The RAC's protocol review role was soon to be further curtailed, for a number of reasons. First, notwithstanding the official compromise between the RAC and FDA, industry spokespersons remained confused over when RAC review was and was not required (65). In addition the RAC's Verma Committee recommended that the RAC devote more attention to policy issues while delegating scientific review of most protocols to FDA (66). Furthermore proponents of biotechnology, like Henry Miller, continued to rail against the RAC's inefficiency and lack of technical expertise, and to argue that overregulation of gene therapy would inevitably delay development of new therapies (67). Miller criticized NIH Director Varmus for failing to eliminate the RAC (67). Pharmaceutical industry representatives concurred that the RAC review of gene therapy protocols was unnecessary. For example, Washington, DC, attorney Bruce Mackler opined that "[i]t is hard to identify in a quantifiable fashion a uniqueness of gene therapy risks and benefits that would call out for a particular regulation that differs from other biological products." Mackler contended that "the RAC's domain should be ... assuaging public fears and advancing scientific quality of knowledge" (68).

1996–1997: The RAC's Role in the Aftermath of Consolidation

During 1996 NIH Director Varmus considered three options: (*1*) terminate the RAC, (*2*) maintain consolidated FDA and NIH review, or (*3*) maintain the RAC as a vehicle for public accountability and access to information, while terminating its role in the review and approval of individual protocols. After much internal debate Varmus initially chose to pursue elimination of the RAC and transfer of its public policy functions to a new body to be developed within NIH. Following public protestations against elimination of the RAC, however, Varmus decided to retain the RAC and also to maintain simultaneous submission of gene therapy protocols to the RAC and FDA, even though only FDA would actually review individual protocols under most circumstances. Significantly, FDA would have exclusive authority to approve gene therapy protocols (after review and approval by local IRBs).

On July 8, 1996, NIH published a Notice of Intent announcing that NIH was considering amending its Guidelines to eliminate the RAC's review of most gene therapy protocols and to transfer *all* approval responsibility for such protocols to FDA (69). At the same time NIH stressed that its oversight of gene therapy would be "enhanced" through three new mechanisms: (*1*) the establishment of the Office of Recombinant DNA Activities Advisory Committee (OAC)—a 6 to 10 member interdisciplinary body that would "ensure public accountability for recombinant DNA research and relevant data"; (*2*) implementation of Gene Therapy Policy Conferences to "augment the quality and efficiency of public discussion of the scientific merit and the ethical issues relevant to gene therapy clinical trials"; and (*3*) "continuation of the publicly available, comprehensive NIH database of human gene transfer clinical trials," including adverse event reporting.

NIH explained its plan as simply another step in the normal "devolution" of NIH authority as scientists gained experience with gene therapy protocols and the concerns about the technology therefore shifted. Specifically, NIH characterized the current plan as a continuation of the 1995 decision to consolidate FDA and NIH protocol review:

> In 1995, a similar devolution of NIH oversight of human gene therapy occurred. By this time, the RAC had reviewed and approved 113 gene therapy protocols and over 1,000 patients had been enrolled in worldwide trials. The RAC, the scientific community, and the public had a substantial base of information regarding the use and safety of many of the vectors employed in, and target diseases addressed by, human gene therapy. Subsequent analyses revealed that the human health and environmental safety concerns expressed at the inception of gene therapy clinical trials had not materialized (70).

NIH described its further curtailment of RAC's protocol review function as resulting from the very success of the 1995 consolidation:

> Since the implementation of consolidated review in July 1995, only six of the 36 protocols submitted to ORDA required RAC review and approval; and five of those six protocols were already in the system before consolidated review. The consolidated review process proved to be so successful in eliminating the need for RAC review and approval, that NIH canceled both the March and June 1996 RAC meetings due to the lack of novel protocols requiring RAC attention (70).

Two features of the NIH notice are particularly noteworthy. First, NIH repeatedly stressed that the proposal should not be viewed as simply an "elimination" of the RAC but rather as a reallocation of NIH resources to avoid regulatory redundancy and permit NIH to carry out its role in leading public discussion: "Eliminating RAC protocol approval reduces duplication of effort with the FDA while enhancing the time and effort devoted to both ongoing anticipated gene therapy policy issues deserving of substantial public discussion" (70). In addition, refocusing NIH's efforts would assure NIH's ability to maintain public accountability over gene therapy research:

> NIH concludes that it is not the RAC per se that is critical for public accountability, but the system by which NIH continues to provide public discussion of the scientific, safety, and ethical/legal issues related to human gene therapy (70).

Second, NIH for the first time publicly acknowledged that only FDA possessed the statutory authority to review and approve gene therapy protocols: "The NIH Director has concluded that the current proposal ... is timely and

appropriate based on ... the duplication of review and approval by the NIH while the FDA holds the statutory authority" (70). Similarly, NIH acknowledged that, while the contemplated Gene Therapy Policy Conferences would enhance NIH's ability to provide advice on policy matters pertaining to gene therapy, "[t]he NIH cannot ... give the RAC, or any other NIH standing or ad hoc body, the authority to give policy advice or make recommendations to the FDA" (71).

In response to its Notice of Intent, NIH received 71 comments from individuals or groups reflecting the interests and concerns of academe, industry, patient advocacy groups, consumer advocacy organizations, professional scientific societies, ethicists, other federal agencies, NIH-funded investigators, past and present RAC members, and private citizens (72). According to NIH, of the 61 comments that addressed the proposal to terminate the RAC, 20 expressed support and 41 opposition (73).

The Biotechnology Industry Organization (BIO) wholeheartedly embraced the NIH proposal, agreeing that NIH review of individual gene therapy protocols had become redundant, and that NIH resources would be "better spent addressing truly novel gene therapies or those raising significant ethical issues such as in utero or germ line gene therapies" (74). Additionally BIO concurred with NIH's proposal to replace the RAC with the smaller OAC: "Since the number of protocols warranting full NIH-RAC review has dropped to close to zero, maintenance of a large panel is no longer necessary" (74). Similar support for the NIH proposal was conveyed in the comments of numerous industry members — ranging from established pharmaceutical companies such as Merck (75), Glaxo Wellcome (76), Parke Davis (77), and Baxter Healthcare Corporation (78) to entrepreneurial biotechnology outfits such as Cell Genesys (79), Genzyme (80), Auragen (81), and IntraImmune Therapies, Inc. (82). Henry Miller applauded the proposal to eliminate NIH oversight of gene therapy protocols as "long overdue" but criticized NIH's proposal to establish the OAC and to maintain a database of gene therapy clinical trials as a step in the wrong direction:

> In the future, NIH should approach gene therapy in a way no different from other kinds of techniques and treatments, except as medical or scientific considerations dictate. Circumstances do not now require retention of ORDA, the creation of a new advisory committee, or the maintenance of a gene therapy database (83).

Opponents of eliminating the RAC — including current and former RAC members, bioethicists, academe, consumer and patient advocacy groups, and some members of the public — were equally fervent in their insistence that the RAC continue to review individual research protocols. They argued, in essence, that the RAC had developed significant expertise in considering the social and ethical consequences of gene therapy experiments and that it had gained the public's trust in carrying out this role. Elimination of the RAC, they feared, would undermine that trust and jeopardize public accountability for or acceptance of gene therapy experiments. They rejected the OAC as a poor substitute that would have neither the experience nor reputation to lead public debate of the social and ethical issues surrounding gene therapy (84). Their concerns were eloquently expressed by a science teacher from Illinois:

> Gene therapy intimately affects the future of the human race and the technology must not be allowed to proceed only in the name of good science. We must work hard to prevent the technology from driving the ethical, moral, and legal issues. While the advisory panel is no guarantee that "what's best for humanity" will drive genetics research and therapy, it does provide a necessary oversight function and should not be disbanded (85).

In response to the number and fervor of comments advocating the retention of the RAC, Varmus retreated, stating that he had "underestimated the historical purpose and significance" of the RAC (86). Varmus offered a "compromise" proposal under which the RAC's size would be reduced but several of its functions maintained (86). However, Varmus contemplated that under the compromise the RAC would no longer participate in reviewing or approving individual gene therapy protocols (86).

On October 31, 1997, NIH announced its final decision. In its revised Guidelines, NIH reduced the RAC from 25 to 15 members while retaining its interdisciplinary composition. The RAC's functions were amended to include (*1*) identifying novel human gene transfer experiments deserving of public discussion by the full RAC, (*2*) transmitting to the NIH director specific comments or recommendations concerning specific experiments or categories of experiments, and (*3*) identifying novel social and ethical issues relevant to specific human applications of gene transfer and recommending appropriate modifications to NIH Guidelines to provide guidance in preparing relevant informed consent documents and in designing and submitting human gene transfer clinical trials (72,87).

The revised Guidelines provided that NIH would relinquish all approval responsibilities for gene therapy experiments to FDA. However, no human gene therapy experiment could proceed if the protocol had not been simultaneously submitted to NIH and FDA. Submissions to NIH would need to comply with NIH's "Points to Consider" (Appendix M), while submissions to FDA would be required to comport with FDA's regulations pertaining to the content and format of IND submissions (88). In addition investigators who had received FDA approval would still be required to report any adverse events to both agencies (89).

The Guidelines provided that submissions to NIH would be for "registration purposes," and would "ensure continued public access to relevant human gene transfer information conducted in compliance with the NIH Guidelines" (72,90). If NIH/ORDA determined that a protocol possessed novel features or raised novel concerns that should be discussed by the full RAC, the principal investigator would be notified. In determining whether the full RAC discussion was warranted, NIH/ORDA reviewers would examine "the scientific rationale, scientific content (relative to other proposals reviewed by RAC), whether the preliminary in vitro and in vivo safety data were obtained in appropriate models and are sufficient, and whether

questions related to relevant social and ethical issues have been resolved" (90). Otherwise, FDA alone would review the protocol. Whether or not the RAC reviewed the protocol, FDA would be solely responsible for determining whether or not to grant approval.

NIH acknowledged that the Guidelines were obligatory for those institutions and investigators receiving NIH funding or entities collaborating with NIH-funded institutions (90). However, it encouraged continued voluntary compliance by all other entities conducting gene therapy research (87).

ANALYSIS OF FDA'S EVOLVING APPROACH TO GENE THERAPY REGULATION

With the October 31, 1997, announcement, NIH formally and finally acknowledged FDA's exclusive statutory authority to approve gene therapy protocols and, by implication, to regulate the development and marketing of gene therapy-derived products, whether privately supported or federally funded. This had been FDA's position from the mid-1980s. FDA's position was that gene therapy protocols represented "business as usual" and that FDA would therefore review gene therapy research protocols — and eventually marketing applications — within the same framework it applied to other medical products.

This part reviews the formal pronouncements that FDA issued describing and justifying this position. It concludes with a brief discussion of the agency's experience applying its "off the shelf" principles of regulation to individual research protocols. The reader should be cautioned, however, that our text does not attempt to provide a full account of what the sponsor of a research protocol will experience in dealing with the agency. This experience varies so much with the technology, the evidence, the agency's current workload, and the personalities of both sponsor and reviewer that no broad generalizations can be reliable. The discussion does not even attempt to describe how FDA will review applications for approval to commercialize gene therapy products. No such applications have come before the agency, and it would be foolish to speculate how it will process the first of these inherently precedent-setting technologies.

Between 1984 and 1998, FDA issued five separate policy documents outlining the agency's plans for regulating gene therapy. These documents provided progressively more explicit guidance for sponsors of gene therapy research regarding the statutory authorities on which FDA relied to regulate their activities, as well as the procedures that should be followed and the clinical data that must be assembled to demonstrate the safety and effectiveness of gene therapy products. From the outset these documents reflected a consistent regulatory approach, one that affirmed FDA's existing legal authorities were broad enough to encompass and flexible enough to fit this emerging technology. There has, in FDA's view, been no need to develop a new regulatory paradigm.

1984 Policy Statement

FDA first described its approach to regulating products derived from biotechnology generally, including gene therapy, on December 31, 1984. The agency's "Statement of Policy for Regulating Biotechnology Products" (27) (Policy Statement) was published for public comment in the Federal Register two months after the RAC Working Group reviewed a draft "Points to Consider in the Design and Submission of Human Somatic-Cell Gene Therapy Protocols," and three weeks before a draft of the RAC "Points to Consider" was published in the Federal Register for public comment. FDA's Policy Statement can therefore be viewed as the agency's response to — and at least mild dissent from — the NIH approach.

The very title of the Policy Statement is revealing; it signaled FDA's (and the Reagan administration's) view, which would be reiterated in subsequent policy documents, that gene therapy should be viewed as merely one example of a much larger class of therapeutic modalities derived from biotechnology, for which FDA already possessed adequate statutory authority and scientific expertise. The introduction to the statement explained:

> A small but important and expanding fraction of the products the Food and Drug Administration (FDA) regulates represents the fruits of new technological achievements. ... It is also noteworthy that technological advancement in a given area may give rise to very diverse product classes, some or all of which may be under FDA's regulatory jurisdiction. For example, new developments in recombinant DNA research can yield products as divergent as food additives, drugs, biologics, and medical devices (27).

The Policy Statement acknowledged that "there are no statutory provisions or regulations that address biotechnology directly" (27), but asserted that the agency's existing regulatory authorities were broad enough to extend to these products and, moreover, that such extension was appropriate:

> The Agency possesses extensive experience with the administrative and regulatory regimens described as applied to the products of biotechnological processes, new and old, and proposes no new procedures or requirements for regulated industry or individuals (27).

Consistent with FDA's existing approach to regulating other medical products, the Policy Statement announced that "the administrative review of products using biotechnology is based on the intended use of each product on a case-by-case basis" (27). FDA thus preserved its discretion to choose among available statutory authorities and to assign administrative responsibility as it judged appropriate.

The statement then proceeded to summarize the basic Act requirements applicable to manufacturers of human drugs:

- Under the FD&C Act, a "drug" is defined to include articles (*1*) "intended for use in the diagnosis, cure, mitigation, treatment, or prevention of disease in man," or (*2*) "intended to affect the structure or any function of the body of man" (91). The Act defines a "new drug" as a drug that is not "generally recognized by qualified scientific experts as safe and effective for

its proposed use" (92). Thus the manufacturer of a new drug must establish its safety and effectiveness before marketing. And, to do this, the manufacturer must submit to FDA clinical data from investigations of the drug in human subjects.

- The "sponsor" of a clinical investigation — the entity responsible for the clinical trials — must first file an IND with FDA and obtain the agency's approval to conduct the study or studies described in it (27,93). (This submission follows approval by a research facility's IRB, whose review typically encompasses both ethical and scientific merit.) The IND must contain information sufficient to demonstrate the propriety of testing the drug in human subjects. This would include, for example, drug composition, manufacturing and controls data; results of animal testing, training, and experience of the investigators; and a plan for clinical investigation (27,94). Furthermore the IND sponsor must ensure that informed consent will be obtained from the human subjects who participate in the studies and that the rights and safety of the human subjects will be protected (27,95).
- At the conclusion of three phases of clinical investigation, the manufacturer of a new drug must, if it wishes to distribute the product commercially, submit a New Drug Application (NDA) to FDA. An NDA must contain information including (*1*) full reports of investigations, as well as the results of clinical investigations, demonstrating the drug's safety and effectiveness, (*2*) a list of components of the drug and a statement of the drug's quantitative composition, and (*3*) a description of the methods used in, and the facilities and controls used for, the manufacturing, processing, and packaging of the drug (27,96).

After outlining the framework for regulation of new human drugs, the FDA Policy Statement compared the NDA process to that required for biological products (27,97). FDA's authority to regulate biological products derives chiefly from section 351 of the PHS Act, which defines a "biological product" as:

> any virus, therapeutic serum, toxin, antitoxin, vaccine, blood, blood component or derivative, allergenic product, or analogous product . . . applicable to the prevention, treatment, or cure of diseases or injuries of man. . . . (98)

The Policy Statement explained that biological products "are regulated similarly to new drugs during the IND phase" (97). Approval for marketing biological products, however, "is granted by license, which is only issued upon demonstration that both the manufacturing establishment and the product meet standards designed to ensure safety, purity, potency, and efficacy" (97). To obtain approval, the manufacturer must submit a Product License Application (PLA) and include information demonstrating that both the manufacturing facility and the product meet FDA requirements (97). The facility must also pass a prelicensing inspection and be separately licensed (97).

The Policy Statement emphasized that manufacturers of both new drugs and biological products must comply with "good manufacturing practice" (GMP) regulations, which specify requirements for, among other areas, (*1*) manufacturing facilities, (*2*) personnel training, and (*3*) processing methods (97). The Policy Statement also reviewed FDA's quite different statutory authority to regulate medical devices, which do not achieve their intended effect through chemical action in or on the body or through metabolism (99).

After completing its survey of FDA's general requirements for drugs, biological products, and devices, the Policy Statement addressed their application to specific products, including products that are "genetically engineered." Here the agency spoke in vague terms. It reiterated that its approach to regulating these products was "product specific" rather than "technology specific" (27,97,100). Taking genetically altered viruses used as vaccines as an example, the agency declared:

> The composition, concentration, subtype, immunogenicity, reactivity, and nonpathogenicity of the vaccine preparation are all considerations in the final review, whatever the techniques employed in "engineering" the virus (100).

The 1984 Policy Statement addressed gene therapy in just a single sentence: "Nucleic acids used for gene therapy trials will be subject to the same requirements as other biological drugs" (100). This brevity was consistent with agency's position that FDA regulation "must be based on the rational and scientific evaluation of products, and not on *a priori* assumptions about certain process" (100). In other words, that gene therapy might or would entail the use of genetically engineered products to achieve a therapeutic effect would not alter FDA's regulatory approach. The agency would place such a product into the statutory framework that best fit the product's intended use and mode of action.

The Policy Statement was similarly terse in describing the role of the RAC Working Group in reviewing gene therapy protocols: "It is possible that there will be some redundancy between the scientific reviews of these products performed by the National Institutes of Health and FDA" (100).

Certain features of FDA's initial Policy Statement bear emphasis. The document surely cannot be described as a "how to" manual for developers of biotechnology products generally, much less for sponsors of gene therapy protocols. It provided no concrete guidance for sponsors of gene therapy products, save that they would be required to submit and gain approval for an IND before undertaking clinical experiments. Indeed, the Policy Statement did not specify whether products used in gene therapy would be regulated as "drugs," "devices," or "biological products," but instead left open the option to regulate them under any one — and perhaps some combination — of these categories. Of course, given FDA's premise — that gene therapies fell within the agency's customary jurisdiction — this lack of specific guidance was not surprising.

The Policy Statement did not specify which biological component or components used in gene therapy would be considered to be the "drug" or "biological product." The agency thus left open the possibility that it would regulate

the genetic material itself, the vector used to deliver the genetic material, some other component used in the gene transfer process, or all of these.

Also notable was the FDA's oblique criticism of the NIH role in regulating gene therapy. To be sure, the regulatory issues addressed in the Policy Statement overlapped in several respects with those identified by the RAC's "Points to Consider," although these points specified the relevant considerations in substantially more detail. Like FDA's Policy Statement, the RAC's "Points to Consider" emphasized the need for sponsors of clinical trials to address the study's design, results of animal studies, investigator and personnel qualifications, and the adequacy of the laboratory facilities. However, the issues FDA addressed were a subset of a substantially larger range of issues that NIH required sponsors to address — some of which FDA's Policy Statement implied were not necessary and perhaps not even appropriate for its consideration.

For example, under "Description of Proposal," NIH asked investigators to address (*1*) why the disease in question was appropriate for gene therapy and what alternative therapies existed, (*2*) what "equity issues" would likely arise in the selection of patients and how they would be addressed, and (*3*) whether the "innovative character" of gene therapy would be discussed with patients (24,101). In addition, under the heading "Social Issues," NIH asked investigators to address (*1*) the steps that would be taken to ensure that accurate information was made available to the public regarding concerns raised by the study and (*2*) whether the investigator intended to protect the products or procedures used in the proposed study under patent or trade secret laws and, if so, what steps would be taken to permit full communication among investigators and clinicians concerning research methods and results (101). The initial draft of the "Points to Consider" stated that the RAC and its working group would also consider (*1*) whether the proposed study would likely affect the reproductive cells of the patient, (*2*) whether the proposed study was an "extension of existing methods of health care" or represented a "distinct departure from present treatments of disease," and (*3*) whether somatic cell gene therapy would likely lead to germ-line therapy (i.e., therapy affecting reproductive cells and therefore future generations, enhancement of human capabilities through genetic means, or government-sponsored eugenic programs (101). However, the final version, adopted on September 29, 1986, deleted the section addressing germ-line and eugenic implications of gene therapy (102).

FDA's Policy Statement reflected the agency's position that, from its perspective, medical applications of biotechnology generally and gene therapy specifically represented "business and usual." By contrast, NIH's "Points to Consider" signaled the RAC Working Group's belief that gene therapy was a fundamentally new approach to therapy, which posed unique social and ethical questions as well as complex scientific challenges.

Following review of public comments, FDA in June 1986 published a substantially unchanged final version of the 1984 Policy Statement. For the next five years FDA issued no other formal statements regarding gene therapy or its regulation.

FDA's 1991 "Points to Consider"

On August 27, 1991, almost a year after the first clinical experiment employing gene therapy, FDA issued a document entitled *Points to Consider in Human Somatic Cell Therapy and Gene Therapy* ("Points to Consider") (44,103). Unlike its 1984 Policy Statement, which addressed a wide range of applications of biotechnology that could be subject to regulation, FDA's 1991 document focused specifically on gene therapy products (as well as somatic cell therapy products). FDA stated that the purpose of issuing its "Points to Consider" was to provide information to "manufacturers engaged in the production and testing of products for these therapies (103, p. 3). Compared to the 1984 Policy Statement, the FDA "Points to Consider" provided concrete guidance to manufacturers regarding the procedures they should be using to develop their products and the type of supporting data the agency would expect. FDA stressed that its "Points to Consider" did not constitute binding regulations but merely "represent issues that the Center for Biologic Evaluation and Research (CBER) staff believes should be considered at this time" (103, p. 3).

FDA's "Points to Consider" set forth two definitions. Somatic cell therapy was defined as "the administration to humans of . . . living cells which have been manipulated or processed ex vivo" (103, p. 3). Gene therapy was defined as "a medical intervention based on modification of the genetic material of living cells." The agency continued:

> Cells may be modified ex vivo for subsequent administration to humans, or may be altered in vivo by gene therapy given directly to the subject. When the genetic manipulation is performed ex vivo on cells which are then administered to the patient, this is also a form of somatic cell therapy. The genetic manipulation may be intended to have a therapeutic or prophylactic effect, or may provide a way of marking cells for later identification (103, p. 3).

The agency observed that initial approaches to gene therapy "have involved the alteration and administration of somatic cells," but it forecast that "future techniques may include approaches such as the direct administration to patients of retroviral vectors or other forms of genetic material" (103, pp. 3–4).

The FDA document then identified several subjects that sponsors of gene therapy and somatic cell therapy procedures should consider during product development, as well as information that should be presented to the agency. Sponsors are expected to address (*1*) quality control, (*2*) development and characterization of cell populations for administration, (*3*) preclinical testing, (*4*) lot-to-lot manufacturing control and release testing, and (*5*) clinical trials (103). FDA emphasized that it is essential to characterize the gene sequence being introduced into cells and the vector used to do this, and specified that "each distinct vector is considered a different product and should be fully characterized and tested for safety" (103, p. 12). The agency also stated that manufacturers should address the methods used to

insert the vector into cells and the implications of the method used. Specifically, manufacturers should be able to demonstrate that the introduced genes were integrating at the correct location in the chromosome, and that they were functioning appropriately once integrated (i.e., were expressing the correct gene product in the correct quantity) (103).

FDA noted that clinical trials using gene therapy raise "some novel concerns due to the nature of the therapeutic agents" (103, p. 19). For example, use of viral vectors "may in special cases require testing of clinical personnel or household contacts to confirm lack of infectious spread," (103, pp. 19–20). In addition "the product of the inserted gene must be considered as a potential source of immune reactions" (103, p. 20); thus sponsors might in some cases need to document whether such reactions were observed and whether they altered the safety or therapeutic effectiveness of the product (103, p. 20).

While FDA's "Points to Consider" provided details not contained in the 1984 Policy Statement, both documents reflected the same regulatory approach. The "Points to Consider" concluded with the observation that somatic cell and gene therapy raise issues common to all biological products as well as issues unique to these types of therapies. It reflected FDA's confidence in its ability to address these issues, and any new issues that the future might reveal, within the framework of existing legislation (103).

1993 Guidance

Shortly after establishing the new Division of Cellular and Gene Therapy, FDA published in the Federal Register a notice entitled "Application of Current Statutory Authorities to Human Somatic Cell Therapy Products and Gene Therapy Products" (44). This document, though it largely reiterated information contained in the 1984 and 1991 documents, said it was being published "in response to requests that the agency clarify its regulatory approach and provide guidance to manufacturers of products intended to be used in somatic cell therapy or gene therapy" (44).

Like its 1984 Policy Statement, FDA's 1993 self-described "guidance" identified the FD&C Act and the PHS Act as the legal sources of its authority to regulate gene therapy. It also reiterated that clinical trials of biological products — including gene therapy — to gather data on safety and effectiveness must be conducted under an IND. In addition the document stated that a product could be subject to regulation under both statutes concurrently: "Products considered to be biological products subject to the provisions of section 351 of the PHS Act are simultaneously also drugs or devices subject to the applicable provisions under the Act" (44). While FDA asserted that products regulated as biological products must also meet requirements applicable to drugs or devices, it also emphasized that sponsors were not required to submit multiple applications for marketing approval; for any product the agency would require only a biologic application (PLA), new drug application (NDA), or a device application (PMA) (104).

The 1993 guidance offered additional but still general information about FDA's statutory authorities over drugs, medical devices, and biological products — including, for example, its authority to regulate labeling, its requirements for licensing and inspection of manufacturing facilities, and its enforcement powers.

The 1993 guidance for the first time provided concrete examples of treatments that the agency would regulate as gene therapy products, either by the mechanism of a PLA or an NDA:

> Final products containing the genetic material intended for gene therapy are regulated as biological products requiring PLA's (e.g., viral vectors containing genetic material to be transferred, ex vivo transduced cells and analogous products) or as drugs requiring NDA's (e.g., synthetic products) regardless of whether they are intended for use in vivo or ex vivo. Gene therapy products that are licensed biological products will be approved as biological products intended for further manufacture if they are intended to be used ex vivo during the manufacture of genetically altered cells.
>
> Examples include the following: (*1*) A synthetic polynucleotide sequence intended to alter a specific genetic sequence in human somatic cells after systemic administration is regulated as a drug requiring an NDA; (*2*) a retroviral vector containing the adenosine deaminase (ADA) gene, intended to be administered intravenously to the patient, is regulated as a biological product requiring a PLA, and (*3*) a retroviral vector containing the ADA gene and intended to modify cells ex vivo is regulated as a biological product intended for further manufacture requiring a PLA (105).

1996 Addendum

In 1996 FDA issued a draft Addendum to its 1991 "Points to Consider" document (106,107). The Addendum focused on the regulatory requirements for viral vectors used in gene therapy. FDA explained that since the 1991 document was issued, "the range of proposals has expanded to include additional classes of vectors and also the in vivo use of vectors (direct vector administration to patients)" (106). Accordingly it was issuing the Addendum to "provide manufacturers with current information regarding current regulatory concerns for production, testing, and administration of recombinant vectors for gene therapy" (107, p. 2). The Addendum instructed manufacturers regarding proper characterization of the gene sequence of the vector, proper maintenance of the cells used to produce the vectors, and appropriate methods for testing vectors for purity, potency, and safety. The Addendum also addressed issues applicable to specific types of vectors.

All three of FDA's previous publications discussed the authority to regulate gene therapy products generally, offering virtually no information about its views on any particular facet or application of the technology. The 1996 Addendum was the first to address the requirements pertaining to a specific component of gene therapy, the gene delivery system. Apparently FDA no longer considered it necessary to repeat its claims to regulatory authority, assuming perhaps that any doubts on that point had been resolved by acquiescence and the passage of time. Now the agency could focus exclusively on what sponsors must do to satisfy their legal obligations.

1998 Guidance

In March 1998 FDA issued a guidance document concerning human somatic cell therapy and gene therapy (108). FDA stated that the guidance document was intended to update and replace the 1991 "Points to Consider" document "with new information intended to provide manufacturers with current information regarding regulatory concerns for production, quality control testing, and administration of recombinant vectors for gene therapy; and of preclinical testing for both cellular therapies and vectors" (108, p. 1).

STATUS OF PROTOCOLS

A recent compilation from NIH's registry of gene therapy protocols reveals that, between 1989 and 1999, a total of 280 gene transfer protocols were submitted to NIH and FDA for review (109–111). These include both protocols intended to provide therapeutic benefit and those in which the protocol's intent is not therapeutic (e.g., "marker" gene experiments). Of the 280, 107 were subject to review by the full RAC, approval by the NIH director, and IND approval by FDA — this review process is no longer in effect (109–111). An additional seven protocols were subject to the accelerated RAC review, NIH/ORDA approval, and FDA IND approval — this review process also is no longer in effect (109–111). Ten protocols were subject to FDA IND approval and full RAC discussion — this form of review is currently in effect for some protocols (109–111). The NIH list does not reflect whether protocols approved by NIH were subsequently approved by FDA.

An additional 151 protocols have been screened by NIH/ORDA and referred for exclusive FDA review (109–111). Submission to NIH/ORDA has been required for the purpose of data monitoring and adverse event reporting. As of February 10, 1999, four protocols are awaiting NIH/ORDA's determination of their review requirements (109–111). Finally, one protocol was submitted for sole FDA review and was also voluntarily submitted to NIH/ORDA, presumably by an individual or entity not funded by NIH (109–111).

In early 1997 FDA and NIH approved the first gene therapy trial to be conducted in healthy volunteers. The protocol provides for the injection of healthy individuals with a viral vector in order to measure their immune response (112). The data can be used to establish a baseline that will help evaluate the vector's therapeutic effect in sick people. Use of healthy volunteers is standard in early phase drug development studies (112).

The early sponsors of gene therapy protocols were NIH researchers or investigators at medical research institutions. Between 1989 and 1991, a total of 11 protocols were approved by NIH, all of which were sponsored by researchers at NIH or in academe (109). Beginning in 1992, the caseload began to include more industry sponsors and the pace of submissions rose dramatically. In 1992 and 1993, 44 protocols were approved by NIH, 8 of which were identified as having industry sponsors (109). Between 1994 and 1996, 27 out of 115 protocols received, reviewed, or approved by NIH were sponsored by industry. (During this time period NIH increasingly began referring protocols for sole FDA review, and NIH's publicly available list of protocols does not reflect the fate of the protocols thereafter) (109). Of 110 protocols received by NIH/ORDA between 1997 and 1999, 44 were sponsored by industry (109). It should also be noted that private firms may, and often do, participate in and contribute financially to government or university-sponsored protocols without being listed as sponsors.

As the private sector has assumed a growing role in financial sponsorship of gene therapy research, the types of protocols submitted for review have changed. Although gene therapy was originally conceived as a means of treating or preventing rare diseases caused by "monogenic" defects, namely defects in a single gene — ADA being a prime example — only 36 experimental protocols for such diseases have been approved (110). Most of the industry-sponsored protocols have been aimed at widespread diseases such as cancer and heart disease, or at AIDS. While these diseases may have a genetic component or be susceptible of treatment through gene therapy techniques, they certainly are not the "classical" genetic diseases for which researchers first contemplated gene therapy (51).

As both researchers and FDA become more expert in and comfortable with the techniques of gene therapy, new, and perhaps more difficult questions are emerging. Initially, FDA's concerns focused on the safety of research subjects, such as how would cells be removed from patients? would these cells become contaminated while outside the patients? how would reintroduction of gene-altered cells be achieved (51)? Increasingly, however, FDA's concerns have shifted from "can you" to "should you." NIH recently sponsored its first Gene Therapy Policy Conference to discuss the use of gene therapy for "enhancement," namely for use in non-life-threatening diseases or conditions, such as baldness (113). Public discussion of this issue, FDA's Noguchi emphasizes, is warranted because "the concept of gene therapy is being pushed to lots of different diseases, some of which are more social than physiological" (51).

According to Dr. Noguchi, the RAC is seen as having a crucial role in ensuring that the social and ethical issues raised by particular applications of gene therapy are fully debated and debated in public. Unlike FDA, which must conduct most of its review of gene therapy protocols in private to protect the trade secret information they embody or contain, the RAC is "well constituted for public discussion" (51).

CONCLUSION

The past two decades have seen remarkable advancements in gene therapy research. Given the pace with which experimental protocols are being pursued, it would not be surprising to see the first approved gene therapy product before the official close of the twentieth century. The rapid pace of research has also posed profound challenges for those federal agencies charged with the task of fashioning social controls on scientific technology. As the story

of FDA's regulation of gene therapy reveals, the very first challenge was to determine which agency — NIH or FDA — would take the lead in designing and implementing these social controls. More recently the NIH has formally recognized FDA's statutory authority to review and approve individual gene therapy protocols, and FDA has in turn acknowledged the important role played by the NIH RAC in leading the public discussion on the social and ethical implications of gene therapy. FDA and NIH, working together, thus seem well prepared to confront the challenges that will soon emerge when gene therapy makes the leap from the laboratory to the pharmacy.

GENE THERAPY: OVERVIEW

LeRoy Walters
Kennedy Institute of Ethics, Georgetown University
Washington, District of Columbia

OUTLINE

TERMINOLOGY

The phrase "gene therapy" was used for the first time in a published article in 1970 (1,2). However, functional equivalents to this phrase had been used in academic discussions from the early 1960s on. Among the synonymous phrases were "genetic surgery," "nanosurgery," "euphenics," "genetic engineering," "gene replacements," "directed mutation," "directed genetic change," "designed genetic change," "algeny," "programming cells with genetic messages," and "genetic therapy" (3–14). The phrase "genetic(al) engineering" had been employed at least as early as the Sixth International Congress of Genetics held in 1932 in Ithaca, New York (15), and some authors continued to use the phrase "genetic engineering" even after the advent of molecular biology in the early 1950s.

As the preceding paragraph suggests, there was during the 1960s a striking diversity in the terminology used by commentators on the new techniques that molecular biology might make possible. This diversity is reflected in several publications and reminiscences from that important decade. At a Ciba Foundation symposium held in London on November 26–30, 1962, Hermann J. Muller suggested that it would be preferable to secure gametes from genetically fit individuals rather than to use what he called "nano-needles" to "cause prespecified changes in [those individuals]" (16,17). In opposition to Muller, Joshua Lederberg advocated the use of molecular techniques in the manipulation of germ cells to achieve "the direct control of nucleotide sequences in human chromosomes, coupled with recognition, selection and integration of the desired gene" (18, p. 265). At an April 1963 symposium sponsored by Ohio Wesleyan University, Salvador Luria, Edward Tatum, and Muller favored the phrase "genetic surgery," although Luria also discussed the "removal, addition, and replacement of genes" (19, p. 10), while Tatum at times employed the alternative terminology of "directed gene mutation" and "genetic engineering" (20, p. 22).

As the decade progressed, additional academic disciplines became involved in the discussion of genetic intervention, and more precise descriptions of the actual techniques that might be employed in gene transfer began to appear. At a symposium held at Gustavus Adolphus College in January 1965, theologian Paul Ramsey and biologist Tatum both considered the theme, "Genetics and the Future of Man" (21). Ramsey described one of two possible approaches to genetic control in the following terms:

> The first [method] is some direct attack upon the deleterious mutated gene, either by what is called "genetic surgery," "micro-surgery" or "nano-surgery" [see Ref. 22] or by the introduction of some anti-mutagent chemical that will cause the gene to mutate back or will eliminate it from among the causes of genetic effects (23, pp. 9–10).

In his presentation at the same symposium Tatum described three methods for achieving what he called "*manipulation* [his italics] of genetic change." The second method identified by Tatum sounds like a blueprint for what in the 1990s came to be called ex vivo gene therapy.

> Another potential future approach to directed mutation is via the synthesis in the laboratory of a desired molecule of DNA. This tailored molecule, or any desired DNA molecule if it can be isolated from an organism or cell, can probably be amplified by already known enzymatic replication processes to any needed quantity. This new or isolated gene can then hopefully be introduced into mammalian cells in culture, as in bacterial transformation.
>
> If the rare desired transformed cell can be selected and cultured, the new cells so derived could conceivably be transplanted into a living organism, there to correct a defective function of the original host cells (24, p. 58).

By the late 1960s biologists were describing what would later be called somatic-cell gene therapy in slightly different terms. For example, in a 1968 essay, Lederberg suggested that

> an attempt could then be made to transform liver cells of male offspring of haemophilic ancestry by the introduction of carefully fractionated DNA carrying the normal alleles of the mutant haemophilia gene. This experiment would appear to be entirely analogous to the typical attempts at transforming bacterial forms. However, it is not clear whether one should regard this as a pure example of genetic engineering, since the practical outcome would probably be best achieved by influencing the nuclear constitution of somatic tissues rather than by direct tackling of the germ line (26).

In the same year, 1968, Robert Sinsheimer gave a lecture at the Fordham Chapter of the Society of the Sigma Xi. This lecture, published in the spring of 1969, drew a clear distinction between somatic-cell and germ-line approaches to what he called "designed genetic change" (27). Sinsheimer's specific suggestion for somatic-cell genetic change was that the almost-available technique could be used for the treatment of diabetes.

> If we could obtain a virus analogous to simian virus 40, able to persist within altered cells and, let us say, carrying an expressable gene for proinsulin [the precursor to insulin] in lieu of a normal viral gene, we might indeed be able to provide a genetic alternative to the daily injection of insulin (27, p. 140).

The most widely cited essay during this era was almost certainly Bernard Davis's paper on "Threat and Promise in Genetic Engineering," first given at a December 1969 symposium, then revised and published a year later in *Science* under the title, "Prospects for Genetic Intervention in Man" (28). Davis drew important distinctions between polygenic (including many behavioral) and monogenic traits and between somatic-cell and germ-cell alteration. He also pointed to the technical obstacles standing in the way of even the simplest types of somatic-cell gene alterations. However, Davis also noted a potential advantage of a genetic approach to therapy.

> Such a one-shot cure of a hereditary disease, if possible, would clearly be a major improvement over the current practice of continually supplying a missing gene product, such as insulin (28, p. 1280).

By 1970 there was a consensus among biologist-commentators like Lederberg, Davis, and H. Vasken Aposhian that the phrase "genetic engineering" was unduly alarming to the public (28–30). As noted above, the phrase "gene therapy" began to be used in the published literature during the same year. By the time of two major symposia on this subject in May 1971 the alternative formulations were virtually always "genetic therapy" and "gene therapy" (31,32). Beginning with two articles by Aposhian in 1970 (1,2), one finds an additional three articles that use the phrase "gene therapy" in their titles in 1971 (33–35), and two additional articles plus the proceedings of an NIH symposium in 1972 (36–38). Perhaps the most decisive publication in this series was Theodore Friedmann and Richard Roblin's widely cited *Science* article from March 1972 entitled "Gene Therapy for Human Genetic Disease" (39). (The phrase "gene therapy" was added to the *Bioethics Thesaurus of Bioethicsline* in 1980, to the Library of Congress Subject Headings in 1985, to the National Library of Medicine's Medical Subject Headings in 1989, and to the Dewey Decimal Classification with the 21st edition of 1996.)

It is worth pausing to note that the transition from "genetic engineering," often associated with the evolution of the human species and with voluntary programs of positive eugenics, to the more modest goals of "gene therapy" paralleled a shift in emphasis from classical genetics to microbiology and molecular biology. H.J. Muller and those who sympathized with his views were concerned about an increasing load of mutations in the human gene pool and accented the difficulty of modifying polygenic traits through molecular techniques. Muller himself argued that the basic unit of genetic improvement was the human sperm or egg cell, derived from a willing donor who possessed many desirable characteristics. In contrast, the microbiologists and molecular biologists who wrote on human genetic intervention in the 1960s and early 1970s extrapolated from laboratory research involving bacteria and bacterial and animal viruses. Some commentators, for example, J. Lederberg, were willing to consider targeted genetic changes in both germ-line and somatic cells, but the general trend of the discussion in the 1960s was clearly toward a focus on somatic cells and on the effort to alleviate diseases like hemophilia or diabetes. By the early 1970s the language of "genetic engineering" had been left behind by most biomedical scientists, and germ-line effects were taking second place to the conception of "gene therapy" as a new kind of drug, or biologic, or transplant. This paradigm shift occurred even before the exquisite techniques of recombinant DNA research were widely available.

The consensus in favor of the phrase "gene therapy" (with the word "human" sometimes included as a prefix) remained intact from 1972 through approximately 1998. Journals called *Human Gene Therapy* and *Gene Therapy* were inaugurated to track developments in the field, and the conceptual distinction between somatic-cell gene therapy and more ambitious programs of genetic intervention became firmly established among both academics and members of the general public. However, in a searching article published in 1998, Larry Churchill and his colleagues criticized the use of the phrase "gene therapy" for implying benefit to patients when, at least until that point, little therapeutic success had been achieved in gene therapy trials (40). Churchill and associates argued that the terms "gene therapy" and "gene therapy research" should be deleted from all federal documents describing this new technique and should be replaced by more neutral and modest terminology like "gene transfer research" (40). In their view, this alternative language "more accurately conveys the experimental practice that is currently at issue" (40, p. 45). In the remainder of this article the phrase "gene transfer" will be employed instead of "gene therapy" whenever possible.

MAJOR MODES OF HUMAN GENETIC INTERVENTION

The foregoing discussion has highlighted one of the central distinctions in scientific and ethical discussions of genetic intervention — the distinction between genetic alterations that affect the recipient of the gene transfer alone and alterations that will be passed on to the recipients' descendants through the germ line. Implicit in the early discussions and in the use of the word "therapy" was a second distinction, namely the distinction between the treatment or prevention of disease, on the one hand, and the enhancement of human capabilities or characteristics, on the other. The possible types of enhancements have been classically categorized by Muller and subsequent commentators as physical, intellectual, and moral enhancements (41,42). Thus one can conceive of two-by-two matrix (Table 1) that depicts these two distinctions (43,44).

More recent commentators, especially Matthew Bacchetta and Gerd Richter, have argued that this simple two-dimensional framework is inadequate to deal with another type of potential genetic intervention, namely a deliberate alteration of the mitochondrial DNA that is present in the cytoplasm of mammalian cells (45). In the

Table 1. Gene Therapy Techniques

	Somatic	Germ Line
Prevention, treatment, or cure of disease	1	1
Enhancement of capabilities or characteristics	3	4

Source: Ref. 44, p. xvii.

view of Bacchetta and Richter, the inclusion of genetic interventions to treat or prevent mitochondrial disease yields a three-dimensional matrix, involving the six possibilities shown in Figure 1 (45).

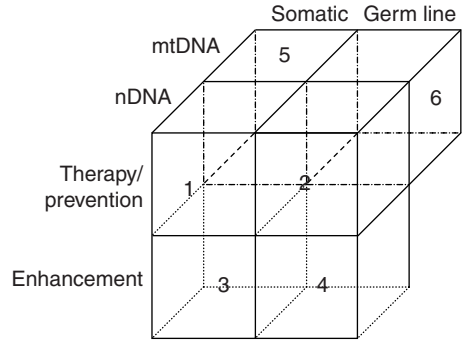

Figure 1. Dimensions of genetic interventions in the human genome: cube 1, somatic gene therapy within nDNA; cube 2, germ-line gene therapy within nDNA; cube 3, enhancement in somatic cells within nDNA; cube 4, enhancement in germ-line cells within nDNA; cube 5, somatic mitochondrial gene therapy; and cube 6, mitochondrial germ-line therapy. *Source*: Ref. 45, p. 456.

EARLY ATTEMPTS AT HUMAN GENE TRANSFER

In 1980 there was clearly an experimental attempt made to perform gene transfer in two subjects who were afflicted with beta-thalassemia. However, three leading accounts of the history of this topic also discuss an event that had occurred a decade earlier, the effort by Stanfield Rogers to infect three German sisters aged 5, 2, and a few months old with the Shope papilloma virus. Rogers, a biochemist and physician at Oak Ridge National Laboratory, hoped that the virus would carry a gene into the sisters' bodies that would counteract the effects of an inherited disease that resulted in toxic levels of an amino acid, arginine, in the children's livers (25,46,47). Rogers later acknowledged that the intervention did not help any of the three girls, although a delay in administration of the virus to the youngest of the three may have rendered the preparation inactive (48–50). The experiment was reported in the *New York Times* on September 21, 1970, by Harold Schmeck (51). At a May 1971 symposium (52) and in a 1972 article published in *Science* (53) Rogers was severely criticized for having undertaken this clinical trial with insufficient preclinical research.

A second early study of gene transfer bore an uncanny resemblance to Rogers's experiment. On May 30, 1979, Martin Cline, a hematologist at the UCLA Medical Center, and three colleagues submitted a clinical protocol to the local institutional review board (IRB) — called the Human Subject Protection Committee (47). What Cline and his colleagues proposed to do was to perform gene transfer experiments in subjects who had hemoglobin disorders like sickle cell anemia or thalassemia. The precise strategy that the researchers planned to follow was to introduce functioning beta-globin genes into bone marrow cells that had been removed from the subject's body. Their hope was to be able to confer a selective advantage on the genetically modified cells so that, when the cells were reintroduced into the body of the subject, they would outgrow the native, deficient bone marrow cells. After modifying the protocol to exclude the use of recombinant DNA and after having waited for more than a year for approval by the local IRB, Cline took matters into his own hands. In the summer of 1980 he flew to Israel and Italy; in each country he performed a gene transfer experiment on a subject who was afflicted with β-thalassemia (47). Once again, the press broke the story about the experiment. On October 8, 1980, Paul Jacobs published a story in the *Los Angeles Times* entitled "Pioneer Genetic Implants Revealed" (54). In response, National Institutes of Health (NIH) Director Donald Fredrickson appointed an ad hoc committee to review Cline's action. After the committee's final report in May 1981, Cline was punished by both UCLA and NIH for having violated both federal regulations that protect human subjects and the NIH "Guidelines for Research with Recombinant DNA Molecules" (47).

DEVELOPMENT OF A REVIEW PROCESS FOR GENE TRANSFER RESEARCH IN THE UNITED STATES

The lively discussion of human genetic intervention that had occurred between 1962 and 1972 came to an almost-abrupt halt in 1972. During the remainder of the 1970s two other topics in genetics and molecular dominated ethical discussion — genetic testing and screening and recombinant DNA research (44). Laboratory research with recombinant DNA, in particular, was brought to the attention of the public by scientists concerned that their work could harm either laboratory workers or the public's health, and the Asilomar meeting held in February 1975 marks a decisive moment in the recombinant DNA debate. Out of the discussion process that led to Asilomar there emerged a public-oversight body for this important field of research, the NIH Recombinant DNA Advisory Committee (RAC). By the late 1970s the concerns of scientists, policy makers, and the public about the potential biohazards had been allayed by additional research and further discussion.

In 1980 public attention began to return to the topic of "genetic engineering," which had so abruptly disappeared from sight in the early 1970s. The resuscitation of the topic began in Europe, where in January of 1980 Mr. B. Elmquist, a Danish member of the Legal Affairs Committee for the Parliamentary Assembly of the Council of Europe, requested that the assembly pass a "recommendation on the protection of humanity against genetic engineering" (44, p. 146). Mr. Elmquist's request initiated a two-year discussion process that

led to a parliamentary hearing in May 1981 and to Recommendation 934 (1982) in January 1982. This recommendation, framed in terms of the postwar human-rights tradition, asserted the right of every human being to "inherit a genetic pattern that has not been artificially changed" (55). On the other side of the Atlantic, a June 1980 letter from three religious leaders to President Carter asserted that "We are moving into a new era of fundamental danger triggered by the rapid growth of genetic engineering" (56, p. 95). In response, an already-existing presidential commission on bioethics decided to conduct a formal study of genetic engineering as applied to human beings. News of Cline's unauthorized experiments, which broke later in the same year, and two widely cited essays on "gene therapy" in the *New England Journal of Medicine* (57,58), also contributed to a renewed awareness of a topic that had been actively debated in the 1960s but almost forgotten during most of the 1970s.

The report of the presidential commission, entitled *Splicing Life*, and a congressional hearing on "Human Genetic Engineering" held in November 1982 led gradually but almost inexorably to the establishment of a public-oversight system for human gene transfer research in the United States (44). The NIH advisory committee that had nurtured recombinant DNA research through its early years, the Recombinant DNA Advisory Committee (RAC), now turned its attention to human gene transfer. Through an interdisciplinary working group that was later renamed the Human Gene Therapy Subcommittee, RAC devised guidelines called the "Points to Consider" for a new arena of human-subjects research. These guidelines were reactive in the sense that Martin Cline had already performed a human gene transfer experiment in 1980. However, they were also proactive: the "Points to Consider" were essentially complete in 1985, yet the first gene-marking proposal was not formally submitted to the RAC until 1988. Two years later the first gene-transfer experiments that aimed to be therapeutic were proposed and publicly debated (46,47).

