cloning was strictly prohibited (39). Each state has modified the Council's rules. For instance, in South Australia and Western Australia, artificial insemination procedures are available to married couples and to couples in de facto relationships of a certain length. In Victoria, access to artificial fertilization procedures is generally limited to married couples. In Western Australia, only married couples or heterosexual de facto couples who have lived together for a total of five years out of the previous six are eligible to be treated with IVF (40).

As far as storage issues are concerned, South Australia prohibits the storage of embryos for more than 10 years (40). In Victoria, there are no statutory time limits on storage, but it is an offense to freeze an embryo unless it is done with the intention of subsequently implanting it in a woman's womb. In Western Australia, storage of reproductive material is prohibited unless undertaken in accordance with a license or exemption. Ova that are being fertilized or embryos must not be stored unless the primary intention of the storage is their "probable future implantation." In any event, they must not be stored for more than three years (40).

In South Australia, Victoria, and Western Australia the rights of control and disposal of gametes and embryos are set down in legislation. In South Australia, the Reproductive Technology Act 1988 (SA) provides that the code of ethical practice will make provision for decisions to be made for the use or disposal of stored embryos (41). Such decisions must be able to be reviewed at least every 12 months. The maximum period of storage for an embryo is 10 years.

In Victoria, under the Infertility (Medical Procedures) Act 1984 (Vic), if an embryo cannot be implanted in a woman's womb due to the woman's death or injury, the embryo may be given to another woman for use in a procedure permitted under the Act in accordance with the consent of the gamete donors. If the donors have died or cannot be located, the Minister will direct the hospital to make the embryo available for use in a procedure permitted under the Act (42). In Western Australia, under the Human Reproductive Technology Act 1991 (WA), the providers of gametes have all rights of use or disposition of the gametes as if they were personal property until the gametes have been used, although the gametes may not be sold. If gametes are donated to a licensee, rights of control and disposition vest in the licensee who, subject to the consent of the donor, may only use the gametes for in vitro fertilization for a person named or chosen by means specified in the consent, for artificial insemination, for approved research, or for diagnostic procedures. If the gametes are not used for one of these procedures, they must be permitted to succumb subject to the rights of control that may be vested in the recipient couple. Where a donor gives conditional consent for use of gametes, provided that the gametes have not been used, the rights in relation to the gametes revert to the donor if the condition is violated. In Western Australia, consent must be given by a person before his or her gametes or any fertilizing ovum or embryo are used or stored and such use or storage must be in accordance with the consent (43). In Victoria, consent must be given by persons who donate sperm or ova or embryos. Victoria permits embryo experimentation up to 14 days after fertilization.

In South Australia, research using human reproductive material will be governed by the code of ethical practice to be formulated by the South Australian Council on Reproductive Technology. The Code will prohibit development of a human embryo outside the body "beyond the stage of development at which implantation would normally occur." Research using human reproductive material may be undertaken in accordance with a license (40).

In anticipation of such cases as the recent *Kass* case in New York, Australian lawyers at a meeting of the executive of the Law Council's family law section in 1992 proposed a novel rule. Their proposal would require all couples who participate in assisted reproductive technology (ART) to execute a disposition agreement for the future fate of their frozen embryos (44). As Michael Watt, a Melbourne barrister who represented the mother in Australia's first dispute over frozen embryos said: "Trying to squeeze it into custody raises the definition of when does life begin. If it's custody, you have to decide whether an embryo is a child. If it is a human life, it isn't property.... At the moment, every country simply says parties have joint property in the embryos, or an equal say in the future disposal and general responsibility for their future disposal, and there is no deadlock-breaking provision in any legislation. ...It avoids having to have definitions on when life begins" (44).

In early 1995 the Victorian state cabinet approved laws permitting noncommercial surrogacy. The revised laws would make commercial surrogacy a crime (45). In the Australian Capital Territory, the Substitute Parent Agreements Act 1994 prohibits commercial surrogacy. Queensland prohibits commercial surrogacy and the publication of advertisements for surrogacy services. In South Australia, surrogacy contracts and procuration contracts are illegal and void. In Tasmania, the Surrogacy Contracts

Act 1993 (Tas) makes it an offense to introduce potential parties to a surrogacy contract, arrange or negotiate a surrogacy contract, or to give or receive valuable consideration in connection with a surrogacy contract (40). In Victoria, commercial surrogacy is prohibited, and it is an offence to publish or advertise surrogacy services. Even in states without specific legislative provisions governing surrogacy, it appears likely that surrogacy contracts would be unenforceable on the grounds of public policy.

In 1996 the Supreme Court of Tasmania heard the case of *In the Matter of Estate of the Late K* (46). Here the issue was whether the product of the ova of a widow and the semen of her deceased husband are children of the deceased upon being born alive. The deceased died intestate, leaving behind three children from a previous marriage. Justice Slicer in his opinion looked at cases from other common law countries (*Paton v. Trustees of the British Pregnancy Advisory Service, Roe v. Wade, R v. Morgentaler*), as well as in Australia. He determined the following:

- A foetus is not recognized, by the law, as a person in the full legal sense.
- The law has long recognised foetal rights contingent upon a legal personality being acquired upon its subsequent birth alive.
- A child, *en ventre sa mere*, is not a human being. To be human a child must have quitted its mother in a living state.
- A child so born is by a legal fiction treated as having been living at an earlier point of time and as if by being so treated the child would receive a benefit to which it would have been entitled if actually born at that earlier time (46).

Slicer concluded that at the time of the decedent's death there were no human offspring in existence. He asked whether the law should distinguish between a child *en ventre sa mere* and a sibling who was a frozen embryo? He stated that the New South Wales Law Reform Commission 1988 recommended that "children conceived posthumously as a result of IVF procedures and children born from stored embryos should be able to make a claim against the estates of their genetic parents under the Family Provisions Act 1982." Slicer ultimately concluded "[t]hat a child, being the product of his father's semen and mother's ovum, implanted in the mother's womb subsequent to the death of his father is, upon birth, entitled to a right of inheritance afforded by law."

Australia reflects the Anglo-American tradition by respecting certain individual rights (e.g., abortion). Yet Australian law does take an activist approach toward issues such as IVF, surrogacy, and embryo experimentation. Although the rules are primarily procedural, certain substantive values are being promoted. For instance, family stability as a societal goal is embedded in the rules concerning artificial reproduction. A definite preference is given to heterosexual unions or de facto marriages that have existed for a number of years. The law, then, gives legal sanction to a cultural norm. Moreover, the 1989 report concerning the status of the embryo clearly compares its status to that of a living person. Such a statement in the United States could easily be in the position paper of a "pro-life" organization.

Compared to the other common law countries surveyed, Australian courts have not had to grapple with issues of fetal status nearly as frequently. Yet Australia has been at the forefront in creating innovative legislation with regard to assisted reproductive technologies. Moreover the myriad rules that have been created suggest that embryonic and fetal life is accorded some respect in Australia.

The Council of Europe, a multinational body dedicated to human rights and the rule of law among its member states, has issued its own regulations regarding reproductive technologies. Two articles in the Convention on Human Rights and Biomedicine prohibits two kinds of activities. Article 14 prohibits the use of reproductive technologies to choose a child's sex. The Article makes an exception, however, to avoid a serious hereditary-linked disease. Article 18 of the Convention prohibits the creation of embryos for research purposes. Moreover, although it allows research on embryos in vitro, the Article states that the embryo will be afforded "adequate protection" (47).

Last, a variety of non-English-speaking countries have attempted to address the regulation of reproductive technologies. They have ranged from legislative bills in Argentina that are prohibitive in nature, to bans on embryo research in Norway, to limits on oocyte freezing in Denmark, to French legislation that limits artificial insemination (AI) to heterosexual couples and prohibits embryo experimentation, to German bans on surrogacy contracts. Although this entry has focused on English-speaking countries, reproductive technologies are being used in a number of settings throughout the world. Regulatory responses are as varied as the countries themselves (48).

CONCLUSION

Among English-speaking countries, a great variety of approaches exist in regulating reproductive technologies. The United States has the most laissez-faire approach, with very little federal regulation. Most regulation is left to the private sector or the states; professional organizations such as the AMA and the ASRM have issued the most comprehensive guidelines regarding reproductive technologies. The United States seems to reflect Robertson's view of a strong sense of procreative liberty. Other English-speaking countries are more hesitant to grant such broad negative rights and they have all adopted to varying degrees a greater amount of formal regulation, whether in the form of the Authority in the UK or among the laws of the different states in Australia. In the late 1990s, however, certain international organizations, such as the Council of Europe, have attempted to formalize certain kinds of prohibitions with regards to some of the reproductive technologies available.

REPRODUCTION, LAW, WRONGFUL BIRTH, AND WRONGFUL LIFE ACTIONS

JEFFREY R. BOTKIN
University of Utah School of Medicine
Salt Lake City, Utah

OUTLINE

INTRODUCTION

Wrongful life and wrongful birth are two closely related medical malpractice actions that have arisen since the 1973 *Roe v. Wade* decision. Both actions typically are brought against health care providers after the birth of a child with congenital malformations or a genetic disease. Wrongful *birth* actions refer to suits by the parents who claim harm from the birth of an impaired child. The claim is that had the parents been adequately informed of their reproductive risk, they would have taken measures to prevent the pregnancy or birth of the affected child. Wrongful *life* claims are brought in similar clinical circumstances; however, these claims arise from the child who claims harm from birth in an impaired condition. The child claims that but for the negligence of the health care provider, she would not have been born to suffer with her condition. Clearly the wrongful life claim poses a complex philosophical challenge. It is important to emphasize that the claims do not allege that the defendant *caused* the impairment through negligent actions. Rather the claims are based on allegations of inadequate or incorrect

information that would have permitted the parents to avoid pregnancy or to detect the abnormality prenatally and terminate the pregnancy. (Physicians who are alleged to have caused a congenital malformation through, say, the prescription of a teratogenic drug, are liable under more traditional tort actions.)

The wrongful life and wrongful birth suits have become increasingly common since *Roe v. Wade* for two reasons. First, *Roe v. Wade* established constitutional protection for abortion decisions through the first two trimesters of pregnancy, and, second, technology has offered an expanding array of tests and procedures to evaluate the health of the fetus. In light of these rights and choices, health care providers are seen to have parallel obligations to offer testing in a variety of clinical circumstances, and to adequately warn couples who have an increased risk of bearing a child with a heritable condition or congenital malformation. Failure to provide timely, accurate information according to the standard of care may leave providers liable under wrongful life and/or wrongful birth suits.

The rapid pace of research in human genetics and fetal imaging means that an ever larger number of conditions will be amenable to prenatal diagnosis in the future. Rare conditions, late-onset diseases and relatively mild health conditions may be identifiable early in a pregnancy. In addition future behavioral traits and normal physical characteristics may be predictable to some degree in an embryo or fetus. A clear challenge for the health professions, and for society more broadly, is to articulate the standards for prenatal diagnosis. How much information should prospective parents have access to about the biologic nature of their future children? The wrongful life and wrongful birth suits raise fundamental legal and philosophic issues about reproductive choice in an emerging era of powerful genetic technologies.

As will be discussed below, the wrongful birth suits have been widely successful in the U.S. court system, while the wrongful life claim has met with limited support. The wrongful life and wrongful birth claims should be distinguished from "wrongful pregnancy" suits in which parents claim damages for the birth of a health child following an alleged negligently performed sterilization or abortion procedure. Wrongful pregnancy suits will not be discussed in this article. This discussion will focus on the medical background of the suits, their legal history and the philosophic issues inherent in these claims.

CLINICAL CIRCUMSTANCES GIVING RISE TO WRONGFUL LIFE AND WRONGFUL BIRTH CLAIMS

Wrongful life and wrongful birth claims can arise from a variety of clinical circumstances. In the majority of cases to date, the claims have resulted from allegedly inadequate information provided to pregnant women about risks to their child. The list of conditions prompting wrongful birth or wrongful life suits is included in Table 1. The usual condition is a pregnant woman of an "advanced maternal age," that is, 35 years or older at the anticipated time of delivery, who is not warned of the increased risk of bearing a child with Trisomy 21 (Down syndrome) and other aneuploidy syndromes (e.g., Trisomy 18 and Trisomy 13). It currently is the standard of care to warn older pregnant women of their increased risk and to offer prenatal diagnosis. Without such a warning, and on the birth of a child with Trisomy 21, the obstetrician would be at risk for a wrongful birth suit by the parents and a wrongful life suit by the child. The suits are based on the assertion that had the warning been provided, prenatal diagnosis would have been pursued, the child's condition would have been detected and the pregnancy would have been terminated.

Table 1. Conditions Prompting Wrongful Birth and Wrongful Life Suits

Down syndrome	Fetal hydantoin syndrome
Congenital rubella syndrome	Leber's congenital amaurosis
Spina bifida	Infantile polycystic kidney disease
Tay Sachs disease	Duchenne muscular dystrophy
Cystic fibrosis	Anhidrotic Ectodermal dysplasia
Sickle cell anemia	Pelizaeus-Merzbacher syndrome
Larsen syndrome	Albinism
Retinoblastoma	"Hydrocephalus and multiple congenital defects"
Neurofibromatosis	No arms and other anomalies
Hemophilia B	"Severely deformed and retarded child"

The second single most common condition giving rise to these suits after Down syndrome is congenital rubella syndrome. Congenital rubella syndrome is due to a prenatal maternal infection with the rubella virus that can cause serious impairments and congenital malformations in the child. If a physician fails to assess the risk of the pregnant woman to rubella or fails to diagnose an active rubella infection, the physician is at risk for suit upon the birth of the impaired child. Again, the allegation here is not that the physician should have prevented the rubella infection, but that she should have provided information sufficient to allow prevention of the birth of the impaired child.

Obstetricians have been subject to the majority of wrongful life and birth suits to date. To the extent that these suits have been successful, obstetricians clearly have an obligation to assess pregnant women for the risk of congenital and hereditary abnormalities and to provide them information accordingly. It is important to note that these suits do not claim that the physician should have provided prenatal diagnosis or pregnancy termination. Providers are free to follow their own ethical standards in the provision of services and there are a substantial number of obstetricians, for example, who are "pro-life" and do not provide these services. In such circumstances physicians still are required to provide risk information according to the standard of care and information about testing options, such that patients can pursue services with other providers, if they wish. Suits may arise either from the failure to provide sufficient information, or the provision of inaccurate information. Clearly, the risk to the child need not be genetic in origin since infections

like rubella and other teratogenic infections and agents can cause impairments as well that may be amenable to prenatal diagnosis.

Prenatal care providers other than obstetricians have been subject to wrongful birth and life cases in the context of prenatal diagnosis. Ultrasound imaging of the fetus has become virtually routine in pregnancy. Failure of the radiologist to accurately diagnose a congenital malformation may give rise to these claims. Similarly failure to accurately perform prenatal tests may give rise to suits against laboratories that process the clinical specimens.

While prenatal care has given rise to most of these suits, care providers in other fields of medicine are not immune, and their liability will increase as genetic information increases. The case of *Schroeder v. Perkel* (1) provides an important example. In this case a child with cystic fibrosis was not diagnosed until seven years of age, despite suggestive symptoms for a number of years. Prior to the diagnosis of the child, a sibling was born who also was affected with cystic fibrosis. The parents claimed, successfully, that had an accurate and timely diagnosis of the first child been made, the parents would have been warned of their reproductive risk and they would have taken measures to prevent the birth of a second affected child. Cases also have arisen due to the provision of inadequate genetic information once an accurate diagnosis of a genetic condition was made. In the case of *Ellis v. Sherman* (2), a surgeon correctly diagnosed neurofibromatosis in an adult patient but failed to indicate that this is a hereditary condition. The patient subsequently fathered an affected child and sued the surgeon for failure to provide sufficient information to allow him to make an informed reproductive decision.

The success of this wrongful birth claim has implications for virtually all clinicians caring for patients who may have a genetic component to their illness. Typically physicians focus almost exclusively on the welfare of the individual patient in making decisions about testing and other evaluations. Genetic conditions may be part of a "differential diagnosis" for a patient (the list of possible conditions that might explain the symptoms), but unless there is a specific reason to pursue the diagnosis, other conditions may be considered first. Since genetic conditions are often difficult or impossible to treat, the diagnosis of genetic conditions may be delayed by the physician's desire to initially pursue treatable conditions. There often is little direct benefit to the patient in making a prompt diagnosis of a genetic condition. However, wrongful life and wrongful birth suits illustrate that there may be benefits to the *family* by making a prompt genetic diagnosis. Such a diagnosis will alert family members to their reproductive risks and potentially permit them to avoid the birth of an affected child. Therefore these legal claims herald a significant change in the responsibilities of health care providers from a narrow focus on the health of individual patient to a broader focus on the reproductive interests of the patient and the patient's family members.

LEGAL HISTORY OF WRONGFUL LIFE

Wrongful life and wrongful birth are tort actions or, more specifically, malpractice actions. As such, a successful claim against a health care provider requires that the plaintiff show (*1*) a duty existed on behalf of the provider to the plaintiff, (*2*) a breach of duty occurred (i.e., negligent conduct occurred), and (*3*) the plaintiff was harmed as a result of the negligence. In addition to these three elements, courts may consider broader public policy issues as they attempt to reach a just conclusion. The first case under the wrongful life term is notable in this regard. In *Zapeda v. Zapeda* (3), an illegitimate child brought suit in an Illinois appellate court against his father who had seduced his mother into intimate relations with a promise of marriage. The child sued his father for the harms associated with illegitimacy. The court was willing to recognize the duty, breach of duty, and harm but was unwilling to invite the flood of suits that might arise from children in similar circumstances.

The wrongful life claim has met with limited success in the U.S. judicial system. To date, five state courts have recognized the wrongful life claim (4), while 19 have rejected this tort. The primary stumbling block for the wrongful life claim has been the notion inherent in the suits that a child would prefer nonexistence to existence in an impaired condition. Recall that existence without the condition was never a possibility for these children, so the choice on behalf of the child was existence with impairments or nonexistence through contraception or pregnancy termination. The children in whose name these suits are brought must assert that, but for the negligence of the defendant, they would not exist. In response to this dilemma, most courts have adopted the reasoning first articulated in the New York case of *Becker v. Schwartz* (5), in which two basic problems with wrongful life suits were identified:

> The first, in a sense the more fundamental, is that it does not appear that the infants suffered any legally cognizable injury.... Whether it is better never to have been born at all than to have been born with even gross deficiencies is a mystery more properly to be left to the philosophers and the theologians. Surely the law can assert no competency to resolve the issue....Not only is there to be found no predicate at common law or in statutory enactment for judicial recognition of the birth of a defective child as an injury to the child; the implications of any such proposition are staggering.

The second problem identified by the Becker court was the inability to calculate damages on any reasonable basis.

In contrast, the courts that have recognized the wrongful life claims have been willing largely to overlook the philosophical problems inherent in the claim and to support the suits based on the medical needs of the child and/or the public policy advantages of deterring negligent medical care. A California court (6) in 1980 concluded:

> The reality of the "wrongful life" concept is that such a plaintiff both exists and suffers, due to the negligence of others. It is neither necessary nor just to retreat into meditation on the

> mysteries of life. We need not be concerned with the fact that had the defendant not been negligent, the plaintiff might not have come into existence at all.

Similarly the New Jersey Supreme Court in 1984 (7), was unwilling to allow the problematic logic of the wrongful life suits to stand in the way of what it judged to be a just outcome for the case. In the case at hand, the parents had been barred from bringing a wrongful birth suit on their own behalf due to the statute of limitations. Since the statute of limitations for suits by children is much longer than for adults, the only available route for the family to receive compensation for the alleged negligence was the wrongful life suit. The court stated that the child should not be denied adequate medical care simply because the parents were unable to sue on their own behalf.

For more than a decade, other states consistently declined to recognize the wrongful life claim. In recent years, however, courts in both Massachusetts and Connecticut have supported the tort. A 1997 decision by the Connecticut Superior Court (8), quotes a 1983 decision: "There is nothing illogical in a plaintiff saying 'I'd rather not be suffering as I am, but since your wrongful conduct preserved my life, I am going to take advantage of my regrettable existence to sue you.'" A Massachusetts court (9) was faced with a case in which a suit was brought against a physician who failed to report abnormalities on a fetal ultrasound and to repeat the examination. The parents of the child, born with heart and bowel abnormalities, relinquished the child for adoption. The court concluded:

> . . .Corey's parents are not entitled to recover against the defendant for the ongoing extraordinary costs that Corey will incur because of his defect (due to the fact that they are no longer his legal guardians or official parents). Nor will Corey's adoptive parents be entitled to recover, since they defendant owed them no duty. Therefore, this Court must consider whether Corey should have this cause of action since no one else can recover the extraordinary costs. . . .In this situation, it appears fair . . . to require the negligent Doctor to pick up these costs if negligence is proven.

Therefore in order to assure adequate care to a child with disabilities, some courts have been willing to recognize wrongful life claims without explicitly declaring that life with disability can be worse than nonexistence. Some commentators have noted that the incentive to recognize the wrongful life claim in selected courts would decrease if the U.S. health care system assured better services for all children with significant health care needs.

The New York court in *Becker v. Schwartz* deferred to the philosophers and theologians on the basic question of whether existence confers a harm on some children. A range of opinions have been offered on this question from bioethicists, theologians, and physicians. John Lorber (10), a British surgeon, wrote in 1975 of the deliberate nontreatment of some severely affected children with spina bifida:

> There are ethicists and moralists, as well as doctors, who consider that life must be maintained at any cost, because any life is better than no life. It may be legitimate to adhere to such principles within their own family, but is it not right to enforce such a philosophy on others who do not hold with it. To my knowledge none of the world's great religions or religious leaders believe that a severely defective innocent newborn infant would be worse off in heaven or wherever they believe their souls will go after death. Is it therefore humane to inflict an immense amount of suffering on such infants and on their families to ensure that they reach this heaven or haven in the end? . . .[Quoting De Lange, a neurosurgeon] "Large numbers of spina bifida children kept alive by early closure of the defect . . . are now adolescents, most of them painfully aware of the deficiencies. Some of us feel their presence not as a tribute to a medical achievement, but as an accusation against misuse of medical power."

Margery Shaw, a geneticist and attorney, argues that fetal abuse, through knowingly bringing a child to birth with a genetic condition, should be made analogous to child abuse in the law. She would sanction not only wrongful life suits against negligent physicians but similar suits against parents.

> . . .[P]arents should be held accountable to their children if they knowingly and willfully choose to transmit deleterious genes or if the mother waives her right to an abortion if, after prenatal testing, a fetus is discovered to be seriously deformed or mentally defective. They have added to the burdens of the other family members, they have incurred a cost to society, and, most importantly, they have caused needless suffering in their child.

Indeed, the wrongful life claim raises this curious question of the parent's responsibility for the birth of an affected child. When prenatal diagnosis detects a fetus with a genetic condition or congenital malformation, some parents choose to continue the pregnancy. Also parents at risk for bearing a child with a genetic condition may choose to forgo prenatal diagnosis and accept the risk of an affected child. As argued by Shaw, might the affected child have a wrongful life claim against the parents? The State of California was concerned enough about this possibility after the success of a wrongful life claim in the case of *Curlender v. Bioscience* that it passed legislation barring suits by children against parents for the harm of their existence (11).

In contrast to these authors, Bopp et al. (12) argue from a "right to life" perspective that one of the very foundations of modern law and civilized society is that all human life has enormous intrinsic value.

> . . .[W]rongful birth/life claims . . . require a new legal theory, in that life itself is considered a wrong, and death is preferred over life with disabilities. By deviating from the general principle, historically found in civilized law, that life, even with disabilities, is valuable and that only wrongful death is compensable, wrongful birth/life actions are a radical departure from fundamental legal philosophy.

Similarly authors writing from a disabilities rights perspective assert that it is simply wrong that those with disabilities lead lives of hopeless despair, devoid of the values that all others experience in their lives (13,14).

The greatest difficulties for those with impairments, it is claimed, are often not due to the condition per se, but to the discriminatory attitudes and barriers in society. Wrongful life suits (and wrongful birth) are seen by many of these authors as reflective of an inaccurate and inappropriate attitude in society toward life with a disability.

Finally, some bioethicists claim that the assertion that the life with impairments is worse than nonexistence is only justifiable for a few extremely severe conditions (15,16). From the perspective of the child, even the most rudimentary awareness and existence might be sufficient to experience a life of value. According to these authors, the kinds of conditions for which wrongful life suits have been brought, such as Down syndrome or congenital rubella syndrome, would not be justified from the perspective of the child.

LEGAL HISTORY OF WRONGFUL BIRTH

To date 26 states and the District of Columbia (17) and 3 federal courts (18) have recognized a cause of action for wrongful birth. One state has enacted legislation recognizing the validity of wrongful birth suits (19). In contrast, five appellate courts have rejected the claim (20) and six states have enacted legislation barring wrongful birth suits (21). Legislative bans have been prompted primarily by the philosophy that the birth of a child, even a child with significant impairments, should not be considered a harm to either the child or the parents. Two state laws banning wrongful birth have been upheld as constitutional (22). Although the national trend is clearly toward the recognition of the claim, wrongful birth remains controversial.

Several courts and scholars argue that the wrongful birth concept is an extension of the constitutionally protected right to privacy in abortion decisions (23). The claim is that abortion decisions are dependent on information about the welfare of the fetus. Therefore reproductive choice is limited if inadequate prenatal diagnostic information is provided. It is argued that the harm in these cases is not the birth of the impaired child, but the infringement on free choice in reproductive decisions.

In contrast, other commentators and courts argue that there is no basis for wrongful birth suits under the umbrella of privacy as articulated in *Roe v. Wade* (12,24). The constitutional right of privacy in reproduction and abortion only prevents state interference with abortion decisions, it is argued, and imposes no positive duties on health care providers to provide information about the fetus. Two state courts (Minnesota and Pennsylvania) have examined these arguments and held that the state laws barring wrongful birth suits are constitutional (22). Therefore, to date, the provision of prenatal diagnostic information has not been held to be a protected right under the Constitution.

Other commentators and courts argue that wrongful birth suits fall more appropriately under the patient's right of informed consent (25–27). Informed consent relates specifically to the amount and type of information that health care providers must provide to patients about medical options. It is argued that in the context of the medical condition of pregnancy, couples should be told the risk of a problem for the child in order to decide whether to obtain prenatal diagnosis. Under the current foundation for wrongful birth as recognized by the majority of the courts, physicians are held to the prevailing standard of care for the provision of timely and accurate information about the welfare of the child.

The requirement that the plaintiff (in this case, the parents) demonstrate harm secondary to the negligence of the defendant has not been carefully evaluated by the courts. In many cases, courts presume that the birth of a child with a impairment constitutes a harm. As noted above, many individuals with disabilities strongly contest this notion. In addition pediatricians and hospital ethics committees dealing with pediatric issues are often faced with the dilemma of parents of a severely disabled child who demand full medical support for the child, even when physicians believe such efforts are futile. Therefore whether a disabled child is a harm to the parents is a subjective issue, and this may change for parents between the birth of the child and later life with the child as a unique individual. Bopp et al. have captured the complexity of this issue by inviting us to imagine a woman with an impaired newborn who is driving to court to enter a claim of wrongful birth. An auto accident occurs and the child is killed. The mother now decides to enter a claim of wrongful death against the other driver. This case vignette illustrates the complex mix of benefits and burdens that children bring to families.

The complexity of the issue of harm is reflected in debate over the appropriate calculation of damages in courts recognizing the tort. There are several options that courts have considered that have tried to balance in various ways the benefits and costs of bearing and raising an impaired child. One method of calculation is to award the parents a monetary sum equal to the costs of the continued pregnancy, the delivery, and the medical and other costs incurred by child's impairment. These are seen as the additional costs directly incurred by the claimed negligence of the physician. Courts also may consider an additional award to compensate for the parent's emotional pain and suffering of bearing and raising a child with a disability. A third element that courts have variously considered is an offset to either of these damages for the benefits that a child brings to a family. Therefore the damages for emotional pain might be reduced by the jury's estimate of the child's positive contribution to the family.

Clearly, the concepts of emotional pain from bearing and raising an impaired child and emotional benefits of raising any child are highly value laden. As a result many courts have been unwilling to allow these kinds of calculations (or, in some circumstances, state law does not permit these kinds of awards or offsets). The majority of the courts have permitted damages to be awarded more simply for the medical and other extraordinary costs incurred by the child's unwanted condition (28).

PHILOSOPHICAL AND PUBLIC POLICY ISSUES

The prevalent acceptance of the wrongful birth concept suggests that this kind of malpractice liability will

encourage health care providers to conform to the contemporary standard of care. However, the standard of care in this arena is ambiguous and may be a moving target as new tests become available. At the present time it is the standard of care in the United States to inform women of advanced maternal age of their increased risk of trisomy syndromes, to offer Alpha Feto-Protein (AFP) screening to all pregnant women, and to offer couples from specific racial or ethnic backgrounds tests relevant to those backgrounds — Tay Sachs screening for Ashkenasic Jews, for example, and sickle cell screening for African-Americans. Further it can be concluded that any prenatal tests or procedures that are performed must be performed and communicated in a timely and accurate fashion. Currently many pregnant women of all ages are offered "triple screen" blood testing to detect a fetus with Down syndrome. This testing has a relatively poor predictive value, and it is uncertain at the present time whether courts would find a physician liable for failing to offer such testing.

Another specific test that remains the subject of controversy is screening for cystic fibrosis carriers in the general population. Cystic fibrosis (CF) is an autosomal recessive condition that primarily affects Caucasians of Northern European heritage. The carrier frequency in the Caucasian population is approximately 1 in 25 individuals. Genetic testing for CF is possible, however the sensitivity of the test remains less than 100 per cent. With the identification of the CF gene in 1989, there was prevalent speculation that carrier screening of the general population would be forthcoming. To forestall this development, professional societies promptly and clearly articulated an opinion that it was not the standard of care to offer CF carrier screening in the general population (29,30). To date, CF carrier screening has not be widely offered to pregnant women in the absence of a family history, although it is conceivable that a wrongful birth suit could force the issue and accelerate the adoption of this technology into general screening. With the development of each new major test, society will have to struggle with the question of whether, or when, it becomes the standard of care to offer the technology.

The broader philosophic issue raised by the wrongful birth concept is the limits, if any, that should be placed on prenatal diagnosis. If parents have a right to be informed of reproductive risks, what is the extent of such a right? Imagine a woman who carries a mutation in the BRCA1 gene that confers a lifetime risk of up to 85 per cent for cancer of the breast or ovary. Such a risk begins when a woman is in her thirties and forties. Should BRCA1 prenatal testing be offered and made available to this woman? Are parents harmed if their child has a genetic susceptibility to an adult onset disease like cancer or Huntington disease? At the extreme, can parents claim harm if a child of the "wrong gender" is born after an inaccurate prediction by ultrasound? It is unlikely that a flood of such suits will be brought to court, but the responsibilities articulated by successful suits encourages society to consider the appropriate boundaries for prenatal diagnosis.

A number of scholars and authoritative committees have raised concerns over the use of prenatal diagnosis for "mild" conditions or "trivial" indications. The President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research (31) focused primarily on prenatal diagnosis for gender selection of the child, stating:

> The idea that it is morally permissible to terminate pregnancy simply on the grounds that a fetus of that sex is unwanted may also rest on the very dubious notion that virtually any characteristic of an expected child is an appropriate object of appraisal and selection. Taken to an extreme, this attitude treats a child as an artifact and the reproductive process as a chance to design and produce human beings according to parental standards of excellence, which over time are transformed into collective standards. . . .[T]he Commission concludes that although individual physicians are free to follow the dictates of conscience, public policy should discourage the use of amniocentesis for sex selection.

The Committee on Assessing Genetic Risks of the Institute of Medicine (32) took a similar stand, recommending that:

> . . .prenatal diagnosis not be used for minor conditions or characteristics. In particular, the committee felt strongly that the use of fetal diagnosis for determination of fetal sex or use of abortion for the purpose of preferential selection of the sex of the fetus is a misuse of genetic services that is inappropriate and should be discouraged by health professionals. . . .The committee believes this issue warrants careful scrutiny over the next three to five years as the availability of genetic testing becomes more widespread, and especially as simpler, safer technologies for prenatal diagnosis are developed.

A statement by the American Medical Association's Council on Ethical and Judicial Affairs supports limitation of prenatal diagnostic services to more serious conditions. The council suggests: "Selection to avoid genetic disorders would not always be appropriate. . . .[S]election becomes more problematic as the effects of the disease become milder and as they become manifest later in life" (33). Several scholars have taken similar positions. Thomas Murray concludes: "In short, we should not offer to provide prenatally information about traits or afflictions that are not substantial burdens on parent and child. We certainly should not assist couples in a misguided quest for the child that embodies their ideal collection of traits, including gender" (34). Like the President's Commission, other authors have framed the issue of limits of technology use around prenatal sex selection. Wertz and Fletcher state: "[W]e believe that it is important that the medical profession take a stand now against sex selection. A posture of ethical neutrality on this issue could lead to unfortunate precedents in moral thinking about future uses of genetic knowledge. . ." (35).

The courts have, on occasion, addressed the issue of the extent of the physician's obligation in the context of wrongful birth. The Supreme Court of Kansas wrote in a 1990 case: "In recognizing a cause of action for wrongful birth in this state, we assume that the child is severely and permanently handicapped. By handicapped, we mean, in this context, that the child has such gross deformities, not medically correctable, that the child will never be able to function as a normal human being" (36).

Certainly there are scholars and others in the general public who reject the notion of prenatal diagnosis and selective abortion entirely. After considering the rationales for prenatal diagnosis, Leon Kass concludes that there is no convincing "moral justification for the practice of genetic abortion" (37). In contrast, Philip Kitcher (38) writes:

> Couples who test their fetuses for the presence of blue eyes or curly hair and who decided to abort otherwise healthy fetuses when an alternative genotype was present would, to say the very least, have a distorted conception of value. Should states therefore limit the liberty of couples to make reproductive decisions? Not necessarily. Freedom of reproductive choice can be defended provided that the fetus is not taken to be a person with rights and interests that the state has a duty to protect. For the moment, we can accept the idea of the testing supermarket, open to free choice with few restrictions.

Similarly John Robertson argues that the legitimate concerns over unlimited access to prenatal diagnostic information do not warrant infringement on the parent's fundamental procreative liberties (39). As noted above, those from a disabilities rights perspective argue that the whole prenatal diagnostic enterprise largely reflects and reinforces negative stereotypes about living with a disability, or parenting a child with a disability. Drawing lines between types of disabling conditions to declare that some are appropriate for targeting with prenatal testing and that some are not is unacceptable for some disability rights advocates. They contend that such a policy decision sends a hurtful message to those living with disabilities who fall on the wrong side of the line.

The broad acceptance of wrongful birth suits and the diversity of opinion on the appropriate uses of prenatal diagnosis leaves medical care providers without clear guidance at the present time. What should the ethical practitioner offer to prospective parents from the expanding menu of tests? What tests should they provide upon request? Should tests for "mild" and late-onset conditions be made available? In the absence of a policy establishing professional standards on this issue, it may be up to the courts to decide if physicians have failed in their professional obligations when wrongful life or birth suits are brought. Wrongful birth and wrongful life suits will provide guidance to the profession on this issue, but malpractice litigation is a painful and inefficient approach to the development of a standard of care.

Prenatal diagnosis promises to be one of the most complex and controversial topics in medicine and in society generally over the next generation. John Fletcher predicts: "[T]he future of prenatal diagnosis and medical genetics will be ethically more complex than its past and present. Practitioners can expect a 'gathering storm' of issues that require societal involvement and establishment of public policy" (40). Society will benefit from mechanisms to reach some measures of consensus on these complex issues that lie at the interface of technology, philosophy, law, and human reproduction.

RESEARCH ON ANIMALS, ETHICS, AND THE MORAL STATUS OF ANIMALS

LILLY-MARLENE RUSSOW
Purdue University
West Lafayette, Indiana

OUTLINE

INTRODUCTION

Animal research involves not only scientific but ethical issues. Indeed, these are not two separate, or separable, issues; they are inextricably interwoven. The ethical side of this issue concerns researchers, regulators, concerned citizens, and society at large. Even though questions about animal experimentation are not the exclusive domain of philosophers and ethicists, a careful look at relevant philosophical arguments and moral theories can give us a better understanding of the nature of the debate. The following discussion takes up the issues listed in the title in reverse order.

THE MORAL STATUS OF ANIMALS

The term "moral status" refers to the place of something with respect our ethical reasoning. An alternative way of phrasing the question of moral status is to ask whether something has moral standing. To say that something has no moral standing is simply to say that it does not enter directly into proper ethical deliberations at all. Such things may figure into deliberations indirectly, as a source of concern for those who do have moral standing. My property, for example, does not have moral standing, but *I* can be benefited or harmed, my rights can be respected or violated, depending on how others treat my property. Thus, we might speak of other people's indirect duties to treat my property in certain ways. Traditionally this has been the status accorded to animals by theologians, philosophers, and legal and social practice (1–3). We have duties not to be cruel

to animals not because they are worthy of our direct moral concern, but because how we treat animals affects humans — because the animals are their property, because cruelty to animals might lead to mistreatment of humans, and so on.

There are two other possible positions on the moral status of animals, one on either side of the 'indirect duties' view just sketched. One might hold that if we set aside questions of property, human concerns for animal welfare are simply misguided, and should not be part of a well-grounded ethical theory at all. This view is admittedly uncommon, but not unheard of (4–6). As one noted neuroscientist states: "I believe that the inclusion of lower animals in our ethical system is philosophically meaningless and operationally impossible and that, consequently, antivivisectionist theory and practice have no moral or ethical basis" (4, p. 169) The other is to accord animals moral standing, to say that we have direct duties toward them independently of how our actions affect other humans, and that they ought to figure directly in our ethical deliberations. It should be noted that moral standing need not be egalitarian: There is a large gap between saying that animals have moral standing, and saying that their moral standing is in any way equal to that of a human being. This position on the moral status of animals encompasses a wide range of positions, from radical "liberation" theories such as those defended by Peter Singer and Tom Regan (7,8) to those that defend the use of animals for research and agriculture but still argue that we have a direct moral obligation to minimize animal pain and suffering (9,10). In all these cases we must distinguish the question of whether X is a moral agent — the sort of thing which has duties, moral obligations, can be praised or blamed — from the question of whether X has moral standing — whether it is the sort of thing toward which moral agents have direct duties. The term "moral patient" is often used to designate this latter category. While some ethical theories hold that only moral agents can be moral patients, most theories entail two different sets of criteria for the two groups. Thus it will not do to reject the idea that animals have moral standing (are moral patients) simply by noting that "they don't respect *our* rights," or "they don't have any compunction about killing *us*."

Most people who are not deeply involved in the animal rights debate tend to endorse a "middle-of-the-road" position regarding our moral obligations to animals. Thus, it is widely accepted that it is morally wrong to cause an animal pain or suffering without a compelling overriding good reason. Although there is much less agreement about what sorts of things constitute a good reason for overriding this injunction, most people would also agree that the suffering of the animal itself, not just the side effects on humans, is morally relevant. On the other hand, most of these same people would object quite strongly to the view that animals are in any way entitled to the same sorts of moral protection owed to other human beings; they would hold for example, that much less justification is needed for causing an animal to suffer than is required for the same amount of human suffering, that we are justified in using animals in ways that we ought not use severely retarded orphaned infants, and that injunctions against killing animals are much less stringent and restrictive than similar injunctions against killing humans.

The position (or constellation of positions, for there are many variations within the boundaries sketched) described in the previous paragraph would apparently be endorsed by the vast majority of Americans and Europeans. It is decidedly not, however, the dominant tendency in philosophical writings on ethics and animals. Most of the contemporary philosophical writings argue some variant of the claim that the position described above sanctions much that is morally reprehensible, and that when correctly understood, our moral obligations regarding animals would disallow currently accepted practices such as meat-eating, much of the research in which animals are used, and more (7,8,11–13).

At this point, let us introduce some labels for the sake of convenience. Let us call the sort of position just described "the liberationist view." It is more popularly called "the animal rights position," but this is inaccurate, since at least some of the defenders of the position — notably Peter Singer — do not appeal to rights-talk in their arguments; although the word "rights" crops up occasionally in (7), in his more careful philosophical arguments, he explicitly rejects the notion of animal rights (14,15). However, for better or worse, the label "animal rights" is the one that has been most commonly associated with this strong position; problems with the label will be discussed more fully in a subsequent section. The first sort of position described above admits that there is a basis for direct moral obligations to animals, but holds that it is different, at least in part, from the basis for our obligations to humans; for that reason, it shall be labelled the "differential view." Finally, there is the view that we have no direct obligations or duties to animals, that even the duty to avoid cruel treatment of animals is based on our moral obligations to humans. This shall be refered to this as the "humanist position."

Clearly, these are less-than-ideal terms for views that have been coarsely defined. The arguments within each category differ in important respects that must be considered more carefully. Nonetheless, the labels do identify some clearly distinct trends, and it will be convenient to be able to refer to those trends in a shorthand way. Details and specifics will find their proper place later. It should also be noted that these views cut across the theoretical commitments we will examine presently: One can, for example find utilitarians in all three categories (7,16,17), and while some deontologists (8) subscribe to a liberationist view, others are definitely in the humanist camp (18).

HISTORY AND THEORY

If the "differential view" is the one most people hold, how did the animal liberationist position gain such prominence? At least in the United States, the answer can be traced back to Peter Singer, and the publication of *Animal Liberation* (19).

Animal Liberation

Singer follows Jeremy Bentham and other proponents of "utilitarianism" to support his opposition to animal research or raising animals for meat. Utilitarianism is the view that an action is right if and only if it produces a better balance of benefits and harms than available alternative actions. That is, our ethical evaluation looks only at the consequences of our actions. Utilitarians may disagree about what constitutes a benefit but two widely accepted candidates are pleasure and satisfaction of preferences and interests. Singer argued that sentience — the ability to feel pleasure and pain, and hence to have interests — should be the basis of our ethical assessment of any action, including animal research. The examples he used to support his claim that animal research does not produce the best possible balance of benefits vs. harms have come under serious attack, both for the sketchiness of the descriptions, and for questions of scholarship (20). Nonetheless, they served to make many more people aware of the sorts of research that had been conducted. Even if the specific examples cited are problematic, the theory does give a way of evaluating animal research, both as a general practice, and specific research projects. This approach of trying to weigh the (expected or possible) benefits against the harms, usually to the animals used, is reflected in the current regulations, albeit in an attenuated form.

The Argument from Marginal Cases

More important from the standpoint of theory, Singer launched the first sustained attack on the differential view, arguing that any attempt to justify the use of animals in research would also justify the use of some humans. This argument, which has come to be known as the argument from marginal cases, has become one of the chief weapons in arguments against animal research. It is also intended to support the claim that "speciesism" — a term coined by Richard Ryder (21) but popularized by Singer — is wrong in the same way that racism or sexism is wrong.

The argument is deceptively simple. If we want to justify differential treatment of animals and humans, we must cite a morally relevant difference. However, the differences that have been proposed — such as self-consciousness, autonomy, or the ability to act as moral agents — do not apply to all human beings. Some severely retarded humans, those in a permanent vegetative state, or, to cite the most dramatic example, anencephalic infants, do not possess those qualities now, may never have them, or have possessed them in the past. Thus any argument that attempts to justify animal research on the basis of one of these properties would also justify using these "marginal case" humans for the same procedures. The term "marginal case" may have originally intended to refer to both animals and humans who are at the margins of whatever line we attempt to draw, but it has come to be used to refer to those humans who are severely retarded or otherwise so impaired that they are not capable of very basic perceptions, emotions, and understanding. Since this term is offensive to many, the following discussion will break with tradition and use the term "misfortuned humans" rather than "marginal cases."

There are three possible responses to this argument. The first, best associated with a "humanist" view of the moral standing of animals, is to attempt to identify a morally relevant property that does separate all humans, even "misfortuned humans," from animals. The only candidate for such a property is membership in the human species; anything else, such as the capacity for reason or moral agency, is not going to apply to severely misfortuned humans. This is often disparaged as "speciesism," but has been defended occasionally (22). The second response, defended by R.G. Frey (23), is to argue that there are important differences between normal adults and animals, but also agree that some humans will lack the morally relevant qualities, and accept the other horn of the dilemma: Some research on misfortuned humans would be justified, perhaps even better than animal research. This would be consistent with (although not entailed by) the "differential" view. The third, dictated by the "liberationist" view, is to accept Singer's conclusion, and still insist that research on misfortuned humans would be immoral, but that entails that we are not morally justified in doing research on sentient creatures that meet or exceed the conditions that protect misfortuned humans. Let us look at each of these in a bit more detail.

If one wants to pursue the first strategy and cast about for a difference that might be morally relevant, it is clear, as already noted, that the standard properties — such as autonomy, rationality, the ability to engage in moral reasoning and mutual respect — will not do. Some people have tried to generate a longer list, and even suggest that we ought to adopt a "cluster" approach: none of the qualities individually are necessary, but any small subset of them is sufficient to justify preferential treatment for humans (24). These are exactly the properties that misfortuned humans lack. There are three other possibilities that have been suggested: (*1*) arguments from potentiality: marginal cases have (or did at one point have) the potential for the morally relevant property, even though they do not actually have it, (*2*) defenses of "speciesism," or arguments that attempt to justify giving preferences to individuals just because they are members of our own species, and (*3*) appeals to side effects, or how misfortuned humans must be afforded special protection for the good of others, not necessarily for the misfortuned human. The first of these will give us either too little or too much. Most advocates of this view restrict their attention to the potential that a misfortuned human has now (25), but it is simply false that most of them have the potential in question. An anencephalic baby or someone who is brain dead does not now have such a potential, and appeals to the fact that medicine might someday be able to help such cases is simply otiose; such resources are not available now. Others extend the notion of potentiality even further. They say that the individual had the potential at some point but lost it due to misfortune (26), or a slight variation, that misfortuned humans actually have some moral status in virtue of the fact that they could have possessed some property (27). This may be true, except for those defects that are genetically fixed at conception and manifest during fetal development. However, this casts the net of potentiality too wide; every germ cell (indeed, since

the advent of Dolly the sheep, perhaps every human cell) has, under the right conditions, the potential to develop into a normal human being. The idea that every human sperm should be accorded a higher moral status than a chimpanzee, or even a laboratory rat, appears to be a reductio ad absurdum of this approach. Finally, those who seek a morally relevant difference between misfortuned humans and animals might point to the so-called side effects of treating such humans as potential research subjects (28). The side effects include the emotions of the parents, other interested observers, possible changes in attitudes toward the medical profession, and weakening of the familial bond. The problem with these side effects is that cultural factors are the main determinant of how strong or deleterious these effects will be. If our obligations towards misfortuned humans rest solely on these factors, they will embody a "cultural relativist" approach to ethics, an approach for which ethical theorists have long had persuasive refutations.

Consider then the second response to the argument from misfortuned humans, championed by R.G. Frey (16,23). Frey argues that the value of life depends on the quality of life, and the quality of life is determined by the opportunities for rich experiences; he like Singer, is a utilitarian. He also agrees that on this criterion, some animals will fare better — rank higher in terms of quality, and hence value of life — than some misfortuned humans. At the same time he rejects the liberationist claim that animal research is universally unjustified. While he agrees that some work is frivolous, trivial, or simply bad science, he cites numerous cases in which he argues that the benefits outweigh the harms. His solution is to raise the stakes: We can justify such beneficial research, but only if we would be willing to do the same research on a misfortuned human who falls lower on the quality/value of life scale than the animal proposed as the research subject. Although his view is perfectly consistent, most of his critics continue to cast about for another way to avoid grasping this particular horn of the dilemma.

The third option, as already noted, is the one preferred by Singer, Regan, and other critics of animal research. The conclusion here is that since we would not sanction most research on misfortuned humans (although there are some exceptions), we should not allow the same sort of research on animals who match or exceed those humans with respect to morally relevant criteria. This poses a very basic challenge to defenders of animal research, in that it seems to rest solely on a demand for logical consistency, rather than allegiance to one or another arcane-sounding ethical theory. Although Singer situated the argument from misfortuned humans in a utilitarian context, the argument is by no means limited to that context. Tom Regan (8) and James Rachels (29) utilize the same sort of argument to argue that any argument that establishes that all humans have the right to life, liberty, or respect will also apply to animals. Indeed, at least one philosopher, Evelyn Pluhar, makes the argument from misfortuned humans so central to her argument that no specific commitment to a broader moral theory is required (12).

Rights-Based Arguments

Although Singer's arguments are the most generally straightforward, accessible, and therefore best known by the general public, other philosophers have given more complex and sophisticated arguments to examine the contention that animal research (as well as large scale animal agriculture) should be abolished. In doing so, surprisingly, they employ a theory most usually associated with "human rights." Some of these are still utilitarian in flavor, but others adopt a more "deontological" approach.

The history of deonotology, as well as most current versions of deontological theories, emphasize the unique status of rational, autonomous, human agents. This is in marked contrast with the utilitarian tradition, which from its first formal articulation by Jeremy Bentham, has frequently acknowledged the inclusion of animals (30). In contrast to utilitarianism, deontology insists that some actions may be right even if the consequences are not good, or as good as they could be, while other actions are ethically wrong even though they would produce good consequences. In short, consequences are not the only factor in moral evaluation. Examples typically cited are lying (which would be wrong even if you and I were both happier if I lied to you), keeping promises, and justice. The term "deontology" is often used interchangeably with "right-based theory," since the concept of rights has often been used as a guard against sacrificing what is right (e.g., respect for individual autonomy in matters of religion) for what might be good for the group (forcing compliance to the majority choice). It is also sometimes called a "Kantian theory," since the German philosopher Immanuel Kant was its first major proponent. Kant famously intended his theory to apply only to rational beings capable of understanding moral imperatives, and explicitly excluded animals from its scope, and until recently that focus was unquestioned. Indeed, the sorts of rights typically associated with deontology are often called "human rights." As noted above, even contemporary philosophers who develop and defend deontological or rights-based theories rarely grant animals rights. However, that exclusion has been challenged.

Tom Regan, for example, follows Kant in rejecting utilitarianism as an adequate moral theory in favor of a theory that emphasizes rights that cannot be overridden merely because such an override would yield good consequences for everyone affected. Bernard Rollin also defends a rights-based approach, although he is neither strictly Kantian nor an "abolitionist" about either animal research or animal agriculture (31,32). In both arguments, however, the concept of rights is consistent with almost universally accepted social and political philosophy: for example, that a person cannot be killed (perhaps to harvest his heart, lungs, and other tissues and organs) just because more people would benefit from his death than would benefit from his continuing to live. The novelty is extending this concept of rights to animals and that, at least in Regan, is justified by a form of the argument from misfortuned humans.

For Regan, the attribution of rights is closely tied to an obligation to respect another's life and inherent value. He rejects a Schweitzer-style reverence for all life and argues

instead that we ought to attribute equal inherent value to what he calls "subjects of a life," individuals who have —

> beliefs and desires, perception, memory, and a sense of the future, including their own future, an emotional life together with feelings of pleasure and pain; preference and welfare interests; an ability to initiate actions in pursuit of their desires and goals; a psychophysical identity over time; and an individual welfare in the sense that their experiential life fares well or ill for them, logically independently of their utility for others, and logically independently of their being the object of anyone else's interest (8, p. 243).

The argument that all subjects of a life have inherent value, and hence deserve respect, depends in part on a version of the argument from misfortuned humans. Regan does not attempt to draw a sharp line between animals that are subjects of a life and those that are not, preferring to leave that issue open pending a better understanding of various animal's psychological abilities. He does claim that *at least* all normal mammals over one year of age are subjects of a life. From the notion of inherent value and what he terms "the respect principle," he concludes that animals have certain rights that are equal in moral weight to those rights possessed by humans. These include, most basically, the right to respectful treatment and the right not be harmed.

The fact that Regan's argument to show that animals have rights represents a minority position raises an interesting question: Do his arguments show that "traditional" deontological theories are merely myopic or biased, or do those traditional restrictions of rights to human beings have a legitimate basis? Both Regan and Rachels rely heavily on the argument from misfortuned humans, but there are at least two other questions to be raised. They can most easily be seen by setting out a condensed form of Regan's argument:

1. All "subjects of a life" have rights.
2. Many animals — at least those noted above — are subjects of a life.
3. Therefore many animals have rights.

Thus the two obvious questions to raise are (*1*) whether being a subject of a life is in fact the appropriate criterion for attribution of rights, and (*2*) if so, whether most animals really are subjects of a life in the sense defined by Regan. Although it might seem as if the first is the domain of philosophers and the second a question to be answered by psychologists, ethologists, and other philosophers, in reality the two are inextricably intertwined. The debate is too complex to pursue here, but it is ongoing (33,34). Quite a lot is at stake here. No matter what Peter Singer says, utilitarianism will necessarily sanction at least some research on animals. Only if Regan can successfully establish his rights-based view can he even approximate the "total abolitionist" stance toward animal research that he advocates.

Other Philosophical Foundations

Although utilitarianism and deontological theories tend to dominate the theoretical landscape, they are by no means the only options. At least two other approaches to ethical theory, contractualism, and what shall be referred to as Humean ethics, have been used to address animal issues explicitly. A third, virtue theory, is enjoying renewed interest among philosophers, but does not seem to have been used by contemporary philosophers to address issues about the use of animals, even though Aristotle, widely regarded as the founder of virtue theory, had quite a bit to say about animals (35). Finally, several philosophers writing on animals do not fit neatly into any of these categories, either because they have theoretical commitments that combine elements of one or more approach, or because their arguments are not as "theory driven" as, for example, Regan's is. The discussion that follows will not attempt a critical analysis of these approaches but will describe them briefly in order to provide a more complete overview.

Contractualism, as the name implies, views moral obligations as the outcome of an implicit or hypothetical contract among members of a society. Such contracts are assumed to have the form: I agree to refrain from doing x, y, and z to you, and to do a, b, and c, if and only if you agree to refrain from doing x', y', and z' to me, and to do a', b', and c'. The "prime" indicators are meant to indicate that while contracts are essentially reciprocal arrangements, they need not be symmetrical. One can have a contract between employer and employee, or sovereign and subject, where the rights and duties of the participants might differ. The essential feature of contractualism is that all parties agree to abide by the rules; hence only creatures who are able to understand an abstract concept of rules and the intention to follow them can enter into the moral sphere and have direct moral standing. Contractualism is sometimes confused with deontological theories, and some philosophers (36) have combined elements of both. But there are important differences between them, some of which will come out in the following paragraphs, and some of which are too complex to address here. What follows will often speak of "contractors" and "contracts" for the sake of convenience, but it is important to remember that these typically refer to hypothetical, not actual, contracts.

It is probably already obvious that animals will not fare well on a contractualist approach to ethics: they, like children, are judged incapable of understanding the abstract rules and reasoning implied by the whole notion of a contract. Being unable to enter into a contractual agreement, they are also ineligible for the protection such contracts provide.

Clearly, contractualism sees moral duties as holding directly only among creatures capable of understanding and abiding by such an abstract contract. As the contrast between Regan and Kant indicates, the basis for obligation or duties in a deontological theory is not necessarily so restricted: Some versions of deontological theories have room for duties to animals, but no contractualist theory can possibly do that: The best it can muster is a "contract" in which participants choose to include certain restrictions on the way we treat animals because the contractors would prefer not to live in a society which, for example, tolerates blatant cruelty. As we have seen, this sort of protection at best generates an indirect duty

toward animals. Moreover such protection is to a large extent voluntary, an "option" for the contractors, unlike the strict imperatives generated by a deontological theory. These differences entail that contractualists may differ in their descriptions of what indirect duties, if any, might be included in the hypothetical contract, and we do find the expected variations in the views of contractualists who have written about animals. The two most prominent philosophers in this category are Jan Narveson (37,38) and Peter Carruthers (6). Narveson thinks that contractors might well choose to extend some protection to animals, while Carruthers argues quite vehemently that it would be irrational and misguided to agree to such an extension of contractual protection.

One of several problems with contractualism is the fact that the moral status of children and other "disadvantaged" individuals — those lacking the capacity to understand and hence legitimately agree to the sort of contract required for admission into the moral sphere — are covered only at the whim of the contractors. Some humans in this category might be covered by dint of the contractors' self-interest; if, but only if, they think they will care about the welfare of their children, they might choose to include some protection for children in the contract. However, if they believe that they will only care about their healthy, or "normal," or male offspring, or children born in wedlock, only those children will be protected; no moral agent will have any duties to those "beyond the pale." More generally, since morality is *defined by* the hypothetical contract, there is no way of saying that the contract itself is unethical, unfair or unjust, or fails to capture some real moral obligation; one can only raise a legitimate objection by pointing out that no rational agent would agree to some putative contracts. These features of contractualism have led most philosophers to reject it as an adequate moral theory, and if it is inadequate as a general analysis of morality, it surely cannot be appealed to as a basis of deciding questions about moral obligations towards animals.

Implicit in at least some popular invocations of contractualism are two ineffective justifications: (*1*) Since animals do not respect our rights, we do not have to respect theirs, and (*2*) morality is a human invention, and thus applies only to humans. The first is problematic because it assumes that only moral agents can be moral patients, something that needs to be argued for rather than presupposed. The second is even weaker: After all, humans "invented" mathematics and science, but that does not mean we can make them do anything we want nor that they only apply to humans.

The collection of views that may be called *Humean*, in recognition of the British philosopher David Hume, represents another approach to ethical theory in general, and the issue of animals and animal research in particular. The views have this in common: They hold that ethics is not something that requires only abstract, impersonal rationality. Rather, it must also involve emotions, including sympathy or empathy, and avoid the complete detached impartiality and abstractness of overly rationalistic approaches. Hume is famous for claiming "Reason is, and ought to be, the slave of the passions." The term "passion," in Hume's day covered a wide range of emotional and personal attitudes, but the basic unifying theme is that, in contrast to the impersonal nature of deontological theories and utilitarianism (both of which hold that, all other things being equal one has no ethical justification for giving preferential treatment to one's best friend, spouse, or child), personal, concrete relations do matter as a foundational concern in ethics. Mary Midgeley, for example, justifies her conclusions about our duties toward animals by arguing against excessive emphasis on rationalism, and for the importance of emotion in ethical reasoning (39). Annette Baier also emphasizes Humean themes in her discussions of animals (40). This de-emphasis of rationality has also been a prominent theme in feminist discussions of animal experimentation (41). A rejection of rationality and impartiality seems ripe for ridicule, but both Midgeley and Baier argue extensively that traditional ethical theories have overstated the role of very abstract, detached reasoning.

ANIMAL WELFARE AND ANIMAL RIGHTS

Defenders of animal research often try to draw a deep theoretical distinction between animal welfare and animal rights. They often assert that researchers who use animals, or farmers who raise animals for food, are deeply concerned about animal welfare but ought to reject the notion of animal rights. A more careful analysis of these concepts, however, reveals, that the distinction invoked here is far from clear and often inaccurate (31,34,42), and is usually divisive rather than clarificatory. It is divisive because it frames the discussion in terms of just two sides rather than recognizing the whole spectrum of subtle differences, and because the two sides are presented in an "us versus them" tone rather than looking for points of agreement. It is inaccurate because, as we have seen many "liberationists" such as Peter Singer do not advocate animal *rights*. Moreover many philosophers who argue that animals do have rights reject the idea that these rights afford them the sort of total protection that the label is usually taken to represent (43), and they also explain why talk of animal rights does not entail anything like equal treatment (44). Finally, as reported by Rollin, 80 percent of respondents to a recent poll affirmed that animals have rights (31, p. 149). Thus advocating animal rights is neither necessary nor sufficient for holding the extremist position that the label "animal rights" is often taken to represent. The label "animal welfare" is similarly unhelpful. It usually involves a rejection of the humanist view, as defined at the beginning of this article (although some who invoke the "animal welfare, but not animal rights," slogan seem to attribute only indirect moral status to animals); even so, it covers such a broad spectrum of views that it sometimes tends to become mere window dressing. One end of the spectrum, it could imply a position as strong as Singer's: Animals do not have rights, but their welfare deserves equal consideration, and harms to animals must be weighed against potential human benefits (the converse is true, in principle, but that rarely arises as a moral issue). As we have seen, this would require a major re-evaluation of animal research. On the other end

of the spectrum, "animal welfare" is merely an injunction not to harm an animal unnecessarily, unless such harm is dictated by some human interest (including any desire to know, economic considerations, personal taste, and entertainment). But if these labels are unhelpful, what vocabulary should be used? First, we need a more accurate understanding of the term "animal rights," something which is best obtained by going back to the philosophical roots of theories of rights.

There are, of course, philosophical disagreements about how best to understand rights-claims and theories about rights. Accordingly, a brief survey of the available options will be helpful. The most important choice for our understanding here has to do with the force of rights-claims: What do such claims entail or suggest, and how are they different from other sorts of claims about moral obligations? We soon find an important distinction between what may be called "broad" and "narrow" views on the force of rights-claims. Roughly speaking, a broad interpretation of rights-claims sees them as alternative ways of expressing a wide variety of moral obligations. To say that someone has a right, such as to liberty, is merely another way of saying that we (moral agents) have a direct duty not to interfere with her exercise of free movement, free choice, and so on. A narrow interpretation demands something more stringent: Rights provide a foundation for only the more basic obligations, obligations that are much harder legitimately to override.

The basic theoretical difference (admittedly a difference in degree rather than kind) is that "ordinary" duties can and must be balanced and assessed against all sorts of competing demands, interests, and inclinations. We as a community have duties to respect residents' use of their private property, but those duties can and often are assessed against, and sometimes overridden by, other wants and desires: hence zoning restrictions and some environmental legislation. Rights, on the other hand, are not so easily overridden: A person's right to free speech cannot legitimately be overridden no matter how many people dislike what is being said. Rights in this narrow sense are often said to be "basic," "inviolable," "natural," or "inalienable." The justification for this narrower, but stronger, sense of rights is analogous to that in the political arena, in which rights are seen as a way of protecting the minority from the potential abuses of majority rule.

It might be interesting to note in passing that the only legitimate way of characterizing Peter Singer — the author of *Animal Liberation* and the so-called father of the animal rights movement — as "a defender of animal rights" would be to rely on the broadest possible interpretation of rights-claims. All interests, costs, and benefits are to be weighed equally, and none are set aside for special protection. Joel Feinberg (44) and James Rachels (45) have also defended broad versions of an "animal rights thesis." Tom Regan, as we have seen (8), defends a more stringent and radical rights-based position on which animals have rights in the narrow sense.

In using a broad concept of rights, when people say "animals have a right to be treated humanely," they usually mean only that it is morally wrong to treat them inhumanely, and it is wrong because of the harm to the animal, not just the indirect harm caused to other humans. Understood this way, the position is eminently reasonable, and not necessarily based on any confusion, misunderstanding, or radical propaganda. Accordingly it does not represent a position to be opposed but rather a welcome opportunity for dialogue and better understanding.

When considering the claim that attributing rights to animals is "eminently reasonable," it is important to keep in mind that neither the broad nor the narrow concept of rights *entails* any assumption of equality between animals and humans. Consider, first, the narrow account of rights: Rights bestow a special sort of protection that cannot be overridden by appeals to a greater general good. There is nothing inconsistent in claiming that an obligation to allow an individual to express her political views cannot be overridden (i.e., she has a right to free speech), but her license to vote or drive a car may be revoked or denied for the greater good. We routinely deny both privileges to children on the ground that their immaturity would render their driving or voting harmful to society. Similarly one can, without any inconsistency, argue that animals have the right not to be tortured without thereby being committed to the claim that they have the right not to be killed. Even when the same right is ascribed to two different individuals, narrow views must and do recognize that one such special claim may be stronger than another, or that if only one can be respected, one has an objectively stronger status. Thus, two people may both have the right to inherit someone's estate — a right that cannot be overridden by the fact that more good might be done by distributing the wealth to agencies that would further the public good — and we can still, in many cases, decide that one right is stronger than another. Similarly, even if one argues that both a dog and a human have the right to life, one might legitimately conclude that the human's right is the stronger of the two, if one is in a position where only one can be respected.

The broad view of rights is even clearer on the issue of equality. Even a moment's thought will uncover a wealth of examples in which it is wrong to treat one individual in a certain way and perfectly legitimate to treat another in exactly that way. Since the broad understanding of rights-talk would automatically translate such differential judgments into different rights-claims, ascribing some rights to animals cannot possibly entail that they must have all the same rights as humans, or that the rights they do share with humans have equal weight.

What follows from all of this? Since there is often confusion about the meaning of rights-claims, and since concerns for "animal welfare" overlap significantly with at least some interpretations, perhaps these divisive labels ought to be retired in favor of a more precise statement of what is actually being claimed. If this suggestion is too extreme, at least one ought to be careful to interpret them in a more flexible and open-minded way, rather than to polarize the debate.

ANIMALS IN RESEARCH

There are, of course, some sustained defenses of practically all animal research, without restrictions or qualifications

(4,17,26,46,47). Some are quite thoughtful, but others convey the impression of defensiveness. One litmus test is whether such defenses agree that there is room for improvement, and that not all animal research meets the highest ethical standards. Contrariwise, attacks on animal research that claim that no significant gains have been achieved through animal research, or that all such research could readily be replaced by alternatives such as computer models and in vitro testing, also undermine their own credibility. There are, fortunately, well-reasoned and detailed discussions of all aspects of the debate (48–51), carefully stated and well-documented arguments against animal research (52), other works that concentrate on specific controversies such as research involving primates (53,54), useful literature surveys (55,56), and anthologies that try to present a varied selection of views on animal research in particular (57,58) or broader philosophical debates that have direct implications for research (59).

Current Regulatory Structure

The subject of current regulations is complex, and constantly changing. In addition to official documents such as the National Institutes of Health (NIH) Guide (60) and U.S. Department of Agriculture (USDA) regulations, there are more helpful and detailed studies of these regulations (50,61) as well as the reference library maintained by Animal Welfare Information Center (AWIC) and numerous on-line sites, so what follows is only meant as a quick overview.

Since 1985, any institution which receives federal funding and uses vertebrate animals is subject to NIH regulations, as set forth in the *Guide to the Use and Care of Animals*. Institutions that use mammals other than mice, rats, or common agricultural species are subject to USDA regulations. The strictest level of control is the voluntary Association for Assessment and Accreditation of Laboratory Animal Care (AAALAC) International accreditation. To a large extent, these regulations and guidelines overlap one another, and in some cases even reference one another.

A key feature of current regulations is the demand that each institution covered by the regulations must establish an Institutional Care and Use Committee (IACUC). This committee must have at least five members, including a veterinarian, a "nonscientist" (defined more precisely as someone who does not engage in animal research), and someone who is not affiliated with the institution. This committee is charged with reviewing protocols for all research involving covered species, conducting semiannual reviews of all animal facilities, ensuring that the institution is in compliance with applicable regulations and guidelines, and generally providing mechanisms for the monitoring and control of animal research. Institutions vary widely with regard to the way in which these duties are carried out: how large the committee is, how members are selected, whether reviews are done by the entire committee or a subgroup, the type of information and documentation required from investigators, how much of the meeting is open to the public, and so on (62). USDA regulations also provide for the licensing of dealers in research animals, both those who breed animals specifically for research — "Class A dealers" — and those who buy and sell animals, typically dogs — "Class B dealers." One of the goals of this licensing process is to answer the public's concerns, fanned by an article in *Life* magazine in 1966, about pets being stolen to be sold to research labs.

In addition to IACUC oversight, covered institutions are subject to regular, unannounced inspections by the USDA. Although these inspections are supposed to take place twice a year, staffing and funding shortages make this more of an ideal than a reality, especially at smaller institutions. Facilities with AAALAC accreditation are also inspected regularly by an independent group of reviewers, and NIH has the right to conduct its own independent inspections, if it chooses to do so. One shortcoming of all these formal reviews is that while they can inspect facilities, animals being held for research, records, and IACUC minutes, they are rarely in a position to monitor ongoing research directly. Thus, it is difficult to guarantee that approved protocols, and only such protocols, are being adhered to. While it is reasonable to believe that the majority of responsible scientists do follow the protocols for which they have received approval, abuses do occur.

The regulatory system just described applies to animal research in the United States; the Canadian system is quite similar. Elsewhere in the world, regulation of animal research ranges from stricter controls than exist in the United States to nonexistent (63–65).

The Three R's

It has become commonplace in justifying animal research to allude to the "three R's," originally formulated by Russell and Burch (66): reduce, replace, and refine.

"Reduction" refers to reducing the numbers of animals used, consistent with obtaining significant results. The latter is an important qualification, since reducing the number of animals too far might render the results statistically questionable and hence a total waste of animals; indeed, IACUCs sometimes find themselves recommending an increase in numbers for just this reason. On the other hand, the goal of reduction could be significantly furthered if the scientific community and research journals were to rethink their definitions of significance. Particularly for preliminary research, a significance level of 90 percent rather than the typical 95 percent would dramatically reduce the number of animals needed for any given test (67).

"Replacement" refers to using nonanimal models, dead animals, or "lower" species whenever possible. In vitro studies are commonly cited as an alternative, but currently tend to be most practical for initial screening of variations on known compounds. Similarly, computer simulation is valuable only when we have enough information to construct an accurate computer model, and thus may be more useful for education than for exploratory research (68,69). The criteria for ranking animals in terms of higher/lower also needs closer scrutiny; it can often mask cultural preferences rather than any objective standard. Thus dogs are often deemed "higher" than pigs, and NIH singles them out, along with cats, primates, and

endangered species as worthy of special status, but there is no clear physiological, evolutionary, or psychological evidence for this distinction. In short, while the injunction to "replace" might be a useful maxim, its application is quite problematic.

Thus, while reference to the three R's has become almost obligatory, it is not at all clear that they still provide useful guidance. As just noted, there is much dispute about the practical applicability of the injunctions in specific protocols, and a general lack of theoretical clarity (70). More work on this topic by both scientists and ethicists is clearly needed.

Teaching and Testing

The strongest arguments in favor of research on animals point to the furthering of basic scientific knowledge or biomedical advances. These arguments are much less convincing when applied to the use of animals in teaching and testing (71). The dividing line between any two of these areas may be fuzzy. Is the lab work of a first-year graduate student teaching or research? When in the process of developing a new drug do we switch from research to testing? Nonetheless, looking at paradigm cases of teaching and testing is necessary in order to have a complete picture of the use of research animals.

When animals are used in the classroom, they are typically described as serving one or more of three purposes: (*1*) as an illustration of a process, event, or state; (*2*) as part of a project designed to help students learn proper research design and practice; (*3*) to allow students (e.g., veterinary students) to learn proper surgical or other techniques.

"Illustration" can range from observation without intervention — keeping a gerbil in an elementary school classroom, or watching a tadpole develop into a frog — to demonstrations of acute medical or pharmacological emergencies — infecting a dog with distemper so that veterinary students can observe the progression of the disease, or dosing a rat with cyanide so that pharmacy students can see the symptoms, and the efficacy of various antidotes. Dissection, particularly at the secondary school level, often falls into this category, as does the use of animals in most science fair projects. Those who use such illustrations often defend them by claiming that a live demonstration or actual dissection is a more vivid and effective teaching tool than a textbook illustration or other alternative; it engages the students more. However, the results of those procedures which are invasive and often painful are almost always known ahead of time, unlike the case of basic research. Videotapes, computer programs, and textbook illustrations can all contain the same information. In the face of the suffering and death that more invasive illustrations cause, appeals to students' interest or attention spans seem trivial. Moreover, such demonstrations can have, either deliberately or inadvertently, a desensitizing effect, conveying to students that animals are mere research tools whose suffering should not overly concern us. This desensitization can develop even in the apparently benign case of having an animal in an elementary school classroom. If children are allowed to handle, observe, or otherwise interact with animals without due understanding of the stress this might cause, or if the issue of animal care over weekends and vacations is trivialized, they may easily pick up a casual, noncaring or nonrespectful attitude toward animals.

As noted above, the dividing line between basic research and testing can easily become blurred. Testing is also easy to trivialize: It is easier to dismiss the claimed need to test the safety of a new mascara than the development of a new treatment for stroke victims. However, many of the basic factors determining toxicity, carcinogenicity, and inflammation are well enough understood that in vitro studies (and, in a few cases, computer modeling) can be substituted. The Johns Hopkins Institute for Alternatives maintains current data on such substitutes. Even when these alternatives are not conclusive — for example, because they fail to fail to detect effects at an organic rather than a cellular level — they can be useful for initial screening. The most infamous tests, including the Draize test and the LD-50, are gradually being replaced by alternatives that use no living animals, or fewer animals in a less invasive way. The Draize test involves inserting the substance to be tested for irritancy into the eye of a rabbit who has been immobilized in a "stock," and then observing changes in the eye over a period of days. Various in vitro tests, or the use of chicken eggs, have often served as reliable alternatives. The use of computers for more sophisticated statistical analysis has allowed researchers to replace the crude LD-50 test, in which increasing doses of a material were given to colonies of mice or other animals until one found the level at which 50 percent of the animals died, with other tests that required fewer animals and did not always use death as an endpoint. Despite the availability of these advances and alternatives, animal testing remains an area in which many advances in animal welfare are still possible.

Continuing Issues

Of course the fundamental continuing issue is when, if at all, animals should be used in research. While many of the relevant arguments have been discussed in the previous section on theory, it will be useful to see how they apply specifically to animal research. Other continuing issues focus more specifically on current regulations and the general contemporary research environment: how well do they provide appropriate protection for the animals (72)?

Another continuing issue reflects society's (including many scientists') demand for a further increase in our moral sensitivity in animal research. The most obvious trend in social pressures is reflected in the growing popularity of animal protection groups, ranging from the radical People for the Ethical Treatment of Animals (PETA) through the more moderate organizations such as the American Society for the Prevention of Cruelty to Animals (ASPCA) or Working for Animals Used in Research, Drugs, and Surgeon (WARDS) whose aim is not total abolition of animal research. More precisely, the moderate groups hold that the use of animals ought to be abandoned when and where it is possible to do so (would any researcher disagree?), but they are more likely to agree with the scientific community about the

fact that the range of productive alternatives is today quite limited, thus accepting that animal research must continue for the foreseeable future. In terms of the three R's, moderates tend to see "refine" and "reduce" as more effective immediate options than "replace" — although they are likely to encourage further research on the development of alternatives. In terms of our categories of views about the moral status of animals, radical groups are generally liberationists while moderate groups at least implicitly adopt a differential perspective. The existence of this range of views within what is sometimes called the protectionist movement again illustrates the danger of the "animal rights/animal welfare" dichotomy discussed earlier. If the scientific community insists on viewing all protectionist groups as radical "animal rights people," opportunities for fruitful dialogue and identification of common ground can be missed.

When fruitful dialogue is possible, and common ground is identified, another trend that is just beginning may blossom. This refers to the increased efforts among scientists and regulators to address ethical issues explicitly and directly, with attention to the general moral principles which underlie our decisions about research on animals can and should be conducted (73,74). The American Association for Laboratory Animals (AALAS), the American Veterinary Medical Association (AVMA), the Animal Behavior Society, and the Scientists Center for Animal Welfare are but a few of the professional societies that have included sessions on ethics at their national conferences. This is in marked contrast to earlier, more polarized efforts in which scientists — sometimes with little background in ethical theory — took it upon themselves to demonstrate exactly what was wrong with animal rights, objections to research on animals, or Regan or Singer. By contrast, the efforts mentioned above represent a collaborative effort to formulate and evaluate the various ethical theories and principles that shape (well or badly) specific choices and regulations about animal research. Such collaborative efforts can give us a more solid grounding from which to address some of the more vexing specific questions about the current state of animal research and its evaluation: Should dogs, cats, or primates be singled out for special protection (as they are today), and if so, why? Should rats, mice, birds, or agricultural animals be excluded from USDA regulations, and why or why not? To what extent must considerations of scientific merit be blended with ethical issues, including but not limited to, IACUC reviews and journal publication criteria? After all, one cannot do a cost–benefit analysis of the sort required by NIH and USDA without some consideration of potential benefits (75).

On the Horizon

Crystal balls are notoriously unreliable, but some future trends are already apparent. Two major social influences on the future use of animals in research are apparent, and they pull in opposite directions. As indicated in the previous section, increased public interest in the use of animals will almost certainly demand that the scientific community continue searching for alternatives to whole animal models. At the same time an increased interest in maintaining good health, especially in an aging population, drives demands for more research on diseases and aging. This apparent inconsistency provides scientists with the opportunity to drive home an essential message: Given the current state of biomedical research, studies will require the use of animals, but such studies can and will be done with ever-increasing sensitivity to the welfare of the animals used.

The largest unknown quantity is the rapidly increasing power and impact of biotechnology and genetic engineering on animal research. Currently the most obvious effect is the ability to develop animal models to aid in the study of human diseases such as cystic fibrosis, Lesch-Nyham's disease, and some forms of cancer (OncoMouse) (76). This raises two sets of issues: The first is simply a new variant of an old problem, and the other poses new problems for researchers, IACUCs, and regulators. The old issue is that of deliberately producing animals with health problems that can sometimes be chronic, debilitating, and painful. While genetic engineering has made it possible for us to produce animals with some new diseases, old-fashioned selective breeding has long been used to produce animals with other equally serious problems. The new issues are that genetic engineering can result in animals that (*1*) have unpredicted, perhaps unpredictable, health and welfare challenges, (*2*) are often considered much more valuable than "standard" animals of the same species, and (*3*) heighten public fears about scientists "playing God" or tampering too much with the "natural" order of things (77).

The variation of the old problem — caring properly for animals that have, or are expected to develop, severe health problems — is related to genetic engineering only insofar as biotechnology affords the possibility of producing animals with diseases hitherto unknown in a given species. This poses important ethical problems for both researchers and IACUCs. The first is when it is justifiable to produce such animals at all, rather than using alternative forms of research such as epidemiological studies of naturally occurring incidents of the disease. Second, one must consider whether the effect on the animals' welfare will require special care — such as different housing or diet, more frequent monitoring by caretakers or veterinarians, or a prescribed regimen of analgesics. While standard procedures are designed to protect an adequate level of welfare for normal animals, they can be inappropriate for animals specifically bred to develop a chronic health problem. This poses a special burden on IACUCs and responsible veterinarians, who must be informed enough about special needs to ensure that those needs are met. Finally, one must consider the problem of identifying an ethically acceptable endpoint. Using death as an endpoint for a procedure, or even waiting until an animal becomes moribund before terminating the procedure and euthanizing the animal, always requires careful scrutiny and detailed justification, but when the research involves chronic, severe, or terminal health problems the issue of determining the appropriate endpoint, and who is responsible for making the necessary assessments, must be fully addressed at the outset.

As noted earlier, the moral questions just described are not unique to genetically engineered animals, even though

biotechnology increases the ability to create animals who are likely to develop a targeted health problem. Other difficulties are magnified even more by advances in biotechnology. What follows are a few examples of problems that have been anecdotally identified; there is a definite need for more carefully controlled studies in this area.

One often-noted difference between genetically engineered animals and those produced through traditional methods of selective breeding is that genetically engineered animals often tend to develop unanticipated phenotypic effects, not obviously related to the desired effect. Some of these effects, ranging from severe joint problems in the "Beltsville pigs" to lack of maternal instinct in mice bred as models for Lesch-Nyham's disease, have a direct impact on animal welfare and ethical concerns about whether such animals should be produced. Second, genetically engineered animals are viewed as more valuable than standard laboratory animals, if only from the standpoint of production costs; this can have both a positive and a negative impact on ethical deliberations. On the positive side, more valuable animals are likely to get more intensive care. On the negative side, researchers with a considerable investment in genetically engineered animals may be more reluctant to terminate a study or euthanize an animal on the basis of welfare concerns that do not coincide with research goals. Once again, this poses ethical challenges for both the researcher and the IACUC that must evaluate and monitor the protocol.

The final concern about genetic engineering, usually expressed as "playing God," is unfortunately too often not very well articulated, which makes the ethical concerns hard to assess. However, it is often likely to focus on research that involves introducing human genetic material or patterns into animals. When such research is specifically targeted — such as aimed at developing pigs whose organs can be used for transplantation into humans, or goats whose milk contains hormones useful for treating human diseases — such concerns seem less apparent. Whether or not "playing God" represents a legitimate ethical objection to genetic engineering, it is surely an area in which the research community must improve communication with the public.

RESEARCH ON ANIMALS, ETHICS, PRINCIPLES GOVERNING RESEARCH ON ANIMALS

JOHN KLEINIG

New York, New York

OUTLINE

INTRODUCTION

Research using live animals goes back at least as far as Galen, though it was not until the rise of medicoscientific experimentation in the seventeenth and eighteenth centuries that the use of live animals in research became systematic (1). In the past half century the increasing professionalization of research and practice and the growth of product-safety regulation have led to their prevalent use in education and product testing.

From its very beginning the practice of live animal research (or, now inaccurately, vivisection) has attracted controversy, even among those who have defended it. At one end of a wide spectrum are those who have wished to apply to animals the whole range of moral entitlements and protections that govern experimentation with humans. At the other end are those who would ascribe to an animal's cries no more moral significance than one would to the noise made by a squeaky door. Informing this vast range are metaphysical, epistemological, and moral

positions that are too complex and controversial to be resolved in the space of a single article.

Most who give the matter consideration would now acknowledge that nonhuman animals make some moral claims on us, even though there are serious disagreements over the nature and extent of those claims (2–4). Should we eat animal flesh? Does the domestication, transgenic breeding, and cloning of animals interfere with their natural integrity? Is hunting morally acceptable? But nowhere are the moral questions more troubling than in the domain of scientific research, experimentation, and testing. For here important values often seem to be in tension, and no simple formula for their resolution appears to be available (5–8). Whereas, in the case of humans, we can at least constrain our endeavors by appealing to the informed consent of research subjects, this is not a serious option in the case of nonhuman animals.

Furthermore, producing ethical guidelines for animal experimentation is not like producing guidelines for the withholding or withdrawal of lifesaving treatment from human beings. Complex though the latter is, there is sufficient congruence of both ends and means to allow the formulation of a reasonably explicit and manageable structure of benchmarks and stipulations for the guidance of those with whom such decisions will lie (9). In the case of animal experimentation, however, such is the plurality of ends and means, not to mention the diversity of subjects, that any general guidelines are likely to be unhelpfully vague or very limited in their application. Participant observation of animals in the wild, genetic experimentation with *Drosophila melanogaster*, and toxicity testing using laboratory-bred rats differ so much in their character and in the specific ethical questions they raise, that no single set of guidelines is likely to be fully responsive to the ethical issues that should be addressed. This is not to gainsay the value of the guidelines that have been produced in recent years (10–12), but it identifies one source of the dissatisfaction they have engendered. At the very least it mandates a plurality of guidelines.

MEANS AND ENDS

The alternative to comprehensive and exhaustive guidelines need not be an absence of moral moorings or of a structure of moral questions that would allow the ordered assessment of animal experimentation and its associated practices. The inadequacies of guidelines need not bespeak the absence of guidance. Indeed, animal experimentation of whatever kind has the form of a means–end relation, and there are established procedures for assessing such relationships. True, there are some very basic questions concerning the moral status of animals on which we are culturally confused and for which there exists no theoretical moral consensus. And these, along with more general theoretical controversies in ethical theory, will continue to bedevil our deliberations. Nevertheless, an ordered structure for identifying and responding to these issues is available and may be articulated as a framework for both primary ethical deliberation and the secondary development of specialized codified guidelines.

To be ethically acceptable, practices that involve a means-end relation must address and perform satisfactorily in relation to each of the following five questions: (*1*) Is the end morally acceptable? (*2*) Are the means appropriate to the end? (*3*) Are the means likely to realize the end? (*4*) Are the means proportionate to the end? and (*5*) Will the means undermine other good ends? Question 1 recognizes that ends, no less than means, need to be scrutinized. Question 2 acknowledges that what may be employed as means may be inappropriate to the end. Question 3 assumes appropriateness, but focuses on the probability that the end will be established. Question 4 allows that the means may establish the end, but it addresses the costs of achieving it. Question 5 concerns itself with external costs — those wider social costs that an institution or practice may have. Although — as will be clear from the discussion that follows — this menu of questions does not represent a simple checklist, in which the questions can be separately considered and okayed, it nevertheless provides a broadly comprehensive and ordered framework for the organizing of moral deliberation. The commentary to follow, though sketchy, will indicate how these questions can function like a main software menu to systematize ethical reflection on animal experimentation. Each menu item then needs to be accompanied by a further set of pull-down menus. We can order even if not simplify the complexity.

Is the End Morally Acceptable?

Research and experimentation are teleologically oriented activities. A subject is investigated or manipulated in the light of some end. Frequently that end is appealed to as a justifying consideration. Although it is commonly — and properly — asserted that "the end does not justify the means," it does not follow that the end is morally irrelevant to the means. The aphoristic prejudice against *any* justificatory appeal to ends tends to reflect the great significance we attach to autonomy or consent in dealings between human beings, and the general presumption against treating them instrumentally or paternalistically. Even so, that should not obscure the fact that an assessment of ends, and human ends in particular, constitutes a relevant and often important determining factor in the appraisal of human practices. Indeed, as the flip side of our concern that humans not be used merely as means, a focus on ends reflects the importance that we ascribe to them as expressions of human purposive activity.

Animal welfare committees, unlike human investigational review boards, will be guided for the most part by considerations of beneficence, largely unmediated by considerations of justice and autonomy, and in their case the evaluation of ends will assume greater significance. To assert this is not to deny that research animals may have ends of their own, or that their ends may not be genuinely competitive with human ends (see question 4), but it acknowledges the considerable justificatory weight that attaches to human ends as human (though not necessarily anthropocentric) ends. If we undervalue such ends, we erode the significance of the very enterprise that allows our questioning of those ends to carry weight.

Even so, we must make important distinctions. Animal experimentation may be directed to a variety of potentially legitimizing ends — the welfare of particular animals or animal populations or species, the welfare of individual human beings or some wider social good, the communication and advancement of human knowledge, organizational profit, some personal benefit to the researcher, and so on. These ends are not exclusive, and they may be given a different value and priority by different researchers, even by researchers engaged in the same series of procedures. And, of course, *we* (the politically potent community) may value some more highly than others. Even if human ends, as human ends, possess an intrinsic value, not all human ends are equally valuable, and some we may think unworthy of human advancement.

Although disagreements about the relative value of ends can make consensus difficult to achieve, we are not left wholly at the mercy or to the vagaries of individual preference. Relevant differentia can be articulated and brought to bear on judgments of priority. For example — though these do not constitute decisive (i.e., lexically ordered) considerations — experimental procedures directed to welfare will generally have better standing than those carried out solely to satisfy our curiosity or to expand or communicate our knowledge; public goods will generally take precedence over private benefits; procedures designed to benefit the subject of those procedures will generally have a stronger claim to our recognition than those designed to benefit others; and human welfare will generally take priority over animal welfare. This is because there is value to benevolence, a communal dimension to value, a special dignity to human life, and an integrity to animal lives that should weigh significantly in our decision making. But these considerations may exist in tension, and it is not possible to read off priorities in a mechanical fashion. Judgments that seek to accommodate them are singular without being arbitrary, and the problem of formalizing them is not peculiar to animal experimentation but reflective of more general problems in the appraisal of human conduct.

Some of the difficulties in making judgments about the relative importance of ends are linked to complexities in the ends themselves. The advancement of human knowledge, for example, may comprehend the satisfaction of curiosity, the exercise and development of our human powers of understanding, an increase in our grasp of the universe and of ourselves within it, and what is sometimes termed "basic research," which, though not directed to some specific application, usually anticipates some later — albeit unspecifiable — usefulness. And where some instrumental benefiting of ourselves is sought, it may be the alleviation or cure of some disease–mild or serious, rare or common, self-induced or unwittingly contracted — some positively enhancing, recreational, labor-saving, or aesthetic end, or some preventive or protective social goal. The possibilities are legion and jointly pursuable, and animal researchers will need to give some detailed account of them. Guidelines that differentiate and categorize ends may assist in this task, even though judgments about their relative importance will require the more sensitive deliberative scrutiny that a review committee may be able to provide. Even then, there is a serious practical problem posed by the fact that the interests of animals can be represented only by proxies who may not be sufficiently sensitive to them.

The fact that different researchers in a single project may have different priorities and may even be in pursuit of different ends highlights one of the difficulties involved in the evaluation of practices independently of their practitioners, and in the development of social policy. Otherwise, justifiable projects may sometimes be compromised by the unworthy, questionable, or only moderately worthy ends of those who engage in them. Dissertation research, the testing of commercially redundant substances whose marketing is designed only to give a company increased profitability, and the development of biological weaponry can represent the compromise or perversion of otherwise justifiable research agendae. Such ends may not justify the moral costs they involve. Unfortunately, we are not usually able to peer into the hidden motives of researchers to determine whether their private motives match their publicly asserted intentions. And social policies can achieve little more than a monitoring of formally stated ends.

As noted earlier, ends, though relevant to the justification of means, are not usually sufficient to justify them. The appropriateness, efficacy, proportionality, and character of the means also need to be taken into account. Means have a "life" of their own which needs to be considered, not just as they are associated with particular ends.

Are the Means Appropriate to the End?

However worthy ends may be, unless the means used to further them are appropriate to their realization, they will fail to provide the justificatory support expected of them. This is particularly important for the use of animals in scientific research, which imposes exacting demands on experimenters if their results are to be valid and reliable.

Experimental design is often viewed only in relation to scientific validity, and the determination of scientific validity is frequently thought to be independent of moral considerations. That, however, is an oversimplification. For one thing, unless an experimental procedure is suited to the realization of scientifically valid results, it will be inappropriate to the ends to which it is supposedly directed, and any justificatory value those ends might have possessed will be forgone. Moral costs will remain uncompensated. Moreover, and more fundamentally, decisions about the level of significance that will be required of experiments involving animals need to take into account the importance of the ends to which the experiments are directed, and the moral costs in suffering or other deprivations that will be caused. The decision to require a p value of .01 rather than, say, .05, has implications for sample size, the level of control that is exercised over variables, and so on, decisions that inevitably confront the researcher with the costs that will be involved in his or her inquiry. In other words, what appears to be only a matter of scientific validity will also involve issues of moral acceptability.

One of the common complaints about experimental procedures involving animals has been that researchers treat their animal subjects in ways that compromise the validity of their results. Rough handling, poor housing, and generally inadequate control over extraneous variables may jeopardize experimental integrity and give rise to misleading or worthless results. Animal life is wasted, needless suffering may be caused, and scarce resources are squandered. The training of those who are to handle experimental animals must encompass not only issues of technique but also sensitivity to the ecology of animal lives. Much of the current concern over experimental conditions was generated as a result of a 1984 raid by the Animal Liberation Front on the Regional Head Injury Center of the University of Pennsylvania, and the subsequent circulation of stolen videotapes by People for the Ethical Treatment of Animals as *Unnecessary Fuss*. Here, worthwhile ends were needlessly compromised by the careless and callous attitudes of researchers and their assistants (13).

But validity is not affected only by careless treatment of the animal subjects. Sample size, species selection, and other elements of research design may also have an important bearing on the credence to be given and conclusions to be drawn from experimental results. The debate over using pound as against purpose-bred animals turned in part on the extent to which the use of one rather than the other would introduce uncontroled variables. And where animal research is intended to have implications for other species or for human beings, there needs to be some assurance that the experimental subjects are similar in relevant respects.

This latter concern is particularly intractable. The evolutionary theory that may seem to allow for some continuity between humans and animal species, such that research results gained from one can be applied to the other, can also cut the other way and be used to suggest that there now exist fundamental discontinuities and that the validity of using animal research for human welfare ends is problematic. Although I think these difficulties have been exaggerated, they are not without force (7). Moreover, how high the probability of transferability needs to be may depend in part on other considerations, such as the importance of the end. The use of simian immunodeficiency virus (SIV) to research AIDS was fairly speculative, but in view of the seriousness of the AIDS problem, there was more to be said for it than would have been the case had the problem been less pressing.

One of the continuing moral dilemmas of human-oriented animal research is the need to affirm two propositions: (*1*) research animals are sufficiently like humans to allow reasonable inferences to be drawn from data involving one for the other; and (*2*) research animals are sufficiently unlike humans to justify (morally) our using them for experimental purposes. The two propositions need not be in tension, though the possibility that they are in any particular case must always be considered.

But even the most rigorously designed and monitored experiment is likely to have little to be said for it if there is a very low probability that the data it yields will advance the end it is ultimately intended to serve.

Are the Means Likely to Realize the End?

Though it is true that a number of significant scientific breakthroughs have been the outcome of happenstance and guesswork more than careful planning, such serendipitous occurrences cannot be appealed to as a substitute for the requirement that researchers make some case for the *likelihood* that their investigation will advance the ends to which their work appeals.

Likelihoods of course are always somewhat speculative, and will vary, and so will increments in knowledge and the advancement of particular ends. There is no measurable probability or simple likelihood of success to which all experiments should be required to conform. The degree of probability that might be expected of a particular project will depend on a variety of factors, such as the importance and/or urgency of the ends, the costs in animal life and suffering, the scarcity of resources, and the availability of alternatives.

Trade-offs between these factors are not easy to craft and require a well-rounded sensitivity. Although moral decision making is not a matter of numbers, one of the arguments for requiring committee approval of protocols involving animals is that the diverse interests involved may not otherwise be adequately represented. In theory at least, representative animal care committees (Institutional Animal Care and Use Committees) may provide an environment for the articulation and rational balancing of interests.

The reasonably expected likelihood of an end's furtherance will also depend on the level of research already undertaken. Some experimental ground has already been so thoroughly explored that the likelihood of new discoveries is very slight; other territory may offer only theoretical possibilities, with (as yet) relatively little empirical data. In some cases the more ambitious protocol may be preferable to the conservative one.

Are the Means Proportionate to the End?

Where good ends are sought, and enter into the justification of means, the costs incurred by those means have to be entered against the goodness of the ends. An experiment directed to and likely to advance a good end may nevertheless be unacceptable because its costs are disproportionate to the goodness of the end. Ends are not privileged with respect to means.

In this context, "costs" include not only straightforwardly economic or utilitarian costs, but what we can more broadly term "moral costs" — including the loss or abridgement of certain values, in particular, the value attaching to a life that is allowed to flourish free of burdensome constraints. The tasks of determining and arbitrating between these costs can raise the most intractable problems for judging animal experimentation.

Experiments involving animals may intrude on them in various ways: They may be killed, but even if not, their "lives" may be disrupted or constrained, and pain/suffering may be caused them. Although animals will obviously differ in the sophistication of their lives, we should not disregard the fact that such lives as they have possess an integrity and intrinsic value not entirely disanalogous to

the organic integrity and value that is possessed by human bodily life. A functioning organism cannot be reduced to a normatively neutral complex of chemical interactions, but is distinguished by an organic *telos* whose invasion should generate justificatory questions. In assessing such intrusions, not only should the immediate experimental protocol be taken into account, but also the costs incurred by housing and care, aftercare, and the destruction of natural environments or social bonds.

Finding an adequate moral language in which to cast these discussions is not easy. That many — albeit not all — (experimental) animals can experience *pain* is not generally disputed, though the extent to which those animals can *suffer* is somewhat more problematic. We might differentiate pain from distress, discomfort, anxiety, and fear, recognizing that each makes different assumptions about the capacities of its subject, and that some animals will be capable of experiencing some but not other kinds of such suffering. Furthermore, whether such pain and/or suffering should count morally for the same as human pain and suffering is even more problematic. There is little doubt that part of what is problematic about causing pain and suffering to humans is the way in which they tend to subvert autonomy and its fruits, and this is not likely to be an issue in (most) animal experimentation. Whether or not it is an issue is reflected in (thought not simply resolved by) debates about whether animals possess "interests" and/or "rights," and whether we have duties *to* them or simply *regarding* them.

The point of these debates is not usually to establish whether we owe animals any moral consideration, but to decide what kind of consideration is appropriate, and — remembering that we are not involved in a simple consequentialist calculus — to determine how weighty it is with respect to the various human interests that might be realized in experimentation. Even if it is argued that human interests, by virtue of their origination in deliberative activity, have morally relevant features that animal interests lack, it does not follow that every human experimental interest will take priority over any animal interest. One of the common complaints about the Draize test (in which potential irritants are tested on the eye tissues of animals) has been that the cost in animal pain/suffering often far exceeds the worth of adding a new product to an already well-supplied market. Human interests, no less than animal welfare interests, must be scrutinized and ranked.

Problematic though these judgments are, we should not assume too quickly that they are impossible to make. Insofar as the evaluation of alternatives is an enterprise undertaken by practical decision makers, it is ultimately up to *us* as decision makers, as rational beings and normative agents, to determine how much weight we will accord to environmental and/or social destruction as against physical pain, and how important these are with respect to the advancement of knowledge or human welfare. Contrary to those who see something fatally anthropocentric in such judgments, the perspective of those who have to take responsibility for what they do is the only appropriate perspective to take.

Although judgments of proportionality are in some ways too complex to allow of simple codification and commensurability, some assistance to researchers can probably be provided by setting out in a roughly ascending order different degrees of intrusiveness (taking into account not only the kind of intrusion caused, but also its intensity, duration, relievability, and so forth), cross-referencing it with different levels of animal complexity. Human ends might be similarly ranked, taking into account such factors as urgency, whether long- or short-term, those likely to be benefited, whether the ends to be served can be served in other ways, and so on. Some have complained that many of the human medical problems to whose alleviation much animal experimentation is directed are the result of voluntarily adopted lifestyles, and that lifestyle changes would not be an unreasonable expectation (albeit not, perhaps, a sufficient reason for refusing to engage in animal experimentation): The costs to animals, along with others, might be incorporated in a motivational package addressed to the problem of "unhealthy" lifestyles.

In one of its associated expressions, the proportionality requirement mandates the use of the least costly alternative consistent with the ends being realized. Using 200 experimental animals when 100 would do, using experimental animals when computer modeling or tissue cultures would do, causing pain and stress when the use of anesthesia would not compromise the outcome, using untrained animal handlers when experienced handlers would cause less animal distress, and so on, all represent abuses of the proportionality requirement, since there is a less costly way of achieving the same end. The so-called "three Rs" of animal experimentation — replacement, reduction, and refinement (14) — express this dimension of the proportionality requirement.

Some judgments here may be very difficult to make. It may, for example, be hard to determine whether or not the multiple use of single animals is to be preferred to the use of fewer procedures on more animals, or how the "costs" of using pound animals are to be assessed against those of breeding animals specially for experimental purposes. Do numbers count, as well as the amount of suffering? And how do we factor in the production of transgenic animals for experimental purposes? If an animal is bred to be disease prone, does this constitute a violation of species integrity, or does the new animal now have a natural end that makes experimental procedures (e.g., the testing of anticarcinogenic agents) more acceptable? Does the patenting of such animals provide some control over their use, or does it take us too far in the direction of an unacceptable commodification of animals, in which we come to see them as *no more than* commercially exchangeable tools?

Will the Means Undermine Other Good Ends?

Even if the ends to which an experimental procedure is directed are eminently worthwhile, and the procedure is appropriate to those ends and likely to advance them, and even if the direct costs of the procedure are proportionate to the ends sought, there may be other dimensions of its implementation that need to be taken into account and ranged against it. Sometimes, in pursuing one end, we

may undermine or jeopardize other ends to which we are independently committed.

Although it would need to be supported by data rather than merely conjectured, the claim that some kinds of animal experimentation tend to brutalize or barbarize researchers suggests how the pursuit of some worthwhile ends — say, human health — might undercut others — say, civilized sensibilities (15,16). One of the deeper anxieties that fueled nineteenth-century opposition to animal experimentation was concern at the dominance of science and its arrogant oligarchy of expertise, the depersonalization of social decision making, a growing detachment from the world of nature of which we are a part (17). It has been followed in the twentieth century by criticisms of human selfishness and profiteering, our concern with self-indulgence and self-advancement without regard to the costs for other living things (18).

A better documented example of the undercutting of other ends might be the effect of primate research on the persistence of an endangered species. The integrity of a species and the value of species diversity may be compromised if primates are used — or used without regard for their survival — for research into cancer or AIDS. Of course, as we noted earlier, ends themselves may be amenable to ranking, and it would not follow merely from the fact that a means of pursuing a good end would subvert another that it should be eschewed. Nevertheless, our consideration of costs should not be limited to those directly associated with the experiment at hand.

Serious though the foregoing claims are, like all claims they have not gone unchallenged. Researchers may just as easily see their activity as one of responsible stewardship rather than one of arrogant domination: the knowledge gained in animal research is seen as serving the good of human and animal well being, a task that falls to humans because of their unique endowments (18).

The resolution of such conflicts is unlikely to be a simple one. Like most human activities, from sport to road building, animal research is likely to be attended with larger social costs, whatever its benefits, and it will behove us to address them as they arise and seek to ensure that they do not fall victim to the political sloganizing that has characterized much of the current debate.

INSTITUTIONALIZATION OF JUDGMENT

In view of the complex nature of the ethical questions confronting the use of live animals in research, a two-part process for evaluating such research can be proposed. The first will consist in the development of formal guidelines for experimentation and research, guidelines that are sufficiently specific to the ends and subjects of the research to avoid the charge of vagueness. Guidelines might, for example, be developed that will be specific to field research (19–22), to biomedical experimentation (10–12), to product testing (23), and to education (24,25), as ends that will tend to generate different requirements and different questions. A further subdivision might have regard to the animals involved, taking into account levels of consciousness, social ecology, replaceability, and so on. Such guidelines will then address questions of intrusiveness with regard to these various "structural" factors.

It is most likely that such guidelines will be seen as the responsibility of national, international, or professional bodies — bodies with a wide enough representation and jurisdiction to ensure not only that a broad spectrum of opinion has been canvased but also that the resultant guidelines will possess the public standing that will allow them to be used as a meaningful standard in holding researchers accountable, whether by assessing eligibility for funding or by informing legal standards of proper use and handling.

Beyond that, however, there will need to be an informed and sensitive application of these guidelines to specific research protocols, and this might be best achieved through the activity of an Institutional Animal Care and Use Committee (IACUC), in which the various interests at stake in animal research may be represented. The task of an IACUC will not be to apply the guidelines in a formulaic or algorithmic manner but to make a judgment, in the light of the guidelines, about the ethical acceptability of a proposed research study or whether existing research facilities meet acceptable standards for animal care. This is important: Bureaucratic guidelines are almost always too crude for the purposes for which they are drawn up (18).

The role of IACUCs is disputed. Some believe that they should provide no more than scientific assessments of research protocols, and even those who believe that their mandate should extend to ethical questions often wish to limit that questioning to means — ends being seen as given — or to questions of general institutional policy. It is argued that the use of IACUCs to monitor specific protocols and even day-today institutional practice allows judgments to made by the inexperienced, diverts valuable resources from research, overburdens the monitoring system, and restricts academic freedom (26). Although these objections are not decisive, they warn that where the power of an IACUC is considerable, there is a corresponding responsibility on the part of institutions to ensure that their memberships are wisely constituted and adequately resourced (13).

Here too, some national guidelines might be appropriate to ensure that the representation of IACUCs does not too easily fall prey to the political winds that often affect even scientific research. Some effort should be made to ensure that the concerns of animal advocates are represented as well as researchers, and that wider public concerns about both scientific research and animal welfare are allowed voice.

Neither the provision of guidelines nor the approval of an IACUC will guarantee that good decisions are made, but they probably represent the best formal steps that fallible and contending humans can take to reach acceptable solutions.

CONCLUSION

The structure of moral deliberation proposed in this article has the merit of providing a framework of questions that forces to raise the basic issues that need to be confronted by

researchers wishing to engage in animal experimentation. In its broad outlines, the structure is both comprehensive and rich. It is comprehensive in that provides for all the morally significant questions to be asked. It is rich in that it allows these questions to be pursued at different levels of generality.

It does not, however, provide a simple procedure for cranking out answers to questions that demand sensitivity and judgment more than formulae. There is great diversity in the ends and subjects of animal experimentation, and researchers in each kind of experimental situation will need to determine that situation's moral ecology before they will be able to grapple with the difficult judgments that will often have to be made. Nor does the general structure provided come with ready made "pull-down" sub-menus. There is little doubt that those sub-menus provide the sites for some of the most difficult and intractable problems.

Nevertheless, this article proposes that within each domain of research — basic research, field research, medical research, product testing, and so on — researchers construct a series of fairly specific questions they will need to ask themselves, based on the general questions canvassed in this article. These questions could then take into account the more particular ends being pursued, the kinds of animals likely to be involved, the costs likely to be encountered by that research, and so forth. If the responses to these questions are then considered by an animal welfare committee or IACUC whose membership is collectively capable of appraising the social value and scientific merit of the proposed experiments, as well as representing the various animal and human interests involved, this might come as close as what can expect to come to a balanced judgment on an issue that will continue to challenge the quality of our moral perception.

RESEARCH ON ANIMALS, LAW, LEGISLATIVE, AND WELFARE ISSUES IN THE USE OF ANIMALS FOR GENETIC ENGINEERING AND XENOTRANSPLANTATION

F. BARBARA ORLANS

Washington, District of Columbia

OUTLINE

INTRODUCTION

A new industry has emerged in recent years that uses laboratory animals in ways that have never before been tried. Animals are used as experimental subjects of studies involving genetic manipulation in which there has been a deliberate modification of the genome — the material responsible for inherited characteristics — to produce genetically modified animals or sources of organs and tissues for transplantation into humans (xenotransplantation). Mice are the most-used species in transgenic studies; pigs are the preferred species for xenotransplantation. As a result of these novel technologies, new animal welfare issues have arisen. There is public concern about the sheer increase in the numbers of animals used, the potential increase in animal suffering, and new forms of exploitation of animals. Existing legislation is not able to give these subject animals the quality of consideration and degree of protection to which they are entitled. U.S. federal laws, last amended in 1985, fall behind the current need for protecting the welfare of these animals. For instance, areas of concern are that mice are not included under the Animal Welfare Act, adequate limits are not placed on the invasion of the integrity of an animal, pigs are confined in limited space and barren environments, and more training of laboratory personnel is needed in clinical monitoring of animal pain and distress.

ANIMAL PROTECTIVE LEGISLATION

Two U.S. federal laws govern the use of laboratory animals in biomedical research. The first, now called the Animal Welfare Act (AWA), was passed in 1966. It required registration of animal research facilities with the United States Department of Agriculture (USDA), federal inspections, and the humane treatment and care of certain species of animals (dogs, cats, nonhuman primates, rabbits, hamsters, and guinea pigs). In 1970 Congress changed this wording so that additional warm-blooded species could be included as determined by the Secretary of Agriculture. Any future changes in what species were included would therefore be up to USDA to announce in its rule making. But no action was taken and numerous other animals were left unprotected. Strengthening amendments to the AWA made in 1970, 1976, and 1985 required the use of pain-relieving drugs, the establishment of Institutional Animal Care and Use Committees (IACUCs) to oversee compliance with the regulations, and promotion of psychological well-being of primates (1).