EARLY YEARS OF PUBLICLY APPROVED GENE TRANSFER RESEARCH

On September 14, 1990, the era of publicly approved gene transfer research with a therapeutic aim began. NIH researchers W. French Anderson, R. Michael Blaese, Kenneth Culver, and their colleagues administered genetically modified T-lymphocytes to a girl named Ashanti DeSilva, who had just turned four. Ashanti was suffering from a rare genetic disease called severe combined immune deficiency, which was caused by a defect in a single gene, the gene that produces an enzyme called adenosine deaminase (ADA). A synthetic enzyme had initially helped strengthen Ashanti's weakened immune system, but the beneficial effects of the enzyme therapy had gradually diminished. The researchers, RAC members, members of the press covering the story, and the general public all hoped that this new mode of somatic-cell genetic intervention would prove to be beneficial (46,47).

During the next four-and-a-half years the field of human gene transfer research grew at a rather steady pace in the United States and commenced in several additional countries. By early 1995 the number of gene therapy protocols approved by RAC stood at 82, and the number of gene-marking studies had reached 25 (59). The number of subjects involved in these 107 early trials was small: Only 597 participants took part in the studies. Of the early gene therapy protocols, all but three were Phase I studies, aimed primarily at determining whether the gene transfer procedure would be toxic to patients. Two studies were categorized as Phase I/II studies, and only one study, approved in March 1995, was a Phase II study — a preliminary evaluation of efficacy (59). The gradual growth of activity in human gene transfer research is indicated in Table 2.

Table 2. Number of Gene Transfer Protocols Submitted by Year, 1990 to 1995

1990	1991	1992	1993	1994	1995
2	9	23	31	33	44

In the early studies of gene transfer in the United States several types of diseases were targeted, and multiple vectors were employed. More than 60 percent of the gene therapy studies (51/82) sought to combat cancers of various kinds. Twenty studies were directed toward monogenic diseases, including cystic fibrosis (11), Gaucher disease (3), and severe combined immune deficiency (1). The remaining 11 protocols sought to combat HIV infection or AIDS (9), peripheral artery disease (1), and rheumatoid arthritis (1). The vast majority of the initial 107 gene transfer studies in the United States employed retroviral vectors (76/107). Adenovirus vectors began to be employed in 1993 and were used in 15 of the initial 107 studies. In 1994 the first adeno-associated viral vector was proposed and approved. Non-viral delivery vehicles included liposomes (12/107), plasmid DNA (2), and particle mediation (1) (59).

GENE-TRANSFER RESEARCH AND OVERSIGHT POLICIES IN OTHER NATIONS

For gene transfer research conducted outside the United States the earliest published information began to appear in the journal *Human Gene Therapy* in December of 1992. In the earliest annual summary of gene transfer research the following three non-U.S. protocols were listed (60):

- Fudan University and Changhai Hospital, Shanghai, China: Hemophilia B
- Centre Leon Berard, Lyon, France: cancer (a gene-marking study)
- San Raffaele Scientific Institute, Milan, Italy: severe combined immune deficiency

By the end of 1993 two additional protocols had been initiated in the Netherlands (61). At the end of 1994, the number of non-U.S. gene transfer protocols had increased to 13. New countries added in the 1994 summary included the United Kingdom, Germany, and Sweden (62). In 1995, or approximately the same time as the U.S. audits

discussed below, the number of non-U.S. protocols stood at 17, with Canada and Poland joining the list as new sites in 1995 (63). At mid-year in 1996, a more comprehensive report compiled by Tony Marcel and J. David Grausz cited the following additional countries in which gene transfer studies either were being planned or had already been undertaken: Switzerland, Egypt, Spain, Australia, Finland, Japan, and Israel (64).

Oversight bodies similar to RAC or FDA regulate the conduct of human gene transfer research in several European countries and in Japan. In the United Kingdom the Gene Therapy Advisory Committee (GTAC) reviews all gene transfer protocols on the basis of guidance that the committee has prepared for researchers (65). In 1996 France passed a special law for cell and gene therapies that requires these biologics to be reviewed by the French Medicines Agency (66). Japan's oversight system for human gene transfer includes two national review bodies, one of which meets publicly and the other of which convenes in private (66).

AUDITS OF 1995 AND THE CRISIS OF 1999 IN THE UNITED STATES

The June 1995 RAC report from which the information in the preceding section was derived reached three primary conclusions about the field of human gene transfer. First, gene-marking studies had advanced the science of bone marrow transplantation by allowing researchers to distinguish between cells that had been removed from a patient's body and purged and cells that had not been removed. Second, there was little evidence of toxicity in the early gene transfer studies. And third, "It is clearly too early . . . to assess the therapeutic efficacy of gene therapy or even to predict its promise" (60, p. 1789).

In December 1995 a committee co-chaired by RAC member Arno Motulsky and Stuart Orkin delivered a more somber verdict to NIH Director Harold Varmus and the NIH Director's Advisory Committee. According to the Orkin-Motulsky committee,

> While the expectations and the promise of gene therapy are great, clinical efficacy has not been definitively established at this time in any gene therapy protocol, despite anecdotal claims of success and the initiation of more than 100 Recombinant DNA Advisory Committee (RAC) approved protocols (67).

The Orkin-Motulsky committee stopped short of recommending a moratorium on clinical trials of human gene transfer, but the committee clearly thought that the balance between preclinical and clinical research should be radically shifted.

In retrospect, one can discern a clear, though gradual downward trajectory in human gene transfer research in the U.S. from the end of 1995 through late 1999. There were several elements in this decline. The early hope for therapeutic success continued to be frustrated, and the 1995 verdicts of the RAC and the Orkin-Motulsky committee remained valid through 1996, 1997, and 1998. During this same period gene transfer research became much less visible in the United States because of changes in the oversight system. The existing system of review and approval or disapproval of all human gene transfer protocols by both RAC and the Food and Drug Administration (FDA) gave way first to a system of more selective review and approval or disapproval by RAC, then to sole regulatory authority by FDA, with informal advice from RAC on protocols that raised novel issues. Researchers were asked to continue submitting reports of serious adverse events both to RAC and FDA, as well as to provide an annual report to the RAC staff on the progress of their research. However, the RAC staff lacked both the number of people and the database capabilities required to tabulate and analyze the reports that were submitted. There was, in addition, increasing evidence that not all of the required information was being provided to the RAC and its staff by researchers and companies. As a result of these multiple factors, no annual reports on progress (or the lack of progress) in human gene transfer research were produced by the RAC and its staff between 1995 and 1999.

The crisis of 1999 for human gene transfer research in the United States began when RAC noted at its September meeting that one researcher and one company had labeled adverse event reports as "proprietary information" and had asked RAC not to discuss the events publicly. Even as RAC responded by insisting that adverse event reports be a matter of public record, a second event occurred that would change the field of gene transfer research for the foreseeable future. On September 17, 1999, Jesse Gelsinger, an eighteen-year-old young man who had ornithine transcarbamylase (OTC) deficiency, died as a direct result of having received gene transfer with an adenoviral vector. The tragedy was compounded by the fact that Mr. Gelsinger's disease had been relatively well controlled through all of 1999 by a combination of drugs and diet (68,69). To their credit, the team of researchers conducting this study at the University of Pennsylvania promptly reported Mr. Gelsinger's death to both NIH and FDA.

The crisis of 1999 continued as FDA placed several gene transfer studies on clinical hold. In addition a vigorous attempt by the RAC staff and FDA to gather all serious adverse events that had occurred in human gene transfer trials, especially those using adenoviral vectors, revealed that less than 10 percent of these events had been reported to RAC and its staff in a timely fashion. At the December 1999 RAC meeting, a working group on adenoviral vectors criticized gene transfer researchers for their lack of standardization in calculating doses of vector and in assuring that the properties of the vector had not changed before it was administered to human subjects. At the same meeting FDA alleged that the University of Pennsylvania research group had committed several violations of FDA regulations in its conduct of the OTC deficiency gene transfer trial. These oral criticisms were followed in January 2000 by FDA's release of "inspectional observations" detailing FDA's charges. The Penn researchers responded to the charges in February, acknowledging some technical errors but denying that those errors were causally related to Mr. Gelsinger's death (70–73).

A February 2000 Senate hearing chaired by Senator William First explored the current oversight system for gene transfer research in the United States. At the hearing Mr. Gelsinger's father, Paul Gelsinger, asserted that he and his son had not been told important information from the preclinical studies that preceded the start of the human gene transfer study for OTC deficiency. More specifically, the deaths of monkeys in preclinical studies employing earlier generations of adenoviral vectors had not been disclosed. Mr. Gelsinger also reported that he and his son had been led to believe that the son's participation in the gene transfer study was likely to be clinically beneficial, even though the study was a Phase I trial. Other witnesses, including the present author, commented on weaknesses in the current oversight system for gene transfer research in the United States and on steps that are being undertaken by NIH and FDA in an effort to remedy those weaknesses.

PROSPECTS FOR THE FUTURE

As of late 1999, approximately 320 U.S. gene therapy (as distinct from gene-marking) trials had been registered with NIH and RAC. For studies being conducted in other countries, the most recent figures available suggest that at least 36 gene transfer trials have been initiated or completed in 11 countries (74). This latter number is almost surely a gross underestimate. Many companies seem to prefer reporting gene transfer trials only on a confidential basis to the regulatory agencies that oversee those trials. The earlier generalizations about the lack of demonstrated clinical efficacy, at least in published articles, continue to hold, although there are rumors of initial success with severe combined immune deficiency in several children and in hemophilia with adults. The 1995 conclusion about the lack of toxicity in gene transfer trials has now had to be reversed, in the light of Mr. Gelsinger's death and several other reported laboratory and clinical toxicities.

It is fair to say that in late 1999 and early 2000 the field of human gene transfer research was undergoing an agonizing reappraisal. Success in this use of these techniques may lie ahead, but it will not be as easy as all hoped and many believed in 1990, when the first approved study was initiated. The precise role for gene transfer, cell transfer (often called "cell therapy"), organ and tissue transplantation (including xenotransplantation), biologics, and drugs in the armamentarium of the future remains to be clarified. The future success of gene transfer in the treatment of disease cannot be guaranteed. What can definitely be achieved, however, is the creation of a transparent, accountable oversight system that assures that the human subjects who make this research possible will be dealt with honestly and with the highest measure of respect.

ACKNOWLEDGMENTS

I wish to thank my colleague, Linda A. Powell, for helpful editorial assistance. I am indebted to my colleague, Martina Darragh, for information on the first recorded usage of the phrase "gene therapy."

GENETIC COUNSELING

ANNE L. MATTHEWS
Case Western Reserve University
Cleveland, Ohio

OUTLINE

INTRODUCTION

Genetic counseling is relatively new as a recognized health profession. The need for genetic counseling services as a discipline unto itself arose out of technological advances in human genetics and their applications to clinical medicine and health care. The profession's continued growth and maturity is a reflection of the continuing explosion of new knowledge in the discipline of human and medical genetics and of its impact on health care.

History

The concept of genetic counseling can be considered eons old. Genetic advice has been provided to families by their relatives, friends, and neighbors since humans began communicating with one another. The Bible, other religious writings, and civil laws have provided families for centuries with rules and laws regulating reproductive behavior based on heredity. However, the term "genetic counseling" as currently utilized is attributed to Sheldon Reed, a Ph.D. geneticist, who published his philosophy of genetic counseling in his text entitled *Counseling In Medical Genetics* (1,2). Reed defined the concept of genetic counseling as "a kind of social work done for the benefit of the whole family entirely without eugenic connotations" (3, p. 335). He stated that the primary function of counseling was to provide people with an understanding of the genetic problems they had in their families. For Reed, in order for one to provide genetic counseling the individual had to have some knowledge of human genetics, have a "deep respect for the sensitivities, attitudes, and reactions of the client," and have a "desire to teach, and to teach the truth to the full extent that was known" (1, pp. 11–12).

Providers of genetic information during the first 40 years of the twentieth century were primarily doctorally trained geneticists in academic institutions. Their major interests focused on laboratory approaches and population genetics to answer questions regarding evolution and how to decrease the presence of disease genes in the gene pool. When consulted, genetics experts provided information dealing with the genetic contribution of heredity and the prevention of genetic diseases and birth defects. Their counseling strategy was one of advice and recommendations. This fit well with the basic tenets of eugenics that were so prevalent in academic and scientific circles during this time period (4). It was not until the later part of the 1940s and 1950s that medicine began to demonstrate an interest in human genetics. Clinics dealing with genetic questions began to appear, two of the first were the Hereditary Clinic at the University of Michigan and the Dight Institute of Human Genetics at the University of Minnesota (5). However, much of this information continued to be presented with the overall intent of decreasing the incidence of genetic disease and birth defects (6).

By the 1960s technological advances in a number of areas — including cytogenetics, biochemical, and molecular genetics, population screening of newborns for phenylketonuira, and the technological advances making prenatal diagnosis a reality (7) — had a tremendous impact on physicians' interests in the field of human genetics (5). Medical genetics was becoming a recognized area of practice as physicians began to replace the laboratory-based geneticist in providing genetic information to patients and families. And while the emphasis of counseling remained preventative in nature, by assisting families in a process of making informed, rational decisions regarding reproductive choices, the need to respond to the psychosocial aspects of genetic disorders was beginning to emerge as an appropriate goal of genetic counseling (8).

In the 1970s the movement in medicine and health care as a whole shifted toward greater patient autonomy (9). In the genetic counseling arena, effectiveness of counseling was no longer solely based on whether or not reproductive plans were altered or information and recurrence risks recollected. It was also reflected by the importance of patients and families making reproductive decisions based on personal values and family circumstances. This philosophical shift, from prevention of genetic disease to concern for the patient's or counselee's total well-being, brought medical geneticists closer to Reed's definition of genetic counseling. Moreover this shift was coincident with the initiation of the first master's level genetic counseling program, a team approach to providing genetic services, and the general public's request for access to such services. This philosophy was also legitimized when the Ad hoc Committee on Genetic Counseling of the American Society of Human Genetics published their definition of genetic counseling that acknowledged the importance of the psychological dimensions of the counseling process and the role of master's level trained personnel who were advocates of this approach (10). The definition that was adopted by the American Society of Human Genetics in 1975 continues to be accepted as the definitive definition of genetic counseling:

> Genetic counseling is a communication process which deals with the human problems associated with the occurrence, or the risk of occurrence, of a genetic disorder in a family. This process involves an attempt by one or more appropriately trained persons to help the individual or family (*1*) comprehend the medical facts, including the diagnosis, the probable course of the disorder, and the available management; (*2*) appreciate the way heredity contributes to the disorder, and the risk of recurrence in specified relatives; (*3*) understand the options for dealing with the risk of recurrence; (*4*) choose the course of action which seems appropriate to them in view of their risk and the family goals and act in accordance with that decision; and (*5*) make the best possible adjustment to the disorder in an affected family member and/or to the risk of recurrence of that disorder (10, p. 240).

THE GENETIC COUNSELING PROCESS

To understand the role of the genetics team, and more specifically genetic counselors, it is helpful to understand what the process of genetic counseling encompasses. In simple terms, genetic counseling can be thought of as an information exchange provided in a team approach milieu (11). Based on information gleamed from the patient or counselee (terms used interchangeably) and working in concert with team members, the genetic counselor provides information and psychological support regarding specific concerns or questions of the family. The process often begins with the identification of individuals within the family affected with birth defects or genetic disorders or with the identification of those who may be at increased risk for a variety of inherited conditions. The process consists of a number of different steps, often posed as questions by families. The first such question is usually: "What is it?" or "Am I at increased risk because of my genetic make-up?" The next step in the

process is to attempt to answer the questions of "What caused it?" and "What can be done about it?" Ideally this aspect of the process involves establishing an accurate medical diagnosis, which in turn forms the basis for genetic counseling. While the genetic evaluation consists of many of the same components found in any medical evaluation, the emphasis is often quite different. In particular, medical information regarding extended family members is often a prerequisite to providing accurate information and genetic counseling. After the establishment of a specific diagnosis, a discussion of the prognosis, treatment, and management options based on the most current information available can ensue. Counseling next addresses the question of "Will it happen again?" Recurrence risks can be discussed and families provided with a variety of options regarding future reproductive choices.

Equally important, the genetic counseling process assists individuals and families in coping with the emotional burdens and adjustments required where the person or a family member is at risk for or affected with a genetic condition.

Data Gathering

In a genetics evaluation the information obtained from families provides important and often defining data needed to reach a specific diagnosis. Major categories of information elicited include prenatal, perinatal, medical, developmental, family, and psychosocial histories. The prenatal and perinatal histories provide an overview of fetal and newborn well-being. Documentation of such information as a potential teratogenic exposure, maternal disease and acute illness, or fetal growth and behavior, such as reflected in fetal movement, may provide important clues to identifying a specific diagnosis and etiology. These specific histories are often helpful in differentiating between prenatal etiologies of abnormalities and those resulting from birth injury (12).

Medical and developmental histories provide the genetic counselor with information regarding the natural history of the disorder in the affected individual. They also provide important information regarding variability, namely how a specific etiology affects what is seen in a specific patient (the phenotype). The medical and developmental histories can also provide the genetics team with direction in delineating a list of differential diagnoses that could help establish a specific diagnosis.

Obtaining a reliable family history can be extremely helpful in clarifying an etiology, diagnosis, and/or risk of recurrence in a family. The genetic counselor constructs a detailed and extensive pedigree that outlines in pictorial format three to four generations in a family. The genetic counselor obtains specific information about family members based on his/her knowledge of the variability of birth defects and the often multiple expressions of a genetic disorder. Families may not always be aware of how variable the expression of a genetic disorder can be, and thus may not be aware that other family members are also affected. For example, a child with a cleft palate, a heart defect, and learning disabilities is diagnosed with velocardiofacial syndrome (a genetic disorder that can have numerous effects including abnormalities of the palate, heart, and other organ systems as well as a characteristic facial appearance) (13). By obtaining a detailed family history and asking questions that would guide the family to describe specific findings, two other family members are identified (and the diagnosis is confirmed on physical examination and/or genetic testing as also having features of velocardiofacial syndrome). Based on this information, the genetic counselor can provide the family with specific information regarding this diagnosis including prognosis, treatment and management options, and specific recurrence risks to future offspring or other family members.

The physical examination part of the genetic evaluation differs somewhat from a routine medical examination. Performed by the physician geneticist, it is aimed not only at detecting major and minor malformations (dysmorphic features) but also at describing a pattern or constellation of findings that may provide clues in determining a diagnosis (14). For example, a congenital heart defect may be an isolated finding. However, if other features are noted such as poor muscle tone, upslanting eyes, and single palmer creases (simian creases), one might suspect a diagnosis of Down syndrome. Moreover such detailed descriptions are helpful in determining whether or not a physical finding is of significance or represents a normal variation or familial finding. Laboratory data collection is another important aspect of the data gathering. If a genetic disorder is suspected, diagnostic studies may be useful in delineating a specific diagnosis. Such laboratory tests as chromosome analysis, molecular DNA or biochemical studies, radiographs, or organ imaging may be appropriate. Additionally the patient may need to be referred to other specialties such as neurology or ophthalmology or for developmental studies.

Lastly, families may be asked for permission to take photographs. In many cases the adage "A picture is worth a thousand words" is well deserved, as photographs provide accurate descriptions of what has been noted on the physical examination. This also allows the genetic counselor to share the patient's findings more accurately with other clinicians in order to get assistance in reaching a specific diagnosis.

Counseling

Once all of the information has been gathered, and the genetics team has had the opportunity to consider possible diagnoses and review pertinent literature and databases, discussion with the client and/or family can begin. If a diagnosis has been identified, the geneticist or genetic counselor discusses the etiology and its genetic basis (what caused it), the medical and developmental implications of the diagnosis (what is it); the prognosis, treatment, and/or management options (what can be done about it); as well as the recurrence risks and availability of prenatal testing (will it happen again). The counselor also identifies and discusses the psychosocial impact of the disorder on the affected individual as well as on other family members, what needs the family may have, and what resources and support groups may be available to help the family or patient to take the next step forward in the process of learning and coping with new information.

If more testing is needed before a specific diagnosis can be made, the team provides the family with their impressions and/or an explanation of the diagnoses being considered. The genetic counselor discusses the specific testing or other specialty evaluations that the genetics team has recommended to confirm or rule out a diagnosis(es) and provide the family with information regarding costs, referrals, insurance issues, and possible date(s) when results may be expected. The team then discusses any interventions that may be useful such as a referral for physical and occupational therapy. And finally, the counselor sets up a plan with the family regarding how best to relay results of recommended tests as well as how best to provide follow-up information to the family and their health care providers.

Finally, if no diagnosis can be made, the ensuing discussion with the family includes the level of suspicion that the condition is genetic and the possibility of further evaluation and new testing in the future. The counselor provides the family with a range of recurrence risks depending on the possible genetic etiologies for similar findings, and with options for monitoring future pregnancies, if appropriate. Discussion also includes any available options regarding management or therapy for symptoms. When no specific diagnosis can be reached, a frustrating experience for both counselor and counselee, the emphasis shifts to helping the family address the impact of the lack of a diagnosis with supportive follow-up counseling for the family as needed.

Follow-up

Perhaps one of the most important, although often unacknowledged, aspects of the genetic counseling process is that of follow-up. As mentioned above, a major aspect of the genetic counseling process is to help the patient and/or family incorporate the information component of the session with the psychosocial, emotional impact of that information. Kessler notes that the "psychological responses of counselees are not only a normal, but often a necessary step in comprehending, integrating and coping with a medical diagnosis or the content material of genetic counseling" (15, p. 19). Following any counseling session, a written summary of the information provided and recommendations made is sent to the family. This written summary provides the family with an opportunity to review and refresh their memories of all the information that they received, as well as allowing them to share the information with other family members if they so desire. Specific recommendations can be reviewed at a later date, or the importance of additional counseling can be reemphasized if reproductive plans or circumstances change. The summary may also identify any misinformation or misconceptions that need to be addressed (9).

The genetic counselor will often follow up with phone contact to answer remaining questions or clarify issues for the family. If further testing or evaluations are pending, the counselor will arrange for the family to return to the clinic to discuss any additional information that has been obtained. These contacts also allow the counselor some ongoing assessment of how the family is assimilating information and coping and adjusting to the condition. In many situations the counselor is able to provide the family with anticipatory guidance and support regarding a number of different issues. However, when situations arise that are beyond their therapeutic expertise, the counselor will refer the client or family to the appropriate health care provider. The counselor may also help families to identify support groups or other resources, such as financial or educational resources, that would be appropriate for their particular situation. In many cases the genetic counselor may have an ongoing relationship with the client and family as new information or family circumstances arise.

GENETIC COUNSELING SETTINGS

Genetic counseling services are provided in a number of different settings. These include prenatal diagnostic clinics, diagnostic or general genetics clinics, and specialty and management clinics. Genetic services may also be available as part of a consultative service in some hospitals. In each setting, while specific aspects may vary and different components of the genetic counseling process may be emphasized, the overall approach and goals of the genetic counseling encounter remain constant.

Prenatal Setting

In the prenatal setting, pregnant women are usually referred for genetic counseling services based on one of two scenarios: the ideal situation when counseling occurs prior to prenatal screening or procedures, and the more common scenario when an abnormality is noted on ultrasound or maternal serum screening results change a woman's risk for abnormalities. In either scenario, genetic counseling can assist pregnant couples by providing a forum for discussion and detailed information on which informed decisions about further procedures can be made.

In the ideal scenario, one in which a referral is made prior to screening or testing because of a known risk factor (i.e., pregnant woman over the age of 35 or a positive history of a genetic disorder), there is usually a two-step process involving a counseling session followed by the actual prenatal testing procedure. Patients meet with a genetic counselor who obtains information regarding their indication for referral, their pregnancy, and their extended family history in the form of a pedigree. The counselor reviews the couple's risk for having a fetus affected with a birth defect or genetic disorder based on all of this information. At this juncture the couple may decide to have further diagnostic testing initiated or may decide not to pursue further evaluation. It is incumbent on the genetic counselor to provide the appropriate support in this decision-making process in a nondirective (i.e., noncoercive) manner (16) so that couples feel comfortable with the process and counseling does not become a mandate for subsequent procedures. Walker notes that "there is still a widespread perception that the sole purpose of prenatal diagnosis is to identify anomalous fetuses so that their birth can be prevented by pregnancy termination" (9, p. 604). There are a number of good reasons beyond termination why prenatal testing may be

appropriate for couples, including reassurance about the well-being of the fetus, anticipatory management based on a fetal diagnosis such as where or how the delivery should occur (in a tertiary hospital setting vs. local facility), the opportunity to plan for treatment in the neonatal setting, and, equally important to many patients, the opportunity to adjust, plan ahead, and gather support and resources prior to the baby's birth (17). If the patient elects to have one of the diagnostic procedures, such as chorionic villus sampling, amniocentesis, or chordocentesis, the procedure is reviewed and discussed in detail. Associated risks of the procedure and follow-up are also described. After the test results are received, which are usually available within 10 days to 3 weeks depending on what studies are being conducted, the referring physician is notified. If the results are abnormal, the patient often returns to the genetic counselor to discuss the test results, what the meaning of such results may have for the present pregnancy, and what options may be available to the family such as termination or continuation of pregnancy and management at delivery. Whatever the decision, the counselor continually acknowledges the impact of such findings and subsequent actions on the patient and the family. Continued acknowledgment and validation regarding couples' decisions should remain a primary concern for the counselor (17). Even if the pregnancy is terminated after a diagnosis of a disorder in the fetus, the genetic counselor provides continued support and referral resources.

The more common prenatal diagnosis scenario occurs when the patient or couple is referred for genetic counseling following ultrasound of the pregnancy where an abnormality is noted or the maternal serum screening test is abnormal. In this all too common situation, the genetic counselor must provide information, counseling, and support in a milieu of anxiety and fear to a couple or patient that did not previously know of any increased risk and is now facing unanticipated decisions (9). The counselor will need to focus the discussion on what is known and not known and what other procedures may be helpful in better delineating the abnormality or problem. This process is conducted within a time-limited framework, where decisions regarding possible options available to the couple must be made quickly amid confusion, stress, and high anxiety.

General Genetics Setting

The general genetics clinic, once thought of as the realm of pediatrics, now often includes a growing number of adult patients as more knowledge is gained regarding late-onset genetic disorders or as affected individuals live longer with excellent medical care. In general, the initial visit to the genetics clinic is preceded by some form of intake process, during which the genetic counselor or clinic staff contacts the family to briefly discuss their concerns, gain some preliminary information, and provide the family with some overview of what they can expect during the visit. Additionally medical records and past testing results are requested prior to the visit.

At the appointment, families are again asked about their understanding of why they were referred, what their concerns are, or what they hope to gain from the visit. Previously obtained information is confirmed and additional prenatal, perinatal, developmental, medical, and psychosocial histories are elicited as needed. A detailed four-generation pedigree is also constructed. If appropriate, the medical geneticist then performs a physical examination, paying particular attention to minor findings and variations. At this point, testing and other evaluations may be ordered or recommended to confirm or rule out a suspected diagnosis. If a specific diagnosis is made, the genetics team provides information regarding the diagnosis, prognosis, treatment, and management, risk of recurrence, and available reproductive options or testing. Available resources and referrals to support groups may be made. Other family members at risk for developing the disorder or for having an affected offspring are identified. It may also be suggested that other family members may wish to seek genetic counseling to discuss the same or similar issues. In most clinic settings, a written summary of the counseling session is then sent to the family and health care providers for their records.

Sometimes, despite the best of efforts and for a number of different reasons, no diagnosis can be established or test results are inconclusive. If the patient is a child, a family may be asked to return to the clinic at some point in the future as, not rarely, a child will "grow into" a diagnosis (12). This also allows the genetics team to observe growth and development over time, since they may provide clues to a diagnosis. In any case, the only options available to the genetic counselor may be reviewing the information that is available regarding possible categories of diagnosis, recurrence risks, and future options. This unfortunate scenario is as frustrating for the genetic counselor as it is for the families. Nevertheless, the genetic counselor will help the family address the issue and impact of the lack of a diagnosis and provide support and follow-up for the family as needed.

Specialty and Management Clinic Settings

Specialty and management clinics, in which the medical geneticist and genetic counselor are integral members of a multidisciplinary team, are designed to assist families and affected individuals deal with a myriad of problems associated with a specific disorder or constellation of findings that can arise over a lifetime. Such specialty or management clinics may deal with a specific genetic disorder such as hemophilia or Marfan syndrome, or with a grouping of disorders or diagnoses such as craniofacial clinic or neuromuscular clinic. The clinic team works closely with the families and their primary care professionals to provide specialized health care services and treatments as well as address such issues as financial concerns and special needs such as equipment. The genetic counselor can provide information and counseling to parents of affected children regarding the genetics of the diagnosis as well as discuss recurrence risks and future reproductive options. These same issues can be discussed with affected adults and their spouses and can continue into the next generation with the children born to these families.

Two of the fastest growing areas of specialty clinics are the hereditary cancer clinics and those that deal with late-onset disorders, such as Huntington disease or Alzheimer's disease. These clinics have seen tremendous growth in the last few years due to the technological advances made in human genetics and the discovery of specific genes responsible for some inherited cancers and certain neurological disorders. In both cancer and late-onset disorders, families are actively seeking information regarding susceptibility or presymptomatic testing (18). In the case of cancer, genetic testing for specific inherited cancers has sparked great interest from individuals and families although only 15 percent of cancer cases are known to have an inherited susceptibility gene (19). For many patients, test results may influence medical management. In late-onset disorders such as Huntington disease, presymptomatic testing (i.e., the ability to identify the gene causing the disorder years before any symptoms appear) has led people to seek testing in order to provide themselves with information on which to make choices about career paths, lifestyle changes, or reproductive decisions. These genetic counseling sessions may be extremely complex as they need to cover a wide range of concerns, not only about the disorder in question, but about the impact of testing and test results on the patient and family, including such issues as confidentiality, discrimination, and possible loss of life or health insurance (20).

In summary, genetic counseling is a complex and multifaceted process that draws on a field of professional expertise that involves diagnosis, provision of information, and counseling of individuals about their genetic makeup and their chances of being affected with a genetic disorder or having offspring with birth defects or genetic disorders. It is usually best accomplished as a team approach by genetics professionals including genetic counselors, medical geneticists, Ph.D. trained geneticists, and other specialized health care professionals such as genetic nurse specialists and social workers.

GENETIC COUNSELORS

Having defined the specific roles a genetic counselor carries out, we turn our attention to the process of acquisition and official recognition of these skills, given the genetic counselor's unique relationship between the counselee and their family. Genetic counselors are health professionals with specialized graduate training and experience in the areas of medical genetics and counseling (21). They work as members of the health care team, providing information and support to families with or at risk for genetic disorders and birth defects. In addition to providing expertise regarding genetic disorders, genetic counselors also provide supportive counseling, serve as patient advocates, and act as educational and resource professionals for their patients, other health care providers, and the general public. Many counselors are also actively engaged in research activities related to the field of medical genetics and genetic counseling. Bartells and colleagues state that "genetic counselors work at the intersection between the information produced by scientists and the hopes, dreams, and fears of clients whose lives could dramatically change as a result of receiving that information" (22, p. ix).

Genetic Counseling Training Programs

Sarah Lawrence College developed the first master's level genetic counseling program in 1969. Program developers, drawing on the expertise of several well-known geneticists, developed a genetic counseling program that balanced theoretical coursework in human and medical genetics with counseling theory and clinical experience in genetics centers providing genetic counseling services (23). This program based its counseling curriculum on a client-centered approach in which students learned interviewing skills, the concept of nondirective counseling, and "employing empathic responses against the background of unconditional positive regard" (23, p. 20).

Curriculum

In continuing efforts to define the role of the genetic counselor as a major provider of genetic services and to standardize the minimum educational requirements for a genetic counselor, directors of genetic counseling programs and other genetics professionals met three times between the years of 1974 and 1979 to address standards of genetic counseling education. The conclusions and recommendations were outlined by Dumars and colleagues in 1979 in *Genetic Associates: Their Training, Role and Function* (24). It was the consensus of the program directors that genetic counseling programs needed to maintain a dialogue among themselves and with other genetics professionals to assure the quality and effectiveness of the professionals being trained (25). Currently, there are 26 genetic counseling programs recognized by the American Board of Genetic Counseling, three international programs, and three graduate nursing programs that have a clinical nurse specialist tract in genetic counseling (26).

Most genetic counseling programs are two year curricula that include theoretical coursework, laboratory exposure, research experience, and extensive clinical training. The curricula have expanded considerably in both depth and complexity from the initial recommendations outlined in 1979. Coursework usually includes human and medical genetics, cytogenetics, biochemical genetics and molecular genetics as well as principles of quantitative and population genetics. Most programs balance the basic science and medical genetics courses with courses that stress the psychosocial aspects of genetic counseling, including principles of genetic counseling and the counseling process, interviewing techniques, ethical, legal, social, and ethnocultural issues pertaining to genetic evaluation, screening, testing, and counseling. Clinical training covers all areas provided by genetic services. Students usually receive extensive exposure in prenatal diagnosis, general genetics and metabolic clinics including both children and adults, specialty clinics such as cystic fibrosis or craniofacial clinic, and such clinics as hereditary cancer and neurodegenerative disorders. Students are expected to take an active role in most counseling sessions under the supervision of a certified genetic counselor and/or medical geneticist in order

for the counseling session to be used toward formulating a logbook of cases (27). Today's genetic counseling student may have well over 1000 hours of clinical practicum (28), far greater than the 1979 "optimum curricula" recommendations that suggested 400 hours of supervised clinical placement in a minimum of two settings (25).

National Society of Genetic Counselors

The genetic counseling profession continued to establish its presence as a knowledgeable member of the genetics health care team with the formation and incorporation of its professional society, the National Society of Genetic Counselors (NSGC) in 1979 (21). NSGC instilled the sense of professionalism needed by this emerging group of health care professionals. Today NSGC has over 1700 members. Its mission is promoting "the genetic counseling profession as a recognized and integral part of health care delivery, education and public policy" (21). NSGC promotes the professional interests of genetic counselors and provides a network for professional communications, local and national continuing education opportunities, and the discussion of issues relevant to human genetics and the genetic counseling profession (21). In 1991 NSGC adopted and then published its Code of Ethics (29). This publication provided NSGC with a framework within which its members could function and practice. Moreover as NSGC continues to grow, its presence and influence are becoming more widespread regarding programs and policy in medical genetics and genetic counseling. NSGC has representatives on a number of policy-making groups and works closely with such groups as the American Society of Human Genetics, the American College of Medical Genetics, the American Board of Genetic Counseling, the American Board of Medical Genetics, the International Society of Nurses in Genetics, and the National Coalition for Health Professionals Education in Genetics.

Certification and Accreditation

Another important milestone in the professional development of genetic counselors occurred with the initiation of a certification examination process in 1981 by the American Board of Medical Genetics (25). Initially physicians, Ph.D. trained geneticists, and genetic counselors who met specific credential requirements could apply to sit for the certification examinations within five categories. Certification, or being eligible to sit for certification examinations, gave employers some degree of confidence that health professionals hired to provide genetic services possess a minimum level of knowledge in human and medical genetics and genetic counseling. Most employers require that genetic counselors be certified or eligible to sit for the certification examinations as prerequisites for employment.

In 1990 the genetic counseling subspecialty section of the certification examinations came under the auspices of its own board, the American Board of Genetic Counseling (ABGC). Current practice requires that applicants applying to sit for certification examinations have graduated from an accredited genetic counseling program. The applicant must also demonstrate that they have acquired a wide range of clinical experiences documented by a logbook of cases supervised and signed by a board certified genetic counselor or medical geneticist. Currently over 1300 genetic counselors have achieved board certification.

The most recent achievement in the professional evolution and development of the genetic counseling field has been the establishment of an accreditation process for master's programs in genetic counseling. Following a consensus meeting that included genetic counseling program directors, members of ABGC and experts in a number of different fields, the ABGC published its criteria for accreditation including the practice-based competencies as defined by the consensus meeting (30). Programs must demonstrate adequate institutional support and facilities, adequate leadership and management, including board certified genetics professionals, and a curriculum that provides educational experiences, including theoretical courses, clinical training, and supplementary activities that would provide graduates with the necessary knowledge and skills to perform, accurately and reliably, the functions of a genetic counselor (27).

Continuing Education. With the explosion of new information in human genetics, genetic counselors are finding it necessary to continue to expand their knowledge base and keep abreast of new developments in the field. This continuing education effort has taken the form of requiring certified genetic counselors to obtain documentation of continuing educational activities through continuing education units (CEUs). While NSGC developed a continuing education model in the early 1980s to ensure quality educational programs, it was not until 1996 that courses and conferences sponsored by NSGC had to meet established continuing education criteria (31). Certified genetic counselors may demonstrate their continuing education by either sitting for a re-certification examination or obtaining a minimum of 250 approved contact hours during a period of 10 years. NSGC is continuing its efforts to broaden the types of activities by which counselors can obtain the appropriate educational experiences.

Employment

As noted previously, genetic counselors usually work as members of the health care team in a number of settings. Once every two years, NSGC conducts a status survey of its membership to obtain information about employment, professional roles, and activities (32). In the survey conducted in spring 1998, almost half (47 percent) of the counselors reported working in a university medical center and 24 percent reported working in a private hospital or medical facility. The remaining counselors were scattered between other categories such as HMO's (7 percent), diagnostic laboratories (6 percent), federal/state/county offices (5 percent), and self-employed (1 percent). Almost three-quarters of counselors (73 percent) stated they worked in two or more specialty areas. These areas included prenatal genetic counseling (70 percent), followed by pediatric genetics (45 percent), and cancer genetics (34 percent). Of potential interest to new graduates of genetic counseling training programs, the 1998 survey noted that it took less than two months for

members to obtain genetic counseling positions following graduation (32).

Issues in Genetic Counseling

While there are a number of issues that genetic counselors encounter such as dealing with nonpaternity or ambiguous findings on genetic test results (covered elsewhere in this text), two issues that continue to be important to the profession are nondirective counseling and financial reimbursement of genetic counseling services.

Nondirective Counseling. From Sheldon Reed's first publication defining genetic counseling as a "a kind of social work done for the benefit of the whole family entirely without eugenic connotations" (3, p. 335), genetic counseling has been equated with the concept of nondirectiveness. Nondirectiveness appealed to the genetics community as a way to distance itself from the eugenics movement associated with Nazi Germany. Genetic counseling embraced Carl Rogers's client-centered counseling approach. Rogers felt that counselors need to provide a warm, accepting environment free from pressure or coercion for clients to reach a successful self-acceptance and self-understanding (33). Nondirectiveness is understood to mean nonprescriptive. Fine defines nondirectiveness as a genetic counseling strategy that supports autonomous decision making by clients (34). NSGC Code of Ethics states, "Therefore, genetic counselors strive to: ... Enable their clients to make informed independent decisions, free of coercion, by providing or illuminating the necessary facts and clarifying the alternatives and anticipated consequences" (35). Genetic counselors therefore are facilitators and advocates of informed decision making, with the goal of having the counselee make a decision based solely on his or her own values and beliefs.

However, consensus regarding the terms directiveness and nondirectiveness is difficult to find among genetics professionals and in the literature (36). Kessler notes that depending on how one defines the term nondirective will determine whether or not it can be achieved (37). White notes that nondirectiveness is often equated with value-neutrality, which may "either imply that the counseling approach as a whole does not represent any values or moral positions, or it may refer to value-free communication, representing an ideal in which concepts and facts are expressed in impartial terms" (38). A number of authors have argued that counseling is never value-neutral. The types of information provided or not provided, the tone of voice, body language, all convey counselor values (39,40,37). Singer elaborates on this theme by noting that many of the decisions that patients make take place in an atmosphere of crisis and that the issues are often highly emotional (41). Counselors relay information that is often highly technical, while most counselees are likely to have limited knowledge of the biological and statistical issues that arise; they are a vulnerable population. Thus a counselor, who has a duty to provide all the information that clients need in order to make informed decisions, must decide what information the counselee needs and how to present the information. In this sense the genetic counselor utilizes her expertise to decide what and how much information the counselee needs to make the best possible decision for her. Brunger and Lippman (42) would agree. They conclude that genetic counseling is not a "one-size-fits all" endeavor; rather, it is information that is tailored to specific counselees in specific situations. For some, this would be considered a directive approach. However, authors such as Kessler or Singer would suggest that the counselor is facilitating the goal of genetic counseling by providing information upon which counselees can make autonomous, independent, and informed decisions (41).

One of the often quoted mechanisms for deciding whether or not a counselor is being directive is to ask whether or not counselors answer questions such as "What would you do in my situation?" Michie and colleagues (43) analyzed 131 transcripts of genetic counseling sessions and quantified directiveness based on how often counselors provided advice (what was best for the client), evaluation (provided views about an aspect of the counselee's situation), and reinforcement (provided statements that affirmed or rejected a counselee's behavior, thoughts or emotions). The authors found a mean of 5.7 advice statements per counseling session. Moreover none of the genetic counselors in these sessions rated their counseling as "not at all" directive. Interestingly there was no significant association found between any of the measures of directiveness and such outcome measures as satisfaction with information, nor any information on whether the counselees' expectations were met or on the amount of anxiety and concern (43). Bernhardt concluded that the study found that the practice of genetic counseling "is not characterized ... as uniformly nondirective" (43, p. 40), and that it provided "data to substantiate the long held impression that nondirective genetic counseling is impossible to achieve" (44, p. 17). Kessler interpreted Michie and colleague's data differently based on a definition of directiveness that emphasizes coercion. He noted that if there is an attempt by the counselor, through deception, threat, or coercion, to undermine the individual's autonomy and compromise his or her ability to make an autonomous decision, that can be defined as directiveness (37). Moreover Kessler points out that one does not have to answer the "What would you do" question to be directive.

In a study by Bartels et al. (45), 781 members of NSGC were surveyed to assess how they defined nondirectiveness and what they actually did in practice. Of the 383 respondents, 96 percent reported viewing nondirectiveness as very important; however, 72 percent stated they were sometimes directive. Bartels concluded that although nondirectiveness was a goal of genetic counseling, it was not the only goal. They found that counselors made important distinctions between concerns for directiveness about the decision-making process and directiveness about decision outcomes. Counselors noted that they should take responsibility for directing a counseling session such as clarifying counselee expectations and questions, sharing genetic information, and facilitating understanding and communication. Counselors felt that recommending genetic or medical testing was consistent with informed consent, and that principle outweighed

being nondirective (45). However, counselors were more conflicted regarding decision outcomes such as having counselors share personal biases or values with their patients. The study participants described the need to be very careful in what and how these values would be presented. However, once counselees made a decision, genetic counselors felt that the decision should reflect the counselee's values and not the counselor's values.

While the literature regarding nondirective counseling remains unsettled, research suggests that nondirectiveness is not the only guiding principle employed by genetic counselors. In their efforts to provide and facilitate autonomous, independent, and informed decision making by counselees, genetic counselors strive to maintain a delicate balance between a nondirective stance and enhanced counselee understanding.

Reimbursement. The issues of financial reimbursement of genetic counseling services is also of major concern to genetic counselors. Currently there is a paucity of literature that speaks to reimbursement of services provided by counselors. In most instances, reimbursement for genetic counseling services provided by a genetic counselor is under the control of the physician provider. While nonphysicians can bill insurers for their services, they may or may not be reimbursed as some insurers do not recognize nonphysicians as health care providers. Moreover Medicare and Medicaid require that professional services of a nonphysician must be rendered under the physician's direct supervision (Medicare Part B Carriers Manual). Currently the Economics of Genetic Services Committee of the American College of Medical Genetics is working with the American Medical Association CPT Editorial Committee in an effort to obtain billing codes that are more representative of genetic services (46).

NSGC has also actively pursued licensure as a possible avenue to improving the reimbursement of services provided by genetic counselors. Currently the only state considering licensure of genetic counselors is California (47). A continuing and frustrating challenge for genetic counselors is to seek avenues of reimbursement within the context of a managed care environment. Another challenge remains how to educate other health care providers, hospital administrators, insurers, and the public to the skills and expertise that genetic counselors have to offer.

OTHER HEALTH PROFESSIONALS

Medical genetics is fast becoming central to the delivery of health care and preventive services. This process is in large part due to the progress in the Human Genome Project which promises, and in some cases has brought to fruition, wide-ranging applications in the diagnosis, treatment, and prevention of human diseases (48). Gene testing for a number of different disorders is now available to large segments of the population. For example, gene testing for breast and colon cancer susceptibility is available for individuals with a positive family history (49), an NIH Consensus Development Conference (50) has advocated offering DNA-based carrier testing for cystic fibrosis to pregnant couples, and population screening is being considered for hemochromatosis (51). These advances, coupled with inquiries regarding genetic testing from patients, have made it increasingly necessary for primary care providers to be informed about genetic information and testing. Ideally genetic services are best provided by geneticists and genetic counselors who have had extensive training and exposure to the complex genetic principles and issues regarding genetic testing, screening, and counseling. Although genetic counselors remain the "gold standard" for the provision of genetic services, there is a growing demand that other health care providers be able to provide some of these services. Nevertheless, it is evident from a number of studies that neither physicians nor nurses, the primary sources of health care, have received the training and knowledge needed to deal with the proliferation of new genetic information. Two recent surveys, one of physicians and one of nurses, demonstrated that while the majority of health care professionals stated they were providing some genetic related services (at least occasionally), provider knowledge of genetics was fragmented and uneven (52,53). Giardiello (54), in a study of the use and interpretation of gene testing for Familial Adenomatous Polyposis (FAP), found that one-third of physicians ordering the tests were misinterpreting the results and did not fully understand their meaning. The authors concluded that the "use of genetic counseling before testing would be expected to eliminate many ... errors" (54, p. 826).

With the move toward managed health care and a focus on primary care, it is the physicians and nurses who will now be ordering and interpreting many genetic tests, providing genetic counseling, and assuming responsibility for obtaining informed consent and protecting client privacy. In an effort to rectify some of the knowledge deficit, a number of organizations have come together to ensure that health professionals are prepared for this era of genetic technologies and testing. The National Coalition for Health Professional Education in Genetics (NCHPEG), a group of professionals spearheaded by the National Institute for Human Genome Research, the American Medical Association, and the American Nurses Association, has brought together genetics and other health care professionals to ensure that physicians and nurses have the knowledge, skills, and resources to integrate new genetic knowledge and technologies into the prevention, diagnosis, and management of disease (55). NCHPEG has established a number of goals for developing and implementing a comprehensive genetics education initiative. Its goals include persuading health care organizations to establish genetics education as a top priority; creating mechanisms for collaboration between genetics professionals, other health care professionals, consumers, industry, and government; and identifying existing and future genetics education activities.

Primary health care providers may assume a number of different roles in the care they give to individuals who have or are at risk for a genetic disorder. There are major areas and roles identified by both physician (56) and nursing genetics professionals (53), in which all primary care providers should be knowledgeable. These include

(*1*) identifying individuals and families who would benefit from genetic services and counseling; (*2*) knowing how to obtain genetic services once a risk factor for a genetic disorder has been identified, (*3*) being able to interpret risk factors and information in genetic test results and explaining the information to patients and their families, and (*4*) having a foundation to read and interpret the medical literature in order to provide competent guidance to patients and families regarding their questions about genetic testing, gene therapy, and genetic disorders. Additionally primary care providers can help families learn about what to expect in terms of a genetic evaluation and the genetic counseling; they can coordinate care for the family by assisting in the arrangements for diagnostic testing, referrals for further evaluations, and appointments with other specialists if appropriate; and they can reinforce, interpret, and clarify information obtained during a genetic counseling evaluation. Certainly the primary care provider could continue to assess family dynamics, coping strategies, and other psychosocial responses and serve as a resource person and educator to his/her patients and families regarding birth defects and genetic disorders.

These roles and responsibilities, however, should not be construed as a substitute for referring patients and families for genetic services and counseling. Ideally the primary care provider will work in partnership with the genetic counselor and recognize that a major component in the genetic counseling process is the opportunity to generate a dialogue that will result in a patient being able to make an informed decision. This is particularly necessary in presymptomatic or susceptibility genetic testing, such as Huntington disease and BRCA1 and BRCA2 testing for breast cancer, or in screening programs such as cystic fibrosis (50). The dialogue becomes part of an informed decision-making process rather than merely the transmission of information (57). Counseling skills required for such interactions must combine respect for a patient's right to make an autonomous decision with an appropriate level of support to facilitate the decision-making process. Genetic counseling provides this component and blends the informational, educational aspect of the counseling session with a dialogue on the benefits and risks of a genetic test. Rarely does a primary care provider have the time or specific training to be responsible for this process.