A second mechanism of control emerged in the 1960s covering the practices of grantees of the National Institutes of Health (NIH), which is part of the Public Health Service (PHS). NIH had provided federal grants for animal experiments since 1946. In 1963, in an effort to forestall the increasing efforts to establish federal legislation, NIH published for the first time voluntary guidelines called the *Guide to the Care and Use of Laboratory Animals* (commonly called the NIH Guide). Under the Health Research Extension Act of 1985 (P.L. 99-158), the NIH Guide is no longer a "guide" but law, and it now covers all federal agencies (e.g., the Department of Defense) and not only PHS. It is now called the Public Health Service Guide for the Care and Use of Laboratory Animals (2). In the 1960s these publications dealt only with husbandry standards — minimal caging size, sanitation, nutrition, and the like. Over time the scope of these publications has broadened to include provisions on experimental procedures as well.

Thus became established the two primary mechanisms for maintaining standards that continue to this day in the United States — AWA and its amendments administered by the Animal and Plant Health Inspection Service (APHIS) of USDA, and the policy of NIH/PHS administered by the Office for Laboratory Animal Welfare, (previously the Office for the Protection from Research Risks) of NIH. These laws and subsequent rule making govern the current conduct of animal research. The two oversight mechanisms cover different constituencies, although there is overlap in their purview. Recent efforts have been undertaken to make the provisions of each compatible with the other.

Funding for enforcement of AWA by USDA has always been a problem. USDA is required to inspect research facilities, dog and cat dealers, and zoos, since these are all covered under AWA. When AWA was first passed in 1966, an appropriation of $300,000 was barely achieved. Annual appropriations rose slowly for several years, but from 1992 to 1999 the appropriation has remained static at $9.2 million. (This compares with a congressional appropriation of over $17 billion to NIH for biomedical research in fiscal year 2000. NIH grants comprise an important national source of funding for animal research.) A shortage of USDA personnel has also been a problem. In Fiscal year 1997, for instance, a staff of about 73 animal care inspectors conducted almost 16,000 inspections to ensure compliance with AWA regulations (3). Currently a consortium of professional scientific and animal advocacy organizations is pressing for an annual increase in funding of at least 3 to 4 million dollars.

In 1998 there were 1227 animal research facilities registered with USDA under the AWA (4). This number

compares with some 970 institutions (in February 2000) that must comply with the PHS policy. Some overlap between the two groups exists. Still outside the provisions of any national policies are the academic and commercial institutions that either do not receive federal funding or use species of animals which are exempted. How many such exempt institutions there are is unknown, but the number probably runs to several thousands and includes privately funded facilities that conduct genetic manipulations on mice and rats.

Animal research facilities now have greater responsibilities than previously. The current legislation mandates that each research facility using animals establish an oversight IACUC with members appointed by the chief executive officer of the facility. Each committee is composed of no fewer than three members: one a veterinarian, and another not affiliated with the institution. In practice, animal researchers both chair the committee and dominate its membership. The most recent inquiry by the NIH office that administers the PHS policy found that only two of the approximately 1000 IACUCs have chairpersons who are not animal researchers.

Since 1985, protocol review by IACUCs has been mandatory. For instance, the PHS policy requires IACUCs to review relevant sections of PHS grant applications to ensure that (*1*) procedures with animals will avoid or minimize discomfort, distress, and pain to the animals, consistent with sound research design; (*2*) appropriate sedation, analgesia, or anesthesia is used; (*3*) animals that would otherwise experience severe or chronic pain or distress that cannot be relieved will be painlessly killed; (*4*) laboratory personnel are appropriately qualified and trained in the procedure(s) they are using; (*5*) methods of euthanasia are consistent with those prescribed by the American Veterinary Medical Association; (*6*) procedures involving animals are designed and performed with due consideration of their relevance to human or animal health, the advancement of knowledge, or the good of society; (*7*) the animals selected are of appropriate species and quality and the minimum number required to obtain valid results; and (*8*) methods such as mathematical modeling, computer simulation, and in vitro biological systems are "considered." In accomplishing these tasks, each IACUC approves, disapproves, or modifies the proposed animal experiment. The effectiveness of these committees is variable.

The AWA 1985 amendments also added other provisions: Training must be provided to laboratory animal personnel in the humane care and use of animals, the environment in which nonhuman primates are housed must promote the animals' psychological well-being, and dogs must be given exercise. The Secretary of Agriculture was required to issue standards governing these provisions.

The first of these new provisions fared reasonably well in the 1991 USDA rule making implementing the AWA amendments. As a result institutions for the first time began to provide training for their personnel in animal handling, anesthesia, and euthanasia, and what the concept of "Three R" alternative means — to replace animal experiments with nonanimal methods where feasible, to reduce the numbers of animals used, and to refine procedures to minimize or eliminate animal pain and distress, concepts that are all included in the laws. In response, the climate changed appreciably. IACUCs began to be more alert to the qualifications of research investigators to conduct traumatic procedures and to insist on training of the laboratory personnel who were not familiar with the techniques involved. The role of the veterinarian in providing this on-site training became progressively important. The legal requirement that the experiments not be duplicative led to greater use of the computerized library resources at the increasingly influential Animal Welfare Information Center at USDA and at the National Library of Medicine.

Psychological Well-Being

The other two new AWA provisions fared less well. The congressional requirements to promote the psychological well-being of primates and to provide exercise for dogs proved highly controversial. Congress had left unclear exactly how it wanted USDA to write the rules. Researchers protested the inclusion of these requirements in the law, arguing that "well-being" was unmeasurable, exercise for dogs was unnecessary, and any changes would be too costly.

There was considerable delay in USDA's promulgating rules governing primate psychological well-being. What appeared finally was permissive vis-à-vis the biomedical community. Instead of setting specific standards (as wanted by the humane community), the regulations allow each laboratory to determine how it will improve treatment of research animals, and a great deal of discretion is allowed (as wanted by the research community).

Former Congressman John Melcher, a veterinarian and the person responsible for adding the amendments regarding primate well-being and exercise of dogs, wrote of his regret about the 1991 rule making in the *Washington Post* (5). He said: "Imagine a small cube of a cage three feet on a side and three feet high. Within this cube lives a primate — often a baboon or a rhesus monkey — that could weigh as much as 55 pounds. Baboons usually stand on all four feet, but in such a space they cannot walk anywhere. They cannot stand upright or stretch their arms in such a cage. Yet this is a common caging for the animals used for scientific research. . . . The USDA has failed [in their new regulations]." The USDA rules went into effect in 1994, nine years after the passage of the law.

In July 1999, many years later, USDA reported that research facilities do "not necessarily understand how to develop an environmental enhancement plan that would adequately promote psychological enrichment," and therefore additional policies have been proposed (6). As of February 2000, public comments on these proposals were being assessed before issuance of additional policies.

Despite all these problems, without the 1985 law, funding for research projects to explore environmental enrichment would not likely have been forthcoming. Importantly, NIH started funding projects designed to test the beneficial effects of primate housing that allowed the expression of normal behaviors so that the animals would not be bored and come to express stereotypical obsessive behavior, such as constant rocking

or bar chewing — signs of psychological trauma. In fact the expression of stereotypic behaviors may indicate a disordered nervous system, bringing into question the validity of data derived from them (7).

Research has established that enrichment schemes are beneficial to the animals (8–10). Examples include group housing, more space, addition of climbing apparatus and manipulative devices such as chew toys and mirrors, and feeding enrichments. As a result of these efforts there has been a reduction (although not elimination) in the proportion of laboratory chimpanzees, baboons, and other primates that are psychologically damaged and a concomitant improvement in the quality of science.

Expanding Coverage to all Species Used

More than 30 years after the enactment of AWA, several widely used species of laboratory animal are still not covered, notably mice, rats and birds, despite the fact that according to commonly accepted estimates, they comprise 80 to 90 percent of all animals used. Farm animals were not included until 1990.

The animal welfare community has long fought to have *all* species of animals used in experiments included in AWA. No act of Congress is needed, only that USDA amend its rule making. (The Public Health Service policy *does* include all species inasmuch as all vertebrate animals are covered, so at PHS grantee institutions this is not an issue.) With regard to AWA, initially USDA had enough on its hands just to get the law into operation. But as time went on, the exclusions of certain species became a glaring problem.

Over the years individuals and groups concerned about the welfare of animals have exerted pressure to drop exclusion of agricultural farm animals, mice, rats, and birds. USDA has resisted on the ground of financial cost. However, in 1990 USDA finally ruled that horses, sheep, goats, cows, and pigs when used for *biomedical or other nonagricultural research* are covered by AWA. (Excluded still are farm animals used in genetic engineering research to increase productivity for food and fiber purposes and also to produce various biologics and pharmaceuticals.) As of 1990, pigs used for xenotransplantation and other biomedical research must be maintained and cared for in compliance with AWA standards and the facilities are subject to USDA inspection. (Pigs used in such research in PHS-funded facilities have always had to comply with PHS standards.) Between 1990 and 1998, the use of farm animals for biomedical research has more than doubled (66,702 to 157,620 per year) (4). In particular, the use of pigs has grown significantly.

Mice, Rats, and Birds. USDA is the target of complaints about failure to expand coverage of AWA to other species. This is because Congress had given USDA discretion about which species to include in addition to those initially mandated in 1966. After years of trying persuasion, in 1990 the Animal Legal Defense Fund brought suit against USDA to amend the regulations to include mice, rats, and birds. USDA objected to these inclusions because of lack of money and resources. The animal rights group won its case. In a judgment issued January 8, 1992, in the U.S. Distric Court, Judge Charles R. Richey ruled that USDA's exclusions were "arbitrary and capricious" and that USDA must issue new rules to include these species (11). USDA appealed the court's decision.

Pressures continued to mount. In 1998 the Alternatives Research and Development Foundation (a branch of the American Anti-Vivisection Society) filed a petition with USDA requesting that the agency amend its definition of "animal" to include mice, rats, and birds. The *Federal Register* announced receipt of the petition as well as the agency's response (12). Again USDA's arguments reflected its previous opposition to inclusion on the basis of lack of resources for implementation. Also USDA stated its belief that the majority of these animals were already being afforded certain protections, asserting that 90 percent of these animals are provided oversight by PHS assurance, voluntary accreditation, or both. The agency stated that most biomedical research in the United States is performed in laboratories funded at least in part by PHS. In addition 600 facilities in the United States are accredited by the Association for Assessment and Accreditation of Laboratory Animal Care International (AAALAC) and therefore voluntarily comply with their standards (which, like those of the PHS, cover mice, rats, and birds).

If mice, rats, and birds were included under AWA, the impact would fall primarily on two groups of animal users: (*1*) two- and four-year liberal arts and community colleges that, in general, use birds, mice, and rats for student education in preference to any other species; and (*2*) commercial genetic engineering companies.

There are an unknown number of facilities that conduct research on transgenic animals. Such facilities neither fall under the PHS policies nor need to be accredited, since the accreditation system is voluntary.

Mice are the species most frequently used to decode human ills. They are genetically modified to have human diseases such as diabetes, cancer, multiple sclerosis, arthritis, and a host of other ailments. In some experiments, multiple pathologies and serious animal welfare problems such as chronic pain and weak legs resulting in inability to stand up have been reported. Since commercial genetic engineering facilities are outside the law, they are not inspected by federal officials, nor do they have to have IACUCs for protocol review. They are also not required to use approved euthanasia methods. Although some companies are doubtless maintaining acceptable standards of animal care and use, there is no public assurance that they are, and there is no overt public accountability. With the added factor of secrecy in this highly competitive enterprise, public concerns arise. Indeed, major ethical concerns arise from a dangerous combination of factors, including lack of federal oversight in an industry based on the use of procedures which can cause considerable suffering in order to model severe human disorders, and the pursuit of profit.

Arguments for and against Inclusion of Additional Species. The vast majority of animal advocacy organizations have voiced support for including mice, rats, and birds. Among the arguments presented is that expanded

coverage is a matter of justice in that animals of similar moral worth should be treated equally (13). On this view, there should be a difference in some morally relevant characteristic if animals are to be treated differently. Mice and rats are so similar to three species currently regulated under AWA (hamsters, guinea pigs, and gerbils) that it is arbitrary, against common sense, and unjust to exclude them from legal protection. Indeed, all five species, mice, rats, hamsters, guinea pigs, and gerbils are similar in many ways. All are commercially purpose-bred for research and widely used; physiologically and anatomically they are, to a large extent, commensurable. Furthermore, and importantly from an ethical standpoint, the burdens they bear as subjects of biomedical experiments are of the same order: They have similar sensibilities in their perception of pain, and all are likely to be killed before the end of their normal life span. It is reasonable to assume that these species have an interest in not being subjected to pain or suffering and not having their lives prematurely foreshortened. Inasmuch as humans cannot be treated differently, unless there is some morally relevant basis on which to do so, dissimilar legal protection cannot be justified for animals that have similar relevant characteristics.

Several organizations have voiced opposition to expansion of coverage to all species used. These include the National Association for Biomedical Research, which states that expansion of AWA to include mice, rats, and birds is "a luxury we can do without" (14). The Federation of American Societies for Experimental Biology argues that expansion "would represent redundant regulation" (15). Other comments underline the fact that this would represent an unnecessary burden and hamper enforcement of existing regulation. However, some scientifically based organizations such as the Association for Accreditation and Assessment of Laboratory Animal Care (the accrediting agency) and the Scientists Center for Animal Welfare have voiced approval of including rats, mice, and birds. As of February 2000, USDA was analyzing the public comments they have received in response to their announcement in the Federal Register to determine what future action to take.

NATURE OF PUBLIC CONCERNS

Public response to new biotechnologies has been both enthusiastic and cautious. Genetically modified animals provide an extremely powerful tool for the development of disease models, since the mechanisms of gene regulation will become better understood. In addition the use of genetically modified mice as models of human diseases closely mimics the human disease and may even, in time, replace the need to use more acutely sentient animals (nonhuman primates) as models. But several reservations have also been expressed. Five issues of public concern are discussed below: the overall increase in (*1*) numbers of animals used, (*2*) the sum of animal suffering, (*3*) the invasions into the integrity of the animal, (*4*) the standards of housing and care of pigs, and (*5*) the monitoring of animal pain and distress. These concerns arise despite acknowledgment that the end result of these novel experiments is likely to be of significant benefit to humans.

Increase in Animal Use

When the U.S. Congress passed AWA in 1966, it recognized that keeping proper records is essential to ensure public accountability. It ordered that the numbers of laboratory animals used be counted and publicly reported each year, and this tabulation has been performed since 1973. But since mice, rats, and birds are not included under the definition of "animal," they are not counted. Data on the most-used species are missing from the statistics. This lack of information is detrimental to animal advocates who wish to track trends in animal use as part of their endeavor to reduce use and to target areas for reduction in animal pain and distress. It hampers commercial estimates of the future need for laboratory animals. It also prevents the public from participating in an informed debate.

Other sources of information show that use of mice is increasing in the United States. A 1999 article reported that Harvard Medical School will probably double its use of mice over the next five years — to about one million mice annually (16). Harvard is no exception. In 1991 NIH reported the use of 294,000 mice in intramural research; this number had increased to 648,000 in 1997. At both institutions, the increased use of mice is attributed to an increased number of experiments involving genetic manipulation.

Even more telling are statistics from the United Kingdom, since these are national data. In UK data both the numbers of animal procedures are reported and their purpose. Of the 1998 total of 2,659,662 animal procedures performed, genetically manipulated animals comprised 447,612 or approximately 20 percent of the total, and their use had doubled since the preceding year (17). In 1998 mice were used in 96.6 percent of the procedures comprising genetic modification. Other species used, in descending order were rat, pig, sheep, and other species.

The data in Table 1 provide some notion of the extent of animal experimentation worldwide. There are over 28 million animals counted in official statistics. This is an underestimate because many countries that use animals for experimentation do not count the numbers used. Not available, for example, are data from South America, Eastern Europe, the Middle East, Russia, Africa, and Asia. Regulations governing the humane use of laboratory animals exist in all geographic areas represented in Table 1 — some regulations being more and others less rigorous than those of the United States. In several countries where animal experimentation is conducted, no legislation exists (18).

In all probability the United States is the largest user of laboratory animals worldwide. In fiscal year 1998, a total of 1,213,814 animals were officially reported to have been used in research in the United States (19). When this figure is adjusted for uncounted species, the total comes to over 12 million animals per year in the United States alone (see Table 1). Over the period from 1973 to 1998, the total numbers of animals counted has fluctuated between 1.7 to 1.2 million animals per year, indicating a decline over the last six years.

Table 1. Number of Laboratory Animals Used in Research, by Country

United States (1998)	12,138,000[a]
United Kingdom (1998)	2,660,000
France (1997)	2,609,000
Canada (1997)	1,472,000
Belgium (1996)	1,516,000
Germany (1998)	1,532,000
Australia (New South Wales, South Australia, Victoria, Tasmania, and Western Australia) excludes fish (1996/7)	1,141,000
Italy (1996)	1,094,000
Netherlands (1997)	713,000
Norway (1997)	630,000
Spain (1996)	507,000
Switzerland (1998)	492,000
Denmark (1997)	380,000
New Zealand (1998)	309,000
Sweden (1997)	267,000
Austria (1996)	205,000
Finland (1998)	195,000
Ireland (1998)	69,000
Portugal (1996)	50,000
Hong Kong (1998)	27,000
Greece (1996)	19,000
Total	28,025,000

Note: Numbers represent official statistics of all countries and regions for which information could be found. Numbers are given to the nearest thousand and figures in parenthesis indicate year of count. The data presented are not necessarily comparable from country to country because of differences in animal species included. For instance, fish comprise 91 percent of the animals used in Norway but are not counted in the United States. Also some countries count experimental procedures and others individual animals.

[a]The United States counts only about 10 percent of all animals used in experimentation, since the most used species — rats, mice, and birds — are not protected under the relevant legislation and are exempt from counting. The official count for 1998 was 1,213,814, and this figure has been multiplied by 10 to allow for uncounted species and to achieve approximate comparability with data from other countries.

Increased Animal Suffering

In 1985 scientists at the USDA Beltsville Research Center called in the media to see the first ever genetically modified animals — creatures who became known as "the Beltsville pigs." In an attempt to produce faster-growing animals, these pigs had been genetically modified to express very large quantities of human or bovine growth hormone. The experimental purpose was to bring potentially greater profits to the food industry The public reaction to the pictures was of shock and criticism because of the obvious animal suffering. Some animals had damaged vision or deformed skulls, and others were unable to walk properly. The long-term deleterious effects for these animals were demonstrated two generations later and included gastric ulcers, arthritis, cardiomegaly, and nephritis (20).

Animals are now increasingly used to model human diseases; these studies can involve severe animal suffering. Among the painful diseases that have already been produced by genetic manipulation of mice are cancer, cystic fibrosis, Huntington's disease, and a rare but severe neurological condition called Lesch-Nyhan's syndrome that causes the sufferer to self-mutilate (21). Because the technology is in its infancy, the outcome for the animals is still somewhat hit or miss. Multiple pathologies are frequent: legless animals have been born, and abnormalities in genital organs, liver, kidney, joints, and vision also appear. Until techniques are worked out, survival levels are poor and considerable wastage of animals can occur. Unexpected, uncontrolled, and even undetected animal suffering often result. Particular attention needs to be paid to the ethical justification in terms of likely benefit to human health compared with the likely suffering of the animals.

In some countries statistical data may become available to measure this increased sum of animal suffering. A refinement in national statistics not found in the United States is that data are presented according to the "severity band" or "invasiveness" of the procedure, either minor, moderate, or severe. As of February 2000, six countries mandate that investigators rank their proposed procedures according to the degree of pain and distress (22). Two countries, Canada (23) and the United Kingdom (24), have also begun categorizing the level of adverse state resulting from specific genetic procedures. The Canadian guidelines on genetically modified animals stipulate that proposals to create novel transgenics initially should be assigned CCAC category of invasiveness level D (moderate or severe distress or discomfort) at least until the phenotype has been evaluated (25). In theory, statistical data on genetic modification procedures could be developed that report both on the numbers of animals used and the severity of the procedures used, ranked as minor, moderate, or severe. The rankings of severity would be made by the investigators in concurrence with IACUC. Over years, this would provide information on, for instance, the reduction in severity of effects from genetic modification procedures as the techniques become refined.

In the United States, major reforms would be needed to equal the data already available from other countries. U.S. official statistical data are deficient in not including mice, rats, or birds at all, in not specifying the experiments' purpose, and in not ranking the procedures' severity. Public concerns are fanned by the lack of animal data and lack of disclosure.

Integrity of the Animal

A particularly troublesome issue is interference with the integrity of an animal. The 1997 Experiments on Animals Act of the Netherlands requires that biomedical experiments on animals must be conducted "in recognition of the intrinsic value of animal life" (26). This is the first law in the world with such a statement. But what limits should be placed on preserving the integrity of a life form?

"Naturalness," "integrity," and "intrinsic/inherent value" are concepts that are open to differences in interpretation. For example, are laboratory animals simply tools to exploit, or do substantial alterations to the genome violate species-specific life — their "telos"? What constitutes the pigness of a pig, that is, the telos of an animal? Some critics believe that a pig should not be altered to the point that it ceases to be recognizably a pig. They question whether the biotechnology industry is attempting to

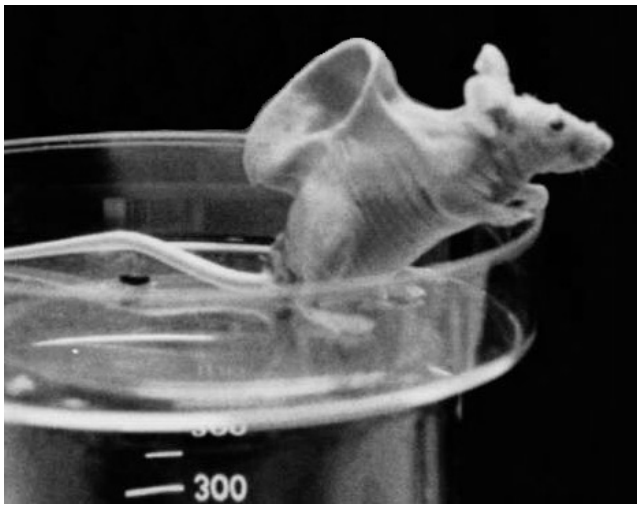

Figure 1. This is an actual photo of a genetically engineered mouse with a human ear on its back. It appeared in the *New York Times*, A11, October 11, 1999, in a full page advertisement protesting this invasion of the boundary between lifeforms. Credit Associated Press.

"capture [control of] the evolutionary process" and distort life forms in ethically unacceptable ways. "Who appointed the biotech industry as the Gods of the 21st Century?" was the heading of a 1998 protest against biotechnological manipulations of living beings. This advertisement, published in the *New York Times*, showed a photograph of a mouse that had been genetically manipulated to cause a human ear to grow on its back, see Figure 1. Many people worldwide were shocked at the sight of this photograph. The sponsors of the protest were a coalition of 19 organizations including the International Center for Technology Assessment, the Council for Responsible Genetics, and the Humane Society of the United States. Amazing mixtures of genes have been tried. For instance, jellyfish genes have been installed in monkey embryos, as well as injected into mouse sperm, and eggs and pregnancies created (27). (The goal of these studies was to test a technique that might eventually be used to create monkeys with added human genes.) The question is: Is there a boundary between life forms that should not be crossed?.

It is true that humans already share many genes with other animals — for instance, about 98 percent of the genes of chimpanzees and humans are identical, so only about 2 percent represent uniquely human characteristics. Because of the similarities, placing a single gene in another species may not, in itself, be so objectionable. But if future developments allow the transfer of uniquely human characteristics to animals, then ethical concerns would be increased. Mench provides a useful discussion of the issues of gene transfer (28).

Standards of Pig Housing and Care

There is considerable public support for the belief that laboratory animals should be provided with humane housing appropriate to their needs. Freedom of movement and the opportunity to express natural behaviors are viewed as basic animal needs. Pigs are intelligent animals with a range of bodily movements and natural behaviors which, if thwarted, result in manifestations of psychological damage such as obsessive, stereotypic behaviors. In this respect, pigs are like baboons and other primates. As discussed above, the living quarters for primates have been significantly improved over recent years. Will lessons learned about the importance of primate environmental enrichment flow over to other species such as pigs?

Among researchers and ethicists, a consensus is emerging that pigs are the preferred species for the routine supply of organs for xenotransplantation. According to the UK Nuffield Council on Bioethics, such use is "ethically acceptable" (29). The rationale for using pigs rather than nonhuman primates is that pigs have less highly developed mental capacities because they are less closely related to humans and that there is less chance of transmitting diseases from pigs to humans than from primates to humans. The use of pigs as a source of tissue for human use introduces the necessity of genetic modification — the creation of transgenic animals bearing human genes — in order to reduce the risk of hyperacute rejection. Further use of immunosuppressive treatments of the patients, to mitigate the danger of rejections, means that all tissues for transplantation must therefore be produced under sterile conditions in order to reduce the transmission of infectious diseases from animals to humans.

Initial production of transgenic pigs begins with impregnation by artificial insemination and removal of fertilized eggs to be microinjected with the required human gene. The pigs produced through this breeding procedures are used to stock the expansion herd through early weaning procedures. The source animal herd is established as a qualified pathogen-free herd. The pigs are born via hysterectomy or hysterotomy, taken from the sow, and reared in groups in isolated environment. The piglets are kept in isolators for 14 days, having no contact with the sow or the sow's milk (30).

Pathogen-free pig housing conditions are restrictive and closely controlled; they can therefore be stressful. Such housing conditions can mean, in some laboratory facilities, completely barren enclosures. The walls may be stainless steel or sometimes they are like tiled bathrooms. Flooring may be slatted fiberglass, or some other sterilizable matting. The flooring may not be ideal for pigs to walk on but is chosen for its hygienic qualities. Social deprivation is another problem because these pigs are individually housed and may be out of visual contact with other animals. There may be plenty of physical room, but if there is nothing *in* the room, the environment deprives the animal of normal social and play behaviors. The intelligent and social nature of pigs makes such deprived housing stressful.

Are such barren environments essential, or could enrichment alternatives be introduced? An alternative is to maintain the pigs in groups that are treated as a microbiological unit. Pregnant sows show a clear preference for a bedded surface rather than an unbedded surface, and sterilized straw is available (31) or possibly irradiated straw, as the pigs particularly enjoy having straw to root in. On the market are toys suitable for pigs housed in pathogen-free environments, such as teflon

balls and other products (32). In cases where pathogen-free environments are not essential, an even greater range of environmental complexity is possible, such as inclusion of wood shavings to provide soft surfaces, scratching posts, chains, footballs, concrete blocks (33), and showers. Often these enrichments are omitted because they are more trouble and take extra time to maintain. Enrichments are being used in some laboratories, but encouragement is needed to make such enrichments standard practice.

A high quality animal welfare system for maintaining pigs, the Nuertinger System (34) developed in Germany, is used by some laboratories conducting xenotranplantation research, such as Imutran Ltd. in Cambridge, UK (35). Neither gestation nor farrowing crates (discussed below) are used. The Nuertinger System has a number of animal-welfare-friendly features: It comprises a warm insulated bed and a cooler area for loafing, feeding and drinking, which gives the pigs a choice of environment and temperature, allowing them to choose where they can rest comfortably; see Figure 2.

Gestation and Farrowing Crates. Another issue concerning the breeding of pigs, not specific to xenotransplantation, is the use of gestation crates (also called gestation stalls) and farrowing crates — controversial practices developed in intensive food production units but now becoming increasingly used in laboratory settings. Both systems involve significant restraint of the sows, so that the animals can only stand up and lie down; they cannot turn around or walk. The animals cannot express their normal behaviors and become severely stressed, especially in gestation crates because the period of confinement is longer. Use of both gestation and farrowing crates is standard practice in the U.S. pork industry. Public protest against the use of gestation crates in particular, and to a lesser extent of farrowing crates, has been raised both in the United States and Europe. In the United Kingdom, confinement of sows during gestation and pregnancy in gestation crates has been prohibited since January 1, 1999 (36).

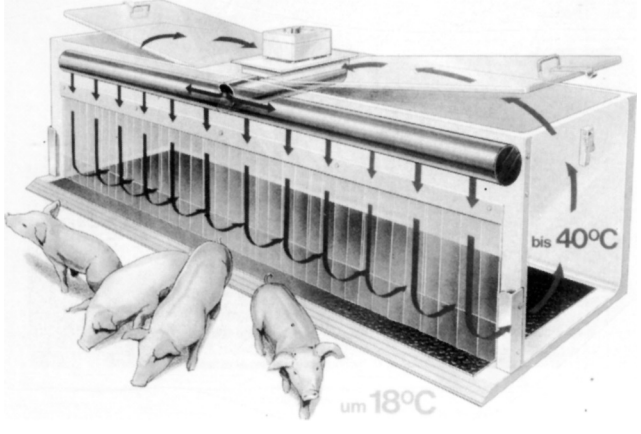

Figure 2. The Neurtinger System for housing pigs. The animals are group housed and can move freely through a plastic curtain between two areas that are maintained at different temperatures, up to 40 °C (104 °F) in one area, and about 18 °C (64 °F) in the other. Among the various environmental variables that can affect the welfare of pigs, temperature is the most important. Often piglets prefer to lie in a warm bed with their heads in the cool fresh air. For suckling, the air can be maintained at a cooler temperature. A controlled ventilation system regulates the temperatures. Credit: HAKA.

Gestation crates are used in food production units because they are economical of space and therefore inexpensive, and because they involve minimal human labor. In the agricultural industry, where profit is a dominating factor, these crates have come into almost universal use. The dimensions and use of gestation crates, as given below, are taken from the *Ag Guide* (37). They have overall dimensions of 5 by 7 feet, with a confining area that is 22 to 24 inches wide that constrains the sow and prevents her from turning around. Swine are large animals and can weight up to 600 pounds. Pregnant females are held in this confinement for four months — the whole period of gestation — and the animals are severely stressed. The animals lack freedom of movement and social interaction with conspecifics: They are unable to root, and they are deprived of expressing their strong maternal instincts of nest building. These deprived housing conditions are beyond the pregnant animals' abilities to cope, and as a result, they frequently exhibit stereotypic behaviors such as bar chewing, vacuum chewing, or head waving. Despite these welfare problems, gestation crates are used to breed animals in some American laboratories. Furthermore pigs are obtained for laboratory use from farms where confinement gestation crates are standard practice.

In laboratories there have been few pressures to avoid using gestation crates despite the fact that humane standards traditionally have been more rigorous for laboratory animals. The one-time clear distinction between farm and laboratory practices has become blurred. Traditionally there have been higher animal welfare standards in laboratories than in farm situations, but this tradition is being broken with the use of gestation crates. The rationale for using gestation crates in laboratory settings is weakened by the fact that the numbers of pigs maintained is relatively small, and there is no pressure to use minimal space to bolster profits as in food production units.

Farrowing crates represent another intensive farming practice that is now in use in laboratories. They too involve restraint of sows and restriction of normal movement but are far less objectionable than gestation crates because they are used for shorter periods, from several days to a few weeks, depending on the period of suckling. The conventional farrowing system, as described and sanctioned in the *Ag Guide*, is rectangular and measures 5×7 feet (1.5×2.1 m). But the sow resides in a crate within that area that is typically 2×7 feet (0.6×2.1 m). This width of 24 inches (0.6 m) restrains the sow so that she can, again, do no more than stand up and lie down. The main objective of farrowing crates is to slow the sow as she lies down, so that the piglets can escape to the sides and avoid being crushed. Piglet death is a serious issue, and a balance should be found between allowing the sow postural adjustments and freedom of movement against the crushing deaths of the babies.

John Webster, professor of animal husbandry at the University of Bristol, England, objects to farrowing crates on the ground that they restrict the opportunity for social contact between sow and piglets, and that the sow that is so confined during the period prior to farrowing is unable to satisfy her powerful motivation to build a nest (38). "The farrowing crate is certainly not designed to assist farrowing. The sow is uncomfortable, frustrated and compelled to drop her piglets on the same spot she drops her faeces," he states. The 1996 UK Advisory Group on the Ethics of Xenotranplantation considers the use of farrowing crates "undesirable" and states that "in theory it may be possible to avoid their use in the future" (29, p. 80).

Some refinements on traditional farrowing crates are already in use. For instance, the ellipsoid crate (39) and the Ottawa crate (40) (both developed in Canada) involve lesser degrees of constraint than conventional farrowing crates. Both systems allow the sow to turn around in addition to other movements and also permit easier visual and tactile contact between the dams with their piglets. They do not increase pig crushing rates. The ellipsoid and Ottawa crates are in use in Canadian farms and are suitable for laboratory use. Additional research is currently being conducted, particularly in the United Kingdom and Europe, to find alternative farrowing systems that are more welfare-friendly.

In the laboratory the choice of minipigs (rather than farm pigs) avoids the use of both gestation and farrowing crates. Miniature swine are preferred for this and other reasons. They are bred specifically for research from small wild species who have a mature body weight ranging from 132 to 198 pounds (60–90 kg) compared with domestic farm pigs who typically weigh in excess of 550 pounds (250 kg) at maturity. Recently minipigs have gained popularity for research studies including genetic modification and xenotranplantation.

Monitoring Animal Pain and Distress

Our understanding and recognition of animal pain and distress has advanced significantly in recent decades, and a considerable literature exists (41–45). Currently what is new is the use of scoring systems to keep track of the health status of laboratory animals during intensive periods when adverse effects are developing. With novel experimental techniques to model human diseases, it is especially important to maintain constant clinical monitoring of animal pain and distress. Researchers need to know when to intervene to relieve suffering by the use of drugs, by intense supportive care equivalent to that given to a human in the same state, or other actions.

In the last few years, several useful programs for intensive clinical monitoring of laboratory animals have been proposed. They require that the health status of the animal be evaluated at regular intervals and graded either on a numerical scale or a simple + or − (presence or absence) of physiological conditions or behavior, which together provide an assessment of severity of adverse conditions (46,47).

One such monitoring system in use at NIH includes assessment of the severity of a neurological impairment of mice on a grade from 0 to 5. Grade 0 is normal and grade 5 is moribund. Grades 1 to 4 show increasing signs of incapacity include clumsiness, incontinence, flaccid tail, abnormal plantar response, mild parapareses, trouble initiating movement, inability to move one or both hind legs, noticeable gait disturbance, moderate quadriparesis, and quadriparalysis (48). Qualified staff make frequent clinical assessments of the animals. At each grade, specific interventions have been established such as administration of fluids, dietary changes, expression of bladder, and provision of supplemental heat. The point at which early euthanizing of the animals should occur is specified.

It has long been recognized that a limit should be placed on the suffering of all animals used in experimentation. One way to achieve this is to set early, humane endpoints of experiments. The experimental design should establish the earliest point at which adequate scientific data have been collected and the experiment can be stopped, thus minimizing animal pain, distress, or lasting harm (49–51). In cancer studies, for instance, the endpoint should not be the death of an animal but the earliest point at which adequate scientific data are obtained. New initiatives are needed to foster use of these humane experimental designs (52).

Currently there are a few veterinary surgeons, animal ethologists, and others who are able to make such intensive clinical assessments and determinations of criteria for early endpoint on genetically engineered animals. But there are not enough persons so qualified; additional training programs are needed. However, evaluation of pain and distress for genetically modified mice may be difficult in some laboratory facilities, particularly those using micro-isolator cages and where there are large numbers of knockouts that are being subjected to a variety of breeding strategies to determine the effect of genetic deletions. Knockouts refer to animals who have had one or more genes removed or "knocked out." Defects in transgenic animals can be subtle but still affect welfare. Examples are mismothering, aggression, and spatial disorientation. These require extra special monitoring.

CONCLUSION

It was in 1985 that two important events took place — public awareness of the Beltsville pigs, and the latest amendment to AWA The Beltsville pigs demonstrated not only the scientific potential of genetically modifying animals but also the new welfare problems involved. With no amendment to the law in 15 years, U.S. laws lag behind existing needs because they were implemented before the full welfare implications of genetic modification were recognized. Scientific advances in genetic research challenge ethical norms, and the implications should be carefully considered before such work is approved. There is an

expectation in the science community and society generally that genetic modifications should occur within a framework of legislative controls that minimizes the impact on the animals involved. Some national guidance and mandates are needed to help deal with these issues. Animal welfare concerns raised in this article are also being grappled with in other countries: policies are being prepared to address societal issues arising from genetically modified animal experimentation. One such proposal directed toward the European Union has just been published (53). It includes a specific cluster of questions around the issues of justification, scientific relevance, animal suffering, and wider social, economic, and environmental impacts of animal studies involving genetic modification. This proposal may help point the way toward a reconsideration of national policies and a development of fresh initiatives.

ACKNOWLEDGMENT

I wish to sincerely thank the following colleagues for their helpful comments during the preparation of this manuscript: Clément Gauthier, Gilly Griffin, John Gluck, Joy Mench, David Morton, and LeRoy Walters. I also acknowledge the able library assistance of D'Anna Jensen.

OUTLINE

INTRODUCTION

Scientists have traditionally tried to shield their work from ethical scrutiny under the guise that they are involved in a value-free pursuit of the truth, but in the second half of the twentieth century this position became untenable. Ethical concerns were expressed by the public as well as some scientists about such issues as the dangers of atomic warfare, nuclear radiation, human subjects biomedical and behavioral research, recombinant DNA, assisted reproductive technologies, and global warming (1–3). In view of the rapid and massive intrusion of scientific discoveries and their application into human affairs for both good and ill, it was becoming difficult to maintain that science was essentially value free. As Stephen Toulmin suggested "it is meanwhile becoming clear that the professional organization and priorities of scientific work can no longer be concerned solely with considerations of intellectual content and merit, as contrasted with the ethical acceptability and social value, either of the research process itself, or its practical consequences" (1). In addition, by the latter half of the twentieth century a good deal of scientific research was being supported by public funds especially in the United States. This introduced political as well as social concerns with how, and for what purposes, scientists pursued their research. With such ethical concerns already in place, it is not difficult to understand the intense dismay that greeted at first, sporadic and then a flood of reports beginning in the 1970s of scientific research papers that were fraudulent, particularly when they involved clinical research and matters related to human well-being. The inquiries into this scientific misconduct raised a series of questions about (*1*) the extent of the problem, (*2*) the definitions that should be applied to misconduct in contrast to scientific error or chance, (*3*) the plight of an accused scientist or the whistleblower, (*4*) the nature of scientific discovery and the role of ethics in the education and practice of scientists, (*5*) the role of the government and public in the oversight process, and (*6*) the roles of the academic community, universities, industry, research laboratories, and the individual scientist in dealing with the problem of scientific misconduct (4).

SCIENTIFIC MISCONDUCT

Incidence and Types of Scientific Misconduct

The incidence of fraud or misconduct in science has in the past generally been considered by scientists, science historians, and sociologists to be rare and inconsequential. The scientist has traditionally been regarded as the seeker of true knowledge. Advances in science and technology have resulted in space exploration, modern forms of transportation and communications, and benefits to humankind in agriculture and medicine. The traditional view is that if there is fraud in an important area of science, it will be uncovered quickly by failed attempts to repeat it by other scientists or by inside information from the laboratory concerned. On the other hand, if the published research work is in an unimportant area of science, or is of a trivial nature, little damage is supposedly done to science or the public except for the cluttering of the literature. This line of reasoning has become suspect. The "romantic ideal" that scientists seek the truth and that errors or frauds are uncovered by a continual process of repeated studies has been challenged. While the ideal model may prevail over the long term for primary or critical data, there are many exceptions. A Noble laureate and director of the National Institutes of Health, Harold Varmus, challenged the idea that science is self-correcting in 1994 at a National Academy of Science convocation on scientific misconduct (5). Kiang suggested that errors (or fraud) in the archival record often are never corrected, simply ignored and eventually forgotten (6). The question of the extent of science fraud is, however, of long-standing. Robert Merton, a sociologist of science wrote in 1957 that he believed fraud was rare in science. For an earlier period, he quoted Darwin who "knew of only three falsified statements" in all of science. From the same period, Merton described Charles Babbage's 1830 "inventory of fraud in science" which included cooking and trimming of research data (7). In the 1990s several reports suggested that scientific misconduct was increasing and more widespread than previously believed and that such fraud in science was potentially damaging to both science and the public interest (8). The American Association

for the Advancement of Science (AAAS) surveyed its membership and reported in 1992 that 27 percent of those replying had personal knowledge of an average of 2.5 cases of *suspected* fabrication, falsification or theft of research in the prior ten years (9). Thirty-seven percent felt the incidence of misconduct was rising. In 1993 Judith Swazey and colleagues reported on a survey that involved 2000 graduate students and 2000 faculty in chemistry, civil engineering, microbiology, and sociology. While the study could not report on the frequency of misconduct, it did provide insight into the rates of exposure of students and faculty to various forms of misconduct (10). The authors reached the conclusion that although science misconduct is not rampant, it certainly is not rare. Between 6 and 9 percent of students and faculty reported knowledge of faculty who falsified or plagiarized data while one-third of faculty reported incidents of student plagiarism. Review of audits by the Food and Drug Administration of drug research conducted between 1977 and 1988 revealed problems in 12 percent of studies before 1985 and 7 percent thereafter. The problems uncovered included failure to perform studies for which results were given or changing of data (11).

That fraud is not always uncovered quickly and is not always innocuous was demonstrated in the criminal conviction of the psychologist Stephen Breuning in 1988 some years after he reported on the clinical effects of drugs on hyperactive retarded children. Much of his research was simply never performed, although his "work" inappropriately influenced the care of the mentally retarded (12). In the industrial arena there was the case involving the officers of Industrial Bio-Test Laboratories, Inc. who were convicted of fraud in the reporting of toxicity data on which drug companies and pesticide manufacturers relied for the effects of drugs and pesticides on laboratory animals. This ultimately affected the review and approval process of pesticides and drugs by the Environmental Protection Agency and the Food and Drug Administration (12).

When oversight of research misconduct was formalized by the National Science Foundation (NSF) and the National Institutes of Health (NIH) in the 1990s, they reported that some 20 to 40 alleged cases a year of various forms of misconduct reached the investigational stage for each agency (13). Whether one is alarmed by the numbers may depend on whether one takes solace in the small percentage of federal grantees actually involved in misconduct or whether one is concerned with a potential corrosive effect of even a small percentage of cases on the education of research scientists and the trust of the public. The actual numbers of misconduct cases also ultimately depend on what is included as research or scientific misconduct.

The types of research misconduct that have been chronicled in books and articles have varied widely and given rise to the confusion about the frequency and seriousness of the problem. One distinction that has been made is between science in general and research specifically, as when the Public Health Service changed the titles of its oversight committee from the Office of Scientific Integrity to the Office of Research Integrity in 1992 (14). The government makes the obvious distinction in its oversight role between research supported by federal funding and that supported from privates sources, as well as research performed to comply with regulatory agencies. The private sector is obviously responsible for research not funded or regulated by the government and the definition of misconduct could be more rigorous (or less) than federal standards. Other distinctions that have been suggested are between basic and applied research and research involving human subjects. Human Subject Research has generally been under separate government oversight over matters of informed consent, risks to subjects, and equity as distinct from concerns about fraud (15). The main emphasis in government definitions with respect to fraud has been on the scientific record with concern for the information published, formally presented at scientific meetings, or offered in progress reports to grants. In this case examples of misconduct have included reporting on work never performed or manipulating research data to obtain desired results as in adjusting points on a curve, omitting points that fall off the curve, or omitting data that make the conclusions less appealing or untenable. Misconduct might also include the use of inappropriate statistics to achieve significance that is not otherwise demonstrable. While sloppiness or gross errors in research might not warrant government sanctions, they might limit academic advancement or job security (13).

The other major source of misconduct involving the scientific record is in the acts of plagiary, which involve misappropriating the words or ideas of another scientist without giving credit for the source and representing them as one's own. The other forms of misconduct fall into such categories as sexual harassment of colleagues or students in the research environment, secreting data or notebooks that are not exclusively ones own, sabotaging or destroying another scientist's equipment or experimental results. Specific misconducts that might or might not be lumped with protecting the research record include failing to follow federal regulations on the protection of human subjects, treatment of animals, environmental protections especially with radioactivity, or appropriate use of grant funds. The Office of Inspector General of the NSF indicated in 1991 that of the cases of alleged misconduct: 20 were about plagiarism, 9 were for fabrication and falsification, and 8 were in the other "serious deviations" category (13).

The choice of what to include in one's definitions or categories obviously depends on anticipated use. If the list is for educational purposes in academic institutions, inclusiveness might be the goal. If the objective is to check compliance with federal funding or regulatory agencies, then definition of the misconduct is expected to be more restrictive and precise.

Defining Misconduct

Formal definitions for research misconduct have originated largely through government oversight of funded or regulated research. The first definition was published in 1986 in the NIH Guide to Grants and Contracts, as part of an interim policy before final regulations were formulated. Prior U.S. congressional hearings on scientific misconduct resulted in a provision of the Health Research

Extension Act of 1985 which required that research institutions establish procedures to investigate scientific fraud, and that the director of the National Institutes of Health develop an administrative method to respond and deal with it. The first definition of misconduct in science was thus established as "serious deviation such as fabrication, falsification, or plagiarism, from accepted practices in carrying out research or reporting the results of research; or material failure to comply with Federal requirements affecting specific aspects of the conduct of research, for example, the protection of human subjects and the welfare of laboratory animals" (16). The scientific community had an opportunity for critical commentary in response to the publication of proposed policies and procedures of the Public Health Service (PHS) in the Federal Register in 1991 and prior to that to advance the final Notice of Proposed Rulemaking in 1988. A similar procedure was followed by the National Science Foundation (NSF) in 1987 to receive public commentary and establish a definition covering grants under its jurisdiction. The final NSF definition developed in 1991 closely followed that of the PHS: "Misconduct in science and engineering is fabrication, falsification, plagiarism, or other serious deviation from accepted practices in proposing, carrying out, or reporting results from activities funded by NSF: and retaliation of any kind against a person who reported or provided information about suspected or alleged misconduct and who has not acted in bad faith." The second portion of this NSF definition covering retaliation was criticized by outside commentators as not being part of scientific misconduct, but the view of the NSF was that retaliation was a serious deviation from accepted practices and would work against scientific integrity. This clause has remained. The PHS has not had retaliation in its definitions but was later called upon by Congress to develop procedures for protecting whistleblowers. It was also noted that the Whistleblower Protection Act of 1989 protects only federal employees and not whistleblowers who are employees of the grantee institutions. The PHS definition of misconduct was later changed in response to some of the commentary it received. The PHS definition established in 1989 is: "Misconduct or misconduct in science means fabrication, falsification, plagiarism, or other practices that seriously deviate from those that are commonly accepted within the scientific community for proposing, conducting, or reporting research. It does not include honest error or honest differences in interpretations or judgments of data." The final sentence was included in response to commentary from the scientific community. On the other hand there has been no dropping of the clause "practices that seriously deviate from those that are commonly accepted" which has been repeatedly criticized vigorously by scientists for both the PHS and NSF definitions as too vague and a potential basis for unfair treatment of scientists (16).

The U.S. Congress as part of the 1993 NIH Revitalization Act created a Commission on Research Integrity (CRI) with a mandate to make recommendations on a definition for research misconduct. Research misconduct had been a continuing subject for congressional hearings in the 1980s and 1990s, and there was apparent dissatisfaction by the Congress over the way the scientific community, academic institutions and federal agencies were dealing with the problem. The Commission was a 12-member public advisory body composed of scientists, lawyers, sociologists, and ethicists that was asked to make recommendations to the Secretary of Health and Human Services on the definition of research misconduct, an assurance process for compliance of institutions with federal regulations, administrative processes for dealing with misconduct, and, finally, recommendations to protect whistleblowers.

The CRI report did make recommendations to change the definition of research misconduct in an attempt to "provide vital guidance for personal and ethical judgments and decisions concerning the professional behavior of scientists and to provide a legal framework for formal proceedings" (14). From the public record and testimony, the CRI developed a sense of the types of research misconduct which were most common and needed addressing in a definition. The Commission felt that a fundamental principle for scientists was to be truthful and fair in the conduct of research and dissemination of their findings. The recommended definition of the CRI was that "research misconduct is significant misbehavior that improperly appropriates the intellectual property or contributions of others, that intentionally risks corrupting the scientific record or compromising the integrity of scientific practices. Such behaviors are unethical and unacceptable in proposing, conducting, or reporting research or in reviewing the proposals or research reports of others." The commission gave as examples of research misconduct to substitute for fabrication, falsification and plagiarism; the categories of misappropriation, interference, and misrepresentation were explained as follows:

> *Misappropriation* is intentional or reckless plagiary. This means presentation of the documented words or ideas of another without attribution appropriate to the medium of presentation, or to the use of any information in breach of any duty of confidentiality associated with the review of a manuscript or grant application.
>
> *Interference* is intentional and unauthorized taking, sequestering, or material damage to research related property of another. This includes, without limitation, the apparatus, reagents, biological materials, writings, data, hardware, software, or any other substance or device used or produced in the conduct of research.
>
> *Misrepresentation* is an intention to deceive or reckless disregard for the truth. This means stating or presenting a material or significant falsehood or omitting a fact so that what was stated or presented as a whole stated or presented a material or significant falsehood (14).

This somewhat complex and legalistic definition was not well received by the scientific community, but it engendered a broad debate on research integrity. The Commission's definition was in fact a more explicit rendering of fabrication, falsification, and plagiary with a substitution of interference for the "serious deviation from accepted practices" clause that many found objectionable (14,16). The CRI definition did introduce the concept that omission of critical data should be identified as misconduct

and made the concept of intent explicit, something that has been discussed by Dresser (17). The Commission further defined two other forms of professional misconduct that included obstruction of research misconduct investigations, which still is in the NSF definition, and noncompliance with federal regulations, which had been in an early PHS definition.

In line with a recommendation of the Commission, a federal interagency task force was appointed to develop a common definition of research misconduct for all government departments. By the end of 1999 they could not agree on a common definition; the secretary had not recommended the CRI definition, and the NSF and PHS definitions from 1991 remained in force.

Plight of the Whistleblower, Plight of the Scientist

The plight of the whistleblower has been championed by the distinguished scientist and journal editor John Edsall who believes that whistleblowers are necessary for the maintenance of honest science. He described cases occurring over a 30-year period in which major harassment and difficulties were faced by the whistleblower, often more severe than the person accused of the misconduct (18). A book entitled *The Whistleblowers* reported on a 6-year study of 64 individuals (19,20). A detailed report on the consequences of whistleblowing for the whistleblower and the exonerated accused was also prepared by the Research Triangle Institute for the Office of Research Integrity in 1995 (21). Sixty-nine percent of whistleblowers and 60 percent of those exonerated of misconduct suffered negative consequences, usually more severe early in the process of investigation and lessening with time. The converse of this is that significant numbers did not suffer adverse outcomes. The public sympathy engendered for the whistleblower from congressional hearings in the 1990s contributed to the inclusion of a mandate to address their protection by the CRI (14). At that time there was much publicity about Margot O'Toole, a junior scientist and whistleblower who had problems with Thereza Imanishi-Kari and David Baltimore at the Massachusetts Institute of Technology. Tom Devine likened whistleblowing to professional suicide. He chronicled the tales of 20 witnesses who appeared before the CRI. They complained of censorship, loss of job, academic expulsion, retaliatory investigations, denial of access to their data and laboratories, as well as threat of deportation and physical harm (22). To quote Tom Devine: "Everyone pays lip service to the ideal that science is the search for the truth, and scientific integrity is a concern for all. But whistleblowers actually live those values." In response to the CRI mandate, a Whistleblower's Bill of Rights was proposed as part of the CRI report (14,22). Even though the National Academy of Science advises beginning researchers that they have an "unmistakable obligation to act" if they suspect someone is violating the ethical standards of science, there is much cynicism. Often the whistleblower must wait years to be vindicated or must resort to the courts to get attention and redress. The scientific community felt that the Whistleblower's Bill of Rights provided too little concern for the accused scientist (4). There is always the possibility that the whistleblower is wrong or is not acting in good faith.

The plight of the scientist has been typified by two cases settled in 1997 in which after many years of turmoil, and adverse effects on their careers and reputations, the accused scientists were vindicated. The case of Thereza Imanishi-Kari, who was a collaborator of David Baltimore, was settled by an appeal board of the PHS some 10 years after the first charges of misconduct were made. No misconduct was ultimately found although there were criticisms of the research record keeping by Imanishi-Kari (4). All this was chronicled in a *New Yorker* article entitled: "The Assault on David Baltimore" (23) and a book, *The Baltimore Case*, both by Daniel Kevles (24). Baltimore, who initially suffered for the defense of a scientific colleague, became a hero in the Kevles book, and Margot O'Toole, the whistleblower, was recast by Kevles in a less sympathetic light. It is not certain that Kevles gave an evenhanded recounting of the controversy, and at the very least the maintenance of research records was inadequate and contributed to the problem. It is likely that Baltimore, Imanishi Kari, and O'Toole were all victims of a bad system for defining and dealing with misconduct by the scientific community, academic institutions, and the government (4). The other case illustrating the plight of the accused scientist was that of Bernard Fisher who ultimately gained vindication by going to court to receive an apology from the government for its inept oversight and an apology and financial settlement from his institution, the University of Pittsburgh. Fisher was the director of an interinstitutional NIH-funded clinical cancer trial. It was reported that a physician from one of the participating hospitals entered ineligible subjects into the study, and Fisher was caught up in the question of how and when to reveal this information, although it had little effect on the conclusions drawn from the study (25). The CRI also heard testimony from many aggrieved scientists, even professors who claimed to have been unjustly accused of misconduct and had their careers destroyed. This is reviewed in the report noted above on those accused but exonerated of scientific misconduct (21).

ETHICS AND SCIENCE

History, Sociology, and Philosophy of Science: Looking for Causes of Misconduct

The history, sociology, and philosophy of science are so interconnected as to make distinction between these disciplines difficult, but each has contributed to the literature about the values held by the scientist in conducting research, in elaborating scientific theories, in relating to other scientists, and in relating to society at large. Ultimately these values held by scientists contribute to the character of science, and they are a promising place to look for the factors that motivate scientists and the means by which progress in science occurs or is hindered. The so-called normative structure of science with its virtual absence of fraud due to rigorous policing by science itself enunciated in the 1940s by Merton may be an unreal perception of how science works today or for that matter how it operated previously (26).

As noted earlier, the ideal of an incorruptible science based upon timely self-correction is questioned in the real world. Harriet Zuckerman has considered the causes of misconduct under three headings: individual psychopathology, anomie, and alienation (26). The cause of misconduct had been attributed by many scientists simply to individual psychopathology, but this has been criticized as "too convenient and self-serving" to explain what is going on. It is not only the individual guilty of misconduct but also the laboratory environment in which he or she works that affects behavior. Anomie is a theoretical sociological construct for deviance based on a high value being placed on a goal for which the means are not readily available, inducing people to choose dubious routes to try to achieve the highly desired end. Another theoretical cause of misconduct is alienation, which occurs when there is a disconnect between the daily laboratory work and the ultimate goals of the research. Also, when there are gross differences in reward and recognition among the laboratory team, alienation, personal animosity, and misconduct are more possible (26). It reached a point in one prominent laboratory in Rockefeller University where attempts at poisoning were reported (27). The rise in misconduct is also believed due to the change in the way scientific research is organized and funded. Research in the last half of the twentieth century has become more costly, competitive, complex, specialized, and collaborative at the same time that being successful in research creates the opportunity for academic advancement, rewards, and recognition (13). Research may be attracting scientists largely because of external and secondary rewards of fame and fortune, which can corrupt, rather than the incorruptible primary pursuits of asking questions and seeking knowledge for its own sake.

Another interesting sociological perspective on scientists was offered by Bernard Barber in his 1961 *Science* article, "Resistance by Scientists to Scientific Discovery" (28). Although it is generally accepted that there may have been outside religious, political, and ideological impediments to progress in science over the years, the idea that science has cultural and social forces within itself that resist progress is a novel concept. Barber noted that new ideas may be resisted because they clash with existing substantive concepts like the notion of the irreducibility of the atom which clashed with the discoveries of electrolytic dissociation, the discovery of X rays, and the theory of the electronic composition of the atom, all of which were resisted when first proposed. Methodological concepts based on the senses or models of mathematics clashed with the ideas of analyzing colors with prisms, radioactive measuring, electromagnetic theory, or experimentation and provided resistance to their introduction. Religious beliefs of scientists were the basis for resistance to Darwin's theories. Low professional standing can impede acceptance of work, as occurred with resistance to Mendel's theory of inheritance. Such social forces working within science may give rise to suspicions of misconduct when none exist merely because it is conceptually difficult to accept the results of a groundbreaking study. Rivalries based on specialization, societies, schools, or seniority have also impeded acceptance of scientific work, but Barber ends on an optimistic note that scientists even with their human faults are in his view more objective and open-minded than society in general.

A major innovation in the philosophy of science was introduced in 1962 by Thomas Kuhn in his *The Structure of Scientific Revolutions*, which introduced the view that discovery and progress in science are not completely rational and that science is not a steady progression toward an "objective" truth (29). Taking into account the work of Bernard Barber and his own studies in the history of science, Kuhn created a new vocabulary and definitions to cover "normal science," paradigms, incommensurability between paradigms, paradigm shifts, and scientific revolutions. Normal science works within a paradigm with shared rules and standards and is closest to the traditional view of how science works. Normal science works on a historical record, but it does not bring about striking new discovery. When anomalies occur and questions arise that cannot be answered within normal science, there may be a paradigm shift or revolution with different rules and standards and a radical break with the past. The switch from the vision of Ptolemy to Copernicus, from Newton to Einstein, and from creationism to Darwin have all been given as examples of scientific revolutions. Again, the workings of science may raise suspicions of misconduct within the rubric of practices that seriously deviate from those commonly accepted within the scientific community unless there is a broad understanding of the history and sociology of science, of how research is actually conducted in specific fields, and of how theories are developed and tested.

History of Scientific Misconduct

There have over the years been many reports of suspected or proven fraud or misconduct in science, but it is best to divide the cases temporally based on whether they occurred in remote or recent times. This is a selected list of cases and is not meant to be exhaustive (30–34).

Science Misconduct in Ancient Times. Science misconduct as ancient history is probably more speculative than factual, and there are usually accusers and defenders for almost every case involving the legendary scientists of the past. The contributions of most of these scientists are little diminished by these accounts, and there is little evidence of any intent to deceive in cases before the twentieth century. For details, reference should be made to listed sources (30–34).

Claudius Ptolemy of the second century A.D. is accused by both French and American astronomers of not making measurements claimed but extrapolating them from an earlier Greek astronomer or of deriving the data from theoretical projections rather than from personal observation. Historians dispute this suggesting instead that his observations were adjusted in keeping with the standards and methods then in use.

Galileo Galilei of the seventeenth century has been accused of not having performed experiments as described but of creating data to conform to his theories.

Isaac Newton, the great physicist of the late seventeenth and early eighteenth centuries, is believed to have used "fudge factors" after the fact to adjust data to

meet theoretical predictions. While some have termed this fraud, others have characterized this as making approximations to test if a theory is in fact feasible.

Gregory Mendel published his work in 1865 that is the basis of modern genetics. It is claimed that the reported observations of the frequency of inherited traits and the expected values are too good to be true. This has been attributed to the manipulation of data by an obliging assistant, experimenter bias, or a more innocent difficulty in sorting the categories.

Robert Millikan published papers in 1910 and 1913 which won him the Nobel Prize in 1923 for determining the electric charge of the electron. Although Millikan claimed to have published all his data points, review of his notebooks reveals that he was selective and left out one-third of his observations. A scientific rival Felix Ehrenhaft of Vienna who lost out in the recognition of the Nobel Prize found fractional charges rather than the exact multiples described by Millikan. With the newer knowledge of subelectronic particles, it is possible that Millikan was wrong not only in his conclusion but also in his selection of data points to publish (31).

Sir Cyril Burt was a famous British psychologist who published studies in the 1950s on identical twins raised together and apart and concluded that IQ is largely inherited. It is claimed that many of the studies were never done and that the conclusions were designed to support his belief that intelligence is determined more by genes than environment (32).

Science Misconduct in Recent Times. Science and research misconduct described in the last 40 years of the twentieth century is based on more substantial evidence than cases dug up from ancient history. In more recent times investigations of misconduct are usually based on laboratory records and often on confessions.

Harold Bates worked in the laboratories of Mel Simpson, Professor at Yale and then with Professor and Noble laureate Fritz Lipmann at Rockefeller University, and published papers with them in the *Journal of Biological Chemistry* in 1960. A paper on the biosynthesis of cytochrome C coauthored with Simpson and a paper on the biosynthesis of glutathione coauthored with Lipmann had to be retracted because the work could not be verified (18).

George Webster, an established investigator of the American Heart Association, joined the Enzyme Institute of the University of Wisconsin and in 1965 published a paper in the *Journal of Biological Chemistry*. His work was challenged by Efraim Racker whose own work was at odds with Webster's. Webster announced that he did not have the original data to back up his work, although the paper has never been formally retracted (18).

William Summerlin was a dermatologist who joined the famous immunologist Robert Good at the University of Minnesota and moved with him to the Sloan Kettering Institute in 1973. Summerlin claimed from his research studies that he could treat mouse skin and human corneal tissue by culture outside the body to abolish immunological rejection when the treated tissue was subsequently transplanted to other unrelated animals. He claimed to be able to treat skin tissue from black mice, which would keep it from being rejected when transplanted to a different strain of white mice. In 1974 it was discovered by a technician that Summerlin had used a black pen to darken the spots on white animals and the credibility of all his work collapsed. The one mouse with a successful transplant was shown to be a hybrid, which would be expected to have a graft survive from the donor strain. The claim of successful transplantation of human cornea to rabbit eyes was also shown to be a deception. After this case there was a good deal of soul-searching about the pressures put on young scientists in large, highly publicized laboratories and the fact that their work is too readily "accepted" by their supervisors who have expectations of the kind of result they are seeking.

John Long was research pathologist at the Massachusetts General Hospital in the laboratory of Paul Zamecnik and rose to the rank of associate professor. He claimed to have a human tumor cell line from patients with Hodgkin's disease. In 1979, when collaborators asked for primary data on some joint experiments, Long was found to have altered data. He later admitting falsifying the results and it was also discovered that his so-called human Hodgkin's tumor cells were derived from a lymphoid cell line of the owl monkey, possibly by contamination. Long resigned his laboratory position and returned to clinical practice.

Vijay Soman was a scientist from India who started as a postdoctoral fellow in the laboratory of Philip Felig, professor of endocrinology at Yale and worked his way up to the rank of associate professor. In 1980 he and Felig published a paper in the *New England Journal of Medicine* that was shown to be partially plagiarized from a manuscript Felig was asked to review and rejected. Felig had given the paper to Soman to read because it was in their area of research. Soman not only plagiarized exact wording from the rejected manuscript; he made up most of the data he submitted. Review of 14 prior publications by Soman with Felig revealed that only 2 had supporting data and 12 of the questionable papers had to be retracted. Soman returned to India, and Felig who had gone on to be chairman and professor of medicine at Columbia, lost his position and returned to Yale.

Mark Spector was a promising graduate student in the laboratory of Efraim Racker at Cornell University when in 1981 he reported an exciting sequence of events, a cascade hypothesis for the process of transformation of normal animal cells into tumor cells. A collaborator became suspicious when only Spector could repeat certain key gel experiments crucial to the hypothesis. It was found that Spector's work was largely a fabrication. After this, Spector's credentials were checked, and it was found that he had a prior record of forgery and previous research work could not be repeated. The irony of this case is that it was Efraim Racker who exposed the fabrication of George Webster some 20 years earlier as noted above, only to be deceived himself in his own laboratory (18,30).

John Darsee was a promising young cardiologist who worked in the laboratory of Eugene Braunwald of Harvard and the Brigham & Women's Hospital. In 15 months of

work at Harvard, Darsee contributed 5 papers coauthored with Braunwald and many abstracts to national meetings. When asked by the laboratory head to submit raw data on some dog experiments, Darsee was observed by other lab workers in the act of fabricating the data in a contrived experiment. Rather than being an isolated event as first believed, it turned out that Darsee had a long trail of fraudulent research stretching back to his medial school and college days. Eight of 10 publications that Darsee had released before coming to Harvard had to be withdrawn or corrected. Darsee left Harvard and obtained a clinical post.

A junior colleague of Dr. Francis S. Collins, head of the Human Genome Project, was accused in 1996 of fabricating data in five research papers on leukemia, which had to be withdrawn. The colleague was identified by the *New York Times* as Amitov Hajra, a graduate student at the University of Michigan who worked in Dr. Collins's laboratory at the NIH. The fraud was uncovered when the reviewer of a subsequent paper submitted for publication by Collins and his student in the journal *Oncogene* questioned the data and suggested intentional deception. Ironically, what was obviously suspicious to an outside reviewer was missed by Collins and others in the laboratory (4,35).

A scientist from Immunex, a biotechnology company, was accused of plagiarizing the gene structure for an interleukin molecule that was obtained by reviewing an article for the journal *Nature* authored by scientists from a competing company Cistron Biotechnology. The paper was rejected, but it is claimed that the reviewer then patented the gene structure presented in the article. The controversy resulted in a suit alleging misappropriation of data during peer review. The case was settled out of court, but at least illustrates the occurrence of alleged misconduct in the biotechnology industry as well as in academic laboratories (36,37).

Plagiarism is a frequently reported form of misconduct. A case often cited is that of Elias Alsabti, an Iraqi who worked in both England and the United States and simply copied previously published works and sent them to obscure journals under his name or took progress reports or grant applications of others as bases for articles. In all he had some 60 fraudulent publications between 1977 and 1980. When found out, he simply went to new positions to ply his deceptions. The checking of references and his past as he went from position to position was obviously seriously deficient.

In 1987 Shervert Frazier, a professor of psychiatry at Harvard, admitted to plagiarizing works of others for review articles between 1960 and 1975. He subsequently resigned his academic post but continued to practice psychiatry at McLean Hospital (33).

The foregoing list of misconduct cases from distinguished laboratories is merely a selection of the many that could be described involving clinical and basic research. While the emphasis is on biological research, misconduct has been a problem in all fields of science, engineering, and technology. It is interesting that in many cases the misconduct was carried out by a junior or mid-level scientist who was inadequately supervised in a high-powered high-profile laboratory. Many of the transgressors were considered brilliant, hard-working, technically skilled, and almost too good to be true. They worked harder and longer and published more than is usually possible or reasonable. These stories are reminiscent of the adage for consumers about deceptive advertising — that attractive offers that seem too good to be true probably are too good to be true.

GOVERNMENTAL ROLES IN SCIENCE AND MISCONDUCT

During World War II scientists were involved in many research projects sponsored by governments in pursuit of advantages in the war effort. Out of such work came the manufacture of Penicillin, the invention of radar, advances in transportation computers, and communications and the use of nuclear energy for the atom bomb. After the war, government science advisor and MIT professor Vannevar Bush in his report to President Truman, "Science: The Endless Frontier" outlined the benefits that would flow from continued governmental support for basic research (38). As a consequence a new system was established that sited the conduct of research at universities, created project grants that could be awarded to scientists for research in their own laboratories at universities, and developed advisory and review committees of private scientists to serve the government on a part-time basis, which gave rise to the peer review system for approving and giving priority to grant applications. David Guston characterized this general arrangement as the "social contract for science" (39). Initially scientists were hesitant to accept government funds lest onerous restrictions and oversight be imposed on their academic and scientific freedoms. The "contract" provided for federal support, but with the responsibility for oversight left to the traditional mechanisms for academic governance at the private universities and institutions. There was considerable faith in the ability of scientists to regulate themselves and to ensure the integrity of the scientific process. Although cases of misconduct in science as described earlier were being reported during the 1960s and 1970s, there seems to have been little interest in the Congress to get involved, trusting instead the mechanisms ordinarily used by scientists and universities to discipline their members. Ironically, the reports of incompetent university and federal investigations of misconduct triggered the interest of congress, rather than the occurrence of the misconduct itself (4,40). The first congressional hearings for oversight on scientific misconduct occurred in 1981, chaired by Albert Gore in the House of Representatives and by Orrin Hatch in the Senate. Gore's committee looked into the Darsee affair and heard testimony from Drs. Philip Felig and John Long about their reactions to their experiences, described in the cases stated above. Philip Handler, president of the National Academy of Sciences, testified before the Gore committee that the problem of science misconduct had been grossly exaggerated by the press and that scientists should be allowed to take care of it by themselves. Senator Hatch was concerned with the institutional responses to the cases and with waste and fraud. He was particularly incensed that a

cancer scientist Marc Strauss from Boston University received new funding from the National Cancer Institute while he was under investigation for prior fraudulent practices (34,40). The Gore hearings did lead to legislation on misconduct which was included in the 1985 NIH reauthorization bill. The provision in the bill dealt with the responsibility of universities to develop mechanisms for dealing with misconduct. Congressional hearings were held again in 1988 when the late Ted Weiss from the House Committee on Government Operations looked into abuse of whistleblowers and delays in dealing with allegations of scientific misconduct at the institutional level. Meanwhile John Dingell, chairman of the House Committee on Energy and Commerce Subcommittee on Oversight and Investigation, started exploring the Thereza Imanishi-Kari, David Baltimore case described earlier. These latter hearings would go on for several more years until 1993 and involve Representative Dingell and David Baltimore in acrimonious exchanges on the congressional committee's aggressive investigation (4). In response to the congressional hearings and wide spread coverage in the press about the plight of whistleblowers and the cases of scientific misconduct, the PHS in 1989 set up an Office of Scientific Integrity (OSI) within the NIH to receive reports from institutions and conduct investigations on alleged misconduct. An Office of Scientific Integrity Review (OSIR) was set up within the Office of the Assistant Secretary for Health as an oversight function for the OSI (16). Dissatisfaction with the way this arrangement dealt with the Iminishi-Kari, David Baltimore case and with one involving Robert Gallo of the NIH brought criticisms of these offices. Congressional, scientist, and press criticisms of the OSI and OSIR were that they had inconsistent policies and vague rules, that they were biased against defendants, and used illegal procedures. The most important issue was they were not bringing the high-profile cases to a satisfactory conclusion as far as Dingell's committee was concerned (4,40). In 1992 the Department of Health and Human Services in response to the concerns merged the OSI and OSIR into one Office of Research Integrity (ORI) and placed it in the Office of the Assistant Secretary of Health (13,14). In addition an appeals process for those found guilty was made available with a trial-like hearing before a Research Integrity Adjudication Panel. These panels were appointed by the DHHS Appeals Board and included a scientist. In 1995 the ORI was moved to the Office of the Secretary DHHS (14). Concerns about the process of dealing with alleged misconduct cases continued to be expressed by the scientific community and the congress. In 1993, as part of the NIH Revitalization Act, the Congress as noted earlier (14) authorized a Commission on Research Integrity (CRI). The mandate was to consider a new definition of research misconduct (described earlier) to recommend an assurance process for institutions to comply with PHS regulations on misconduct, to recommend government and institutional policies to deal administratively with investigations, and to make recommendations on the protection of whistleblowers (14). From 1987 the National Science Foundation (NSF) handled cases of misconduct out of their Office of Inspector General, which conducted any investigation. An adjudication process separate from the investigation was available with due process rights. The NSF drew much less criticism than the PHS for the way misconduct cases were investigated. It is not clear whether the more favorable reaction by scientists to the way misconduct cases were handled by NSF was due to the types of cases chosen or the process used. For both the PHS and NSF, investigations were carried out by the scientist's own institution whenever possible as long as they were handled competently (14,40). An interesting phenomenon was the activities of two NIH scientists, Ned Feder and Walter Stewart (41,42). For about 10 years the pair devoted their time, without NIH authorization, to checking out accusations of fraud and plagiarism in science research at the NIH and elsewhere, and urging action by anyone who would listen to them. They championed the side of the whistleblower, Margot O'Toole in the Thereza Imanishi-Kari case and probably increased congressional interest in the problem. They also looked at a neglected aspect of the Darsee case, the responsibility of his many coauthors. They reviewed 109 papers published by Darsee with 47 coauthors, even papers in which fabrication was not alleged. Stewart and Feder reported what they thought were many cases of errors, republication of information, use of common controls for several studies, and lapses from standards that they felt reflected poorly on the coauthors, journal editors, and reviewers. Their paper took four years to be published because of criticisms and even threats of libel by Darsee's coauthors. The article was finally published in the journal *Nature* with an editorial and with a critique of the paper by Dr. Braunwald, Dr. Darsee's mentor at Harvard (43,44). In the four years required to have their paper published, Stewart and Feder made much of the idea that they were being "censored," and had a sympathetic ear in the U.S. Congress. The pair also developed a software package that proved useful to substantiate or refute allegations of plagiarism, the so-called plagiarism machine. Since they were working without authorization while on the government payroll and their zealousness offended many scientists, they were finally moved to new positions at NIH in 1993 and told to restrict work on misconduct investigations to their own time (42).

Office of Research Integrity (ORI)

The role of ORI, which was formed in 1992, is to manage PHS research integrity activities. One function is to investigate misconduct in the NIH intramural programs, but the major activity is to oversee extramural misconduct investigations conducted by grantee institutions. ORI also develops model policies and procedures for handling allegations of misconduct which institutions can adapt for their use. Other responsibilities include evaluation of institutional policies and procedures, and investigation of whistleblower retaliation complaints. The ORI, despite much criticism from scientists and whistleblowers, remains as of 1999 the major federal watchdog for PHS grants (14).

ACADEMIC AND INSTITUTIONAL ROLES IN SCIENTIFIC MISCONDUCT

As the reports of misconduct cases increased and persisted over several years, universities and professional organizations began to study the problem and develop policies and procedures for dealing with alleged cases of misconduct (45,46). Since 1992 the NIH had required that all institutions receiving NIH training grant awards provide educational programs in research integrity for the trainees. As educational materials were developed, common themes emerged for normative rules of behavior. Guidelines for laboratory research practices were developed and shared by many academic institutions. The common features covered the areas where problems had arisen. These included laboratory procedures for recording, storing, and safeguarding research data used for the preparation of scientific papers and progress reports. Also covered were authorship practices such as whose name goes on a paper and in what order; who can be legitimate authors, the responsibility of coauthorship, the problems with honorary authorship, and, finally, mentoring responsibilities for junior research investigators when research is carried out in a training environment (45,46). Unacceptable behaviors were identified in the form of lists with definitions, with some derivations from the PHS and NSF definitions of research misconduct outlined previously. These included falsification and fabrication of data, plagiarism, dishonesty in publications, deliberate violation of regulations, failure to report misconduct, and failure to respect property of others. As factors that might influence behavior were considered, attempts were made to relieve pressures on faculty in the area of promotion and consideration for tenure. For example, some universities began to reduce the number of publications that may be considered in a promotion file for each rank considered (46). With the transfer of basic science findings into biotechnology and the opportunity for scientists to receive stock from joint ventures with industry, academic institutions developed rules about conflicts of interest and disclosure. It became apparent that if scientific integrity were to be considered an important value within an institution, the leaders of the institution would have to pay more than lip service to the concept (47). In addition the PHS and NSF requirement that institutions deal effectively with allegations of misconduct and protection of whistleblowers led to administrative changes within individual universities. In general, a specific official was identified within institutions to receive all allegations and to start the process of response in motion (46).

The Scientific Research Society Sigma Xi prepared a booklet for science students in 1984, with a third printing in 1991, entitled *Honor in Science* (48). This covers misconduct in science and whistleblowing. It starts with a section on "why honesty matters." The Committee on Science, Engineering, and Policy of the National Academy complex updated an educational booklet in 1995, *On Being a Scientist*, as a guide for teaching about scientific integrity (49).

A Panel on Scientific Responsibility and the Conduct of Research was formed under the sponsorship of the Committee on Science, Engineering, and Public Policy of the National Academy complex and published in 1993, in two volumes, a comprehensive report entitled: *Responsible Science, Ensuring the Integrity of the Research Process* (13,46). One critical review of the work noted three shortcomings: (*1*) "It insists on an unworkably narrow definition of misconduct." (The definition was fabrication, falsification, and plagiarism; see the discussion above.) (*2*) "It acknowledges studies of science as a social endeavor without taking to heart their arguments and implications." (*3*) As a consequence of the preceding weaknesses, the report's analysis of putative causes of misconduct and its proposed remedies are inadequate to the challenges now confronting science" (50). The argument has been also made by John Bailar, who works in epidemiology and biostatistics and for many years was statistical consultant to the *New England Journal of Medicine*. He feels that falsification, fabrication, and plagiarism are less a threat to the integrity of science than the day-to-day handling and reporting of data and the use of statistical methods (51). Some professional societies have developed codes of ethics or guidelines for responsible research. The American Society of Biochemistry and Molecular Biology developed a code of ethics in 1998 and seemed to learn a lesson in the process that trust can be expected only by acting responsibly (52). The Society for Neuroscience developed guidelines for scientific communications (53).

Another group that is responsible for publication and authorship practices consists of the editors of scientific publications. They have changed policies to discourage honorary and irresponsible authorship (54). A suggestion has been made by Drummond Rennie that experimental auditing of published manuscripts be undertaken after advance warning to scientists, with an eye to establishing what the real frequency of science fraud is. The information would not be used to investigate or prosecute cases. Although this process was never implemented, there have been calls for much more aggressive audits such as those conducted by the FDA (11) or suggested by the CRI (14). Since 1989 the *Journal of the American Medical Association* requires authors to sign a statement that they will produce data upon which the manuscript is based for examination by the editors or their assignees (55), and many journals now require disclosure of any conflicts of interest.

When all else has failed in bringing cases of misconduct to some satisfactory resolution, whistleblowers have occasionally gone to court. There is a tendency now to use the False Claims Act, which results in triple damages if successfully prosecuted. In one such case Dr. Condie in 1983 felt that a colleague had falsified or fabricated data in published papers and grant applications and brought this to the attention of officials at the University of Utah and University of California, San Diego. The ORI was also involved, and neither they nor the universities found misconduct. In 1989 Condie brought the action to court and asked the Justice Department to take over the case which they did. The universities were ultimately found negligent in 1994 and ordered to pay a total of $1.6 million dollars of which Condie would share 15 percent. After the court findings, the ORI then reached a settlement with the

investigator to be excluded from federal grants for 3 years and to publish retractions or corrections of the disputed scientific papers (56). The 11-year time frame certainly indicates that the wheels of justice turn slowly when it comes to dealing with misconduct cases.

The tension between the scientific community and the government that supports it remains, but learning how to deal with scientific misconduct has been recognized by scientists as a serious challenge. In the meantime U.S. government policies are still in the process of evolution (4,57,58), and a common definition for misconduct is still being developed.

No one believes that misconduct can be completely prevented, but there is hope that it can be discouraged, and that if it occurs, it can be detected early and its impact mitigated. The FDA experience suggests that an audit system will reduce misconduct and have the greatest impact on the most serious and flagrant violations (11). Quality control has been used in industry to maintain adequate standards in general, and some forms of this process could be adapted to the research setting to deal with both inadvertent error and misconduct.

OUTLINE

INTRODUCTION

This article reviews recent scholarship to demonstrate ways in which science is value laden and how these value dimensions have ethical importance. It identifies the values scientists generally accept as those that should govern their work, as well as other values that influence support for science, its conduct and outcomes. It discusses some implications of these values for ethical issues in biotechnology. The approach is to review relevant philosophical and social science literature that examines relationships among science, ethics, and values, and to identify and analyze some examples of ethical issues in biotechnology.

The article contains two basic themes. One focuses on values and science. It reviews literature in the philosophy and sociology of science to describe a controversy that occupies the attention of scholars in those fields, as well as that of some scientists. The philosophers and scientists want to answer a question like: Does science tell us something important and true about reality? The sociologists want to answer a question like: Does the scientific community have a distinctive set of norms or values?

This first theme considers such topics as: Is science value laden or value free? What is the relationship of intrinsic and extrinsic values to science? What are constitutive and contextual values in or in relationship to science? From philosophical and sociological perspectives, these are the issues that comprise an attempt to answer the questions: What is science? Is science a set of independent and abstract criteria? Or is it what scientists do, and where they do it, and what they do it with? Or all of the above (1)?

The second theme focuses on the ethical implications of values in science. It takes the position that the embedding of science in society means the conduct of science, and its outcomes always have ethical implications. Furthermore societal commitments to innovation mean that these ethical implications are momentous and complex. Thus people can, and should, make moral judgments about science in its undertaking and with respect to its influences and outcomes. These are judgments about the moral responsibilities of individuals and the social responsibilities of institutions, about the moral and social implications of scientific practices, and about the effects from these endeavors for humans and their communities and environments. Making well-considered judgments can be assisted by moral theories and conceptual analysis, by systematic research to understand phenomena, and by public deliberation that takes care to include a wide variety of views. The proportionality principle in ethics assigns greater responsibility to persons more likely to influence outcomes. It would follow that people in positions of influence in biotechnology have greater responsibility to promote activities that encourage these kinds of considerations and deliberations.

The contemporary world and the political states that comprise it have made a substantial commitment to the production of science and its integration into society. Research institutes and educational, industrial, and governmental organizations house scientific laboratories and research facilities. Thereby the conduct of science has societal impacts in and of itself. To do science requires social institutions and social commitments. The production of this encyclopedia and the attention of its readers testifies also to the societal influences of science. Many entries demonstrate and discuss the changes in individual lives, social institutions, and the environment that result from doing science. It is clear, then, that science in its conduct and impacts cannot be value free. But this is only the beginning of the story.

SCIENCE AND VALUES

Numerous terms are used in the debate over whether or not, and how, science incorporates values. Perhaps one of the earliest and simplest contrasts is between value-free and value-laden science. This contrast goes back to the philosophers of the Vienna Circle in 1924 to 1936 (2). From their perspective, meaning itself was to be limited to value-free statements that lent themselves to sensory proof, or some kind of derivation from sensory proof. Later philosophers could not reconcile this position with quarks and genes, or the logical difficulty of moving from data to evidence to theory, and the philosophers of the Vienna Circle gave up that project. However, the questions of what are the distinctive features of science and whether they lead to results with a special claim to value-free truth remain important to scientists and those studying science. They are of social importance too, since scientific claims and claims about science often underlie large social expenditures and influence political and social outcomes.

In examining this issue further, it is useful to consider the contrast between objectivity and subjectivity, and between constitutive and contextual values. Scientists are content to view science as having constitutive values. These values are also called epistemic, as well as internal or intrinsic to science. They are contrasted with external or extrinsic values. Constitutive values would include the value placed on observation and experiment, on prediction and explanation, on the building and testing of theory and models, and on the development and testing of methods

that can reduce the probability of error or self-deception in scientific work. Science remains self-contained in satisfying these values, or most scientists view it to be so. Scientists and others have thought their satisfaction provides objective methods leading to objective truth. For good reviews of recent debates in philosophy of science about the status of scientific claims to privileged standing in understanding the natural world, see Couvalis (3) or Klee (4). Both argue for the preservation of scientific claims to objective understanding of the natural world.

The strength of this perspective on scientific values can be seen in the wide acceptance of the work of sociologist Robert Merton. In 1942 Merton characterized science as satisfying four norms: communism (open sharing of findings), universalism (use of general criteria for judging knowledge claims), disinterestedness (not acting for personal advantage), and organized skepticism (withholding belief). Only after several decades, in the 1970s, was this view challenged. Ian Mitroff proposed that the opposite views operated as counternorms in science, while Aaron Cicourel and Michael Mulkay challenge the sociological foundations of norms as categories, by arguing that norms are comprised in particular acts of individual actors (1, pp. 398–400).

Philosopher Joseph Rouse provides a current critique of both realist views that science tells how things really are and relativist or constructivist views that all scientific beliefs can be explained sociologically. He believes that both of these accounts suffer from their presupposition that a global assessment of science as one kind of knowledge is possible. Instead of a global view, the study of the actual variety of scientific practices might provide better grounds for an assessment of their significance. Understanding science as historically situated responses to past scientific effort in anticipation of and contest over its future development allows people to evaluate particular scientific claims without the presumption of a particular view about the coherence of scientific knowledge or about the relationship of that knowledge to reality (5).

From time to time some scientists and policy makers indicate that science is value free, or objective. Often in doing so, they want to use such statements to provide support for a favored position or to undermine one they do not support. If constitutive, or epistemic, values and the Mertonian norms were the only values in science, perhaps it would be possible for them to do this. Scientists would (sooner or later) find the truth. The hard work involved in making social decisions using that truth would be "handed off" from scientists to policy makers or other social decision makers. Scientists discover what they can, and then societal values and priorities need to take over. This model implies a clean division of labors and categories, value-free science, and value-laden policy.

Before identifying some flaws in this position about the separability of science from values, this entry needs to point out one immediate limitation. No one believes that technologies are value free. Technologies, from abacuses to zylophones, are devised and selected specifically to serve human purposes or values. If science is used in the development of technologies, that development is not value free. Furthermore technologies often make science possible, so at least in this sense, science is not value free. This encyclopedia is about biotechnology, indicating a kind of science that is not separable in entirety from technology. Thus, even if there is a kind of science that can fulfill the conditions for a value-free science, it does not seem to be the kind under consideration here. Discussing the ways in which science, thought to be value-free, can and does incorporate values is important both for an adequate understanding of what science is, and of its ethical implications. If a strong case can be made that science does incorporate nonconstitutive values, the case for their presence in the science (or sciences) of biotechnology is strengthened.

This entry uses notions of constitutive and contextual values found in the work of Helen Longino (6). Contextual values are values independent of the scientific goals or constitutive values identified above. Contextual values are social, cultural, economic, political, moral, and personal. These values can influence science, while it remains what all might agree is good science according to those constitutive values. Consider, for instance, a social or political commitment to fund materials science and engineering to understand properties of corrosion and fracture; consider the commitment to protection of human or animal subjects. These social values influence whether and what science gets done, but they do not necessarily result in bad science or science whose epistemic value is affected negatively. There are many examples that show that contextual values affect constitutive values, even when such science remains good science according to the constitutive values identified above. Reports of data falsification leading to retractions of published papers and findings provide obvious examples where contextual values produce bad science. A notorious example in the 1970s involved coloring mice to indicate successful skin grafts; the miscreant blamed personal stress and exhaustion (7).

Longino identifies five ways in which contextual values affect science. They affect scientific practices, the questions that get attention, and the description of data. Contextual values also affect the background assumptions and the global assumptions with which science operates (6, p. 86).

A good example of the deep interpenetration of science and contextual values comes in Nelly Oudshoorn's socio-historical analysis of the development of understanding about female sex hormones, which led to the invention of birth control pills (8). Her analysis shows how society influences questions that get attention, scientific practices, and the data that get collected.

This story about the making of sex hormones arose with new developments in the chemical life sciences at the turn of the twentieth century. The actors in the drama were physiologists working in laboratories, gynecologists treating women, and the pharmaceutical industry. The materials these actors needed influenced what would count as knowledge. The episode produced and transformed gender bias in science.

Before the 1920s the three groups began to interact over hormonal products. In the 1920s they ran up against problems in getting the amounts of gonadal material required to do the work they wanted to do. The

material was expensive and difficult to find, especially for the laboratory scientists. Because of this need, cooperation began to intensify between the scientists and pharmaceutical companies that supplied hormones from animal gonads. Gynecologists relied on these groups for quality hormonal products — whose benefits for their patients were, by the way, quite unclear.

In 1926 two German scientists happened on the long-sought source — human urine. Urine from pregnant women was particularly good. To gain access, pharmaceutical companies and laboratory scientists relied on the gynecologists' new, inexpensive source. But this was a prolific source of female sex hormone, not male. Urine from men would certainly be a suitable source for male sex hormone, but there was no institutional context for its collection. There were no clinics specializing in men's reproductive systems in the 1920s.

Though laboratory scientists had been interested in the role of both male and female sex hormones in growth and development of the body and in sexual differentiation, the ease of access to certain kinds of research materials lent support to, or privileged, the development of certain knowledge claims rather than others. This material source, along with the institutional context that focused on women's reproductive disorders, saw men disappear as a focus for research. Not until the late 1960s was the study of male reproductive disorders institutionalized as a medical specialty (8, p. 80).

This example demonstrates how contextual factors — ranging from the values different groups placed on social desiderata, such as potency or birth control, to the possibilities created by access to particular material such as a kind of urine — influence the very *constituents* of science. What counts as evidence, and for what — what can be used for the purposes of constitutive values — is intimately wrapped up in the social circumstances and priorities of times and places. This in turn influences what diseases or disorders get so labeled and treated, and when they do. This result has unavoidable ethical implications.

Background and global assumptions in science have implications for the interpretation of data in questionable ways that carry both policy and ethical implications. Longino provides the interesting example of research on human origins. This research uses one of two organizing principles: man-the-hunter and woman-the-gatherer. Each uses a story of the gendered development of tool use to promote a view of the favored sex as the initiator of activities from which defining human traits of intelligence and cooperation evolve. Each story promotes the view that men and women make tools for different purposes. However, while the remnants used to construct these stories provide evidence sufficient to conclude humans shaped them, they do not provide evidence sufficient to conclude if men or women used them, or how (6, pp. 106–108).

These examples demonstrate that contextual values affect science at very fundamental levels, but that these effects might not overthrow claims of scientific objectivity — in the sense of trying to work toward scientific understanding of natural phenomena, no matter how partial or influenced by nonepistemic motives and understandings. Recognizing this kind of partiality places a severe limitation on the adequacy of science or scientific answers at any particular time, for non-scientific purposes. The social responsibility for recognizing this limitation, and figuring out how to respond, falls both to scientists and non-scientists, particularly those in influential policy positions.

Another kind of partiality is less esoteric. Scientists and their academic sponsors, with commercial interests in development of products that follow from their discoveries, can be found using press conferences to promote their latest results. The tragicomic episode announcing the discovery of cold fusion provides a recent example demonstrating the limits of Mertonian norms in influencing scientific behavior (7, pp. 11–12). If the public is somewhat skeptical in its reception of such activities, the skepticism can be regarded as healthy prudence. Scientists who wish to honor the constitutive ideals of replication or peer review would also be likely to withhold approval. Here too, the social responsibility for recognizing this limitation, and figuring out how to respond, falls both to scientists and nonscientists. The proportionality principle would require more from scientists and others in positions to be influential than would be expected or required from those not so placed.

SCIENCE, ETHICS, AND THE STATE

The previous examples demonstrate that and how scientific endeavors require societal support. Science occurs in organizations and institutions and plays an important role in promoting particular social goals and interests. Public and private sector organizations sponsor scientific research with the expectation that their support will lead to public and private gain. These results bring with them questions about the nature and extent of gain; these questions have both utilitarian and distributional components.

Jurgen Schmandt and James Everett Katz identify three ways in which contemporary societies value science — as a product, as evidence, and as method. As a product, science is promoted and controlled in the interests of innovation. As evidence, science is used and interpreted for policy purposes. And scientific methods — analysis, experiment, empirical techniques — are valued in themselves (9). They are valued at least in part because they can serve for purposes of innovation and evidence.

The use of science in these ways means that, inevitably, people in democratic societies that encourage public involvement will call it to account. They will ask whether the use is justified, and consider the ethical implications of the choices that are made. As human interventions become pervasive (ozone holes), mammoth (Three Gorges Dam), and more sophisticated (recombinant DNA technology), so do the scale and requirements of human accountability, including scientific accountability. Two kinds of ethical issues for biotechnology are worth examining in this regard. One concerns ethics and risks; the other, the relationship of science to political consent (10).

Ethics and Risks

As a force for innovation, science brings inevitable risks. When human beings engaged in scientific activities or the use of science-based technologies create risks, those affected will ask whether the activities have been undertaken responsibly. Below are some examples.

Differential Impacts. Equity issues that arise in the management of radioactive or hazardous wastes provide a useful example of the kinds of problems resulting from commitment to science for innovation. Placement of these wastes raises questions of differential impact for locus, labor, and legacy (11). Locus raises the ethical isues of locating facilities that may harm those nearby while benefiting those far away. Legacy raises a similar question for those removed in time. These are issues of distributive justice; they ask about the fairness of the distribution of benefits and costs. Similarly for labor, although here the questions are complicated by issues of consent. Good justification of any state decision requires attention to these ethical issues.

Science and Differential Impacts. Looking more closely at the issue of evidence in this waste disposal example illustrates a particularly important quality in the value dimensions in science and how they raise ethical questions. To determine whether or not people are harmed, a scientific test is used. The decision to use a test has moral dimensions. It is a choice made by human beings, and it may help or harm them or their surroundings. Once the choice is made, decisions about which test to use also involve moral dimensions. Whichever tests are used, they will result in false negatives or false positives, at least to some degree. The choice in either direction will be a moral choice; thus a science-based choice involving constitutive values contains contextual value implications. If the test selected will result in false positives — that is, one that will tell us that some persons are affected who are not — these persons may be subjected to a variety of harms ranging from risky treatments to stigmatization or job loss. If the test selected will result in false negatives — that is, one indicating that affected persons are not affected — persons may suffer unattended illness and premature death. Independent of purposeful wrongdoing, application of science to questions of individual and societal well-being will involve value choices of ethical importance (12).

The previous examples show how science contains values dimensions with ethical implications. They show that these dimensions are not avoidable. Governments as well as other social institutions need to take these implications into account in order to behave responsibly. The sociopolitical context in which biotechnology is developing requires persons and institutions promoting it to pay attention to the contextual and constitutive values that affect biotechnology, as well as the ethical implications that are part of and follow from its promotion.

Value Conflicts. The case of deliberate release of genetically engineered organisms gives examples of direct relevance to this encyclopedia. Using Longino's categories, Soemini Kasanmoentalib provides a list of examples in which contextual values influence the scientific development and assessment of biotechnologies (13). Under practices, he points out that the multinational operation of companies doing biotechnology R&D allows them to select countries with less rigorous regulations for testing. In this case the commercial values of the company may coincide with the values some scientists place on being free to do their research, but they may conflict with those of the public and other scientists who are more concerned with the potential for harm. Here the conflict arises between the positive constitutive value scientists place on doing research and the negative contextual value placed on potential harm to vulnerable human populations. In another case in which constitutive and contextual values conflict, scientists at a university working with commercial support may find the value they place on open discussions and publication challenged by the need to patent or keep secret their findings. Here the value conflict can involve the constitutive value of open discussion and what a firm might argue is the utilitarian value that its product will provide. The firm might also point to the contextual value of promise keeping, if the scientists have signed an agreement. All of these kinds of cases, where values conflict, need careful ethical consideration.

Science and Short-Term/Long-Term Interests. Commercial interests are not the only interests in economic growth. Governmental desires to foster innovation may result in limiting the kinds of questions that are asked and data that are required before approvals to plant or market products of biotechnology are gained. The Kasanmoentalib article notes that criteria of what should count as risk or damage, or appropriate ecological end points by which environmental stress can be measured, are difficult to establish, and can be limited to the gross and near-term. Under specific assumptions the selection of a model on which to base the risk assessment can be less conservative, ignoring synergistic effects for which it is difficult to devise tests. Thus global assumptions favoring the reductive approaches to assessing risk found in molecular biology and genetics can be favored over those from ecology which incorporate more concern for synergistic, inclusive, and long-term effects.

Here, keep in mind that the decision to delay introducing a new genetically engineered organism may pose ethical risks also. For instance, a plant engineered to resist a pest may require less pesticide and provide more food to an impoverished area. The decision to hold off on its introduction may trade off short-term need for more crop against long-term concern for ecosystem health. How to identify and balance short-term and long-term interests is a difficult ethical question. The stories in June 1999 in the science journal *Nature* and many of the world's newspapers about the lethal effect of bioengineered corn pollen on Monarch butterflies show that these concerns are of more than theoretical importance.

Particular choices in these circumstances are no more scientific than their opposites. Given that this is so, the answers to the questions: What is risk? What is acceptable risk? What is acceptable evidence of risk?, are themselves

not just scientific. On the one hand, parties outside the sciences must help to establish standards for acceptable risk. On the other hand, careful scientific or what can better be called meta-scientific considerations of epistemic issues for science, of what scientists are entitled to say they know, are essential (12). Careful analysis of the justifications for the assumptions and findings of various sciences is essential, both to identify and show the limits of science, and to help make scientific progress possible, by challenging the conventional wisdom in particular fields. It is better not to call these choices scientific, since that can connote value-free or objective choices, in a way that they cannot be.

Science and Political Consent

Science and Political Values. Recent controversies over labeling of food products that contain elements that are biotechnologically engineered show another dimension of the intricacies of interactions between science, technology, values, and ethics. The U.S. government and some commercial biotechnology interests are arguing that there are no grounds for labeling bioengineered products as such, since they pose no additional safety risks because of the bioengineering. They are using a narrow definition of a safety risk here. Such risks would be those, for instance, created by incorporating an allergen or toxin into a plant. Engineering an herbicide or herbicide resistance into a plant would not constitute such a risk. Long-term risks to ecosystems are not being considered (13).

Another category of ethical concern needs to be mentioned here. As Paul Thompson points out, people want to know a great many things about food products besides and beyond the kinds of safety concerns identified above (10, p. 75). They want to know where the foods come from. They want to know the processes by which they have been made. It is one thing to say that government should ensure that health-related claims on a product are not false and misleading, and that science should be used to assist in making that determination. It is quite another thing to say that no information except for scientifically validated claims about safety should be allowed on food products. Saying that is to substitute science for the consent of the governed. For persons who wish to buy hot sauce from Louisiana, or free range chickens, or organic produce that is not bioengineered and is raised on farms that use no manufactured pesticides or herbicides, such rulings would abolish choices they currently have and value having. It would substitute scientific rule-making for democratic choice, indirectly silencing a political voice.

Science and Moral Theory. Moral theories, unlike scientific theories, provide judgments about what human beings should do, not what the world is. However, the previous discussion serves to illustrate how science involves values and moral implications. It illustrates how human judgments about the worth of science exist in a context in which questions central to moral discourse — about what promotes human well-being and what is fair — arise. It illustrates how human judgments called scientific may incorporate contextual as well as constitutive values that presuppose particular answers to the questions: What kinds of scientific research should be done? Who should own the results? How should the results be described in the open market? Who is benefited or harmed? How? And how much?

The previous discussion can also illustrate limits of moral theories in resolving issues. Some scientists and regulators in government agencies and industry spokespeople might insist on utilitarian grounds that no products be labeled not to contain bioengineered components. They might believe that the greatest good for the greatest number will be served by having people buy less expensive safe products than they might otherwise choose, because of unjustified fears, if they see an equivalent, more expensive product with the "no biotech" label. Insisting on the right to have such a label gives pride of place to, or privileges, the rights view. That view insists that persons have rights to make choices that others think they are making for less than satisfactory reasons. Is one of these views the morally right one? On what grounds would that decision be made?

One way to try to answer this question is to try to resolve the facts of the case, where the facts are the empirical claims that are being made. Is the utilitarian claim true? Is it true in all circumstances? There may be circumstances in which ungrounded fears will influence consumer purchases, but these may be relatively few. It is easy to imagine ways to overcome such fears. Further, consumers may begin to feel manipulated and distrustful of a system in which they believe information is being kept from them because of commercial interests. With this scenario, utilitarian theory itself may be better served in a marketplace which allows labeling that includes information in addition to scientific claims about safety. A world in which more rights and freedoms can be honored may be a better world, by utilitarian standards, even when it allows choices that are ostensibly less well grounded by some current scientific standards. While science can be enlisted to serve a particular moral point of view and, in this case, given a utilitarian cast, the claims underlying such an outcome needn't be accepted. If this response is accepted, a moral conflict can be settled by finding a creative middle way in which moral theories can be reconciled (14).

This creative middle way may allow the preservation, or perhaps even the transcendence of utilitarian and rights-based moral theories. Another moral point of view is worth mentioning, one that William Aiken called holistic (15). This view, also referred to as the interconnectedness approach, points out that utilitarian approaches that proceed by examining trade-offs, or costs and benefits, risks and benefits, can lose sight of the connections that mean that the natural world does not operate like a balance sheet. These connections mean that negatives cannot simply be traded off against positives; negatives may be necessary to the maintenance of a desirable whole. Life requires evolution, predation, and death. From this perspective, neither rights views nor trade-off views give due recognition to larger values that need consideration in the relationships between human beings and the larger environment or natural world. This approach demands attention to the values we wish to maintain in our social

practices as well as the kinds of long-term consequences that may be overlooked in standard moral theories. The satisfaction of these values for such things as communities and ways of life requires consideration of long-term consequences and the connections that structure and sustain wholes. The interconnections approach may not reduce to either utilitarian or rights-based approaches. However, it may provide a connection between ethical and ontological theories, between theories about what ought to be the case and what is the case. It may require and provide a context which is hospitable to raising new ethical issues and challenges.

Currently scientific approaches to risk in the formulation of environmental policy take what Thompson labels a purist, rather than a hybridization, view. The purist view separates risk into its components: risk to human health, animals, environment. While social consequences could be a component also, the current policy process in the United States does not recognize social consequences as a legitimate topic for discussion. For the public, however, risk is an amalgam or hybridization of at least all of these components (10, pp. 232–236). Additionally, the public view of risk contains a concern for the responsiveness of those with authority and power — be it scientific, political, financial, corporate, organizational — to this amalgam. Unless science and scientists recognize that the approaches they take to risk incorporate these constraints, which have moral dimensions, they are operating under false assumptions with respect to both the ethical and value implications of their work. If scientists and others with the kinds of power identified above can recognize and be responsive to these implications, it may be possible to reconcile scientific and social progress.

SUMMARY

The task of this entry is to show some of the ways in which science is value laden and how its doing and results have ethical implications. The first section shows that both intrinsic or epistemic and extrinsic or contextual values inhere in science. The discussion and examples show how contextual values affect the scientific search for explanations of natural phenomena and the outcomes of that search, and how the search and outcomes incorporate social priorities and biases. The discussion and examples point out that these outcomes have ethical implications. Thus, the material and institutional circumstances surrounding hormonal research in the 1920s led to an emphasis on the study of female rather than male reproduction. Scientific discoveries in this area have been of enormous social benefit. However, the partial understanding that science provided placed limits on its appropriate use as an underpinning for societal decisions. Less esoteric, current examples of scientific partiality — for instance, that arising from scientific promotion of research results for commercial purposes — also give rise to healthy caution. These limits on scientific understanding require careful attention from scientists and others in positions to influence social policy and programs.

The second section continues the discussion of how values enter science and discusses ethical implications in the pursuit of science as a social or national priority. This pursuit affects individuals, organizations, communities, and the environment, and brings with it inevitable ethical questions about the nature and distribution of benefits and harms. The section examines issues of ethics and risks from science-based innovations, and issues of science-based innovations and conflicts over consent. Science-based technologies include and create differential risks. Figuring out what these risks are, and what their ethical implications are, is a complex task. The findings deserve careful attention from those in positions to influence social policy and programs. The same is true with issues raised by the relationships between science and regulation, as the example of food labeling makes clear. The call for science-based labeling gives priority to particular moral and political views as well as a particular view of scientific truth. Once again, these views require careful identification and consideration from those in positions of authority, if they wish to be accountable and responsible for their actions.

Washington, D.C.

OUTLINE

INTRODUCTION

Individual scientists and their research institutions (academic, nonprofit, or industrial) risk a variety of penalties if they engage in scientific misconduct. Penalties may be imposed administratively by the federal agency (if any) that supported the research or by the Food and Drug Administration (FDA) which must approve each new drug, biologic, or device before it may be marketed. Additional penalties may follow criminal prosecution or civil claims pursued through the courts.

Potential penalties range from increased supervision of research to sizable fines and imprisonment. The scientists and their institution may also be excluded from further participation in government funded or federally regulated research for a period of years (or sometimes, permanently). In addition, if the discredited research was supported by a federal grant or contract, the funding agency may demand that the full amount be returned. The agency invariably insists that articles or reports found to be the result of misconduct be formally withdrawn, and the publicity surrounding findings of scientific misconduct can tarnish the reputation of the research institution and destroy the career of the scientists involved. When the research institution is a commercial entity, the misconduct findings and penalties also may affect sales of its products and the value of its stock or its ability to make an initial public offering.

ADMINISTRATIVE SANCTIONS

The two government agencies that provide most of the funding for biomedical research in the United States are the National Institutes of Health (NIH) and the National Science Foundation (NSF). Each has regulations requiring investigation of alleged research misconduct and appropriate action if the allegations are confirmed (1). (Table 2) The FDA has similar authority to impose sanctions for violations of rules governing the development and evaluation of new drugs and medical devices. The actions taken by the agencies supplement any disciplinary action imposed by the research institution.

The NIH and NSF developed their scientific misconduct procedures following a series of congressional hearings in the 1980s which criticized the responses of government agencies and the recipients of federal grants to allegations of fraud in science. The hearings and related press accounts publicized several incidents in which data were fabricated or falsified, and others in which papers submitted to a journal were found to have been plagiarized.

The federal definition of research misconduct has been controversial. Whatever the definition, confirmation that one or more scientists engaged in such misconduct will lead NIH or NSF to impose administrative actions and civil or criminal penalties appropriate to the nature and seriousness of the misconduct that occurred.

The Public Health Service and National Science Foundation

The Public Health Service, of which NIH is a part, and the NSF may take one or more of a range of administrative actions at the conclusion of a scientific misconduct investigation, unless an appeal is filed. In addition the research institution or the funding agency, or both, may impose "interim administrative actions" even before an investigation has been concluded, if necessary to protect human or animal subjects, prevent improper use of federal funds, or safeguard the public interest (2). Although described as administrative actions rather than penalties, the distinction may make little difference to the scientist or institution subjected to the action.