SUMMARY

The advent of recombinant DNA research and the initiation of the Human Genome Project has produced a revolution in human genetics. Every week scientists announce the identification and chromosomal location of another gene associated with a human genetic disorder. With these discoveries comes the ability to test for these disorders, both diagnostically and predictively. For some people it may mean the development of new treatment strategies. It is imperative that health professionals, in particular primary care providers, be informed about human genetics, genetic testing, and the ethical, legal, and social issues that accompany these areas of research and practice. Primary care providers are on the front line of providing health care services to families. Thus they need to be able to identify, assess, counsel, and refer patients, clients, and families with or at risk for genetic disorders and birth defects.

Finally, as new tests for carriers are developed and the diagnosis of genetic conditions and genetic susceptibility to disease continues to grow, the number of individuals utilizing genetic services will also increase. As the number of individuals and families seeking services increases, the need for genetic counselors to provide quality genetic counseling will also grow. Genetic counselors, utilizing their expertise and skill within the genetic counseling process, will be needed to explain facts, educate patients regarding inheritance and recurrence, provide counseling about benefits and risk, aid in decision making, and help set public policy. Well-trained, board-certified genetic counselors will continue to expand their presence in a number of settings: in hospitals and clinics to counsel families who are affected or may be at risk for genetic disorders; in diagnostic labs as resources for physicians and their patients; and in government agencies to design genetics education programs for health care providers, shape public health policy, and develop more effective ways of communicating the many new findings to employers, insurers, and the general public.

GENETIC DETERMINISM, GENETIC REDUCTIONISM, AND GENETIC ESSENTIALISM

ROBERT WACHBROIT
University of Maryland
College Park, Maryland

OUTLINE

INTRODUCTION

In the public debate over the significance of genetic discoveries, the terms "genetic determinism," "genetic reductionism," and "genetic essentialism" are often used interchangeably. This is unfortunate because these terms refer to quite distinct claims about the importance of genes, claims that vary greatly in their plausibility, their implications, and their popular acceptance. Thus, for example, few people would accept genetic determinism, but many would subscribe to doctrines that are characteristic of some version of genetic reductionism or essentialism. The purpose of this article is to clarify what each of these terms mean, and how they differ from each other. The first, I will show, is a claim about causation; the second, about explanation; and the third, about identity.

Being clear about these terms is not just a matter of lexographic tidiness; it is critical for avoiding serious misunderstanding. The significance of this misunderstanding can be illustrated by contrast with another common confusion in the area of genetics; between genes and alleles.

Articles and discussions about genetics often confuse genes and alleles, using "genes" when the proper term should be "alleles." But this muddle is usually harmless. The knowledgeable and attentive reader can usually understand which term the writer intends even if they happen to be misused at the time. No significant issue is raised by this common conflation.

The situation is quite different with regard to the above "isms." Many writers reject what they regard as an inflated importance attached to genetics by rejecting genetic determinism, genetic reductionism, or genetic essentialism. These three positions are, however, quite different ways of articulating what the importance of genetics consists in. Not only does one not entail either of the other two, but also, as we will see below, each raises different significant issues.

The underlying assumption of this article is that the semantic structure of these "isms" should be taken seriously: Genetic determinism is a kind of determinism. Its implications, significance, considerations for and against, should be shaped by the history of the dispute over determinism itself. Otherwise, the expression is misleading. Similar assumptions hold for genetic reductionism and genetic essentialism. If they are not a kind of reductionism and a kind of essentialism, respectively, then we need to be told what they mean.

Finally, let me repeat, the purpose of this article is to clarify succinctly the differences between these "isms." The aim is not to provide a comprehensive survey of the many issues and the extensive literature surrounding these terms. If interested, the reader is advised to look to the bibliography.

DETERMINISM: GENETIC AND OTHERWISE

Determinism is a thesis about universal causation — every event has a cause sufficient for its occurrence. Thus identical states of the universe would have identical outcomes (1). The phrase "genetic determinism" would, strictly speaking, mean that every event has a genetic cause that is sufficient for that event's occurring. No one takes genetic determinism in this way. It is usually understood to be restricted to a specific class of events or properties — such as organism's physical and mental traits. Thus genetic determinism is the thesis that an organism's physical and mental traits are entirely the causal result of its genes.

So understood, the general consensus is that genetic determinism is false. This view is embedded in the standard distinction in genetics between an organism's genotype — the combination of the organism's genes — and its phenotype — its set of mental and physical traits. Genes alone do not yield any traits; various environmental factors must be present for the trait to arise. Regardless of how close the tie is between a certain gene and trait, there is always an environment where the presence of the gene does not result in the presence of the trait, including hostile environments in which the organism does not survive long enough to develop the trait.

Nevertheless, noting that genetic determinism is false does not mean determinism is false as well. One could reject genetic determinism and still hold that the combination of genes and environment determines traits. Or one could reject determinism even for the genes plus environment combination, noting the role of various stochastic processes in the development of traits (2, chap. 2). As we will see, this difference affects the significance of claiming that genetic determinism is false.

The significance of genetic determinism lies in its implications for predictability and manipulability. If genetic determinism is true, then it should be theoretically possible to predict people's traits solely from a knowledge of their particular genes. Furthermore the only way to alter an individual's particular trait would be to manipulate the relevant genes. If the rejection of genetic determinism is a rejection of determinism, then predictability and manipulability are also rejected. But if genetic determinism is rejected in favor of a "genes plus environment" determinism, then the rejection is much less significant. Prediction is still theoretically possible, though practically much more difficult given the complex variety of environmental factors that need to be considered. And manipulability becomes theoretically easier since there are now more options available.

Despite the widespread rejection of genetic determinism, we should acknowledge the occasions when researchers will talk about a gene "determining" a trait — for example, they might say that having a certain structure on chromosome 4 determines that the individual will develop Huntington's disease. This expression of genetic determinism rests on a special restriction on the events being considered. All circumstances in which the individual dies before he manifests the disease are being excluded. Furthermore we are confining attention to only known circumstances — no one is denying that researchers might some day discover that currently unknown circumstance in which we are able to prevent or cure that disease. Once these restrictions are understood, such talk does not really amount to an endorsement of genetic determinism.

REDUCTIONISM: GENETIC AND OTHERWISE

Reductionism is one of the main topics of modern philosophy of science, and during that time it has undergone considerable sophistication and complexity in its formulation and arguments. For a standard introduction, see Ref. 3. For an advanced discussion of this topic as applied to genetics, see Refs. 4–6. Fortunately, for our purposes, many of these details can be ignored. The core claim of reductionism — a thesis about the relation between two kinds of things (X and Y) — is that X's are nothing but Y's. Different ways of specifying the meaning of the relation "is nothing but" as well as the different sorts of things at issue yield different types of reductionism. For example, taking the "is nothing but" relation to be that of composition, we get a class — sometimes called "ontological" — of reductionist positions. Illustrations from the physical sciences provide some of the least controversial examples, such as "physical objects are nothing but swarms of atoms" and "water is nothing but hydrogen and oxygen."

One of the most familiar reductionist positions in this class is variously called "materialism" or "physicalism." It is roughly the view that everything is nothing but atoms, parts of atoms, and their interactions. This reductionism is a central principle of modern biology. Biologists reject vitalism and instead believe that biological objects are composed entirely of the stuff of physical objects — molecules, free-floating atoms, electrons and the like.

Genetic reductionism, understood ontologically, is the position that organisms consist of nothing but genes. It should be clear that no one is a genetic reductionist in this sense since the position is so obviously false. We are clearly composed of more than just DNA molecules. Indeed, the occasional expression such as "we are nothing but our genes" cannot be seriously meant literally. It must be understood as figurative way of referring to a different sense of reductionism, to be described below. Thus, while all biologists, including geneticists, are reductionists, in the sense of being materialists, no one is a genetic reductionist, understood ontologically. There is therefore no need to discuss it further.

The other major class of reductionist positions are those where the "is nothing but" relation is understood in terms of explanation and Y is understood as a theory. X can itself be a theory, where Y is a more fundamental or basic theory than X. Or X can be a representation or description of one type of phenomena, and Y is a theory typically about phenomena of a different, more fundamental realm. As opposed to ontological, this class of reductionist positions is sometimes called "epistemological" or "methodological." Fairly uncontroversial examples from the physical sciences would be "chemistry is nothing but physics" and "heat is nothing but molecular motion." In the first case, the thesis is that chemical theories can be reduced to physical theories: For example, the correctness of explanations in chemistry can be explained by physics. In the second case, the thesis is that heat, a phenomenon characterized by thermodynamics, can be explained by the more fundamental theory of statistical mechanics. In the end, both types of cases are similar: Chemical explanations can be replaced, at least in principle, by physical explanations; thermodynamic explanation can be replaced, at least in principle, by statistical mechanical explanations. Their differences are more in the methods of achieving reduction. In the first case, reduction is achieved by translating or associating the language of one theory into the language of a more fundamental theory; in the second case, reduction is achieved by directly explaining the phenomenon by using a fundamental theory.

Genetic reductionism, understood in this sense, can refer to either the thesis that biological explanations can be translated into or reformulated as genetic explanations or the thesis that biological phenomena can be explained by genetics. As we will see, unlike genetic determinism, genetic reductionism is an open question. It depends on how the science of genetics develops. Given the present state of the science, genetic reductionism is at best a working hypothesis, although some scientists claim that it is not a particularly promising hypothesis. In any case, whether genetic reductionism is true or false is an empirical matter.

Assessing the truth of genetic reductionism plainly turns on our understanding of what constitutes a genetic explanation. A precise characterization of genetic explanation is challenging, especially since there is considerable dispute over what constitutes an explanation (particularly explanations in biology!), but the intuitive idea is fairly clear. An explanation of a phenomenon is genetic just in case all the nongenetic activities or interactions that are part of the phenomenon are relegated to the background or are deemed to have minor importance. Thus a genetic explanation does not need to deny the existence of any nongenetic activity. Consider, for example, the genetic explanation for the probability of inheriting a certain (i.e., Mendelian) trait. One begins by determining whether to associate the trait with a dominant or recessive gene, and then one calculates the probability that the gene will be transmitted to offspring. The role of environment in the development of the trait is not denied; it is relegated to a background condition, deemed not a salient factor in the cases to be explained.

Similarly nongenetic explanations, such as environmental explanations, need not deny the existence of genes or genetic processes. A sociological explanation of family dynamics need not deny that genetic processes typically play a role in the existence of families. Such processes are deemed background conditions.

Not surprisingly, just as there is a controversy over what is an explanation, there is a controversy over what constitutes a background condition. Some have suggested objective criteria — for example, if it makes a comparatively small contribution to the phenomena, it is a background condition. An illustration of this can be found in explanations of differences. Suppose that we wanted to explain the differences in health between monozygotic twins. One might argue that since there is little genetic difference between the twins, genetic factors will be background conditions. So the explanation of differences in health will not be a genetic explanation.

Others have suggested subjective or pragmatic criteria — for example, factors that are not salient for the context of inquiry are background conditions. An explanation is here seen as primarily a response to a particular question, which characterizes, explicitly or implicitly, certain factors as salient. For example, a traffic accident is the result of how the car functions and how the driver functions. Whether we explain the accident in terms of the driver's behavior or the car's functioning can depend on which is, from the context of inquiry, deemed normal. Normality — either in behavior or in functioning — is usually relegated to a background condition.

We need not pursue any further the details of the concept of a background condition — or of explanation or of theory — in order to discuss the significance of genetic reductionism. As a scientific hypothesis about the power and scope of genetic explanations, it is plainly important for scientific research. But, as we will see, it also has social and ethical significance.

From the standpoint of science, genetic reductionism is a thesis about the direction scientific research should take. If genetic reductionism is true, investigations that focus on the genetic aspects of biological phenomena are

more likely to come up with interesting or important results. The patterns that emerge are more likely to reflect fundamental principles of biology than accidental or derivative correlations. Moreover such research is more likely to discover unifying themes in that divers biological phenomena might be explicable by the same type of (genetic) explanation. Indeed, genetic reductionism indicates what constitutes progress in biology — being able to account for more and more biological phenomena in terms of genetics.

The social significance of genetic reductionism is closely connected to these scientific implications. Genetic reductionism suggests that the "real" explanation of a biological phenomenon is a genetic explanation. Even if a nongenetic explanation of a particular biological phenomenon were available, it would not get to the heart of the matter. Nongenetic factors play a relatively minor role. It is a short step from this to holding that the nongenetic is of little importance or value. The significance of this becomes especially clear in the case of explaining human behavior. If many of our standard ways of explaining human behavior — explanations in terms of character or in terms of motivation or in terms of intentions or in terms of beliefs, desires, and circumstances — are held to be not "real" explanations or are held to be genetic explanations in disguise, then it can seem that character, intention, circumstances, and so forth, are unimportant or are themselves reducible to genetics. Indeed, some writers reject genetic reductionism because they maintain that nongenetic factors can be important.

At this point it might be worth summarizing some of the differences between genetic determinism and genetic reductionism. Their clearest divergence is with interactionism — the view that both genetic and nongenetic factors play a causal role in most biological phenomena. Interactionism is incompatible with genetic determinism but can be compatible with genetic reductionism. Recall that a genetic reductionist can acknowledge nongenetic causal factors as long as they amount to no more than background conditions of proper scientific explanations of biological phenomena. Thus the falsity of genetic determinism does not entail the falsity of genetic reductionism. (Whether the converse is true — whether genetic determinism entails genetic reductionism — turns on issues concerning the relation between causation and explanation, which we cannot pursue here.)

ESSENTIALISM: GENETIC AND OTHERWISE

The general doctrine of essentialism is linked to a particular conception of what change and identity consists in. It begins with the question, What is the difference between an object changing and an object ceasing to exist and being replaced by a different object? According to essentialism, an object has two kinds of properties — essential properties and accidental properties. An alteration in an accidental property results in the object being changed; an alteration in an essential property results in the object ceasing to exist. For example, the temperature of gold is an accidental property; change the temperature, and the result is still gold, only warmer or colder. In contrast, the atomic number of gold is an essential property; change it by even one digit and the result is no longer gold.

Genetic essentialism is the view that the genetic properties of an organism are essential. Given the multitude of genes, genetic essentialism fans out into a spectrum of specific views. At the extreme is the view that every gene — and hence every genetic property — is essential; if even one gene in the organism changes, say, from some environmental damage, the result is a different organism. Indeed, there is no such thing as a harmless error in gene replication on this view. An error means that the organism has ceased to exist and a new one, albeit quite similar, is now in its place. Moreover gene therapy must be seen as logically impossible. A procedure that alters the gene of an individual could not be therapy for that individual, since the alteration would destroy the individual and replace him with another. Hardly anyone is a genetic essentialist of this sort.

The situation becomes more complicated once we consider changes in certain genes or in many genes. How many and which phenotypic traits of an organism would have to be different — and to what degree — in order for us to regard the result as no longer the same organism? Some might hold that changing the genes that determine the organism's sex results in a different organism. Others might hold that in the case of persons, altering the genes associated with mental capacities and abilities can result in a different person. And others might hold that only those genetic changes that constitute a different species result in a different organism. Where we draw the line — when (genetic) change becomes replacement — is the central controversy regarding genetic essentialism. It also indicates the conceptual limits of gene therapy since altering an essential property can never be therapeutic (7).

This last point has been especially important in discussions of the alleged paradox of "genetic harm," which refers to a harm that is the result of an abnormal gene. The paradox arises if the abnormal gene is an essential gene. In that case, removing the harm, altering the essential gene, would not be altering the organism — presumably for the better — but rather replacing that organism with a different one. It would seem then that treating genetic harms when they involve essential genes could never be beneficial to the individual.

Genetic essentialism makes no claim about causation and so is distinct from genetic determinism, as we would expect from general discussions in philosophy regarding essentialism and determinism. Essential properties need not be deterministic (i.e., sufficient causes) and deterministic properties need not be essential. But see Ref. 8 which treats genetic essentialism as incorporating theses of determinism and reductionism.

Nor need genetic essentialism have anything to do with genetic reductionism of either type. A genetic reductionist of the ontological type — one who believes that organisms are composed of nothing but genes — need not be committed to any view regarding which or how many genes are essential to the identity of the organism. This claim is in line with the larger view that materialism doesn't entail any view about which material is essential. A genetic

reductionist of the epistemological type — one who believes that biological phenomena can be entirely captured in genetic explanations — need not be committed to any particular genetic essentialism. Essential properties do play a critical role in the explanation of change — how an organism can remain the same even when some of its properties are different — but it plays no role in scientific explanations. In short, a genetic reductionist need not have any view about which genes, if any, are essential.

CONCLUSION

Advances in genetics have highlighted the role genes play in various biological phenomena. This increased attention to genetics has led to various assertions and denials of the importance of genes.

Genetic determinism, genetic reductionism, and genetic essentialism are three different ways of stating what that importance consists in. The primary purpose of this article has been to articulate these differences. Any useful discussion of where genes are important and where they are not, if it invokes any of these "isms," must be clear about what exactly is meant.

GENETIC INFORMATION, ETHICS, AND INFORMATION RELATING TO BIOLOGICAL PARENTHOOD

JEAN E. MCEWEN
National Human Genome Research Institute
Bethesda, Maryland

OUTLINE

INTRODUCTION

Genetic testing now makes it possible to determine parental and other familial relationships with a remarkable degree of accuracy. For this reason genetic testing in disputed paternity cases (at least in cases of the traditional type, where the paternity of a child born to unmarried parents is at issue) has gained increasing acceptance, and the ethical and legal concerns raised by such testing are lessening. However, new ethical and legal concerns are being raised in the growing number of cases in which either putative or presumed fathers seek genetic paternity testing to rebut the longstanding legal presumption that a child born to a mother during the course of a marriage is the biological offspring of the mother's husband. The practice of artificial insemination by donor is also creating new challenges in the area of forensic paternity determination.

As techniques such as surrogacy, egg donation, and embryo donation come to be used more widely, forensic challenges regarding *maternity* determinations can also be expected to arise with greater frequency. In addition the increased use of all types of alternative reproductive methods (coupled with advances in genetic testing more generally) is presenting courts with complicated questions regarding the posthumous determination of parentage or other familial relationships. Should human cloning eventually become feasible, the task of sorting through the myriad potentially recognizable familial relationships will become even more complex.

Unanticipated findings regarding parentage (or regarding other familial relationships) can also sometimes occur as a consequence of genetic testing undertaken for nonidentification purposes, raising challenging ethical and legal dilemmas. Incidental unexpected findings of misattributed paternity, in particular, occur quite frequently in the course of genetic testing. Several possible strategies are available for dealing with findings of this type, ranging from full disclosure, nondisclosure, partial disclosure, or disclosure only to the woman, to handling the issue through the informed consent process. However,

each approach carries with it a separate set of potential problems.

Previously undisclosed adoption, artificial insemination, or an incestuous mating within the family can also be inadvertently brought to light in the course of genetic testing. In rare cases, genetic testing may also reveal prior mix-ups, such as that two babies were switched in a hospital nursery, that sperm samples were switched in the course of artificial insemination, or that frozen embryos were switched during in vitro fertilization (IVF) procedures. These situations raise problems similar, although not identical, to those that arise when misattributed paternity is discovered, and they will require novel approaches.

GENETIC DETERMINATION OF PARENTAGE FOR FORENSIC PURPOSES

General Background

Objective scientific methods for the determination of biological parentage are a relatively recent development. Only a few decades ago the methods available for determining disputed paternity were limited and relatively primitive. Courts were typically required to calculate the date of the child's conception to determine whether or not the putative father could have conceived the child (1) and to make highly subjective assessments of physical resemblances (2).

Modern scientific tests provide far more reliable evidence of biological parentage by analyzing inherited characteristics: either the physical expression of the DNA in the child (phenotype) or the DNA itself (genotype) (3). The earliest phenotypic tests for paternity involved the ABO blood grouping system, but ABO testing, while capable of excluding an individual (i.e., ruling him out) as a child's father, could not make a definitive positive determination of paternity (4). However, ABO testing can be combined with other kinds of phenotypic testing, such as the analysis of red blood cell antigens, serum proteins, enzymes, and human leukocyte antigens (HLA) (5). When this is done, the cumulative impact of the test results including an individual as the child's father (i.e., placing him within a population of men who could be the father) becomes considerably stronger.

Direct genotypic testing of the DNA, which first became available in the late 1980s, provides an even more highly discriminating form of parentage testing. It can establish paternity (or maternity, if disputed) to degree that experts today agree is nearly conclusive (6). Every state in the United States now has a statute that provides for the admissibility of genetic paternity test results (7). Although the language of these laws varies, most states have patterned their laws on one of two model uniform paternity statutes: the Uniform Parentage Act (UPA) (8) or the Uniform Act on Paternity (UAP) (9).

State statutes vary in the statistical analysis methods (if any) that can be invoked in court to help describe the probative value of a test result including a man as the possible father. For example, some statutes require use of the "paternity index," which is the probability that a child born to the mother and the alleged father would have the observed phenotypes or genotypes divided by the chance of such types appearing in the child of the mother and a man randomly selected from the general population of men. Others require use of the "probability of paternity," which is obtained by multiplying the paternity index by the prior odds of paternity and converting the resulting "posterior odds" to probability form. Still others mandate the "probability of inclusion" (or exclusion) approach, which simply asks which proportion of the male population would be included (or excluded) as the possible father (10).

Regardless of the particular statistical analysis authorized, most state statutes mandate that when paternity test results reach a specified level (typically in the range of 95 to 99 percent), they create a rebuttable presumption of paternity; some statutes go even further and mandate a *conclusive* presumption of paternity when the results exceed a certain threshold (11). The growing confidence of legislators and courts in the reliability of genetic paternity testing, and federal child support enforcement legislation enacted in 1993 requiring all states to enact laws authorizing simple voluntary procedures for the establishment of paternity (12), have resulted in most disputed paternity cases now being settled by agreement of the parties without the need for trial (although statistical issues and questions regarding the adequacy of laboratory procedures are still often raised) (13). As the subjectivity and unreliability of the methods associated with earlier methods of determining paternity have been replaced by modern genetic testing, the ethical and legal issues associated with the determination of paternity (at least in the traditional situation involving unmarried parents and child support) have also gradually lessened.

Emerging Issues in Genetic Determination of Parentage

Rebutting the Presumption of Paternity. Although most paternity disputes continue to arise out of proceedings for the support of children born to unmarried parents, courts are increasingly being called upon to adjudicate paternity in other contexts. For example, notwithstanding the longstanding legal presumption that the parent of a child born during the course of a marriage is the mother's husband (unless the husband was sterile, impotent, or geographically distant at the time of conception), a growing number of putative fathers of children born to married mothers (i.e., men who are not married to the children's mothers but who believe they may have fathered the children) are filing lawsuits to rebut that presumption and assert various parental rights. Although the United States Supreme Court has held that such putative fathers have no right to challenge the presumption of paternity as a matter of constitutional law (14), the continued usefulness of the presumption might well be questioned in cases where undisputed evidence shows that the mother's husband could not possibly be the biological father.

In a related development, some former husbands of women who gave birth to children the former husbands believe were fathered by someone else have begun to challenge their own legally presumed paternity, typically in an effort to relieve themselves of postdivorce child support obligations. At the time of this writing, a petition for *certiorari* in a case raising this issue was pending before the United States Supreme Court (15). On the one hand, it

can be argued that no man should be compelled to support a child for whose birth he is not actually responsible, and that no court should be complicit in aiding such a fundamental deception. On the other hand, overfocus on biological parenthood in such cases, and underfocus on the role of social parenting, could harm the children involved, some of whom could be left altogether fatherless and with a great sense of betrayal should their presumed fathers be permitted so easily to relinquish responsibility. While a wrong may clearly have been perpetrated against the husbands in these cases, the question becomes whether the law should create the potential for an even greater wrong to be visited against the innocent children involved. Still, where a family situation has already deteriorated to the point that a man who has previously held himself out as a child's father announces publicly his belief that the child is not biologically his and states that he no longer wishes to be responsible, there may be little to be gained by perpetuating a legal fiction.

Paternity and Artificial Insemination by Donor. Continuing increases in the numbers of children conceived through alternative methods of reproduction, such as through artificial insemination by donor (AID), will further expand the range of cases in which courts will be asked to make forensic parentage determinations. For example, currently state statutes modeled either on the UPA or on the Uniform Status of Children of Assisted Conception Act (USCACA) provide that in a case of AID of a married woman, the woman's husband — not the sperm donor — is treated as the natural father of the child conceived (so long as the husband has consented to the procedure) (16). Likewise statutes patterned on the Uniform Putative and Unknown Fathers Act (UPUFA) accord no legal recognition to men who donate sperm under circumstances indicating that the donor did not anticipate having an interest in the resulting child (17). Moreover the current practice in AID is to keep the identity of sperm donors strictly anonymous, thus making it virtually impossible for anyone (including their resulting children) ever to trace their identity (18). For this reason genetic testing is unlikely to play a role in the establishment of biological paternity in the context of AID, at least for the immediate future. This could change, however, should the standard of practice for AID move toward the adoption of enhanced recordkeeping and liberalized disclosure policies. Significantly the anonymity that currently pervades AID is quite analogous to the secrecy and sealed records practices that for many years pervaded traditional adoption. The justification for such practices is increasingly being called into question as the public becomes more and more aware of the importance for every child of having access to a complete and accurate family history (19).

Genetic Determination of Maternity. Before the advent of modern reproductive technology, determining the *maternity* of a child was essentially never at issue. The woman who gave birth to the child was considered the child's mother as a matter of biological necessity. Increasingly, however, techniques such as surrogacy, egg donation, and embryo donation are raising questions regarding who should be recognized as the legal mother of a child so conceived when agreements involving the use of these technologies break down (20). The UPA expressly creates an action to declare the mother-child relationship but contains no specific provisions regarding the adjudication of such cases.

Surrogacy agreements are presenting especially novel challenges for the courts. There are two forms of surrogacy. In a traditional surrogacy arrangement, a woman agrees to be artificially inseminated with the sperm of the intended father (a man other than her husband), to carry to term the child thereby conceived, and to relinquish the child after birth to the intended father (and presumably also to his wife or partner). In a pure gestational surrogacy arrangement, by contrast, a woman agrees to carry an embryo created not through her own genetic material but through in vitro fertilization of the egg and sperm of the intended parents (or of a donated egg and/or sperm), and later to relinquish the child to the intended parents. The distinction between the two forms of surrogacy is thus that whereas the "traditional" surrogate mother both provides the egg for the pregnancy and gestates the baby to term, the pure gestational surrogate bears no actual genetic relationship to the child.

Judicial resolution of the question of who should be considered the child's legal mother in surrogacy cases has differed depending whether the underlying agreement was one for traditional surrogacy or gestational surrogacy. In the leading U.S. case, the New Jersey Supreme Court held that the woman who gestates (and provides the egg for) the child — not the partner of the man who contracted with her to bear the child — is to be treated as the child's mother (21). By contrast, in the leading case involving a purely gestational surrogacy agreement, the court held that while both genetic consanguinity and giving birth are recognized means of establishing a mother–child relationship, in cases where the two means do not coincide in one woman, the woman who intended to raise the child at the time the agreement was entered into — not the woman who gave birth — should be treated as the mother (22). The court distinguished this situation from a true "egg donation" situation, in which a woman gestates and gives birth to a child formed from the egg of another woman with the intent to raise the child as her own.

The USCACA is drafted so as to give states the option either to accord legal recognition to preapproved surrogacy contracts that meet specified statutory requirements, or to make surrogacy contracts unenforceable, and it specifically provides that except in those cases involving preapproved contracts, a woman who gives birth to a child is to be considered the child's mother. However, in states that have not adopted the USCACA or that have not otherwise clarified this issue legislatively, considerable uncertainty remains regarding the establishment of maternity in surrogacy cases, as well as in cases involving egg and embryo donation. Moreover, outside the United States, approaches to surrogacy have been quite different. For example, in most countries, in a contest between a genetic mother and a pure gestational mother, the gestational mother generally prevails (23).

Posthumous Determination of Parentage or Other Familial Relationships. Because DNA is present in almost all human cells and remains unchanged long after a person has died, DNA testing technology now makes it possible to make an accurate determination of paternity (or of grandpaternity, great-grand-paternity, or even more distant relationships) long after the putative father (or other more distant relative) has died (24). For this reason the advent of DNA testing has brought with it an increase in requests for exhumation of remains to conduct such testing. Persons may be interested in establishing paternity (or other family relationships) posthumously for a variety of reasons, ranging from establishing entitlement to inherit, immigrate, or receive government benefits, to satisfying concerns of purely genealogical interest.

In the 1990s DNA testing was used for the first time to support the claims of several persons long claiming to be descendants of deceased celebrities or historical figures, and there is reason to expect that the number of such cases will increase in the future (25). Issues may also arise posthumously concerning the parentage of children conceived through alternative reproductive methods. For example, the sperm of a man may be frozen and then used after his death to artificially inseminate a woman, resulting in the conception of a child months or even years later. In such a situation, resort to posthumous genetic testing may become necessary to establish the biological relationship between the resulting child and the deceased father. At least one such case, involving an application by Social Security survivor's benefits on behalf of a child, who was conceived by gamete intrafallopian transfer three months after the death of her biological father, has already been litigated (26). The Social Security Administration initially denied the claim, reasoning that because the child was born 13 months after her biological father's death, she could not have been his legal heir. However, the agency subsequently reversed its position, reasoning that conclusive proof of the child's biological paternity could provide a constitutional nexus for securing her entitlement (27).

The technology for the freezing of eggs has not yet developed sufficiently to allow for eggs to be fertilized and successfully implanted following the death of the woman from whom they were derived, but should this technology improve, analogous issues will arise as the resulting children seek posthumously to establish their genetic maternity. Related issues will also emerge as a growing number of children are created from embryos that have been cryopreserved for use in IVF procedures and that are not implanted until after (perhaps even many years after) the death of both biological parents. For example, in Australia, in the early 1980s controversy erupted when a married couple died simultaneously in an airplane crash after having frozen embryos for use in IVF. Because the couple was exceptionally wealthy, a question arose over whether the not-yet-implanted embryos should be provided to a third party for implantation — and if so, whether any resulting children would be legally those of the deceased couple (and thus eligible to inherit their estate) (28).

The USCACA would resolve some of the legal uncertainty regarding the posthumous determination of genetic parentage by providing that an individual who dies before the implantation of an embryo, or before a child is conceived other than through sexual intercourse, using the individual's egg or sperm, is not considered the parent of the resulting child. Once again, however, in states that have not patterned their laws on the USCACA, the resolution of these issues remains unclear. In fact, separate and apart from resolving issues of the *parentage* of children resulting from the use of such techniques, courts are still struggling with preliminary questions regarding the legal status of frozen sperm (29) and the frozen embryos (30) *themselves* — that is, whether they should be treated as property, as human life, or as something "in between."

Human Cloning and the Determination of Familial Relationships. Should human cloning (the creation of a human being through somatic cell nuclear transfer technology or a similar technology) someday become feasible, the task of sorting through the myriad potentially recognizable familial relationships will become even more complex. Although the National Bioethics Advisory Commission concluded in its 1997 report on human cloning that it would at this time be morally unacceptable for anyone to attempt to create a child using somatic cell nuclear transfer technology (31), it is nonetheless likely that successful attempts at human cloning will eventually occur, and when they do, the question will arise who is the "parent" of the clone. The process of cloning will result in a child having genetic material from as many as four individuals: the person from whom the cell nucleus was derived, that individual's two biological parents, and the woman contributing the enucleated egg cell (which contains a small fraction of mitochondrial DNA). In addition, if the egg with the transferred nucleic material is implanted in a surrogate gestational mother, the child will have two other potential parents: the gestational mother and (if she is married) her husband. There may also be intended parents unrelated to the person who is cloned, such as in cases where the cloned person is deceased or a celebrity (32). In such cases, not only will it be necessary to decide whether the child's genetic parent(s) should be given precedence over the biological (but nongenetic parent) or over the purely social parent(s), but it will also be necessary to determine who should be recognized as the child's genetic parent(s) in the first place.

GENETIC DETERMINATION OF PARENTAGE AS A CONSEQUENCE OF GENETIC TESTING FOR NONIDENTIFICATION PURPOSES

Findings of Misattributed Paternity

While genetic testing in the forensics context is the common way in which information regarding biological parentage or other familial relationships is brought to light, such information can also be uncovered inadvertently in the course of genetic testing undertaken for completely unrelated purposes, such as in clinical medicine. The common incidental finding that occurs in the context of nonforensic genetic testing is the finding of misattributed paternity (or sometimes grand-paternity). The true incidence of misattributed paternity is unknown,

and undoubtedly varies widely depending on geographical region, age group, and cultural or ethnic group, among other factors. However, 10 percent is the figure most commonly cited, and estimates as high as 30 percent have been proposed (33). While more recent studies suggest that both of these figures may be substantial exaggerations (34,35), the accumulated experience of large-scale genetic screening programs (e.g., newborn screening programs) shows that the aggregate number of children born each year whose paternity is misattributed is by no means insignificant.

The incidental finding that the presumed father of a child is not the biological father can arise in a number of situations, such as when several family members are being tested to locate a suitable donor for a bone marrow or organ transplant, to take part in genetic linkage testing, or to participate in other types of genetic risk assessment that require samples from multiple family members. In cases where testing for bone marrow or donor organ compatibility yields evidence of misattributed paternity, it is often possible to communicate the fact that the individual tested and the intended recipient (e.g., two half-siblings) would not be a good match without mentioning anything about misconceptions regarding the degree of their biological relatedness. This is because it is easy to explain the *fact* of a mismatch without going into the apparent *reason* for the mismatch; there may be many reasons other than misattributed paternity why two people might not be suitably matched for transplantation purposes. The nondisclosure approach in the transplantation situation can also probably be justified ethically and legally because at least in most cases the nondisclosure is unlikely to have any direct, potentially adverse, effect on the parties' future personal medical or reproductive decision making.

On the other hand, when a finding of misattributed paternity surfaces in the context of genetic risk assessment, the stakes are higher because genetic risk estimates are based on the assumption that the biological relationships assumed to exist within a family are correct. A person's misunderstanding about his or her biological relationship to other family members can confound the clinical determination of whether he or she is at increased risk for an inherited disorder or for passing on an inherited disorder — with crucial ramifications for health and reproductive planning.

A common situation regarding misattributed paternity occurs when genetic testing is sought to determine recurrence risk following the birth of a child affected with an autosomal recessive genetic disorder, for which both parents must be obligate carriers. In some cases the woman may already suspect that another man fathered her child, and may thus seek out counseling on her own without involving her husband or partner. However, where the woman does not realize (or is in denial of the possibility that) the child has a different father, the entire family may become involved. If carrier testing in such a case reveals the presumed father not to be a carrier, this means that he cannot be the biological father. The genetic counselor or other provider then faces a dilemma: how to convey to the couple the reason *why* they are not at increased genetic risk for bearing another affected child without simultaneously disclosing the fact that the child they already have must have been fathered by someone other than the husband (or other presumed father).

Reconciling the competing interests in cases like these can be very difficult, and no one strategy for resolving the issue is likely to be entirely satisfactory. In fact international surveys of genetic service providers performed as recently as the 1990s revealed a marked lack of consensus regarding the appropriate resolution of this dilemma, even though it is one that genetics professionals have been wrestling with for years (36,37).

Alternative Approaches to Handling Findings of Misattributed Paternity

Full Disclosure. One approach to the problem of misattributed paternity — the approach recommended in 1983 by the President's Commission for the Study of Ethical Problems in Medicine and Medical and Behavioral Research — is for the genetic counselor or other provider frankly to disclose the finding, including the conclusion that the recurrence risk in any future pregnancy of the couple is virtually zero because the existing affected child is not biologically the husband's (38). This approach accords maximal weight to the principles of autonomy and beneficence. It also reflects the practical consideration that deception regarding a child's paternity is likely eventually to be discovered in any event, and that in the long run, greater disruption to the family may result from this than from the frank revelation of misattributed paternity made when the information first surfaces in the clinical setting.

However, this approach can been criticized (at least in many cases) as placing form over substance, giving insufficient allegiance to the integrity of the family unit, and naive in its failure to recognize that many women — especially those who are in abusive relationships or who are economically disempowered — may suffer tangible detriment, in the form of physical, psychological, social, or economic harm, from the disclosure to their husbands or partners of misattributed paternity. In fact, in some cultures, the social environment may be such that an almost certain consequence of such a revelation would be clear harm to both the woman and the child. Indeed, it was this concern that led the Hereditary Diseases Programme of the World Health Organization to conclude that there is probably never a justification for a provider to reveal such a finding to a husband (39). Thus, at the very least, in cases where a decision is made to reveal information regarding misattributed paternity to both partners simultaneously, the provider should be prepared to offer appropriate psychological and other support.

Nondisclosure, Partial Disclosure, or Disclosure Only to the Woman. Another possible approach to dealing with findings of misattributed paternity is either to misrepresent the finding (or the basis for the finding) or skirt the issue in some other way, either through some form of partial disclosure or by telling the woman alone. The justification for this approach is that the genetic counselor owes greater loyalty to the integrity of the family unit than to any one family member, and that

for the reasons mentioned above, revealing the complete truth simultaneously to both the husband and wife could do more harm than good.

An approach that misrepresents the facts, however, is also problematic, both from an ethical and a legal standpoint. First, to the extent that overt deception is involved (e.g., explaining away the child's disorder, and thus the reason for the lack of recurrence risk, as merely a spontaneous mutation or some other anomaly, or explaining away the test results as having been confounded by a mix-up in the testing laboratory), it risks jeopardizing the provider's professional integrity and lowers the standards of practice (40). Moreover, if the explanations given are viewed by the couple as implausible, the approach is likely to engender suspicion and mistrust. In fact, should the deception eventually be discovered, the provider could conceivably be liable for medical malpractice.

A particularly risky practice from the standpoint of legal liability is for the provider to lie outright if asked by the husband whether he is in fact the biological father (41). Nevertheless, surveys indicate that many providers follow this approach, sometimes justifying it on the basis that because the genetic testing is not being done for the purpose of discovering paternity, they have no obligation to reveal the finding, even when asked. In fact two-thirds of all United States geneticists in one survey stated that they would not tell a man that he is not the father of a child, even if he asked (42). On the one hand, in cases where a genuine and serious risk of harm to the woman or to the family appears likely if the information were to be disclosed, this approach may have considerable justification. On the other hand, as earlier discussed, it can be argued that making a genetic counselor complicit in the woman's intentional deception is always unethical, that secrets of this type are in any event unlikely to remain buried forever, and that when the truth does come out, the well-being of the woman and the family may be even more seriously jeopardized than if the deception had never been perpetuated in the first place.

A form of partial disclosure that may be less risky legally but that still raises significant ethical concerns is simply to avoid any discussion of the specifics regarding actual recurrence risk (e.g., by characterizing the results as inconclusive), thus obviating the need to discuss the husband's noncarrier status. This approach, however, may lead the couple to make inappropriate future reproductive decisions based on the erroneous belief that they are both in fact carriers (and thus have a 25 percent chance of having another affected child), when the actual risk is close to zero. Based on this inaccurate assumption, the couple may later resort unnecessarily to artificial insemination by donor, forgo future pregnancies altogether, or even divorce and seek new noncarrier mates. If they do decide to conceive another child together based on the misapprehension that such a child is at increased genetic risk, they may suffer needless anxiety and incur needless risk and expense associated with amniocentesis or other prenatal testing that is not in fact medically indicated.

Another approach is to convey to the couple the actual risk (close to zero, in the example discussed) while withholding the information about genetic transmission that would explain the reason for the risk and raise suspicions regarding nonpaternity (the fact that in order for a child to be born with an autosomal recessive disorder, both parents must carry the gene). This approach, however, may leave the couple feeling anxious and confused and lead them to suspect that something important is being withheld.

Yet another approach is to relate the finding only to the woman (who is likely in many cases to suspect anyway that another man fathered her child) and leave with her the choice as to whether or how to tell her husband or partner. This approach — the approach recommended by the Institute of Medicine's Committee on Assessing Genetic Risks in its 1993 report (43) — avoids the above-described difficulties that may arise when such a finding is revealed by an outsider, and at the same time, requires no overt misrepresentation or skirting of the issues in the provider's conversations with the couple. However, the approach seems difficult to reconcile with the notion that the ethical and legal obligations of genetic counselors run equally to both partners (44). Thus, if this approach is followed, the potential psychological benefits of disclosure, including relief from the burden of keeping a secret and greater honesty in family relationships, should be stressed with the woman. However, the potential for adverse consequences should also be raised, and once again, the provider should stand ready to provide other necessary support.

Informed Consent Approach. An emerging approach to dealing with unexpected findings of misattributed paternity is to try to avoid many of the above-described problems by addressing the issue before the testing takes place, as part of the informed consent process. Under this approach the woman (or in some cases, both partners) are informed, prior to taking the test, of the possibility that misattributed paternity will be discovered. The woman (or the couple) can then (at least in theory) agree *in advance* on the way such information, if discovered, will be handled. This approach has the advantage of making the persons most likely to be affected active participants in any decision about disclosure. However, it too has limitations, due the practical realities of the context in which genetic testing typically occurs. The very inclusion of the subject of paternity among the subjects treated in an informed consent document may provoke anxiety, and where the woman is aware that misattributed paternity may be an issue, she may well "panic" in the situation, having never seriously thought before about the ramifications of that possibility. Even if the pre-test counseling is done separately, the woman may feel confused about how to now "get out of" a test she had previously seemed to agree to (before the possibility was called to her attention). In the end this approach could discourage some women who would like to obtain genetic information from participating in genetic testing — perhaps, in some cases, to the future detriment of themselves and their families.

Some genetic testing centers include in their standard informed consent form a reference to the possibility of an incidental finding of misattributed paternity, but

simply state what the center's policy is regarding the communication of such findings without giving the woman (or the couple) an opportunity to communicate her (or their) preference in this regard. This approach is problematic for many of the same reasons. In addition it is based on the (typically erroneous) assumption that a couple who is uncomfortable with a center's policy can simply "go elsewhere" for testing. Testing for some genetic disorders (particularly those that are relatively rare) may, as a practical matter, only be available at a single location. Insurance and other practical constraints may also limit a couple's ability to "shop around" for a center with a more favorable disclosure policy.

Other Possible Unanticipated Findings Regarding Familial Relationships

Misattributed paternity is not the only type of unanticipated finding regarding biological parentage that may surface when genetic testing is sought for nonidentification purposes. Genetic testing may also bring to light the fact that a child has been adopted, was conceived through donor insemination or another alternative reproductive method, or is the product of an incestuous mating (perhaps within the extended family). Situations like these raise ethical concerns similar to, but slightly different from, those present in cases where paternity has simply been misattributed by the mother to her husband or partner. Unlike in the misattributed paternity situation where disclosure of the finding is likely to come as a surprise to the presumed father, the basic facts surrounding an adoption, donor insemination, or incest will already (presumably) be known to both the husband and the wife. For this reason the risks associated with disclosure of the child's biological status are unlikely to interfere directly with the couple's relationship. The decision whether to disclose could, however, have crucial ramifications for the *parent–child* relationship, as well as for the child's own sense of psychological stability, because in such cases it is the child who has not yet been made aware of the family secret. Thus, once again, in these situations the genetic counselor is faced with a dilemma: Disclosing to the child his or her biological status may upset both the parents (who may arguably have sound reasons for opposing such disclosure) and the child (who may be upset by the revelation). On the other hand, *not* disclosing the information may make the counselor complicit in a deception that could ultimately be viewed by the child as a betrayal should the facts later come to light.

In general, where the child has not yet reached majority, it would generally seem appropriate for the counselor to respect the parents' wishes not reveal the information (although the counselor should advocate strongly that the child be told). Once the child has reached adulthood, however, the situation becomes more complex. In general, if the adult individual (perhaps suspecting that certain information has long been withheld) specifically *asks* whether the genetic test results reveal anything unusual regarding his or her parentage, it would seem ethically required for the counselor to reveal the information, even if doing so may upset the parents. If the adult individual does *not* ask, but if it appears that the information could be highly relevant to his or her own health or reproductive planning, the provider must balance the possible medical risks associated with nondisclosure against the possible psychological risks associated with a disclosure that turns out not to have been desired by anyone in the family (including the individual adult most directly affected) (45). The optimal approach is to try to anticipate such eventualities before the testing takes place, by raising the issue directly during the informed consent process.

Genetic testing performed in the context of clinical medicine may occasionally reveal that babies were switched (whether inadvertently or deliberately) in a hospital nursery. It may also bring to light the finding that sperm samples were mixed up in the course of artificial insemination (e.g., that the husband's sperm was confused with that of an anonymous donor, resulting in the birth of a child whom the parents had mistakenly believed was biologically related to both of them). Or, it may reveal that embryos used in the process of IVF were switched (e.g., where a woman gives birth to a baby whose phenotype suggests strongly that it had been fathered by a man of another race). In these cases any deception or other fault is unlikely to lie with either party to the marriage, but rather with the physician or other hospital personnel who were responsible for the mistake. For this reason the primary considerations underlying the decision whether to disclose will involve not so much potential risks to the mother's well-being as the potential for disruption to the family as a whole. The decision whether to disclose will also have important ramifications for the legal liability of the persons responsible for the original error. There are no easy resolutions in such extremely sensitive cases, and such cases are likely to arise even more frequently in the future as the number of children created through alternative reproductive methods continues to grow.

OUTLINE

INTRODUCTION

Research using human tissues and cells has contributed immensely to progress in the medical and basic biological sciences. These materials have been essential in developing and testing new drugs and vaccines, investigating infectious diseases, and exploring the mechanisms of virtually all disease processes. The use of human tissues and cells is also the foundation upon which much of the current biotechnological revolution has been based. The project to identify, map, and ultimately sequence the human genome would not be possible without the thousands of human tissue specimens from which DNA is routinely extracted and analyzed. Human tissues are also used for a variety of other medical purposes, including the transplantation of

whole organs (kidney, heart, liver, eye), the transfusion of blood and blood products, and diagnostic testing (blood chemistry, pathological identification of diseased tissues). In addition human tissues may be used in nonmedical contexts, such as the forensic identification of suspects based on trace tissues left at crime scenes, or the identification of the remains of soldiers.

As the collection, storage, and use of human tissues in biomedical research has increased, and the power of the scientific methods to analyze and unlock the secrets held within these tissues has grown, a number of ethical and public policy issues have been identified and debated in the research community. Traditionally excess tissues removed at the time of surgery or in other diagnostic procedures have been viewed as "waste" abandoned by patients and left to the disposal of the hospital or clinical lab. It has been presumed that patients would have no further interests in the disposition of their tissues and that most if not all would be glad to have medical researchers putting them to productive use. However, with recent advances in biotechnology, especially in the area of genetics, suddenly these "waste" tissues have become what one commentator has called a "coded future diary" of the individual and his/her family (1). Intimate knowledge about a person's medical condition (both their current status and potential future status) may be gleaned from the tiniest samples of human tissue.

Since many human tissues are used in research without the knowledge or consent of the persons from whom they are derived (tissue sources), the new-found powers of molecular and genetic analysis raise many difficult questions: What, if anything, should tissue sources be told about the results of research findings? Since information gleaned from tissue specimens, especially genetic information, can adversely affect an individual's employability and insurability, how can sources of research tissues best be protected from these social risks? Who *owns* these tissues and what rights, if any, do tissue sources have to financial gains derived from the use of their tissues in research? And, indeed, is "ownership" even an appropriate concept in this context? How do we protect individuals whose religious faiths or cultural practices impose special restrictions upon the disposition (or burial) of body parts? And, most important, should the informed consent of the tissue source be required for the research use of their tissues, and in what circumstances and how much information should be provided in the process?

HUMAN TISSUES: WHAT THEY ARE, AND HOW THEY ARE USED

Tissues (also referred to as "human biological material") can include everything from organs and parts of organs, cells and tissues (like bone, muscle, connective tissues and skin), to subcellular structures (e.g., DNA) and cell products, blood, gametes (sperm and ova), embryos and fetal tissue, and waste (urine, feces, sweat, hair, nail clippings, epithelial cells, placenta (2,3). Tissue specimens can be stored in many forms depending on both the reason for their collection, and their intended use: in paraffin blocks, slides, formalin fixed, frozen, tissue culture, extracted DNA, or dried blood spots (e.g., on Guthrie cards). Cryogenic storage is generally used for cord blood, gametes, and embryos.

Human tissues are collected and stored (or banked) through a variety of means and for a variety of purposes. They are most commonly collected in conjunction with diagnostic procedures or surgical treatment. For instance, at the time an individual has a surgical procedure to remove diseased tissue, that tissue may be examined to determine whether it contains malignant cells. The diseased tissue is generally preserved and maintained by pathology laboratories for several years (indeed, some tissue archives retain samples that were collected over 100 years ago). This storage of clinically derived specimens may be legally required in some states since they are regarded as part of the patient's clinical record. If questions arise at a later date about the adequacy of the laboratory testing of the specimen, the preserved specimen may be used to confirm (or refute) the original diagnosis.

Additionally excess diagnostic specimens may be used for follow-up clinical care, but most commonly they are used for educational and research purposes, as well as laboratory quality control. For instance, tissues can be used to ensure that equipment in diagnostic and pathological laboratories is functioning properly. Pathology slides may be used for the education of medical students and other specimens may be used to train technicians in testing procedures. Excess specimens are often made available to researchers for a variety of purposes. Fresh specimens may be cultured into immortalized cell lines which provide a perpetual source of DNA and may be used for a variety of other research purposes. Live tissues may also be cultured for use in pharmaceutical research. For instance, the first anti-viral drug for the treatment of AIDS — AZT — was initially demonstrated to be effective by testing it on HIV-infected cell cultures (4,5). Preserved pathological specimens may be used for a variety of research purposes, from studies of enzymes, proteins, and cell physiology to genetic analyses.

Many tissues enter into biomedical research through explicit research protocols. In gene mapping studies, for instance, DNA samples will be collected from entire families suspected of harboring a specific disease gene. Often, immortalized cell lines will be cultured from their blood samples to provide a constant source of DNA without having to return to the family members for further blood samples. Tissue specimens collected for one research purpose may also be used for secondary research investigations, either related to the initial research purpose or for completely unrelated research purposes.

Tissues may be stored in a variety of locations, depending upon the reason for their collection and their ultimate use. The storage facilities include military facilities, forensic DNA banks, government laboratories, diagnostic pathology and cytology laboratories, university- and hospital-based research laboratories, commercial enterprises, and nonprofit organizations (6). Tissue collections can range in size from fewer than 200 specimens to over 92 million, with a conservative estimated total of at least 282 million specimens (from over 176 million

cases) (6). The two largest collections of human tissue in the world (National Pathology Repository and the DNA Specimen Repository for Remains Identification) both reside within the U.S. Armed Forces Institute of Pathology (AFIP), which stores over 94 million specimens (3). An additional 13.5 million specimens are accounted for by newborn screenings, and an estimated 160 million or more specimens can be found throughout the various U.S. graduate medical education teaching institutions (3). These figures do not capture the additional information and tissues that may be found in cancer registries in many states, nor do they contemplate specimens that may be collected as part of the Human Genome Diversity Project.

In all these applications and uses, the tissues themselves can retain varying levels of identifiability — namely the ease with which the identity of the tissue source can be established. The protections afforded human research subjects in the United States are closely tied to how easily the identity of the tissue sources can be discerned. It is thus useful to lay out a general taxonomy of tissue identifiability:

- *Identified*. The tissue source is known and the individual's identity is tied to the sample. (This would be the case with specimens being analyzed for diagnostic and treatment purposes.)
- *Identifiable*. The tissue source is tied to the specimen through the use of a link (e.g., a code number), but the identity of the source is not directly known without tracing the link. Many pathology specimens, for instance, are archived according to a pathology record number.
- *Anonymized*. The tissue source's identity is irrevocably unlinked from the specimen, so that the individual's identity cannot be discerned (i.e., the tissue is unidentifiable).
- *Anonymous*. The tissue source's identity is never known, since the specimen is collected with no identifiers at all (i.e., the sample is unidentified).

It should be noted that as biomedical research progresses, becoming increasingly sophisticated in its ability to tease apart the molecular components of tissues and cells, the notion of having an "anonymous" or even "anonymized" sample will likely diminish, if not disappear altogether. In the future, determining the sequence of a tissue sample's (and tissue source's) DNA could become a routine procedure. If this were to happen in the clinical context, which is quite likely given the different analytical systems now under development (7), this information will invariably end up in a patient's medical record. Since these records are increasingly being stored and processed electronically, it could require only a small endeavor to match sequences from a medical record against the sequences from stored tissues. When that happens, the protections to safeguard tissue source identity currently in place, discussed in the next section, could become wholly inadequate to the task.

CURRENT FEDERAL REGULATIONS FOR PROTECTING HUMAN SUBJECTS IN BIOMEDICAL RESEARCH

The U.S. federal regulations (8,9) governing the use of human subjects in biomedical research establish three primary requirements intended to protect human subjects. First and foremost is the requirement for informed consent, which includes among other things a statement of the purpose of the research and its probable risks and benefits to the subject. Second is the requirement that all research involving human subjects be reviewed by an Institutional Review Board, (IRB) that is composed of other scientists and physicians, at least one nonscientist, and at least one member not affiliated with the institution. This committee is charged with evaluating the adequacy of informed consent, establishing that the research poses a favorable risk benefit ratio to the subject, and ensuring that the research design will yield useful results.

The third requirement is that institutions conducting federally funded research file an "assurance" with the Department of Health and Human Services (DHHS) Office for the Protection from Research Risks (OPRR), which administers and enforces the regulations. This assurance contains a statement of the ethical principles to be followed in conducting the research as well as the constitution of the IRB and its operating procedures. Institutions which conduct multiple research protocols may apply for a "multiple project assurance" which permits a single IRB to review each protocol. Institutions holding an MPA are required to ensure that *all* research involving human subjects conducted by their employees and affiliates complies with the regulations, including projects not funded by the federal government. Thus a wide array of research is subject to these regulations. There are approximately 450 institutions in the United States currently holding an MPA (10). Institutions which do not regularly conduct federally funded research may not be covered by these regulations. Privately funded research institutions, such as pharmaceutical firms, may engage in research involving human tissues outside of the regulatory context, including review by an IRB and requirements for informed consent. The Food and Drug Administration maintained until 1991 separate regulations governing research involving human subjects that was undertaken by drug and medical device manufacturers. In 1991, regulations governing research on human subjects conducted by the many agencies of the Federal government were consolidated into what is known as the Common Rule. However, the FDA maintains a separate system of enforcement (largely by audit) and its regulations do not cover the use of human tissues or medical records, but apply only to research conducted under the auspices of an Investigational New Drug application (IND) or an Investigational Device Exemption (IDE) as part of the FDA approval process prior to marketing. Thus, basic research conducted by private corporations and research labs prior to an application to the FDA for marketing approval is not regulated, unless these labs are otherwise regulated through their receipt of Federal funds.

The current regulations and the IRB system of peer review are recent phenomena that grew out of revelations

in the 1960s and 1970s of unethical research practices, including the infamous Tuskegee syphilis study. These abuses led to the first formal regulations issued in 1974 by the U.S. Department of Health, Education, and Welfare (HEW) (11). That same year, Congress passed the National Research Act, which established a National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, which was charged with reviewing all aspects of the involvement of human subjects in research and making recommendations to improve the system of protections. The National Commission issued a series of reports, including the *Belmont Report* (12) which set out the broad ethical guidelines that research involving human subjects should follow. The Commission also issued specific recommendations regarding the IRB review process. HEW was required by law to codify these recommendations into its regulations. Proposed regulations were published in 1979 by HEW (13) and after public comment, were finally adopted in January 1981 by what had then become DHHS (14).

The research use of tissues (and medical records) was explicitly considered by the National Commission and as part of its recommendations to HEW, the Commission suggested that these research projects need not obtain informed consent provided that "the importance of the research justifies the invasion of privacy" (15). The National Commission recognized that the use of human tissues and medical records constituted an "invasion of privacy," but argued that if adequate safeguards to protect individual's confidentiality were provided, this research was of minimal or no risk to subjects and could proceed in the absence of informed consent. Nevertheless, the Commission's recommendation would have required IRB review of all such research protocols. The National Commission also recommended that institutions that anticipate using tissues and records in research should in lieu of informed consent, notify all patients and provide a mechanism (i.e., a blanket consent) by which they could opt out, if they so desired.

However, in codifying these recommendations, HEW opted not to follow completely the National Commission's recommendations. Concerned about IRB workloads and convinced that much of this research was of minimal or no risk, HEW instead proposed two exemptions for such research from the IRB regulations. In addition, in these cases, HEW provided that IRB's could waive or modify informed consent.

The first exemption from the requirements of IRB review and informed consent is implied by the definition of "human subject" and the statement [at 45 CFR 46.102(f)] that the regulations apply only to research involving *human subjects*. It is possible that some research protocols can claim that their use of human tissues, under narrowly defined circumstances, do not involve human subjects as defined, and therefore the regulations do not apply. The second exemption is an explicit exemption governing the use of existing specimens and records, provided only that investigators do not record any patient identifiers or links to identifiers. Protocols that meet the requirements of either exemption may proceed in the absence of IRB review and in the absence of any informed consent, unless state laws or institutional policies provide otherwise.

For protocols that do not meet the requirements for either exemption, it is possible that the IRB nonetheless may permit a waiver or modification of informed consent. There are four conditions to be met before an IRB may waive or modify consent. Because of their ambiguity and because they point to important ethical issues, the discussion of these conditions below will extend to some of the important ethical and policy questions surrounding the use of human tissues in research, including the recontact of tissue sources with research findings, the ownership and commercial use of tissues, as well as the potential risks to which new biotechnologies may give rise.

Research protocols involving the use of human tissue that do not meet any of the above conditions for exemption or waiver of consent are required to obtain the informed consent of the subjects. Many tissue protocols may follow standard informed consent requirements used at the investigator's institution, but some protocols, especially those involved in genetics research, may require special considerations.

Exemption Implied by the Definition of "Human Subject"

This first exemption from IRB review arises out of the regulation's definition of "human subject." If a research protocol can demonstrate that it does not involve human subjects, then the regulations do not apply. The regulations define "human subject" as a "living individual about whom an investigator (whether professional or student) conducting research obtains" either of the following: (*1*) data through intervention or interaction with the individual, or (*2*) identifiable private information (§46.102(f)).

Interventions and Interactions. Criterion 1 is an important consideration because obtaining human tissues may often require some intervention or interaction with a person, usually an invasive procedure such as a needle stick to draw blood, or a tissue biopsy. Since these procedures may involve pain or risk harm to subjects, the regulations require that the interventions be subject to the oversight of an IRB, though it is possible that the IRB may waive the requirement for informed consent (see below).

One circumstance that easily gives rise to confusion in the application of this criterion is when tissues are removed from a patient for clinical reasons. If the attending physician is also a researcher who hopes to use some of the tissues for research purposes, and if the diagnostic procedure is genuinely clinically indicated, then the physician might assume that there is no interaction or intervention which would not have taken place in the absence of the research use of the tissue. However, the regulations do not distinguish between such dual roles of clinician and investigator. If the clinician is also an investigator, then, by definition, there is interaction, if not intervention, by the clinician qua investigator — whether or not the procedure is ordered solely for clinical purposes. The duality of roles in such cases presents the possibility that individuals may be subjected to research procedures under the guise of clinical care, or at the very least that a clinician's judgment may be influenced by his or her research interests, and thus would modify the patient's

care accordingly. Such modifications of patient care for research purposes, however, present the possibility of further risks to these subjects, and as such, the regulations require at least the oversight of an IRB to evaluate those risks, and to advise the investigator on appropriate procedures and safeguards.

Identifiable Private Information. Many protocols that seek to collect, store, and experiment on human tissues use excess tissues from clinical procedures with which the investigators are not associated. These tissues may be gathered from blood banks, blood chemistry labs, pathology labs, cytogenetics labs, or any other clinical diagnostic laboratory. Since more diagnostic specimens are routinely collected than are strictly necessary to perform the clinical tests and analyses, there is often excess tissue which may be made available to investigators. In these cases, research protocols can clearly meet the first criterion in the definition of human subject, namely that the protocol does not involve any intervention or interaction with an individual.

In order to meet the second criterion of the exemption, however, the investigators must not obtain any "identifiable private information." OPRR has interpreted this phrase to mean that if investigators have access, *however briefly*, to individual identifiers (such as names or social security numbers) or to links to identifiers (such as a medical record number or pathology record number or other such code) then the research involves human subjects as defined and the protocol would fail this exemption (16).

While some research protocols involving human tissue may be able to use anonymized tissue specimens, more powerful research can be conducted on identified or linked specimens. By maintaining a link back to the originating laboratory and/or the medical record, it is possible to update a tissue bank's database with subsequent morbidity and mortality data from the sources of the tissue specimens. Several tissue banks and tissue procurement services exist (17) or have been proposed in the literature (18) that are designed to maintain a one-way flow of information from medical record to tissue bank and on to individual investigators, while ensuring through the use of codes that no research information finds its way back to individual patients or subjects. Since some research, especially in genetics, can generate sensitive information about an individual, it is important to maintain a clear distinction between research results and clinical information in order to protect the source from the harmful consequences of research as well as from the uncertainty of results that have not been further validated. While such one-way tissue banks make very powerful research tools, they would fail to meet the exemption implied by the definition of "human subject," since they must maintain linking codes back to the originating laboratories and ultimately back to patient identifiers.

Exemption for Existing Tissues and Medical Records

The second exemption for research involving human tissues is in Section 46.101(b) of the regulations and it lists a number of specific exempt categories of research. Most of these categories pertain to educational, social or psychological research which involve the use of surveys and questionnaires. However, §46.101(b)(4) explicitly addresses the use of tissues and medical records in research. It exempts:

> [r]esearch involving the collection or study of existing data, documents, records, pathological specimens, or diagnostic specimens, if these sources are publicly available or if the information is recorded by the investigator in such a manner that subjects cannot be identified, directly or through identifiers linked to the subjects.

The key determination in applying this exemption is that the research materials must be *existing*. OPRR has clarified the interpretation of "existing" to mean that the materials (specimens, medical records, etc.) must be already existing *at the time the research is proposed* (19). Thus this exemption only applies to tissues and records that have already been produced and are being stored when the protocol solicits exemption status from the IRB. Such protocols are typically referred to as *retrospective*. Although the historical record of the promulgation of these regulations does not discuss the reasoning behind this limitation, it can be easily seen that it serves two purposes. First, because the specimens must already be in existence and therefore will already have been removed from individual patients, it would be impossible for investigators to influence clinicians — diagnostic technicians, surgeons, and so forth — to alter their procedures to obtain more or different kinds of tissue than they would otherwise remove in the course of clinical care and diagnosis.

Second, it would be much more difficult and in many cases impossible to recontact former patients to inform them of the intentions of the investigators to use their tissue specimens in research and to ask their consent. Many patients will have moved or died and recontact could only be made at great expense; expense that would be prohibitive for many research protocols. It is also possible that sampling bias might result if investigators were limited to only those tissues for which consent could be obtained.

It should be noted that this exemption does permit investigator access to patient identifiers, though it requires that investigators *record* no identifiers or links to identifiers. The purpose of this limitation is the same as that expressed in the limitation under the definition of "human subject" that investigators obtain no "identifiable private information." Because the exemption for existing specimens is more liberal in permitting investigators access to identifiers, the first exemption based upon the definition of "human subject" applies primarily to *prospective* protocols, that is, protocols that seek to collect specimens produced or procured after the protocol is proposed to the IRB.

While tissue banking and collection protocols that meet either of these exemptions are therefore exempt from the federal requirement of informed consent, the regulations do not preempt state laws. While some states laws defer to the federal regulations in matters concerning the protection of research subjects, other states may have independent laws and regulations governing human

subjects research. Before investigators proceed on the basis of exemption from the regulations they, or their IRBs, would be prudent to confirm their compliance with local law.

Who Decides What is Exempt? One problem in applying the exemptions that is not addressed in the regulations is deciding *who* determines what is exempt in the first place. Applying the exemption categories can be complex and confusing. Investigators may easily misinterpret them and fail to submit to the IRB research that in fact would not be exempt and may in fact even require informed consent. The MPAs at some institutions may require that the IRB or IRB chair make this determination. In other cases, it may be institutional policy that only the IRB may make exemption determinations. This is the safest policy, provides for a uniform application of the regulations, and limits the possibility that institutional funding could be jeopardized by the failure of an investigator to properly interpret the regulations.

Conditions Necessary for the Waiver of Informed Consent

For protocols that do not meet the criteria for exemption from the regulations, as described above, the possibility remains that the IRB could waive or modify the requirements for informed consent, as provided for in §46.116(d). In order to do so, the IRB must find and document that a protocol meets all four of the following conditions:

1. The research involves no more than minimal risk to the subjects.
2. The waiver or alteration will not adversely affect the rights and welfare of the subjects.
3. The research could not practicably be carried out without the waiver or alteration.
4. Whenever appropriate, the subjects will be provided with additional pertinent information after participation.

The discussion that follows will look at the ethical issues that arise in the application of each of these four conditions, since many of the issues that arise in tissue research will do so within the context of one or more of them. The more general ethical question of whether informed consent should or should not be required for these protocols (and this includes the exemptions) will be taken up later in this article.

Minimal Risk. Minimal risk is defined in the regulations at §46.102(i):

> Minimal risk means that the probability and magnitude of harm or discomfort anticipated in the research are not greater in and of themselves than those ordinarily encountered in daily life or during the performance of routine physical or psychological examinations or tests.

This definition presents two pairs of issues that need to be clarified. First, the scope of the term "harm" needs to be established, and second, the distinction between the *probability* and the *magnitude* of harm that may result from participation in a research protocol needs to be clarified.

Physical Harms. Many research protocols involving the collection, use, and storage of human tissues involve no contact with the tissue sources, the tissues being procured from excess diagnostic or pathological specimens which have been generated for clinical (or other) purposes. In such protocols, there is virtually no risk of physical harm to these sources that may result from the research use of their tissues. Thus the use of genuinely excess tissue specimens, procured by whatever means, is generally of minimal *physical* risk.

One exception to this may arise when the investigators explicitly solicit tissues from the clinicians who order the diagnostic or surgical procedures, or when these clinicians are the investigators themselves. In such cases, it is possible that clinical procedures may be altered to accommodate the research need for more tissue. Whether or not the extraction of additional tissue constitutes a greater than minimal risk to the subject depends on the kind of procedure the patient will undergo. If it is simply a matter of drawing an additional vial of blood, then the additional physical risk is minimal if not non-existent for most subjects. The same may be true of procuring additional bone marrow during a biopsy procedure. But risks may be heightened, for instance, if additional spinal fluid is procured during a spinal tap or additional liver tissue is procured during a liver biopsy. The risks of taking additional tissue will depend on the specific circumstances of the procedures being used. See Holder and Levine (20), who argue that in many cases, small amounts of additional tissues taken during surgery for research are of minimal or no risk and do not require informed consent. There are no hard and fast guidelines in this area and ultimately IRBs must make their own judgment of whether the procurement of additional tissue for research purposes during a clinical procedure is of minimal risk or not.

It is important to note, however, that the risks that result from the procurement of additional tissue for research purposes do not include the risks of the procedure itself, which is being conducted for clinical purposes. Thus the risks of infection from a spinal tap procedure are not a result of the research use of the additional spinal fluid taken, but result from the procedure itself which is ordered for clinical purposes. Likewise the risks of surgery are not a *research risk* if the surgery is undertaken for clinical purposes, while a small amount of additional tissue is taken for research. On the other hand, if an invasive diagnostic procedure is undertaken strictly for research purposes, then the full risks of the procedure must be considered in determining whether it is of minimal risk. A blood draw, for instance, is a routine diagnostic procedure and may be judged to be of minimal risk. A bone marrow biopsy, however, entails greater risks of infection and greater possibility of pain and discomfort and therefore may not be of minimal physical risk.

Psychosocial Harms. In addition to the physical risks of harm and discomfort, tissue sources may be at risk of social, psychological, economic, and legal harms if research results and any medical record information collected from the tissue source are not kept confidential. Such risks

will depend on the specific experiments to be conducted upon the tissue specimens. Analyses of protein structure may have little impact on one's self-image, insurability, or employability, but some genetics research results can have a devastating impact on the source if the results were to find their way back to the individual's medical record or into the hands of insurers and employers. Although the definition of minimal risk adopted in the current regulations does not clearly identify these risks as relevant considerations, the National Commission in the *Belmont Report* clearly indicated that IRBs should be concerned with these possible consequences:

> Many kinds of possible harms and benefits need be taken into account. There are, for example, risks of psychological harm, physical harm, legal harm, social harm and economic harm and the corresponding benefits. While the most likely types of harms to research subjects are those of psychological or physical pain or injury, other possible kinds should not be overlooked (12, p. 15).

A number of commentators have argued that, depending upon the specific circumstances, genetic information developed in research protocols may entail more than minimal risks to subjects (21–24). Others have argued that the excellent record of researchers in the United States in maintaining the confidentiality of research data is a sign that the risks of a breach of confidentiality are so low that we may judge all research involving tissues to be of minimal risk (25–28). Part of this judgment will depend on what, if any, information is communicated back to the tissue sources. If the sources are identified and research results either are or can be communicated back to them, then clearly these persons may be at risk of learning things about themselves which they never consented to finding out. If sources are not identified, or there are no intentions to provide sources with research results, then the risks that these results may have an adverse impact on them are greatly minimized.

However, despite the intentions of investigators not to inform sources of research findings, there may be occasions when research records are used in public health or even criminal investigations. If codes are maintained that would link to individual identifiers, it is possible that individuals will become involved in such activities as a result of the use of their tissue specimens or medical records. For instance, tissue specimens from the Navaho Health and Nutrition Survey maintained by the Centers for Disease Control were used in the investigation of the hanta virus outbreak in the four corners region of the southwest, even though the sources of these tissues never consented to such use (29). Public health investigations are not governed by these regulations and because they often involve infectious diseases and seek to minimize imminent risks to the public, they may override the usual considerations for the protection of human subjects. The same justifications can be made in criminal investigations, though for certain classes of research, especially research involving illicit drug use, psychiatric problems and even genetics, investigators may obtain a "certificate of confidentiality" from DHHS (30,31) which protects research data and materials from most court ordered subpoenas. Certificates of Confidentiality are issued under the Public Health Service Act §301(d), 42 U.S.C. §241(d). Categories of research information for which such certificates are issued include what "would normally be recorded in a patient's medical record, if the disclosure ... could reasonably lead to social stigmitization or discrimination," "information ... damaging to an individuals financial standing, employability, or reputation," and "genetic information."

Distinguishing between Probability and Magnitude of Harm. Whether the risks are physical, psychological, or social, it is essential to clearly distinguish the difference between the *probability* of harm and the *magnitude* of harm that may result from a subject's participation in a research protocol (12, p. 15). Some harms may be of very low probability. For instance, the record of researchers maintaining the confidentiality of private information is excellent. Thus, in general, the probability of a breach of confidentiality may be quite low in many research projects, especially when investigators take steps to protect confidentiality by the use of codes and locked file cabinets. However, the magnitude of the harm such a breach would cause depends on the sensitivity of the information itself and the context in which the breach occurs.

For instance, disclosure of the histological tissue type of an identified specimen may be of little consequence to the tissue source, since this information has little or no clinical or social relevance, except in organ transplantation. However, disclosure that a given identified tissue contains the genetic mutation for Huntington's disease may have a profound impact upon the source, both psychologically as well as socially and economically. Such an individual may find it difficult or impossible to obtain health insurance, or even find a job. While the risk of a breach of confidentiality may be low, the magnitude of social, psychological, or economic harms that may result if confidentiality is breached may be quite high. Again, the definition of minimal risk does not provide a great deal of guidance on how IRBs are to weigh the risks and magnitudes of harms and the current literature is divided on this question as well. Under the current regulatory framework it remains to the individual IRBs to make this judgment as best they can.

Rights and Welfare. The second criterion to be met is that the waiver or modification of informed consent does "not adversely affect the rights and welfare of the subjects." This has been a difficult phrase to interpret. The phrase "rights and welfare" has served as a catch-all idea at least from the earliest days of federal involvement in the protection of human subjects of biomedical research (32,33). It is hard for investigators and IRB members alike to know precisely what is meant by this wording (34). On the one hand, if informed consent is a "right" which the regulations bestow (or recognize), then clearly the waiver of informed consent violates such a right (35). On this interpretation, requiring that the waiver not violate a subject's rights would be self-contradictory. Furthermore, since "minimal risk" is a

requirement for the waiver of informed consent, it is difficult to understand how this waiver could be construed as adversely affecting the welfare of a subject, since a protocol would have to already minimize any such adverse effects.

Nevertheless, it is necessary for IRBs to interpret this clause and document that the waiver of consent does "not adversely affect the rights and welfare of the subjects." Since the promulgation of these regulations in 1981, biological science and technology have advanced at an ever-increasing pace, and issues which at that time were perhaps just beyond the horizon have come to the fore with increasing frequency. In particular, two issues that may fall within the scope of "rights and welfare" have been debated and are relevant to the waiver of informed consent for the research involving human tissues: (*1*) the ownership and/or commercial exploitation of human tissues and cells and the patenting of gene sequences; (*2*) the adverse impact some genetic research may have upon ethnic, racial, or other groups.

Ownership and Commercial Use of Human Biological Specimens. A potentially contentious issue is that of "ownership" of tissues, for it may juxtapose the rights and welfare of tissue sources against the interests of researchers in freely pursuing scientific knowledge. From this pursuit of scientific knowledge comes most of the breakthroughs that allow new drugs and therapies to be developed, and any concomitant financial rewards. Part of this tension arises because the issues of "ownership" are enmeshed in the language of "property rights," and the attendant legal lexicon. Additionally "ownership" implies that all interests associated with the tissues can be couched in economic terms.

Probably the most famous court case involving these issues is that of John Moore. In its 1990 decision in *Moore v. Regents of Univ. of Cal* (36), the California Supreme Court ruled that Mr. Moore did not have property rights in his removed tissues/cells (which had been transformed into a profitable product by his physician, a colleague of the physician, and a pharmaceutical company, without his knowledge or consent). However, the court also ruled that his physician had breached his fiduciary duty to Mr. Moore by not disclosing his financial interest in treating and extracting tissue specimens from Mr. Moore. This case has become the touchstone for how many institutions deal with issues of tissue "ownership," even though, as legal precedent, it applies only in California.

The Moore case does not exhaust the possible ways to address "ownership" of tissues. Indeed, there are at least four different ways in which to view these issues:

1. Tissue sources have no "ownership rights" in their tissues; researchers do (e.g., the Moore paradigm).
2. Tissue sources share "ownership rights;" the question becomes how best to compensate them and when.
3. Tissue sources do not have "ownership rights" but researchers owe them recompense when their tissues become profitable.
4. "Ownership" is not an appropriate construct in this context, either for researchers or sources.

1. *Tissue sources have no "ownership rights," researchers do*. On this view, tissue sources are presumed to either abandon tissues (if provided in a clinical encounter) or donate their tissues for research use. Consent forms for clinical encounters (e.g., where surgery is involved) may have merely stated that removed tissues would be disposed of by the institution. Most patients would probably interpret this to mean that their excess tissues would be thrown out, even though this has generally not been the case. "In many — perhaps most — cases, individuals were not aware that their specimens were being stored or had no knowledge that they might be used for various research purposes by a number of investigators" (6, p. 41). Furthermore, according to a 1995 study of informed consent forms for genetics research, of the 23 documents reviewed, 4 explicitly mentioned that the investigator or institution were the sole owners of any tissue samples or transformed cell lines. The other 19 were silent on the issues of ownership or recompense to tissue sources in the case of profits realized (37).

In the language of John Locke, the sort of property right in tissues that would be claimed by researchers would be a natural right claim — namely that they have a right to any amount of wealth the fruits of their labor have produced. On this moral theory, whenever researchers come into possession of tissues they presume are abandoned, which they then modify in a way that renders the materials commercially valuable, the right to the financial rewards inheres to the researcher — the tissue source does not share in the profits, for s/he did not contribute to the labor that produced the value from the tissue.

2. *Tissue sources share "ownership rights," and the question is one of compensation*. According to this view, tissue sources and researchers share the profits realized from the transformation of tissues. There would be several challenges in trying to implement this sort of model, many of them logistical in nature. First, there is the problem of identifying at the outset which tissues might, through transformation, produce a marketable product. For instance, the case of John Moore is highly exceptional in that his doctor saw the commercial potential in the unique characteristics of his cells at the outset of his clinical treatment. This has rarely been the case, not only in terms of the early recognition of potential value, but also in the exclusive existence of the cells within one person. In most cases, any individual's "raw" tissues are of low economic value (leaving aside any questions of organ donation).

Even if one were able to predict at the outset which extracted tissues could produce value, the next challenge would come in instituting a scheme that could compensate the tissue sources. The issues here include keeping track of individuals whose tissues eventually do lead to a valuable commodity, often years after the tissues are obtained, which could eventually cost more than the actual compensation realized from any commercial product made from those tissues. In addition it is infrequent that any *one* person's tissues will lead to a viable product. That means that an additional logistical hurdle would have to be overcome, that is, calculating proportionality. In other words, researchers would have to determine what proportion of each person's tissues led to the product

(assuming there was a desire to achieve compensation based on the value of each contribution of the unique tissues), and distribute compensation accordingly. This presumes that researchers would have a methodology to keep track of whose tissues were transformed in what ways, and that this "inventory" carried forward to other researchers who might also get the tissues for related or unrelated research. Finally, most profitable discoveries are made on the basis of a variety of tissues, and the proportional compensation of each tissue source would create a logistical ordeal to administer.

In a different context, a similar issue has led some scholars to argue that individuals should have property rights in the personal information about them that is bought and sold. The sale of personal information forms the basis of and supports a multi-billion dollar industry. In this context, these scholars propose forming a clearinghouse (similar to ASCAP and BMI in the music industry) that would receive royalties on behalf of individuals whose personal information is bartered (38,39). While their schemes have not been adopted by the information industries, the idea is still one worth considering for compensating tissue sources for the contribution their tissues make to science.

3. *Tissue sources do not have "ownership rights" but they are owed recompense when their tissues become profitable*. Because the body and its parts are generally not held by most people to be commodities, some have suggested that as an alternative to "ownership" in their tissues, when tissues do form the basis of a profitable product, some recompense should be provided to those individuals. As Thomas Murray has stated,

> There is something very special about human organs and tissues, even when removed from the body. We do retain moral interests in them, so that at the least they are not misused or treated in an undignified manner. And we have certainly recognized that body parts, whatever their dignity, can also have a price. But, on balance, we have rejected the idea that they should be bartered on the market (40).

Researchers finding a way to compensate tissue sources for the contribution their tissues have made to a profitable product would demonstrate respect for the people from whom the tissues came, and an appreciation for their contribution. While it may still not be easy to determine precisely whose tissues led to the profitable product, the issue does not have to be determined definitively, since "ownership" by tissue sources is not involved. For instance, for groups of related individuals (see the discussion that immediately follows), products that are derived from their tissues can be fairly easily compensated, since the group's collective contribution makes the product possible. Consider some of the new genetic tests that are now available. Research done on tissues collected from Ashkenazi Jews looking for a genetic basis for some types of breast cancers led not only to the discovery of BRCA1 and BRCA2 but also led to the marketing of genetic tests for the mutation. One possible way for researchers and pharmaceutical companies marketing these genetic tests to show their respect for the research subjects would be to donate some of their profits to Jewish organizations or synagogues that serve the communities from which the research subjects came. Alternatively, the groups that would most likely be tested (if they formed the pool from which researched tissues came) could receive a discounted price on the testing. In the former case, the compensation is spread over more of the community, while in the latter, it is concentrated on those potentially most likely to directly "benefit" from the testing.

4. *"Ownership" is not an appropriate construct in this context, either for researchers or sources*. Finally, there is a case to be made for the outright rejection of the concept of ownership in this context. It may be that it is more productive to think of the holding of tissues for research purposes as a "custodial" relationship between the tissue source and the researcher. Certainly the legal discourse surrounding property "rights" could be abandoned. Moreover this approach can also accommodate more readily the noneconomic interests people have in their tissues. Some have suggested that an alternative is an independent trust model, where a disinterested nonprofit organization could hold cell lines (or other tissues) in a custodial arrangement, and grant licenses for use of the cell lines or other tissues to researchers and others (41). The licensing agreements could conceivably contain conditions under which tissue sources do not want their tissues used (e.g., genetic research). Any such alternative model will require great care and thought to ensure that the shortcomings of the current "property paradigm" are actually accommodated.

There is little regulatory guidance for researchers and IRBs alike in this controversial area, and it thus remains to IRBs to individually determine how they will handle questions of ownership and the commercial exploitation of human tissues in biomedical research. Some tissue banking protocols, such as the Cooperative Human Tissue Network (17), have stipulated that their tissues may not be used for commercial purposes nor patented by the researchers who use them. But it must also be recognized that for better or worse, private enterprise is increasingly becoming the economic engine that drives scientific progress. How these economic interests fit into the other ethical considerations — particularly the presumed altruism which has historically justified researcher access to tissues and records — which must be considered when weighing the waiver of informed consent remains an open question.

Risks to Ethnic and Racial Groups. The rights and welfare of groups of related individuals are becoming more of a concern in the context of biomedical (and, for now, genetic) research. The concept of "groups" used here is identical to that which was used in a paper written for the National Bioethics Advisory Commission on privacy issues in analyzing tissues (42):

> . . .a collective of individuals who are culturally or ethnically related, where shared genetic characteristics are either likely or possible (or perhaps simply inferred). "Groups" can usually be characterized by a demographic label; e.g., African-American; Pacific Islander; American Indian; Scandinavian American; Ashkenazi Jew; etc. This notion of "group" does not necessarily extend to nuclear families as the unit of analysis, although certainly nuclear families may be members of larger

> cultural/ethnic groups. Culturally or ethnically related people are, for the *present time*, the most easily recognizable as members of particular groups, within social contexts, and therefore, potentially the most readily stigmatized by genetic characteristics predominantly associated with that group. The distinction amongst different types of groups may become less relevant in the future, as we accumulate more knowledge about the genetic makeup of the entire population and all its constituent groups.

With the increase in molecular genetic research, groups of genetically related individuals are increasingly becoming a desirable "unit of analysis," particularly where there is thought to be a "group" component to the genetic trait — namely that the trait is more prevalent in certain genetically-related individuals. That members of these groups might have concerns about how their group is understood and characterized should not be too surprising, since much of one's self-identity comes from their interactions with others like them (i.e., other members of their group). This is particularly the case where some groups historically have been the targets of discrimination and stigmatization. Many individuals find that their associations with groups make important contributions to their self-development, self-discovery, and even their self-image. The often mutually supportive nature of groups and collectivities plays a key role in making these contributions. This may be even more the case in groups in which the members have an ethnic, racial, or cultural commonality. In other words, group identification, particularly in these latter cases, can be as important to the development of an individual's self-definition and self-respect as it is to the group's self-definition and continuity. When an encroachment on an individual (as a member of a group) or on the group itself occurs, the violation may be felt as being an affront to both the individual and the group (42). As Larry Gostin writes:

> Derogatory information associated with a group can result in real harms such as discrimination against members of the group in employment, housing, or insurance. Derogatory information can also cause intangible hurt to groups such as lowering their self-esteem or racial or cultural pride. Derogatory information about a sub-population can stigmatize and wound its people as much as breaches of confidentiality can affect an individual. The information collected from groups, just as information about individuals, need not be blatant or intentional to cause harm or hurt. Even the best intentioned and careful research can trigger concerns about privacy (43).

As discussed above, the federal regulations exempt both the retrospective and prospective collection of some tissues and records from IRB review, provided investigators meet the specific requirements for access to identifiers. From the standpoint of public policy, these exemptions from the regulations may need to be rethought, where the tissues are known to originate *within a particular group*. The current policies make the presumption that *individual* identity is the only form of identity that is relevant to the research being conducted — and to ensure the protection of human subjects. Of particular concern is the possible impact upon various ethnic and racial groups of genes associated with personality, behavior and intelligence, though other less socially charged genetic traits may give rise to economic discrimination based on ethnicity or race. Such concerns have led several commentators to argue that the current exemptions from IRB review should be abandoned (23,42,44,45) in order that there be some "independent, social mechanism to ensure that research is ethically acceptable and that the rights and welfare of subjects will be protected" (13, p. 47692).

Where a group or identifiable community is the "unit of analysis" for the genetic research, researchers should involve members of the affected community in the research process, from recruitment through to the publication of results. The Human Genome Diversity Project (HGDP) provides much guidance in this regard. Henry Greely states that:

> Research inevitably provides information about a group, as well as the individuals who constitute it. The group . . . is really the research subject. It is the group's collective autonomy that is challenged if researchers, with the informed consent of only a few individuals in the group, can probe for information about the whole group (46).

Indeed, it is partly for this reason that the model protocol for HGDP requires that researchers obtain the informed consent of the population, "through its culturally appropriate authorities where such authorities exist" (47) prior to sampling. Furthermore, if the population's authorities choose not to participate, HGDP would not accept any samples from any member of that population. "We believe . . . that the population-based nature of this research requires population-based consent, and we will insist on it" (47, p. 1444).

Within the United States, finding the "culturally appropriate authority" can be a difficult, if not impossible task for many groups. While it may be possible to find people who can facilitate discussions within the community (e.g., religious leaders), many groups are simply too populous and dispersed (e.g., Scandinavian-Americans or African-Americans) to have an authority with the power to make decisions for the entire group. In these cases, it is still important to hold frank discussions within the community to facilitate trust in the process (42).

Moreover, even though the regulations to protect human subjects address only the protection of individuals and not the protection of identifiable groups, when researchers propose additional retrospective research on tissues belonging to such groups, they should utilize the full IRB process (e.g., not expedited review) to justify that additional research. Part of the justification should be an indication of how the researcher can mitigate the harm that can be caused by the information obtained as a result of the research. In other words, even though the regulations treat these tissues as anonymous, researchers and IRBs would be prudent to do more than the regulations require in this case, and treat protocols using these tissues as using identified samples.

"Practicality" of Research without the Waiver. Of the four conditions this requirement is the easiest to interpret, though it may be the condition upon which most protocols

founder. The waiver or modification of informed consent cannot be granted unless it can be demonstrated that "the research could not practicably be carried out without the waiver or alteration." The key term to interpret is "practicably." While the regulations provide no further guidance, this criterion was explicitly commented upon by the National Commission in the *Belmont Report*:

> In all cases of research involving incomplete disclosure, such research is justified only if it is clear that (1) incomplete disclosure is truly necessary to accomplish the goals of the research ... Care should be taken to distinguish cases in which disclosure would destroy or invalidate the research from cases in which disclosure would simply inconvenience the investigator (12, p. 12).

The primary concern in considering the "practicality" of the research without the waiver is the *scientific validity* of the study. The National Commission had in mind primarily social and psychological research which required some element of deception or incomplete disclosure, and the Commission expressed its concern that such alterations and deceptions not be taken lightly, but be justified by scientific necessity. This concern was underscored in the Commission's recommendations to HEW in 1978:

> *Nondisclosure must be essential to the methodological soundness of the research* and must be justified by the importance or scientific merit of the research (48).

The Commission was also clear to distinguish such methodological issues from the question of whether obtaining informed consent was *inconvenient* to the investigator (see also Ref. 35, p. 62). Accordingly, then, if we are to base our interpretation of this clause on the National Commission's own reflections, "practicality" refers to scientific necessity and not to the extra work an informed consent requirement might entail.

Although the National Commission had in mind primarily deception and incomplete disclosure in social and psychological research in its comments on this criterion, their application to tissue collection, use, and storage protocols is relatively straightforward and is best analyzed in light of those categories of protocols that fail to meet the exemption criteria discussed above: (*1*) retrospective and identified and (*2*) prospective and identified. Following this discussion, we will (*3*) analyze the role of prior "blanket consent" in the waiver of consent for specific protocols.

Retrospective and Identified. Many studies involving tissue specimens and/or medical records benefit by the inclusion of identifiers, or indeed may methodologically require such identifiers. Such studies are not therefore candidates for exemption under §46.101(b)(4). Especially in epidemiological studies based on medical record reviews, a number of commentators have argued that waivers of consent are methodologically necessary to the statistical validity of the studies (27,49). The same considerations arise in some epidemiological research involving the collection of tissue samples that already exist (50). Such protocols can involve thousands of tissues and medical records, making the attempt to obtain consent not only exceedingly expensive but impossible in many cases where the patients have moved and no forwarding address is available (51). The impossibility of obtaining consent in these cases undermines the validity of the study by introducing selection bias in the data.

On the other hand, some studies may involve smaller numbers of tissues, and in other cases the issue of selection bias will not be relevant. In those cases recontact of individual patients to obtain their consent may be practical, though an inconvenience to the investigators. It will remain for individual IRBs to judge what number of subjects is too many to make obtaining informed consent impractical, as well as when the scientific validity of the study depends on the waiver or modification of informed consent.

Prospective and Identified. There are two issues to be analyzed here. First, there is again the problem that obtaining consent will lead to selection bias, since some subjects will inevitably refuse. As in the case with retrospective protocols, investigators would have to demonstrate that selection bias is genuinely a problem for the study they are conducting, that there are no alternative methods that would provide equally valid results without the waiver, and that the value of the research to society justifies the violation of subjects' privacy and autonomy. Since the validity of some studies will not suffer as a result of selection bias, it is disingenuous to propose that *all* tissue protocols should be exempt from requirements for informed consent.

The second problem concerns the time and expense of obtaining informed consent. Although these protocols are *prospective* and hence do not face the obstacle of contacting subjects that *retrospective* studies face, still investigators may argue that because they have no professional relationship with the subjects, who may be surgical patients or patients undergoing routine or invasive diagnostic procedures, contacting these patients is *impractical*. Some have argued, for instance, that even if contact were practical, the consent process itself is more burdensome to the subject than the minimal risks involved in the research (20).

Again, however, the validity of these arguments will depend on the specific nature of the protocols and where the patients interact with the health care system. When the investigators are directly involved in ordering or performing the clinical procedures from which the tissues are collected, obtaining informed consent for the research use of tissues and review of medical records is convenient and feasible. Other studies, however, may involve the collection of tissues from a large number of satellite hospitals and clinics and enormously increase the burdens on the investigators if consent is required. One solution to this problem is to name local personnel at these institutions as co-investigators, who can then make the necessary arrangements to obtain informed consent.

We should be careful though, to distinguish between *impractical* in the sense that a study would be methodologically impossible to perform and *impractical* in the sense that the consent process is simply burdensome to the investigators. Would it be just an inconvenience to investigators

in a pathology lab to contact surgical patients to inform them about the nature of a tissue bank to which they hope to send samples of the patient's tissues, or would such a requirement make the collection impossible or impractical? How burdensome must the consent requirement be in order to find it impractical? Is the financial cost of obtaining informed consent a relevant consideration in these cases? Several commentators have argued that the increased costs to research of obtaining informed consent wastes limited financial resources because the informed consent process provides virtually no further protection from harm to subjects since the protocols under consideration for the waiver are by definition "minimal risk" (27,49,50,52). Melton has argued that since well over 95 percent of patients surveyed in Minnesota would gladly consent to the research use of their medical records (27), the requirement for informed consent is an added burden to patients at a time of stress, and the high costs of requiring consent are not justified by consideration for the abstract right of patient autonomy. As Phillip Reilly puts it:

> The cost of such research would be indirectly increased by the invocation of rules that, to me, only abstractly protect individual autonomy. So few people are likely to forbid their samples to be used for anonymous research that the expense attached to asking the question and tracking the few samples that are not available for study seems a poor use of resources (53).

However, as Veatch has argued, since disclosure of the purposes of research is an essential element of informed consent (35, p. 46), the federal regulations take seriously the right of subjects to decide for themselves what research purposes they wish to contribute to, a point not discussed by those who argue that consent should not be required for the use of tissues in research. Individuals may have a variety of reasons for wishing not to have their tissues used for different research purposes, from religious convictions regarding the disposition of body parts, to concerns about specific types of research and the commercial exploitation of their tissues or the patenting of genes (see Ref. 54 for a full discussion of these issues). The question of increased costs to research of requiring informed consent, and at what point those costs make the research *impractical*, leads to a direct confrontation with the respect for individual autonomy. We will discuss this dilemma later, but note here that judgments regarding the practicality of research without a waiver of informed consent are ethically complex, and there is little guidance in the regulations for IRBs and investigators alike. At the very least, it is prudent for IRBs to judge the impracticality of the consent requirement for each protocol on a case-by-case basis.

Blanket Consent. One important modification of informed consent should not be overlooked in applying this criterion to tissue collection protocols. Some hospitals contain either in their admissions literature or in their surgical and diagnostic consent forms provisions notifying the patient that tissues and medical record information may be used for research purposes. A few institutions provide the patient with the option to dissent from this use of these materials. These "blanket" consents or notifications simply tell patients in advance that their records and specimens may be used for research purposes. The National Commission had recommended that this type of notification or blanket consent be used in institutions that anticipated using tissues and records for research, and indeed, the National Commission tied this recommendation to their recommendation that explicit informed consent may then generally be waived for specific research protocols. Unfortunately, HEW/DHHS opted not to include this recommendation in the regulations. Nevertheless, institutions which employ blanket consents give researchers and IRBs the opportunity to use notification as a *modification* of informed consent that would not violate individuals' autonomy. Explicit informed consent may be waived since the subject has already consented to the use of their tissues and records for any research purpose.

The adequacy of these blanket consents and notifications, typically included in the small print of surgical consent forms, has been questioned however. In the context of genetics research, some commentators have argued that broad statements that tissues and medical records may be used for research purposes are inadequate to the complexities of genetics research (22, p. 1791; 35, p. 173; 55–58). Others, including the National Commission and the Privacy Protection Study Commission, concluded that the benefits of relatively unrestricted access to tissues and records, coupled with the minimal risks to subjects involved in their use, justify the use of blanket consent or notification measures (15,25, pp. 111–112; 59–61). Lacking further regulatory guidance, IRBs must rely upon the collective judgments of their members in determining the adequacies of blanket consent or notification for the specific protocols that they review.

Providing Subjects with Additional Pertinent Information after their Participation. The history of the promulgation of these regulations makes it clear that this requirement was intended to be applied primarily to psychological and social research which for methodological reasons involved deception or incomplete disclosure. In these studies, debriefing subjects afterward can help allay anxieties and stress that may have arisen through the deception, and in general speaks to the respect of the subjects as persons. In research involving solely the use of human tissues and associated medical records such issues do not arise, and in the absence of informed consent prior to the use of the tissues, recontacting subjects would place researchers in the difficult position of explaining to them that — through their tissues and medical records — they had been involved unawares in a research protocol.

Nevertheless, in some research involving identified or identifiable human tissues, researchers may discover clinically relevant information either as a direct result of the research or by happenstance. If informed consent is required at the outset, then it is possible to state up front under what conditions, if any, subjects will receive research results, and when necessary, be provided with adequate pre- and post-test counseling. A difficult problem arises when *unanticipated* research findings are discovered, as happened for instance, when a strong

correlation was discovered between the apo-E4 gene and Alzheimer's disease upon analysis of data gathered to study the relationship between apo-E family of genes and hypercholesterolemia and heart disease (62). These cases present the same dilemma that arises in studies for which the requirement for informed consent has been waived by the IRB. Such studies will typically involve identified or identifiable tissues (studies involving anonymous and anonymized tissues for the most part being exempt from the regulations), and therefore researchers may find that their results could be of clinical relevance to the tissue sources, who in these cases, will never have been informed of, much less consented to, the research use of their tissues.

This requirement for the waiver of informed consent stipulates that "*where appropriate*, the subjects will be provided with additional pertinent information after participation." The central question then is whether it is *appropriate* to provide research findings to subjects who have not given prior consent to the use of their tissues. The literature on this question, which has focused primarily on genetics research, is split. Those who argue for a duty to contact tissue sources do so based on two arguments: (*1*) a legal argument drawn on analogy to the clinical duty to recontact past patients with new information regarding their treatment, and (*2*) the obligation of researchers to *benefit* subjects whenever possible. Arguments against the duty to contact cite (*1*) the increased financial and administrative burdens that contact would place on research protocols, (*2*) the uncertainty of research generated results which may not be fully understood or validated by subsequent investigations, and (*3*) the psychological, social, and economic harms to subjects that may result if research findings are disclosed without adequate prior consent and counseling.

Arguments for a Duty to Contact

1. *Do Researchers Using Tissues Have Clinical Obligations?* To date there have been no cases litigated that would establish an investigator duty to contact tissue sources. Legal arguments suggesting such a duty have been based on analogy to cases in which physicians and health care institutions have been held liable for not re-contacting former patients with important findings regarding treatments previously provided. One of the most famous cases is that of the drug DES given to women in the 1950s. The University of Chicago was held liable for delaying notification to women who received this drug at their hospital four to five years after its toxic side effects became known in 1971. Pelias comments that the court found that the doctor–patient relationship is "on-going, especially when future injury to a client can be attributed to the relationship" (63). Pelias suggests that courts may also view the relationship of investigator to subject along analogous lines.