Interim Administrative Actions. The stated government purpose of interim administrative action is to ensure the

proper use of public funds, the protection of research subjects, and the fitness of the principal investigator to continue to direct the research project. Although research institutions are expected to take interim administrative actions as appropriate, the funding agency may take one or more actions in addition, to protect the federal interests. Administrative actions once taken are reviewed periodically and may be modified as necessary in light of new information. The possible interim actions that may be taken by a federal agency are as follows:

- Total or partial suspension of ongoing research
- Total or partial suspension of the accused researchers from eligibility to receive additional federal grants or contracts
- Prohibition or restriction of certain research activities (e.g., research involving human subjects or animals)
- Requirements for supervision and prior approvals to ensure/ compliance with federal law and to protect public health and safety
- Delaying the award of pending grants or contracts
- Revoking agency approval of key research personnel to direct or perform research activities

Administrative Sanctions for Scientific Misconduct (Table 1). If allegations of scientific misconduct are confirmed by an investigation, the funding agency may impose one or more of the following sanctions:

- Send letter of reprimand to the scientist's institution
- Require increased supervision of the scientist's research and publications
- Require that a supervisor certify the accuracy and integrity of information submitted to the agency in grant applications and progress reports
- Restrict the use of agency funds to certain activities
- Conduct special reviews of all grant applications from the guilty scientists or their institutions
- Prohibit the scientists from serving on agency advisory committees
- Suspend or terminate ongoing research support
- Debar the scientists or their institution from eligibility for federal research support for a given period of time

Table 1. Penalties for Scientific Misconduct: Federal Regulations

FDA regulations	Citation
Administrative actions for noncompliance	21 CFR, pt. 56, Subpart E
Civil money penalties	21 CFR, pt. 17
Disqualification of clinical investigators	21 CFR, §312.70
Disqualification of testing facilities	21 CFR, §§58.200-58.219
HHS regulations	
Government-wide debarment and suspension (nonprocurement)	45 CFR, pt. 76
Responsibility of PHS awardee and applicant institutions for dealing with and reporting possible misconduct in science	42 CFR, pt. 50, Subpart A
NSF regulations	
Government-wide debarment and suspension (nonprocurement)	45 CFR, pt. 620
Misconduct in science and engineering	45 CFR, pt. 689

The U.S. Food and Drug Administration

Under the Food, Drug, and Cosmetic Act, new drugs, biologics, and devices must be approved by FDA before they may be marketed. Approval is based on data collected in clinical trials demonstrating that the product is safe and effective for its intended use. Sponsors of new products must first apply to FDA for permission to conduct the clinical trials. Sponsors (usually drug or device manufacturers) or the clinical investigators who repeatedly or deliberately fail to follow FDA rules for the conduct of the research, or who fabricate or falsify their data, may be disqualified from further participation in clinical or laboratory research involving investigational products (3). Such disqualification by FDA is similar to debarment, although FDA also may debar research entities, drug and device manufacturers, and individual scientists for serious research misconduct such as submitting false statements to the agency, conviction of a crime related to the development or approval of a drug or device, or involvement in a conspiracy to commit any such crime (4). Debarment is also authorized following conviction of a crime such as bribery, fraud, perjury, falsification or destruction of records, and similar acts related to product development. The period of debarment may be as short as one year or permanent, depending on such factors as the nature and seriousness of the offense, the extent to which management was involved (either in encouraging or participating in the criminal activity or in failing to report it), and the extent to which management tried to correct the causes of or mitigate the offense.

FDA also has authority to take administrative actions similar to those described above for PHS-funded research (e.g., immediate suspension of research in order to protect research subjects or public health and safety). In addition FDA may refuse to accept data from a clinical trial to support an application to market the product being evaluated and may even withdraw approvals previously granted (5).

Finally, FDA may seek criminal convictions or civil money penalties. When a person (individual or corporate) submits a false statement of a material fact to FDA, or knowingly fails to disclose information required to be submitted (e.g., the number and severity of adverse events observed in a clinical trial), that person may be liable for a civil penalty, under the Food, Drug, and Cosmetic Act (6). Individuals may be fined up to $250,000 for each violation, while fines against manufacturers may reach $1 million

per violation. Civil fines may be imposed in addition to other authorized civil, criminal, and administrative remedies. Criminal prosecutions are typically based on claims of wire fraud, mail fraud, or submission of false statements to a federal agency. These actions are described below.

Government-wide Debarment and Similar Exclusions

Debarment is an extended exclusion from government grants and contracts, while suspension is a temporary exclusion. Both are viewed by federal agencies as serious actions to be used only to protect the federal government's interests and are not considered to be punishment (7). The actions nevertheless have decidedly punitive effects.

In order to avoid providing government support to anyone found guilty of serious misconduct, President Reagan in 1986 ordered that the debarment of an individual or institution by one agency should have government-wide effect. The order applies as well to suspensions, disqualifications, and "voluntary exclusion agreements," which the agency negotiates with individuals or entities who are willing to settle misconduct charges to avoid the cost and disruption of hearings and appeals. Accordingly debarment of a scientist or technician for research misconduct prevents that individual from receiving research support from any federal agency for the period of debarment (8). The same restrictions apply to any research institution or corporate entity that has been suspended or debarred. As of September 1997, however, no institution had been debarred as a result of a finding by the Department of Health and Human Services (HHS) Office of Research Integrity (ORI) confirming scientific misconduct (9). A suspended, debarred, disqualified, or excluded scientist may not even participate in another scientist's federally funded research without special permission from the funding agency. Periods of debarment or exclusion for scientific misconduct typically range from 3 to 10 years but sometimes are permanent (10). A consolidated list of all agency suspensions, debarments, disqualifications, and voluntary exclusions is maintained by the General Services Administration (GSA) for enforcement purposes and is available to the public (11).

Publication of Misconduct Findings

The PHS, FDA, and NSF policies differ in their approach to publicizing misconduct findings. The PHS publishes the names of the scientists and their research institution, together with a brief summary of their misconduct and the sanctions imposed. These notices appear in both hard copy and Internet versions of the *Federal Register*, the *NIH Guide to Grants and Contracts*, and the *ORI Newsletter*. The PHS also may notify state licensing boards (if the scientist involved is a licensed health practitioner), professional associations, and journals in which the scientist has published reports of past research. FDA publishes notices of disqualifications and debarment in the *Federal Register* and also may notify sponsors of products being tested and collaborating institutions. The list of investigators who are ineligible to receive investigational drugs, or whose use of investigational products is limited, is available to the public. By contrast, NSF publishes summaries of misconduct findings and sanctions, but it does not identify either the scientists or the institutions involved (12). The summaries of NSF cases are included in semiannual reports to Congress from the NSF Inspector General.

Retraction or Correction of Publications

Both PHS and NSF require a formal correction or retraction of journal articles found to contain fabricated, falsified, or plagiarized material. Although previously these notices were submitted as letters to the editor, most biomedical journal editors now agree that retractions should be labeled as such and appear independently on a numbered page of the journal, in order to include references to the retraction or correction in standard bibliographies (13). The National Library of Medicine, for example, annotates in its computerized databases (e.g., MEDLINE) articles that have been corrected or retracted, and provides a citation to the withdrawal or correction notice (14). This practice was challenged in 1994 by a scientist who was then under investigation for scientific misconduct as a result of patients improperly enrolled, by a collaborating researcher, in a multicenter breast cancer clinical trial. The principal investigator challenged the Library of Medicine's annotations of numerous articles from the collaborative trials but was rebuffed by a federal district judge, who ruled that the entries in the Library's databases pertained to publications, not to their authors (15). The district court's ruling was affirmed by a federal appellate court and motions for reconsideration were denied. In a letter to the editor in *Science*, the acting ORI director emphasized that the annotations had not been added to the Library's databases until after there had been a formal finding that the collaborating researcher had committed scientific misconduct. He added: "Scientists should not be concerned that annotations have been in the past or will be in the future placed in databases before a misconduct investigation is completed. They have not and will not be" (16).

Recoupment of Government Funds

Federal agencies have authority to require that institutions return any public funds that have been misused. In the context of research grants, this is typically accomplished by asserting that the funds in question were used improperly, and therefore the institution was not entitled to them and must refund the money (17). When ORI closes a case with a finding of scientific misconduct, it reports its findings to the institute at NIH that awarded the grant or contract. NIH in turn may seek recoupment of the research funds involved. In 1995, for example, NIH recovered $296,478 from an institution after ORI found that a principal investigator had submitted progress reports for three years describing research he had not performed. In 1994 NIH recovered over $1 million from three institutions involved in two scientific misconduct cases. NIH recoveries of research funds are actions independent of ORI's and are not routinely reported in the *ORI Newsletter*.

In late 1996 the Department of Justice sued for restitution of over $100 million from the University of Minnesota which allegedly obtained research grants fraudulently from NIH and illegally sold an antirejection drug that FDA had not approved for marketing (18). In July 1997 a U.S. district judge reduced the amount at stake from $109 million to $60 million by dismissing the False Claims Act portions of the suit (19). That ruling was reversed on appeal (20), and the university ultimately paid $32 million to settle the case (21).

At NSF, recoupments of research support are regularly reported in the Inspector General's Semiannual Reports to Congress and commonly result from findings of scientific misconduct. Restitution often results from criminal or civil litigation but may also result from internal agency determinations.

CIVIL MONEY PENALTIES

In addition to the administrative actions described above, scientists and their employers may be subject to civil money penalties and recoupment of publicly funded research support for offenses related to the development and testing of new drugs and devices. Other agencies have similar authority.

Program Fraud Civil Remedies. The Program Fraud Civil Remedies Act of 1986 was designed to deal with the submission of false statements to the government involving claims of less than $150,000. Under that Act, anyone submitting a claim or statement to a government agency, with knowledge that the claim or statement is false, fictitious, or fraudulent (or acting in deliberate ignorance or reckless disregard of the truth or falsity of the claim), is subject to a civil penalty of up to $5,000 for each such claim and twice the amount of each claim (22).

False Claims Act. If more than $150,000 is involved, the government may proceed under the False Claims Act, 31 U.S.C. §§3729–3730, which authorizes civil fines up to $10,000 plus recoupment of three times the amount of damages suffered by the agency as a result of the false claims. Alternatively, if the person who submitted the false claim cooperates with the government's investigation, the amount assessed may be reduced to two times the amount of damages. Under this provision universities and other research entities have been induced to cooperate and plea bargain, to avoid the treble damages.

In 1994, for example, the University of Utah and the University of California agreed to repay NIH more that $1.5 million in grants allegedly obtained through false data submitted in the grant applications. The universities' alternative to settlement was to risk treble damages (totaling $3.6 million) under the False Claims Act for knowingly presenting a false or fraudulent claim for payment to a government agency (23). Federal research grants are within the Act's definition of a "claim."

Qui Tam Actions. The "qui tam" provisions of the False Claims Act permit private citizens to bring suit in the name of the United States to recover funds paid out by the government of the basis of fraudulent claims. "Qui Tam" means "who as well ..." and denotes actions initiated by private citizens or informers who sue on behalf of the government as well as for themselves. In return for prosecuting the case, or at least alerting the government to the false claims, the informer (called a "relator") is entitled to a significant portion of the amount recovered. If the government successfully prosecutes the case, the relator may receive between 15 and 25 percent of the damages recovered. If the government declines to participate in the litigation, the relator who litigates in the name of the United States — and wins — is entitled to receive up to 30 percent of the damages awarded, in addition to costs and reasonable attorney fees. With damages trebled and potentially reaching millions of dollars, the informer's share can be sizable. Critics of the qui tam provisions say that the process offers an opportunity to settle personal scores while, at the same time, collecting a windfall and posing as a public citizen.

The qui tam provisions were enacted during the Civil War in response to sales of defective supplies to the Union Army. Amendments to the law in 1986 strengthened the role of relators and resulted in a surge of qui tam cases over the next decade. In fact, recoveries under the False Claims Act increased from $2 million in 1988 to over $200 million in fiscal 1995 (24). At the same time the portion of qui tam cases involving fraud related to HHS has surpassed those at the Department of Defense, which dominated the field in the past. HHS fraud cases involve primarily Medicare, Medicaid, and similar third parties who pay for health care services and supplies (24). A growing segment, however, relates to allegations of scientific misconduct in NIH-supported research activities.

A recent case illustrates how the qui tam law operates. In 1994 a former graduate student from Cornell, Pamela Berge, filed a qui tam suit against the University of Alabama, Birmingham, and four of its faculty members for allegedly submitting false statements in grant applications to NIH. A jury returned a verdict favorable to the informer/relator, which resulted in a judgment of just under $2 million (plus costs and attorney fees). Berge's claims were based on allegations of plagiarism, or misappropriation of intellectual property, which had been investigated and found to be meritless by a series of academic, scientific, and administrative reviewers. She therefore transformed her plagiarism charges into a qui tam action on behalf of the United States, asserting that a series of annual reports and grant applications submitted to NIH by the university incorporated plagiarized material and therefore constituted multiple false claims. Following the jury verdict, a federal district court judge awarded Berge 30 percent of the $1.6 million judgment, plus costs and attorney fees. The judgment subsequently was overturned by the Fourth Circuit Court of Appeals (25), which found no evidence on which a reasonable jury could have concluded that the challenged statements were even false, much less the basis for any NIH-funding decisions. The appellate court also ruled that there was no plagiarism and that Berge's claim for misappropriation of intellectual property was preempted

by the U.S. Copyright Act. The United States Supreme Court declined Berge's petition for review; thus the Fourth Circuit Court opinion stands as the last word in this case.

The likelihood that personal grievances will generate False Claims Act litigation is increased by the bounty-hunter (qui tam) provisions and the publicity attending successful cases. In addition a Washington-based group called Taxpayers Against Fraud actively solicits and supports potential qui tam plaintiffs, with a Web site on the Internet offering referrals to counsel, loans for litigation, help with legal research, and production of amicus (friend of the court) briefs. Supporters of qui tam view this as a public service, while opponents see disgruntled employees and students being encouraged to file multimillion dollar claims in the name of good citizenship (24). A similar support group has been established in Michigan to encourage and assist "whistleblowers" alleging scientific misconduct more generally. The likelihood is that agency actions and qui tam litigation both will increase in the foreseeable future.

CRIMINAL PROSECUTION

Statutory Penalties

Submitting false statements or information to the federal government, and similar offenses involving deceit, false statements, or fabrication, may result in criminal prosecution. It is a felony knowingly to submit a false statement or false claim to a government agency (26). A statement may be false either through omission (i.e., failure to disclose a material fact) or through submission of a false statement or representation. Conviction may result in incarceration for up to five years, debarment, imposition of fines, and recoupment of grant or contract monies.

When a scientist submits false statements in an application for a research grant, or in an annual report to the granting agency, that constitutes a false claim (request for money) and is punishable under the criminal False Claims Act by imprisonment for up to five years, a fine, or both (27). When the false claim is submitted by telephone or through the mail, the scientist and research institution may also be charged with wire fraud or mail

Table 2. Penalties for Scientific Misconduct: Federal Statutes

False claims and statements	**Penalties**
Administrative remedies for false claims and statements, 31 U.S.C. §§3801–3802 (applies to claims less than $150,000)	$5000 for each false claim, plus up to twice the amount of the claim
False Claims Act (civil actions), 31 U.S.C. §3729 (false claims exceeding $150,00)	$10,000 for each false claim, plus treble amount of each claim
False claims actions by private persons (qui tam), 31 U.S.C. §3730(d); Informer ("relator") may receive up to 30% of damages, plus attorneys' fees and costs	$10,000 for each false claim, plus treble the amount of each, plus costs and attorneys' fees
False, fictitious, or fraudulent claims (criminal), 18 U.S.C. §287	Fines and/or imprisonment up to 5 years
False statements or entries (criminal), 18 U.S.C. §1001	Fines up to $10,000 and/or imprisonment up to 5 years
Related crimes	**Penalties**
Conspiracy, 18 U.S.C. §371	Depends on underlying violation(s)
Mail fraud, 18 U.S.C. §1341 and Wire fraud, 18 U.S.C. §1343	Fines (up to $250,000, depending on amount of fraud), restitution, and/or imprisonment up to five years
Presidential order (Ronald Reagan)	**Penalties**
Debarment and suspension (government-wide effect), Executive Order No. 12549; *Fed. Regist.* **51**, 6370 (1986)	Individual or entity debarred or excluded by one federal agency may not receive grants or contracts from any federal agency
Food, Drug, and Cosmetic Act	**Penalties**
Withdraw approval of abbreviated drug applications, 21 U.S.C. §335c	Approval withdrawn; drug may not be marketed
Civil penalties (fines), 21 U.S.C. §335b; (informants may receive $250,000 or one-half of penalty, whichever is less)	Fine up to $250,000 for individuals; fine up to $1 million for corporate entities, partnerships, etc.
Debarment, and suspension; also, temporary denial of approval, 21 U.S.C. §335a	For corporation, partnership, etc., exclusion from research involving investigational products for 1–10 years; for individual convicted of felony related to product development, permanent exclusion
Public Health Service Act	**Penalties**
Office of Research Integrity, 42 U.S.C. §289b	Limitations on use of grant funds, supervision, suspension/termination of grant, debarment (exclusion) from future grants/contracts

fraud, and if more than one person is involved, a conspiracy charge may be added as well (28). Nothing in the law precludes prosecution under multiple federal statutes, and each grant application, status report, or request for payment constitutes a separate claim and, thus, an additional offense.

Examples of Cases

The first scientist to be indicted for research fraud was Stephen Breuning, a psychologist who fabricated data in federally supported studies on the use of stimulant drugs to treat hyperactivity in retarded children. Following indictment for fraud and making false statements to the National Institute of Mental Health, Breuning entered into a plea agreement which resulted in a conviction. Because of the potential impact of his fraud on treatment decisions for vulnerable individuals, Breuning was sentenced to incarceration for two years (suspended except for 60 days on work-release in a halfway house), five years' probation (during which he was required to perform 200 hours of community service), exclusion from federal research support for 10 years, and reimbursement of $11,352 to his university (29,30). He was also forbidden to work as a clinical psychologist for 10 years.

In a case that involved research submitted to FDA but did not involve federal research support, Dr. Robert Fogari, a physician who fabricated results over a period of eight years in a study of investigational anti-inflammatory drugs, was convicted of criminal fraud and obstruction of justice, sentenced to four years in jail, fined over $3.8 million, and ordered to make restitution (29).

Another case, that of Barry Garfinkle, demonstrates the multiple penalties that may be imposed for misconduct in clinical trials of new drugs (31). Dr. Garfinkle was convicted in 1993 of mail fraud and making false statements to the FDA while serving as principal investigator in studies of Anafranil. The drug was being tested as a treatment of obsessive-compulsive disorder in children and adolescents. The prosecution was triggered by complaints from the study coordinator that Garfinkle had ordered her to enter false data about weekly clinical evaluations that either never took place or were conducted by the coordinator rather than a physician. In addition the study coordinator alleged serious breaches of the research protocol. The indictment included charges under the Food, Drug, and Cosmetic Act, False Claims Act, and statutes prohibiting mail fraud.

Garfinkle was sentenced to six months in a halfway house, followed by six months of home detention, 400 hours of community service, and over $200,000 in fines. Based on his conviction of multiple felonies related to drug development, Garfinkle also was permanently debarred by FDA from serving in any capacity in connection with a new drug application. In addition the FDA served notice that it would not accept or review any abbreviated drug applications prepared by, or with the assistance of, Dr. Garfinkle, and that any person with a pending or approved drug application who knowingly used Dr. Garfinkle's services would be subject to a civil money penalty.

Such prosecutions are not limited to research involving NIH or FDA. In 1993, for example, a federal appellate court upheld the conviction of a scientist for conspiracy and fraud in connection with a grant, funded by the Agency for International Development, to create a diagnostic field test for malaria (32). Following a jury trial, the researcher was convicted and sentenced to eight months in prison (five of which were suspended), three years probation, and was ordered to make restitution in the amount of $75,000. The NSF also, together with the U.S. Attorney's Office, has successfully prosecuted individual scientists and biotech companies for fraud and false statements relating to Small Business Innovative Research (SBIR) grants. Within a six month period in 1996, these prosecutions resulted in criminal fines, civil penalties, restitutions, and other savings amounting to over $6 million (33).

DAMAGE TO PERSONAL HEALTH AND PROFESSIONAL REPUTATION

Perhaps the most devastating penalties are the effects of scientific misconduct allegations on the personal and professional life of the accused. Researchers who have been accused and later exonerated report that the investigative process alone has had prolonged and significant adverse effects on their lives (34). Approximately three-fifths of the exonerated scientists who responded to a 1996 survey believed they were stigmatized by the accusations, and nearly 40 percent reported adverse effects on their professional careers, such as damage to their reputation, reduced job mobility, and diminished opportunities for presenting papers. Over three-quarters of the respondents reported negative effects on their mental health, and nearly half reported adverse effects on their physical health. Disruptions of family relationships are not unusual. These outcomes, reported by scientists who were ultimately exonerated, suggest that even more serious personal and professional consequences must follow confirmation of scientific misconduct. Scientists who are found guilty of scientific misconduct, however, have not been surveyed. In many instances, they seem simply to have left the scene.

A widely publicized example of a scientist accused and later cleared is the case of Thereza Imanishi-Kari, who coauthored a paper in 1986 with Nobel prize-winning scientist David Baltimore (35). Imanishi-Kari was accused by a coworker of faking her data. Baltimore was never accused of scientific misconduct, but his name was linked invariably with that of Imanishi-Kari in the scientific and lay press, as well as in congressional hearings. Both scientists suffered personally and professionally throughout a 10 year investigation, although neither ultimately was found to have committed scientific misconduct. Imanishi-Kari's faculty status was suspended and, with it, her eligibility for NIH grants. Baltimore was ultimately forced from his position as President of Rockefeller University and was ostracized for years by many members of the scientific community. In 1997, with his reputation in recovery, he was appointed President of California Institute of Technology. Other scientists, perhaps less conspicuously, have suffered

a similar damage to reputation, personal anguish, curtailed career, and diversion of significant emotional, intellectual, and financial resources to defend against the accusations.

Occasionally the accusation of research fraud has led to even worse tragedy. Paul Kammerer, for example, was an Austrian scientist who believed he had developed proof of the heritability of acquired characteristics. As described by Arthur Koestler in *The Case of the Midwife Toad*, Kammerer's controversial support of the Lamarckian theory of inheritance was challenged repeatedly by the followers of Darwin. One vigorous critic ultimately accused Kammerer of having faked his results. Although essential facts about the research remain murky, the effect of the accusation is clearly documented. Despairing of ever proving his innocence to the satisfaction of his critics, Kammerer went into the Vienna woods and shot himself. A note found in his pocket stated:

> Dr. Paul Kammerer requests not to be transported to his home, in order to spare his family the sight. Simplest and cheapest would perhaps be utilization in the dissecting room of one of the university institutes. I would actually prefer to render science at least this small service. Perhaps my worthy academic colleagues will discover in my brain a trace of the quality they found absent from the manifestations of my mental activities while I was alive (36, p. 13).

Kammerer's suicide occurred in 1926. Six decades later, a professor of neurology and neurosurgery at the Montreal Neurological Institute (affiliated with McGill University), together with her husband (a faculty member at another university), committed suicide following publication of anonymous allegations that she had committed research fraud (37). As her lawyer explained: "Given that her work was her life, and she felt that her ability to continue was being seriously undermined, it was obviously more than she could live with" (38).

SCIENTIFIC RESEARCH, POLICY, TAX TREATMENT OF RESEARCH AND DEVELOPMENT

DAVID L. CAMERON
Willamette University College of Law
Salem, Oregon

OUTLINE

INTRODUCTION

Research and development (R&D) in the field of biotechnology typically requires a significant investment before any marketable products may be produced. In an effort to encourage greater private sector investment in research and development activities, Congress has enacted several provisions under the Internal Revenue Code, including Sections 174, 41, and 45C, that authorize tax benefits for certain types of expenditures incurred in connection with R&D activities. Specifically, Section 174 provides a current tax deduction for research or experimental expenditures while Section 41 permits a tax credit for increases in research expenditures from one tax year to another.

Importantly, a taxpayer can take advantage of both the Section 174 deduction and the Section 41 tax credit with respect to many of the same research expenditures, subject only to the limitations of Section 280C. In addition Section 45C permits a tax credit for qualified clinical testing expenses incurred in the development of so-called orphan drugs. This article explores the requirements of Sections 174, 41, and 45C, as well as the limitations under Section 280C, and the implications of these statutory provisions in the context of R&D activities in biotechnology.

THE DEDUCTION OF RESEARCH AND EXPERIMENTAL EXPENDITURES UNDER SECTION 174

Overview

Under Section 174 a taxpayer may elect to deduct currently all research and experimental expenditures made in connection with the taxpayer's trade or business (1) or to amortize the expenditures over a period of not less than 60 months (2). If the taxpayer fails to treat the expenditures under one of these methods, then the research and experimental expenses are to be capitalized (3). The decision either to deduct Section 174 expenses currently or to defer and amortize them constitutes the adoption of an accounting method, which cannot be changed without the consent of the Commissioner of the Internal Revenue Service (IRS) (4). Although the current deduction of research and experimental expenditures is permitted for regular income tax purposes, for purposes of the alternative minimum tax, research and experimental expenditures must be capitalized and amortized ratably over a 10-year period beginning with the taxable year in which the expenditures were made unless the taxpayer materially participates in the activity within the meaning of Section 469(h) (5).

The "In Connection With" Standard

Importantly Section 174 applies to research or experimental expenditures paid or incurred "in connection with" a trade or business and thus is available to taxpayers who are not yet engaged in a trade or business. In this way the "in connection with" standard of Section 174 is distinguishable from, and less stringent than, the "carrying on" standard of Section 162, which allows the deduction of trade or business expenses more generally. In *Snow v. Commissioner* (6), the Supreme Court held that Section 174 does not require that the taxpayer actually be carrying on a trade or business in order to deduct otherwise qualified research and experimental expenditures. The Supreme Court based its decision on statements contained in the legislative history that Section 174 was intended to equalize the tax treatment of "small and growing businesses" with their "large and well-established competitors" (7). As a result a start-up business may deduct research and experimental expenditures under Section 174. Ordinarily, a start-up business must capitalize its start-up costs and amortize them over not less than a five-year period (8).

The fact that Section 174 applies to allow the deduction of research or experimental expenditures by a start-up business does not completely obviate the requirement that a trade or business exist, however. The courts have concluded that research and experimental expenditures are not deductible under Section 174 if the taxpayer does not have some realistic prospect of entering into a trade or business involving the technology under development or, in fact, never eventually enters into the active conduct of a trade or business. For example, in *Harold J. Green* (9), the Tax Court stated:

> Although the Supreme Court established in *Snow* that the taxpayer need not currently be producing or selling any product in order to obtain a deduction for research expenses, it did not eliminate the "trade or business" requirement of section 174 altogether. For section 174 to apply, the taxpayer must still be engaged in a trade or business *at some time*, and we must still determine, through an examination of the facts of each case, whether the taxpayer's activities in connection with a product are sufficiently substantial and regular to constitute a trade or business for purposes of such section (10).

The requirement that deductions under Section 174 be incurred "in connection with" a trade or business also means that Section 174 is unavailable to taxpayers who merely fund the research of a third party for the development of a product when the taxpayer does not possess the intent or ability to exploit the fruits of that research on its own. These arrangements frequently involve partnerships that enter into agreements to fund research and simultaneously lease or license the rights of that research to the developing party. In such cases the courts closely scrutinize the business arrangements involved and have frequently held that the partnership is not sufficiently engaged in a trade or business to satisfy the requirements of Section 174 (11). This determination, however, must be based on an examination of all the facts of the particular situation (12). As the Tax Court has stated:

> [W]hen a partnership contracts out the performance of the research and development in which it intends to engage, all of the surrounding facts and circumstances are relevant to the inquiry into whether it has any realistic prospect of entering into a trade or business with respect to the technology under development. The inquiry includes consideration of the intentions of the parties to the contract for the performance of the research and development, the amount of capitalization retained by the partnership during the research and development contract period, the exercise of control by the partnership over the person or organization doing the research, the existence of an option to acquire the technology developed by the organization conducting the research and the likelihood of its exercise, the business activities of the partnership during the years in question, and the experience of the partners. Absent a realistic prospect that the partnership will enter a trade or business with respect to the technology, the partnership will be treated as a passive investor, not eligible for deductions under section 174 (13).

For example, in *Kantor v. Commissioner* (14), the Ninth Circuit Court of Appeals affirmed the decision of the Tax Court denying the taxpayer's claimed deductions under Section 174. In *Kantor*, PCS, Ltd. was formed to fund the adaptation of a particular computer software program for use on various types of computer systems. PCS, Ltd. entered into an R&D agreement with PCS, Inc. under

which PCS, Inc. agreed to perform the research involving the software program with PCS, Ltd. retaining ownership of the resulting software. The parties also entered into a technology transfer agreement under which PCS, Ltd. granted PCS, Inc. an option to acquire an exclusive worldwide license to market the software on payment of $5,000 and future royalties based on prospective sales. PCS, Ltd. also granted PCS, Inc. a 13-month review period in which to exercise its option.

The Ninth Circuit agreed with the Tax Court that PCS, Ltd. did not possess the objective intent nor the capability of marketing any software that might be developed. Importantly the court noted that by granting PCS, Inc. the right to market the software on payment of a nominal fee, PCS, Ltd. "made it more probable than not that the research firm [PCS, Inc.] would exercise these rights if the software that resulted from the research was at all valuable" (15). The court reached its conclusion that PCS, Ltd. did not posses the capability to market the software despite the fact that the general partner of PCS, Ltd. had significant sales and technical experience in the computer industry, was actively engaged in the research effort, negotiated an arrangement to secure financing, and negotiated licensing agreements for the marketing of the software. Rather, the court likened the general partner's activities to "those of any investor who applies his knowledge and expertise to insure that an investment is successful. . ." (16). The court concluded that permitting a deduction in such circumstances would simply allow the taxpayer to use Section 174 to deduct its capital investment.

Nevertheless, in *Scoggins v. Commissioner* (17), the Ninth Circuit Court of Appeals concluded that a research partnership was entitled to deductions under Section 174 despite the existence of facts similar to those in *Kantor*. In *Scoggins*, B&B Research and Development Partnership (B&B) contracted with Epitaxy Systems, Inc. (Epitaxy) to perform research to develop an epitaxial reactor. B&B agreed to provide Epitaxy with up to $500,000, consisting of $43,000 to be paid at the time of executing the agreement and additional amounts to be paid at the partnership's discretion. B&B granted Epitaxy a 15-month nonexclusive license to market the technology in return for royalties of 20 percent on net revenue from sales during that period. B&B also granted Epitaxy an option exercisable for one year thereafter to purchase the developed technology for $5 million.

The Ninth Circuit reversed the decision of the Tax Court and permitted the taxpayer's deductions under Section 174. Significantly the two partners in B&B, who also owned the controlling interests in Epitaxy, had previously developed and successfully marketed epitaxial reactors. The court concluded that B&B therefore possessed the technical expertise and financial ability to conduct a trade or business using the developed technology. The court also noted that the license granted to Epitaxy was nonexclusive and that Epitaxy was under no obligation to market the technology. Significant, too, was the amount of the payment to acquire the technology, $5 million, compared to the research cost. The court specifically noted that this fee was a significant impediment to Epitaxy's ability to engage in the marketing of the technology and contrasted this payment to the nominal amount to be paid in *Kantor*.

Definition of Research and Experimental Expenditures

For purposes of Section 174, "research or experimental expenditures" are limited to those expenditures incurred in connection with the taxpayer's trade or business that "represent research and development costs in the experimental or laboratory sense" (18). The regulations expand on this definition through the adoption of an "uncertainty test," conditioned on the quality of the information available to the taxpayer at the time that the expenditures are undertaken. The regulations provide that

> [e]xpenditures represent research and development costs in the experimental or laboratory sense if they are for activities intended to discover information that would eliminate uncertainty concerning the development or improvement of a product. Uncertainty exists if the information available to the taxpayer does not establish the capability or method for developing or improving the product or the appropriate design of the product. Whether expenditures qualify as research or experimental expenditures depends on the nature of the activity to which the expenditures relate, not the nature of the product or improvement being developed or the level of technological advancement the product or improvement represents (19).

Under the regulations, the word "product" is defined to include "any pilot model, process, formula, invention, technique, patent, or similar property, and includes products to be used by the taxpayer in its trade or business as well as products to be held for sale, lease, or license" (20).

While considerable uncertainty exists with respect to the precise contours of the definition of "research or experimental expenditures," the regulations are clear that the costs of obtaining a patent, including such expenditures as attorneys' fees expended to make and perfect a patent application, are included within the definition (21). Because the costs of perfecting a patent are "inextricably a part of the research and development work," such costs reasonably fall within the definition of expenditures for research or experimentation (22).

The application of Section 174 to the development of property protected by copyright law, as opposed to patent law, requires additional consideration. As previously described, research or experimental expenditures must "represent research and development costs in the experimental or laboratory sense" (23). Because such expenditures are limited to the reasonable costs incident to the development or improvement of a product including any pilot model, process, formula, invention, technique, or similar property (24), this definition by itself might exclude from Section 174 any research and development costs typically incurred in creating a work subject to copyright protection. In addition the regulations explicitly state that expenditures incurred for "[r]esearch in connection with literary, historical, or similar projects" do not fall within the definition of research or experimental

expenditures (25). In Revenue Ruling 72-395 (26), the IRS expanded on this regulatory provision and concluded that Section 174 did not apply to permit the current deduction of the costs of writing and editing, as well as design and art work for, textbooks and visual teaching aids (27). Importantly, however, the exclusion for literary, historical, and similar projects does not apply to certain expenditures incurred in connection with the development of computer software despite the fact that computer software is frequently protected under the copyright laws (28).

Although the precise contours of the definition of research or experimental expenditures are not fully described under the regulations or in other IRS pronouncements, the regulations are clear that certain costs incurred in the development of a product do not qualify as research or experimental expenditures under Section 174. For example, costs incurred for ordinary testing or inspection of materials for purposes of quality control — in addition to costs incurred for efficiency surveys, management studies, consumer surveys, advertising, or promotions — do not qualify as research or experimental expenditures (29). The regulations also specify that research or experimental expenditures do not include the acquisition costs of another's "patent, model, production or process" (30). The costs of materials or labor used in the construction, installation, acquisition, or improvement of property are also excluded from the definition of research or experimental expenditures (31). In addition Section 174 does not apply to expenditures for the acquisition or improvement of land or depreciable property (32). However, allowances for depreciation may be considered research or experimentation expenditures under Section 174 to the extent that the property is used in connection with activities involving research or experimentation (33).

A significant issue arising under Section 174 concerns the proper treatment of expenditures to a third party to develop a product or process, the expenses of which would otherwise qualify as research or experimental expenditures under Section 174 if incurred directly by the taxpayer. The regulations are clear that the definition of research or experimental expenditures includes expenditures paid or incurred for research or experimentation carried on on the taxpayer's behalf by another person or organization except to the extent that the expenditures are for the acquisition or improvement of land or depreciable property used in connection with the research or experimentation and to which the taxpayer acquires rights of ownership (34). In addition, the regulations under Section 174 provide that research or experimental expenditures made to a third party for the construction or manufacture of depreciable or amortizable property are deductible under Section 174(a) only if "made upon the taxpayer's order and at his risk" (35). Consequently no deduction is allowed if the property acquired is regularly produced or is constructed or manufactured under a performance guarantee. A performance guarantee includes any guarantee, whether express, implied, or imposed by local law, that concerns quality of production or quantity of production in relation to the consumption of raw materials and fuel, unless the guarantee is limited to engineering specifications such that economic utility is not taken into account (36).

Section 174 Election

A taxpayer's election currently to deduct all research or experimental expenditures applies to all qualifying expenditures (37). With the permission of the Commissioner, however, a taxpayer may change to the deferred method with respect to those expenditures attributable to a particular project or projects. In no event will a taxpayer be permitted currently to deduct some of the expenditures and defer and amortize other expenditures relating to the same project (38). Finally, even with the consent of the Commissioner to defer expenses attributable to a particular project, a taxpayer who originally elected currently to deduct research or experimental expenditures may not defer those expenses attributable to a new project without again obtaining the consent of the Commissioner (39).

Instead of currently deducting research or experimental expenditures under Section 174(a), a taxpayer may elect to capitalize and amortize such expenditures over not less than a five-year period under Section 174(b) (40). Under the regulations the amortization period begins with the month in which the taxpayer first realizes benefits from the expenditures. According to the regulations, the taxpayer will typically be deemed to realize benefits from any deferred expenditures in the month in which "the taxpayer first puts the process, formula, invention, or similar property to which the expenditures relate to an income-producing use" (41). Importantly, the taxpayer may select amortization periods of differing lengths for deferred expenditures attributable to different projects.

As a basic rule, deferral under Section 174 is permitted only for those expenditures that are otherwise chargeable to a capital account and that are not chargeable to depreciable or depletable property. However, such expenditures may be deferred only in part under Section 174 if they later become chargeable to depreciable or amortizable property, such as patents (42). In that case any unrecovered expenditures are to be either depreciated or amortized under Section 167 at the time that "the asset becomes depreciable in character" (43). To illustrate this situation, the regulations provide the following example:

> [F]or the taxable year 1954, *A*, who reports his income on the basis of a calendar year, elects to defer and deduct ratably over a period of 60 months research and experimental expenditures made in connection with a particular project. In 1956, the total of the deferred expenditures amounts to $60,000. At that time, *A* has developed a process which he seeks to patent. On July 1, 1956, *A* first realized benefits from the marketing of products resulting from this process. Therefore, the expenditures deferred are deductible ratably over the 60-month period beginning with July 1, 1956 (When *A* first realized benefits from the project). In his return for the year 1956, *A* deducted $6,000; in 1957, *A* deducted $12,000 ($1,000 per month). On July 1, 1958, a patent protecting his process is obtained by *A*. In his return for 1958, *A* is entitled to a deduction of $6,000, representing the amortizable portion of the deferred expenses attributable to the period prior to July 1, 1958. The balance of the unrecovered expenditures ($60,000 minus $24,000, or $36,000) is to be recovered as a depreciation deduction over the life of the patent commencing with July 1, 1958. Thus, one-half of the annual depreciation deduction based upon the useful life of the patent is also deductible for 1958 (from July 1 to December 31) (44).

Consequently the opportunity to defer research or experimental expenditures under Section 174 in connection with assets that are otherwise amortizable under Section 167 may be limited.

CREDIT FOR INCREASING RESEARCH ACTIVITIES UNDER SECTION 41

Overview

Section 41 establishes a research tax credit in connection with "qualified research expenses" and "basic research payments," frequently referred to as the incremental research credit and the basic research credit, respectively. The incremental research credit is equal to 20 percent of the excess of the qualified research expenses for the tax year in excess of a base amount, and the basic research credit is equal to 20 percent of any basic research payments in excess of a base amount (45). The purpose of the credit is to provide an incentive for increased research activities in the private sector. According to the legislative history to the research credit as originally enacted in 1981, "Congress concluded that a substantial tax credit for incremental research and experimental expenditures was needed to overcome the reluctance of many ongoing companies to bear the significant costs of staffing and supplies, and certain equipment expenses such as computer charges, which must be incurred to initiate or expand research programs in a trade or business" (46).

The incremental research credit is available in connection with the costs of any qualified research activities incurred in carrying on the trade or business of the taxpayer, including both in-house expenses and contract research expenses (47). Originally the "carrying on" standard of Section 41 generally corresponded to the same requirement found in Section 162 and thus was more restrictive than the "in connection with" standard of Section 174 (48). According to the legislative history,

> it is intended that to be eligible for the credit, research expenditures must be paid or incurred in a particular trade or business being carried on (within the meaning of sec. 162) by the taxpayer; no credit is available for expenditures for research relating to a potential trade or business which the taxpayer is not carrying on at the time the research expenditures are made. Thus, the credit is not available (either for current or carryover use) to a new entity which undertakes research with a view to using the resulting technology through future production and sales, and is not available to an ongoing business which undertakes research with a view to entering a new trade or business (49).

This requirement has been relaxed somewhat in connection with in-house research expenses. A taxpayer will be treated as meeting the trade-or-business requirement of Section 41 with respect to in-house research expenses if, at the time the expenses are paid or incurred, the principal purpose of the taxpayer in making the expenditure is to use the results of the research in the active conduct of a future trade or business of the taxpayer or of another member of the same controlled group (50).

In determining the amount of the research credit, members of a controlled group of corporations are to be treated as a single taxpayer, and the credit, if any, is to be allocated among the members in proportion to their respective increase in qualified research expenses (51). Similar aggregation and allocation rules apply in connection with the research credit available to S corporations, partnerships, estates, and trusts that are under common control (52).

Incremental Research Tax Credit

Definition of Qualified Research Expenses. The incremental research tax credit is equal to 20 percent of the qualified research expenses for the tax year in excess of a base amount (53). The definition of qualified research expenses under Section 41 is more narrow than the definition of research or experimental expenditures under Section 174. This is reflected in the three-part definition of qualified research under Section 41(d):

1. Research that satisfies the requirements of Section 174.
2. Research undertaken for the purpose of discovering information that is technological in nature, whose application is intended to be useful in the development of a new or improved business component of the taxpayer.
3. Research where substantially all of the activities constitute elements of a process of experimentation related to the development of a new or improved function, performance, reliability or quality of a business component (54).

Consequently the second and third parts of the three-part definition limit the range of activities that constitute qualified research as compared to those activities that constitute research or experimental activities for purposes of Section 174.

The second part of the three-part definition requires that the research be designed to discover information that is technological in nature. The legislative history states that qualified research must be within the basic sciences:

> The determination of whether new or improved characteristics of a business item are technological in nature depends on whether the process of experimentation to develop or improve such characteristics fundamentally relies on principles of the physical or biological sciences, engineering, or computer science — in which case the characteristics are deemed technological — or on other principles, such as those of economics — in which case the characteristics are not to be treated as technological. For example, new or improved characteristics of financial services or similar products (such as new types of variable annuities or legal forms) or advertising do not qualify as technological in nature (55).

Importantly research does not rely on principles of computer science merely because a computer is employed (56).

The proposed regulations under Section 41 provide definitions for the terms "discovering information" and "technological in nature." According to the proposed regulations, "discovering information" means "obtaining

information that exceeds, expands, or refines the common knowledge of skilled professionals in a particular field of technology or science" (57). The examples contained in the proposed regulations show clearly that research may constitute qualified research when the information is known to others but remains a closely guarded secret and is beyond the common knowledge of skilled professionals in the relevant fields (58). Research may also constitute qualified research even when the taxpayer abandons the project and attempts to develop the technology prove unsuccessful (59). Finally, research may be qualified only in part where research activities advance to the point where further analysis is within the common knowledge of skilled professionals in the relevant field (60). Relying on the language cited from the legislative history, the proposed regulations also provide that information is "technological in nature" if "the process of experimentation used to discover such information fundamentally relies on principles of physical or biological sciences, engineering, or computer science" (61).

The third part of the three-part definition requires that the research constitute a process of experimentation related to the development of a new or improved function, performance, reliability or quality of a business component. In defining the term "process of experimentation," the legislative history refers to

> a process involving the evaluation of more than one alternative designed to achieve a result where the means of achieving that result is uncertain at the start. This may involve developing one or more hypotheses, testing and analyzing those hypotheses (through, for example, modeling or simulation), and refining or discarding the hypotheses as part of a sequential design process to develop the overall component (62).

Although this definition of the term "process of experimentation" suggests that the result itself must be uncertain, subsequent legislative history has emphasized that only the means of reaching the result need be uncertain. "Thus, even though a researcher may know of a particular method of achieving an outcome, the use of the process of experimentation to effect a new or better method of achieving that outcome may be eligible for the credit. . ." (63). As examples of processes of experimentation, the legislative history specifically notes experiments undertaken by chemists or physicians in developing and testing a new drug and the work of engineers in designing a new computer system or an improved or new integrated circuit.

The proposed regulations under Section 41 follow the legislative history in describing a process of experimentation (64). Interestingly the focus of both the legislative history and the proposed regulations on uncertainty in defining a process of experimentation suggests a certain similarity to the uncertainty test under Section 174 (65). Nevertheless, the proposed regulations provide, as an illustration, that expenditures incurred to resolve uncertainty in manufacturing an improved widget may be treated as research or experimental expenditures under Section 174 but not be undertaken to obtain knowledge that exceeds, expands, or refines the common knowledge of skilled professionals in the relevant technological fields necessary to satisfy the requirements under Section 41 (66). In addition the proposed regulations provide that, in testing and analyzing one or more hypotheses, the taxpayer must design a "scientific experiment" that, "where appropriate to the particular field of research, is intended to be replicable with an established experimental control" (67). Finally, the statutory definition of qualified research requires that substantially all of the activities that constitute the process of experimentation must relate to the function, performance, reliability, or quality of a business component (68). The proposed regulations provide that the "substantially all" requirement is satisfied only if 80 percent or more of the research activities, measured on a cost or other consistently applied basis, constitute elements of a process of experimentation (69).

Importantly the test of whether particular research is to be treated as qualified research is determined with respect to each business component. A "business component" is defined to include any "product, process, computer software, technique, formula, or invention" held by the taxpayer for sale, lease, or license or used by the taxpayer in its trade or business (70). The proposed regulations under Section 41 provide that the research credit is not available for research activities relating to the development of a manufacturing or other commercial production process unless the activities satisfy the requirements of Section 41 without taking into account the research activities related to the development of the product (71). Similarly the research credit is not available for research activities relating to the development of a product unless the activities satisfy the requirements of Section 41 without taking into account the research activities related to the development of the manufacturing or other commercial production process (72).

The tests to establish eligibility for the credit are applied to each business component or sub-component under the so-called "shrinking-back" concept:

> [T]he requirements for credit eligibility are applied first at the level of the entire product, etc. to be offered for sale, etc. by the taxpayer. If all aspects of such requirements are not met at that level, the test applies at the most significant subset of elements of the product, etc. This shrinking back of the product is to continue until either a subset of elements of the product that satisfies the requirements is reached, or the most basic element of the product is reached and such element fails to satisfy the test (73).

This "shrinking back" concept allows the taxpayer to obtain the benefits of the credit with respect to any portion of its research activities undertaken in the development of a business component that satisfies the requirements of Section 41 (74).

In *Norwest Corporation* (75), the Tax Court considered the definition of qualified research in the context of the development of internal use computer software. The court interpreted Section 41(d) as imposing the following four separate tests:

1. The Section 174 Test (Test 1), which requires that the research expenditures qualify as expenses under Section 174.

2. The Discovery Test (Test 2), which limits the type of information discovered to that which is technological in nature.
3. The Business Component Test (Test 3), which requires that the taxpayer's activities provide some level of functional improvement to a business component of the taxpayer.
4. The Process of Experimentation Test (Test 4), which requires that initial uncertainty concerning the technical ability of the taxpayer to develop the product be eliminated through the development, testing, and analyzing of one or more hypotheses as part of a sequential design process to develop the overall component.

The Tax Court provided content to each of these tests by relying on the legislative history of Section 41 and the policy objectives of the research tax credit.

With respect to Test 2, the Discovery Test, the court concluded that in order to be eligible for the credit, an objective of the taxpayer's activities must be the creation of new knowledge in the field in which the taxpayer is working:

> The legislative history of Section 41 dictates that the knowledge gained from the research and experimentation must be that which exceeds what is known in the field in which the taxpayer is performing the research and experimentation — in this case the computer science field. The fact that the information is new to the taxpayer, but not new to others, is not sufficient for such information to come within the meaning of discovery for purposes of this test. The purpose of the R&E credit was to stimulate capital formation and improve the U.S. economy — not merely the taxpayer's business (76).

The court referred to the legislative history of Section 41 to conclude that the discovery of information must concern the principles of the hard sciences which could result by either "expanding" or "refining" those principles (77). The court also concluded that the Discovery Test of Section 41 differs from the uncertainty test of Section 174. The court pointed out that the uncertainty test under the Section 174 regulations was not adopted until 1994, eight years after the introduction of the Discovery Test under Section 41 in 1986. In addition the court cited the legislative history to Section 41 to suggest that, in amending Section 41 in 1986, "Congress sought to tighten the requirements for obtaining the R&E credit" (78). The court reasoned that because Congress did not change the requirements of Section 174 at that time, the congressional purpose could only be achieved by viewing the two tests as different. Finally, the court viewed the uncertainty test of Section 174 and the Discovery Test of Section 41 as relating to the discovery of different types of information. According to the court the regulations under Section 174 refer to "uncertainty concerning the development or improvement of a product" while Section 41 relates to information that is "technological in nature" and which "fundamentally relies on principles of the hard sciences."

In reaching its decision, the Tax Court also considered Tests 3 and 4. Unfortunately, the court provided only a limited description of Test 3, the Business Component Test. The court only noted that the taxpayer's activities must provide some level of functional improvement, at a minimum, to a business component of the taxpayer. The court provided a greater explanation of its view of Test 4, the Process of Experimentation Test. After quoting from the legislative history, the court stated that this test requires a more structured method of discovery than that required under Section 174, a process in which one or more hypotheses must be developed, tested, and analyzed. According to the court this requirement is to be applied in concert with the shrinking back test until the 80 percent standard is satisfied or the most basic element of the product is reached and that element fails to satisfy the standard. The court concluded by noting that the shrinking back test must be examined on a case-by-case basis to determine which activities are part of the same process or product and which are sufficiently discrete as to warrant separate evaluation.

Exclusion of Certain Research Expenses. Costs incurred in connection with several types of research activities are statutorily excluded from the definition of qualified research expenses under Section 41. Research expenditures are excluded if the research relates only to style, taste, cosmetic, or seasonal design changes (79). More importantly perhaps, qualified research expenses do not include expenses incurred in connection with research conducted after commercial production of a component has started (80). According to the legislative history, "commercial production" is achieved when "the component has been developed to the point where it either meets the basic functional and economic requirements of the taxpayer for such component or is ready for commercial sale or use" (81). The proposed regulations provide that the following activities are deemed to occur after the beginning of commercial production of a business component: pre-production planning for a finished business component, tooling-up for production, trial production runs, troubleshooting involving detecting faults in production equipment or processes, and debugging or correcting flaws in a business component (82). In addition the legislative history states that the credit is not available for the costs of additional clinical testing of a pharmaceutical product after the product is made commercially available, except when the testing is necessary to establish new functional uses for the existing product. For example, "testing a drug currently used to treat hypertension for a new anti-cancer application, and testing an antibiotic in combination with a steroid to determine its therapeutic value as a potential new anti-inflammatory drug, are eligible for the credit" (83).

Qualified research expenses also do not include the costs of research designed to reproduce an existing business component (84). This provision is intended to exclude the costs of "reverse engineering" activities from eligibility for the credit and applies to the reproduction of an existing component by another person based on a physical examination of the business component or on plans, blueprints, detailed specifications, or publicly available information (85). In Private Letter Ruling 9346006 (a Technical Advice Memorandum), the IRS invoked this

exclusion and denied the taxpayer's claimed research credit in connection with the development of the generic form of certain drugs that had previously received FDA approval and for which information concerning active and inactive ingredients was publicly available (86). However, this exclusion does not apply if a taxpayer examines a competitor's product in developing its own component through a process of otherwise qualified experimentation.

Section 41 also excludes from the definition of qualified research expenses the costs of research that is fully funded by another entity (87). Under the regulations, research does not constitute qualified research to the extent that it is funded by a grant, contract, or otherwise by another person, including any governmental entity. However, amounts payable under any agreement that are contingent on the success of the research are considered as paid for the results of the research and are not treated as funding (88). In addition research is considered fully funded if the taxpayer retains no substantial rights in the products of the research under the terms of the agreement providing for the performance of the research (89).

The exclusion for fully-funded research was the subject of Private Letter Ruling 9410007 (a Technical Advice Memorandum). In this ruling, the taxpayer was engaged in fixed price contracts with the U.S. government to conduct research and develop certain types of equipment. Under the contracts the taxpayer retained title and rights to any inventions developed as a result of the research, including patents and copyrights, subject to a "non-exclusive, nontransferable, irrevocable" license in favor of the government. The IRS rejected the taxpayer's claimed tax credit under Section 41 for expenditures incurred in conducting the research required under the contracts. Because the contracts provided for progress payments that were subject to little risk of termination or withholding by the government, the IRS viewed the payments for the contracted research as "expected and likely in the normal course of events." As a result the IRS concluded that, because the payments were not contingent on the success of the taxpayer's research, the research was fully funded. In addition the IRS concluded that the research was fully funded because the taxpayer retained no substantial rights in the research. The IRS reasoned that the taxpayer's rights to use and transfer the technology, copyrights, and technical data resulting from the research were subject to "significant restriction" by the U.S. government (90).

The exclusion from the definition of qualified research for research that is considered fully funded was also the subject of review in *Lockheed Martin Corp. v. United States* (91). As previously noted, the regulations provide that research will be treated as fully funded where the taxpayer retains no substantial rights in the research under the agreement to provide the research. In *Lockheed*, the taxpayer performed research under a number of defense contracts with the federal government and claimed a tax refund of over $63 million under Section 41. The court rejected the taxpayer's claim that the "substantial rights" requirement under the regulations was invalid. The court also rejected the claim that a taxpayer fails to satisfy the substantial rights requirement only when the taxpayer retains *no* rights to the research. Instead, the court looked to Section 1235 for guidance and concluded that the government's unlimited right to use and disclose the research results, as well as the considerable restrictions on the taxpayer's ability to use the research results in the form of security classifications and export restrictions, prevented the taxpayer from claiming that it retained substantial rights in the research. Consequently none of the taxpayer's research expenses qualified for the research credit.

The definition of qualified research expenses also excludes the costs of preparing various types of surveys or studies (92). Under the proposed regulations, this exclusion applies to efficiency surveys; activities (e.g., studies) related to management functions or techniques, market research, market testing, or market development (e.g., advertising or promotions); routine data collections; or routine or ordinary testing or inspection of materials or business components for quality control. Management functions and techniques include the preparation of financial data and analysis, development of employee training programs and management organization plans, and management-based changes in production processes (e.g., rearranging work stations on an assembly line) (93).

Finally, qualified research expenses do not include the costs of research designed to adapt an existing component to a particular customer's needs (94); research involved in the preparation of certain types of computer software (95); research conducted outside the United States, Puerto Rico, or any possession of the United States (96); and research in the social sciences or humanities (97).