This point is also made by Hannig et al. who argue that the obligations of physician to patient are recognized, both legally and morally, to spread over the entire health care team, including consultants whom some state courts have found to have a legal duty of care to patients they may not have even seen in person (64). Research is then understood as just another part of a complex health care system, and the obligations placed on clinical health care providers should apply to researchers as well:

> Yet the law imposes a host of requirements on the practice of medicine regardless of the individual physician's actual motives. One cannot avoid these obligations simply by asserting that research is somehow different. Where, as here, research requires the assistance of certain individuals because they or their relatives have a problem that is the object of study and where the research is directed toward the diagnosis or treatment of this condition, research assumes the mantle of health care. In that setting, the law should not hesitate to impose on the researchers some duties of care toward those subjects as well, at least in the absence of explicit agreements to the contrary (64, p. 259; 65).

There are three responses to these arguments. First is the claim that their position risks confusing the separate roles of researcher and clinician. A number of commentators (25, p. 2; 66–67), including the National Commission, have argued that a clear separation between clinical and investigator roles must be maintained, even (and especially) when they are borne by the same person. Though this argument has historically been addressed to research involving the evaluation of therapeutic interventions, it applies equally well to the use of *information* derived from tissue specimens that may be of clinical relevance.

Ultimately the ground for clearly distinguishing research from clinical practice is based on the second argument, which concerns whether research findings are of sufficient validity on which to base clinical decisions. We will take this argument up below, but in short, the claim is that research findings are preliminary and may not be fully validated. The use of such research findings in the clinical context risks basing clinical decisions on incomplete or possibly false information that may lead to substantial harms to the patient.

The third argument seeks to dissolve the entire dilemma by ensuring that subjects are *informed* and counseled up front about what, if any, research findings they may expect to receive. Adequate planning at the start coupled with an explicit informed consent process will head off most dilemmas that may arise out of the research findings, anticipated or not (56, p. 87; 57). But this requires informed consent, and so the argument here is really against the waiver of informed consent entirely, if it is possible that research findings may be of clinical value to the subject. This question will be analyzed later in the general discussion of the ethics of the waiver of informed consent.

2. *The Obligation of Researchers to Benefit Subjects*. Several commentators have argued that researchers always have an obligation to serve the best interests of their subjects. Robert Veatch in particular has argued that human subjects should be viewed as *partners* in the research enterprise (35), a view also expressed by Jonas in a famous essay of 1969 (68). Veatch argues subjects of research are entitled to any benefits that the research may produce, including being informed of research results. If the results are merely preliminary, then subjects may be counseled regarding their uncertain status. Veatch does not, however, address the problems of contacting subjects who have never consented to the use of their tissues in research, since he argues that the waiver of consent

(and the exemptions) are inconsistent with the respect for individual autonomy that underpins the regulation and ethics of human subjects research.

Arguments against a Duty to Contact

1. *Increased Administrative and Financial Burdens*. The burdens to a research protocol of contacting subjects whose tissues have been used in research without their consent will depend on the individual protocol itself and the origin of the tissues used. Some protocols may involve relatively small numbers of tissues. In these cases the added record keeping, time, and resources spent in contacting the tissue sources would be small. Other protocols may involve larger numbers of tissue specimens, anywhere from hundreds to the tens of thousands. For instance, the NHANES III study conducted by the CDC (69) contains over 17,000 blood and DNA specimens (55,70). Many genetic epidemiological protocols similarly will involve very large numbers of tissue specimens. Although these research protocols may generate genetic or other information that would be of value to the tissue sources (and may even be of high quality and certainty), the costs of keeping track of and contacting large numbers of tissue sources could often exceed the entire budget of the research protocol in the first place.

Second, and in rejoinder to the argument that researchers owe subjects the benefit of research results, some commentators (55,71) have argued that the goal of biomedical research is to provide benefits to society at large and that insisting on providing benefits to research subjects whose participation is of minimal risk diverts resources that otherwise would contribute to medical and scientific progress and ultimately to the public good. If and when research results find their way into clinical practice, individuals whose tissues are used for research will have the same opportunity as the rest of the population to benefit from this new knowledge.

2. *The Uncertainty of Research Generated Results*. Data and conclusions derived from individual research protocols are often tentative and uncertain. The path from an intriguing research result to a validated clinical test, treatment, or procedure is long and arduous, requiring a series of clinical trials with increasing numbers of subjects. Many results that flow directly from research protocols are unsuitable for use in the clinical context without further testing and evaluation. If the conclusions derived from a research protocol are flawed and yet the results are passed along to the tissue source and their physician, it is possible that they will decide on an inappropriate course of action that may end up producing more harm than good for the patient. Here again, commentators on this problem have pointed to the necessity of maintaining clear distinctions between the often dual roles of researcher and clinician. Merz et al. in particular have recommended that tissue procurement and banking protocols be constructed so as to permit only a one way flow of information from patient to tissue bank to investigators so as not to confuse research and clinical information (18; see also Ref. 28).

In any event, the clinical validity of research results must be evaluated by investigators and IRBs on a case-by-case basis. The possibility that some research results are relevant to clinical care should not be ruled out, especially when there are interventions available that may reduce or minimize harm to the patient. When contact is made with an unconsenting subject, however, a number of problems may arise which are discussed in the next section.

3. *Disclosing Research Results without Adequate Prior Counseling*. When informed consent has not been required for researchers to obtain and use human tissues, contacting subjects presents a dilemma. In standard clinical practice, diagnostic tests typically are preceded by either the tacit consent of the patient whose presence in the physician's office indicates their willingness to investigate a particular health problem, or by the explicit and sometimes written authorization of the patient if the test is particularly invasive or will produce sensitive information. For instance, most genetic testing clinics require extensive pre-testing and post-testing counseling of their patients (72–77). Such counseling includes information about the nature of the test itself, its relation to symptoms and disease, including the penetrance of the gene and limits of the predictive value of the test, and the social consequences of the genetic information, including the possibility of various forms of economic and social discrimination. When the test results come back, patients are more psychologically and emotionally prepared to cope with the consequences of bad news and often undergo further counseling.

It is a well documented fact that depending on the disease gene in question (and especially whether any treatment for it exists), many patients who contemplate a genetic test opt not to perform the test after initial counseling (78,79). Some patients decide that the burdens and risks of knowing are not justified by the benefits. However, if individuals have never consented to the research testing of their tissues, there is no way for investigators to know whether they would want to know the results or not. It is largely a value judgment that individual patients make for themselves when they decide for or against having a given diagnostic test. If unconsenting subjects are recontacted, some subjects may be forced to learn things about themselves and their potential medical future to which they never would have consented in the first place had they been given the opportunity.

One solution to this dilemma advocated by a number of commentators is the use of a general newsletter from researchers describing aggregate results to subjects (56). This presupposes prior informed consent in order to justify this form of contact with the subjects, but publication of study results to the general population from which the tissue sources were derived may fulfill the same role. It should also not be overlooked, as pointed out above, that as research knowledge finds its way into clinical practice in the form of validated procedures, the unwitting tissue sources will have the same opportunity to benefit from these procedures as the general population and in a manner in which their autonomy and values are respected.

The duty to contact is a complex issue, but despite the ongoing debates, the research community has generally tended to limit contacting unconsented tissue sources. There may be instances where this has not been the case, and IRBs and investigators should look at each

case carefully, but in general it is more prudent not to permit contact of unconsented tissue sources with research findings. Investigators who find themselves with information that they feel is compelling enough to warrant the risks of contact should certainly consult their IRB before proceeding.

General Requirements for Informed Consent and Special Provisions for Genetics Research

Protocols that fail to meet the criteria for either exemption or the waiver of informed consent are required by the regulations to be reviewed by the IRB and must conform to the requirements for informed consent. Since these protocols may be eligible for expedited review we will in this section examine (*1*) the conditions for such review, and then turn to the general discussion of (*2*) informed consent and (*3*) the special provisions for genetics research.

Expedited Review. The review of tissue protocols, if they present no more than minimal risk to subjects, may be done on an expedited basis according to the conditions outlined in §46.110 of the regulations. These regulations refer to the Expedited Review List published by DHHS in 1981 (80). A large number of the items contained in this list refer to the collection of human biological specimens, including the collection of hair and nail clippings, external secretions, amniotic fluid and placenta (at the time of birth), excreta, blood draws of less that 450 ml, dental plaque and saliva, and the study of existing pathological and diagnostic specimens. This latter category would involve only studies in which identifiers or links are recorded by investigators, since otherwise these protocols would be exempt.

The expedited review may be carried out by the IRB chair person or an experienced member of the IRB. This reviewer may exercise all the powers of the IRB, including the waiver of informed consent, but protocols under expedited review must meet all the conditions for IRB approval stipulated in the regulations. The expedited review process simply permits a more timely review of protocols and was designed to minimize the work of the full IRB.

DHHS recently expanded the list of expedited review categories (81). The list increases the amount and frequency of blood drawn and most notably includes research which collects identifiable records and pathological and diagnostic specimens, whether they are collected retrospectively or prospectively, provided that they are excess or have been produced for nonresearch purposes. However, a report by the DHHS Inspector General's Office on IRB performance noted plans to give IRBs "added responsibility in the areas of genetics and confidentiality" (10). Permitting more of these and related protocols to be reviewed on an expedited basis would seem to work against the need for greater IRB vigilance and expertise in these areas.

General Requirements for Informed Consent. Section 46.116 lists eight elements required for informed consent:

1. A statement that the study involves research, an explanation of the purposes of the research and the expected duration of the subject's participation, a description of the procedures to be followed, and identification of any procedures that are experimental.
2. A description of any reasonably foreseeable risks or discomforts to the subject.
3. A description of any benefits to the subject or to others that may reasonably be expected from the research.
4. A disclosure of appropriate alternative procedures or courses of treatment, if any, that might be advantageous to the subject.
5. A statement describing the extent, if any, to which confidentiality of records identifying the subject will be maintained.
6. For research involving more than minimal risk, an explanation as to whether any compensation and an explanation as to whether any medical treatments are available if injury occurs and, if so, what they consist of, or where further information may be obtained.
7. An explanation of whom to contact for answers to pertinent questions about the research and research subjects' rights, and whom to contact in the event of a research-related injury to the subject.
8. A statement that participation is voluntary, refusal to participate will involve no penalty or loss of benefits to which the subject is otherwise entitled, and the subject may discontinue participation at any time without penalty or loss of benefits to which the subject is otherwise entitled.

Not all of these requirements are appropriate for tissue protocols: Specific consent requirements depend on whether the intervention is research related or for clinical purposes, or whether only excess tissue specimens are used or the collection of additional tissue is required. Many research institutions maintain standard informed consent templates that investigators may then customize to fit the individual needs of their protocol. It is important to remember that the risks of procedures ordered for clinical purposes need not be detailed in the research consent process. Only those risks that arise from the specific research activities need to be detailed, since the clinical consent process should cover the risks attendant to the diagnostic or surgical intervention.

Special Provisions for Genetics Research. Some research protocols using human tissues requiring informed consent will be of little risk to the subject. For instance, research that uses normal blood specimens to study the clotting process is relatively straightforward, and the informed consent process need not be lengthy or complex. However, the use of tissues, especially for genetics studies, can present an array of problems that must be dealt with in the informed consent process. The purposes of the research, the communication of research results to the sources, the psychosocial risks of such disclosure, questions of ownership of tissues and rights to commercial profits, the use of specimens for other research purposes or the

disposal of specimens after the research is complete, may all be relevant considerations.

While the clinical genetics community has reached a consensus on the elements of clinical informed consent, good counseling practices, and the protection of patients from psychosocial harms arising from the dissemination of genetic testing results, the research community continues to debate both the need for, as well as the extent of, informed consent for genetic studies. On the one hand are those like George Annas, who advocate for a robust informed consent requirement. Annas has proposed that:

> No collection of DNA samples destined for storage is permissible without prior written authorization of the individual that a) sets forth the purpose of the storage; b) sets forth all uses, including any and all commercial uses, that will be permitted of the DNA sample; c) guarantees the individual (i) continued access to the sample and all records about the sample and (ii) the absolute right to order the identifiable sample destroyed at any time; and d) guarantees the destruction of the sample or its return to the individual should the DNA bank significantly change its identity or cease operation (56).

Annas would further require that DNA samples be used only for the purposes for which they were originally collected and would prohibit the use of open-ended consents that permit the use of the sample for any other research purpose. He would also prohibit third-party access to research results but would require notification and adequate counseling of sources concerning research results that may have a significant health impact.

Annas's proposals as embodied in the Genetic Privacy Act (GPA) (82), a proposed model law, have been influential in a variety of legislative proposals around the country, but they have met with opposition from the research community. Some commentators have argued that singling out genetic information from other types of medical information ("genetic exceptionalism") is impossible to apply in practice, since a variety of medical information can be considered "genetic" (28,83). It is also suggested that elaborate informed consent, more consistent with interventional research, is inappropriately applied to the collection and use of tissues and medical records, since little or no risk is involved in the research use of tissues. Furthermore an elaborate consent may frighten subjects and raise the spectre of significant harms that are of extremely low probability, leading to what Korn has called "uninformed denial" (28, p. 25). Most of the objections to Annas's position concern the question of whether informed consent should be required at all for such protocols, and we will discuss this question in detail below.

An alternative idea — a tissue "advance directive" — has been proposed by Robert Weir (84). This document would be filled out by patients as they enter a health care institution and could limit the research use of their tissues to specific types of diseases, allow no research use at all, or permit any research use. This detailed blanket consent could then be entered into the patient's computerized medical record and easily tracked by pathologists and researchers. This proposal would have the virtue of avoiding a detailed consent process each time a researcher wanted to use an individual's tissue. Individuals could update their "tissue directive" as well as specify whether they desired to be informed of any research results. Whether such a system is feasible warrants further study, for it would obviate the need for specific informed consent for many research uses of tissues and records, while giving individuals more control over the purposes for which these materials are employed.

AUTONOMY, PRIVACY, AND THE SOCIAL GOOD

Although some controversy still surrounds the extent and detail of informed consent for the use of human tissue in research, the primary debate has centered on the question of whether informed consent should be required at all for these protocols. As seen above, the regulations support several exemptions from both informed consent and IRB review in addition to the waiver of informed consent. Those who support these measures and would seek to expand them make six general arguments: (*1*) requiring informed consent is administratively and financially burdensome; (*2*) requiring informed consent may introduce selection bias into research; (*3*) the informed consent process is itself a burden to patients and subjects and as such outweighs any benefits the consideration for autonomy and privacy would produce through informed consent; (*4*) there is a long tradition in medicine of free and unfettered access to tissues and medical records for research purposes, and requirements for informed consent and/or IRB review for currently exempt categories of research would infringe upon academic freedom; (*5*) the social benefits of minimal regulation of research involving human tissues and medical records, including the omission of informed consent, greatly outweighs any violation of individual autonomy; and (*6*) there is no violation of individual privacy in the use of tissues and records, since confidentiality is scrupulously protected by researchers.

In response, those who advocate for greater individual control over their tissues and records as well as regulatory and IRB oversight of this research argue that (*1*) the ethical foundation of informed consent is a respect for individual autonomy, and permitting research on tissues and records without informed consent violates a growing tradition in research ethics that has served patients and subjects very well; (*2*) social benefits are not a sufficient ground to undermine the respect for autonomy by not requiring informed consent, and indeed, social benefit is incommensurate with respect for autonomy and cannot simply be weighed against it; (*3*) as a result of the successes of the Human Genome Project, human tissues contain a vast amount of medical information that easily can increasingly be tapped, and subjects have a right to determine whether and how this highly personal information is used; (*4*) public trust in the health care industry and in biomedical research is undermined when researchers use individuals' tissues without their consent or knowledge for purposes they may not share, and especially when researchers might profit financially from them; and (*5*) our current health care system does not distribute its benefits equally across the population, and

many minorities and the poor are excluded or underserved. Justifing the violation of individual autonomy by the claim that research on tissues serves the public good fails to recognize that this public good does not return equally to all segments of the population.

With the exception of this last argument which is predicated upon the principle of *justice*, it can readily be seen that the core of the ethical debate over whether to require informed consent pits those for whom social benefit — a concept derived from the general principle of *beneficence* — is held as the highest moral principle, against those for whom the principles of individual *autonomy* and *privacy* take precedence over competing principles and values. Beneficence, according to the National Commission, implies two separate obligations: "do not harm and maximize possible benefits and minimize possible harms" (12). These benefits and harms may serve to advance or hinder the interests of either individuals or society in general. Those advocating less regulation and no informed consent typically will view autonomy as a species of this more general category of beneficence: autonomy and privacy simply represent *interests* that are important to individuals but that must be weighed against competing *interests* such as general social benefits. On the other hand, those who advocate for the requirement of informed consent typically will understand autonomy as a principle independent of beneficence and either conceive of it as a moral *right* or as entailing a moral *duty*.

How the Regulations Encode and Interpret Autonomy and Beneficence

The involvement of the U.S. government in the regulation of human subjects research evolved out of revelations in the 1960s and 1970s of various abuses that risked or caused grave harm to research subjects. It was recognized that such abuses would be less likely to occur if subjects were fully informed of the purposes of, and risks (and benefits) of the research, since subjects would be reluctant to submit to risks without the corresponding possibility of benefits. But informed consent also came to serve another purpose: respect for individual autonomy, both moral and legal. Legally, those who practiced medical interventions upon unconsenting individuals were liable for *battery*, defined as unwanted or unconsented touching of one's body. In the legal domain, autonomy is expressed as a right to control one's body and what is done to it. This legal right entails an obligation or duty on the part of others not to violate this right. Morally, the requirement of informed consent is an expression of the respect for the independent will or freedom of the individual to associate and participate in activities of their own choosing. In the moral domain, autonomy is expressed first as a duty, not as a right, though some have inferred a corresponding moral right of autonomy. This duty is one that demands that in all our actions we respect the free will and self-determination of others. As a moral right, autonomy has come to mean, in our society, the freedom to choose.

In most cases the principles of autonomy and beneficence work hand in hand for the protection of human subjects in biomedical research. However, research involving human tissues and medical records, insofar as it is genuinely of minimal or no risk requires that we evaluate the justification for informed consent solely on the basis of autonomy, since the beneficence role informed consent plays in minimizing harm is, by definition, out of play. The role that the principle of beneficence then plays is to ground the research project itself as contributing to the social good. Thus the stage is set for the conflict between autonomy (*informed consent*) and beneficence (*social good*).

In its seminal *Belmont Report*, the National Commission identified three basic ethical principles that apply to research involving human subjects: justice, beneficence, and autonomy. The National Commission recognized that informed consent served two ethical masters (beneficence and autonomy), but constructed its recommendations to HEW in such a manner that neither came into conflict with the other. The commission did indeed recognize that research involving human tissues and medical records involved an "invasion of privacy," but this invasion, in the absence of informed consent, was justified, on the one hand, by the social value of the research and, on the other hand, by the recommended requirement that institutions conducting such research institute a blanket consent at the time of admission. The commission also recognized that IRB review was necessary to evaluate the social value of the research, which, in the absence of informed consent, would entail a judgment that the research is of a socially acceptable nature — that is, that the research would not likely be objected to by those whose tissues and records are conscripted without their informed consent.

In its reasoning, the National Commission was guided by the conclusions of the Privacy Protection Study Commission (PPSC), which had published its report in 1974. The PPSC had not considered the use of tissues but did examine carefully the research use of medical records and recommended that this use is legitimate provided that individuals are *notified* in advance (59). The National Commission took a stronger stance with regard to tissues and records, recommending blanket *consent* rather than mere notification. The debate over the adequacy of blanket consent aside, this provision represents the recognition by the National Commission of the independence of autonomy as a ground for informed consent. IRB review would stand as proxy for the *informed* consent of individual subjects, what Veatch has called "constructed consent" (35, p. 63; see also Ref. 25, p. 150, and Ref. 85), while blanket *consent* for the research use of tissues and records would permit those who might object, for whatever reasons, to opt out of any research use of their tissues and records.

As we have seen in the discussion above, HEW did not follow the National Commission's recommendations for a standard waiver of consent for tissue and medical record research coupled with a blanket consent requirement at institutions conducting such research. Instead, HEW proposed, and DHHS adopted, the two exemption categories as well as a general provision for the waiver of informed consent. But neither the proposed nor the final regulations contained any provision for blanket consent. There is no comment on this omission in the public record, but HEW/DHHS may have decided that it would have been an unwarranted intrusion of government regulation into *clinical* affairs to require blanket consent at all

hospitals and health care facilities that might supply tissues and records for research. But blanket consent was an essential element in the National Commission's recommendations that preserved respect for autonomy while greatly simplifying research access to tissues and records. And IRB review was essential to ensure that the purposes of the research were generally unobjectionable in the public eye. There are two ways, then, to interpret this omission by HEW/DHHS. Either the compromise reached in the final regulations does not recognize the independent validity of autonomy as a ground for informed consent, or the compromise reached simply distorted the ethical ground so carefully crafted by the National Commission.

There is good reason to believe that the latter is the correct interpretation. In his *Patient as Partner*, Veatch has argued that the informed consent requirement (§46.116(a)(1)), that subjects be informed of the *purposes* of the research protocol, can only be justified by appeal to subject autonomy and cannot be based on any beneficence considerations to prevent or minimize harm (35, p. 99). By requiring that the purposes of the research be stated clearly in the consent form, subjects are given the opportunity to accept and adopt such purposes as something to which they are willing to contribute. Informing a research subject that a protocol will contribute to the treatment of a particular disease or, perhaps, make abortion less risky to women, plays no role in the subject's evaluation of the physical risks of participating in the protocol but speaks instead to the values they wish to promote or not promote.

Veatch argues that the exemption categories as well as the provision for the waiver of informed consent are fundamentally at odds with the independent role of autonomy in the justification and constitution of the informed consent requirement. By exempting a large class of research protocols as well as permitting the waiver of informed consent, the regulations usurp the ability of individual subjects to make value judgments regarding the goals of the research protocols to which their genomes, tissues, and medical records contribute. It was perhaps the view of the authors of the regulations that biomedical research was of such a high and uncontested value that no one would reasonably object to contributing their tissues and records to the common good. But this notion would apply equally well to invasive and physically risky research protocols as it does to protocols involving only the use of tissues and records. There is no sufficient ground for explaining to subjects the purposes of research in the one case but not in the other. It therefore follows that the regulations must recognize the independent validity of autonomy as an ethical justification for informed consent (86).

Defining Privacy

We noted above that the National Commission viewed researcher access to tissues and records in the absence of informed consent to be an "invasion of privacy." It is useful at this point to clarify the concept of privacy, since it is intimately related to the concept of autonomy and suffers from the same ambiguity of interpretation.

One of the most influential articulations of what is meant by the legal "right to privacy" (as distinct from "privacy" as a moral interest or value) appeared in a now-famous *Harvard Law Review* article in 1890 by Samuel Warren and Louis Brandeis. The right to privacy, they said, is "the right to be let alone" (87). It was from this simple articulation that common law began to recognize a right to privacy in certain circumstances. This recognition, however, has not made defining the concept of "privacy" any easier. Indeed, privacy is a "notoriously vague, ambiguous, and controversial term that embraces a confusing knot of problems, tensions, rights, and duties" (88).

Privacy is usually described as being related to notions of solitude, autonomy, anonymity, self-determination, and individuality: It is experienced on a personal level. Within socially and culturally defined limits, privacy allows us the freedom to be who and what we are as individuals. By embracing privacy, we exercise discretion in deciding how much of our personhood and personality to share with others. Moreover we generally feel less vulnerable when we can decide for ourselves how much of our personal sphere we will allow others to observe or scrutinize (89). Complicating the process of defining what privacy "is" is the fact that it often means something different to nearly everyone, and the experience with and perception of what invades privacy will likely differ significantly from person to person (42).

In trying to "break apart" the notion of privacy, much of the literature focuses on the following elements:

1. *Autonomy*. Respecting the dignity of each individual to make decisions for themselves, free from coercive influences. It also encompasses our need for solitude and intimacy. A National Research Council report stated that the protection of individual autonomy is a fundamental attribute of a democracy (90). Autonomy is also addressed in other analyses as "decisional privacy" (91).
2. *Informational privacy*. Defined by how much personal information is available from sources other than the individual to whom it pertains. Informational privacy encompasses the ability to limit access to one's personal information (which also supports the autonomy aspects of privacy), from both a quantitative and qualitative perspective — namely the amount and type of information one surrenders, either voluntarily or by coercion. It also involves when such information should be communicated or obtained, and what uses of it will be made by others. It includes the collection, storage, use, maintenance, dissemination/disclosure, and disposition of personal information.
3. *Freedom from intrusion / surveillance*. Encompasses, in part, an individual's desire to preserve his or her anonymity and solitude (both physical and emotional solitude). This notion includes not only the individual's desire to limit access to information about him/herself but also to be free from physical intrusion and observational surveillance by others. Surveillance can have a chilling effect on individuals,

> as noted by many sociologists and studies of electronic monitoring. Individuals often change their behavior to conform to what they believe those monitoring their movements/actions will find "acceptable" or "normal" (92,93). Freedom from intrusion is addressed in other analyses as "physical privacy" (91).

The concept of privacy is often confused with or treated as synonymous with two other distinct concepts: confidentiality and security. Confidentiality

> refers broadly to a quality or condition accorded to information as an obligation not to transmit that information to an unauthorized party. . . .Confidentiality has meaning only when the promises made to a data provider can be delivered, that is, the data gatherer must have the will, technical ability, and moral and legal authority to protect the data (90).

The following is a simple way to differentiate between these three concepts: *security* measures provide the technical (and sometimes physical) means to safeguard the *confidentiality* of personal information, which in turn protects the *privacy* of individuals. Within the doctor–patient relationship, confidentiality is used to describe the relationship of trust that must exist for appropriate clinical care to be rendered. In its essence, confidentiality advances the protection of personal information that is exchanged or generated between doctor and patient (whether through verbal exchanges of information or information generated through physical examinations). This is the most fundamental way in which the patient's privacy is preserved (42).

One of the arguments made against the unconsented use of human tissues and medical records is that it violates this fundamental trust between patient and physician. Even if health care is delivered by a team of nurses, physicians, and other personnel, there is a fundamental expectation on the part of patients that their medical information will be kept confidential. What this means to most patients is that this information will not be divulged to other persons or institutions for purposes other than what the patient initially provided it for, namely their own medical benefit and, correlatively, for purposes of payment. The Privacy Protection Study Commission (PPSC) concurred with this understanding in its 1974 report when it recommended that medical records could be used for:

> . . .conducting a biomedical or epidemiological research project, provided that the medical-care provider maintaining the medical record: (i) determines that such use or disclosure does not violate any limitations under which the record or information was collected (59, p. 306).

Of course, virtually all standard medical record information is collected with the expectation of confidentiality. It was thus necessary for the PPSC to insist in its recommendation 12:

> . . .that each medical-care provider be required to notify an individual on whom it maintains a medical record of the disclosure that may be made of information in the record without the individual's express authorization (59, p. 313).

The National Commission, as we have seen, took a stronger stance and recommended blanket consent rather than mere notification. But regardless, only through such notification or blanket consent procedure could private medical information be disclosed for research purposes in a manner that did not violate the *expectation* upon which the information was first gathered.

We may therefore understand and interpret "privacy" according to the intentions and expectations of patients when they provide specimens or medical information to their providers. Confidentiality is the *respect* providers pay to these intentions of their patients by not disclosing medical information. Or, confidentiality is a respect for the autonomy of the individual to determine the purposes to which information (and their diagnostic specimens) are put. In the medical context, privacy becomes a species of autonomy and confidentiality a species of the respect for this autonomy, or more generally, a respect for persons. Thus privacy is not violated if the patient knowingly *consents* to the disclosure of information (or the use of tissue). It should therefore be clear that privacy and autonomy with respect to one's tissues and records is of equal concern whether the records are identified or used anonymously. Although the use of identifiers or links to identifiers may raise the risks of harm to the source and correlatively the use of anonymous tissues protects *confidentiality*, it is the expectations placed upon the information and tissues by patients which determines them as private in the first place. Only through *consent* can their use respect the privacy and autonomy of sources (for a contrary view, see Ref. 85, p. 176).

As thus interpreted, either privacy may then be evaluated as an *interest* patients have in controlling their medical information and therefore may be evaluated alongside other such interests and goods within a consequentialist framework, or privacy may be understood deontologically as a duty on the part of others to respect what is private, that is, not to violate the intentions according to which one may receive private information. The ambiguity that attends the interpretation of autonomy — whether it may be subsumed by beneficence or is independent of beneficence concerns — also attends the interpretation of privacy. Indeed, autonomy and privacy are so intertwined that it may well be the same ambiguity in either case.

Consequentialist Interpretation of Autonomy

As we have seen the exemptions and waiver provisions of the regulations appear to simply disregard the independent role of autonomy as an ethical justification for the requirement of informed consent. Because the regulations permit research access to tissues and records in the absence of specific informed consent and yet do not require any form of blanket consent, the regulations appear to authorize an "invasion of privacy" that two federal commissions recognized as violating patient autonomy.

There remains one route out of this dilemma that would save the consistency and coherence of the regulations. It

is the argument offered by some proponents of greater research access to tissues and records without informed consent. The only way in which autonomy can be traded off against beneficence concerns (informed consent balanced against, or sacrificed for, the social good) is if autonomy itself is understood as the expression of certain *interests* that individuals and society regard as especially important. Once autonomy is understood as the expression of interests, the task is either to minimize the harm to these interests that research may cause or to demonstrate that such harms to them as do occur are minimal and do not *outweigh* the benefits to society of the research. In a paper commissioned by the National Bioethics Advisory Commission (NBAC), Allen Buchanan has made precisely this argument. Since this argument has formed the basis of many of the recommendations the NBAC report (6) on the use of human tissues in research, it is worth while analyzing this argument in detail.

This argument begins with the assertion commonly made by those who would require informed consent for tissue research that individual autonomy is a *right* that permits patients to control private information about them, including their tissues. The language of rights is an appealing framework for moral argument, since rights often stand as moral trump cards overriding other interests.

If we begin with the assertion of individuals' autonomy rights, or privacy rights, against the interest researchers have in freer access to tissues and medical records, the outcome of the argument will be determined by how these putative moral rights are justified or grounded. Buchanan suggests, in line with some traditions of moral and political thought, that rights are "protectors of morally important interests" (94). Specifically:

> . . .rights-statements are assertions that certain interests are of such importance from a moral point of view that they deserve especially strong protections (94).

The claim that such interests are protected by "rights" simply asserts that the interest is of such high priority as to overrule other competing interests and rights. As Buchanan points out, such assertions are the conclusions to moral arguments that must be provided in order for the assertion to be justified.

Having established that a right is simply a proxy for an important interest, the task is to demonstrate that the interest that justifies the right is of greater or lesser priority relative to competing interests. Interests are defined as "an ingredient in someone's well-being" (94, p. B-5). Well-being in turn relates to the goods and benefits that individuals pursue, either as a matter of necessity or to satisfy their desires. Interests thus represent goods or benefits. Insofar as a right is violated, the interest in that benefit is set back; that is, the individual is harmed. This argument has succeeded in converting the principle of autonomy into a species of the more general principle of beneficence, and the deontological force of autonomy, that is, the *duty* to respect another's autonomy, is measured according to the consequences of respecting or violating the interest expressed by this putative right. One simply reckons up the benefits and harms according to a utilitarian calculus.

In the case of the research use of human tissues and medical records, one need only reckon up the harms (and benefits) to individuals alongside the harms and benefits to the social good that the use entails with and without consent. The argument from this point is straightforward. Since only in special circumstances does society permit the unconsented risk of harm to individuals for the sake of social benefit (e.g., military conscription), the task of research interests is to demonstrate that harms to individuals are minimal or *inconsequential*. By protecting confidentiality, adverse psychosocial consequences to subjects are minimized. We are then left with what Reilly has called the abstract protection of individual autonomy (53) weighed against the obvious social benefits of biomedical research. Since little of *consequence* hinges upon the exercise of autonomy in this instance, and the benefits of biomedical research to health care and the economy in general are so high, overriding the "right" of autonomy is easily justified. Thus Buchanan concludes that even blanket consent may not be necessary:

> But it would be hyperbole to say that a system that does not include the requirement of blanket consent violates anyone's "right to autonomy." For one thing, . . . not all choices warrant the stringent protections that talk about a right to autonomy implies; some choices are relatively insignificant because they are largely irrelevant to a person's well-being and value (94 p. B-18).

If we interpret autonomy along these lines, the exemptions and waiver of informed consent provisions in the regulations in the absence of a blanket consent requirement no longer appear inconsistent with the otherwise independent validity of the principle of autonomy. On this interpretation, stating the purpose of research when informed consent *is* required is justified by the respect for the autonomy *interests* of the subjects. It costs research little to include this. The requirement for informed consent itself is justified by the beneficence concern to avoid harm by affording individual subjects the opportunity to evaluate the risks and benefits, as well as the overriding legal concern not to put individuals at risk without their prior informed consent. In the case of the research use of tissues and medical records, however, since there are few or no risks that cannot be managed through the maintenance of confidentiality, the beneficence ground of informed consent does not apply. Lacking any further ground for informed consent, it is morally justified, according to this argument, not to require it.

This argument forms the foundation for the six arguments cited at the beginning of this section supporting researcher access to tissues and records without the informed consent of sources.

1. The requirement for informed consent, in addition to the requirement for IRB review, adds administrative and financial burdens to research protocols. It requires the filing of paperwork and the tracking of subject consent documents in addition to the time and personnel resources to contact patients

and go through the informed consent process with them. When protocols involve multiple centers for the collection of tissues and records, these burdens are multiplied many times over. In addition some epidemiological studies include such large numbers of subjects that the costs of obtaining consent would far exceed the protocol budgets, thus making the studies impossible to perform (27,49). If the risks of confidentiality are minimized through appropriate protections, the social benefits of research can be maximized by eliminating the costly burdens of informed consent.

2. Selection bias may be introduced into research by requiring informed consent. Many protocols examine trends and small statistical differences. Permitting some subjects to opt out of the use of their tissues and records can introduce uncontrollable statistical bias. Furthermore, in some areas of research, because of the sensitivity of the topic (e.g., psychiatric or sexual dysfunction), informed consent may make it difficult to obtain sufficient specimens and records, making such research impossible. As a result some areas of research could be abandoned that could produce important benefits for these same populations (27,49,50,53).
3. Requiring informed consent for the use of excess surgical and diagnostic tissues would place an added burden upon patients, often at times of emotional stress. Approaching patients prior to surgery may confuse them and raise unnecessary fears in their mind because they may fail to understand the complexities and subtleties of the research use of their tissues. Furthermore, since the risks to subjects are minimal if not nonexistent, there is little benefit to be gained by informing subjects and asking their consent. The informed consent process itself is a burden to the subjects with little or no corresponding benefit (20, p. 76).
4. Researchers have long enjoyed unfettered access to human tissues and medical records. The benefits of this access are innumerable, and the record of researchers protecting the few risks that might arise is impeccable. This argument is partially predicated upon the claim that sources simply do not have any rights to control the use of their tissues, rights which they gave up when the tissues were removed (53). Researchers and hospitals consider tissues not used for direct patient benefit in diagnostic testing or treatment to be "waste," which the institution may dispose of as it sees fit, provided it does not directly harm the patient in the process (51, p. 6).
5. The social benefits of research outweigh any putative violation of individual autonomy (53, p. 380). Indeed, since autonomy has no other meaning in this argument than to promote certain benefits and prevent certain harms, and since researchers control for these harms by maintaining confidentiality, autonomy has no role to play in such research. This is the essence of the consequentialist argument presented above.
6. There is no violation of any putative "right" to privacy as researchers scrupulously protect the confidentiality of the information and tissues they receive. Patients in the contemporary health care system must consent to a wide array of individuals and institutions gaining access to their medical records. Research is an integral part of the health care system and provided protections are in place to maintain confidentiality, subject privacy is maintained (95).

It is worth noting here that there is also one argument that employs the idea of the social good as a justification for the requirement of informed consent. Clayton et al. argue that respect for autonomy is an important social good that the informed consent requirement promotes. We should not sacrifice this good for the lessor goods of scientific progress, which could undermine public trust in the research establishment (22, p. 1787). In a similar vein Hans Jonas has argued that scientific progress is an *optional* good, one which brings benefits but not benefits that are so *essential* to the public welfare that they justify overriding individual autonomy (68, p. 230). Although a majority of individuals would gladly consent to such uses, they also find benefit in the asking. For instance, in a 1993 Harris Poll survey, 64 percent of patients surveyed indicated that permission should be obtained before medical records are used for research, even if individuals are not identified in any publication (96). Whether the *benefits* of respecting the autonomy of patients and subjects by requiring informed consent outweigh the social benefits of research conducted in the absence of this requirement is fundamentally a value judgment, which in the regulatory context must be decided through political process.

Deontological Approach to Autonomy

The consequentialist interpretation of autonomy is predicated upon two premises: (*1*) moral duties derive from moral rights and (*2*) moral rights are nothing more than the expression of strong moral interests. Accepting these two premises leads inevitably to the conclusions analyzed above. The fateful move, however, is to accept the first premise. Although the use of the language of rights in moral discourse may be quite common today, it is a relatively recent phenomenon. In the history of ethics, ethical *duties* have rarely been interpreted according to rights language, and even more rarely actually derived from rights.

The derivation of duties in a deontological system may be seen by way of contrast to the consequentialist approach. We may evaluate actions according to their *consequences*, that is, the value of the results of particular actions. This is the core of utilitarian ethics in its many different forms. It depends, then, on how we define the *good* we seek to promote by our actions before we can evaluate these consequences. Alternatively, we may evaluate the actions according to the motivations or reasons for the action. This is the way of a *deontological* ethics. In the former case, it is the ends that justify the means, whereas in a deontological system, the means must be justified independent of the ends, that is, the action itself must

have moral worth independent of any consequences which flow from it. The method according to which we define the *good* in action will depend upon the ethical system we employ. In a deontological moral system, agents have a *duty* to perform those actions which are good, regardless of the consequences.

There have been several articles in the literature that employ deontological reasoning to evaluate the question of requiring informed consent in general and in particular for the research use of tissues and records. In a general analysis of consent, both Lebacqz and Levine (97) and Marshall (98) cite autonomy as defined by Immanuel Kant as the foundation of informed consent alongside the beneficence concern to minimize harm. Clayton et al. cite a deontological interpretation of autonomy as the ground for requiring informed consent for research involving tissues and records (22, p. 1788). And Faden et al. follow the historical rise of autonomy in the regulation of research (and in the practice of clinical medicine) as an increasingly important ethical foundation for informed consent (33).

Capron provides an intuitively clear argument that highlights the difference between a deontological and consequentialist ethics by distinguishing between harms and wrongs (99). Suppose someone enters your house without permission and looks through your belongings without taking or damaging any of them. Capron argues one may not be *harmed* by this invasion of privacy, but one is certainly *wronged* by it, since one's private life has been exposed without one's permission. This analogy is then extended to the medical record that contains a great deal of intimate information about the individual, which is also the case with human tissues. The use of medical records and tissues *without consent* may not *harm* the individual (though harm is possible), but it does violate the individual's privacy, or *wrongs* them. In the consequentialist domain, wrongs are simply measured by the severity of harms. In a deontological framework, the wrong is constituted not by any harm to the individual but rather by the violation of their own self-determination. The intruder into the home and the medical researcher who obtains private medical information without consent, both fail to respect the self-determination, or autonomy, of the individual, regardless of whether harm is suffered or not.

The concepts of *respect for persons* and *autonomy* have long been used interchangeably. The National Commission interpreted respect for persons in the *Belmont Report* as the requirement that individuals "should be treated as autonomous agents" (12, p. 4), and defined such an agent thus:

> An autonomous person is an individual capable of deliberation about personal goals and of acting under the direction of such deliberation. To respect autonomy is to give weight to autonomous persons' considered opinions and choices while refraining from obstructing their actions unless they are clearly detrimental to others (12, p. 5).

The key to this interpretation of autonomy is the idea of self-determination, that individuals may set their own goals and act accordingly, within the limits of not acting in a detrimental fashion toward others, that is, either harming them or violating their autonomy. Autonomy is thus related to the concept of *freedom*, and is typically understood as a matter of *choice*.

Our contemporary concept of autonomy derives for the most part from the moral philosophy of Immanuel Kant, and is intimately related to the concept of freedom (100). For Kant, freedom has two aspects: negative and positive. Negative freedom is the absence of constraint. One is free to the extent that one is not constrained in one's actions by external constraints (chains, iron bars, poverty), or by internal constraints, such as the influence of desire upon one's decision making. But negative freedom is incapable of steering one toward any particular action. For this, we need *positive* freedom — a ground for the determination of our actions. This positive freedom Kant argued is *autonomy*, which he understands in its etymological meaning of *self* (auto) *law* (nomos). Far from being the freedom to do anything that one wishes or wants, autonomy for Kant is the freedom to legislate the moral law *for oneself* and in this sense is genuinely self-determining. Positive freedom is thus the ability to self-legislate the moral law. For Kant, autonomy is a much richer concept than the mere "freedom to choose" by which it is typically understood.

In Kant's famous categorical imperative, the moral worth of an action (and the moral law) may be determined by whether its maxim — a simple statement of the principle of the action — can be willed as a universal law. If the maxim can stand as a universal law for all to follow and does not lead to logical contradiction in the process of universalization, then the maxim is lawful and it becomes a duty of the person to act in accordance with it. For Kant, moral worth, or the *good*, is determined simply and solely by the *lawfulness* of the maxim of the action, that is, its ability to be applied universally and without contradiction, and duty is the necessity to act in conformity to this law which one has legislated for oneself. Thus, autonomy derives from each person's ability to formulate for themselves the moral law that applies to everyone, since a law that applies only to some is not universal. It is by virtue of the light of reason in each person that they have moral freedom and moral responsibility, since it is through our reason that we are able to conceive and indeed legislate the moral law.

This capacity — autonomy — is the *highest good* according to Kant, for it is the condition of all other goods, which are of relative worth. Only *persons* may be accorded this *respect*, all other goods and values being merely *things*. "Things," according to Kant, have a relative price and can be exchanged with one another, but persons are accorded a *dignity*, that is, a worth that is beyond all measure and comparison. Therefore persons cannot be bartered or traded for something of equivalent value, for each person has the capacity to legislate the moral law. Consequently the *value* of autonomy cannot be exchanged, balanced, weighed against, or superceded by other values, for instance, social benefit.

Insofar as individuals determine the moral good through their self-legislation of the moral law, and thereby determine themselves to action, it follows that each individual sets his or her own moral *ends* or purposes. Kant

thus offered an alternative formulation of the categorical imperative which is most helpful in this context: "Act in such a way that you always treat humanity, whether in your own person or in the person of any other, never simply as a means, but always at the same time as an end." "Rational nature," writes Kant, "exists as an end in itself" (100, p. 96). Respect for persons is the necessity or duty to always treat others as ends in themselves, that is, as persons who set their own goals and purposes and who in their actions determine the moral law.

Kant recognized that in everyday interactions we are constantly involved in relations with others through which we are reciprocally means to each others' ends. The force of this imperative is to stipulate that in these relationships we always *also* respect each other as self-determining persons — autonomous — that is, as persons who set our own goals. Thus in our everyday activities it is wrong to use other persons for purposes (ends) that they do not share. To do so is to treat other persons merely as *means*, that is, as mere *things*, and thus to violate their dignity as persons (101).

There are three conclusions to be drawn from Kant's argument. First, there is no claim here to a moral *right* of autonomy. Rather, duty derives from the rational capacity of each agent. Respect for autonomy is a *duty* of the researcher who seeks to use human subjects as a means to the production of scientific knowledge, just as it is a duty of every individual to always treat others as ends, even as we use each other as means. Only through such respect can actions have moral worth. This duty is the necessity of the researcher to submit their purposes to the dignity and sovereignty of the person who is the research subject, which is to say, it is their submission to the moral law itself. Moral duty thus does not derive from a "right," the right of the other to determine their own ends, but rather duty derives from the moral law itself. By starting with the premise that autonomy is a right that simply represents important moral *interests*, the consequentialist interpretation of autonomy fundamentally loses sight of the deontological dimension of the concept, that duty depends on the moral law. Autonomy may indeed represent certain "interest," but these are not the basis of the deontological concept of autonomy and the duty to respect others as ends in themselves.

Second, although other goods may be achieved through failure to respect the dignity of persons and the moral law, it is the goodwill of each rational agent that is the highest good and prerequisite of all other goods. To sacrifice this highest good, from which all other relative goods derive their value, for the sake of a dependent and relative good is to undermine the very good that one would hope to achieve in the action. It is self-defeating. From this deontological point of view, the respect for autonomy has nothing to do with the consequences of action, good or bad, but is rather the condition for achieving any good at all. Social good is not an end in itself but rather is a relative good, or means, to the realization of the highest good, the achievement of morally good action. The fundamental claim Kant is making is that there can be no good at all, including social good, without moral freedom, or autonomy.

In usurping this freedom by failing to inform and ask the consent of patients for the use of their tissues and records, we limit the moral freedom of individuals and thereby diminish the possibility of realizing the good to be achieved through the social benefits of the research. It is the problem of putting the cart (social good) before the horse (individual moral freedom). Individuals whose privacy has been violated are indeed *wronged* as Capron argues. The wrong is a violation of their moral freedom and consequently a violation of their *dignity*. The pejorative *abstract autonomy* to which Reilly refers, and which the consequentialist interpretation produces in this context, fails to recognize that the very possibility of moral freedom and responsibility is at stake when we fail to respect the autonomy of others.

Third, it is necessary that research subjects, in order that they not be treated *merely* as means, be informed of the purposes of the research and freely accept these purposes as their own in their participation in the research protocol. This is the insight for which Veatch argues so strenuously. It is also the basis of the National Commission's definition of autonomy. It follows, as Veatch argued, that the exemption from, and waiver of, informed consent is immoral, since only through informed consent is it possible to respect the autonomy of the persons who are subjects of research. Failure to inform subjects and ask their consent for participation is to treat them merely as *means* to ends which they may or may not share. It is to treat persons as *things* which lack dignity.

Autonomy, understood in this light, conflicts with the consequentialist interpretation which would subsume autonomy as a species of beneficence. On the contrary, the deontological interpretation of autonomy places consequentialist reasoning as subordinate to and derivative from the concept of good which autonomy determines. This good is incommensurate with the relative goods to be achieved through the consequences of particular actions. For the deontologist, arguments concerning the increased social benefits to be derived from research simply miss the point or end up subverting the concept of autonomy. Beneficence concerns are legitimate but not overriding.

It can readily be seen that the absoluteness of the duty to respect autonomy in the deontological interpretation is behind some of the arguments for requiring the informed consent which we cited at the beginning of this section.

1. The ethical foundation of informed consent is a respect for individual autonomy, and permitting research on tissues and records without informed consent violates a growing tradition in research ethics that has served patients and subjects very well. We have demonstrated the independent validity of autonomy as an ethical underpinning of the requirement for informed consent, and the National Commission gave a deontological interpretation of autonomy. Although the independence of autonomy has emerged through the historical rise of government regulation in human subjects research, it has served as an important and powerful check against researchers who would privilege the social benefits of scientific knowledge over the free will of research

subjects, which in the past has led to disasterous consequences.

2. Social benefits are not a sufficient ground to undermine the respect for autonomy by not requiring informed consent. This is the heart of the deontological argument which finds that benefits and harms in general are incommensurate with deontological principles.
3. As a result of the successes of the Human Genome Project, human tissues contain a vast amount of medical information that can be tapped with increasing ease. There was a time when tissues represented very little of consequence, either directly to patients or indirectly by virtue of the purposes to which researchers might put them. But the production of scientific knowledge is less of an unequivocal good now. Not all research subjects may share the research purposes of some or even many protocols. Thus the moral freedom of individual subjects is at stake when the research community argues for less stringent requirements for informed consent.
4. Public trust in the health care industry and in biomedical research is undermined when researchers use individuals' tissues without their consent or knowledge for purposes they may not share, and especially when researchers profit financially from them. This argument, as we saw above, may be grounded on a consequentialist analysis, but it also may be grounded on the deontological requirement not to involve other persons in purposes that they do not share or have not accepted. Especially when research is increasingly motivated by profit, the presumed altruism that has played a role in justifying researcher access to tissues and records without informed consent is undermined. This presumed altruism is really the presumption that individuals *share* the goals of biomedical research. But the ulterior motives that also animate research to an increasing degree cannot so easily be presumed to be shared by the general public.