Determination of the Incremental Research Tax Credit. Provided that the research at issue satisfies the definition of qualified research, Section 41 allows a tax credit in an amount equal to 20 percent of the qualified research expenses for the taxable year in excess of a base amount (98). Qualified research expenses for the taxable year include both in-house and contract research expenses (99). In-house research expenses include wages paid to employees engaged in qualified research or directly supervising or supporting activities that constitute qualified research (100), the cost of supplies used in the conduct of qualified research (101), and the cost of computers and computer time used in qualified research efforts (102). Contract research expenses, on the other hand, are generally limited to 65 percent of any amount paid or incurred by the taxpayer to a person other than an employee for qualified research (103). However, if the contracting party that will conduct the research is a qualified research consortium, 75 percent of any amounts paid or incurred by the taxpayer to the consortium for qualified research on behalf of the taxpayer and one or more unrelated taxpayers will be treated as qualified research expenses eligible for the credit (104). Contract research expenses that are prepaid are considered as paid or incurred during the period in which the qualified research is actually conducted (105).

With respect to contract research expenses, the regulations specifically require that the qualified research be performed "on behalf of the taxpayer" and that the payments not be contingent on the success of the research (106). The

former requirement is satisfied even if the taxpayer retains only a nonexclusive right to the research results (107). In *Norwest Corp.* (108), the IRS argued that the taxpayer's right under a software development agreement to a "perpetual, nontransferable, nonexclusive and . . . royalty-free license" to use the developed software did not satisfy the regulatory requirements. The IRS suggested that a difference existed between rights to research results and rights to any final product. The court rejected this argument stating that "the right to use the results of the research without paying for that right is at least a right to the research results as that term is applied [under the regulations] — although it may or may not constitute 'substantial rights in the research' within the purview of the regulations" (109). The IRS also maintained that the taxpayer's ability to terminate the development agreement at selected times violated the regulatory requirement that payments not be contingent on the success of the research. The court rejected this argument as well, noting that the taxpayer had no ability under the agreement to recover any payments that it might have previously made.

Importantly a contract research expense will not be a qualified research expense if the product or result of the research is intended to be transferred to another in return for a license or royalty and the taxpayer does not use the product of the research in the taxpayer's trade or business (110). In such a situation, the taxpayer will not be deemed to be engaged in a trade or business to satisfy the "carrying on" requirement of Section 41(b). The legislative history was emphatic about this point:

> [U]nder the trade or business test of new section [41], the credit generally is not available with regard to a taxpayer's expenditures for "outside" or contract research intended to be transferred by the taxpayer to another in return for license or royalty payments. (Receipt or royalties does not constitute a trade or business under present law, even though expenses attributable to those activities are deductible from gross income in arriving at adjusted gross income.) In such a case, the nexus, if any, between research expenditures of the taxpayer and activities of the transferee to which research results are transferred (e.g., any use by an operating company, that is a general partner in a limited partnership which make the research expenditures, of the research results in the operating company's trade or business) generally will not characterize the taxpayer's expenditures as paid or incurred in carrying on a trade or business *of the taxpayer.* (Under appropriate circumstances, nevertheless, the nexus might be deemed adequate for purposes of the section 174 deduction elections.) If, however, the taxpayer used the product of the research in a trade or business of the taxpayer, as well as licensing use of the product by others, the relationship between the research expenditures of the taxpayer (i.e., those research expenditures paid or incurred after such time as the taxpayer is considered to be carrying on the trade or business in which such expenditures are paid or incurred) and the taxpayer's trade or business in which the research expenditures are paid or incurred generally would be sufficient for credit purposes (111).

As previously noted, Section 41 allows a tax credit in an amount equal to 20 percent of the qualified research expenses for the taxable year in excess of a base amount (112). The base amount is determined by multiplying the average annual gross receipts of the taxpayer for the four taxable years preceding the taxable year for which the credit is being determined by the fixed-base percentage (113). With certain limited exceptions, the term "gross receipts" means "the total amount, as determined under the taxpayer's method of accounting, derived by the taxpayer from all its activities and from all sources (e.g., revenues derived from the sale of inventory before reduction for cost of goods sold)" (114). The "fixed-base percentage" is the ratio of the taxpayer's aggregate qualified research expenses for the taxable years between December 31, 1983, and January 1, 1989, to the taxpayer's aggregate gross receipts for that same period (115). Special rules for the determination of the fixed base percentage apply with respect to start-up companies, under which the fixed-base percentage is typically three percent (116). Two statutory limitations also apply, however, in the determination of the taxpayer's fixed-base percentage and base amount. In no event can the taxpayer's fixed-base percentage exceed a maximum of 16 percent or the base amount be less than 50 percent of the qualified research expenses for the current taxable year (117).

The purpose behind the determination of the tax credit as an amount in excess of a firm specific percentage of gross receipts is described in the following excerpt from the legislative history to the Omnibus Budget Reconciliation Act of 1989:

> Although the committee believes it is important to readjust the base amount annually in a way that does not undercut the incentive effect of the credit (which occurs when a firm's base is adjusted solely by reference to its own prior levels of research spending), the committee also determined it was appropriate that the base adjustment reflect firm-specific factors. By adjusting each taxpayer's base to its own experience, the committee wanted to make the credit widely available at the lowest possible revenue cost.
>
> Because businesses often determine their research budgets as a fixed percentage of gross receipts, it is appropriate to index each taxpayer's base amount to average growth in its gross receipts. By so adjusting each taxpayer's base amount, the committee believes the credit will be better able to achieve its intended purpose of rewarding taxpayers for research expenses in excess of amounts which would have been expended in any case. Using gross receipts as an index, firms in fast-growing sectors will not be unduly rewarded if their research intensity, as measured by their ratio of qualified research to gross receipts, does not correspondingly increase. Likewise, firms in sectors with slower growth will still be able to earn credits as long as they maintain research expenditures commensurate with their own sales growth.
>
> Adjusting a taxpayer's base by reference to its gross receipts also has the advantage of effectively indexing the credit for inflation and preventing taxpayers from being rewarded for increases in research spending that are attributable solely to inflation (118).

Alternative Incremental Research Tax Credit

Section 41 also provides for an alternative incremental research tax credit that a taxpayer may elect (119). As described above, the incremental research tax credit is equal to 20 percent of the qualified research expenses in excess of a base amount. The base amount is determined

by multiplying the fixed-base percentage by the taxpayer's average annual gross receipts for the four taxable years preceding the taxable year for which the credit is being determined. Because the fixed-base percentage is the ratio of the taxpayer's aggregate qualified research expenses for the taxable years from December 31, 1983, through January 1, 1989, to the taxpayer's aggregate gross receipts for that same period, a taxpayer may not be entitled to the incremental research credit if the growth in the taxpayer's gross receipts has been significantly greater than the growth in its qualified research expenses. For example, assume that a taxpayer had a fixed-base percentage of 10 percent because gross receipts for the taxable years between December 31, 1983, and January 1, 1989, were $10 million and qualified research expenses for that same period were $1 million. If the taxpayer's average annual gross receipts for the four years prior to the taxable year for which the credit is being claimed increased by 20 percent over the average of the taxpayer's annual gross receipts for the 1984 through 1988 taxable years ($2.4 million = 120 percent × [$10 million ÷ 5 years]), but the taxpayer's qualified research expenses for the taxable year increased by only 10 percent as compared to the average annual qualified research expenses over the 1984 through 1988 period ($220,000 = 110 percent × [$1 million ÷ 5 years]), no credit would be available because the taxpayer's qualified research expenses of $220,000 would not exceed the base amount of $240,000 (10 percent of $2.4 million).

To alleviate this problem, the alternative incremental research tax credit dispenses with the fixed-base percentage of the incremental research tax credit and determines the amount of the credit based on the extent to which the qualified research expenses for the taxable year exceed fixed percentages of the taxpayer's average annual gross receipts for the four taxable years preceding the taxable year for which the credit is being determined (the "Section 41(c)(1)(B) amount") (120). The alternative incremental research tax credit is equal to the sum of the following three amount (121):

1. 2.65 percent of the qualified research expenses for the taxable year to the extent that the expenses exceed 1 percent of the Section 41(c)(1)(B) amount but do not exceed 1.5 percent of such amount.
2. 3.2 percent of the qualified research expenses for the taxable year to the extent that the expenses exceed 1.5 percent of the section 41(c)(1)(B) amount but do not exceed 2 percent of such amount.
3. 3.75 percent of the qualified research expenses for the taxable year to the extent that the expenses exceed 2 percent of the section 41(c)(1)(B) amount.

Thus a taxpayer who is not entitled to a credit under the standard incremental research credit may be entitled to relief under the alternative incremental research credit.

Basic Research Tax Credit

Section 41 also permits a basic research tax credit in the amount of 20 percent of any "basic research payment" made during the taxable year in excess of a base amount (122). The basic research credit was enacted in its current form to provide incentives for corporate support of basic scientific research:

> By contrast to other types of research or product development, where expected commercial returns attract private investment, basic research typically does not produce sufficiently immediate commercial applications to make investment in such research self-supporting. Because basic research typically involves greater risks of not achieving a commercially viable result, larger-term projects, and larger capital costs than ordinary product development, the Federal Government traditionally has played a lead role in funding basic research, principally through grants to universities and other nonprofit scientific research organizations. In addition, the research credit as modified by the [Tax Reform Act of 1986] provides increased tax incentives for corporate funding of university basic research to the extent that such expenditures reflect a significant commitment by the taxpayer to basic research (123).

Basic research for purposes of the credit is defined as "any original investigation for the advancement of scientific knowledge not having a specific commercial objective. . ." (124). A basic research payment includes any amount paid in cash by a corporation to a qualified organization for basic research provided (*1*) the basic research is performed by the qualified organization and (*2*) the payment is made pursuant to a written agreement (125). Qualified organizations include colleges and universities, tax-exempt scientific research organizations, and certain tax-exempt organizations operated primarily to promote scientific research by colleges and universities (126).

As previously noted, the credit is equal to 20 percent of the basic research payments in excess of a base amount. The purpose of calculating the tax credit as a percentage of basic research payments in excess of a the base amount is to ensure that the credit is used to encourage increased taxpayer support of basic research and not to encourage taxpayers simply to switch donations from general university giving to forms of support for which the credit is available (127). This base amount is referred to as the "qualified organization base period amount" and is equal to the minimum basic research amount plus the maintenance-of-effort amount (128). In determining the qualified organization base period amount, the minimum basic research amount is an amount equal to the greater of (*1*) 1 percent of the average amount of any in-house and contract research expenses paid or incurred over the base period or (*2*) the amount of basic research payments treated as contract research expenses under Section 41(e)(1)(B) during the base period (129). For calendar-year taxpayers, the base period is the three-year period from 1981 to 1983 (130). For taxpayers not in existence during the base period, the minimum basic research amount is not to be less than 50 percent of the basic research payments for the taxable year (131).

The maintenance-of-effort amount is equal to the average of the nondesignated university contributions paid by the taxpayer during the base period in excess of the nondesignated university contributions paid by the taxpayer during the taxable year (132). Nondesignated university contributions are equal to any amount paid by

the taxpayer to a qualified organization as defined under Section 41 for which a charitable contribution deduction was allowable under Section 170 and which was not taken into account in determining the basic research credit or as a basic research payment (133). Consequently any reduction in the amount of charitable contributions to qualified organizations from the average amount of contributions made during the base period will offset basic research payments eligible for the basic research credit.

LIMITATIONS ON SECTION 174 DEDUCTIONS

Because qualified research expenses and basic research payments under Section 41 may also be deductible as research or experimental expenditures under Section 174, the Code requires that Section 174 deductions be reduced by the amount of any credit taken under Section 41 (134). The legislative history provides the following example of this requirement:

> For example, assume that a taxpayer makes credit-eligible research expenditures of $1 million during the year, and that the base period amount is $600,000. The taxpayer is allowed a tax credit equal to 20 percent of the $400,000 increase in research expenditures, or $80,000. . . .Under the provision, the taxpayer's deduction is reduced by the $80,000 credit, leaving a deduction of $920,000 (135).

In addition, if research and experimental expenditures are capitalized rather than currently deducted, the capitalized amount must be similarly reduced by the amount of any research credit available under Section 41 (136).

ORPHAN DRUG CREDIT UNDER SECTION 45C

Section 45C of the Code creates the so-called orphan drug credit, which permits a credit equal to 50 percent of the qualified clinical testing expenses paid or incurred for the taxable year (137). The orphan drug credit is so named because it permits a tax credit for certain expenses incurred in the development of drugs used to treat those rare diseases or conditions that affect fewer than 200,000 persons in the United States or that affect more than 200,000 persons but for which the developer of such a drug would have no reasonable expectation of recovering the cost of developing or marketing the drug from its sales in the United States (138). Such diseases and conditions include Huntington's disease, myoclonus, amyotrophic lateral sclerosis (ALS or "Lou Gehrig's disease"), Tourette's syndrome, and Duchenne's dystrophy, a form of muscular dystrophy (139).

Qualified clinical testing expenses are those amounts that would satisfy the definition of qualified research expenses under Section 41(b), with certain modifications (140). One such modification permits 100 percent of any contract research expenses to fall within the definition of qualified clinical testing expenses rather than only 65 percent of such expenses that fall within the definition of qualified research expenses (141). Nevertheless, qualified clinical research expenses do not include any amount otherwise funded under any grant or contract by another person or governmental entity (142). Under the regulations, if the taxpayer conducting the clinical testing for another person retains no substantial rights in the testing, the taxpayer's testing expenses are treated as fully funded (143). Incidental benefits such as increased experience in the field of human clinical testing do not constitute substantial rights in the clinical testing. When the taxpayer conducting the clinical testing retains substantial rights in the testing, the testing expenses are reduced to the extent of any payments and the fair market value of any property to which the taxpayer becomes entitled by conducting the clinical testing (144).

Importantly qualified clinical testing expenses are limited to human clinical testing (145). Human clinical testing requires the use of human subjects to determine the effect of the designated drug on humans necessary to receive approval under Section 505(b) of the Federal Food, Drug, and Cosmetic Act or be licensed under Section 351 of the Public Health Services Act (146). A human subject is an individual who is a participant in research, either as a recipient of the drug or as a control, and may be either a healthy individual or a patient (147). The clinical testing must also occur within the United States unless an insufficient testing population exists within the United States and the testing is performed by a U.S. person or any other person unrelated to the taxpayer (148).

Because qualified clinical testing expenses will also constitute qualified research expenses under Section 41, such expenses are not taken into account for purposes of the research credit under Section 41 if the taxpayer elects the orphan drug credit for the taxable year (149). Nevertheless, such qualified clinical testing expenses are taken into account in determining base period research expenses for purposes of applying Section 41 in any subsequent taxable year (150).

Boston, Massachusetts

OUTLINE

INTRODUCTION

This article explores the roles of strategic alliances and licensing in the biotechnology industry. Two areas that have attracted considerable attention from academics and practitioners are highlighted. First, the article considers the reasons for the prevalence of alliances and licensing agreements in the biotechnology industry. The hypotheses and evidence about the structuring of

these agreements are then considered. Corroboratory evidence from recent field research is then summarized. The final section highlights additional issues for future research.

At the outset, it is worth mentioning the complexity of these agreements, which reflects the costly and uncertain nature of biotechnology projects. The complexity and unpredictability of the research presents challenges in drafting enforceable agreements that specify the contributions of each party in the face of all contingencies. A great deal of innovation has consequently been devoted to the design of these contracts, which makes it difficult to generalize about this phenomenon.

Despite these difficulties, the understanding of strategic alliances is critical to those who wish to understand the biotechnology industry, or high technology industries more generally. The availability of equity from public investors for new high technology firms has been variable, with biotechnology a particularly extreme case. The financing activities of biotechnology firms between 1978 and 1995 are summarized in Figure 1 and Table 1 (1,2). During periods with little financing activity, young high technology firms suffer tremendous financial stresses and have few alternatives to raise capital other than strategic alliances.

Furthermore, the economic importance of technology alliances has been increasing. Panel A of Table 2 shows the number of such alliances has been growing in a variety of industries. While obtaining a comprehensive view of alliance financing is exceedingly difficult, tabulations suggest that alliances are the dominant source of external financing for R&D by young firms in many industries, including advanced materials, information technology, and telecommunications (3). Surveys of corporate research managers suggest that alliances will be an increasingly important mechanism through which R&D is financed in the years to come (4).

Nowhere is this trend clearer than in biotechnology, where alliances with pharmaceutical firms have become in recent years the single largest source of financing for biotechnology firms, accounting for several billion dollars of funds annually. Panel B of Table 2 illustrates the growth in the number of alliances involving U.S. biotechnology firms and other private-sector entities. The economic importance of these transactions is also shown by the willingness of firms to spend substantial amounts litigating them and the size of the damage awards: for example, Genentech and Eli Lilly's dispute over their alliance to develop human growth hormone, which led to the filing of at least six suits between 1987 and 1993. One indication of the importance of these agreements is the

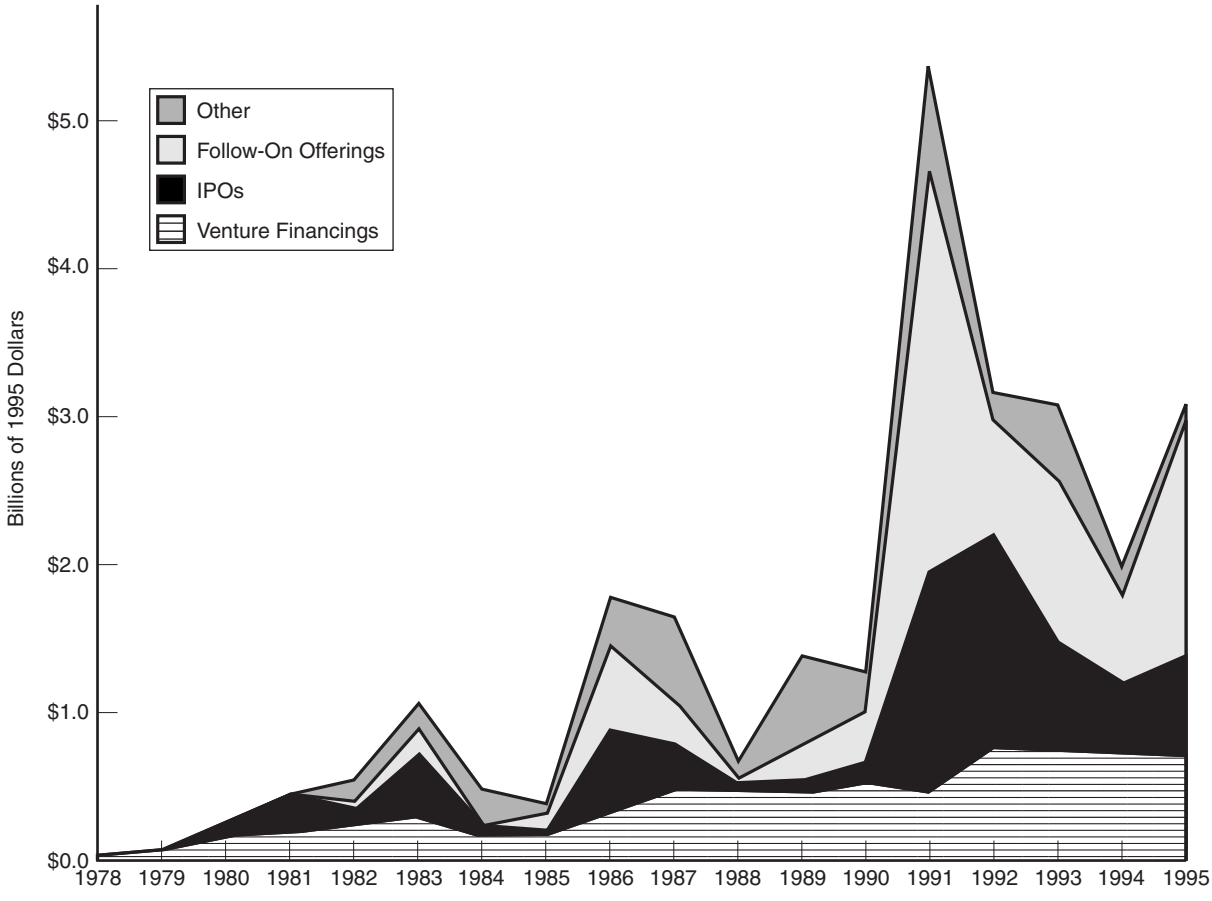

Figure 1. External financing of the U.S. biotechnology industry. The chart depicts the amount raised by U.S. new biotechnology firms through private venture financings, initial public offerings, follow-on public equity offerings, and other sources. (Alliance-related financings are excluded.)

Table 1. External Financing of the U.S. Biotechnology Industry

Source: The methodology for the construction of the venture financing and biotechnology index series is described in Lerner (1). The IPO and follow-on offering series are from unpublished databases of Recombinant Capital. The private placement, debt and convertible, and RDFO compilations are based on the compilations of Shane (2), extended in time and comprehensiveness through searches of a wide variety of sources.

Note: The table summarizes the total raised (in millions of 1995 dollars) by U.S. new biotechnology firms through several major sources: venture capital investments in private firms, initial public offerings (IPOs), follow-on public equity offerings, private placements by financial investors in public firms, debt and convertible security issues, the issuance of shares in R&D financing organizations (RDFOs), and the sum of these offerings. Alliance-related financings are excluded. The table also indicates the year-end level of an inflation-adjusted index based on the valuation of publicly traded biotechnology firms in this period, normalized to be equal to one on January 1, 1978.

fact that in 1995, the dollar volume of commitments to new alliances in the biotechnology industry was almost equal to venture capital disbursements *in all industries* ($3.4 billion vs. $3.7 billion).

Two limitations of this article should be acknowledged at the outset. First, I do not attempt to duplicate the guides that explain the intricacies of the alliance process to practitioners. Numerous excellent volumes exist (5–7), that document the legal and institutional considerations associated with undertaking biotechnology alliances and technology licenses at much greater depth than could be done here. Second, my focus is primarily on the empirical evidence about these alliances. While a number of works about the theory of technology alliances and licensing are mentioned in passing, the primary focus is on the empirical research.

WHY ARE ALLIANCES AND LICENSING SO IMPORTANT IN BIOTECHNOLOGY?

Academic technology transfer officers and executives at small biotechnology companies often face the challenge of commercializing early-stage biotechnologies with tremendous promise. But a variety of considerations make it difficult to raise financing from traditional sources — such as banks and public investors — for some of the most potentially profitable and exciting technologies. As a result in many cases they are required to turn to strategic alliances for financing. These difficulties can be sorted into four critical factors: uncertainty, asymmetric information, the nature of firm assets, and the conditions in the relevant financial and product markets.

The first of these four problems, uncertainty, is a measure of the array of potential outcomes for a company or project. The wider the dispersion of potential outcomes, the greater the uncertainty. By their very nature, young biotechnology companies are associated with significant levels of uncertainty: Only a relative handful of drugs actually become commercial products, and a small subset of these proves to be profitable. The extent of intellectual property protection that a new biotechnology product will receive is also often very uncertain. High uncertainty means that entrepreneurs and investors cannot confidently predict what the company will look like in the future. Uncertainty affects the willingness of investors to contribute capital, the desire of larger firms to license unproved technologies, and the decisions of firms' managers.

The second factor, asymmetric information, is distinct from uncertainty. Because of his day-to-day involvement with the technology, a scientist knows vastly more about his discovery's prospects than prospective investors. Various problems develop in settings where asymmetric information is prevalent. For instance, the entrepreneur may take detrimental actions that outsiders cannot observe: perhaps undertaking a riskier strategy than

Table 2. Interfirm Alliances in Three Industries, and by Biotechnology Firms

1989	71		205
1990	81		851
1991	115	741	647
1992	75	931	392
1993	113	1373	806
1994	66	1772	
1995	171	3421	
1996		2334	
1997		4352	

Source: The first panel is from National Science Board (3). The number of new alliances and precommercialization payments series in the second panel are from Recombinant Capital and its unpublished databases. The actual payments series is from Shane (2). It has not been extended beyond 1993 or to include additional firms.

Note: The first panel presents the number of publicized alliances by U.S. firms in three industries — information technology, biotechnology, and advanced materials — between 1980 and 1994. The second panel examines only alliances involving U.S. biotechnology companies between 1981 and 1995 filed with the U.S. Securities and Exchange Commission or state regulatory bodies who make such information public. Presented are the number of new filed alliances each year, the sum of all promised precommercialization payments in the filed alliances that year (the sum of the nominal payments is expressed in millions of 1995 dollars), and the actual payments to a sample of 49 of the largest biotechnology firms in each year (in millions of 1995 dollars).

initially suggested or not working as hard as the investor expects. The entrepreneur might also invest in projects that build up his reputation at the investors' expense.

Asymmetric information can also lead to selection problems. The scientist who makes a potentially important discovery may exploit the fact that he knows more about the project or his abilities than his investors do. Licensees may find it difficult to distinguish between truly revolutionary technologies and impractical ones. Without the ability to screen out unacceptable projects, outsiders are unable to make efficient and appropriate decisions choices regarding where to invest. These problems have been particularly severe in biotechnology, due to the scientific complexity of the development of new products and processes.

The third factor is the nature of the assets. Firms that have tangible assets — such as machines, buildings, land, or physical inventory — may find financing easier to obtain or may be able to obtain more favorable terms. The ability to abscond with the firm's source of value is more difficult when it relies on physical assets. When the most important assets are intangible, raising outside financing or entering into strategic alliances may be more challenging. In the biotechnology industry, firms have tended to rely on patent protection to protect assets. Those firms that have relied on trade secrets or informal "know-how" have found attracting investors or entering into licensing agreements to be very difficult. For instance, trade secrets offer exceedingly narrow intellectual property protection, only protecting against misappropriation: "the acquisition of a trade secret by a person who knows or has reason to know that the trade secret was acquired by improper means" (8). Thus a firm cannot sue a rival who discovers its trade secret independently or through "reverse engineering" (the disassembly of a device to discover how it works). This is unlike patent protection, which allows the awardee to prosecute others who infringe, regardless of the source of the infringers' ideas. Pooley (9) notes that very few "naked" trade secret licenses are observed, suggesting that the information covered only through this very narrow property right is difficult to transfer in an arm's-length exchange. Further evidence of the importance of broad patent protection in biotechnology is found in Lerner (10).

Market conditions also play a key role in determining the difficulty of financing firms. Both the capital and product markets may be subject to substantial variations. The supply of capital from public investors and the price at which this capital is available may vary dramatically. These changes may be a response to regulatory edicts or shifts in investors' perceptions of future profitability. The availability of equity from public investors for new biotechnology firms has been particularly variable. As Figure 1 indicates, the amount raised by publicly traded biotechnology firms in follow-on offerings (measured in 1995 dollars) went from $340 million in 1990 to $2.7 billion in 1991, then fell again to $788 million in 1992. Since young biotechnology firms face enormous costs while developing new products, they are typically very aggressive in raising capital. Practitioner accounts suggest that during the periods when there are few public equity issues, the markets are essentially "closed" to biotechnology firms.

As a result of all these problems, biotechnology firms often have little choice but to turn to corporations for financing. A pharmaceutical firm or other corporation with a related line of business can overcome many of these information problems, by undertaking extensive due diligence prior to the transaction and monitoring the firm afterwards. As discussed in Lerner (11), this type of intensive oversight is also provided by venture capitalists, though the resources that venture capitalists invest in the typical company are much smaller than those that a major corporation will devote to a substantial technology alliance. The corporation may have assets, such as sales forces and manufacturing know-how, which young biotechnology firms lack and yet are essential to the successful introduction of a new product. Small, research-intensive firms frequently rely on alliances with larger corporations to avoid having to construct these capabilities, which may take years to develop. Furthermore, the ongoing operations of the corporate partner may enable it to overcome some of the problems associated with the intangible nature of the biotechnology firm's assets.

Described in this manner, these problems may appear to be quite abstract. But they have very real implications for academic technology managers or corporate executives seeking to commercialize early-stage biotechnologies. They may find investors unwilling to invest the time and resources to examine early-stage technologies, or offering only modest payments in exchange for large stakes in innovations that the scientists, technology transfer officers, and company executives believe to be quite valuable. In the remainder of this section, I will summarize the evidence regarding these claims.

This set of suggestions has been most directly examined in two recent Ph.D. dissertations. Both Shane (2) and Majewski (12) examine the decision of biotechnology firms to raise capital through the public markets and through alliances. Through their different methodologies, these works show that firms turn to alliance financing when asymmetric information about the biotechnology industry is particularly high. During these periods — which are measured through such proxies as the variance of the returns of biotechnology securities — firms are likely to delay the time until their next equity issuance, and to rely on alliances rather public offerings as a source of external financing. The authors argue that the greater insight on the part of the pharmaceutical company into the nature of the biotechnology firm's activities allows it to make successful investments at times when uninformed public investors are deterred by information problems.

A challenge to this view is Pisano's (13) examination of the outcome of biotechnology firms' research projects that are and are not developed with the help of alliances with pharmaceutical firms. He examines the probability that a biotechnology company successfully develops a drug being pursued through an alliance, as opposed to one developed by the firm itself. His conclusion that a "lemons problem" leads biotechnology firms to only undertake alliances with pharmaceutical companies that involve inferior technologies, however, seems difficult to reconcile with the large number and dollar volume of these transactions. (A lemons problem can arise when, because of his day-to-day involvement with the firm, an entrepreneur knows more about his company's prospects than investors, suppliers, or strategic partners. Because the counterparty in the exchange is at an informational disadvantage, the potential partner or investor may refuse to enter into a transaction at all.) One way to reconcile these observations is the possibility that biotechnology firms pursue projects through alliances that have lower expected probabilities of success, but whose ultimate payouts are greater.

A related set of work has looked at the decision of the larger company to undertake an alliance. Pisano (14) examines pharmaceutical firms' choices between developing new drugs in-house versus through alliances in the

case of 92 drug development projects. He demonstrates that the insights of transaction cost economics (15) and incomplete contracting theory (16) are highly relevant here. In brief, both sets of work highlight the difficulties that two parties may have in undertaking contracts when there is considerable uncertainty. (Among the barriers to writing optimal contracts are the difficulty of negotiating detailed contracts and the problem of being unable to foresee all contingencies.) In particular, when there are few small biotechnology firms working in the field, the pharmaceutical company is more likely to undertake the project in-house. This is consistent, Pisano argues, with the theoretical suggestions that "hold up" problems — that is, efforts by one of the parties to renegotiate the contract on terms more favorable to itself after the agreement is signed — will be greater in this setting. Pisano also finds evidence that firm-specific factors are critical in the decision to undertake alliances.

The determinants of the firm-specific differences in the rate of alliance formation by various pharmaceutical and biotechnology firms are the other major focus of the writings on why firms form alliances. Arora and Gambardella (17) are two of the few economists to examine these firm-specific factors. (Most researchers of these questions have come from an organizational or sociological perspective.) They (17) examine four strategies — alliances with biotechnology firms, research collaborations with universities, purchases of minority interests in biotechnology firms, and acquisitions of these firms — by large pharmaceutical and biotechnology firms. They present a model that suggests that these activities will be complements: If a firm pursues one of these activities, it should be likely to undertake all of them. Furthermore they suggest that these activities should be disproportionately pursued by firms with a greater internal knowledge of biotechnology. On the basis of their analysis of 81 firms, the authors conclude that the four activities are indeed complements, and are disproportionately undertaken by firms with large existing stocks of biotechnology patents. Similar conclusions emerge from a later study by Arora and Gambardella (18). [These studies should be viewed in light of the critique by Athey and Stern (19) of studies of complementarities.] Other studies that have highlighted the importance of firm-specific factors in biotechnology alliance include Argyres and Liebskind (20) and Roberts and Mizouchi (21).

Another approach to firm-specific factors has characterized the organization literature. In particular, these works have highlighted the importance of networks of firms. In industries with rapidly changing and evolving technologies, this literature argues, knowledge is diffused across a variety of firms. As a result firms seek to learn through the formation of alliances. This literature highlights the importance of alliances early in an industry's evolution. These can form the foundation for repeated relationships and further learning.

Powell, Koput, and Smith-Doerr (22) highlight the path-dependent nature of alliance formation in biotechnology. The decision by both biotechnology and pharmaceutical firms to establish alliances seems to be driven less by characteristics such a biotechnology firm's age or growth rate, but rather by earlier experience with such alliances. The authors argue that these firms learn about how to manage and absorb knowledge from their initial strategic alliances. The authors further suggest that firms that are more "centrally" located in alliance networks are more likely to expand their alliance activities.

Some of the consequences of alliances are highlighted in Stuart, Hoang, and Hybels (23) and Koput, Powell, and Smith-Doerr (24). These studies show that biotechnology firms with prestigious sponsors (e.g., financing from well-established venture capital groups and collaborations with prominent pharmaceutical companies) benefit from these relationships. In the former paper, it is shown that biotechnology firms with prestigious partners are likely to complete an IPO sooner and to command a higher market capitalization at the time of the offering. The latter paper documents that companies with such partners are more likely to enter into other collaborations, whether with other elite or non-elite firms.

HOW ARE ALLIANCES STRUCTURED?

The second broad question that this article considers is the manner in which alliances are structured. Unlike the formation of alliances, which as highlighted above has been explored by both economists and sociologists, economists have played a leading role in the study of this issue. Given the dynamic and complex nature of R&D alliances, it is not surprising that there are multiple potential explanations for their structure. This section will begin by highlighting three classes of relevant theoretical research.

The first of these is incomplete contracting theory. A wide range of models, beginning with Grossman and Hart (16) and Hart and Moore (25) and summarized in Hart (26), consider incomplete contracting between a principal and an agent. A typical assumption is that it is impossible for the two parties to write a verifiable contract that could be enforced in a court of law that specifies the effort and final output of the two parties. This is because there are many possible contingencies, all of which cannot be anticipated at the time the contract is drafted. Because of this nonverifiability problem, these models argue that it is optimal for ownership of the project to be assigned to the party with the greatest marginal ability to affect the outcome. This party, who will retain the right to make the decisions that cannot be specified in the contract, should also receive any surplus that results from the project. Because of this incentive, the party will make the decisions that maximize — or come close to maximizing — the returns from the project. An alternative, though complementary, view suggests that firms may write "excessively" incomplete contracts. In particular, Bernheim and Whinston (27) show that in settings where one set of behaviors cannot be contracted upon, it may be optimal to leave other aspects of ownership unsettled. Such "strategic ambiguity" is more likely in settings with greater uncertainty, consistent with the predictions of the Grossman-Hart-Moore class of models.

Aghion and Tirole (28) adapt this general model to a R&D alliance between two firms. As long as the R&D-performing firm has the initial bargaining power or does not face capital constraints, the results are as discussed above: The control rights are assigned to the party whose marginal contribution to the project's success is greatest. When the financing firm has the initial bargaining power and the R&D firm is capital constrained, however, a different pattern may emerge. In particular, if it is optimal for the property rights to be transferred to the R&D firm, the best outcome will not be achieved: The financing firm will be willing to transfer ownership, but the cash-constrained R&D firm will not have enough resources to compensate the financing firm. As a result, an inefficient allocation of the property rights occurs, with the financing firm retaining the rights to the invention.

Biotechnology research has numerous features that resemble the setting depicted in the theoretical literature on incomplete contracts. Biotechnology projects — particularly early-stage efforts — are highly complex and uncertain, making it very difficult to specify the features of the product to be developed. As one biotechnology executive relates:

> Redefining the work when the unexpected happens, as it invariably will, [is essential]. Research is by its very nature an iterative process, requiring constant reassessment depending on its findings. If there is a low risk of unexpected findings requiring program reassessment, then it is probably not much of a research program. (29, pp. 220–221)

Similarly the complexity and unpredictability of the research presents challenges in drafting an enforceable agreement that specifies the contributions of the R&D firm. In particular, firms that contract to perform R&D in alliances frequently have ongoing research projects of their own, in addition to the contracted efforts. In case of a dispute, it may be very difficult for the financing firm to prove that the R&D firm has employed alliance resources to advance projects that are not part of the alliance.

At the same time biotechnology alliances present a more complex picture than many incomplete contract models. Typically these models assume a one-time contracting process between the two parties. Actual alliances reveal more complex contracting patterns. For instance, pairs of firms undertake repeated sets of alliances on different topics. These prior interactions may allow firms to develop reputational capital, and at least partially address some of the contracting problems. Second, these models often assume a vertical relationship: The agent contributes all the effort. In actuality, the relations between some alliance parties are likely to have horizontal elements. For instance, some of the alliances are between pairs of biotechnology concerns, each of which may contribute knowledge. Third, typically parties in these models bargain over a very reduced set of parameters, with a single ownership right being divided between the parties. Real-life agreements, as noted above, are much more complex. Finally, in many models, such as Aghion and Tirole (28), there is no consideration of the impact of asymmetric information on the negotiation of the alliance: Both parties are assumed to be fully informed at the time the agreement is signed. Rather, the major concern of the negotiating parties is reducing the potential for suboptimal effort after the agreement is signed. In actuality, the situation may be more complex. In particular, the financing party may not be fully informed about the prospects for the project. This may lead to contractual terms that seek to force the informed party to reveal if he has additional information.

This class of models suggests a variety of empirical implications. In general, among alliances where informational asymmetries are greater, the period during which the R&D firm maintains active control over the project should be longer. For instance, alliances that focus on drug development, which is a much more expensive and complex process than the development of diagnostics and other biotechnology applications, are likely to have much greater informational asymmetries. The incomplete contracting hypothesis consequently suggests that these alliances should be associated with longer contract lives.

A second and quite contrasting explanation is the need to provide monitoring. An essential assumption of the incomplete contracting literature is that addressing the agent's (R&D firm's) behavior after the contract is signed is very difficult for the principal (financing firm). In particular, because the contractual agreements cannot foresee every contingency, even if the financier observes problematic behavior on the part of the agent, he cannot address the behavior in a court of law.

The costly monitoring hypothesis, on the other hand, assumes that such behavior can be addressed, but to do so is expensive. Provisions that allow greater oversight and control on the part of the principal are expensive to negotiate and oversee. As a result these terms should be only included in contracts when the danger of opportunistic behavior is high or the costs of oversight modest. The costly monitoring hypothesis [as articulated, for instance, in Smith and Warner (30) and Williamson (15)] predicts that because the ease of monitoring and incentives to pursue opportunistic behavior vary, the optimal degree of restrictiveness will differ across contracts.

One manifestation of these trade-offs should be in the period that the corporation commits to finance the R&D of the smaller firm. If corporations could costlessly monitor the firm, they would monitor and infuse cash continuously. If the project's expected value fell below some value, the corporation would halt funding of the project. (The R&D firm might still wish to continue because the funds are enabling the firm to continue its existing projects, or because the management team itself is enjoying private benefits from the funding.)

The renegotiation or extension of a strategic alliance, however, is a costly process. Particularly within the financing firm, there is likely to be the need for extensive analysis and review prior to the modification of an existing agreement. The renegotiation process is likely to involve a variety of internal and external legal advisors. As a result alliances are negotiated for distinct periods, not continually reviewed and funded.

This view suggests that the duration of these alliances should be a function of the degree of potential agency

problems and the cost of providing monitoring. For example, alliances that focus on the complex drug development process are likely to face much greater informational asymmetries. In these settings the costly monitoring hypothesis suggests a greater need for monitoring and shorter alliance lives.

A third explanation is the need for avoiding the costs of financial distress. An extensive corporate finance literature has documented these costs, which can be divided into three classes:

- The liquidation of a biotechnology firm can be highly destructive of value. In particular, it is often difficult to sell "naked" patent awards without the associated know-how and trade secrets. Without the researchers who developed the concept, most patent awards are likely to be worth little. More general evidence of the substantial indirect costs of financial distress is found in Lang and Stultz (31) and Opler and Titman (32).
- Even if the biotechnology firm is not liquidated, concerns about financial distress may cause the firm to be unable to pursue value-creating investment opportunities. Models such as Stultz (33) and Froot, Scharfstein and Stein (34) suggest that if information asymmetries at times preclude external financing or else make it very costly, firms may be unable to pursue value-creating projects.
- Even if financial distress imposes few costs on the firm's shareholders or society as a whole, managers may still seek to avoid distress. In particular, Smith and Stultz (35) formally show that a risk-averse manager who owns shares in a company is likely to engage in socially undesirable levels of risk management. Managers may fear that the bankruptcy of the firm for which they work will be very costly, both in terms of personal wealth and future earning potential (due to the reputational consequences).

This danger of financial distress is very real in the biotechnology industry: Numerous firms have been forced to liquidate or radically trim back promising research programs because of an inability to access external financing.

Motivated by any one of these reasons, the managers of R&D firm may seek to limit the firm's potential exposure to financial distress. The managers may see undertaking one or more corporate alliances as an attractive mechanism to this end. In exchange for giving up much of the eventual profits from an innovation, the R&D firm receives a guaranteed stream of payments from the financing firm. The R&D firm's desire to engage in such "risk management" is likely to be an increasing function of the potential costs of financial distress and the probability that such an event will occur. (Presumably a risk-neutral financing firm would acquiesce to such an agreement in exchange for a lower royalty other concessions.)

While the variation in the extent of the social or managerial costs of financial distress is difficult to observe, it is possible to identify characteristics of the R&D firm that are likely to be associated with a higher probability of distress. For instance, firms whose research focuses on costly drug development are likely to face a greater probability of financial distress, and may be more willing to enter into alliances that guarantee protracted financial payments.

Pisano (36) first examined these questions in a pioneering work. He studied 195 collaborative agreements between biotechnology and pharmaceutical firms, and asked where purchases of equity by the pharmaceutical company were used alongside contractually specified governance rights (e.g., the pharmaceutical company's right to obtain periodic briefings on the progress of the biotechnology firm). Consistent with the costly monitoring view, he found that in settings with greater information problems and information asymmetries (e.g., when the project was R&D intensive or the alliance entailed multiple projects), the pharmaceutical company was more likely to purchase equity as a part of the agreement. The added rights associated with equity ownership can be seen as strengthening the pharmaceutical company's ability to control the biotechnology firm.

Lerner and Merges (37) examine the determinants of control rights within a sample of 200 alliances. They analyze the share of 25 key control rights allocated to the financing firm by regressing the assigned number of rights on independent variables denoting the project stage and financial conditions, as well as controls for a variety of alternative explanations. Consistent with the framework developed by Aghion and Tirole (28), the greater the financial resources of the R&D firm, the fewer control rights are allocated to the financing firm. For instance, a one standard deviation increase in shareholders' equity at the mean of the independent variables leads to an 11 percent drop in the predicted number of control rights assigned to the financing firm. Evidence regarding the relationship between control rights and the stage of the project at the time the alliance is signed is less consistent with existing theory. Projects in their early stages at the time of alliance formation actually assign significantly less control to the R&D firm.

Lerner and Tsai (38) explore the impact of the financing environment at the time was signed on the success of agreements. They show that in periods where financing availability was strong, the agreements were more successful, whether measured by the probability that the drug advanced to the next stage in the clinical trials or was approved. They show that the effect was more pronounced in those agreements where the biotechnology company received little of the control, as Aghion and Tirole predict. This helps address concerns that the result is driven by shifts in an unobserved third factor. Lerner and Tsai also examine the likelihood of renegotiation. If it would maximize innovative output to assign control to the small biotechnology company, though this allocation of control is precluded by financial market conditions, then there should be evident a distinct pattern in renegotiations. In particular, when financing conditions improve for biotechnology firms, it is those agreements assigning the bulk of the control to the major pharmaceutical firm that should be disproportionately renegotiated. The empirical results are consistent with this pattern.

There is also a small but growing empirical sociology literature on the governance of inter-firm transactions. (My thanks to the referee for highlighting this literature. Also related is the much larger literature in the area of social networks, which addresses the communication properties of networks in situations characterized by embedded exchange.) These issues were framed by a theoretical essay by Granovetter (39), who argued that the structure of the alliance network in any given industry plays an important role in diffusing information about the reliability of various industry participants. Access to this information, in turn, will play an important role in influencing how a new alliance will be governed. For instance, a major pharmaceutical company already engaged in a number of alliances will find that its existing relationships provide access to reliable and cheap information about other actors. Information flowing through connections such as shared third parties (i.e., when two firms have an alliance with the same third organization) are quite effective, which allow well-connected contracting parties greater flexibility in structuring collaborative arrangements. The empirical findings in this literature, most importantly Podolny (40) and Gulati (41), are consistent with Granovetter's reputation model. Two of the more robust findings in this literature are that alliances are less likely to have an equity component when two firms have previously formed an alliance or when they are proximately located in the network of prior deals.

Research into contract structure is at an earlier stage than that about the determinants of alliance formation. Thus, the extent of uncertainty about the key drivers of contract structure is not surprising. The proliferation of information on alliances available through database companies such as Recombinant Capital (much of which is publicly accessible on the Internet at *http://www.recap.com*) and the Securities and Exchange Commission's EDGAR database (available at *http://www.sec.gov*) should encourage future researchers.

WHAT IS THE EVIDENCE FROM FIELD RESEARCH?

Another important source of information on biotechnology alliances is case study research. The conclusions of these cases are often not as "neat" as statistical analyses that are crafted to examine a particular question, but field-based analyses can generate a variety of insights. This section highlights the experiences of three companies that have been examined in case studies. While not exhaustive of the case study literature on biotechnology alliances, they suggest the richness of insights that field-based research can provide.

These three young companies all were developing advanced human therapeutics and grappling with the challenges posed by alliances. The biotechnologies pursued by the three firms are quite different: antigen-based allergy drugs (ImmuLogic Pharmaceutical Corporation), advanced drug delivery mechanisms (ALZA Corporation), and monoclonal antibody-based treatments of inflammation (Repligen Corporation). There were considerable differences in the location and sophistication of strategic partners and the stage of development of the technologies.

One point that these cases raise — consistent with the literature discussed above — is how the allocation of control rights is determined both by concerns about behavior after the alliance is signed and by relative bargaining power. One alliance that may be considered successful in many respects was Repligen's May 1992 alliance with Eli Lilly regarding a very early-stage effort to develop a monoclonal antibody-based treatment of inflammation after heart attacks (43). The net-of-market return for Repligen in the three-day window around the announcement of the transaction in May 1992 was +9 percent, and that of Lilly, +2 percent. [These increases can be compared to the +2.1 percent reaction to 55 announcements of R&D initiatives by high-technology firms found by Chan et al. (42).] The early-stage project succeeded in getting its lead product candidate into Phase I trials in just 13 months. (After extending the project in June 1995, however, Lilly canceled its involvement three months later, citing shifting internal priorities.)

In the Repligen-Lilly alliance, three control rights were the subjects of protracted negotiations. The first was the management of clinical trials: the right to decide which drugs would be pursued and when. A second was the control over the marketing strategy, an arena in which Lilly had extensive experience and Repligen only a slight acquaintance. Finally, both parties wished to control the process development and ultimate manufacturing of the drug. Repligen compared favorably on various financial measures to other biotechnology firms at the time that the alliance was signed. Similarly the firm had outperformed an index of biotechnology securities over its history by over 40 percent. (Stock price performance is measured from the close of the day of Repligen's initial public offering to avoid including the "underpricing" of the offering — i.e., the discount at which the underwriters sold the shares to the original investors. Repligen's beta did not differ materially from that of other biotechnology firms.) At the same time, investment banking analysts had expressed concern about the financial pressures that might result if Repligen's earlier alliance with Merck was terminated.

The terms of the alliance that emerged from the negotiations appeared to assign the control rights to the parties whose behavior would have the greatest impact on the product development effort. Repligen was allowed a great deal of control over developing the lead product candidate, an area where it had considerable experience, but tangential product development activities were subject to extensive review by Lilly. Lilly was assigned control over all aspects of marketing, while Repligen was assigned all manufacturing control rights, unless it encountered severe difficulties with regulators.

Other alliances illustrate the importance of the relative bargaining power of the two parties. An example was the January 1978 alliance between ALZA and Ciba-Geigy (44,45). At the time of the alliance, ALZA faced a major financial crisis. The firm had little more than $1 million in the bank, was spending $2 million more per month than it was receiving in revenues, had nearly exhausted its bank credit line, was in violation

of several loan covenants, and was precluded from a sale of equity to the public by unfavorable market conditions and the perception that ALZA had been excessively optimistic in its earlier communications with investors and analysts.

The alliance assigned almost total control to the Swiss pharmaceutical giant. Ciba-Geigy was given a supermajority on the joint board that reviewed and approved potential research projects, the right to license and manufacture any of ALZA's current or future products, the ability to block any other alliances that ALZA proposed to enter into, and 8 of the 11 seats on ALZA's board of directors. In addition the Swiss pharmaceutical giant received a new class of preferred shares. If converted into common stock, the new preferred shares would represent 53 percent of the equity in ALZA. Until conversion, however, Ciba-Geigy had 80 percent of the voting rights, an allocation that allowed it to employ ALZA's tax losses.

At the same time it is reasonable to believe that concerns about the postalliance behavior of ALZA also motivated Ciba-Geigy to demand strong control rights. ALZA's leaders had displayed little ability to direct the firm's research effort over the course of the 1970s. This may have led Ciba-Geigy to conclude that the benefits of allocating control rights to ALZA's management were limited. Despite the strict control rights contractually assigned to Ciba-Geigy, there were frequent disputes between the two firms as ALZA researchers sought to either circumvent the pharmaceutical firm's middle management or ignored their instructions outright. Frustrated by these problems, Ciba-Geigy agreed to terminate the alliance and sell back its equity to ALZA in November 1981.

A contrasting illustration is presented by ImmuLogic (46). In March 1991 the firm was considering either entering into an alliance or raising equity in an initial public offering. One concern that led the firm to decide to go public was that a potential strategic partner might exploit its relatively weak financial condition. In other words, ImmuLogic feared that a pharmaceutical company might obtain numerous concessions on key governance and financial issues by protracting the negotiations until ImmuLogic was close to running out of capital. It consequently deferred negotiating an alliance to develop and market its allergy drugs until the firm went public in May 1991. The firm announced an alliance with Marion Merrell Dow in December 1991, which allowed ImmuLogic to retain numerous control rights, such as an equal role in planning marketing strategy in the United States: *In Vivo* magazine hailed the transaction as "push(ing) the limit of the biotech deal . . . a partnership in fact as well as name" (quoted in Ref. 46, Teaching Note 5-293-118, p. 7). Just as ALZA's relinquishment of almost total control to Ciba-Geigy was in large part a consequence of its weak financial position, ImmuLogic's ability to obtain these control rights reflected its financial strength.

These cases also emphasize two issues that are not highlighted in the theoretical literature. One is the interaction between the allocation of control rights and the financial terms of the transactions. For instance, in the negotiations that led to Repligen's retention of control over manufacturing, the firm agreed to an alteration in its compensation. Repligen accepted a lower royalty than originally envisioned, 5 percent of the sales price, but agreed to supply the drug to Lilly at a price (about 15 percent of the sales price) above what it believed its true manufacturing cost would be. Repligen agreed to reduce the price that it charged Lilly if it was able to manufacture the drug for less, but only if its cost was below 8 percent of the sales price.

A second interesting and unexplored aspect is the apparent signal that the allocation of control rights provided to potential investors and other outsiders. Both ImmuLogic and Repligen highlighted their retention of key control rights in the press releases announcing the transactions described here. Their ability to obtain these rights attracted favorable comments in the trade press and analyst reports alike. These patterns suggest a richer set of interactions than theoretical treatments of these issues imply.

WHERE IS FURTHER RESEARCH NEEDED?

This article has sought to suggest the importance, richness, and complexity of alliances and licensing in the biotechnology industry. While much has been learned from the economic and sociological research into biotechnology alliances over the past decade, much more remains to be discovered. This final section will highlight two issues that deserve to be a particular focus of attention.

The first of these relates to the structure of the payments between the financing and the R&D firm. The design and implementation of incentive schemes in general is a major focus of the finance and economics literature, but payments in alliances have been little examined except in theoretical works (47,48). This lack of attention is a reflection of the difficulty in analyzing them. The payments typically are of several types: an initial up-front payment, a purchase of equity (which the financing firm may be able to force the R&D firm to repurchase if the alliance is unfruitful) or warrants, commitments to contract for R&D on specific topics, milestone payments contingent on the achievement of technological and marketing objectives or the renewal of the agreement, and a royalty on the eventual sales generated by the product. Assessing the expected net present value of these payments is very difficult. The magnitude and timing of eventual sales that the project will generate are difficult to anticipate. The amount of the R&D to be contracted for is often ambiguous. Alliances may also include contingent payments for remote outcomes. (The rationale for their inclusion is that firms frequently report — and analysts tabulate when assessing firms — the sum of all precommercialization payments from new alliances, whether the funds are likely to be received or not. These contractually specified contingent payments may thus convey important strategic benefits, even if the probability of payment is very low.) Clearly, this is a difficult but important area for research.

A second question relates to the impact of this contracting regime on the rate and direction of technological innovation in the biotechnology industry. Zucker, Darby,

and Brewer (49), in their analysis of the impact of academic research on the development of the biotechnology industry, suggest that academic licensing practices are one of the reasons for geographic clustering of innovative biotechnology firms around top-tier universities. Theoretical work by Gans and Stern (50) provides reasons to believe that the impact of contracting on the pace of innovation may be complex and multidimensional. The impact of intercorporate licensing on innovation is an important issue for future research, given the number and financial significance of these transactions. While a few initial steps along these lines have been taken (51,52), much more remains to be done.