The idea of patient altruism has a correlate in the idea that patients who benefit from biomedical advancement owe a *debt* to past research subjects and thus have an *obligation* to contribute to the future advancement of biomedical science. One relatively easy way for patients to discharge this obligation is to provide easy access to tissues and medical records for research purposes. However, both Caplan (102) and Jonas (68) have argued that while we may owe some debt of gratitude to past subjects of biomedical research, those subjects cannot possibly have considered that this debt would be discharged through violating the autonomy of subjects that follow, though they may well hope that others would make similar contributions to the common good. Furthermore, were this debt one that the research community could *exact* from the population of patients, there would be no reason why the requirement to participate in research would not extend to all biomedical research, including the testing of invasive procedures and drugs. Contributing to biomedical progress is like the general moral obligation to be charitable. We do indeed have an obligation to be charitable, but charity must be given freely and according to the individual's own view of the good to be achieved thereby. To require that patients contribute their tissues and records to biomedical research amounts to a *tax* on patients, in much the same way that welfare programs for the poor are funded by a tax on the public. It would be a serious mistake to refer to one's tax contributions to welfare programs as charitable, and it is no less a mistake to presume that the health care industry can collect on patient debts to medical progress by collecting their tissues without consent.

The last argument for requiring informed consent derives from the fact that our current health care system does not distribute its benefits equally across the population. Many minorities and the poor are excluded or underserved. The justification that the violation of individual autonomy by the claim that research on tissues serves the public good fails to recognize that these benefits do not return equally to the individual sources of tissues and records. This argument is founded on neither beneficence nor autonomy but the independent principle of justice. Justice in this context concerns the *fair* distribution of benefits and burdens and relates to the previous argument concerning the obligations of patients to participate in research. Clearly, those who have not shared in the benefits of biomedical research as fully as others cannot be said to have an equal obligation to that system, especially when the inequities of our health care system are largely the result of a conscious political choice not to remedy them. Autonomy does play a role here insofar as those who have received less than equal share in the benefits of biomedical science and treatment may no longer share the goals of this industry, at least, until they and others are included as full partners.

CONCLUSION

Having formulated the contrast between the consequentialist and deontological interpretations of autonomy so starkly, or what amounts to the same thing, the contrast between beneficence and autonomy, we must be careful how we proceed. It would be tempting, perhaps, to simply *weigh* these two principles against each other. But this would beg the question, for we must have some criteria by which to evaluate these competing principles, a common scale as it were, and by definition there can be no such common scale. Marshall (98) has argued that the National Commission fell prey to this error by viewing autonomy, beneficence, and justice as principles to be *weighed* or *balanced* against each other when they lead to contradictory conclusions. The metaphor of *balancing* implies that the contradictory terms are commensurate. But as Marshall concludes "...the point of the Kantian principles is precisely to say that certain things cannot be 'balanced out'" (98, p. 6). The metaphor of "weighing" and "balancing" is primarily a utilitarian strategy of reckoning up the goods and ills of consequences. To suggest that a

deontological principle may be balanced against a consequentialist principle is to eviscerate the deontological core of the concept, and thus begs the question.

We are left therefore with incommensurate principles which, when applied to research involving tissues and records, lead to contradictory conclusions. Each principle appears to assert its priority over the other. Either we must sacrifice autonomy as an independent deontological principle if we wish to privilege beneficence in justifying not requiring informed consent, or we must accept the deontological principle of autonomy as taking precedence over beneficence considerations, and thus sacrifice some measure of the common good to be achieved through the use of tissues and records without informed consent. Notice that in this dilemma, privileging beneficence over autonomy does violence to its deontological interpretation, while recognizing the priority of autonomy does not in any way corrupt the principle of beneficence. Consequentialist reasoning is inherently blind to its deontological counterpart, while from the deontological point of view, there is no inherent contradiction in reckoning up consequences, provided only that in doing so we conform to our moral duty. If we are to accept the deontological interpretation, the inevitable conclusion is that autonomy is an independent moral principle that cannot be subsumed under beneficence.

If public policy is then to recognize the independent validity of autonomy, we must reconsider the exemptions and waiver of informed consent that the current regulations permit. This does not necessarily mean that we must default to always requiring the full informed consent of subjects for the use of their tissues and records in research. As we have seen, the National Commission was reluctant to give up the social benefits of scientific research that would be lost if specific informed consent were required for all uses of tissues and records. But recognizing that individual autonomy could not simply be sacrificed at the altar of social expediency, the commission recommended two provisions that would preserve the respect for autonomy. First, it required IRB review of all research involving human tissues and records, and second, it required that institutions notify all patients that these materials may be used for research and provide patients with a blanket consent to opt out if they so chose. The requirement of IRB review ensures the social acceptability and value of the research and thus stands in as proxy, or "constructed" consent, for subjects who do not specifically consent to these protocols. The requirement for blanket consent recognizes, however, the sovereignty of the autonomous subject to choose whether to participate in such research activities. Clearly, this compromise crafted by the National Commission limits the exercise of individual autonomy, but at the time it was perhaps much less likely that subjects would object to the research use of their tissues.

Research involving tissues, however, has changed dramatically since the late 1970s when the National Commission issued its recommendations. The revolution in genetics and biotechnology in general raises a host of new risks to subjects, and the erosion of privacy in our evolving information society and within health care itself has made the public more aware and more cautious in guarding privacy. It may be that blanket consent is no longer an adequate expression of respect for the autonomy of patients. Robert Weir's concept of an advance directive for tissues would go a long way toward returning to patients and subjects the control that is an expression of their self-determination. It is at least worthwhile exploring the feasibility of instituting such a system.

If we are to pay more than lip service to autonomy, it will be necessary for IRBs to pay close attention to the scientific necessity of the waiver of informed consent. The current categories of exemption should be abandoned in favor of IRB review in which IRBs may decide that the waiver of the informed consent requirement is necessary to accomplish the goals of the research protocol, and not just a matter of inconvenience to the investigators. The current exemption categories permit investigators to use human tissues and records for virtually any purpose without the knowledge and consent of the sources. While most such purposes are generally laudable and serve the public good, this may not always be the case. If the waiver of informed consent is genuinely necessary to conduct the research, then the research community owes it to the individual sources of tissues and records to submit the research to an independent evaluation to ensure that the research is not foreseeably objectionable. This does not provide for those who may have particular objections, but those who are concerned not to have their tissues and records used for purposes to which they might object would have the opportunity to opt out of participation ahead of time through a blanket refusal of consent or an advance directive prohibiting the research use of tissues and records.

In order for IRBs adequately to take on this increased responsibility, the conditions for waiver of informed consent need to be tailored specifically to research involving tissues and records. The ambiguities in the waiver criteria analyzed in the second part of this article should be clarified, and specific criteria relating to tissues and records should be made explicit. The questions concerning risks, "rights and welfare," ownership and commercial use, recontact of subjects and especially the "practicality" of research, that is, the scientific necessity of the waiver, need to be specifically tailored to research involving tissues and records.

Second, IRB membership, as noted in the Inspector General's report on the reform of IRBs (10), needs to be broadened with additional noninstitutional and nonscientific members representative of community interests so that evaluations of the social value or objectionability of research conducted without specific informed consent can be more representative of the local populations. IRBs also need greater expertise in the areas of genetics and biotechnology in order to be in a position to recognize and analyze the many issues these protocols may raise.

These modifications to the current system of protections would ensure that both autonomy is respected and that

the benefits of scientific research may accrue through as minimal interference with the research enterprise as is consistent with this respect for autonomy.

GENETIC INFORMATION, ETHICS, FAMILY ISSUES

ERIC T. JUENGST
Case Western Reserve University
Cleveland, Ohio

OUTLINE

INTRODUCTION

Of all the many "publics" that are affected by advances in genetics, families that use genetic services are the closest to our society's grass roots: They cut across all other sociological categories and lie behind all the usual interest groups that contend over our society's health policies and practices. Moreover these families and their members have always been portrayed by the biomedical community as the focus of the genetic services it generates. In the absence of effective therapies, the promise of accessible genetic information lies almost entirely in its ability to allow families to identify, understand, and sometimes control their inherited health risks. Against the excesses and abuses of the eugenicists' population-oriented concerns, contemporary geneticists are firm in their conviction that "the fundamental value of genetic screening and counseling is their ability to enhance the opportunities for individuals to obtain information about their personal health and child-bearing risks, and to make autonomous and non-coerced choices based on that information" (1). This puts families at the moral fulcrum of the enterprise: If genetic services are to be judged a success, it must be from the recipients' point of view, in terms of their ability to use the results to support their flourishing as individuals and families. That, in turn, gives a special urgency to getting clear about the impact of genetic services on family life, and the ethical issues they can raise for family members. This article summarizes what is known about these "family matters" in genetics and suggests an agenda for futher research in this crucial area.

FAMILY VIRTUES AND GENETIC TESTING

Over the last decade a large literature has evolved anticipating and addressing the ethical, legal, and social implications of advances in human genetics. For overviews, see Juengst (2) and Thomson (3). One of the weakest spots in that literature, however, is work addressing the ethical issues faced by the individuals and families who might avail themselves of the fruit of those advances. This relative neglect is not entirely surprising, despite the centrality of the issues to the success of the genetic enterprise. First of all, most of our efforts have been directed toward the development of policy capable of optimizing our uses of genetic advances: rules, guidelines, agreements, and positions that can be generalized across all the situations that raise the issues they address. That is much easier to accomplish for entities like states, institutions, and professions than it is for "the family," since our many different families subscribe to no unified process for making universally binding "family policy" on ethical issues. Moreover there is no well-received generic account of the moral dynamics of family life to draw upon in even attempting to develop such policies. With some recent exceptions (4,5), the ethics of family interactions has been a black box for contemporary applied ethics, protected from intellectual scrutiny as well as state intervention by our liberal traditions. In part, this is because there is such a rich pluralism of strongly held specific theories on the subject, which reflect the convictions and experiences of different family histories and traditions (6). Since these specific theories are usually intertwined tightly with our most important beliefs and values, contemporary moralists tend to give them the deference that we give to other transrational matters of conscience, like personal religious commitments. Against that variegated and sensitive background, the thinking goes, one would be foolish to try to generalize about what ethical issues any new genetic service might raise for families outside of some parochial cultural perspective (7).

Be that as it may, the existing literature does suggest three ways in which advances in genetics will challenge the ethics of at least many American families. Despite our differences, there are three familial virtues that most socialized Americans would not be surprised to find listed among the qualities that have traditionally been ascribed to the "good family" in our culture. I will call these qualities the familial virtues of loyalty, intimacy, and security. While these three virtues are neither necessary nor sufficient to an adequate ethical theory of family life, they are keys to the familial ethics of genetic testing, because they are value commitments that do seem particularly challenged by our emerging genetic testing practices. To the extent that these virtues are at least widely intelligible as ingredients in the moral dynamics of family life, their analysis provides a starting point for further discussion. New advances in genetics will challenge the ability of the families who endorse them to live up to the ideals that they represent.

Loyalty

The members of good families accept special obligations to serve their kin. Whether this means grown children joining their parents' businesses, siblings helping each other out of debt, or cousins hosting visiting cousins, members of a good family are expected to aid and assist one another without having made any of the explicit promises,

offers, or agreements to do so that would govern such service between strangers. Moreover this familial loyalty can supersede the interests of individual family members in significant ways: when mothers delay careers to raise unexpected children, for example, or when children's educational interests are sacrificed in order to care for their infirm grandparents, or when siblings come home for the holidays at the cost of their holidays. Of course, like any virtue, familial loyalty can become a vice *in extremis*, as when excessive concern for "family honor" generates vendettas between families, or self-sacrifice becomes unnecessarily self-destructive. Identifying the proper demands of family loyalty and balancing them against our other interests is one of the perennial challenges of moral life within a family. However, the way we approach that balancing problem is itself oblique evidence for the value we give to the virtue. As Nelson and Nelson (5, p. 76) point out, "Moral relationships among family members can certainly be strained by betrayal or violence, but it takes a catastrophe to dissolve them." ... In our culture we understand the vices of extreme loyalty precisely as a problem of overdoing a good thing: we can sympathize with their perpetrators in ways that we cannot with those who abandon or betray their kin. On the whole, we applaud the families that stick together because we see a reciprocal concern for each other's best interests as a constitutive ingredient of what it means to be a good family. For example, Post (4, pp. 81–108) argues that the balance between giving and receiving love in the context of the family is a common moral expectation that is a truly universal intuition.

New advances in human genetics challenge the virtue of familial loyalty in two ways. They simultaneously illuminate both the connections among and the differences between family members. First of all, genetics is, by definition, a science of family connections. Clinically useful genetic information about individuals often requires knowing the background against which the individual's genome presents itself: the pattern of inheritance of the traits and markers in question within the larger family. This means that in order for a genetic test to be useful to an individual family member, other members of the family have to be willing to provide that background and, in the process, discover their own status within the pattern.

Moreover, like most medical interventions, genetic testing usually motivated by a crisis — someone diagnosed with breast cancer or genetic disease — which creates a sense of urgency to "get the family in for testing." For those other family members, the decision to participate in a testing program raises a basic moral question: What are the demands of my loyalty-based obligation to help my kin learn their genetic risks? In particular, must I sacrifice my own "right not to know" in order to help my relative enjoy the "right to know," and join him or her in braving the psychosocial risks of having that personal information known about me? When family members decide to protect their own interests and decline to participate, the same question is passed "downstream" to their children and grandchildren: If those downstream kin should decide to be tested, the status of the declining member could be revealed as a simple matter of deduction. What interests must they sacrifice, then, in order to give the decliner the filial respect that they deserve (8)?

Finally, if a decliner's kin do become interested in learning their own genetic risks, but cannot do so without involving the reluctant relative, to what lengths may the family go to persuade the unwilling to do their familial duty? Split decisions about genetic testing have already been observed by genetic counselors to lead to familial discord in some cases (9), while unanimous decisions in other cases have raised suspicions of undue familial pressure to participate (10).

The moral bite of these questions within families can be seen by the ways in which they seem to be provoking health professionals involved genetic testing to clarify their own allegiances. Despite the long-standing reluctance of clinical geneticists to interfere in the personal choices that their clients make about genetic testing and the use of test results, some now argue that clinicians should help their clients persuade reluctant family members to participate, by reminding them of their familial obligations (11). Others stand by the conviction that each family member has equal standing as a client, and thus, "it is important that individuals within families are supported to make their own decisions about testing and are not coerced by eager relatives" (9, p. 25). Still others now argue that, if the clinical geneticist's "patient" is best understood as the family as a whole, perhaps clinicians have no more business attempting to regulate the influences on the family's collective decision than they would in second-guessing an individual's informed consent. From that point of view, whatever internal dynamics produce the decision are protected from the clinician's interference by the same sphere of familial privacy that grounds their commitment to nondirective counseling at the individual level (12). Just like the family members involved, the professionals are forced by genetic testing to think about the moral significance of the genetic connections that link up the individuals with whom they interact.

Of course, genetic information is as much about our differences as it is about our shared traits, and illuminating those differences is another way in which genetics can challenge the familial virtue of mutual loyalty. As we are able to sort out which lineages within families, and which individuals within a lineage, carry a family's risk-conferring mutations, tension will be created between the divergent interests of the two groups. Whatever their commitment to family solidarity, the family will have to face the fact that it will be in its "normal" "members" interests to reveal their noncarrier status in some circumstances and in the interests of the carriers to conceal theirs. Family members free of the mutations in question, for example, will find it in their interests to use that information to counter their family history of a disease in applying for insurance (13). In doing so, however, they will inevitable raise questions about their kin who do not volunteer their test results in turn. Should families be expected to stick together "in sickness and in health" as we ask of married couples, or do the "limited sympathies" of human nature give us leave to concentrate on the welfare of our own threads within the familial patterns of inheritance?

For families in our society, market institutions like risk-rated health and life insurance that create serious competitive advantages out of genetic differences make it increasingly difficult for even conscientious families to present a united front on the matter of disclosing test results. As a spokesman for the insurance industry recently wrote, for high risk families faced with gaining access to adequate health and life insurance, "Harsh as it may sound to ears of a society that subscribes to egalitarian principles, solidarity ends with a negative genetic test" (14). Since, short of cloning, human families will always weave together a combination of different genetic threads, new abilities to identify those differences will continue to expose families to this kind of external pressure, as long as we live in a society that uses such differences to allocate its opportunities.

Intimacy

A second traditional virtue of family life is intimacy. As our concept of "family secrets" suggests, we expect family members to communicate with each other about private matters more readily than they do with their neighbors, coworkers, or even friends. Family members are allowed to know more about each other, and expected to share important personal information with each other (births, deaths, marriages) before they tell the rest of the world. Again, it is possible to see this virtue reflected in the way we treat its vicious distortions. Thus excessive communication (i.e., gossip) within families is a recognizable moral problem for family life, but we are usually more concerned about the keeping of secrets between close family members, particularly when the secret bears on their own relationship. In theory, disclosures of behavior that would be scandalous in public can be safely made within families not only because the secret is safe there but also because the expected reaction is not a moral judgment; it is rather an attempt at understanding. Intimacy in family life is not only about exposing our vulnerabilities to one another; it also requires taking no offense at the disclosures.

Unfortunately, despite our commitments to intimacy, information about shared genetic health risks seems particularly hard to share with our kin. For families that are already aware that they have a hereditary history with a particular disease, revealing that one is a mutation carrier can invite stigmatization as a bearer of the "family curse," and premature assignment to the sick role. On the other hand, "survivor guilt" seems to be relatively common among those testing negative in these families, and it also inhibits disclosure (15)? In these "at risk" families, genetic test results place individual members on one side or the other of the "watchful waiting" that characterizes their family's corporate identity and, in the process, segregates them from one of the central dramas of their family's life. For example, Alice Wexler explains her own decision to remain uncertain about whether she carries the gene for Huntington disease this way:

> One man who tested negative felt as if he were missing a limb, a part of his identity. "I had lost my creative terror" he said. . . . Choosing not to take the test is a decision one can easily revoke, unlike the situation after testing. A Geri Harville said, "You and your family will be affected by this information forever. Once you have the information, you cannot give it back." I have made my peace, more or less, with uncertainty. . . . Perhaps I even enjoy the ambiguity, resisting sharp categories and binary definitions, the border guards insisting that we place ourselves in one camp or the other. (16, p. 238)

Clearly, genetic test results can fall in with mis-identified paternity as among the hardest kinds of personal secrets to share with kin: secrets that seem to deny the very kinship that licenses their intimate disclosure.

On the other hand, genetic test results are also almost always "about" more than the individual who undertakes them. For some, this overlap serves to strengthen the obligation to share genetic test information, because they understand themselves to be privy to a secret about their at risk kin (17). For members of families that do not have a recognized history of the genetic risk, their test reveals this poses another kind of challenge to familial intimacy. In these situations the disclosure does not segregate the source from kin but rather exposes a new and troubling connection between them. Here, feelings of shame and the urge to shield the family from harm seem to combine to encourage keeping genetic risk information secret from kin (18).

These pressures raise for family members the question: What are the limits of my intimacy-based obligations to share my genetic test results? Can my personal sphere of privacy extend to information that is also about my relatives without becoming secrecy? Of course, the problem with keeping specific secrets from other family members is that families are particularly hard organizations to keep individual secrets in without leaving the family altogether. Yet, when secrets have been kept and do emerge, it immediately calls into question the true intimacy of the relationships involved, with potentially devastating effects. Thus Alice Wexler writes that, in the wake of her mother's diagnosis with Huntington disease, and its exposure of her long-held secret about her family history,

> [W]hat my sister and I thought we knew about our family suddenly shifted and everything had to be rethought, reinterpreted. Who we were had suddenly been called into question, and everything had to be reconfigured taking into account the presence of the disease. It was as if we had been experiencing fallout from some unseen bomb for all these years, and suddenly the great mushroom cloud had come into view and we could see the source of all that radiation (16, p. 75).

Looking to law and social policy for indications of social consensus on these questions is only partially helpful. For example, the fact that there are laws that ensure adoptees access to genetic information about their birth parents suggest that we do feel strongly about the obligations of parents, like the Wexlers, to share their genetic health secrets with their children (19). On the other hand, most policy statements on the genetic testing of children stress the need to protect their genetic privacy even in the face of parental requests, suggesting that these intimacy obligations are not always reciprocal (20). Moreover, as Lori Andrews points out in her review of the issue, the law is particularly silent on familial duties outside the

parent-child relationship: "With respect to an individual's duties towards other relatives (such as siblings or cousins), there might be a moral duty to disclose a person's genetic information, but there is probably would not be a legal one" (19, p. 273).

Again, the importance of these ethical questions for families can be seen by the extent to which they bleed over into professional ethical questions for clinicians. Thus clinical experience with patients' reluctant to warn their families of their risks has spawned a renewed discussion of the limits of the professional's commitment to confidentiality in the genetic testing context, with some arguing that the patient's familial obligation to disclose shared risks should translate into a professional duty to warn third parties (21), others standing by the individual proband's authority to make disclosure decisions, and still others arguing that if clinicians take the family seriously as a collective client, they should never make promises of privacy to any particular piece of it but interact with the family as a whole throughout the testing process (22).

Security

Good families are safe places for their members, as the virtues of loyalty and intimacy both suggest. In part, that is because good families accept special obligations to protect their vulnerable members from harm, even when those members cannot ask for help. Thus we expect adult family members to practice a benevolent paternalism with their immature and infirm kin, and we expect our kin to defend us against calumny and slander even when we are unaware of it. Of the three familial virtues, this is the one whose applications and dynamics have been most discussed in biomedical ethics, because it is the one that is called into question in health care when parents are faced with making medical decisions about the welfare of their children (23), and adult children are called to make medical decisions for their aged parents (24). At both ends of life, our bioethical discussions are often struggling to define the limits of people's duties to stand guard over the bodies of their loved ones in particular circumstances, but they almost always start from the premise that they do have those duties.

Like the others, this familial virtue is also thrown into relief by our responses to the vices on its borders. We can sympathize with overly protective parents even as we criticize them as excessive, but we find cultural practices that seem to deny special protections for the vulnerable (e.g., prenatal sex selection) morally callous and hard to understand when they occur in our society. Moreover the strength of our allegiance to this virtue is reflected again in professional ethics and law, with the recognition that "In general, the appropriate presumption is that the family of the incompetent individual is to be the principal decision-maker." Thus it is received wisdom in medical ethics that:

> The chief reasons in support of the presumption that the family is to serve as surrogate decision-maker are both obvious and compelling. The family is generally both knowledgeable about the incompetent individual's good [e.g., intimacy] and his or her previous values and preferences [e.g., loyalty], and most concerned about the patient's welfare. [e.g., security]" (25).

With genetic testing, the limits of this virtue are pressed most vividly by the questions raised by the prospect of testing our offspring. How far should parents go in seeking to protect their vulnerable children from genetic harms? Does prenatal testing and selective abortion count as a "preventive" or "protective" intervention for the children tested, or simply a means of choosing which children to bear (26)? Studies already show that declining to have prenatal testing is perceived as causing the bad outcome when a disabled child is subsequently born, which suggests that many families do think that prenatal screening falls within the protections that parents should afford their offspring (27). This perception, in turn, can put the pressure on couples to be "responsible reproducers" in their own eyes and the eyes of other family members in ways that can seriously compromise their own reproductive autonomy (28). Clinicians, however, have traditionally viewed prenatal testing as enhancing familial rather than fetal security: It is understood as a service to the prospective parents that allows them to reduce the risk of burdening themselves and their family with more than they can handle. This perception of prenatal testing simplifies the professional ethical challenges that the practice poses, but challenges parents to clarify the limits of their ability to nurture children with disabilities, and to define for themselves what will count as an acceptable quality of life for their children (29).

Similar challenges accompany decision making about pediatric genetic testing. Should parents include screening for diseases of late adult onset amongst their obligations to protect the welfare of their children? There has been a lively debate in the literature on this topic, aimed at establishing clinical policies for practitioners (30). Interestingly, however, much of the argument is parental ethics, not professional ethics. Critics of such practices see in them the vice of over-protectiveness and "pre-emptive paternalism," while defenders argue that:

> Children are not discrete monads who develop in isolation until they reach adulthood when they can seize autonomy and begin to make significant decisions about their lives. They are shaped within the context of their family and community as they make their way to adulthood. It is the responsibility of parents to provide for their children's nurture and education. . . . While such socialization can affect the choices children will make as adults, it is considered so much a part of parental responsibility that parents who fail to teach their children a value system can be said to have failed in their duty to them. . . . Yet responsible parenthood would have it no other way. Moreover, refraining from predictive testing is, in effect, teaching children that ignorance is a good way of life. That is at best a controversial message (31).

FAMILY STYLES

Of course, it would be naive to believe that the families in our society that still subscribe to the three familial virtues of loyalty, intimacy, and security all resemble one another. The institution of the family has undergone tremendous change in our society, and it continues to evolve in several directions at once (32). Unsurprisingly, the challenge that

genetic testing will pose to a family's ability to uphold the three virtues will vary with the kind of family involved.

For convenience, consider three of the many kinds of American families that sociologists describe: The sessile organic family, the blended social family, and the diasporadic virtual family. Each of these will feel the challenge of genetic testing differently. Interestingly, however, it is the first, most traditional form of the family, presumably the source of these virtues, in which the challenge may be most severe.

Organic Families

The organic family is the kind of family that best exemplifies what some authors call the "biological" concept of family (33): a multigenerational clan that lives together in geographic proximity, like the Walton's on Walton's Mountain, for example, or the Venezuelan "Huntington disease families" of Lake Maricaibo. In some ways this kind of family might be best situated to benefit from a genetic testing program. Experience with presymptomatic testing for Huntington disease, for example, suggests that in families of "blood relatives" of any particular proband, intrafamilial communication is efficient, and the familial nature of any recurrent health problem will be readily understood. Clinical case studies show that familiarity with the disease in relatives may also improve family members' motivation for testing and diminish the stigmatization of those affected (34).

On the other hand, this kind of family is also more likely to be hierarchically organized, with clear lines of internal authority over decisions that affect the family as a whole. Under this structure the same features that make it possible to support strong family loyalties, intimacies, and protections can also exacerbate ethical problems for individual family subunits. For example, consider the following case report, described in a recent review of the experience of Indiana University's testing program for Huntington disease:

> Mr. Crawford's son married a woman at risk for HD. The couple, now divorced, were married for eight years and had a son and a daughter. These children are at 25 percent risk for HD. The former daughter-in-law has repeatedly said that she is not interested in testing for herself. Mr. Crawford is contemplating setting up a trust fund for his son's children to ensure adequate care for them if they should develop HD. In order to know whether he should make these arrangements, Mr. Crawford wants to have his grandchildren tested (35).

Cases of this sort pose ethical problems for genetic counselors to manage because of the way they challenge the individualistic, "nondirective" ethos that characterizes the profession's ideal. From the counselor's point of view, the principal issue in this case is the appropriateness of testing the children for a late onset disorder like Huntington disease before they are able to give their own autonomous consent to the procedure, and that is how the case is discussed in the review that reports it. But for the family, the scenario raises more fundamental moral questions than the children's ability to consent. Rather, they are more likely to be preoccupied with the relative weight of the various familial loyalties, protections, and intimacies involved. In seeking to improve the security of his grandchildren, has Mr. Crawford overstepped the proper limits of his role? Is it fair to ask the ex-daughter-in-law to risk discovering her own status in order to help Mr. Crawford in his attempt to improve her children's welfare? What role should the history of her divorce from his son play in the deliberations? As this case suggests, families that are organized in ways that facilitate power differentials between members may be most at risk for becoming coercive in pressing members to be tested on behalf of their relatives, and for holding individuals to familial standards of "responsible parenting" that curtail their parental autonomy and procreative liberty. This is also the family structure in which it is most difficult to keep a secret, raising concerns about how to protect the interests of those who choose not to learn their own genetic risks and what information is fair to use in deciding to override them. Moreover all these challenges can emerge insidiously within these families, because they all begin in positive affirmations of the familial virtues. Unlike abandonment, neglect, and silence, the risks of coercion, paternalism, and gossip will be hard to detect and difficult to demonstrate, especially by the less powerful family members who, by definition, will bear the burden of their harms.

Social Families

At the other extreme are families that are the products of serial monogamy, adoption, and new reproductive technologies: the "Brady Bunch," for example. These families exemplify the "household" concept of family: "an aggregate or group of actual (living) members, who are closely associated by living arrangement or by commitment, for better or worse (36). For these families the medical value of genetic testing is lowered by the fact that fewer family members are expected to share the same genetic risks. For these families genetic testing may be less threatening, if only because they are likely to be less attractive. Families seeking to build their identities on ties of love and commitment rather than blood will tend to downplay the importance of shared health problems, which will lower pressure to test "loyalty" through genetic testing. On the other hand, by underlining the differences between the lineages that make up the family, genetic testing does pose another kind of risk for social families: the potential divisiveness that testing could create within the blended family structure between at-risk and low-risk members. For example, consider this case report:

> Angela Smith, a 30-year-old Caucasian woman, came to an outreach clinic for genetic counseling because her husband, David, had two half siblings who died from cystic fibrosis. She was interested in finding out her risk to have an affected child. . . . Angela was tested first; the results showed that she carried the F508 deletion. David had blood drawn for testing. No mutations were detected. Based on this information and family history, the lab calculated his carrier risk to be 1 in 8. His carrier status could potentially be clarified by testing his father, an obligate carrier. Mr. Smith Sr. was tested but no mutation was identified. For further clarification, studies were proposed for David's stepmother, Sue, and his surviving half siblings, Robert, Dale and Karen. If Sue had an identifiable

> mutation which was also present in one of the half siblings, linkage analysis could potentially establish whether David had inherited a chromosome with a high risk of carrying as mutation. Sue, Karen and Robert lived in another state, but agreed to be tested. Sue and Karen had the F508 mutation. Robert was negative for any mutation. Because Robert fell into the same category as David, his sample could not be used to clarify risk. An additional complication arose when Ruth learned that linkage studies indicated that Karen was not Mr. Smith Sr.'s daughter. The family was told that linkage studies were uninformative. If they wished to proceed, a sample would be needed from Dale. The family has made no further efforts to pursue testing (37).

In discussing this case report, its authors focus on issues raised for the genetic counselor by the inadvertent finding of Karen's mis-identified paternity. But behind the counselor's dilemma, the outlines of this blended family's own moral struggle can also be seen. How far should their sense of familial loyalty oblige Sue and her children to go to help her husband's son's wife clarify her reproductive risks? Most of them are willing to be tested, and to endure the inconvenience of out-of-state testing. By agreeing to be tested, Sue even risked exposing the secret of Karen's paternity and the familial harm that might have resulted. Should Dale now also agree to be tested in turn, despite his initial reluctance? How hard should Angela and David press to convince him to help them? Familial fractures along risk status lines are already observed in other disease contexts, in which at-risk members become overly zealous in protecting their branches from the disease of the afflicted. In the analogous context of HIV testing, see levine (38). Genetic testing in Blended families will impose the additional tension of tracing health risks along lines already marked by parentage.

Virtual Families

Somewhere between the extended and the blended family are families that retain the identity of a biological extended family but no longer live together. Here is the incarnation of what some call the "abstract" concept of families: "an idea or ideal that refers to a family name or genetic line, the extended family in the largest sense, whose boundaries or members extend over both space and time" (36, p. 47). They are "virtual families" in that except for high holidays, most of their interactions are mediated by communication technology. Like organic families, these families may be motivated to seek testing, since they define themselves in terms of their biological connections. However, both distance and increased control over communication serve to make extended family members more inaccessible and more autonomous. As sociologists point out, for today's virtual families, "contact with relatives outside the nuclear family depends not only on geographical proximity — not to be taken for granted in our mobile society — but also on personal preference. Even relations between parents and children are matters of individual negotiation once children have left home" (39).

Clinicians involved in genetic testing already describe cases that suggest how the familial virtues might be challenged in families that fit this description as well. For example, consider the following case from the Indiana study:

> Paul, a healthy twenty-five year old man, contacts a testing center to request genetic testing for Huntington disease. Paul's father has HD. The father and his family live in another part of the country and are not known to the center. Paul has an identical twin brother, Michael, who does not wish to have the predictive test. Paul has moved away from his family for work reasons, but he maintains regular telephone contact with his parents, twin brother, and older sister. . . . (35, p. 21).

In discussing the management of this case, the authors frame its professional ethical challenge as a conflict between Paul's "right to know" his HD risk status, and Michael's "right not to know" his own identical risk. Interestingly, however, Paul apparently uses no "rights" language at all in framing the issue he faces. The case notes simply report that:

> Paul is planning to get married; he and his partner Linda are determined to find out whether he will develop HD before they start a family. Michael is single, and, according to Paul, does not think he could cope with the knowledge if he knew that he carried the HD mutation. Paul understands that his test result will reveal Michael's gene status. He states that he will not tell Michael or other family members that he is undergoing the predictive test. If he receives a positive result, he says that he will not tell Michael. However, he might tell Michael if he were to receive a negative result.

Against the background of his loyalty to his future family, Paul is wrestling with the tension between his existing obligation to protect his vulnerable brother and the costs to his natal family's intimacy such secrecy will exact. While he thinks he could succeed in keeping the test a secret from his natal family in order to protect Michael from bad news, how could he not share good news with Michael if he got it?

It is interesting that the authors of this case study concur with Paul's reasoning in this case and recommend accepting him for testing, despite their strong defense of obligate carriers' "right not to know" in more organic familial circumstances. As a result of the structural loosening of family ties in virtual families, it is also often easier to keep secrets within these families, increasing local control over both decisions to be tested and the privacy of test results. On the other hand, virtual families also face a structural challenge in preserving their intimacy for the same reasons, and that challenge poses its own risks. Paul and his wife will find themselves having to conceal increasingly more important aspects of their life if his test is negative, or else attempt to reveal their secret to Michael without the benefit of the mental preparation their own pre-test counseling provided them. Moreover efforts to recruit dispersed families for studies of hereditary mental health problems have shown that as familial communication becomes attenuated, it is possible for the dispersed branches to lose familiarity with the health problems to which they are prone, making it potentially more stigmatizing to reveal genetic risks across the family tree and reducing the motivation for distant members to contribute to clinical studies of the extended family (40).

CONCLUSION

From the current discussions of professional ethical problems in clinical genetics, it appears that at least three traditional virtues of family life are being severely tested by the increasing availability of predictive genetic risks assessment tools: loyalty, intimacy, and security. For blended and virtual families, the prospect of genetic testing can threaten our commitment to the familial virtues by focusing us on what separates us from each other. Within organic families, however, genetic testing can serve to reinforce our sense of solidarity. In that context the risk is not that the traditional virtues will be undermined but that we will be encouraged to go too far in pursuit of what it means to be a good family and our black sheep will suffer for it. To that extent, ironically, it may be that it is the most traditional form of the family, the sessile organic family, in which the challenge to our traditional familial virtues will be most difficult to anticipate and address.

Clearly, these claims can only be suggestions for further empirical research at this point: They assume that the categories of families employed here are useful within the context of genetic testing and that the associated familial virtues are the values that are at stake. To the extent that these ideas are worth exploring further, however, they do serve to suggest one important conclusion: as important as the professional ethical and public policy challenges of human genome research are, they may ultimately be eclipsed by the impact on how we, the public, understand our relations with our closest kin and the obligations those relations entail.

OUTLINE

INTRODUCTION

The rapid advance of genetic knowledge in the past decade has led to dramatic increases in our ability both to diagnose individuals with a variety of genetic disorders as well as to identify individuals at increased risk for developing genetic disorders at some time in the future. The relative newness of this technology, as well as its rapid dissemination into general medical practice, has raised numerous issues regarding the role of genetic testing in public health, in medical care, and in the lives of individuals at risk for or affected by diseases of genetic origin. Debates on these issues are clouded by the fact that our ability to treat many of these disorders lags far behind our ability to identify those at high risk, the treatments that are available are often expensive and less than entirely satisfactory, and the cost of testing remains fairly high. In the absence of general societal consensus on the larger issues surrounding genetic testing such as who should be tested, for what indications, what type of treatment and counseling should be available prior to testing, who pays and who should have access the information, the issue of informed consent has gradually emerged as a central focus in the testing debate. This article will discuss the general issue of informed consent, delineate the differences between genetic screening and genetic testing, and present the salient informed consent issues to be considered.

DEFINITION OF INFORMED CONSENT

An in-depth analysis of the issue of informed consent is beyond the scope of this article, and the reader is referred to other articles that address this topic at length. For our purposes it is important simply to understand the basic concept of informed consent. Informed consent has been defined as an *autonomous authorization* by a subject or patient that allows a professional either to involve the subject in research or to initiate a medical plan for the patient, or both (1). Informed consent occurs if and only if a patient or subject with a substantial understanding and in a substantial absence of control by others intentionally authorizes a professional to do something (2).

Traditionally medical ethics has been dominated by a commitment to the principle of medical beneficence — the principle that obligates physicians to further the medical best interests of their patients (1). Within this tradition and over time, the general consensus has emerged that "informed consents should be obtained for research or experimental interventions (therapeutic as well as non-therapeutic), for innovative interventions, for interventions that carry with them substantial or unknown risks and in situations of choice between substantially different medical plans. Also, all other things being equal, informed consents need not be obtained for routine interventions that pose little or no risk to the patient and that are not part of a research protocol" (1, p. 39). This level of general agreement as to when informed consent is required provides little guidance for specific medical treatments, interventions, or innovations such as genetic testing, although one author has advanced the idea that most applied genetic technology — screening, diagnosis, counseling, or treatment — should be characterized as therapeutic clinical research (3) requiring informed consent. The history and development of the concept of informed consent for genetic testing and screening is relatively recent, and it has been affected by myriad historical events, public policy and economic shifts, and technological innovations. These variables have resulted in two divergent approaches to informed consent such that consent is usually required for genetic testing but not always for genetic screening. The development of these two approaches to consent will be discussed below.

GENETIC SCREENING AND THE PUBLIC HEALTH MODEL

Definition of Genetic Screening

The term "genetic screening" is generally reserved for the public health context in which interventions that can detect disease or risk of disease are employed on a populationwide basis without regard to family history. A committee of the National Academy of Sciences (NAS) has defined genetic screening as "a search in a population of apparently healthy individuals for those genotypes which place them or their off spring at high risk for disease" (4). With genetic screening, carriers of deleterious genes who have never had an affected child can be identified as can fetuses, newborns, or adults who do not have an affected relative (5). For this reason, in most of the populations targeted for genetic screening — African-Americans for sickle cell, Jews of Ashkenazi descent for Tay-Sachs, virtually all newborns for PKU — parents or individuals will have no first-hand knowledge of the disorder, its

symptoms, severity, course, or risk for recurrence due to a lack of family history.

Public health is concerned with the prevention and reduction of morbidity and mortality in a given community. Within the public health framework, the principle of beneficence, which focuses on considerations of human welfare or well-being, is the guiding ethical principle. The principle of beneficence asserts a duty to confer benefits and to work actively to prevent and remove harms (2). Equally important is the duty to balance possible benefits that might accrue as a result of screening against possible harms. In the public health context, the benefit to be sought is the health or welfare of the community as a whole rather than that of the individual. The goal of genetic screening therefore is to reduce the incidence of morbidity and mortality related to genetic diseases in the community (6). If the benefit to be sought is the welfare of the community, what might some of the harms be? In general, harms that may occur during screening programs will occur to individuals and include labeling (7), stigmatization (8), misunderstanding (9), and false reassurance (10).

The degree to which a screening program, once implemented, is successful in reducing morbidity and mortality depends on several variables. These include the prevalence of the condition in the population to be screened, the sensitivity and specificity of the screening tool, the availability of a treatment or intervention for the condition, and the follow-up plans for those identified as positive.

Criteria for Screening

Principles to be followed with regard to genetic screening have been suggested by several authors (3,11,12) These principles include the following:

1. The disorder should be of high burden to the affected individual.
2. The inheritance and pathogenesis of the disorder should be understood.
3. The disorder should be preventable and practical therapy available, including genetic counseling and reproductive alternatives.
4. Patient's right to informed consent, voluntary participation, and confidentiality should be protected.
5. The benefit-to-cost ratio to the patient (public) should be greater than one.
6. The laboratory screening method should minimize false positive and exclude all false negative results.
7. A diagnostic test should be available.
8. Both screening and diagnostic tests should be available to all who require it.

In practice, however, these recommendations are rarely followed. A short history of our experience with newborn, prenatal, and carrier screening may prove instructive.

Experience with Screening

Newborn Screening for PKU. The first widespread experience with newborn screening emerged in the early 1960s with the invention by Robert Guthrie of the Guthrie assay to detect phenylketonuria (PKU). PKU is a hereditary metabolic disorder in which a deficiency of an intracellular enzyme results in the accumulation of the amino acid phenylalanine. PKU has an incidence in the United States and Europe of approximately 1 in 10,000 live births with the primary manifestation of the disorder being severe mental retardation (13). The Guthrie assay could be performed on apparently healthy newborns using a blood sample obtained by heel prick and was simple, inexpensive, and relatively painless. These characteristics were seen to weigh in favor of testing as many individuals as possible relative to the cost of not screening. At the time, however, the ability of a low-phenylalanine diet to prevent retardation had not been proved. Despite this lack of a clear medical benefit to screening, lobbying by Guthrie and the National Association for Retarded Children soon resulted in laws in most states that mandated the screening of newborns for increased concentrations of phenylalanine in the blood (14) even in the face of opposition to mandatory screening on the part of prominent groups including the American Academy of Pediatrics (15). In the rush to initiate widespread screening, some normal children with transient hyperphynylalaninemia were incorrectly labeled as having PKU and prescribed diets deficient in phenylalanine with deleterious outcomes including death (4,16).

Today, in most states, parental consent for PKU screening is not sought (17). In fact genetic screening, especially for newborns, is often carried out without informed consent or parental permission (18). Current common newborn screening tests performed without express informed consent include tests for hypothyroidism, PKU, sickle cell, and/or other hemoglobinopathies, although parents may object to screening on religious grounds (17). This exception to mandatory screening, however, may be seen as meaningless because parents seldom learn about the test until after it has been performed (19).

Some have concluded that informed consent ought not to be necessary for a procedure that offers great benefit and little risk (20). According to this argument, parental autonomy in decision making about newborn screening is grounded in the principle of beneficence, which holds that parents are the people best suited to act in the best interests of the infant. If it is generally agreed that it is in the best interest of the child to be screened, parental consent is superfluous and need not be sought. While this argument has clear appeal in the case where treatment is available (i.e., PKU), it is less compelling in situations in which the benefits of screening are less clear-cut. A second justification for not seeking informed consent in the context of newborn screening has been lodged in the notion of *therapeutic privilege* according to which a physician may legitimately withhold information based on sound medical judgment that to divulge the information would be potentially harmful. Harmful outcomes that would qualify for consideration of therapeutic privilege include endangering life, causing irrational decisions, and producing anxiety or stress (2). Physicians have justified the lack of informed consent by "maintaining that they do not wish to alarm women unnecessarily, since the tests will be normal in the vast majority of cases" (5, p. 184).

Finally, a third reason underlying the sentiment favoring lack of informed consent is that women might actually refuse to have the test done (5). Empirical investigation of this question for PKU, however, has shown that parents can be educated about this test at little cost (21) and that, if asked, less than 0.05 percent of parents would refuse testing (19). Some commentators feel that the scope of therapeutic privilege should be severely circumscribed and that at the very least, the privilege should not apply in situations when the potential harm to the patient from full disclosure would result not from the disclosure itself but from the decision that the practitioner fears that the patient might make as a result of the information disclosed (22).

Prenatal Screening. In addition to screening tests performed on newborns, screening tests are also often performed on pregnant women without providing any explanation or obtaining informed consent (23). This screening includes conditions that are primarily of interest because of the risk they pose to the developing fetus, such as rubella and Rh factor, as well as diseases with medical implications for both mother and fetus, such as tuberculosis, gonorrhea, gestational diabetes, and herpes simplex. Justification for this practice lies in the fact that for each of these disorders, effective interventions are available to prevent or markedly reduce harmful consequences (20).

Carrier Screening. The history of carrier screening in the United States might be characterized as one of mixed success. One notable failure is the experience with screening for sickle cell disease in the 1970s (23). Sickle cell disease is an autosomal recessive hemolytic anemia occurring most frequently in blacks but also in persons of Mediterranean, Asian, Caribbean, Middle Eastern, and South and Central American origin. Sickle cell disease is estimated to occur in as many as 1 in 400 African-American newborns (24). The public health implications of sickle cell disease, especially for African-Americans were brought to national attention in the early 1970s. By April 1973, 10 states had laws requiring mandatory screening for sickle cell disease despite the fact that no effective treatment was available. This rush to mandatory screening was not accompanied by provisions or funding for either genetic counseling or education of those screened (14). As a result there was great confusion between sickle cell trait or being a carrier for sickle cell and actually having the disease, on both the part of the general public and those who were screened. Identification of having sickle cell trait or sickle cell disease resulted in documented cases of job discrimination most notably in the military where for years the U.S. Air Force did not train black recruits with sickle cell trait to become pilots (25). Life insurance companies charged higher premiums for individuals with sickle cell trait or refused to insure them at all (26). Other reported hazards of screening for sickle cell included inappropriate medication and treatment of individuals whose symptoms were falsely attributed to sickle cell disease, delays in the adoption of children suspected to have the disease or trait, and the exposure of nonpaternity (27).

This experience made clear to what extent hastily planned, poorly executed, and underfunded screening programs mounted in the name of public health had the potential to cause great harm to individuals. When coupled with the growing importance of the principle of autonomy which advanced the right of those approached for testing to be fully informed as to the profound effects that testing may have on their lives as well as the lives of other family members, this experience led some to question the wisdom of the old approach. The genetics community, if not the wider medical community, also became sensitized to the concept that psychosocial risks, in contrast to medical/physical risks, were most likely to occur as a consequence of these programs and others like them. More recently our experience with screening for the evidence of human immunodeficiency virus (HIV) infection has further dramatized the psychosocial risks of diagnostic or predictive testing (coerced diagnosis, anxiety, loss of privacy, stigmatization, and discrimination). For the individuals most intimately involved, these risks came to be seen as important as physical risks and highlighted the potential downside of being identified as having or being at risk for developing a disorder that was poorly understood or considered highly undesirable by the society at large (14). These lessons have become apparent in the relatively recent handling of genetic screening for another autosomal recessive disorder, cystic fibrosis.

As early as 1983 the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research saw cystic fibrosis (CF) as a likely candidate for widespread genetic screening (12). CF is the most common autosomal recessive disorder among northern Europeans, with 1 in 25 being known carriers (10). The President's Commission came out in favor of explicit informed consent for CF screening and emphasized the fact that in their view, the "fundamental value of genetic screening and counseling lies in its potential for providing individuals with information they consider beneficial for autonomous decision-making" (12, p. 97).

In 1985 identification of DNA probes linked to the CF gene allowed prenatal diagnosis for families who had a previous child with CF and for whom specimens for the affected child and both parents could be analyzed. In 1989 the DNA sequence of the gene associated with CF was published (28) making widespread screening for carrier status possible. Mass screening was widely advocated for several reasons, with the most compelling being the ability to counsel heterozygote carriers of reproductive age. Arguments against mass screening were equally compelling. The initial test was able to detect only 75 percent of carriers (the frequency of the first detectable mutation ΔF_{508}). In addition the cost of screening was estimated to be as high as 2.2 million for each cystic fibrosis birth avoided (29). Shortly after the announcement of the CF gene, the board of directors of the American Society of Human Genetics (ASHG) issued a statement that "Routine CF carrier testing of pregnant women and other individuals is not yet the standard of care in medical practice" (30).

Continuing research showed that CF was genetically heterogeneous with over 100 different mutations giving

rise to the same symptoms. As more mutations were found and the ability of the test to detect carriers improved to over 90 percent, CF came to be seen as a test case for the application of future genetic technologies. Funding for pilot projects was made available by the National Center for Human Genome Research with the express research goals of gathering information to identify clinical practices that best increase patient understanding of disease–gene carrier testing and test results, and best protect individuals and families from test-related psychological harm, stigmatization, and discrimination (31).

In contrast to the previous experience with sickle cell screening, two important developments had taken place. The first was that changes in technology had spawned the development of numerous biotechnology companies eager to capitalize on the potential market for genetic tests and poised to market tests directly to physicians and consumers. The prospect of a test that could potentially be marketed to every Caucasian of child-bearing age was an enormous incentive to tout the benefits of testing. The second development was a major shift in perception of what the proper goals of routine carrier screening ought to be. Rather than promoting the public health model, wherein the goal of a carrier screening program would be a reduction in the incidence of genetic disease, there now appeared to be some level of agreement that the appropriate goal of carrier screening is to help clients make more informed decisions (32). With this change in emphasis came a concomitant change in the definition of what would count as the mark of a successful program. If the public health context dictated that a successful program should result in the reduction of morbidity and mortality in a population, the new emphasis on informed consent suggested that the effectiveness of screening programs should be assessed by whether the participants in the screening program have become informed (29) regardless of the ultimate decision made and regardless of that decision's ultimate effect on morbidity and mortality.