T

TRANSFERRING INNOVATIONS FROM ACADEMIC RESEARCH INSTITUTIONS TO INDUSTRY: OVERVIEW

MICHAEL D. WITT

Troy, Michigan

SUSAN K. LEHNHARDT
Morrison & Foerster LLP
New York, New York

OUTLINE

ACADEMIC RESEARCH INSTITUTIONS

Congress has made a national priority of bringing academe and industry together because of the beneficial effect of biomedical technology transfers on U.S. competitiveness and public health (1).

The importance of this interaction has evolved over time. Traditionally academe viewed its mission as above the fray of industry. Industry, likewise, relied on itself for research and development of new products and viewed academe as the "ivory tower" and not producing anything of commercial value. Since the 1960s academic research centers have attracted the best and brightest scientists and researchers to their laboratories. Large numbers of available and qualified applicants enabled research facilities to be rigorous and selective in their review of medical school and graduate school candidates. The students who survived this process were skilled, exceptionally talented, and dedicated to achieving success in the academic environment. With substantial federal support for research, mostly at the basic research level, a productive, unique, yet eccentric atmosphere developed where research was not inhibited by commercial or financial restraints.

Although this research capability is still largely in place, tremendous fiscal constraints for the last decade or more have eroded the ability of scientists to pursue basic research without at least some consideration of practical, commercial applications of their research. In addition federal reimbursement levels for medical care at academic medical centers (which also funds teaching, capital improvements and medical research) is increasingly restrictive.

The fiscal drain on academic science is exacerbated by heightened bureaucratic demands on medical research center personnel. Independent yet federally mandated peer review organizations, quality assurance programs, boards of medical examiners, state, federal and private insurance cost containment programs, and malpractice suits, each detract from the institutional mission, and cumulatively extract a profound professional toll on academic scientists. As a result frustration and anger is endemic, even among the most idealistic and dedicated.

In light of these developments, scientists still willing to work in the non-profit sector are turning to industry for research support (2). Research scientists who long eschewed corporate contacts are now more willing to seek out and perform corporate sponsored research.

Many corporations, similarly squeezed by considerable international competition, restrictive federal tax policies, product liability costs, and reduced access to the public financing markets, are looking anew at research centers (3). Corporations sense that internal research and development (R&D) might be productively supplemented with outside research efforts and technology, initially developed at government expense (3).

The resulting relationships between academics and industry require considerable patience. The parties also need to understand each other. Their motivation, stress, pressures and conflicting obligations are quite different.

Academics is Different than Industry

Scientists in the nonprofit sector are accustomed to responding to academic pressures. They are relatively unaccustomed to conducting exploratory research at the applied level as do their industry counterparts. The rate and method of academic research, the selection of research objectives, limited resources, and accountability are fundamentally different.

When an academic scientist and his peer group are convinced of a given result, the result often raises other questions and additional effort, but the given result, even if appropriate, is generally not developed into a product — in industry, this often is only a starting point. The result must be developed into a product, and tested further to the full satisfaction of management and the regulatory and licensing agencies. The scope of the commercial-grade scientist's work may be less purely inventive at times,

but the cost and effort required to create a product, then testing it, may be several hundred to thousand-fold the cost of the initial discovery.

Qualitative and Quantitative Differences in Research

Job security in the academic world requires quality teaching, writing, research, and a financial base provided by grants and government research funds. Reduced grant funding threatens this job security. It gives rise to tremendous pressure to generate research funds, and causes scientists to seek funding from any available resource. One source of research funding is the commercial sector. The commercial sector is willing to pay for research, and to pay for intellectual property that may lead to a product. Historically academicians were not financially rewarded for turning their research results into products. Thus they tended to carry the research effort only to the "proof of concept" stage, then moved on to their next activity. Policy changes at most academic centers now allow scientist to receive financial rewards from commercial successes (4).

As nonprofit organizations, academic research institutions are primarily funded by the federal government. Since the federal government has a major interest in promoting the development of innovations, it implemented legislation to facilitate the transfer of new technology from academic research institutions to industry, ensuring that scientists have an added incentive to turn their research results into products. On December 12, 1980, nearly 20 years ago, Congress enacted the Bayh-Dole Act to "reform U.S. patent policy related to government-sponsored research" (4, p. 3). The Bayh-Dole Act has two primary purposes:

- To enable universities, small business, and not-for-profit corporations to "patent and commercialize their federally funded inventions"
- To enable "federal agencies to grant exclusive licenses for their technology to provide more incentive to businesses" (4, p. 3)

The Bayh-Dole Act also has eight key regulations (4):

1. At the time of funding, an agency must make the funding university aware of its intention to hold title to an invention due to extraordinary circumstances or conditions.
2. Within two months of the date the inventor makes the university aware of the invention in writing, the university has to inform the proper federal agency of any invention created with the use of federal funds. This is the disclosure date.
3. To maintain ownership of an invention, the university basically has to inform the agency of its decision to keep the title within two years of the disclosure date. When the one year statutory period is initiated by public use, sale, or publication from which "valid" patent protection can be secured in the United States, the agency may reduce the "period of election to not more than 60 days prior to the end of the statutory period."
4. In order to use its invention, the university must give the U.S. government a paid-up, nontransferable, nonexclusive license (confirmatory license).
5. The government has "march-in rights" over the invention. This means that the government may relieve the university of its title to an invention if the university does not try to develop an invention or if there is a need to "alleviate health or safety concerns" (4,5).
6. The university has to give preference to small businesses when granting licenses for the use of the invention.
7. The university has to make sure that the invention will be developed primarily in the U.S. when it "grants an exclusive license."
8. The university has to share a portion of the royalties with the inventors (4–6). Hopefully this Act and its implementation will exert subtle pressure on the academic researcher to work with companies to develop products.

With the implementation of legislation such as the Bayh-Dole Act, it is not difficult to understand that the historic pressure on the academician to publish, teach, and receive grant funding has increased. Nevertheless, the fundamental differences between academe and industry create challenges for any commercial industry wishing to build on discoveries found in the research center.

Governance and Decision Making

Traditionally research institutions have benefited from corporate and personal charitable donations. These funds are now less available. The trustees of the research centers have responded by requiring management to pursue other forms of support.

To their credit, research institutions have created a variety of constructive programs aimed at addressing the concerns of industry regarding the scope and commercially useful nature of academic center research. In fact some universities have expended considerable funds to facilitate transferring technologies and programs to meet the specifications of the Bayh-Dole Act. Under these programs certain units and personnel are instructed to manage activities relating to inventions" (4).

If the approaches adopted by research centers are well managed, and carefully selected, then the research resulting from the collective endeavors of its scientists will more often lead to products, which in turn, should lead to fees and royalties to the researcher center and its scientists.

Most of these programs are designed to support the educational and basic research mission of the academic center. This is required by their nonprofit charter. The programs identify potential commercial products within the facilities, protect the inventions, and then identify and/or build companies for commercializing the discovery. Researchers are not forced into taking a role in the commercialization process. Through this mechanism academic freedoms traditionally enjoyed by the academician are maintained. It is not clear, however,

that in the long term the fundamental mission of the research center will not be subverted, a major risk for and concern of academic governing bodies.

In order to benefit from academic inventions, both academe and industry must develop sensible and affordable cooperative relationships that meet the goals of both parties. While an academician may be aware of commercial tasks required to create a product, commercially oriented research projects are not a typical part of academic research. Through education and by understanding the cultural, administrative and professional constraints on industry, the academic can contribute to the commercial success of the project. One approach which works for some corporations is to recognize the high level of skill and quality research conducted at the academic research center, and effectively integrate them into the corporate R&D process.

PROGRAMS AT UNIVERSITIES TO COMMERCIALIZE INNOVATIONS

Goals of Research Institution Technology Transfer Programs

Licensing executives at most technology transfer offices (TTOs) will state that their primary mission is to enhance the flow of innovations from the institution's laboratories to the commercial sector. This mission statement usually derives from their nonprofit charter, as well as a long history of teaching and research, not for private gain but for the greater good of the community that the research center serves. The logic is that by transferring technologies to the private sector, people will benefit from the innovations, and thus the general welfare of the state is enhanced.

This mission statement also reflects pressure from community leaders to refrain from competing with taxpayers. By conferring nonprofit status on the universities, the federal, state, and local tax codes restrict research facilities from competing with commercial entities. While there is continual and lengthy debate at the trustee level about amounts of unrelated business income derived from for-profit activities conducted under the nonprofit charter, rarely are the amounts of income and commercial activity a serious problem for the research center.

The second most often stated goal of the technology transfer program (TTP) is to make money for the university provided that the activity is consonant with the nonprofit and educational goals of the institution. So long as such is the mission of the institution, the TTP and its staff have complete freedom to conduct business as they wish.

Academic medical centers have been most often criticized for the results of their efforts to maximize health care reimbursement. In pursuit of this effort, hospital corporations restructured, developing series of for-profit and nonprofit corporations. Some of the nonprofit businesses were travel agencies, laundries, janitorial services, or power stations, often far afield from the basic mission and directly in competition with local area businesses. Community reaction and abhorrence held much of this in check. Some state and local tax authorities occasionally successfully levied property taxes on the research centers, pursuant to the logic that the research center was not benefiting the public welfare by offering such services.

The general threat of loss of nonprofit status, which rarely is a serious issue for well-planned research centers, continues to keep the research center focussed on its obligations to its community.

Other stated missions of the TTO include improving patient care by developing innovations that benefit the public, and to reward (and thus retain) talented faculty by allowing them to share in the financial benefits of fees and royalties from their discoveries. Scientists rightly observed that they could make more money by working for private companies, so universities responded by allowing them to consult, for fees and equity, and to share in royalty and fee income. While this raises questions of conflict of interest, most institutions allow and encourage such activity so long as scientists comply with institutional conflict of interest policies.

Probably the most important benefit of transferring a new technology to a local company is to increase community good will. This transfer often translates into donations and additional corporate sponsorship. Many of the research centers are also large area employers, thus further strengthening the local economy.

Effectiveness

Financial performance of the TTOs are difficult to assess. Some of the larger institutions have well-established programs and successfully generate fee income. These programs tend to have substantial revenues — much of those fees derive, however, from only several innovations which are, in turn, used to support an aggressive licensing and technology transfer operation. The surveys conducted by AUTM (Association of University Technology Managers, a nonprofit organization formed to assist university intellectual property administrators in the effective transfer of technology to the public) (4), indicate that some universities have had success with activities involving inventions and the report released by the U.S. General Accounting office on Technology Transfer: The Administration of the Bayh-Dole Act by Research Universities, further indicates that many universities believe that the Bayh-Dole Act is accomplishing its objectives (4).

Licensing Operations

Modern TTPs take a variety of forms. The most common program is a licensing operation (LO). The operational role of this operation is to arrange for intellectual property (IP) protection of discoveries made by university faculty, and to negotiate, prepare, and monitor license agreements with outside companies.

Initially such activities were part of the contracts and grants office. The general role of this office was (and is) to negotiate contracts and maintain relationships with private and government granting agencies.

As federal laws changed to allow title to discoveries to vest in research institutions, the contracts and grants

officers were additionally required to arrange for the protection of rights and to create royalty and fee income for the institution by transferring such rights to companies via license agreements. These influences and pressures required different skills and approaches, and the TTO resulted.

TTOs were initiated with high hopes and aspirations. The revenues that were expected to roll in did not. To compound the problem, decisions to patent inventions were made without sound business rational. Patent costs soared.

Additionally the skill set necessary to manage the complex licensing process typically resides at companies accustomed to licensing — there were not many seasoned business executives employed by universities in this role at that time.

It became apparent that the institution undertaking such a program required substantial institutional commitment, a sound business approach, and a long-term view to the process, at least 10 years. Some of the more fortunate institutions capitalized on early discoveries that were highly profitable, encouraging them to pursue other licenses. If these early successes are removed from their revenue streams, it is still clear that they now are investing tremendous resources on the assumption that their current licenses will be profitable. The result of this will not be known for some time, when many hundreds of licensed innovations mature. Although, some of the early licensing programs are beginning to yield substantial returns, it is not a widespread phenomenon (4).

Program Resource Requirements

Underfunding. University TTOs tend to suffer from a variety of dilemmas. Most institutions underestimate the length of time required for their patents to mature and yield returns. If they have a 10 year time horizon, they generally will be able to withstand the criticisms and pressures to perform by university administration.

Most institutions underfund and understaff their TTOs. Usually the cost of maintaining an effective program is greater than the university can afford. The result is that the licensing officers are responsible for handling hundreds of patent disclosures in a variety of technical areas, and the overall effort is diminished.

Patent Process. Because of this lack of personnel and financial resources, licensing officers tend to conduct minimal market, business, and/or technical research to validate their initial decision to patent an invention. This results in waste and inefficiency in the patenting process.

It also results in portfolio of patents that may be too limited for full commercial utility for some valuable discoveries, and an overly optimistic assessment for most of the inventions. The most sensible approach is to invest the requisite time and effort to conduct a business and technical assessment of the invention prior to embarking on the patent process.

Technology Audits. Institutions should take stock of invention inventory through a thorough technology audit. Each invention is assessed for its market potential, feasibility, time lag to product, and regulatory and financial requirements. The inventions are then ranked according to institutional priorities, and resource allocation requirements. They may also be ranked according to their commercial potential.

This invention assessment allows the institution to make sound business judgments about funding, its level of interest in seeing the products reach the marketplace, and its appetite for pursuing licensing or new enterprise development.

Any subsequent financial decisions with respect to the inventions are weighed against other institutional commitments, and its priority ranking. This is especially valuable in assessing whether to proceed with the patent process, and how seriously the effort should be pursued. Subsequent marketing efforts are also measured against their priority on the list. Those below a certain level, weighed in light of other resource demands, can be returned to the inventor. In this way, the most technologies considered most valuable to the institution are properly and rationally protected.

Marketing Effort. The scope of some discoveries justifies new company formation, with the requisite involvement of capable management and proper funding. For a variety of reasons, however, most successful technologies, perhaps more than 95 percent, are suitable only to be out-licensed. Selecting the proper licensees, unfortunately, requires a considerable amount of time and effort. This effort, due to funding, time, and personnel constraints, is generally beyond the scope of most TTOs. The result then is predictable: The technology licensee is usually the company, any company, that first makes an offer, any offer, to the university.

The more sensible approach is to develop a marketing plan for the technology, beginning with the data that resulted from the technology audit. This information needs to be supplemented with fresh technical, market, business, and regulatory analyses and summarized in both nonconfidential and confidential disclosures. This effort aids the TTO staff in its search for appropriate licensees, which are targeted in a defined marketing program. This defined marketing effort is calculated, if successful, to result in serious and appropriate partners, and new corporate relationships for the institution. Even if the technology is not purchased by the potential licensees, a well-reasoned and sensible approach to a serious company will create a favorable impression. This may well lead to subsequent opportunities — it definitely improves the likelihood that a prospective licensee will take the TTO seriously.

Drafting and Maintaining Licenses. Once a licensee has evaluated the technology, and wishes to enter into a license agreement to acquire the rights to the technology, the license negotiation process is initiated. The drafting and negotiation process is rarely routine. Many treatises have been written, and numerous license agreement forms have been generated, all of which serve as useful tools for the experienced and inexperienced TTO personnel.

Licensing Check List. A typical license agreement should address at least the following:

- Exclusive versus nonexclusive
- Restrictions in freedom to License and Sublicense
- Contamination — e.g., commingled funding by federal and/or other industrial money
- Collateral agreements may restrict rights
- Confidentiality agreements — any confidential information used from any/other restricted sources?
- Any nondisclosure agreements that encumber the invention?
- Collaborations with other scientists on site —
  - any visitors that were employees of other institutions that signed institutional
  - patent agreements
  - off-site collaborations
  - any scientists who have left.
- Financing/Royalty Clause Consideration
- License issue fee/varies —
  - fully paid up/lump sum
  - running royalty, royalty cap, or minimum/maximum
  - equity in lieu of or addition to royalties
  - credits given against royalties for earlier expenditures
  - reimburse for research expenses
- Milestones/upfront payments/termination fees
- Background rights —
  - define patent/other intellectual property with care
  - follow on patents, improvement patents
  - improvements
  - subservient to basic patents
  - retain option to these background rights
  - negotiate a separate royalty rate, short time
  - window for improvements (6–18 months)
  - subject to the rights of other parties
  - define field of use
- Know-How —
  - carefully define and transfer it
  - its delivery is very amorphous — if well defined, then know-how transfer is easier
  - treat via field of use
  - typically nonexclusive
  - if exclusive, only if it can be protected, and only if it is no longer needed
  - retain the rights to use know-how
  - consider using separate agreement
- Infringement and patent protection
- Indemnity
- Disclaim warranty provisions
- Territory Infringement
- Field of use
- March in rights and due diligence
- Use periodic payments, with reversion of rights
- Automatically for nonperformance
- If patents are assigned, pre-execute grant back of patent rights subject to conditions

Once a licensing relationship is in place, it must be regularly and objectively reviewed. Maintaining and monitoring licenses, communicating with licensees, and enforcing the terms of the agreement are time-consuming, and must be planned for in advance, and in light of their ranking in the priority list. Those agreements that have gone awry must be analyzed as to the reasons for their failure, utilizing in-house and independent peer review personnel. Nonperforming or minimally productive licenses should be terminated.

If the licensee does not proceed in a timely and businesslike manner, the technology should revert to the institution, pursuant to defined and clear terms that do not hamper the licensee's ability to raise funding or pursue the technology. Most often, if the company is not willing to commit to financial benchmarks, it is the wrong licensee.

Licensing Agreement Controls. Proper controls to ensure quality license agreements must be in place. Standardized forms are usually a useful starting point, and should be used where possible. Associates preparing the licenses must be subject to performance reviews. In order for the process to result in an appropriate business result, the expectations and demands on both the licensee and licensor must be adhered to, requiring the licensing office to ensure that the institutional commitments are met and that the office is operating in a businesslike fashion.

Patent Decisions. With respect to the decision whether to apply for a patent, claiming certain inventions, the typical licensing officers do not conduct technical analyses of the technology, relying instead on the inventor to do so. With some unusual inventors, this might be adequate provided that they know the industrial side of their research. Most, however, do not have the appropriate skill set. A careful search for and review of relevant technical literature by a scientist other than the inventor may reveal very sound reasons why the patent expenditure does not make any sense. For example, if a use patent is filed on a known compound, but the literature reveals that the use applied for may give rise to an adverse reaction that conclusively eliminates its commercial value, then the licensing office should not expend its resources to patent the invention. Unfortunately, most of these important pieces of information appear when the USPTO examines the patent application, or, more often, when a licensee conducts its due diligence, and it becomes obvious that the money spent on the patent was wasted. It also dilutes the effectiveness of the office staff, who could better use their time on other licensing projects.

If the TTO's decision is not to file the patent application, the university should relinquish its rights to the invention and return such rights to the inventor. It should do so as soon as practicable. It should also describe why it has

declined the opportunity to file a patent application and give the details of its business rational.

A corollary to the technical literature search is a careful analysis of the prior art in the patent literature. While this usually is done well by competent patent counsel, the licensing officer can glean valuable information about competing patent estates that impinge on the value of the technology. Learning to operate the computer search software programs is easy; learning to use them well is very, very difficult, and is best done by someone who is in a dedicated service role to the licensing associate.

Another problem is created when the licensing operation fails to plan for the cost of enforcing patents. Usually the decision to prosecute an infringer is made in a hurried manner, without fully appreciating the potential costs and benefits. Prosecuting infringers is a very expensive proposition.

Other Agreements. A typical hazard for the licensee and licensor are "hidden documents" that appear at the last minute, or are discovered very late in the patenting, licensing, or due diligence process. These hidden documents may contain restrictions that limit the university's ability to grant free title to the licensee. Consulting agreements and material transfer agreements may have been executed without appropriate terms and conditions. Federal funding, commingled funding, university collaborations, whether formal or informal, nonconfidential and confidential disclosure agreements, and joint inventorship of patents, each raise case-specific problems that affect the value of the technology. Analyzing these issues and optimizing all aspects of ownership is most effective when done before the TTO approaches or is approached by a potential licensee.

Faculty Communication. The licensing officers must have early and frequent communication with their inventors. By involving them in the decision-making process, the faculty are recruited into the process, learn about the rationale for decisions made, and become a valuable resource. If decisions are made without their involvement, the faculty will be alienated, and resentful of business and administrative decisions, which at many points will detract from the office's effectiveness.

CONFLICT OF INTEREST DILEMMAS IN BIOMEDICAL RESEARCH

Industry–academe collaborations have costs. These collaborations create conflicts among the researchers, the institutions, industry, and the researcher's academic and financial interests. These conflicts of interest threaten the objectivity of science, the integrity of scientists and institutions, and the safety of medical products.

One such example of a conflict of interest between the researcher, the institution, and the industry can be observed from the Synthroid Marketing Litigation case (7). In this case researcher Dr. Betty Dong "discovered" that there were less expensive alternatives to the Synthroid medication (8). Dr. Dong's research was funded by the University of California, San Francisco, and Knoll Pharmaceutical Company, which manufacturers a thyroid medication called Synthroid. When Dr. Dong attempted to publish the results of her study, the representatives of Knoll informed her that she was barred from doing so because she had signed a contract agreeing to publish her results subject to the approval of the company when she initially began the project (9).

Claiming the right to academic freedom, Dr. Dong took the Knoll Pharmaceutical Company to court (10). This case illustrates a wide range of conflicts. Was it permissible for the company to suppress Dr. Dong's study for its own reasons? Was it permissible for Dr. Dong as a university employee and beneficiary of funding from Knoll to comply with the suppression of her article for seven years? If Dr. Dong were to be penalized for breaching her contract with the company, would the university be liable as well, or would she be treated as an independent contractor? Hopefully these questions will be answered once the case has been resolved (11).

To avoid conflicting interests that undermine scientist's integrity such as was the case with the Dong study, adherence to uniform federal standards should be mandatory. Federal rules are necessary to require disclosure of conflicts, limit the most troublesome forms of conflict, and create uniformity in ethical standards across the country.

Federal Legislation Supporting Industry–University Collaborations

Federal legislation, since 1980, has facilitated industry–university collaborations, and speeded promising new products from the laboratory to the market. This legislation, however, has brought academe and industry together without adequately regulating the consequences of the interactions.

The Stevenson-Wydler Technology Innovation Act of 1980 (12) established a policy of "stimulating improved utilization of federally funded technology developments by state and local governments and the private sector" (13). The Act created an Office of Research and Technology Applications, whose primary purpose was to investigate projects that could be utilized by government or private industry (14). Each Agency implemented this requirement by having it own version of such Office (i.e., the Office of Technology Transfer at the National Institutes of Health, NIH, handles this function for the Department of Health and Human Services, DHHS). The Act also created the Center for the Utilization of Federal Technology, established within the National Technical Information Services, to provide industry with a central source of information on federally owned or developed technologies with potential commercial application (15).

Later in 1980, Congress accelerated technology transfers by amending the patent and trademark laws, and for the purpose of supporting small business. As mentioned previously, the Bayh-Dole Act (16) gave inventors in small business firms and nonprofit organizations the power to retain ownership rights to patents protecting inventions developed with federal funding (17) (Licenses are intended to be granted to small businesses in the United States. If this is not possible, the licensing institution is to use its

best efforts to ensure that the licensee, whether foreign or U.S. based, manufactures the product in the United States, and for consumption in the United States). Prior to the Bayh-Dole Act, the federal government owned the rights to most federally-supported inventions and for-profit firms wishing to develop federally supported inventions had to wade through a bureaucratic maze to obtain a license (18). Congress recognized that the federal government had been unsuccessful in nurturing the development of new products to the market, and that it was in the public interest to bring innovative ideas into clinical practice without unnecessary delays (19). A policy statement by the Reagan Administration extended the Bayh-Dole coverage beyond small business firms and nonprofit organizations (20). The Bayh-Dole Act enabled institutions and their investigators to license patents from federally-supported work to companies interested in developing the products for market. This has allowed the institutes and researchers easier access to money, both for research and for personal profits, and opened up to industry a large market for potential commercial advantage (21).

Liability Risks of Research Institutions and Investigators

Despite the progress of the current federal legislation supporting industry–university collaborations, the collaborators still have to contend with the potential for a conflict of interest leading to legal liability. This potential is derived from several sources. First, state tort law imposes liability on institutions for the misconduct of their employees. A research institution could be held liable for the negligence, misrepresentation, or fraud of its investigator or employee. For example, if a researcher misrepresents the quality of an invention that is commercialized, and the company relies on false claims, the university could be held responsible. Considerable damages may be assessed resulting from the delay in marketing the product and/or in wasted or misdirected investments.

Second, research institutions have various obligations under state nonprofit corporation laws and federal tax laws, any breach of which could jeopardize the institution's nonprofit status, or subject the institution to enforcement actions by the state attorney general. Typically these laws require the directors to operate the research institution in a manner consistent with its charitable purpose; forbid certain director conflicts, interlocking or interested director transactions; and require the directors to preserve and prudently invest corporate assets. Although research institutions need to closely adhere to the current regulations, the court has recently given them some flexibility with respect to managing an invention the has been assigned to the institution by an employee. In *Kucharczyk v. Regents of the University of California* (22) addresses the ability of inventors to influence negotiations for the sale of their inventions.

The Regents had negotiated a licensing agreement with Nycomed for the use of a patented medical technique developed by Dr. John Kucharczyk and Dr. Michael Moseley (22). The doctors assigned their rights to the patent to the Regents which then sold these rights to Nycomed for $25,000. Fifty percent of the sale price went to inventors, Drs. Kucharczyk and Moseley in compliance with the Bayh-Dole Act (4,22). The doctors then filed suit against the Regents of the University and Nycomed alleging that the defendants "acted improperly to deprive plaintiffs of their rightful share of the financial rewards of the patented medical technique they developed" (4). In their lawsuit, the plaintiffs claimed that the medical technique invented by them was "worth substantially more than $25,000."

The court ruled that the actions of the University of California and Nycomed did not constitute a breach of contract since the University doctors had contracted out their right to sue when they assigned their inventors rights to the University. The court further ruled that the plaintiffs might have a claim against Nycomed for fraud and interference with contractual relations, because there was sufficient evidence of Nycomed's suggestion to the University doctors that their medical technique had substantial profit-making capacity, and that this information was omitted from the negotiations with the University.

CONCLUSION

With increasing sophistication and skill, technology transfer offices are successfully commercializing useful inventions and generating fee income. The recent court decisions of *Kucharczyk v. Regents* and *Synthroid Marketing Litigation* threaten the delicate balance within and bring unpredictability to the contracting process. Many challenges lie ahead, including conflicting university, faculty, and societal interests; competition; change in structure and focus of the university; congressional intervention; and availability of personnel, among other factors. An enlightened technology transfer office will move past these "speedbumps" and continue down this creative and energetic road.

TRANSGENIC ANIMALS: AN OVERVIEW

RIVERS SINGLETON, JR.
University of Delaware
Newark, Delaware

OUTLINE

INTRODUCTION

To present an overview of animal use in modern biotechnology is a difficult task because of both the multitude of procedures and the types of animals involved. Procedures vary from small-scale laboratory research programs, involving a range of different animals from across the evolutionary spectrum to biotechnology product production facilities that may involve herds or colonies of a single animal species. Early biotechnology was restricted to procaryotic organisms, such as insulin production by strains of *Escherichia coli* constructed by recombinant DNA techniques. Since those early 1970s protocols, however, the diversity and complexity of organisms used in biotechnology now varies greatly across taxonomic lines from relatively simple procaryotes to nematodes to fish to mammals. Furthermore, since a major goal of biotechnology is to create organisms possessing genetic properties of other organisms, a pivotal result of these procedures is that taxonomic lines can be blurred as genetic elements of one organism are introduced into another.

The recent development of facile techniques to clone mammals further complicates the view of animals in nature and their role in biotechnology. Previous technologies created chimeric (An organism consisting of two or more tissues of different genetic composition, produced as a result of mutation, grafting, genetic engineering, or the mixture of cell populations from different zygotes.) organisms by combining genetic attributes from differing taxonomic lines. Because cloning bypasses genetic recombination, the technology leads to monophyletic (Of or concerning a single taxon of animals, relating to, descended from, or derived from one stock or source.) organisms, which may have highly unusual genetic traits, that are essentially unique in the biological world.

The point of the previous paragraphs is that both animals and procedures gathered under the rubric of "biotechnology" vary greatly. Because of this complexity, the focus of this article, in large measure, is on transgenic organisms as a model for some of the ways biotechnology uses animals. Thus a goal is not to provide a comprehensive overview of all animal use but rather to provide a paradigm by which the reader may gain insight into other arenas of biotechnology animal use. Some related issues have been discussed elsewhere (1,2).

HUMAN AND NON-HUMAN ANIMALS: SOME HISTORICAL REFLECTIONS

It is a truism to state that humans and animals have always interacted with each other. All living plants and animals are linked together through a shared evolutionary origin. While we are all part of nature's evolutionary web, however, our interactions with the nonhuman world are unique in nature. As human beings have domesticated the world around us, we have interacted with a diverse array of organisms across broad taxonomic lines in pervasive and complex ways. Indeed, our domestication of nature for utilitarian purposes appears a uniquely human activity. Consider, for example, that wheat domestication

is viewed as the hallmark of human civilization, yet humans have arguably domesticated dogs for a longer time (3–7). [For a nontechnical but very readable account of canine evolution, see Budiansky (8).] Since those initial domestication forays at our emergence as modern human species, we have radically altered the permanent form and function, through selective breeding, of an immense variety of plants and animals.

Domestication has been driven primarily for human utilitarian benefit, although many organisms have undoubtably benefited from this close human association. While dogs frequently serve as human companions and pets, historically they have also been invaluable for herding sheep, pulling sleds, and other utilitarian purposes. For millennia an immense variety of animals served as both food supply and labor savers (it is not coincidental that a unit of work expenditure is "horse power") for human beings.

Animals have played another vitally important role in human culture. By studying animals, humankind gained an immense knowledge about the natural world. In antiquity Galen speculated about human physiology (often erroneously) and based his observations on animal dissection and vivisection. In the sixteenth century, William Harvey's brilliant description of pulmonary, cardiac, and circulatory physiology was deeply rooted in a variety of animal observations and experiments. As scientific knowledge exploded during the next four centuries, animal study played an important role in that expansion of human knowledge. Since the Renaissance vivisection and animal experimentation have increased human understanding of both basic physiology and pathological disease processes. It is reasonable to conclude that many advances of modern medicine would have been impossible without animal use. Indeed, we can conclude that much of our knowledge of fundamental biology would not have been achieved without recourse to animal experimentation and vivisection (9,10).

The historical streams of both animal domestication and experimentation are important to understand the place of animals in biotechnology. A definition of technology is "the application of scientific discoveries to the production of goods and services that improve the human environment" (11). Biotechnology thus is simply using biological systems, biological processes, or exploiting living organisms as part of the process of producing "goods and services that improve the human environment." The National Agricultural Library defines biotechnology as:

> . . . a set of powerful tools that employ *living organisms* (or parts of organisms) to make or modify products, improve plants or "animals," or develop microorganisms for specific uses. Examples of the "new biotechnology" include the industrial use of recombinant DNA, cell fusion, novel bioprocessing techniques, and bioremediation (12; p. 1 emphasis added).

Thus animals — *living organisms* — are central to biotechnology in several vital aspects. The basic science upon which biotechnology is structured would not exist in the absence of animal experimentation and vivisection. Selective breeding continues to produce a variety of animals, ranging from shrimp to cattle, of great commercial importance. Modern techniques of molecular biology, such as marker-assisted selection, have enhanced domestic breeding programs to make them more effective and efficient.

Equally important, however, is the notion that — for many people — animal use in biotechnology is a simple extrapolation of human domestication of nature. Domestic breeding can enhance only genetic traits that naturally occur in an organism. Creation and use of transgenic organisms can "leap-frog" these genetic limitations, however, and introduce traits not normally found in particular species. Consequently transgenic animals represent and illustrate notions of domestication and experimentation as well as the general utility of animals in biotechnology.

BIOTECHNOLOGY AND DOMESTIC BREEDING

Traditional Breeding Perspectives

As noted previously, domestication of plants and animals for human utility and companionship has been a characteristic of human beings since our early evolution as a species. The power of selective breeding to bring about radical and relatively stable alterations in the form and function of animals was so well recognized by the nineteenth century that Charles Darwin devoted the first chapter of *Origin of Species* to the subject as a model for natural selection. Modern concepts of molecular biology, such as marker-assisted selection, combined with traditional selective breeding practices have greatly enhanced the power of domestic selection.

In traditional breeding practices, as Darwin noted, a breeder identifies a desirable physical trait in an individual organism within a population, such as increased milk production in a dairy cow. The exemplary animal is then used for breeding purposes. Those progeny exhibiting the desired trait are in turn used as further breeding stock, yielding — after a period of several generations — a population of animals that expresses the desired trait, namely a herd of cows with increased milk production.

Marker-Assisted Selection

A variety of new molecular methods — such as restriction fragment length polymorphism (RFLP) and polymerase chain reaction (PCR) — now allow breeders to identify DNA sequences associated with specific animals. These sequences may or may not be responsible for the particular trait the breeder desires to enhance. For breeding purposes, importance rests in expression of the genotypic "marker sequence" in progeny carrying the desired phenotypic trait; for example, in the case of increased milk capacity, a "marker sequence" of DNA should always be found in progeny expressing increased milk production.

Although the notion rests on numerous molecular methods for cutting, isolating, and analyzing specific segments of DNA, which have evolved over the past several decades, the concept of marker-assisted selection appears to have achieved practical application during the 1990s. For example, a Medline© database shows

initial papers, specifically mentioning marker-assisted selection, beginning to appear around the early to mid-1990s. Since then, the number of papers has increased dramatically. Citation analysis also suggests a curious bias in the ways marker-assisted selection is used. A Medline© database search of 80 papers published since 1994 showed approximately 60 percent of the publications dealing with animals. However, another search of 250 publications in several agricultural databases showed only 20 percent dealing with animals. While both searches are anecdotal in nature, they suggest that the concept of marker-assisted selection is receiving wide application in enhancing agricultural plants.

Currently there is an international effort underway to generate a detailed description of the molecular genomic structures in a diverse array of organisms; the Human Genome Project is one part of this effort. As we increase our understanding of these genomic sequence details, and the biological function of particular genetic sequences is clarified, the power of marker-assisted selection will be greatly accelerated and enhanced. Nevertheless, despite advantages introduced by molecular techniques, selection-based breeding programs will always be limited to genetic attributes inherent within a species. There is, for example, a statistical distribution of milk production within cows; all that domestic selection can do is to skew that distribution toward a desired goal. To breach that genetic restriction, the new techniques of transgenic organisms must be employed.

BIOTECHNOLOGY AND TRANSGENIC ORGANISMS

What is a Transgenic Animal?

A simple definition of a transgenic animal is one "to which copies of a gene sequence have been artificially added" (13). However, there is difficulty in such definitions. The *Hastings Center Special Supplement* on animal biotechnology concluded that a transgenic organism "carries and expresses genetic information not normally found in that species of organism" but also noted that such a definition was literal and restrictive. Thus the definition was broadened "to include the purposeful amplification, spread, or dissemination of a *gene* within a *species* at a rate much faster than would have occurred in the absence of artificial interventions" (1; emphasis added). A view of animals possessing *desired* genetic properties, which in turn express novel phenotypes, emerges from this definition. These animals have been intentionally *designed* using modern biotechnological tools.

Some of these terms need further clarification. Our notion of a *gene* emerges from the central dogma of molecular biology:

$$\text{DNA} \Rightarrow \text{RNA} \Rightarrow \text{protein}$$

In traditional biological terms, DNA represents an organism's "genotype," and protein expresses its "phenotype." We can consider a gene as a section of a DNA molecule that provides biological information and is ultimately transcribed and translated into a protein molecule; proteins, in turn, perform various cellular activities. Changes in DNA molecular structure will alter cellular function because of the resulting changed protein. Thus a transgenic animal carries a novel sequence of DNA [referred to as the *transgene* (13)]. If the transgene is stably incorporated into the animal's chromosomal DNA and its products functionally expressed, the animal — *and its progeny* — will possess an altered phenotype.

Species is more difficult to define, and Ernst Mayr (14) noted that biologists have understood the term in at least three different ways. Historically biologists viewed species from an *essentialist* perspective, which held that "each species is characterized by its unchanging essence and separated from all others by a sharp discontinuity (14, p. 256)." Charles Darwin helped change that view to a more *nominalistic* concept that rejected notions of "essential character" and conceived of species as groups of organisms that shared common attributes with a common descriptive name. Finally, while some biologists might argue with it, the modern notion of species, namely "a reproductive community of populations (reproductively isolated from each other) that occupies a specific niche in nature" (14, p. 273), is acceptable by most of the biological science community.

How are Transgenic Animals Created?

How do we go about this process of "purposefully amplifying, spreading, and disseminating" a gene within a species? Before describing transgenic technology, two brief reflections are important. First, transgenic technology with eucaryotic (also eucaryote, A single-celled or multicellular organism whose cells contain a distinct membrane-bound nucleus.) organisms is a logical and conceptual extrapolation of the recombinant DNA technologies with procaryotes in the 1960s. Intentionally creating a transgenic organism in a laboratory or factory is deeply rooted in the recombinant DNA work of the 1960s (1,2,13). Paul Berg's colleagues created an early transgenic organism when they used restriction enzymes and plasmid vectors to insert genetic elements from Simian Virus 40 into *Escherichia coli*. A significant difference between modern technology and these early techniques is that the latter were unidirectional. One could only introduce genetic material from a foreign source into bacterial (procaryotic) systems. Modern technology allows the manipulation of genetic information between virtually any plant or animal.

Second, clarification of two experimental distinctions is important. A *knockout experiment* is one that creates a mutation in an organism's own genome. Some genetic element native to an organism is inactivated so that the resulting progeny lack the functional capability associated with that gene or genes. In true *transgenic experiments* novel genetic elements, not normally found in that organism, are inserted into an organism's native genome. Thus this type of experiment creates an organism that "carries and expresses genetic information not normally found in that species of organism." Despite the different outcomes, both experiments use similar technological approaches.

A somewhat typical knockout experiment, which involved creation of a mouse with a defective *fosB*

mutation (15), illustrates the technology. The knockout experiment discussed here illustrates some of the general technology used to create transgenic organisms. The specific experiment is also important because of the unexpected outcome (see below), which illustrates the serendipitous nature of science. Some background on the *fosB* gene and its protein product is important to understand the experiment and its somewhat unusual results. The FosB protein is one of many transcription factors found in cells; they facilitate the phrase in the central dogma of molecular biology:

$$\text{DNA} \Rightarrow \text{RNA}$$

The *fos* genes, which produce these proteins, are activated during a variety of adaptive neuronal responses in several brain regions. Despite extensive work that correlated *fos* gene products with mRNA production, their role in nervous system function and development remains unclear (16). Thus Brown et al. decided to create a knockout mouse, which lacked the *fosB* genes, in order to gain insight into its regulatory function; their experimental protocol for creating this *fosB* gene "knockout" mutation is summarized in Figure 1.

Initially murine DNA containing an incomplete fragment (and therefore nonfunctional) of the *fosB* gene was isolated and incorporated into a vector, which permitted three important experimental tasks. First, unique information present on the vector allowed investigators to screen transformed embryonic cells for the presence of the mutant gene. Second, specific sites on the vector, which were easily recognized at a molecular level, facilitated sequencing the incorporated genetic material. Finally, when genetic elements on the vector were phenotypically expressed, they served as a type of "marker-assisted selection" (although not referred to as such). Individual offspring expressing these traits were easily recognized as carrying the vector, and selecting them for further breeding purposes was eased. Once constructed, the vector containing the mutant *fosB* gene was electroporated into embryonic mouse cells.

Transformed embryonic mouse cells, namely those containing the mutant *fosB* gene, were implanted into mouse blastocysts. The blastocysts were then implanted into pseudopregnant female mice, which gave birth to pups expressing various levels of *fosB*. Ultimately the authors derived three strains of mice that exhibited normal Mendelian inheritance of the *fosB* mutation: one group was homozygous for the mutation [*fosB* (−/−)], one group was

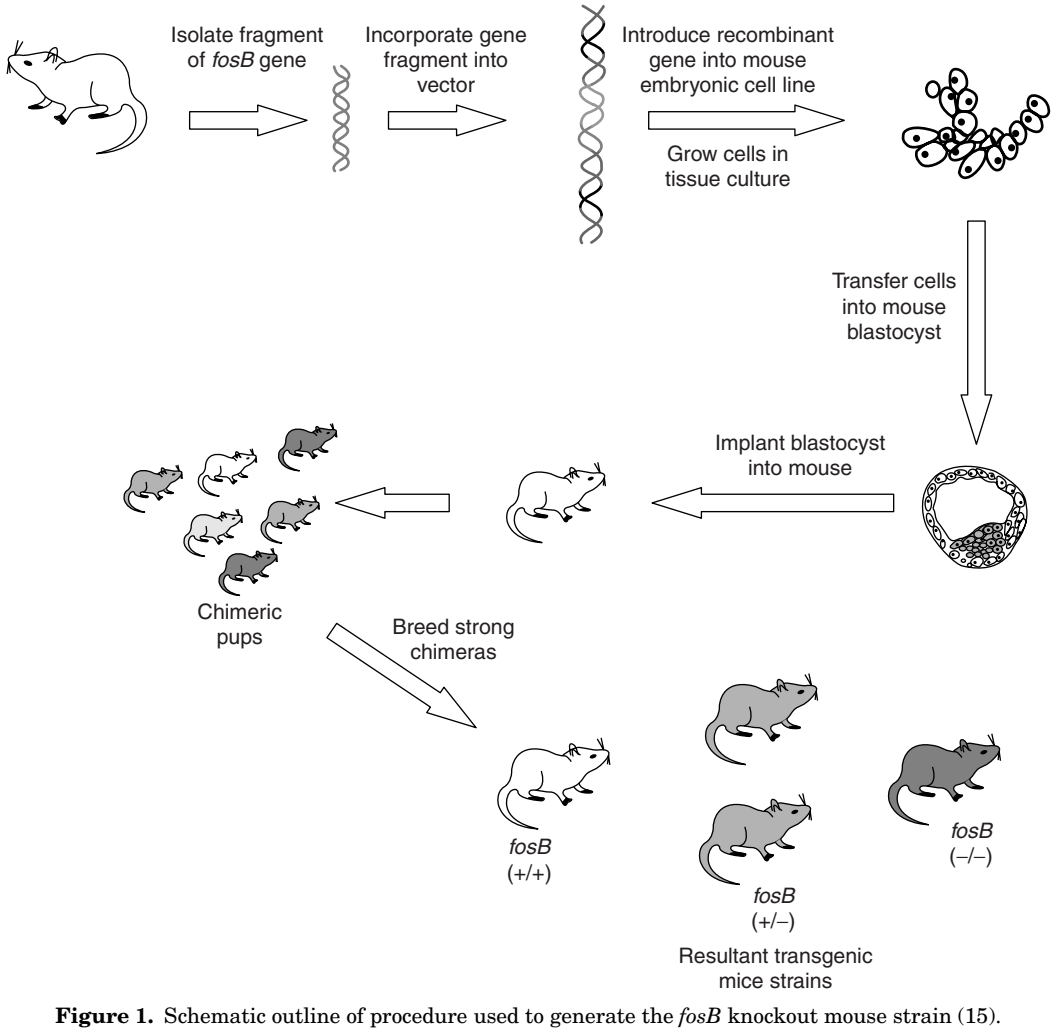

Figure 1. Schematic outline of procedure used to generate the *fosB* knockout mouse strain (15).

heterozygous for the mutation [*fosB* (+/−)], and a third group was homozygous for the wild-type state [*fosB* (+/+)].

These mice had interesting phenotypes: (*1*) the homozygous knockout mutants [*fosB* (−/−)] were health and viable; (*2*) there were no apparent histologic abnormalities, suggesting that *fosB* products are not required for normal mouse development; (*3*) the mutant strain was about 10 percent smaller than wild-type mice; and (*4*) pregnancies are normal and carried to full term. However, one phenotypic difference in the *fosB* mutant was unexpected and very significant. Pup lethality in early postnatal period was eight to ninefold higher in *fosB* knockout mutants than in wild-type mice. Serendipitously the authors discovered that lethality did not arise from a pup defect but rather arose from a failure of mothers to nurture pups. A graduate student involved in the project was concerned about put lethality. She returned to the lab one evening and discovered that the mother was in one corner of the cage and the pups isolated in another corner. When she moved the mother to the pups, they nursed normally (16). Mutant strain mothers simply abandoned the pups and failed to nurse them properly. Furthermore this was a loss of maternal "nurturing behavior" and was not due to a lactation defect in mothers.

The major significant difference in the knockout experiment discussed here and creation of a transgenic animal is the source of donor DNA. In the above knockout experiment, mouse DNA was incorporated into another mouse. In a transgenic experiment, DNA from *any* source (plant or animal) is incorporated into an organism unrelated to the source. The goal in discussing this experiment is to illustrate the relative ease of transgenic technology. Thus discussion of the ethical implications of the experiment will be deferred. However, two additional reflections are important to remember about this brief sketch. First, the technique and many potential technical complications have been greatly simplified or ignored. Furthermore there are a variety of other technical approaches to create transgenic organisms; this experiment simply serves to illustrate the basic technological concepts. Fundamentally, however, the techniques are relatively easy to perform, and new technological innovation are constantly appearing.

UTILITY OF TRANSGENIC ORGANISMS

Given this relative ease of the technology, what can it be used for? Like the recombinant DNA technology that preceded it, potential applications of transgenic technology is probably limited only by the human imagination (17). The various technological innovations that allowed development of transgenic animals have great potential utility for humankind (18,19). While there is tremendous overlap in various applications, these applications generally fall into three broad areas: commercial utility, improving human health, and furthering basic biological scientific knowledge.

Commercial Applications

We should not forget that the first type of transgenic organisms, that is, organisms intentionally engineered for specific utilitarian applications, were recombinant bacteria. Since the 1960s procaryotic organisms have been designed to carry out numerous industrial and agricultural processes, including (but not limited to) frost control on plants, increased efficiency of nitrogen fixation in soil bacteria, biodegradation and waste treatment, mineral processing, and other processes (20).

Like their procaryotic predecessors, transgenic animals can be used to produce, or are themselves, new commercial products. Utilitarian applications of transgenic organisms promise to provide humans with a variety of new capabilities not readily available by other means. The actual or potential list of commercial applications is immense, a potential briefly suggested by the following examples.

Agricultural Utility. Many early eucaryotic transgenic experiments sought agricultural benefit, and transgenic farm animals, with a variety of potential commercial applications, were created containing various growth hormones. Pigs that expressed enhanced levels of growth hormone exhibited significant daily weight gain, increased efficiency of food utilization, and a decrease in subcutaneous fat (21). While these animals had enhanced growth and improved feed efficiency, their immediate commercial utility was not feasible because of serious health complications including abnormal bone growth, enlarged internal organs, and diabetes.

Despite early enthusiasm over application of transgenic technologies to agricultural animals, that expectation has been tempered by experimental reality. In comparison with laboratory models, production of transgenic livestock is an inefficient process, and research has been hampered by lack of embryonic stem cell lines in farm animal species (22). Ward and Nancarrow (23) noted that, while it was feasible to produce transgenic animals with enhanced agricultural utility by modifying growth hormone levels, this could be done only if ways were found to tightly regulate hormone production. Nevertheless, optimism continues in areas ranging from mariculture (Cultivation of marine organisms in their natural habitats, usually for commercial purposes.) (24) to more conventional livestock (25,26). In the later area, confidence in transgenic technology is such that Murray stated: "Recent advances suggest that within the first decade of the 21st century the first transgenic animals will become available to the livestock industry, with acceptance depending upon their cost versus their potential economic benefit to the producers" (26, p. 149).

Pharmaceutical Utility. Transgenic animals have been effectively and efficiently used to produce many protein pharmaceutical products that are difficult if not impossible to produce by other means (e.g., traditional recombinant DNA techniques). As Wall et al. noted: "The objective of the emerging gene 'pharming' industry is to produce pharmaceuticals for treating human diseases. It is argued that mammary glands are an ideal site for producing complex bioactive proteins that can be cost effectively harvested and purified" (27, p. 2213).

There are two general obstacles to synthesizing these products via many traditional approaches. First, procaryotes (e.g., bacteria *E. coli*) lack the post-translational processing machinery necessary to synthesize many biologically active proteins from eucaryotic organisms. A second major difficulty arises from the difference in genetic organization between procaryotes, where genes are arranged on a single chromosome without interruption, and eucaryotes. Eucaryotic genes are often arranged in fragments so that mRNAs must be joined together before a biologically active protein can be expressed.

Large transgenic animals have been developed and successfully exploited to bypass these difficulties. Such animals are often referred to as "bioreactors" and the process called molecular or gene farming (or "pharming"). Approximately a dozen biotechnology companies now produce a variety of pharmaceuticals in larger amounts this way than can be achieved via other approaches. In addition to obviating the technical difficulties discussed previously, there are distinct advantages to using transgenic large animals to produce valuable human pharmaceutical proteins (27,28).

One advantage of using transgenic animals to produce pharmaceutical proteins is low operating cost, once the transgenic animal strain has been constructed. Furthermore, once the strain has been established, a virtually unlimited bioreactor supply becomes available by way of embryo cloning techniques (29).

However, the major advantage of using transgenic mammals in pharmaceutical protein production is that these genes can be inserted into mammary gland gene control elements so that the transgene product is expressed in milk. Complex pharmaceutical proteins, with correct post-translational modifications and full bioactivity, are correctly expressed and secreted in large amounts (in the order of grams per liter) in the milk. Since a large mammal, such as a cow, can produce 10,000 liters of milk a year, kilogram quantities of pharmaceutical protein can be synthesized per animal annually. As Smith commented, "No other production system can compete with bioreactors in production levels" (28, p. 681).

The technology now uses transgenic sheep, goats, pigs, and cattle to provide a ready supply of previously rare pharmaceutical proteins, such as Alpha 1 Antitrypsin (α-1-AT), Factor IX, and tissue plasminogen activator (t-PA). The later proteins are important therapeutic agents for a variety of human clotting disorders. Estimates of the U.S. market for pharmaceuticals transgenically produced approach $3 billion annually, and several products produced in this way are now in human clinical trials or actual therapeutic use (27).

This technological approach to pharmaceutical production is not without potential health hazard for the animal. Most of the hazards are recognizable, however, and appropriate design considerations can be developed to avoid problems (30).

Applications for Improved Human Health

Second, and of equal importance to their commercial utility, transgenic animals represent a variety of actual or potential improvements for generalized human health and welfare. Of major importance, these techniques allow researchers to develop laboratory organisms that mimic or duplicate many human diseases. Nomura noted that transgenic animals can be valuable models to follow the sequelae and treatment possibilities for these diseases and proposed criteria to evaluate objectives to develop valid animal models (31).

These animals promise exciting models to understand and conceptually intervene in human disease processes and thereby lead to alleviation of human suffering. [For an summary of the diversity of pathologies amenable to study by transgenic technology, see the text edited by Monastersky and Robl (18).] More recently, many individuals have speculated about the possible use of transgenic mammals as organ sources for human transplant. Ultimately, of course, the technology has potential for direct application to human beings. On the one hand, it holds out the promise of correcting debilitating genetic diseases. As our understanding of the interaction of genetics and human personality increases, however, the technology also has the potential to radically alter human nature.

Human Disease Models. Transgenic animals can provide insight into the development and progression of many human diseases, and cystic fibrosis (CF) is a classical example of a disease amenable to such study (1). Cystic fibrosis is a recessive, autosomal disorder and is inherited in classical Mendelian fashion. Disease symptoms originate from abnormal function of epithelial cells in the respiratory, digestive, and reproductive tracts. The abnormal function of these cells is due to a defective chloride ion channel protein called the cystic fibrosis transmembrane conductance regulator (CFTR). Defective chloride transport causes secretory tissues (e.g., lung, pancreas, intestine) to accumulate a thick mucus, characteristic of the disease. The pathology of CF arises from mucus accumulation in affected organ systems, such as lung infections and inadequate intestinal function.

The human CFTR gene has been identified and characterized. Although numerous mutations in this gene have been shown to lead to CF symptoms, defects in a very small region of the gene are responsible for 70 percent of reported cases.

While the biological basis of CF is clear, this understanding did not clarify its pathological basis or progression mechanism, nor did it lead to effective therapeutic approaches. The specific causal relationship between a defective chloride channel in a cell membrane and accumulation of mucus in the surrounding tissue remained unresolved. Consequently development of rational and effective therapies for the underlying disease has been difficult (32).

Previous work demonstrated that mice contain a gene equivalent to the human CFTR gene. Thus creation of a strain of mice with defective CFTR genes seemed to present a reasonable model to study CF in humans (32,33). Since the CF transgenic mouse apparently truly mimics human CF, it can serve as an important means to both clarify disease etiology and facilitate rational therapies. In an animal model we can follow disease sequelae in ways

that are impossible or ethically repugnant in humans. Furthermore animal models allow us to develop and explore potential treatment modalities that would also be impossible or would pose ethical questions in humans. The list of genetic diseases that can be studied by such technology is appreciable and accounts for a significant aspect of human suffering (34,35).

Transgenic animals also provide insight into other, nongenetic, diseases. For example, transgenic mice serve two roles in AIDS research (36). First, a transgenic mouse strain was developed with a complete HIV proviral transcript. Progeny mice from this strain, which develop diseaselike symptoms, can potentially serve as a model system to study the etiology of AIDS. Second, transgenic mice have been created that carry only parts of HIV. These strains can play an important role in drug development and allow testing of certain antiretroviral drugs. Both the strengths and weaknesses of using transgenic animals in AIDS research has recently been reviewed by McCune (37).

Organ Transplantation and Xenobiotic Sources. During the past quarter century organ transplantation as a relatively common clinical therapeutic approach for many disease conditions has rapidly increased. However, the procedure has been restricted by two major difficulties: (*1*) organs available for transplant are in extremely limited supply relative to the potential clinical need (38,39); and (*2*) despite use of immunosuppressive drugs, even ideally tissue-matched organs often undergo host rejection (39–41). The latter problem arises from immunological reactions elicited by the recipient's immune system to antigens present on the donor organ. Xenotransplantation initially seemed to provide a means to address the first of these difficulties, namely animals were an unlimited source of organs (39). The procedure was sufficiently promising that *Science* mentioned it as a hot research area in 1996 (42).

While xenobiotic sources seemingly promised an unending organ supply for transplantation, the procedure did nothing to address the second, and equally problematic, phenomenon of host rejection. Transgenic animals, however, have recently been considered as potential sources of organ donors to address both problems, and initial research has focused on the initial, and potentially most overwhelming, transplant immunological barrier, namely hyperacute rejection (39–41).

Hyperacute tissue rejection is triggered by complement system activation in the recipient against proteins recognized as "non-self" on the foreign tissue. Complement activation can be inhibited by a variety of drugs; however, this technique leaves the recipient with a compromised immunological defense against infectious organisms. To obviate complement system mediated host rejection, transgenic animals, such as pigs, that express human complement proteins on their cell surfaces have been created (39–41,43). Animal organs with such cell surfaces do not trigger the complement cascade reaction in an organ recipient. Because complement activation does not occur, hyperacute rejection is prevented; the host's complement defense system is also left intact (39–41). Enthusiasm for the technology has become so intense that commercial involvement has grown (29,44).

Despite initial encouragement about transgenic xenobiotic organ sources, however, serious concerns have arisen regarding potential transmission of infectious agents, especially retroviruses, from transplanted animal organs (39–41,44–49). These concerns are sufficiently pressing that while the British government gave qualified approval for continued research into the transplantation of pig organs into humans, it ruled out clinical trials until further research demonstrated safety and efficacy of the procedure (50,51). The United States will allow limited clinical trials to go forward under stringent guidelines established by the Food and Drug Administration (FDA), the Centers for Disease Control and Prevention (CDC), and the National Institutes of Health (NIH) (52,53).

Human Gene Therapy. Because the difference between human and animal is a matter of evolutionary degree, ultimately transgenic technology promises direct intervention into human genetic diseases by replacing dysfunctional genes. Although somewhat dated now, Friedmann (34) provided an excellent and very readable summary of this area of research. He noted that diseases arising from bone marrow defects would be most amenable to genetic intervention. Because bone marrow cells are readily susceptible to infection by retroviruses, a common way to introduce foreign genetic material into mammalian cells, these cells would be relatively easy to alter genetically. Furthermore, because these cells can be removed from a patient, altered and manipulated in vitro, and then reintroduced back into the patient, the potential rejection of altered gene products by a recipient's immune system is reduced.

For similar reasons, diseases resulting from hormonal or other diffusible protein deficiencies (e.g., insulin or blood-clotting factor deficiencies) may also be amenable to genetic treatment. Skin cells can be readily transformed by a variety of methods and then reintroduced back into the patient. Since the process again involves a tissue autograft, host immune rejection is again reduced. The technique has theoretical therapeutic implications for many diseases such as hemophilia and insulin-deficient forms of diabetes.

Transgenic Organisms and Basic Science

While it is difficult to draw sharp distinctions between utilitarian goals and the basic science necessary to achieve them, transgenic technology now plays a profound role in fundamental biological science. Like the recombinant DNA technologies that preceded them, undoubtedly the most significant role of the transgenic technologies will be as tools to gain new insights into nature. Reflecting on the current state of biological science, Verbeek noted, "The fast growing knowledge about the complex biology of higher eukaryotic systems demanded new experimental models. Transgenesis of mammals is one of the most fruitful techniques to create these models (54, p. 1)."

Transgenic organisms are radical new tools for fundamental research in all of the biological and medical sciences; they are powerful new instruments that are opening new windows to understand the natural

world. Since transgenic technology first began in 1980, it has grown exponentially. Transgenic animals have contributed greatly to elucidating complex biological processes at the molecular level (31). The magnitude of this new technology's impact on research inquiry is illustrated by citation analysis of Medline© references to transgenic organisms. In 1987 Medline© cited 163 references to *transgenic organisms* (including both plants and animals). Since that time the number of references has increased exponentially; by 1992 there were over 1000 Medline© citations in which the word *transgenic* was either in the title or was listed as a keyword (1). A cursory Medline© search indicates that in 1997 alone, there were almost 25,000 references to *transgenic animals*.

Organisms Used and Research Goals. Given the ubiquity of mice or rats in laboratory research, a majority of the studies noted above involved these animals. Nevertheless, these transgenic research programs also used a diversity of other animals. They span a wide evolutionary range and include relatively common laboratory organisms, such as fruit flies, zebrafish, and *Caenorhabditis elegans* (a nematode used extensively in developmental biology studies), to more exotic organisms such as the medaka fish and silkworms. Many animals reflect an ultimate commercial or agricultural interests such as goats, pigs, sheep, and cows.

Research involving transgenic organisms is as complex and diverse as the organisms themselves. Projects range from those with immediate, pragmatic goals — such as increases in agricultural products or solutions to human health concerns — to basic inquiries about the behavior of biological systems, such as antisense RNA, ribozyme action, gene expression in *Drosophila*, zebrafish developmental processes, or the role of molecules like FosB proteins described earlier.

Why Are Transgenic Organisms Important? As previously noted, development of transgenic organisms parallels the use of recombinant DNA in the early 1970s when many researchers were excited by potential commercial applications of recombinant DNA. Despite the utilitarian role, however, these same scientists saw the technology as a powerful tool to explore nature. The technique provided a means to isolate individual genes (or gene clusters) and their products away from a complex organism into a much simpler procaryotic organism. Researchers believed that such isolation would lead to a clearer understanding of gene function, regulation, and interaction (17). Indeed, the history of recent molecular biology has confirmed the validity of that belief, and our understanding of such diverse phenomena as gene action, immunology, ecological processes, or neurobiology has grown immensely during the past 20 or more years as a direct result of recombinant DNA techniques.

Furthermore it would have been difficult to create a list of new things scientists expected to discover with the early recombinant DNA research. One could point to potential societal benefits, such as new understandings of gene function and similar phenomena, expected from the work. For most scientists, however, this was a technique with tremendous investigatory power that could be used to open new vistas of biological knowledge. It was this epistemological dimension of the research that animated many scientists' interest in recombinant DNA technology (17).

In a similar fashion, it is problematic to create a tidy list of projects that transgenic organisms will solve. The dilemma arises from the nature of scientific inquiry that does not permit clear predictions about its own nature and direction, a point marvelously illustrated by the outcome of the *fosB* knockout mouse experiment described previously. Scientific inquiry fundamentally is more than a simple *accumulation of facts* about nature; rather it is a *method to understand* the natural world.

How is this digression into epistemology connected with the technology of transgenic organisms? Simply it is this: Despite their artificial creation, transgenic organisms are now a part of the natural, empirical scientific world. As such, they are important tools to gain a greater understanding of nature. Like the transgenic procaryotes that preceded them in the repertoire of scientific investigative tools, transgenic eucaryotes will ultimately provide humankind with fundamental and valuable knowledge of the natural world.

ANIMALS, BIOTECHNOLOGY, AND ETHICS

Like many technological innovations, development of transgenic organisms presents us with ethical quandaries. In addition to their wondrous utility, their creation also raises potentially troubling ethical questions. While these questions are complex, and often appear refractory to solution, they have been addressed elsewhere (1,2,55,56) and will be extensively dealt with in this volume. Only brief reflection on the issues raised in this article is appropriate here. The ethical questions seemingly fall into four broad areas: breaching species boundaries, potential for animal harm, environmental concerns, and potential human application.

Species Barriers

Transgenic organisms raise obvious concerns about "species barriers." Are *species* physical entities so inherent in the fabric of nature that we are morally culpable in breaking the barrier between them? Is there anything morally significant about being a member of a *species*? These questions might be put another way. Should sheep be allowed to be sheep without carrying burdens of non-ovine genes, some of which are intended only for human benefit?

A scientific perspective suggests negative answers for these questions. The notion of *species* as fixed natural entities is relatively new in human thought and is contrary to modern scientific views. From antiquity all species were seen as eternal and immutable, and this *essentialistic* notion of species dominated Western thinking well into the nineteenth century. From this view, the organisms we encounter in daily existence reflect an essential form that exists within created nature itself.

As noted previously, Charles Darwin began to shift the scientific notion of *species* away from this *essentialist concept*, and post-Darwinian biologists reject all *essentialist* notions of species. Thus there is nothing unique about being a member of a *species* that would seemingly command moral recognition. *Species* do have biological reality, but it is not an *essentialist* reality (14).

Species are not immutable "type-forms" woven into the fabric of nature but are defined in populational terms, a reality that is contextual and is spatiotemporally bounded (14,57). Moreover, as a scientific heuristic device, the *species* concept provides a way to organize and simplify the complex diversity of living organisms; *species* provide what Mayr refers to as a *taxon*, namely an entity in nature with taxonomic significance. Again, it is not readily apparent that taxonomic significance can mandate moral significance.

Transgenic Animal Welfare

Sentient transgenic animals raise serious concerns about potential pain or suffering that we might cause to an animal capable of such experiences. Are we morally permitted to intentionally "create" an organism that we know will ultimately suffer severe debilitation or experience great pain? CF mice exhibit many physical symptoms common to the human disease, including premature death. Creation of the CF mouse, or any animal as a model of human disease, involves potential harm or suffering to individual transgenic animals. So the moral question arises, Do we have a right to intentionally create such an animal capable of experiencing pain that we know will develop such a debilitating and painful disease?

The argument has been made elsewhere (1,2) that transgenic animals are not, in principle, significantly different from other animals. If one accepts this claim, then resolution of questions about pain and suffering are similar to questions regarding animal use in general. Commercial and laboratory use of sentient animals is controlled by regulations and principles established by the Department of Agriculture and by National Institutes of Health Guidelines (9,10). As McCarthy noted, most use of transgenic organisms will be governed by these entities. He also noted, however, that "there are gaps in oversight due in part to whether the particular methods are publicly or privately funded" (58, p. 526).

Like many questions involving research use of animals, the moral parameters for using transgenic organisms must be contextually defined (59). Potential animal suffering must be weighed against potential human suffering alleviated through knowledge gained by animal use. After due consideration we might conclude that creating a strain of mice as models of CF is morally justified because it may ultimately alleviate the acute suffering of a significant number of human children. On the other hand, using similar techniques to create a strain of dogs with some serious physical abnormality (e.g., severely shortened legs) to become novel pets would arguably be morally reprehensible.

Ecological/Environmental Concerns

A third ethical concern entails possible ecological damage arising from intentional or unintentional release of transgenic organisms. How do we ensure that these novel organisms do not unduly disrupt natural habitats and cause serious environmental damage? The potential environmental impact of transgenic organisms has been poorly studied; these questions are probably quite significant, however.

In many respects the environmental impact of organisms used in biotechnology should be minimal, as there is no intent for the animal to be released. Indeed, because of the great expense involved in their creation, extreme precautions are taken to prevent the animal from escaping the laboratory or farm environment. Serious environmental concerns arise, however, in two areas. First, care must be exercised in projects where there is a high potential for a genetically modified organism encountering naturally related organisms, for example, in mariculture. Second, one need only drive through any kudzu-covered forest in the United States to envision the potential ecological havoc that a genetically altered plant might create. (Kudzu, of course, is not a genetically altered plant.) Both of these issues have been fully addressed elsewhere (1,38,55).

Human Application

A fourth ethical issue arising from transgenic technology is perhaps the most serious and the most difficult to resolve, namely application of transgenic technology to humans. The articles by Friedmann and Jaenisch demonstrate that the clear direction of this research is toward human application. As is noted elsewhere in this volume, the ethical issues in this area are complex and often troublesome. On the one hand, for many people we are morally culpable if we have the ability to alleviate the suffering of an individual with a profound genetic defect, such as CF, Tay-Sachs, or sickle cell anemia, and we fail to use that ability. This conclusion, however, clearly places us onto the moral philosopher's slippery slope. Moral distinctions between significant genetic defects (e.g., CF or sickle cell anemia), with their associated suffering, and merely attractive traits that individuals might like for their children to possess (e.g., large body mass so that a son could become a highly paid NFL linebacker) are reasonably clear. Moral distinctions with such extremes, however, are rare. More often we face subtle and less clear choices that are thus more ethically problematic.

These moral considerations become even more problematic when we ask about our obligations to future offspring of individuals suffering from a treatable genetic disease (38). Many people readily find moral obligations to treat individuals with somatic cell deficiencies. However, obligations to treat such deficiencies at the germ-cell level are more complex. While we may be obligated to alleviate the suffering of a person with a genetic disease, are we obligated to ensure that those individuals can produce children who lack the genetic defect? Alleviation of immediate suffering, if we can do so, seems a reasonable obligation. However, does that obligation extend to some

future individual not yet conceived? These moral questions intuitively appear problematic, and answers do not appear readily obvious.

CONCLUSIONS

For many people, animal biotechnology promises a powerful new vision of general welfare and health for both humans and other animals. Domestic breeding, enhanced by modern techniques such as marker-assisted selection, and transgenic organisms (and the various technologies associated with their creation) may present a cornucopia of new wealth (both financial and abundance of valuable material possessions or resources).

Creation of transgenic animals, especially, is a new tool for scientific inquiry and has the potential to alter science itself. New questions about nature, which were impossible in the technology's absence, could be asked and radical new answers proposed. Like many new scientific tools, studies with transgenic organisms often have serendipitous turns. The apparent maternal behavior pattern linked to the *fosB* gene discussed in this article is a good example of the unexpected paths this technology can reveal.

Concomitantly the technology's power also creates profound possibilities for moral abuse and environmental chaos. Our most deeply felt sense of human values can be seriously distorted and corrupted by even moderate abuse and potentially could lead to distortions of fundamental and essential aspects of both human and animate nature. From some perspectives, transgenic technologies represent a Frankenstein-like bargain with nature and are the realization of Chargaff's prediction of the "Devil's Doctrine," that what can be done (technologically) will be done [regardless of broader social concerns (60)].

Nevertheless, transgenic organisms are not fictional or creatures of ancient mythology; they are a reality of nature that we humans must deal with. Like most scientific inventions, transgenic animals pose complex moral issues. And, as with any truly moral issue, the fashioning of transgenic organisms present us with moral ambiguities and treacherous slippery slopes. They pose questions about our moral obligations to both our fellow humans as well as the other living beings with whom we share this planet. The moral problems are made more complex as we attempt to discover our obligations to others members of the biological web within which all living beings are intertwined (1).

Science may help enlighten and focus the moral landscape of these questions; however, it does not provide us with adequate tools to derive answers. This difficulty is inherent in the limitations of scientific inquiry, for these answers "are as many as there are different cultural, religious, and philosophic perspectives" (59, p. 518). Because these pluralistic perspectives are not subject to empirical boundaries or testable propositions, science, as a mode of inquiry, is ill prepared to deal with them. Thus answers to questions on our moral obligations must lie in other aspects of the broader human condition. Wrestling to find anchors on the slippery slopes of our moral landscape nevertheless is a natural aspect of our humanity.

ACKNOWLEDGMENT

Part of the work on this article was completed during a sabbatical year at Case Western Reserve University, and the author thanks his many colleagues there for their helpful comments and criticisms. Drs. Melinda Duncan and Milton Stetson, at the University of Delaware, also provided help defining technical terms. Finally, the author thanks the National Science Foundation for financial support (Grant number SBR 9602023).

U

UNIVERSITY–INDUSTRY RESEARCH RELATIONSHIPS, ETHICS, CONFLICT OF INTEREST

ROBERT P. LAWRY
THOMAS W. ANDERSON
Case Western Reserve University
Cleveland, Ohio

OUTLINE

INTRODUCTION

Since World War II, and increasingly since the early 1980s, there has been a widespread public policy initiative to increase and deepen research and development relationships between industry and academic institutions. The hope is that new technologies will be more rapidly and effectively produced both to promote the general welfare as well as to increase U.S. dominance in the global marketplace. Ethical concerns, however, have arisen simultaneously. Scientific and educational integrity are threatened in a variety of ways by these new academic-industry partnerships. As questions of conflicts of interests increase and deepen, good public policy answers lag behind.

HISTORICAL CONTEXT

Until the late nineteenth century, colleges and universities in the United States were primarily teaching institutions. Their role was largely confined to the transmission of knowledge. The discovery or enlargement of knowledge was secondary to the application of practical subjects that would have utility for students and for the larger society. In the public sector, the Morrill Act of 1862 allocated federal lands to states for the founding of "at least one college where the leading object shall be, without excluding other scientific and classical studies ... to teach such branches of learning as are related to agriculture and the mechanic arts" (1). The Act led to the founding of new state institutions and to the support of recently established state colleges, embodying a vocational, practical educational focus.

Nothing changed the educational landscape in the United States more than the founding of Johns Hopkins University in 1876. It has been described extravagantly but not inaccurately as, "perhaps the single, most decisive event in the history of learning in the Western Hemisphere" (2). Prior to the founding of Johns Hopkins, graduate education and the research associated with it were left to the leading European universities, the German universities in particular. The Hopkins model gave primacy to graduate education over undergraduate instruction and brought together the German concepts of advanced training and the generation of new knowledge, particularly in the natural sciences, into the teaching environment of American universities. During the next 50 years, the uniquely American research university took root and began to flourish.

From 1900 to 1920, private and public universities were participants in the general economic well-being of the era. For private institutions, endowments were established and began to grow. The philanthropies of John D. Rockefeller and of Andrew Carnegie set examples for decades to come. Public institutions secured their places as important and useful state resources requiring more than tuition income to accomplish their increasingly diverse objectives.

It was not yet clear, however, how much of the nation's scientific research would be done in universities. Government agencies and independent research institutions competed with universities for the resources to hire researchers, build facilities, and support research activities. Public universities looked with modest success to their state legislatures for research support and both public and private universities began to appreciate the power of private philanthropy. Early in the century, Harvard President Charles Eliot noted, "it is clear that men of means, who reflect on the uses and results of educational endowments, are more and more inclined to endow research" (3). While the American research university hallmark of combined teaching and research was being firmly established in the first quarter of the twentieth century, the funding structures to adequately support these no longer discretionary activities were not yet in place.

World War I effectively nationalized the research universities, focusing all faculty and student efforts on winning the war. The role of science was enhanced, and the bonding of applied and basic research was seen as important to the war effort. Following the war, the major philanthropic foundations, established in the late nineteenth and early twentieth centuries, began to take notice of scientific research as a means for the "amelioration of the human condition through the advancement of knowledge" (3). Foundation grants enhanced and expanded university research in the years between the two world wars. Fears of foundation control over university educational and research efforts did not materialize as it became clear that the needs of

research universities would far surpass the resources of the foundation community.

Following World War I, the advancement of scientific knowledge through university-based research began to require a partnership of universities, private philanthropists, foundations, and now corporations. Major corporate laboratories had been established early in the century for applied research purposes. Interactions between applied industrial researchers and university basic scientists became common. University graduates were recruited to industrial laboratories and faculty members consulted with corporations. Corporate financial support for university research followed naturally from these relationships. Even early on, the differences between universities (dedicated to the advancement of knowledge) and corporations (dedicated to financial gain) raised the potential for misunderstandings. Corporations were not convinced of the importance of basic research and faculty members found that corporate interests were often too narrow to be of educational or scientific interest. But, interactions continued in a variety of forms (graduate fellowships, research contracts, consulting relationships, etc.) in generally ad hoc institutional arrangements.

World War II again found universities deeply involved and effected by the war effort. The Manhattan Project and the Radiation Laboratory at the Massachusetts Institute of Technology were major scientific collaborations between university scientists and the federal government. While it may be overstating the case to say that science won the war, it nevertheless played such a decisive role that neither academic research nor federal scientific interests would ever be the same again. The war not only highlighted the need for a federal science policy, it brought the federal government into a permanent funding relationship with university research. World War II marked the shift from primarily private to primarily public funding for major research projects. Postwar foundation support became focused on three broad objectives: medical and health fields, strengthening the system of university research, and social and behavioral sciences (4). Foundation funding increasingly nudged research universities in the direction of academic excellence rather than the targeted defense related research necessary for a war effort.

Federal Government Involvement

In 1950 the National Science Foundation (NSF) was created to fund basic academic science with public funds. Until this time the postwar research agenda had been driven largely by programmatic funding from the armed services. University administrators and researchers were increasingly concerned about the source and direction of military research. California Institute of Technology President Lee A. DuBridge called the prevailing military authority over the nation's research program "an anomalous and precarious situation to have the future of basic research hang by the thread of continued appropriations to the military agencies, or of their continued interests" (4). In response to this concern, the National Science Foundation was created to fund basic research, by "greasing the wheels of science," funding scientific research, and developing "a national science policy" (4). Although initially inchoate in its mission, both the role of the NSF and the nation's interest in basic research changed on October 4, 1957, with the Soviet Union's launch of Sputnik, the first space ship to orbit the earth. Because of the threat of an attack from space during the height of the cold war, the days immediately following *Sputnik* were consumed with much national soul-searching. Initial responses included the establishment of the National Aeronautics and Space Administration (NASA) and increased federal appropriations to existing agencies for basic scientific research.

While funding levels would vary over the next 40 years, commitments to basic versus applied research would wax and wane, and the interests of social justice and economic development would often compete, the foundational commitment of public funds for academic research would not be seriously threatened. Basic academic research became a growth industry, largely funded by federal money. This federal commitment also included the beginnings of a federal scientific establishment, initially presided over by the Presidential Science Advisor but eventually permeating all branches and levels of government. As the NSF gained its footing, it was joined (in federal priority) by its sister institution the National Institutes of Health (NIH), the research arm of the Public Health Service. The NIH was to biomedical science and scientists what the NSF was to natural science and scientists.

The 1960s placed significant strains on research universities — student unrest, sluggish economic conditions, governmental oversight, and changing values — leading to a loss of confidence in these institutions and their primary missions of teaching and research. Egalitarian federal programs and the proliferation of institutions seeking research funding led to changes in both the recipients of public funds and the role of private funding sources. In the 1970s one response to these conditions found the leading research university faculty and administrations beginning to seek closer relationships with corporations. While driven partially by funding considerations, these initial efforts by research universities also "implied a break with the cloistered mentality that had flourished in the 1960s" (4).

In the early years of the twentieth century, corporations purchased research capability from universities either through direct support of specific research activities or through joint institutes for applied research. By the beginning of World War II, however, many corporations had established their own laboratories, and thus looked to universities for the theoretical work that would underlie their corporate research interests. But corporate and university interests were inevitably different since universities seek to advance knowledge while industry must apply it. Universities were organized horizontally and corporations were organized vertically. Individual faculty members determine whether they will work with corporations no matter how friendly their university policies may be to corporate interactions. But despite these differences in culture, by the 1980s corporate

support of university scientific research was growing at unprecedented rates.

The mid-1970s saw fledgling efforts by the NSF to encourage university–industry interaction for the specific purpose of technology transfer. At about the same time the first large ($23 million) university–corporate contract (Harvard Medical School and the Monsanto Corporation) based on mutual research interests was announced. Unprecedented on both sides, "Monsanto provided funds for endowment, research support, and facilities for a pair of Harvard scientists. In return the company was promised the patent rights to any discoveries that resulted from their research" (4). Viewed with both interest and suspicion, the agreement was only the beginning of similar arrangements at other institutions and corporations, particularly in microelectronics and biotechnology. This highly structured form of technology transfer was supplemented by small start-up companies seeking to commercialize scientific discoveries. Such companies often were founded by scientists, engineers, and graduate students from research universities with funding from venture capital firms.

The blueprint for biotechnology start-up companies was drawn by Genentech, a firm founded in 1976 by a venture capitalist who struck an agreement with a molecular biologist who was interested in commercializing his new technology that led to synthesizing the human gene for insulin. Genentech licensed the discovery to the Eli Lilly Corporation and "thus validated the idea that genetic engineering could produce valuable commercial products..." (4). Venture capitalists, scientists, and universities immediately understood the potential for significant wealth in similar relationships. Scientists could continue their research — either within the academy or at the new firms — with private funding that could lead to both important scientific breakthroughs and the prospect of enormous wealth. Over 200 biotechnology firms were founded between 1980 and 1984, and half of all biotechnology venture capital raised by 1988 was raised during the two years following the Genentech announcement (5). The potential for conflicts of interest and commitment were recognized as enormous, although not always immediately.

The explosion of biotechnology research was coupled with the highly charged business climate of the 1980s. Government deregulation, junk bond financing, and declining federal support for research universities all enhanced the environment for business–university collaborations and partnerships of almost infinite variety. Both state and federal governments enacted legislation to encourage these partnerships in the hope of transferring technology, increasing corporate competitiveness, and retaining business and industry within state boundaries. Universities scrambled to compensate for reduced funding levels and to retain key faculty members who were increasingly being lured outside the academy by entrepreneurial opportunities.

At the federal level, the NSF had two programs (the Industry–University Cooperative Research Projects Program and the Industry–University Cooperative Research Centers Program) which were established in the 1970s to develop and sustain corporate–university research partnerships. By 1989, 41 Research Centers around the country were operational and 22 were self-sustaining. A second part of the Research Centers program was founded in 1985 to support Engineering Research Centers with 18 established by 1989 (6). All potential economic benefits from the collaborative arrangements encouraged by these centers remain with the centers despite significant funding by the NSF.

Significant Legislation

Perhaps more important were changes by federal agencies allowing universities to retain patent rights from inventions and technologies discovered in federally funded research projects. The Bayh–Dole Act of 1980 specifically granted such rights. The Federal Technology Transfer Act of 1986 permitted federal scientists and university scientists to collaborate with industry to develop commercially patentable ideas. The Act specifically authorized "private companies to gain the exclusive rights to patents, while universities and scientists could receive royalties" (6). These federal efforts, along with complementary state legislation, nudged, if not pushed, universities into the technology transfer business and into increasing collaborations with industry with the objective of commercializing the results of research.

As the Harvard Medical School–Monsanto relationship was followed by equally large and potentially controversial business-university partnerships in the 1980s, issues of academic freedom, freedom to publish, conflicts of interest and commitment, and secrecy began to surface both inside and outside of the academy. Conferences were held with academics, business, and government participants to consider and address such matters. The Government–University–Industry Research Roundtable was founded by the National Academy of Science, the National Academy of Engineering, and the Institute of Medicine in 1984 to "provide a forum where scientists, engineers, administrators, and policy makers from government, university and industry can come together on an ongoing basis to explore ways to improve the productivity of the nation's research enterprise" (6). Although decidedly "pro" business–university relationships, the Roundtable developed a model agreement for business–university research partnerships which set standards for publication, intellectual property ownership, and licensing and patenting procedures.

Despite a climate generally favorable to university–industry collaborations, there was also concern about abuse. Particularly troublesome were ethical issues arising from conflict of interest questions. In 1989 the NIH proposed guidelines that required individual decision makers involved in funded research to disclose "all financial interests and outside professional activities." Any perceived conflict of interest uncovered by these reporting requirements was to be especially noted and resolved prior to funding. Moreover, researchers were prohibited from holding equity or options in any company affected by the outcome of their research. Record keeping was extensive on the part of universities, which bore much of the

burden of administering the guidelines. Harsh and wide-ranging criticism of the proposed guidelines resulted in their withdrawal within months of publication. NIH then proceeded to develop formal regulations on the subject, which, together with similar regulations proposed by the NSF, became binding in 1995. Less restrictive, these rules required researchers funded by NSF or NIH to notify their home institution if "they, their spouses, or their dependent children have financial interests — exceeding $10,000 or 5% ownership — in companies that might be affected by their research" (7). But once the researcher has complied with this threshold requirement, it is up to the institution to decide whether it is a conflict of interest and what to do about it. The rules do not cover the situation when an institution has a financial interest in the outcome of federally funded research. Thus it became important to understand both what the concept of conflict of interest entails and to examine proposed remedies for conflict situations.

CONFLICT OF INTEREST

One widely approved definition of conflict of interest is that it is "a set of conditions in which professional judgment concerning a primary interest (such as a patient's welfare or the validity of research) tends to be unduly influenced by a secondary interest (e.g., financial gain")) (8). Although there is some scholarly debate about what is the key concept in conflict of interest analysis (9), a growing consensus seems to find in the risk of impaired professional judgment the locus of the problem. Thus, as one modern legal scholar has put it, "[T]he common feature which brings each of ... (a variety of) questions within the doctrinal niche labeled 'conflict of interest' is concern with the existence of some particular incentive which threatens the effective and ethical functioning of a 'person acting in the role of a fiduciary for the benefit of another or others'" (10). The widespread concern is that an individual, employed by the university to perform one or more of a multiplicity of tasks in its behalf, may be compromised in his or her judgment by an incentive that should be subordinate to what he or she is employed by the university to do. Under the NSF and NIH rules, only a "significant financial interest" counts as a problematic secondary incentive; however, since the university is responsible for determining initially what counts as a conflict of interest and how to deal with it, the university may also enlarge the parameters of their internal policies to deal with incentives beyond the financial. A further complication exists because of institutional conflicts of interest, that is, when the university has a financial stake in the research conducted by those employed by the university. Much less attention has been paid to this topic, and discussion of it will be postponed until later.

Conflict of interest describes a situation of risk, not actual impairment of function. If there is actual impairment, then there is true blameworthiness. Simply being in a conflict situation, however, is usually benign in and of itself (11). Although scholars realistically warn that the phrase as often used is "accusatory" (12), this should not be the case. Since federal public policy strongly supports university–industry partnerships, conflicts of interest are inevitable, at least at some times and in some ways, for a great many researchers in university settings. It is necessary first to recognize a conflict situation, and then to determine what to do about it. The identification question is logically and realistically prior to the remedy question. For some conflicts, nothing needs to be done. Others, of course, need, in the words of the federal regulation, to be "managed, reduced or eliminated."

Judgment

Although conflict of interest problems are not new, serious academic consideration of them is relatively recent. Using the legal professional literature extensively, Davis was the first professional ethics philosopher to isolate the importance of the risk to judgment impairment as of central importance (13). Previously Margolis had suggested that conflict of interest entailed "an avoidable exploiting of conflicting roles" (14). Davis argued that the issue was really the threat to judgment within a role, rather than a conflict between roles, which suggested a typical but different ethical dilemma. For Thompson, this was the key difference:

> "In ethical dilemmas, both of the competing interests have a presumptive claim to priority, and the problem is in deciding which to choose. In the case of ... conflicts of interest, only one of the interests has a claim to priority, and the problem is to ensure that the other interest does not dominate. This asymmetry between interests is a distinctive characteristic of conflicts of interests (8).

This asymmetry may not be characteristic, however, of all conflicts of interest. In the legal literature, for example, conflicts do occur when lawyers sometimes try to represent two or more clients with "conflicting interests." Nevertheless, in university–industry conflicts, Thompson's point regarding an asymmetry in interests seems well-taken because it is generally understood that the obligation to the university is primary for the researcher.

Luebke challenged Davis's analysis regarding the centrality of judgment, claiming that the issue was not the "correctness of the decision," but "the potential damage to the trust relationship existing between the bearer of the conflict and the person or entity for which the primary interest was to be maintained." (15). Trust is important to the maintenance of the relationship, but as Pritchard noted in defense of Davis, "... The maintenance of trust is what is under threat in conflict-of-interest situations, but precisely, as Davis says, because the reliability of professional judgment is thrown into doubt" (11). So "judgment" is the more precise term. Nevertheless, since the issue of trust is essentially one of trust of the professional judgment, there may be no substantive divergence between the two positions. The appearance issue will be discussed later.

Judgment for Davis "implies discretion" (13). It is not something mechanical or routine, something a clerk could do. Still it is important to stress that the idea must be generalized; it is judgment within a role, not a particular judgment in a role. To suggest otherwise is to fall into the

trap Davis himself fell into. In addressing the following hypothetical, Davis declared the answer to depend on whether discretion was called for in the case at hand. The issue was: "Is it a conflict of interest to recommend to one's own company a contract with another firm in which one holds substantial stock?" The question of whether there is a risk of impaired judgment cannot depend on whether the judgment involved discretion in the particular case but only on whether, in general, this role demands judgment-as-discretion at least some of the time. Surely we are as concerned in the above hypothetical with the avaricious person who deliberately seeks to line his pocket at the expense of the person or entity that has a fiduciary claim upon him just as we are concerned with the person who subconsciously or confusedly makes a bad judgment to the detriment of his institution. We want to recognize both kinds of problems as conflict of interest problems because both evidence a risk that there will be impaired performance. In establishing conflict of interest rules or guidelines, there is a need to have everyone treated alike before the fact. This cannot be done if we have to know the subjective answer concerning how discretionary the judgment was before we can determine whether the matter demanded some review. The risk must first be identified category by category before a proper remedy can be determined. Thus, the word judgment might better be replaced by the word "decision" to capture all that we want, especially because the former may imply discretion while the latter may not. Thus McMunigal says it better when he suggests the real concern is with an incentive which threatens "the effective and ethical functioning" of the conflict holder in his fiduciary role (10).

Interests

Thompson's formulation stresses the need for one or more "primary" interests being at risk of subordination to a secondary interest. For an academic working as a researcher in a university setting, there seem to be three primary interests: (*1*) research integrity, (*2*) the well-being and education of students, and (*3*) if in a clinical setting, the welfare of patients (8). Although the NIH and NSF rules focus on financial interests alone, there are surely other secondary interests that university watchdogs will want to be on the lookout for. Pritchard suggests some of these secondary interests: tenure, promotion, satisfaction from supporting one's graduate assistants, or colleagues or institutional connections, or even one's reputation (11). The problem here is that the list can be extended indefinitely. Davis would include "all those influences, loyalties, concerns, emotions, or the like that can make (competent) judgment less reliable than it might otherwise be" (13). Davis even includes "moral constraints." Surely this goes too far. Pritchard finds in Feinberg a more modest and more objective definition: "something one might attempt to advance, protect, or even modify" (11). Although this excludes things like moods and emotions, it may still be too broad to be manageable because it may include rather personal predilections concerning, say, working hours and conditions, irrelevant to real conflicts of interest concerns. But surely financial interests are too narrow a concentration, though Thompson is right in asserting that financial gain is more "pernicious and more objective and more fungible, and easier to regulate by impartial rules" (8). Since the federal government's regulations focus only on money, universities may lose sight of other secondary interests — some hardly trivial for the individual — that require enumeration and care in determining whether they threaten to impede a good, independent professional judgment/decision which damages a primary interest.

REMEDIES

There are a number of different ways to assess how problematic a conflict of interest might be. Thompson proposes two standards for assessing the severity of a conflict. First, there is the "likelihood" that the judgment will be affected. Rules of thumb under this standard include (*1*) the greater the value of the secondary gain; the greater the likelihood the judgment will be affected, (*2*) the longer and closer the association with those connected to the secondary interest, the greater the likelihood the judgment will be affected, and (*3*) the greater the degree of discretion in judgment, the greater the chance for judgment to be improperly affected. Thompson's second standard is cast in terms of the "seriousness" of the conflict. Crucial concerns here are (*1*) the value of the primary interest, meaning the potential effects on patient care or on the integrity of the research, (*2*) the scope of the effects on the project itself, but also on others, including the indirect harm that comes from loss of confidence in the researcher or in his or her institution, and (*3*) the relative accountability of the researcher. There is presumably less concern if there is reliable review of the work (8).

Another approach to standards can be drawn from the legal literature, which distinguishes at least three kinds of conflict of interest: actual, latent and potential. These categories are distinguished by the closeness of the conflict to the actual impairment in professional judgment that is the underlying concern. An actual conflict therefore is one that is certain to affect the judgment. A latent conflict is one for which there is a reasonable probability that the judgment will be impaired. A potential conflict is one that is reasonably foreseeable (13). Although there is confusion in the legal literature concerning the proper use of these categories (10), if they are simply standards to make the remedies chosen for a given situation more amenable to sorting out, perhaps they can be helpful. Use of these terms in any substantive way is simply confusing.

In any event, it is to standards like the ones articulated by Thompson and in the legal literature that those responsible for determining what to do about conflicts of interest instinctively turn. For example, Blumenthal suggests that the seriousness of the potential harm to patients and to the integrity of research in a clinical research setting require the most restrictive rules. Generally he would ban any conflicts of interest in these settings, except if the financial gain through the secondary interest is *de minimus*. Blumenthal is equally concerned with situations where students and trainees may be affected by the conflict of interest. Because restrictions on scientific communications are frequent

in university–industry partnerships, and the students' careers may be hampered by their lack of publishing results of the work, conflicts affecting educational decisions should be allowed but rarely, and then only under the closest of supervision. More empirical research needs to be done, Blumenthal argues, before it is clear what ought to be the approach to other conflict of interest categories.

In nonclinical settings not involving students or in clinical settings where the secondary interests are "nonexistent or attenuated," it is not clear how restrictive the rules ought to be. Here Blumenthal is thinking of things like "straight-forward academic–industry research relationships" and "patenting and licensing arrangements, in which clinical research may affect whether and how much royalties are received on patented products of research." Preliminary empirical data suggests, on the negative side, that industry sponsorship tends to affect the choice of research topics and also results in scientific information being held back longer, even beyond the time necessary to file a patent. On the positive side, technology transfer activities have increased in a variety of ways, and so far, there have not been reports of actual research misconduct attributable to academic-industry relationships.

Finally, there is a mixed result regarding scientific publications. Generally the relationships seem to spawn more publications, except among researchers who "receive more than two-thirds of their total research budgets from companies or add more than 20 percent to their total salaries from consulting to industries" (16). This last finding seems to confirm Thompson's notion that more intense relationships may have negative effects on researchers. This is based on the supposition that more publications are part of the primary interests on the part of the researcher in that role within the university. While this may be true as a general proposition, it may not be true in any individual case. Quality is, of course, often more important than quantity. This points up the need for careful scrutiny of actual situations, rather than blanket rules, except in the most serious kinds of cases, namely the ones Blumenthal identified as involving risks to patient care, to research integrity, and to students' careers.

Categories of remedies include disclosure, oversight, or some form of escape. Disclosure is usually warranted in all cases where a conflict of interest exists. Obviously no one can investigate and determine how serious is a given risk if they have no knowledge of the conflict to begin with. Even in the more controversial area of disclosure of research funding accompanying publications, one study showed that an overwhelming percentage of researchers who came out positively in favor of a certain type of drug received funding from companies that make the drug, while a much lower percentage of those critical of the class of drugs received such support. The authors of the study did not suggest that the researchers favoring the drugs were dishonest; however, they did recommend that disclosure occur "to avoid suspicion" (17). Critics of disclosure of funding for research that results in a publication claim that the reading public does not know what to do with the information (12). Whatever the merits of the two sides to that debate, there is no application to the question whether disclosure to university officials ought to be made. The better analogy here is to the lawyer in a conflict situation who must disclose the conflict to the client potentially affected. The client, after being informed, usually has the option to determine whether or not to continue to be represented by the lawyer or to ask for some change to be made. Analogously, the university has the right to know about a conflict situation, to determine whether further action is warranted or not.

Oversight may be by a standing committee within the university or by a person or group outside the university. Here the relationship between the researcher and the company may be welcomed, but the size and nature of the financial arrangement may cause sufficient concern that some additional regulation seems necessary. Since the 1995 federal guidelines require researchers to notify their own institutions if they or their close relatives have a financial interest in companies affected by the research exceeding $10,000 or 5 percent ownership, it is likely that the institutions will want to have some oversight of research that meet the federal criteria. Presumably whether that oversight is to be conducted by a committee within the university or outside it may depend on such variables as the expertise required to perform the oversight function or the manner in which the oversight must be conducted.

The last category of remedies, "escape," is a catchall to gather all those situations where it is deemed necessary or wise to prohibit the arrangement either through divestiture, abstention from decision making or some other mechanism to insulate the researcher from the work or the potential financial gain. This is obviously the most costly and serious remedy with which to handle a conflict situation; but, at times, it will be the only reasonable one.

INSTITUTIONAL CONFLICTS

Most of the literature concerning academic–industry relations has focused on the individual researcher and his or her own conflicts of interest, with the primary interest being to the academic institution and only secondary interests obliging the researcher to industry. Little attention has been paid to the problem of conflicts of interest that may affect the academic institution itself. Universities may have equity interests in companies affiliated with their institutions. Universities may also own patent rights that they license to companies and investigators employed by the institution. Institutional practices may thwart individual investigators or conspire with them to enhance the value of their equity interest or stock holdings to the detriment of their true primary interests. As the university is being asked to develop internal rules and procedures to guard against abuse in conflict situations, who will be the watchdog, guiding the university officials on the firing line from succumbing to the temptation to seek a secondary interest of the entity in preference to one or more of the institution's primary interests (18)?

Clearly, there are different conflict problems when the focus shifts from the individual researcher to the institution. First, the individual may not be at all compensated by a company, but the institution may be benefiting directly from the fruits of the research by increased value to its equity holdings or its licensing agreements. Again, no matter the situation with respect to the researcher, the institution may put subtle or not-so-subtle pressures to prefer a secondary interest in some way, which the individual researcher may be hard-pressed to avoid. The secondary interests of the institution may not be limited to economic gain either. Increased reputation may also be a secondary interest, which complicates the pursuit of the primary missions of teaching and research, and in the case of university clinical matters, the patients' welfare. There have already been suggestions made that any institutional conflict should prima facie be grounds for avoiding the conflict altogether. Of course similar remedies to those put forth for individuals have also been offered, with disclosure — even to individual patients — mandated, while internal or external monitoring providing supplementary remedies (18).

APPEARANCE OF A CONFLICT

A theme that constantly appears in all discussions of conflicts of interests is the problem of "appearance." Since conflicts are simply questions of risk, and what to do to prevent risks from ripening into actual breaches of duty, the question of appearances may arise more often in the remedy area than in determining whether or not a conflict exits. Once a conflict exits, there is, de facto, a risk that some impairment will follow. Even reasonable people may be skeptical that the remedy chosen *will truly prevent* the impairment from taking place. Since the university depends so much on its reputation for integrity in the pursuit of knowledge, these concerns are real and potentially problematic to deal with. However, it is not at all clear what should be done with appearance questions. In the absence of solid empirical evidence, it is hard to know whether any particular conflict category is seriously "risky." Nevertheless, there are those who believe the value of keeping the university's reputation clean requires curtailment of much of the activities that are now underway to foster academic–industry relationships (18).

OBSERVATIONS

Foundational to one's view of the risks and the necessary remedies for conflict of interest in corporate–university relationships is the public policy issue of the value of commercializing scientific research. During the past three decades the federal government has encouraged public–private collaborations through legislation and agency rule making. Scientists and universities, for whom the stakes may be very high economically, have encouraged and facilitated technology transfer. However, even for the strongest advocates of technology transfer and university/corporate relationships, 25 years of experience suggests that government, universities, and corporations need to remain diligent if they are going to preserve the benefits of commercialization of scientific ideas without sacrificing either scientific rigor or sound educational policy. Corporate–university agreements and federal rules need "to require disclosure of conflicts, limit the most troublesome forms of conflict, and create uniformity in ethical standards across the country" (19). The alternative seems to be an unacceptable slippery slope that threatens both the essence of the scientific process as well as the integrity of educational institutions.

On its face, technology transfer is relatively uncomplicated. Scientific researchers in universities and research institutes pursue new scientific knowledge with financial resources provided largely by the federal government. Commercially viable results are licensed to corporations who support the scientist and the scientist's institution in exchange for the opportunity to develop the idea. Scientists are often given personal consulting contracts or an equity interest or a board seat or a financial interest in future sales or all of these financial incentives by the company developing the scientific idea. The scientist's institution may also receive significant long-term financial incentives for its role in the process.

Inherently the problem is not the financial incentives for scientists or institutions to transfer technology. Within the free-enterprise system, scientists deserve the same opportunity for financial rewards from their work as do other professionals. Nor is the problem the personal gain for individual scientists and their institutions from work financed by public funds. As a matter of public policy, the federal government has determined that the benefits to society of the technology transferred outweigh the costs to taxpayers of allowing financial incentives to scientific researchers and their institutions. It is not an irrational or immoral trade-off.

The problem is the risks that standards of scientific inquiry will be compromised, diminished, or sacrificed for financial gain, or that the primary interests of educational institutions are subordinated to secondary interests. If the scientist's financial enrichment becomes tied to the success of the scientific outcome, then "society runs the risks that researchers will knowingly influence the outcome of 'neutral' scientific inquiries" (19). If the pursuit of economic gain harms students or patients, then the price is too high to pay.

Conflicts of interest threaten the integrity not only of individual scientists and their educational institutions but of the scientific process itself. Scientists caught by the potential for enormous financial gain between research for the public good and research for corporate interests, between their duties as teachers and mentors to graduate students and their duties as corporate consultants or officers, between their employer university or research institute and their corporate sponsor, or between the health interests of their research subjects and patients and the marketing interests of their corporate funders are on precariously thin ice when they record and report scientific results from an alleged position of scientific objectivity.

The classic remedies for conflict of interest of disclosure, oversight, and escape take on new meaning, and the path through the thicket of conflicting claims on the scientist's

objectivity and rigor is obscured as the potential for financial gain increases. Many would argue that scientific researchers, "particularly those conducting clinical trials, carry a fiduciary duty to the public. Like fiduciaries, there is a presumption against conflicts of interest" (19).

Current NIH and NSF rules rely on universities to decide whether there is a conflict of interest and what to do about it. Recent experiences, particularly in biomedical research, suggest that the university record to date leaves much to be desired. As pressure mounts on institutions and thus on scientists to seek corporate support and relationships, many argue that "the conflict of interest policies and standards of disclosure that universities rely upon don't do enough to protect academic freedom or the integrity of research in an environment where corporate interests are playing a growing role" (20).

Almost all current university and research institute policies are based on a principle of disclosure. But such disclosure principles are interpreted broadly, and often disclosure documents are not made public. Only a limited number of states require that disclosure documents be available under public record laws.

Very few scientific or lay publications inquire about conflicts or require disclosure by scientists writing on scientific and public policy topics. In 1992 a study of 14 journals showed that one out of three authors of nearly 800 scientific articles had a financial interest in the results of their research. Few if any of these conflicts were disclosed in the articles (20). In a 1997 study of scientists funded by drug companies it was found that 96 percent of the authors of favorable articles on a particular class of drugs had financial ties to the makers of the drugs. These conflicts were reported in only 2 of the 70 articles surveyed. Of those authors who published articles critical of the class of drugs, only 37 percent had financial conflicts of interest (17). While the mechanics of disclosure are neither easy nor obvious, it seems certain that institutions must find ways to make their disclosure requirements more visible and apparent. Moreover disclosure is only the first line of defense in conflict of interest situations when independence of judgment may be compromised.

It is not possible, or even desirable, to remove all conflicts of interest in scientific research. The benefits of collaboration between universities and corporations and the interactions of nonprofit and for profit scientists and investigators are already documented, particularly in biomedical research fields. But, as corporate relationships with universities, research institutes, and research scientists increase in number, size, and complexity, public confidence in the objectivity and rigor of the scientific process will erode rapidly in the face of undisclosed and unresolved conflicts of interest, real or perceived. Educational values and, in clinical settings, patient care may also be compromised by unattended conflicts of interests. The antidote is vigorous and persistent pursuit of institutional, governmental, corporate, and agency policies and practices that provide disclosure, oversight, and escape from conflicts of interest.

SUPPLEMENT

Every effort was made to obtain articles for this Encyclopedia on all key organizations, government offices, industry groups, interest groups, and so on. However, it was impossible to obtain some of these entries in time for inclusion in this work. The following brief summaries are provided to call the readers' attention to important groups and organizations that treat aspects of the subjects covered by this Encyclopedia, as well as to provide suitable contact information. It is hoped that this will be helpful for the reader seeking additional information.

BIOTECHNOLOGY INDUSTRY ORGANIZATION (BIO)

BIO is a trade association for the biotechnology industry.

1625 K Street NW
Suite 1100
Washington, DC 20006
Tel: 202-857-0244
Fax: 202-857-0357
www.bio.org

The BIO Website includes information on the following topics: the biotechnology industry, the biotechnology record on ethics, legislative issues, biological warfare, biotechnology in agriculture, agricultural biotech products on the market, biotechnology in health care, approved biotechnology drugs, industrial uses of biotechnology, applications of industrial biotechnology, biotechnology for the environment, applications of environmental biotechnology, biotechnology in animal health, and marine biotechnology.

THE FOUNDATION ON ECONOMIC TRENDS (FET), headed by Jeremy Rifkin, is a nonprofit organization whose mission is to examine emerging trends in science and technology and their impacts on the environment, the economy, culture, and society.

The Foundation on Economic Trends (FET)
1660 L Street, NW, Suite 216
Washington, DC 20036
Tel: 202-466-2823
Fax: 202-429-9602
E-mail: office@biotechcentury.org
www.biotechcentury.org

The FET Website *www.biotechcentury.org* addresses environmental, social, economic, and ethical issues related to biotechnology and provides links to other organizations engaged in biotechnology issues.

HUMAN GENOME ORGANIZATION (HUGO)

HUGO is an international scientific organization.
Contact information (U.S. and Canada):

HUGO Americas
Laboratory of Genetics
National Institute on Aging
NIH/NIA-IRP. GRC, Box 31
5600 Nathan Shock Drive
Baltimore, MD 21224-6825, USA
Tel: 410-558-8337
Fax: 410-558-8331
E-mail: schlessingerd@grc.nia.nih.gov
www.gene.ucl.ac.uk/hugo

Contact information (international):

HUGO
142-144 Harley Street
London W1N 1AH
United Kingdom
Tel: (44) 171 935 8085
Fax: (44) 171 935 8341
E-mail: hugo@hugo-international.org

The Human Genome Organization (HUGO) is the international organization of scientists involved in the Human Genome Project (HGP), the global initiative to map and sequence the human genome. HUGO was established in 1989 by a group of the world's leading genome scientists to promote international collaboration within the project.

HUGO carries out a complex coordinating role within the Human Genome Project.

HUGO activities range from support of data collation for constructing genetic and physical maps of the human genome to the organization of workshops to promote the consideration of a wide range of ethical, legal, social, and intellectual property issues. HUGO fosters the exchange of data and biomaterials, encourages the spreading and sharing of technologies, provides information and advice on aspects of human genome programs, and serves as a coordinating agency for building relationships between various governmental funding agencies and the genome community. HUGO provides an interface between the Human Genome Project and the many groups and organizations interested or involved in the human genome initiative.

PHARMACEUTICAL RESEARCH AND MANUFACTURERS OF AMERICA (PhRMA)

1100 Fifteenth St. NW
Washington, DC 20005
www.phrma.org
President: Alan F. Holmer

PhRMA membership consists of approximately 100 U.S. companies that have a primary commitment to pharmaceutical research. The mission of the pharmaceutical Research and Manufacturers of America is to help the research-based pharmaceutical industry successfully meet its goal of discovering, developing, and bringing to market medicines to improve human health, patient satisfaction, and the quality of life around the world, as well as to reduce the overall cost of health care.

To achieve its goal, the industry aspires to foster a favorable environment that encourages innovative drug research; swift development and approval of safe and effective drugs; consumer and patient access to medicines in an open and competitive marketplace; support and understanding from the public and other key constituents regarding the critical role and value of the pharmaceutical industry in improving human health and quality of life and in reducing overall health care costs; public policies that allow sufficient returns to foster continued innovation.

U.S. DEPARTMENT OF COMMERCE, TECHNOLOGY ADMINISTRATION

The Technology Administration (TA) (*www.ta.doc.gov*) is a bureau of the U.S. Department of Commerce (*www.doc.gov*). The Technology Administration leads civilian technology for the Department of Commerce and works with U.S. industries to promote U.S. economic competitiveness and growth.

The Undersecretary for Technology supported by the Deputy Undersecretary for Technology, manages the Technology Administration's (TA) three agencies:

(1) The Office of Technology Policy (OTP) is an office of the federal government with the explicit mission of developing and advocating national policies that use technology to build America's economic strength.

(2) The National Institute of Standards and Technology (NIST) promotes economic growth and an improved quality of life by working with industry to develop and apply technology, measurements, and standards.

(3) The National Technical Information Services (NTIS) collects and disseminates scientific, technical, engineering, and related business information produced by the U.S. government and foreign sources.

WHITE HOUSE OFFICE OF SCIENCE AND TECHNOLOGY POLICY (OSTP)

1600 Pennsylvania Ave N.W.
Washington, DC 20502
Tel: 202-395-7347
E-mail: information@ostp.eop.gov
www.whitehouse.gov, then link White House Offices and Agencies

OSTP was established in 1976 to provide the President with policy advice and to coordinate the science and technology investment.

OSTP Divisions: Environmental Division; National Security and International Affairs (NSIA) Division; Science Division; and Technology Division.