The CF pilot studies established an important precedent by incorporating the assessment of psychosocial impact into clinical studies usually dominated by concerns of medical safety, reliability and efficacy (31). This change reflected the now-common assumption that genetic "screening is a medical intervention with serious psychosocial risk" (29). The feeling was now that mass genetic screening programs should be considered experimental public health programs, implemented only after a favorable assessment of a program design that effectively achieves its goal while minimizing the potential medical, ethical, legal, and social problems (29). For that reason informed consent should be obtained to ensure that the client understands the risks of taking the test and is willing to accept them (33). Pre-test counseling or education has become the most accepted means to promote patient autonomy by providing accurate and understandable information designed to allow patients to decide for themselves whether the benefits outweigh the risks. In the context of screening for CF, the information to be presented should include information about CF, including its prognosis, treatment, and costs. The fact of screening raises the possibility that both members of a couple may be identified as carriers of the CF gene. In that case such a couple would have a one in four chance of having a child affected with CF. This possibility raises the issue of alternative reproductive options. Because one or more of these options, such as abortion, may not be acceptable to some families, these options need to be discussed in detail. Finally, the risks of testing, including testing errors and the possibility of stigmatization or discrimination, should be disclosed (29). This advancement of patient autonomy as the proper goal of screening programs may serve as a potent counterweight to commercial and other pressures in favor of mass screening.

Future of Informed Consent for Genetic Screening

There is a clear precedent for performing prenatal, newborn, and carrier screening for a variety of disorders without obtaining informed consent, although recent experience with screening for cystic fibrosis has placed informed consent clearly on the table as desirable if not required. As the Human Genome Project proceeds apace, the number of screening tests that can be performed on a single blood sample will increase rapidly. The proliferation of genetic screening tests coupled with a perceived shortage of personnel trained in genetics (29) has raised the question of whether obtaining informed consent, or even attempting educational efforts about the tests and their potential findings, is practical (34). George Annas and Sherman Elias have suggested that "generic consent" may be a more useful approach because it may not be feasible to explain the risks and benefits of each test. This approach is based on the presumption that "it will soon be impossible to do meaningful prescreening counseling about all available carrier tests" (34, p. 1611). The authors warn against the dangers of "information overload" and envision a situation in which patients would be informed of broad concepts and common denominator issues in genetic screening rather than specific information about each test and each condition that may be detected. The authors stress that the concept of generic consent is not a waiver of the individual patient's right to information. Rather, "it would reflect a decision by the genetics community that the most reasonable way to conduct a panel of screening tests to identify carriers of serious conditions is to provide basic, general information to obtain consent for the screening and much more detailed information on specific conditions only after they have been detected" (34, p. 1612). This view raises the issue of who will decide for what disease, symptoms, or conditions the screening will be done. Ultimately a single blood test may determine not only the risk to infants for Down syndrome, trisomy 18 and 13, but also sex chromosome abnormalities such as Turner's syndrome and Klinefelter's syndrome and conditions not present at birth but manifest in middle age including breast cancer, Huntington's disease, and Alzheimer's disease. This approach needs to be evaluated in view of the fact that now, and in the foreseeable future, we have few cures or treatments to offer for these genetic disorders. Individuals identified as affected, at risk, or carriers face difficult choices involving mating, reproduction, and abortion. The continued subtle but

steady erosion of a woman's right to abortion should be factored into the prospect of potentially identifying hundreds of thousands of individuals as affected, or at risk for, serious untreatable disorders.

This model has been criticized as driven primarily by technological capabilities rather than one based on established ethical principles (35). However, this model is perfectly in keeping with the historical framing of genetic screening as a public health issue whereby a group of influential experts decides what is in the best interest of the health of the population. A more sober note regarding this practice, and one that we might do well to ponder, is the observation that public health, rather than individual therapy, was the driving force behind the Nazi medicalization of eugenics that brought about the horrors of the holocaust (36).

GENETIC TESTING AND THE PSYCHOSOCIAL MODEL

Definition of Genetic Testing

The term genetic testing encompasses a number of technologies used to detect genetic traits, changes in chromosomes, or changes in DNA. Genetic testing is normally performed for two purposes; (*1*) to confirm a diagnosis in a person with symptoms of a particular disease, or (*2*) to clarify risk in an asymptomatic person who is known to be at risk for a specific disorder. This risk clarification in asymptomatic individuals can be further divided into presymptomatic or predictive testing in those individuals where disease genes have been identified that have high sensitivity and specificity and penetrance, and so-called susceptibility testing where the presence of a particular disease gene may be a necessary but not sufficient precondition for the development of the disorder. Examples of diseases for which predictive genetic testing are available would include Huntington disease, caused by an expanded trinucleotide repeat on chromosome 4 (37), and early-onset Alzheimer's disease associated with mutations on chromosomes 1 (38), 14 (39), and 21 (40). Examples of diseases for which susceptibility testing is available (although not necessarily recommended) include colon cancer (41) and breast cancer associated with mutations in BRCA1 (42) or BRCA2 (43).

In contrast to genetic screening, individuals, whether affected or at risk, for whom genetic testing might be appropriate usually have first-hand knowledge of the disease in question by virtue of having an affected relative. One advantage with regard to informed consent is that these individuals will often have a deep and personal familiarity with the disease, its symptoms and its course. They may not, however, have a clear understanding of the risk to their own offspring or of their options for avoiding the conception or birth of an affected child (5).

Genetic testing is typically initiated by a patient and/or his or her family and is performed in consultation with his or her medical care provider. Until very recently almost all genetic testing was performed in specialized medical centers primarily by professionals trained in the various subdisciplines of genetics including clinical genetics, genetic counseling, molecular genetics, and cytogenetics. The issue of context is important in this discussion. Although medical genetics may be viewed as a subspecialty of medicine as evidenced by the recent formation of the American College of Medical Genetics and the recognition of medical genetics as a primary subspecialty by the American Board of Medical Subspecialties in 1991, medical genetics has evolved with a very different moral tradition. Because of a previous history of eugenics, and for many years its almost exclusive involvement in highly personal and difficult issues of human reproduction, medical genetics almost from its inception has adopted as its primary moral principle respect for autonomy of the client or patient (44). "Respect for autonomy obligates professionals to disclose information, to probe for and to insure understanding and voluntariness, and to foster adequate decision-making" (2, p. 127).

In part, this commitment to respect for autonomy in genetics can be explained by the fact that most of what medical genetics has had to offer is information regarding recurrence risks for specific disorders rather than the more traditional medical benefits such as treatment or cure. What has evolved in genetics is a commitment to the idea of nondirective counseling in the provision of genetic information (45) and in the convention of obtaining informed consent prior to all diagnostic genetic testing (46). The goal of genetic testing is seen as to improve the ability of people affected or at risk to make informed personal and reproductive decisions in light of their genetic status (47). It has been argued therefore that before an individual agrees to be tested for a genetic condition, pre-test education and informed consent are necessary, and post-test counseling must be provided (29).

Genetic Testing for Huntington's Disease

This approach to genetic testing is most clearly seen in the experience with predictive testing for Hunting's disease (HD). In 1983 a linked marker to the HD gene was found (48). Ensuing discussions among genetic researchers, clinicians working with HD patients and their families as well as interested laypersons resulted in preliminary guidelines for predictive testing including eligibility criteria and testing protocols. These protocols included neurological examination, psychiatric and psychological screening, pretest counseling and follow-up (49–51). National and international guidelines for testing were soon issued by the Huntington's Disease Society of America (HDSA) (52–53) and the World Federation of Neurology Research Group on Huntington's chorea (54–55).

These protocols were guided by two main ethical principles, nonmaleficence and autonomy. Nonmaleficence is termed a negative duty to avoid doing harm. Many argue that predictive genetic testing is a complex endeavor and despite ten years of experience the jury is still out on the overall benefits of testing (56). Many of those most intimately involved in the testing process, either as persons at risk or experienced clinicians continue to urge caution (57–59). Mandatory pre-test counseling was, and remains to this day, a major element of testing for HD. The purpose is to ensure, to the extent possible, that individuals considering tested have clearly understood the

risks and benefits of testing to them, and have made a decision regarding testing that is consistent with their own personal goals and values. In other words, mandatory pretest counseling was seen as a means by which to promote autonomous decision-making regarding this predictive test. While this approach has been criticized as being overly paternalistic (60), there is some evidence that this approach is useful. A recent survey of 12 testing centers following recommended testing procedures in Canada has indicated a small number of catastrophic events, defined as a completed suicide, suicide attempt, or psychiatric hospitalization, have occurred as a result of testing (61). A recent survey of all testing centers in the United States has indicated that one advantage to the recommended approach to testing is the ability to identify the estimated 3 percent of individuals for whom testing is inappropriate or who would benefit from further counseling prior to testing (62). Debate continues regarding how much a person needs to know prior to testing and whether the standard approach to informed consent (33) can be maintained as the number and complexity of potential genetic tests increase.

The experience with HD and other disorders, as well as thoughtful commentary by a number of people, have alerted us to a number of other ethical issues that need to be considered in the context of informed consent for genetic testing. One of these is the issue of confidentiality with regard to genetic information. In truth, the results of a genetic test often have important ramifications beyond the individual patient including children or other blood relatives. For example, if an individual at risk for HD by virtue of having an affected parent tests positive for the mutation that causes HD, each of his or her children now has a 50 percent of having inherited the HD mutation from his or her parent. While confidentiality is basic to all health care relationships, limits to confidentiality have been accepted in the case of communicable diseases or intent to harm another person. In the HD testing, a common example is the situation in which an individual who has tested positive refuses to inform his or her children about their risk for HD. Situations such as these have led to discussions that at least consider the justification of breaching confidentiality, although the issue remains a thorny one (63).

A different, but related issue is that of privacy of genetic information. Should results of genetic tests be placed in medical records whereby they might be easily accessed by employers or insurance companies. Concern for confidentiality and privacy of genetic information is highest in those situations were the results of a genetic test may affect an individuals ability to obtain or to keep health insurance. This concern has been heightened by reports of individuals denied insurance, especially those stories based on misunderstanding of the genetic condition, confusions between being affected with a particular disease and being a carrier, or between having a positive genetic test and actually being affected with a particular condition (64). These concerns also extend into the arena of employment where individuals fear being asked to undergo genetic testing as a prerequisite for employment.

Genetic Testing for Cancer

As discussed above, genetic testing has traditionally been performed for well-defined, monogenetic syndromes that are inherited in a strict Mendelian fashion such as cystic fibrosis and HD. For these diseases, inheritance of the disease gene leads to the expression of the disease phenotype. While raising interesting issues in their own right, these diseases are not the best models for the future of genetic testing and the challenges that are likely to arise. For a better view of the future of genetic testing, we must look to the inherited cancers to understand the full complexity of genetic testing and counseling.

Although chromosomal locations for several cancer-predisposing genes, including those for hereditary retinoblastoma (Rb) gene, the WT1 gene for Wilms's tumor, neurofibromatosis type 1 gene, the APC gene for familial polyposis coli, and the p53 gene for Li-Faumenia syndrome, have been mapped, cancers due to these mutations are rare or are usually preceded by distinctive clinical manifestations. For these reasons, discussions concerning genetic testing for these disorders are rare (65). With the discovery of a major breast–ovarian cancer susceptibility gene on chromosome 17, the situation has changed dramatically.

In 1997 alone, approximately 180,000 American women developed breast cancer and 44,000 of these women died of this disease (66). The first breast cancer predisposition gene (BRCA1) was located to chromosome 17q in 1990 (67) and cloned in 1994 (42). BRCA1 is a large tumor suppressor gene with 22 exons, and more than 100 mutations have been identified. A second breast cancer predisposition gene on chromosome 13 was identified in 1995 (43). While mutation analysis is possible in high risk families, it is not yet feasible in the general population (68). It is estimated that as many as 1 in 300 women may carry germ-line mutations in one or more breast cancer susceptibility genes (69). In contrast to the Mendelian disorders, studies of inherited breast cancer susceptibility provide evidence of incomplete penetrance suggesting that the inheritance of an altered breast cancer gene is not sufficient to produce the disease. Other factors, including additional genetic and/or environmental factors may be necessary. The fact of incomplete penetrance presents the potential for prevention, a factor that may weigh heavily in favor of testing unaffected individuals from families with known hereditary breast cancer (70).

The prospect of widespread screening for cancer susceptibility provides the opportunity to take a close look at the process of informed consent, not only for cancer but for any clinical context in which there is inherent uncertainty about the benefits and risks of a specific test (71). From the beginning, those involved in genetic testing for breast cancer took the approach used in HD as their model and structured testing protocols based on the principles of autonomy, beneficence, confidentiality, and equity or justice (71). The research protocols through which testing for breast cancer was first offered included pretest counseling and education and follow-up (73). In virtually all discussions of genetic testing for breast cancer susceptibility, the issue of informed consent is considered of crucial importance. Reasons for this emphasis may be

the influence of the HD model, the fact that most testing involves adults and/or the fact that the benefits of testing are unclear while the risks and limitations of testing are becoming better known.

Three key limitations of genetic testing for breast cancer susceptibility have been identified (74). First, genetic testing for breast cancer susceptibility may not be informative. Second, the genetic information is probablistic in nature indicating an increased or decreased risk but not certainty. A negative genetic test result for BRCA1 leaves an individual with the population lifetime risk of breast cancer due to environmental and other factors and which is estimated at approximately 11 percent (75). Third, there are very real limitations to the current methods for cancer prevention and early detection. It is unclear whether current prevention methods of treatment (surgery, radiation, chemotherapy) or surveillance practices (mammography, clinical breast examination, and self-examination) actually reduce morbidity and mortality or what role genetic testing should play. In addition individuals must consider the risk of genetic discrimination in employment or in obtaining or maintaining insurance (64) and the potential for negative psychological consequences of learning one's genetic status (74,76–77).

The major benefit of genetic testing for susceptibility is the possibility of reassuring information if one is found not to carry a particular genetic mutation associated with increased risk for cancer (78). For those who test negative, one risk may include survivor guilt and shame (77). For those who test positive, testing may prove beneficial if this information facilitates actions to help prevent cancer or to aid in its early detection. This benefit will not be realized, however, if increased worry about cancer interferes with adherence to surveillance measures such as breast self examination, clinical breast examinations, and mammograms (79). Data suggest that a substantial proportion of women identified as gene carriers experience some level of psychological distress including persistent worries, depression, confusion and sleep disturbance (76).

Several studies have been designed specifically to determine what people want to know about susceptibility testing for cancer. In one study the authors concluded that at a minimum, disclosure statements needed to include information on (*1*) risk factors for cancer, (*2*) practical details of testing, (*3*) current limitations of testing, (*4*) available follow-up options, (*5*) known benefits of testing, and (*6*) known risks of testing (80). Other groups have recommended that informed consent be obtained through full disclosure of all the risks and benefits of testing including information about test accuracy, importance of correct cancer diagnosis, laboratory error rate, physical risks of blood drawing, potential problems with insurance or employment, psychological risks, and benefits of health care planning (68). A third study focused on two essential goals of informed consent, assuring that patients have substantial understanding and that their decisions whether to accept or to reject interventions are substantially voluntary. Two specific concerns arose with regard to these two goals, the relationship between patients' backgrounds, beliefs, and their understanding and the role of provider recommendations in voluntary decision making (71). One conclusion reached was that patients often expect and request that their providers play an active role in decision making. This approach is somewhat at odds with the traditional stance of nondirective counseling as held by genetic counselors and is time intensive, presenting a major challenge to our current system of health care delivery.

Genetic Testing for Children and Adolescents

The genetic testing of minors, especially for late-onset disorders, has long been a subject of much controversy due to questions about the ability of minors to give informed consent and because of the sometimes conflicting views of lawyers and ethicists. Anglo-American common law has long granted almost absolute authority to parents (81), and in the context of medical treatment, parents are allowed to do almost anything that is not harmful in and of itself or not clearly against the best interests of the child (82). From the beginning, however, general testing protocols and guidelines for HD prohibited the testing of those under 18 years of age at their parents' request (52–55). This prohibition was based on a desire to preserve the autonomy of the child and the ability to make his or her own decision about testing, and the desire to avoid causing harm. Several professional societies have published statements upholding the presumption against testing asymptomatic children for late-onset disorders for which there is no treatment or cure (83–85). Research has shown, however, that many health professionals would test children at their parents' request including 53 percent who would test for HD (86), and the issue remains controversial (87–88).

Potential harms of testing are seen to include misconceptions about the future, stigmatization, feelings of unworthiness, fear of intimacy or interpersonal relationships, harm to self-concept, guilt, and blame. Depending on the condition, potential benefits may include increased medical surveillance in those at high risk, relief in those found to be at low risk, the opportunity to obtain accurate information from a trained professional rather than reliance on parental knowledge, and allowing more time for adaptation to the possibility of future illness (89).

In general, genetic testing of minors can be seen to fall into four general categories based on utility where (*1*) testing offers immediate medical benefits for the minor, (*2*) there are no medical benefits but testing may be useful in making reproductive decisions, (*3*) the parents or the minor requests testing, and (*4*) testing is done solely for the benefit of another family member (90). The general consensus on the acceptability of testing varies widely among these categories as does the discussion of what might consitute proper counseling, how to assess minors' ability to give informed consent, and what are the actual outcomes of such testing. While the debate goes on, evidence suggests that more and more children are being tested (91).

Future of Informed Consent for Genetic Testing

The traditional role of informed consent for genetic testing is facing many challenges. One major challenge to the role of informed consent is the rapid movement of

genetic testing out of specialized genetics centers and into general medical practice. The increasing use of heavily marketed, commercially available tests by physicians who may not have the necessary training or background in genetics to either inform patients properly about the risks and benefits of testing or to interpret the results of testing accurately may seriously undermine the current practice of obtaining informed consent. One recent study examining genetic testing for the germ-line mutation of the adenomatous polyposis coli (APC) gene that causes colon cancer found that patients who underwent APC testing often received inadequate counseling, did not provide informed consent, and would have been given incorrectly interpreted results (92).

Evidence exists that biotechnology companies are also offering tests directly to consumers raising questions of whether patients and families are adequately informed about the tests, their limitations, and the risks and benefits of choosing to be tested (91). As the number of tests increases, especially for disorders that are relatively common in the population, the pressure on the part of biotechnology companies to market these tests will increase as well as the pressure on health care professionals to make them available. It remains to be seen whether and to what extent the fragile adherence to the notion of informed consent will survive.

GENETIC INFORMATION, ETHICS, PRIVACY AND CONFIDENTIALITY: OVERVIEW

MADISON POWERS
Georgetown University
Washington, District of Columbia

OUTLINE

INTRODUCTION

Research into the genetic contribution to disease holds out the promise of scientific discoveries that will revolutionize the diagnosis, prevention, and treatment of numerous medical conditions, thereby reducing premature mortality and excess morbidity. However, the expected benefits from genetic research and the incorporation of its techniques into clinical practice are accompanied by risks to individual privacy. The importance of protecting individual privacy, especially in circumstances involving highly personal,

often sensitive information such as that revealed by the analysis of an individual's genome, finds justification in a number of closely related moral arguments.

A major defense of stringent privacy protection is the claim that the ability to limit the access others have to personal, highly sensitive information is an essential element in any social policy committed to the preservation of individual autonomy (1). The ability to limit third party access to personal information also is necessary for establishing trust and intimacy within personal and professional relationships, for making reproductive and other medical decisions without the undue influence and interference of others, and for preserving valuable social and economic opportunities for persons whose life prospects may be diminished unfairly by the disclosure of information to persons with competing interests (2,3).

Genetic testing reveals just the sort of information that those concerned with the preservation of individual privacy are most anxious to protect. It may reveal a person's current medical condition, increased susceptibility to particular illnesses, or status as a carrier of genes that affect offspring. Such information can be used in ways highly detrimental to many of an individual's most fundamental opportunities and greatly limit his or her range of available economic and social choices. The potential adverse consequences of unwanted disclosures include limitations on access to health, life and disability insurance, lowering of medical treatment priority within public or private health care programs, loss of employment and educational opportunities, restriction of or added burdens placed upon available reproductive options, and social stigma and discrimination (3).

Although the present or future impact of the proliferation of genetic information regarding individuals remains uncertain and not easily quantifiable, persons having first hand experience with genetic testing within their immediate families view the threats to privacy as substantial, and many within the scientific community are concerned that public policies and clinical practices should be designed to mitigate or prevent the kinds of harms that can result from unwanted disclosure of personal genetic data (4). Indeed, many favoring increased genetic research and the rapid translation of genetic knowledge into clinical and public health benefit also favor enhanced efforts to protect the privacy, confidentiality, and anonymity interests of patients and research subjects.

PRIVACY, CONFIDENTIALITY, AND ANONYMITY

Although the precise contours of privacy and related concepts remain the subject of ongoing debate within both legal and philosophical circles a few basic definitions are needed to better understand the issues associated with the collection and use of genetic information. Privacy is often regarded as a state or condition in which personal information about an individual is inaccessible to others (3,5). A person can therefore be said to enjoy genetic privacy when there are limitations or constraints on the access third parties have to information about a person's individual genetic makeup. The most stringent genetic privacy protection policies, accordingly, are those that allow individuals to decide for themselves what if any individualized genetic information will be collected and analyzed.

Complete privacy, however, is both impossible and often undesirable for a variety of reasons. Genetic privacy, or the inaccessibility of others to genetic or any other type of information about individuals, is often a matter of degree. In some instances, what matters most to individuals is not complete privacy — namely where no one has access to personal information — but control over the access particular individuals or institutions have to information regarding one's genetic makeup. Often the central moral concern focuses on the identities of those who have access to their genetic information and the purposes for which that information will be used. For example, individuals often have prudential medical or reproductive reasons to make information about genetic susceptibility to some disease available to their spouses, children, physicians, or genetic counselors, but they may not want to reveal that information to their employers, insurers, or specific family members. In short, the paramount concern in many circumstances is for confidentiality: persons may not want information disclosed in confidence to health professionals to be shared with third parties for whom subsequent disclosure is not authorized.

Complete genetic privacy is impossible to assure for more basic scientific reasons as well. One reason is that sophisticated techniques for collecting and analyzing DNA make it impossible to guarantee that individual genetic information will not be obtained without his or her consent and subsequently used to his or her detriment. Blood, hair and other bodily materials from which DNA can be extracted are available to many third parties in numerous medical settings, non-medical institutional settings such as prisons and the military, as well as the conduct of criminal investigations (6,7). The opportunities third parties have for gaining unwanted and unconsented access to individual genetic information thus extend well beyond the clinic and research institutions.

Another reason that complete genetic privacy is impossible to assure is that many conclusions about genotype can be inferred from phenotype. For example, medically knowledgeable persons can make reliable inferences about the existence of genetic conditions such as Marfan's syndrome from visual observation of physical attributes. Moreover genetic privacy is more difficult to assure because often it is not information over which any individual always can retain exclusive control. Third-party knowledge of the genetic makeup of some individuals can be obtained from testing conducted on an individual's relatives. Researchers and health care providers will therefore learn about the genetic makeup of persons who are neither research subjects nor patients and will have access to genetic information about those who had no opportunity to refuse disclosure.

In other instances, a central concern is the prevention of unwanted third party access to genetic information through the preservation of anonymity. For example, individuals may be motivated by altruistic reasons to make DNA samples available to researchers studying inheritance of a particular disease within a family

or population geneticists studying genetic variation. Apart from any concern about subsequent disclosures of confidential information there are, in addition, risks that others may inadvertently obtain genetic knowledge about an individual who provided DNA samples. In such cases those persons providing the sample reasonably may insist on complete anonymity, or the assurance that once DNA is made available for research the researchers will not retain any personally identifying links (8,9).

Even the term anonymity can be misleading in what it implies about protection from loss of privacy. Genuinely anonymous collection of genetic information occurs when samples are not linked to specific persons. Studies using genetic information where specific personal identifiers have been collected but later discarded have been "anonymized" and thus direct identification of individuals is impossible (9). In instances in which personal identifiers have been stripped but a researcher retains the possibility of linking individuals to samples through a code persons who contributed the samples are not directly identifiable. The possibility of loss of privacy, however, is not eliminated entirely for anonymized (or even anonymous) samples. Under some circumstances (discussed below) researchers or members of the general public may be able to infer the identity of individual participants in studies, and a prudent privacy protection policy may include additional precautions to prevent publicly available or published information about the population from whom DNA samples were collected to be used to gain access to information about specific persons (10).

Privacy thus appears to be the most central conceptual category of moral analysis. Confidentiality, anonymity, and other policies may be largely strategic in achieving the goal of limiting access others have to personal information.

UNIQUENESS OF GENETIC INFORMATION

Those responsible for public policies, research protocols, or clinical practices designed to ensure the privacy, confidentiality, or anonymity of individuals must address the question of whether genetic information is uniquely sensitive and subject to a greater degree of abuse than other types of information. Such claims are often referred to under the rubric of "genetic exceptionalism," or the view that because the risk of privacy loss and its potential for adverse consequences may be greater for genetic information than for other types of medical information, separate and more stringent genetic privacy standards and policies are sometimes warranted (11).

There are three distinguishable questions within the genetic exceptionalist debate. First, is genetic information sufficiently distinct from other types of medical information? Second, does the intimate nature and sensitivity of such information represent a greater threat to individual privacy interests, thus justifying a heightened degree of protection? Third, are there feasible mechanisms for treating genetic information differently than other medical information?

The issue of distinctiveness is a threshold concern. Unless some workable definition of genetic information can be found, neither the question of its special sensitivity nor the issue of appropriate policies for its protection can be resolved. Genetic information clearly includes knowledge that may be gained from genetic testing of individual DNA samples. However, knowledge of an individual's genome also can be obtained by biochemical tests designed to detect gene products such as the production of enzymes or proteins that result from a particular genetic mutation (11,12). Moreover, inferences about an individual's genetic makeup can be made from family histories. For example, hemophilia A is an X-linked, recessive condition, and a diagnosis of a male child with hemophilia A reveals that it was inherited from the mother, and that the mother's female siblings also have a 50 percent probability of being carriers of the disease-causing gene (13).

To the extent that the aim is restriction of access third parties have to genetic information about specific individuals, a focus on limiting access to the results of genetic tests may be too narrow. However, the case for employing a broader conception of genetic information presents a dilemma; the fact that matters of family history and the results of biochemical tests are integral parts of patients's medical records undermines efforts to afford more stringent protection for genetic information than other types of medical information. Moreover the goal of improved clinical care will necessitate increased availability of genetic information, including the incorporation of results of individual tests into the patient record. Thus effective protection of genetic privacy often will be dependent upon the development of effective medical privacy protection policies generally (14).

The special privacy concerns about genetic information mirror similar concerns for other highly sensitive medical information that, if made available to third parties, may undermine individual autonomy and result in arguably unfair economic and social burdens on those whose genes have been identified. There is already a fairly well-established social consensus regarding the special sensitivity of medical information bearing on sexual behavior, mental health, sexually transmitted diseases, alcoholism, and drug use. These matters are deemed especially sensitive because they reveal intimate details of an individual's life and often carry a degree of social stigma or may result in discrimination in employment or insurance. Even without stigma or loss of social opportunities, many persons will view public knowledge of intimate aspects of an individual's life as an assault on human dignity and the ability to exercise autonomous control over matters at the heart of individual personality (3).

Genetic information can be seen as analogous to these already established categories of sensitive medical information because of similar risks associated with their disclosure to others, and accordingly it is not unreasonable to argue that genetic information should be added to the list of medical information for which added privacy precautions are warranted. Moreover, to the extent that stigmatized medical conditions such as alcoholism and mental illness have a genetic component, the case for more stringent privacy protection of these types of genetic information is strengthened.

There are other aspects of genetic information that enhance the arguments for the view that the collection of genetic information poses even greater privacy risks than other similarly sensitive medical information. One such argument is that genetic information, unlike cholesterol screening or testing for treatable sexually transmitted diseases, has more significant familial and reproductive implications. Because testing of one person can reveal information about an individual's siblings, parents, and children the privacy interests at stake go well beyond the risks any unwanted disclosure poses for a single individual (14). Hence, even if the genetic information arguably is no more sensitive or intimately revealing than some other types of nongenetic information, the privacy interests of many more persons may be implicated with each instance of privacy breach.

Another argument for the special moral importance of genetic privacy is the fact that much genetic information is merely probabilistic, and that learning the existence of some genetic susceptibility to disease often does not predict a particular individual's risk of acquiring a disease, its severity, or its date of onset. Thus the disclosure of genetic information is said to carry an inherent risk of being used to falsely label an individual on the basis of an increased statistical risk of having a mental or physical disease that has not and indeed may not result in any symptoms or disability (5,15). Of course, many other kinds of medical tests are merely probabilistic indicators of increased risk of disease as well, and genetic information may not be unique in this respect (11). However, the deeper concern seems to be that genetic predictors often are mistakenly seen as deterministic, immutable guides to assessing an individual's mental and physical capabilities (15).

A further argument for the uniqueness of genetic information and the need for more stringent genetic privacy protection lies in the observation that our DNA contains hidden information that may in the future reveal more about us than either we or those who collect and analyze DNA samples now realize. DNA has been called a "future diary," "a code not yet cracked," holding currently undecipherable but highly personal, sensitive information bearing on one's medical and social prospects (6,7,16). Two points are of special concern in this claim. First, the availability of DNA samples that have been analyzed for one gene may be subject to later analysis for another gene whose existence and function are not known at the time of consent to testing. It may not be reasonable to suppose that those who have consented to tests revealing one type of genetic information would have consented to the disclosure of genetic information of another type.

A second worry is that even testing for an allele with a known function can in the future reveal knowledge about an individual that no one could have anticipated at the time of testing. Genes typically have many functions, only some of which are known. A single gene may contribute to some disease burden such as sickle cell anemia but that same gene also may play a protective role such as improving one's resistence to malarial infection. Because there are no inherently "good" or "bad" genes, even testing for a "good" gene today may reveal the same gene as a "bad" gene tomorrow. Because persons who consent to testing may not be able to anticipate all that is revealed by a single test, adherence to the duty of confidentiality is a crucial moral component of any comprehensive genetic privacy protection approach.

It remains an important empirical question whether genetic information is inherently more sensitive than other types of information, and whether there is likely to be any consensus on what types of information are more important to protect than others. Certainly, all types of genetic information are not on par in their sensitivity, given the differences in what genetic tests may reveal about individuals and the potential consequences of their disclosure. Some persons may be more concerned with limiting the information others have about their sexual behavior and drug use than their increased genetic susceptibility to beryllium disease. Or a well-known trial lawyer may have great concern about the public disclosure of a heart condition for fear that potential clients will doubt his capability for aggressive advocacy, while being indifferent to what others know about his sexual conduct.

Individual differences in privacy attitudes are of tremendous moral significance. To the extent that the moral arguments for privacy protection are grounded chiefly in the protection of individual autonomy and dignity, matters that ought to be accorded the greatest protection are largely for the individual to decide for herself. However, to the extent that privacy interests are grounded in more general concerns for the protection of valuable social opportunities, then the issue of whether genetic information is more sensitive and therefore deserving of greater protection will depend on the extent to which the configuration of the major social and economic institutions leave persons more vulnerable to unfair disadvantage based on individual genotype.

Given uncertainties of whether genetic information is uniquely sensitive, its increasing integration with other types of medical information, and the competing moral rationales offered for its protection, debate about how best to deal with the protection of genetic privacy is likely to continue for some time.

RESEARCH CONTEXTS

Many who have considered the moral demands of privacy within research contexts argue for individual control over the creation of individually identifiable genetic information. Concerns about individual privacy take on great significance when there is a more than minimal risk of privacy loss for the subject and the contribution of DNA samples by research subjects offers little or no realistic expectation of any personal benefit. Such protections are embodied in current guidelines for federally funded medical research in the United States, and others also argue that this should be the norm in clinical practice, especially when collection of samples involves subsequent research uses of genetic information (9). These policy guidelines and suggested moral norms recognize the fundamental importance of obtaining informed voluntary consent to the collection of blood or other DNA samples for a variety of moral reasons, including but not limited to privacy concerns. Thus there is broad consensus that

individually identified stored blood or tissue samples ought not be made available to others for subsequent analysis without the explicit consent of the persons providing the samples, and that in instances where additional testing not contemplated at the time of obtaining the initial informed consent is proposed researchers should recontact subjects to obtain appropriate consent for these new uses (8,9).

Moreover many argue that in addition to the routine disclosure of medical risks associated with research, risks of privacy loss should be included among the core elements of the informed consent process (17,18). When links to identifiable persons who contributed genetic material to a study are retained, researchers cannot guarantee that confidentiality will not be compromised, but they can and should provide subjects with information about the steps they plan to take to minimize the risks to confidentiality.

One issue that continues to divide knowledgeable commentators is when informed consent for analysis of DNA samples is necessary. Some have concluded that identified or identifiable subjects should be given the option of restricting the use of their samples to the study for which samples were initially collected (8). Others also recommend that since many samples are obtained in nonresearch settings, all individuals should be given the opportunity to decide whether their samples may be used in research and whether they are willing to have those samples used in identifiable or linked research (9).

An alternative approach is to ask research subjects to give a blanket consent to additional testing for other genes or other genetic conditions not examined initially and perhaps not possible for researchers to contemplate at the time of obtaining informed consent (6–8,17,18). The main benefit of such a proposal would be one of efficiency. Researchers would have ready at hand a supply of DNA samples, perhaps in the form of immortalized cell lines, which can be used as a resource for many research studies, and in the process save both time and money associated with collecting and preserving DNA samples.

The major drawback in such a proposal is a concern over whether is it plausible to suppose that genuinely informed consent is possible for types of research not within the contemplation of the research community. In particular, informed consent to subsequent research uses may pose privacy risks (as well as other moral concerns about use or purpose of the research itself) that differ in kind or in magnitude from those that might be recognized initially. Even if the probability of privacy loss is not increased with re-testing for a different genetic condition, the magnitude of harm from an unwanted identification of any individual may be much greater than the harm the subject would have had in mind at the time of contributing the DNA samples. For example, agreeing to be tested for a remote risk of unwanted disclosure of some genetic mutation with no obvious adverse implications for a subject's ability to obtain insurance is quite different from testing for a different condition that does have insurance implications. The upshot of any policy of obtaining broad, open-ended consent for genetic testing for research purposes is that the subject may end up waiving any rights to protect his or her privacy interests without any feasible basis for knowing how significant those privacy interests might be.

Another area of continuing debate concerns the use of anonymous and anonymized samples and how best to deal with the risk of inferential identification of individual subjects mentioned previously. The recommendations of some commentators restrict the requirement of informed consent for research to instances in which actual personal identifiers are linked to the samples and are retained by the researchers performing the genetic tests. They therefore conclude that no informed consent is necessary either for prospective or retrospective tests when samples are collected anonymously or later are anonymized (8). Where genetic analysis is performed and the identities of subjects are removed from the samples but individual subjects remain directly identifiable through means of a code maintained by researchers, informed consent for the use of such samples is claimed to be necessary for prospective studies and usually necessary for retrospective studies, unless there is no more than minimal risk to privacy and the research could not be carried out practicably otherwise.

Others, however, suggest that in some instances, even anonymized samples may pose nonnegligible risks to individual privacy when it is possible for researchers or others to identify individual persons having a genetic mutation putting them at increased risk for some specific disorder. In such cases they conclude that there may be a need for recontacting individuals to obtain informed consent for subsequent use of samples originally contributed for a different purpose, and that only genuinely anonymous samples — where it is impossible under any circumstances to identify the individual source — clearly qualifies as exempt from any need for informed consent or other institutional efforts to safeguard individual privacy (9). Critics, however, point out that conducting research without specific informed consent has been the norm for most retrospective studies using patient medical records not involving genetic analysis, and while the critics do not reject categorically the stricter recommendations, they do worry that the proper balance between the legitimate aims of public health research and individual privacy requires further reflection and public discussion (19).

Inferential identification of individual subjects may occur in a variety of ways. Suppose that a group of researchers obtains DNA samples for a longitudinal study of several hundred members of families with a high prevalence of some type of cancer (e.g., cervical cancer) and that as a part of that study researchers also collect detailed medical histories of each study participant. The researchers therefore need to retain identifying links to each individual that are necessary for follow-up and for purposes of contacting the subjects with new information that might be of medical benefit to those subjects. Researchers therefore promise only confidentiality because the needs of the study as well as the medical needs of the subjects make anonymous collection of DNA samples undesirable. Suppose then that a later date a second group of researchers propose to conduct a different study of another medical condition

also suspected of greater than average prevalence in those families, and they therefore seek permission to reanalyze the DNA samples for a second gene mutation. Even if the second group of researchers receive the samples without individual identifiers — an anonymized study — publication or other dissemination of study results may enable family members to infer the identities of specific individuals who were tested and thereby reveal previously undisclosed information about who among those families had been affected either by cervical cancer or the second medical condition. Moreover publication of detailed family pedigrees showing family lineages and various characteristics — including additional medical data such as miscarriages or abortions potentially relevant to findings regarding cervical cancer risk — can magnify both the likelihood of inferential identification of specific individuals and the harm flowing from inadvertent disclosure of other sensitive medical information in the process (10).

The risk of inferential identification may be increased, for example, when the initial pool of subjects is small, subjects are drawn from a patient population publicly associated with some particular medical or research institution, the second medical condition tested for is rare, or some discernible phenotypic characteristics are described in the publication of the study findings (9). The publication of study results may allow individual researchers, and perhaps more significantly, other family members, to more easily infer the identities of individual subjects.

Genetic research poses other privacy risks not ordinarily raised by many other types of medical research. It is not only patients whose medical records may be examined by researchers and research subjects who voluntarily contribute DNA samples for analysis that risk having others learn information about mutations predisposing them to genetic disease or their status as carriers of mutations that may affect their offspring. Personal genetic information about individuals with no personal relationship to researchers or medical caregivers may appear in another family member's medical records used by researchers or become part of a data bank or genetic registry developed and maintained by researchers from information obtained from probands (5,14,17). Detailed, comprehensive, and accurate family histories may be essential to genetic linkage studies, and thus sensitive and perhaps inaccurate information about family members not participating in the research may be obtained without their permission or knowledge.

Some risks of breach of confidentiality can be minimized through efforts to build a strong wall of separation between these specialized research records and other medical data banks and individual patient records. While the risks may be small that persons will be harmed through third-party access to these records, individuals concerned about privacy on the ground that respect for human dignity requires an ability to control the kinds of sensitive personal information others can maintain in data banks will not agree that confidentiality protections are sufficient. As the boundaries between research and clinical practice erode the feasibility of more stringent privacy protections for genetic information is diminished and the burdens of privacy protection will fall increasingly on the shoulders of medical practitioners, genetic counselors, and researchers alike (20).

CONFIDENTIALITY IN CLINICAL CONTEXTS

The fact that genetic testing of one individual can reveal information relevant to the health status and medical care of other family members is the source of one of the most hotly debated moral issues in clinical genetics. When patients refuse to disclose genetic information that would benefit other family members, health care professionals are presented with a dilemma: They must choose whether to preserve patient confidentiality or to breach that duty of confidentiality for the benefit of third parties. The dilemma is often especially keenly felt when information regarding increased familial risk for some disease can be used by other family members to seek medical interventions that may prevent or delay the onset of disease or reduce its likely severity (e.g., familial breast or colon cancer), make informed reproductive decisions (e.g., CF, thalassemia, or Tay-Sachs), or make social and financial plans to cope with an anticipated physical or mental impairment when no treatment is available (e.g., Huntington's disease).

The dilemma, of course, is not unique to cases involving physicians, genetic counselors, and the family members of patients; researchers without any clinical connection to the person tested may obtain information bearing on the well-being of others, and interests other than those of family members may be at stake (21). For example, a widely discussed case involves researchers who learn that an airline pilot has the gene for Huntington's disease, which ultimately will impair his ability to perform his job safely.

Nonetheless, the dilemma is often felt more acutely in contexts involving clinical caregivers and those who are genetically related to their patients. The prospect of breaching patient confidentiality runs against the grain of the clinician's deepest professional commitments (22). That commitment in its strongest form is reflected is reflected in the fifth-century B.C. Hippocratic Oath: "What I may see or hear in the course of the treatment or even outside the treatment in regard to the life of men, which on no account one must spread abroad, I will keep to myself holding such things shameful to be spoken about."

More recent formulations of a physician's duties of confidentiality are more permissive. A 1980 statement of the American Medical Association (AMA), for example, states that a physician shall "safeguard patient confidences within the constraints of the law." The implication of the AMA statement is that legal requirements may override moral duties of confidentiality, and in fact court decisions in the famous *Tarasoff* case and in similar cases subsequently have provided much of the grist for moral discussions of the morally permissible exceptions to the ordinary duties of confidentiality (22,23). Although the *Tarasoff* case involved the issue of whether a psychologist must breach confidentiality in order to protect a third party from impending threats of bodily harm learned in the course of a therapeutic relation, both courts and the

numerous legal and ethical commentators have extended the reasoning to other contexts as well. For example, analogous duties to disclose information to persons at risk of harm have been argued for in the context of contagious diseases such as HIV. Predictably lawyers and ethicists have pondered the extension of these duties to cases involving genetic information.

The legal and ethical issues are, of course, distinct, but the reasoning relied upon in both realms is strikingly similar and the answers given by lawyers rely heavily on ethical concerns (22–25). Both raise the fundamental question, Under what conditions, if at all, a health care professional's duty to protect third parties from harm outweighs the duty to maintain the confidentiality of genetic information obtained from a patient? A secondary question is, To what extent ought these moral duties be reflected in the law?

Several positions on these questions can be found in the literature. Some, such as the members of the President's Commission on Biomedical Issues, the Nuffield Council on Bioethics, and the authors of the recent Institute of Medicine report on genetic testing counsel against disclosure of any medical information, including genetic test results, except in very narrowly defined circumstances (3,23,26). The analytic framework of the President's Commission provides the starting point for most of the discussions the exceptions to confidentiality for genetic information. They recommended four necessary conditions that should be met before disclosure is justified:

1. There must have be an unsuccessful attempt to persuade the patient to disclose the information to the relevant party.
2. There must be a high probability of harm without disclosure and a high probability that the disclosure itself will avert the anticipated harm.
3. The potential harm must be serious.
4. Only the degree of informational detail necessary to avert harm should be disclosed.

These criteria restrict significantly the instances in which confidentiality may be overridden. For example, in cases where no effective treatment is available, no disclosure would be warranted. Similarly, where third parties have other opportunities through which they may learn of their increased genetic risk for some specific disease, the duty of confidentiality would not be overridden.

Other commentators appear sympathetic to a more liberal attitude toward disclosure in a broader array of cases. They appear more concerned, for example, about the role of health professionals in promoting the health of the entire family and often speak of the family unit rather than any individual as the patient. When conceptualized in this fashion, strictly speaking no duty of confidentiality is broken. If, as Dorothy Wertz and John Fletcher claim, "hereditary information is a family possession rather than simply a personal one" the dilemma of confidentiality versus the duty to protect others is dissolved, and the issue is recast as a question about how best to discharge the health care professional's duty to make decisions for the best interests of their patients collectively (27).

The shift to viewing the family as patient nonetheless fails to resolve what may be the central issues lurking behind claims on behalf of patient confidentiality in the context of these familial disagreements. Important questions include whether health care professionals should be presumed to possess superior knowledge and insight about what is best in these circumstances, and whether they should be seen as having the moral authority to act as enforcers of a view of family communication or of an ideal of familial loyalty and connectedness which everyone may not share. Indeed, part of the moral justification given by the defenders of patient privacy is the claim that individuals, not governments or members of professional elites, ought to control highly personal, sensitive information, even in cases where failure to disclose such information may make it harder for others to take steps to prevent harm to themselves.

Others cite a second reason for their reluctance to leave it to health care professionals to decide when to breach patient's confidentiality. They argue that genetic harm is different from some other cases in which the duty to protect from harm is thought to outweigh the duty of confidentiality. They note that the patient, whose interest in confidentiality is sacrificed, is not normally the direct causal vector of potential harm to third parties (24). Disclosure of patient information in the genetic context imposes burdens on persons who simply fail to assist others, not on persons who, for example, through their own violent or risky behaviors impose risks on innocent third parties. Thus, unlike the psychiatric or HIV cases, where it can be claimed that individuals, through their own behavior, may have forfeited their privacy rights, no such claims can be made for genetic information.

Whether a particular factual situation meets the criteria set out by the President's Commission will vary considerably. To the extent that there is any agreement on these thorny issues, most concede that case for breach of patient's confidentiality is strongest when it involves a disclosure of information obtained from a patient who is the direct and morally culpable cause of another's harm, and the harm to third parties is grave, not otherwise preventable, and immediate.

NONMEDICAL USES OF GENETIC INFORMATION

The range of potential nonmedical uses of genetic information is lengthy and limited only by available technology and imagination. Moreover, the loss of genetic privacy may result from the generation or disclosure of genetic information gathered in nonmedical contexts, many of which are not governed by established ethical and legal norms of privacy governing conduct in medical and research arenas. A few widely discussed examples illustrate the extent to which genetic privacy concerns arise outside of traditional clinical and research contexts.

Two of the nonmedical uses of genetic information receiving the most critical attention arise within employment and insurance contexts. The use of such information to deprive a person of employment or health, life or disability insurance, are among the most economically consequential implications of a loss of genetic privacy (28,29).

The connection between genetic privacy issues related to employment and various forms of insurance is especially close in the United States, since a great majority of working persons obtain their insurance as a benefit of employment (30). The consequence, for example, of an employee having some genetic predisposition for increased susceptibility to some substance found in the industrial workplace are powerful economic incentives for employers to avoid hiring persons who may be both expensive to maintain as a member of its group health insurance plan and may in the future expose the employer to some additional risk of greater tort liability for employee illnesses developed after exposure to workplace hazards.

Many other potential nonmedical uses of genetic information also may arise as a consequence of their relevance in judicial proceedings. One such use now in the public spotlight is the collection of DNA samples for criminal forensic use (31). While the use of what is popularly known as DNA fingerprinting may aid in the identification of criminals and the exoneration of persons falsely accused of crimes, the widespread and systematic collection of DNA samples from convicted felons has some attendant privacy risks. The use of DNA in forensic analysis relies on a pattern of DNA sequences often referred to as junk DNA because they do not reveal specific portions of the genome believed to be associated with any medical condition, increased susceptibility to disease, or a person's carrier status. However, state and federal law enforcement agencies that collect DNA samples for identification purposes often retain the original DNA sample, and it can be analyzed and sensitive genetic information about individual persons may be revealed. In addition to the routine ways genetic information may be used to the detriment of any individual, such information could further be used as a basis for subsequent judicial decisions about sentencing, parole, or postconviction confinement to mental health or sex offender treatment programs (32).

The potential uses of genetic information in civil litigation are limitless as well. In addition to the defensive use employers might make of such information in exclusionary hiring and other workplace decisions, employers may also assert genetic predisposition as a partial defense against lawsuit by employees, consumers, and members of the general public who are exposed to substances in their products found to contribute to illnesses that also have a genetic component in their development. The scenario some envision is one in which genetic privacy may be routinely sacrificed for the sake of apportioning legal liability for harm suffered by workers and consumers (33). Beyond the strictly legal aspects of such uses of genetic information the use of genetic information in judicial contexts raises profound ethical worries about the fairness or justice of how risks and benefits are distributed within society's major social institutions.

Other morally problematic uses of genetic information in judicial contexts raise related issues of how individual responsibility for conduct and wrongdoing are assessed and the fitness of individuals to occupy professional roles involving a high degree of trust and fiduciary integrity. For example, in a California disbarment proceeding, DNA evidence was used to show that a lawyer who had embezzled client funds was genetically disposed to alcoholism (34). Although the California case resulted in the lawyer being placed on probation on the grounds that his genetic predisposition should be viewed as a mitigating factor in assessing his responsibility for his ethical lapses, other equally controversial uses of genetic information can be imagined as well. For example, some might argue that genetic information should be relevant in the assessment of an individual's fitness for entry in to professions such as law, medicine, or nursing. The moral objection this prospect raises — apart from the obvious worries that statistical associations between certain genes and behavior may not survive subsequent scrutiny by researchers — is that such information may be both a poor predictor of any specific individual's behavior and too intrusive into the private lives of individuals.

A few final examples reflect the potential uses of genetic information by courts, schools, and parents in making decisions affecting the custody and education of children. If detailed genetic information is added to the existing body of health information prospective adoptive parents can receive about children, problems of hard-to-place children will be exacerbated. If couples come to view genetic information as relevant to their decisions about adding an abandoned child to their family the risk is that more of the already unfortunate children will be put in an even greater disadvantage (35).

Similarly a parent, grandparent, or other party to a divorce or custody battle may make information regarding an opposing litigant's genetic illness or predisposition to illness a factor in determining the child's best interest, which is the touchstone of how judges make these difficult decisions (34). In addition schools and day care centers may assert a need to know genetic information about a child in order to make assessments of potential learning disabilities or judgments regarding the behavioral traits bearing on their suitability for enrollment (36).

The use of genetic information by those who resort to judicial proceedings to resolve disputes related to family life is already a fact of modern life, and the extent that role such information may hasten greater governmental intrusion into family life remains an open question.

CONCLUSION

In each context discussed in this article, we have seen how the increased collection and use of genetic information adds layers of complexity to old and familiar ethical problems, takes us into novel and poorly charted moral terrain in balancing privacy claims against other legitimate social goals, and often requires a fresh look at the moral foundations and value assumptions underlying the practices of many of our most basic social, medical, legal, and economic institutions.

OUTLINE

INTRODUCTION

Jean Ann Broderick was sexually assaulted and murdered on November 17, 1991, in Minneapolis. There were no suspects, and the possibility of another unsolved crime loomed large. The police, however, discovered semen at the crime scene, extracted a DNA profile from this evidence, and entered the profile into the state DNA databank.

The computer responded with what is known as a "cold hit" — a match that in an electronic second transformed a "no suspect" case to one with overwhelming prosecutorial merit. It was the "first case in American history in which the new tool of DNA databanking was used to solve a rape or murder case" (1). The prosecutor would later remark, "Without a DNA pool, there is no way we would have been able to identify the suspect. And we certainly would not have been able to get the conviction" (1).

As the Broderick case illustrates, DNA databanks are a significant advancement in crime solution. As of January 1999, over 400 "hits" have been recorded. These databanks are similar to the computerized fingerprint databank, called AFIS (Automated Fingerprint Identification System), which has been operational during the last decade. In some ways DNA databanks may be of greater utility than AFIS. While the wearing of gloves prevents the leaving of fingerprints, it is more difficult to prevent the deposition of some type of evidence that contains the perpetrator's DNA — especially in rape cases. Indeed, Virginia officials claim that "material susceptible to DNA analysis, including blood, skin tissue, hair follicles, and semen, may be found at thirty percent of all [violent] crime scenes" (2). Saliva and sweat should be added to this list (3). Furthermore, fingerprints cannot be dated; they can place a suspect at a specific location but cannot, by themselves, establish when the suspect was there, a significant limitation in cases in which the suspect has innocent access to the crime scene location. In contrast, semen found in a rape victim eliminates the "dating" problem in cases where the suspect claims mistaken identification.

An understanding of the role of DNA databanks in the criminal justice system requires some appreciation of the impact of DNA evidence in criminal prosecutions.

DNA EVIDENCE

In 1985 Dr. Alec Jeffreys of the University of Leicester, England, recognized the utility of DNA profiling in criminal cases. Its first use in American courts came the following year. The initial appellate case, *Andrews v. State* (4), was reported in 1988. By January 1990 forensic DNA evidence had been admitted in at least 185 cases by 38 states and the U.S. military (5). Today DNA evidence, in one form or another, is admissible in every state and federal circuit (6). These developments are remarkable. No other scientific technique had gained such widespread acceptance so quickly. No other technique had been as complex or evolved so rapidly. DNA profiling raised issues at the cutting edge of modern science (7). New DNA technologies were introduced even as cases litigating the older procedures worked their way through the court system; there have already been three generations of tests — Restriction Fragment Length Polymorphism (RFLP), Polymerase Chain Reaction (PCR) for discrete alleles, and the current state of the art, Short Tandem Repeats (STRs). In addition, testimony based on mitochondrial DNA has been admitted in evidence (8). Moreover, nonhuman DNA has proved useful in litigation, "ranging from homicide prosecutions to patent infringement litigation, with organisms as diverse as household pets, livestock, wild animals, insects, plants, bacteria, and viruses" (9).

Finally, no other technique has been as potentially valuable. One court commented that DNA evidence may be the "single greatest advance in the 'search for truth' ... since the advent of cross-examination" (10). Even its critics acknowledge that "[a]ppropriately carried out and correctly interpreted, DNA typing is possibly the most powerful innovation in forensics since the development of fingerprinting in the last part of the 19th Century" (11). For instance, in the World Trade Center bombing prosecution, an FBI expert matched saliva on an envelope sent by the terrorists to the *New York Times* with the DNA of one of the defendants (12). The next crime tool on the horizon is a credit-card-size device that would permit the analysis of DNA at a crime scene (3).

DNA evidence's power to convict is matched by its power to exculpate. This was underscored by a Department of Justice report that discussed the exoneration of 28 convicts through the use of DNA technology — some of whom had been sentenced to death (13). By mid-1999, more than 70 convicts had obtained postconviction relief based on exculpatory DNA test results. This development has already resulted in a change in some legal procedures. For example, the basis for motions for new trials has historically been quite limited; after a trial with the full panoply of constitutional protections, "finality" becomes a significant, if not paramount, interest. Thus, courts are skeptical of witnesses who subsequently "change" their testimony or post-trial "confessions" by unavailable third parties. Due to its reliability DNA evidence alters the calculus between "finality" and justice. Consequently, New York and Illinois have statutorily extended the time period for post-trial challenges to convictions based on DNA evidence, and the Department of Justice's Commission on the Future of DNA has advocated adoption of similar provisions in other jurisdictions (14).

Similarly, legislatures are reconsidering time limits on statutes of limitation in criminal cases (15). Ohio, for instance, has increased its statute of limitations for felonies from 6 to 20 years. DNA evidence reduces, to some extent, the danger of conviction based on evidence that is unreliable because it is stale. Indeed, to toll the Wisconsin statute of limitations, one creative prosecutor indicted a "John Doe" rapist based solely on his DNA code (16).

DNA DATABANKS

There are a variety of organizations that collect samples for DNA analysis — the Department of Defense collects blood and tissue samples from every U.S. service member, states authorize laboratories to secure dried blood samples (and often other tissue samples) from newborns, and reproductive laboratories and blood banks store samples from patrons. Each of these DNA systems raises a number of important privacy concerns (17). This discussion will focus, however, only on DNA databanks created by state or federal law for criminal enforcement purposes. These databanks present the full range of privacy and related issues in the much more dramatic context of criminal

enforcement, with the government, rather than a private employer or insurer, poised as the entity that threatens an individual's right to genetic privacy.

The first DNA databank used for criminal enforcement purposes was established by the Virginia legislature in 1989 (18). Today every state has enacted databanking legislation (19). The DNA Identification Act of 1994 provides federal funds to assist in this endeavor (20). Although each state legislates the conditions under which DNA samples are taken, the FBI has established a national databank system, called CODIS (Combined DNA Index System), into which the state profiles can be entered (21,22). Now states can search the databases of other states (23).

The state databank statutes vary widely with respect to their coverage. Some states require only sex offenders to provide samples for databank use (24). Other states also include different crimes of violence (25). Still others reach all convicted felons (26). One statute extends to those arrested for felony sex offense crimes or other specified offenses (27). Some states include juvenile offenders (28,29) and others cover probationers as well as parolees (30). Several databases also contain DNA profiles of missing persons and victims of mass disasters (31). The method of collection differs; some statutes require the collection of blood (sometimes a finger prick) (32) while others collect cheek swabs (33). Some statutes contain expungement procedures, under which a person's profile may be removed from the database if that person's conviction is reversed on appeal (19,34).

The state databanks also vary in other respects. Some states have legislated the circumstances under which their database can be searched. For example, two states allow their databases to be searched only for the investigation of sex-related or violent crimes (19). States also vary in the resources dedicated to DNA collection and analysis. Some jurisdictions have made considerable headway entering samples into their databases, while others face a tremendous backlog of samples yet to be analyzed (19,35,36). One report notes: "So while a new national FBI databank and state databanks now hold a total of 270,000 DNA profiles, there is also a backlog of roughly 500,000 unanalyzed DNA specimens. And the DNA of an estimated 1 million more people is supposed to be added by law, but some jurisdictions are already so far behind they're not even bothering to collect new samples" (37).

While variations in the coverage and procedures for state databases produce inconsistencies, state databanks do share important similarities as well. First, DNA profiles are generally kept in a database that identifies them by a coded identification number. To determine the identity of the person, a separate database must be accessed that decodes the identification number and links the profile to a specific individual. These security measures help to ensure that the DNA profile does not provide readily usable information about the identity of a particular individual (38). Second, databases generally contain one set of DNA profiles that have been taken from identified individuals, and a second set of profiles, usually taken from crime scenes, for which a match is sought (39). If a crime scene profile does not result in a match, it remains in the system. Some time in the future it may be matched with the profile of a subsequently convicted offender (39). Or, it may be matched with another crime scene profile, alerting the police that they are looking for a serial offender (40).

The present success and future potential of these databases for determining the identity of criminal perpetrators is clear. Commentators have suggested that dramatic deterrence and criminal enforcement benefits will be gleaned from the enhanced enforcement potential (19,36,39). Much of the criticism of these databases, in fact, focuses not on the lack of benefits to criminal enforcement but rather on deficiencies in confidentiality assurances that protect individuals' remaining rights to privacy.

PRIVACY AND RELATED CONCERNS

The privacy issues associated with DNA profiling were recognized from the beginning. In 1990 Congress's Office of Technology Assessment highlighted this issue: "Citing the inherent intimacy of genetic information, the current and developing ability to test for personal information other than unique identity, and the difficulties of maintaining the confidentially in a computer network, experts raise concerns that genetic information could be used unfairly to deny future benefits to persons with criminal records, and that genetic profiling within the criminal justice sphere could lead to wider testing and broader threats to privacy" (5, p. 35).

The National Academy of Science's 1992 DNA report also took note of privacy concerns, citing developments in both molecular biology and computer technology. "Molecular geneticists are rapidly developing the ability to diagnose a wide variety of inherited traits and medical conditions. The list already includes simply inherited traits, such as cystic fibrosis, Huntington's disease, and some inherited cancers. In the future, the list might grow to include more common medical conditions, such as heart disease, diabetes, hypertension, and Alzheimer's disease. Some observers even suggest that the list could include such traits as predispositions to alcoholism, learning disabilities, and other behavioral traits (although the degree of genetic influence on these traits remains uncertain)" (41). The report goes on to state: "Even simple information about identity requires confidentiality. Just as fingerprint files can be misused, DNA profile identification information could be misused to search and correlate criminal-record databanks or medical record databanks. Computer storage of information increases the possibilities for misuse. For example, addresses, telephone numbers, social security numbers, credit ratings, range of incomes, demographic categories, and information on hobbies are currently available for many of the citizens in our society from various distributed computerized data sources" (41).

Privacy concerns also arise from inadequate confidentiality protections for the DNA profiles, and more importantly, for stored samples in many state DNA databanks (17,42). Only some of the states provide a meaningful penalty for the unauthorized use of DNA samples or profiles by private parties (43–45). There also appear to

be few, if any, common law remedies available to deter this avenue for abuse, although there has been some discussion about legislative reforms that would provide individuals with protected privacy rights in their genetic information (45). It is not clear whether the unauthorized use of DNA profiles will ultimately present serious privacy intrusions, since the profiles are done with "junk DNA" that is currently believed to reveal little if any information about personal traits (46). Inadequate protection of the original biological samples is a completely different matter, however, and there is unanimity that these samples contain very private information about an individual (38,47,48). Yet in some state databank laws, the original biological samples receive less protection than the DNA profiles (19,48). The danger that DNA information contained in original samples may be disseminated in unauthorized ways becomes even more worrisome, since states may retain samples indefinitely in order to adapt to possible future changes in the profiling system (48).

In sum, DNA databanking will be a powerful tool in solving, and perhaps deterring, crime, but the possibility for misuse exists — probably in ways that cannot be anticipated. Some prior precedents demonstrate the possibility of abuse. For example, a former assistant U.S. Attorney "recalls an incident from his days as a prosecutor in the 1970s in which police officers were caught selling confidential police records to private investigators" (39). The harm that can result from unauthorized release of genetic information could be still greater. Because of privacy concerns, bioethicist Eric Juengst argues that "any DNA taken for identification purposes should only be typed for information-free markers" and "no physical DNA samples should be banked" (44, p. 64).

LEGAL CHALLENGES

Databanks have been challenged on a wide range of constitutional grounds — for example, freedom of religion (49) and the right to privacy (50). Also statutory attacks under the Religious Freedom Restoration Act have been advanced (51). Several attacks have been quite creative. For example, the Tenth Circuit has rejected arguments that taking DNA samples violates the Ninth Amendment and deprives offenders of a property interest in their blood without due process (52). None of these challenges has prevailed; often well-accepted legal principles foreclosed many of these attacks (53).

Six constitutional grounds are discussed in this article: (*1*) self-incrimination, (*2*) ex post facto, (*3*) equal protection, (*4*) due process, (*5*) cruel and unusual punishment, and (*6*) unreasonable search and seizure. In addition, states may provide greater protection under state constitutions or statutes than the U.S. Supreme Court has recognized under the federal constitution; independent state grounds have been raised, but no challenge has yet prevailed on this basis (54–57).

SELF-INCRIMINATION CLAUSE

Challenges to the collection of blood or saliva grounded in the Self-incrimination Clause of the Fifth Amendment have been quickly dismissed based on well-established precedent. The leading case is *Schmerber v. California* (58). While being treated at a hospital for injuries sustained in an automobile collision, Schmerber was arrested for driving under the influence of alcohol. At the direction of the investigating police officer, a physician obtained a blood sample from Schmerber. Although the defendant objected to this procedure on the advice of counsel, his blood was extracted and analyzed for alcoholic content. Before the Supreme Court, Schmerber argued that the extraction of blood violated the privilege against self-incrimination. Rejecting this argument, the Court held that the privilege covers only *communicative or testimonial evidence*, not *physical or real evidence*. According to the Court:

> It is clear that the protection of the privilege reaches an accused's communications, whatever form they might take.... On the other hand, both federal and state courts have usually held that it offers no protection against compulsion to submit to fingerprinting, photographing, or measurements, to write or speak for identification, to appear in court, to stand, to assume a stance, to walk, or to make a particular gesture. The distinction which has emerged, often expressed in different ways, is that the privilege is a bar against compelling "communications" or "testimony," but that compulsion which makes a suspect or accused the source of "real or physical evidence" does not violate it (58).

Subsequent Supreme Court cases reaffirmed the testimonial-physical evidence distinction recognized in *Schmerber*. In *United States v. Wade* (59), the Court held that compelling an accused to exhibit his person for observation was compulsion "to exhibit his physical characteristics, not compulsion to disclose any knowledge he might have" (59) and thus not proscribed by the privilege. In *Gilbert v. California* (60), the Court concluded that the compelled production of a "mere handwriting exemplar, in contrast to the content of what is written, like the voice or body itself, is an identifying physical characteristic outside [the Fifth Amendment's] protection" (60). Similarly, in *United States v. Dionisio* (61), the Court ruled that compelling a defendant to speak for the purpose of voice analysis did not violate the Fifth Amendment because the "voice recordings were to be used solely to measure the physical properties of the witnesses' voices, not for the testimonial or communicative content of what was to be said" (61,62). Cheek swabbing falls into the same category.

Courts addressing the Fifth Amendment arguments in the databank context have applied these precedents when rejecting such arguments (63–65).

EX POST FACTO CLAUSE

The United States Constitution prohibits the retroactive application of criminal laws. Article I provides that neither Congress nor any state shall pass an "ex post facto Law" (66). According to the Supreme Court, this prohibition means that "[l]egislatures may not retroactively alter the definition of crimes or increase the punishment of criminal acts" (67). The ex post facto argument is limited to convicts who were already

incarcerated at the time the databank legislation took effect; prospective application does raise this issue (68). Nevertheless, the efficacy of the databanking program would be severely undercut if only the profiles of persons convicted of sex offenses in the future were in the databank; many of these new defendants would not be released for years, while previously convicted inmates would be released into the community without inclusion in the databank.

Some courts have ruled that the ex post facto prohibition does not apply because databanking statutes are not *penal* in nature (69–71). For example, the Ninth Circuit rejected such a challenge to the Oregon statute because its "obvious purpose is to create a DNA data bank to assist in the identification, arrest, and prosecution of criminals, not to punish convicted murderers and sexual offenders" (72).

The ex post facto issue, however, does not necessarily disappear merely because a statute is labeled "non-penal." Ex post facto principles apply when punishment is retroactively increased (73), and that may occur if a sanction for refusal to provide a DNA sample is the denial of parole or the forfeiture of good time credits (credits awarded for a period of good behavior in prison). Much depends on how a parole or good time statute is written. Of course, many states have eliminated both parole and good-time credit.

Parole Release

If parole is purely discretionary, a parole board may consider a refusal to comply with a valid prison regulation, such as one requiring a DNA sample, in determining the appropriateness of parole. In contrast, an increase in the length of a sentence caused by new conditions in a mandatory parole jurisdiction is suspect. For example, the Virginia parole statute mandated parole six months before the sentence release date, and the Fourth Circuit ruled that withholding release for failure to provide DNA samples would be unconstitutional (74). This does not necessarily mean that these inmates can escape providing a sample; a state may make it a new crime to refuse to provide a sample (75).

Good-Time Credit

Reduction of good-time credit raises somewhat different issues. In *Weaver v. Graham* (76), the Supreme Court ruled that the elimination of good-time credit constituted an increase in punishment because "a prisoner's eligibility for reduced imprisonment is a significant factor entering into both the defendant's decision to plea bargain and the judge's calculation of the sentence to be imposed." *Weaver*, however, involved inmates whose good-time credit was legislatively reduced across the board, even if they had *not* violated any prison regulation. Several courts have distinguished databank statutes on this basis, finding that at the time of sentencing good-time credits were known to be contingent on compliance with legitimate prison regulations and the nature of those regulations may be amended while the prisoner is serving penitentiary time (77–79).

EQUAL PROTECTION CLAUSE

The Fourteenth Amendment establishes that no state may "deny any person within its jurisdiction the equal protection of the laws." Several inmates have asserted equal protection grounds as a basis for striking down databank statutes. They claim, for example, that sex offenders are treated differently from other offenders in violation of the equal protection mandate.

The Supreme Court has developed a multi-tiered classification for reviewing equal protection claims. A state statute is subjected to "strict" scrutiny if it adversely affects a suspect class. Utilizing strict scrutiny analysis, a court will require the state to prove that it has a *compelling* governmental interest and that it is employing the *least restrictive means* to achieve its compelling goal. Suspect classifications that warrant strict scrutiny under the Equal Protection Clause are race, alienage, and national origin (80).

A statute can be challenged under the Equal Protection Clause even if it does not adversely affect a suspect classification. Thus, a databank statute that requires DNA sampling only of sex offenders and violent felons may be attacked on the ground that it treats those particular criminals unequally in violation of the equal protection requirement. If no suspect classification is involved, however, courts use a lower level of scrutiny, namely, what is known as the "rational basis" test.

The rational basis test is derived from a long line of Supreme Court decisions (81). Under this type of judicial review, a "statute is presumed to be valid and will be sustained if the classification is rationally related to a legitimate state interest" (82). In *Boling v. Romer* (83), the Tenth Circuit rejected the argument that taking DNA samples only from sex offenders violated the Equal Protection Clause. The court held that there was a "rational relationship" between the "government's decision to classify inmates as convicted sex offenders and the government's stated objective to investigate and prosecute unsolved and future sex crimes" (83, p. 1341).

In *State v. Olivas* (84), the Washington Supreme Court considered a challenge to the state statute that required a DNA sample from anyone convicted of a sexual or violent offense. The court held that "[t]here is a rational relationship between the interest of the government in law enforcement and the application of the statute to this class of persons" (84, p. 1087). The statute's purpose of facilitating the investigation and prosecution of sex offenses and violent crimes was sufficiently important to defeat the equal protection challenge.

DUE PROCESS

Both the Fifth and the Fourteenth Amendments forbid the denial of life, liberty, or property "without due process of law." Inmates have asserted two different due process arguments: substantive due process and procedural due process.

Substantive Due Process

The Supreme Court has stated that "[d]ue process of law is a summarized constitutional guarantee of respect for those personal immunities which ... are 'so rooted in the traditions and conscience of our people as to be ranked as fundamental' ... or are 'implicit in the concept of ordered liberty'" (85). Recognized fundamental rights include the right to bodily integrity (86), which is arguably violated when the state conducts a medical procedure over an individual's objection. State action that infringes a fundamental right protected by the Constitution is subject to the strict scrutiny test (87).

In the 1952 case of *Rochin v. California* (85), the Supreme Court held that the forcible stomach pumping of a suspect to recover narcotic pills "shock[ed] the conscience" and did not comport with traditional ideas of fair play and decency, thereby violating due process. By contrast, the Court, faced with a due process challenge in the 1957 case of *Breithaupt v. Abram* (88), upheld the involuntary extraction of blood from an unconscious suspect after an automobile accident in order to determine whether he was intoxicated. In distinguishing *Rochin*, the Court emphasized that unlike the extraction of stomach contents, the extraction of blood was performed "under the protective eye of a physician" and was a routine and scientifically accurate method that did not involve the "brutality" and "offensiveness" present in *Rochin* (88, pp. 435–437).

The *Rochin* and *Breithaupt* decisions predated the applicability of the Fourth Amendment to the states through the Due Process Clause of the Fourteenth Amendment in 1961 (89,90), and thus the continued validity of an independent substantive due process analysis in these cases is questionable. Challenges to databank statutes no longer need be addressed in terms of due process, but rather as possible violations of specific constitutional guarantees enumerated in the Bill of Rights, such as the right to be free of unreasonable searches and seizures (91). The Supreme Court specifically held in *Schmerber v. California* (92) that the manner in which evidence is obtained from a suspect is subject to the reasonableness requirement of the Fourth Amendment (92, p. 771), and in *Winston v. Lee* (93), the Court applied the Fourth Amendment to the surgical removal of a bullet from a suspect. Thus, virtually all DNA databank and other cases that are potentially subject to attack on substantive due process grounds are better analyzed under the Fourth Amendment (94–96).

Procedural Due Process

Procedural due process mandates that a person cannot be deprived of "life, liberty, or property" without a hearing and attendant procedural safeguards, although the nature of the safeguards differs depending on the interest involved (97). Some inmates have challenged DNA databank statutes on the ground that the taking of a DNA sample without a hearing deprives them of a liberty or a property interest in their genetic material without due process of law. These challenges have uniformly failed.

In *Rise v. Oregon* (98), the plaintiffs argued that the Due Process Clause required prison officials to provide an opportunity for a hearing before requiring felons to submit a blood sample in accordance with Oregon's databank statute. The court held that "[t]he extraction of blood from an individual in a simple, medically acceptable manner, despite the individual's lack of an opportunity to object to the procedure, does not implicate the Due Process Clause" (98, pp. 1562–1563; 99). Consequently, the felons did not have a liberty or property interest at stake.

Similarly, in *Boling v. Romer* (100), the plaintiff challenged a Colorado statute that required inmates convicted of sexual assault offenses to submit a DNA sample as a condition of release on parole. Without providing the sample, inmates could not regain their liberty. The court nevertheless found that plaintiff's argument that the state "unconstitutionally deprived him of a property interest in his blood without due process" was "unpersuasive" (100, p. 1340). The court explained that parole in Colorado was discretionary and that convicts have no constitutional right to be conditionally released before the expiration of their valid sentences.

CRUEL AND UNUSUAL PUNISHMENT

Several challenges to DNA databanks focused on the Eighth Amendment, which proscribes cruel and unusual punishment (101). In *Sanders v. Coman* (102), inmates argued that the use of force to obtain blood samples violated the amendment; they alleged: "The uses of force have included instances of several officers surrounding an inmate while one held his arm still, the spraying of mace, and bending inmates' wrists in a painful manner to induce compliance." An Eighth Amendment violation, however, occurs only if force is applied for the purpose of causing harm (103), or if the force is excessive (104). Neither theory, in the district court's view, applied in this context. Here, force was used to compel compliance with a valid prison regulation (105,106).

Courts have also held that placement in solitary confinement for failing to comply with an order to provide a blood sample does not violate the Clause (107). In *Boling v. Romer* (108), the plaintiff argued that DNA sampling in a prison constituted cruel and unusual punishment because it exposed him to potential abuse from fellow inmates. He claimed that when prison authorities indicated in front of other prisoners that he was required to submit to a DNA test, they identified him as a sex offender and thus made him vulnerable to possible physical harm from inmates who were apparently particularly hostile toward sex offenders (108, p. 1341). The Tenth Circuit rejected this argument, finding it insufficient to support an Eighth Amendment claim.

Another prisoner asserted that DNA testing violated the Eighth Amendment because the blood test itself was painful (109). Not surprisingly, the district court found that the argument lacked merit, noting that the blood was withdrawn by a trained technician in accordance with medically accepted procedures.

The Cruel and Unusual Punishment Clause also prohibits deliberate indifference to an inmate's serious medical needs (110). Inmates asserting that they were

injured because of the blood test, however, must show more than mere negligence in withdrawing blood (111).

Consequently, the Eighth Amendment does not present an obstacle to databanking. Moreover, DNA samples need not be blood. Profiles can be created from cheek swabs, which inflict no pain and are extremely unlikely to cause injury.

SEARCH AND SEIZURE

The most significant legal challenge to databanks is based on the Fourth Amendment's prohibition of unreasonable searches and seizures. Although the U.S. Supreme Court has yet to address the issue, its decisions in other areas provide a framework for analysis.

The Fourth Amendment is intended to ensure "privacy, dignity, and security of persons against certain arbitrary and invasive acts by officers of the Government or those acting at their direction" (112). There are three distinct Fourth Amendment issues raised in this context. First, there is a "seizure" of the person, which brings that person under the control of the government agents. Second, there is a subsequent search for and seizure of a biological sample or trace evidence from this person (113). Third, the use to which the genetic information in the sample is put raises a final Fourth Amendment issue.

A finding that the Fourth Amendment applies does not mean that a procedure is unconstitutional. That is merely the first step in the analysis. As the Supreme Court has often remarked: "[T]he Fourth Amendment does not proscribe all searches and seizures, but only those that are unreasonable" (114).

Applicability of Fourth Amendment

Seizure of the Person. In the databanking context the first issue — seizure of the person — is not problematic because convicts are already incarcerated. The seizure would be an issue for parolees, probationers, or previously released convicts. Nevertheless, notifying such persons to report and provide DNA samples would be a reasonable seizure. Indeed, it is probably not a "seizure" within the meaning of the Fourth Amendment (113). As for arrestees, probable cause is required, but an arrest warrant is not mandated if the arrest takes place in a public place (115).

Search to Obtain Samples. The leading case on defining which governmental activities are "searches" within the meaning of the Fourth Amendment is *Katz v. United States* (116). *Katz* substituted a privacy approach for the traditional property approach to this issue. According to the Supreme Court: "[T]he Fourth Amendment protects people, not places. What a person knowingly exposes to the public, even in his own home or office, is not a subject of Fourth Amendment protection. . . .But what he seeks to preserve as private, even in an area accessible to the public, may be constitutionally protected" (116, p. 351).

There is little dispute that taking blood samples is a search. In *Schmerber* the Supreme Court held that the extraction of blood for the purpose of scientific (blood/alcohol) analysis "plainly constitutes searches of the 'persons'" within the meaning of the Fourth Amendment. In *Skinner v. Railway Labor Executives' Ass'n* (117), which involved a drug testing program, the Court wrote that "it is obvious that this physical intrusion, penetrating beneath the skin, infringes an expectation of privacy that society is prepared to recognize as reasonable" (117, p. 616). In addition to blood samples, lower courts have generally treated the taking of hair (118–120) and saliva (121) samples as searches.

In contrast, the taking of fingerprints (122), voice exemplars (113), or handwriting samples (123) do not constitute searches because such physical characteristics are constantly exposed to the public. (Note the difference between fingerprints and blood or cheek swabbings; it will be important in discussing arrestees later in this article.)

Use of Genetic Information. In *Skinner* the Supreme Court also ruled that the subsequent chemical analysis of the blood sample to obtain physiological data "is a further invasion" of privacy interests — informational privacy (124). This point was further refined when the Court considered the collection of urine samples. Even though this procedure did not involve a bodily intrusion, the Court held that it was a search. Like blood, the chemical analysis of urine can "reveal a host of private medical facts," including whether a person is epileptic, pregnant, or diabetic (124, p. 617).

The courts addressing the constitutionality of databank statutes have acknowledged the applicability of the Fourth Amendment to the taking of a sample (125–127) as well as its subsequent analysis (127). Consequently, the databanking litigation has focused on the second step in Fourth Amendment analysis — the reasonableness of these programs.

Reasonableness of Search

As noted above, the Fourth Amendment does not prohibit all searches, only unreasonable ones. Traditionally, reasonable searches are those conducted pursuant to a warrant issued by a neutral and detached magistrate and based on probable cause. Moreover, search warrants must describe the place to be searched and the items to be seized with "particularity." The particularity requirement circumscribes the police's discretion in executing a search warrant. Nevertheless, exceptions to these traditional requirements have been recognized, and courts have cited several in upholding DNA databank statutes.

The databank cases can be grouped around three lines of Supreme Court precedents: (*1*) administrative searches, (*2*) "special needs" searches, and (*3*) prisoner searches (127). These categories, however, are not mutually exclusive — and they all involve a balancing of interests in determining the reasonableness of the procedure. The next sections focus on sex offenders, the most common category in DNA databank statutes. Later sections discuss persons convicted of other crimes and arrestees.

Administrative Searches. Originally, the phrase "administrative search" was used to describe non-law enforcement searches. For example, the landmark case, *Camara v. Municipal Court* (128), involved housing inspections. The

purpose of these inspections was not to gather evidence of criminal conduct but rather to ensure compliance with health and safety standards. Housing inspectors rather than police officers conducted these searches, although violation of the regulations could result in criminal prosecution.

In *Camara*, the Court held that the reasonableness of an administrative search is determined by balancing the governmental interest against the nature and extent of the intrusion on privacy.

> The ... argument is in effect an assertion that the area inspection is an unreasonable search. Unfortunately, there can be no ready test for determining reasonableness other than by balancing the need to search against the invasion which the search entails. But we think that a number of persuasive factors combine to support the reasonableness of area code-enforcement inspections. First, such programs have a long history of judicial and public acceptance. Second, the public interest demands that all dangerous conditions be prevented or abated, yet it is doubtful that any other canvassing technique would achieve acceptable results. Many such conditions — faulty wiring is an obvious example — are not observable from outside the building and indeed may not be apparent to the inexpert occupant himself. Finally, because inspections are neither personal in nature nor aimed at the discovery of evidence of crime, they involve a relatively limited invasion of the urban citizen's privacy (128, pp. 536–537).

The Court found the inspection system "of indispensable importance to the maintenance of community health" (128, p. 537). Thus, in *Camara*, the Court concluded that housing inspection programs were supported by the compelling government interest of avoiding dangerous living conditions and maintaining housing stock and that the inspection programs were a reasonable means for achieving these societal interests.

Later cases involved the inspection of gun dealerships (129), mines (130), and the workplace pursuant to the Occupational Safety and Health Act (OSHA) (131). Perhaps the most familiar administrative search is the metal detector procedures at airports (132).

New York v. Burger (133), decided in 1987, is a transitional case. It involved a New York statute authorizing warrantless administrative searches of automobile junkyards, which the Supreme Court upheld. The *key* point is that the statute was aimed specifically at finding evidence of *crime*. In contrast, prior administrative searches had focused on governmental interests such as health and safety. Moreover, the junkyard inspections were conducted by the *police*. In a later case the Court employed the balancing test to uphold sobriety roadblock checkpoints (134).

While the balancing approach provides flexibility in achieving significant government objectives, such as airline passenger safety, the danger exists that this approach will result in the "balancing" away of constitutional rights. Therefore, this analysis demands rigor. For example, while the Supreme Court upheld the drug testing of railroad employees after an accident and custom's officers involved in drug interdiction operations, it has struck down the drug testing of political candidates as mandated by a Georgia statute (135). The Court found that the justification for the latter procedure was simply not compelling. In one case, which involved jail searches, the Supreme Court explained the "balancing" analysis as follows:

> The test of reasonableness under the Fourth Amendment is not capable of precise definition or mechanical application. In each case it requires a balancing of the need for the particular search against the invasion of personal rights that the search entails. Courts must consider the scope of the particular intrusion, the manner in which it is conducted, the justification for initiating it, and the place in which it is conducted (136).

Roe v. Marcotte (137), a Second Circuit case decided in 1999, can be used to illustrate this approach. In this case the court reviewed the Connecticut databank statute, which is limited to sex offenders. First, the court correctly found the government interest — solving past and future violent sex crimes — both legitimate and significant. Moreover, the databank system "may" deter future crimes by those whose profile is in the system. Second, the means selected to accomplish these objectives were reasonable. The state cited studies showing a high rate of recidivism for sexual offenders and DNA evidence is "particularly useful" in investigating these crimes "because of the nature of the evidence left at the scenes of these crimes and the demonstrated reliability of DNA testing" (138). Third, the blanket testing of all sex offenders eliminated the need for discretionary decisions, an historical concern in Fourth Amendment jurisprudence. Fourth, the intrusion — the extraction of blood — was slight ["minimal" in the Supreme Court's view (124)] and did not raise a health risk. In these circumstances, the court held that the balance tipped in favor of the databanking statute.

Three other aspects of the Connecticut scheme are noteworthy. First, trained medical personnel are required to take the blood sample. Second, the identifying information associated with the DNA profile remains anonymous until a match is made. Third, procedures limiting access to and dissemination of information in the system are specified.

"Special Needs" Searches. Over time, the rationale underlying administrative searches was extended to other procedures, commonly called "special needs" searches. The Supreme Court in *New Jersey v. T.L.O.* (139) applied this rationale to searches of public school children by teachers; the "special need" was the maintenance of a safe, orderly, and contraband-free school environment in order to create a healthy learning atmosphere. To achieve the desired environment, the Court recognized that "the school setting requires some easing of the restrictions to which searches by public authorities are ordinarily subject" (139, p. 340).

Similarly, in *Griffin v. Wisconsin* (140), the Supreme Court upheld a Wisconsin regulation that permitted a warrantless search of a probationer's home if there existed "reasonable grounds" to believe that the probationer possessed contraband. The Court observed that "[a] State's operation of a probation system, like its operation of a school, government office or prison, or its supervision of a regulated industry, likewise presents 'special needs' beyond normal law enforcement that may justify

departures from the usual warrant and probable-cause requirements" and that "in certain circumstances government investigators conducting searches pursuant to a regulatory scheme need not adhere to the usual warrant or probable-cause requirements as long as their searches meet 'reasonable legislative or administrative standards'" (140, pp. 873–874).

Subsequently, the Court applied this rationale in cases involving government-required alcohol and drug testing for railroad employees (124) and customs agents involved in drug interdiction (141). In the school and probationer cases, the special need resulted in a lesser standard (reasonable suspicion instead of probable cause) to justify an invasion of privacy (142), while the drug testing cases upheld regulatory schemes that did not require any quantum of proof.

A number of courts have used the "special needs" rationale to uphold databank statutes (143–145). In contrast, other courts have balked at applying the "special needs" rationale in this context, noting that this category is limited to governmental objectives "beyond normal law enforcement" (146,147). These courts note that DNA databanks are intended *only* for law enforcement purposes. Other courts point out, however, that "special needs" searches, such as probationer searches, are also associated with law enforcement but do not involve the investigation of a specific crime (148).

More important, as noted above, the administrative search and "special needs" categories are not mutually exclusive — indeed, they often overlap. This is because the "special need" beyond normal law enforcement is typically some administrative objective. For example, an inventory search of the personal belongings of arrestees prior to placement in a jail cell is reasonable, whether classified as a "special need" or an administrative search (149). Similarly, this procedure could also be considered a prisoner search, the next category to be considered. The important point is the "balancing" rationale employed in determining reasonableness. There may, however, be a tendency in some opinions to use "special needs" as a talismanic incantation, curtailing further inquiry.

Fourth Amendment Rights of Prisoners. In *Jones v. Murray* (150), the Fourth Circuit adopted a third type of analysis. In upholding the Virginia statute, the Fourth Circuit relied on several Supreme Court decisions that had held that prisoners had reduced expectations of privacy under the Fourth Amendment. In *Bell v. Wolfish* (151), for example, the Supreme Court upheld the constitutionality of body cavity inspections of pretrial inmates following "contact visits," even in the absence of probable cause. The Court's rationale in determining the reasonableness of the procedure focused on the significant security dangers inherent in this environment: "A detention facility is a unique place fraught with serious security dangers. Smuggling of money, drugs, weapons, and other contraband is all too common an occurrence. And inmate attempts to secrete these items into the facility by concealing them in body cavities are documented in this record" (151, pp. 558–560).

In a later case, *Hudson v. Palmer* (152), the Supreme Court upheld cell searches ("shakedown" inspections) for the purpose of discovering contraband in a prison. The Court, in a 5–4 decision, ruled that a prisoner did not have a reasonable expectation of privacy in a cell. Yet, this holding (like *Wolfish*) was justified on institutional security needs. The Court wrote: "The recognition of privacy rights for prisoners in their individual cells simply cannot be reconciled with the concept of incarceration and the needs and objectives of penal institutions" (152, p. 526).

There are no institutional security needs in the databanking context, and thus this rationale is simply inapplicable. Indeed, some statutes apply even in the absence of incarceration (146). Moreover, both *Wolfish* and *Hudson* acknowledged that the Court's jurisprudence in prisoner rights cases recognizes the applicability of constitutional protections: "There is no iron curtain drawn between the Constitution and the prisons of this country" (153,154). Similarly, in another case the Court recognized that although lawful incarceration "brings about the necessary withdrawal or limitation of many privileges and rights," a retraction had to be "justified by the considerations underlying our penal system" (155).

Finally, these cases are, in the words of one court, "nothing more than special needs cases" (146). In sum, the administrative search rationale provides the best approach; it does not torture the "special needs" rationale, nor misapply the Fourth Amendment prison cases.

Inadequate Remedies. Under any rationale the most troublesome aspect of the databank statutes is the lack of meaningful remedies. As discussed previously, in many states there is little to no deterrent for unauthorized dissemination of DNA profiles and samples. The Virginia statute makes unauthorized dissemination of databank information a misdemeanor, but other statutes do not. By contrast, unauthorized disclosure of information in the federal databank system is punished by a $100,000 fine. While significant criminal penalties should be enacted, criminal prosecution may be insufficient. It often requires proof of intentional conduct, a standard that may be difficult to establish beyond a reasonable doubt. More important, prosecutors have enormous discretion in charging crimes, including the power not to charge at all — a distinct possibility considering the close relationship between prosecutors and the police.

Civil remedies should thus also be included in all databank statutes. Because databank statutes involve constitutional rights, civil rights suits under Section 1983 are possible, although not without impediments. Appropriate remedial models are not hard to find, however. For example, the federal eavesdropping and wiretap act provides for civil damages and injunctive relief in addition to felony sanctions (156). For some violations a plaintiff may recover actual damages or statutory damages of $100 a day or $10,000, whichever is greater. In addition, punitive damages are permitted as well as reasonable attorney's fees and other litigation costs (157). The Privacy Protection Act of 1980 provides for civil (actual) damages but not less than liquidated damages of $1000, reasonable attorney's fees, and other litigation costs (158).

Comparable provisions should be added to the databanking statutes. Proponents of databanking could not

object to such provisions because they assert that violations will be few.

Expansion of Coverage Beyond Sex Offenders

Most databank statutes are limited to sex offenders. These provisions are supported by empirical research on recidivism; more than 50 percent of brutal and violent crimes, e.g., rape and murder, are carried out by repeat offenders (3). Recidivism is noted by several courts in upholding databank schemes (159). The nature of these offenses — their brutality and their often serial nature (3, p. 48) — is a critical point. However, some statutes also encompass homicides and other crimes of violence. Still others include all felons. The justification for including prisoners who have been convicted of white-collar felonies is difficult to discern. Even the sex offender category is problematic if it includes prostitution and public indecency as some statutes do.

Jones v. Murray (160), the Fourth Circuit case discussed above, addressed this issue because all felons are included in the Virginia DNA databank system. To buttress its position, the court cited recidivism studies encompassing all felons (161). The inmates, however, argued that the statistics on nonviolent felons undercut the state's position. The inmates' "statistics indicate[d] that 97% of the cases in which DNA evidence was used to link a defendant with a crime involved murder or rape, and further, less than 1% of all nonviolent offenders are later arrested on murder and rape charges" (162). In response, the majority merely noted that the percentages need not be high where the objective is significant and the privacy intrusion is limited.

The dissent in *Jones* believed that the distinction between violent and nonviolent felons was critical: "The only state interest offered by the Commonwealth for including non-violent felons is administrative ease," but such an interest does not suffice "to outweigh a prisoner's expectation of privacy in not having blood withdrawn from his body when that prisoner is not significantly more likely to commit a violent crime in the future than a member of the general population" (162, pp. 313–314). Indeed, the Virginia senate report concluded that the recidivism data *only* "supported the inclusion of plaintiffs convicted for felony sex offenses, assault, capital murder, first and second degree murder, voluntary manslaughter, larceny and burglary" (162, p. 314). All felons were added to make the databank "more efficient and cost effective." The dissent also pointed to other statistics in the record: "United States Justice Department statistics provided in the record show that only %0.4 of non-violent felons are later arrested on rape charges, and only %0.8 are later arrested on murder charges. One might assume non-violent drug offenders would be more likely to commit violent crime subsequent to release than other non-violent felons; yet, only %0.4 of them are later arrested for rape, and %0.3 for murder." The dissenting judge concluded: The lack of justification "leads me to a deep, disturbing, and overriding concern that, without a proper and compelling justification, the Commonwealth may be successful in taking significant strides toward the establishment of a future police state, in which broad and vague concerns for administrative efficiency will serve to support substantial intrusions into the privacy of citizens" (162, p. 314).

The British experience, which commenced earlier than that of the United States, may be instructive. The British initially focused on sex offenses but later included burglaries and car theft because of the high number of matches. They found cross-over among offenses. According to one official, "People who commit serious crime very often have convictions for petty crime in their history" (163). While the cross-over concept is significant, the scope of the British system is breathtaking; they expect to "eventually include a third of all English men between 16 and 30, the principal ages for committing crimes."

The category of crimes subject to databanking should be supported by empirical data or persuasive reasons. There is apparently some support for including some nonviolent crimes (23), such as burglary, but each offense should be specified. For example, historically, burglary was not considered a "property" crime; it was a crime against habitation, intended to protect people in their dwellings (164). The crime that is the objective of the burglary need not be larceny or theft; it could be any felony including murder or rape. Burglars must anticipate what action they will take if surprised by an occupant, including the use of force. Therefore an argument to include burglary could be made, but felony tax evasion would be a different issue.

Expansion of Coverage to Arrestees

The Louisiana statute applies to sex offender and other specified *arrestees*. New York Police Commissioner Howard Safir has proposed that DNA be collected from *all* arrestees (23). Not satisfied with that proposal, New York Mayor Rudy Giuliani suggested that all newborns be tested (39). These proposals raise significant legal and policy problems.

Unlike a conviction, which is either based on a jury verdict and the "beyond a reasonable doubt" standard or a guilty plea with its attendant constitutional safeguards (including the right to counsel), *one* police officer can make an arrest based on his or her own view of probable cause, which is not a high standard. If the arrest occurs in a public place, an arrest warrant is not required (165). There is a requirement for judicial review of the probable cause determination within 48 hours (166,167), but the DNA sample will have been taken by then. In any event, this judicial review occurs in an ex parte procedure — that is, without the presence of the arrestee or defense counsel. The difference between an arrest and conviction is immense. In 1994, 65.3 percent of murder arrests resulted in conviction, but the conviction rates for some other crimes were much lower: robbery (39.3 percent), aggravated assault (14.1 percent), and burglary (38.8 percent) (168). Moreover, the FBI has reported that one-third of the initial rape suspects identified by the police are exonerated by DNA profiling (169); this statistic further underscores the difference between arrest and conviction. In short, the expansion of databank coverage to arrestees raises significant constitutional issues. Several theories that may

be used to justify such expansion are discussed next and rejected.

Search Incident to Arrest. One possible theory for obtaining blood samples or cheek swabs would be a search incident to apprehension, a well-established exception to the warrant requirement (170,171). Under this exception, once a suspect has been arrested based on probable cause, a search of the arrestee's person and the area within her immediate control is permitted. In *Chimel v. California* (172), the Supreme Court set forth a twofold justification for this exception: (*1*) protection of the arresting officer and (*2*) prevention of the destruction of evidence. The search is automatic once there is an arrest; no additional showing is required.

The Supreme Court, however, has shown a greater concern about searches involving bodily intrusions than about other types of incident searches. In *Schmerber v. California* (173), the Court considered the constitutionality of extracting blood for the purpose of blood-alcohol analysis. The Court rejected the notion that the extraction of blood would automatically be encompassed by the search incident to arrest doctrine. According to the Court, the justifications underlying the search incident to arrest rule

> have little applicability with respect to searches involving intrusions beyond the body's surface. The interests in human dignity and privacy which the Fourth Amendment protects forbid any such intrusions on the mere chance that desired evidence might be obtained. In the absence of a *clear indication* that in fact such evidence will be found, these fundamental human interests require law officers to suffer the risk that such evidence may disappear unless there is an immediate search (173, pp. 769–770).

The Court further considered the necessity of securing a warrant based on probable cause as a prerequisite to the extraction of blood. It found the purpose underlying the warrant requirement — the intervention of a neutral detached magistrate between the police and the citizen — applicable to bodily intrusions: "The importance of the informed, detached and deliberate determinations of the issue whether or not to invade another's body in search of evidence of guilt is indisputable and great" (174). Nevertheless, because the alcohol content of blood diminishes with the passage of time, the Court recognized an "emergency" exception to the warrant requirement, which was necessary to preclude the destruction of evidence. This emergency exception, however, does not apply in other contexts — for example, when blood is sought for the purpose of genetic testing, including DNA profiling, a physical characteristic that remains constant (175,176).

Search for Blood. There may be grounds to take a DNA sample for testing *outside* the databank context. For example, if the crime that is the basis for an arrest involves blood, semen, or other evidence, there may be probable cause to issue a search warrant in that *specific case*. Often the probable cause to arrest also provides probable cause to search the arrestee for a DNA profile — for example, to compare the suspect's DNA with that from a semen stain in a rape case. A search warrant, as distinguished from an arrest warrant, requires probable cause that (*1*) the subject committed a crime and (*2*) blood analysis results would be evidence of that crime (177). In other words, the search is not automatic upon arrest, and this type of search differs from an administrative search (databanking), which is based on future or past crimes. Once a sample is obtained for this purpose, a search of a databank (for past offenses) would involve only a slight incremental privacy invasion (178).

Identification Rationale. Another rationale that has been suggested is an "identification" exception, applicable at a stationhouse "booking" after arrest. *Jones v. Murray* (179) alluded to this rationale: "[W]hen a suspect is arrested upon probable cause, his identification becomes a matter of legitimate state interest and he can hardly claim privacy in it. . . .[T]he identification of suspects is relevant not only to solving the crime for which the suspect is arrested, but also for maintaining a permanent record to solve other past and future crimes" (179, p. 306). While *Jones* did not involve an arrestee, it went on to cite an analogy to fingerprinting — as have other databank cases (180,181).

Unquestionably, the proper identification of a person arrested is a legitimate governmental objective (182); it is not unusual for fugitives to use an alias (183,184). Moreover, fingerprinting arrestees is a reasonable method to accomplish this goal, as a number of courts (but not yet the U.S. Supreme Court) have recognized (185–187). Prior to the time that fingerprinting became routine, photographing (188) and the Bertillion system (based on physical measurements) were used for this purpose (189).

Nevertheless, the "identification" rationale is problematic for several reasons. First, there are significant differences between fingerprinting and DNA sampling. The former does not involve the kind of privacy issues raised by DNA samples (as opposed to profiles). As the Supreme Court has noted, "[f]ingerprinting involves none of the probing into an individual's private life and thought that marks an interrogation or search" (190). The fingerprint system is less intrusive and not as subject to abuse as some present methods of DNA sample collection. Second, the availability of fingerprinting undercuts the need to use DNA for the purpose of identification; every person whose DNA profile is in the database has fingerprints in AFIS. There are 226 million fingerprint cards in the FBI's Criminal Justice Information Services Division.

Third, fingerprinting arrestees as a means of identification developed before computers automated the process in AFIS. Prior to AFIS, the FBI used the Henry classification system, which was based on friction ridge patterns (e.g., arches, loops, whorls, ridge counting) and required prints from all *ten* fingers to identify arrestees. This took weeks if not months. In contrast to the classification of fingerprints, the identification of a partial crime scene print was based on ridge detail (e.g., ridge endings, bifurcations, enclosures) and required *suspects* because prints of all ten fingers are rarely left at a crime scene (191). In short, a single crime scene print could not be matched to the FBI's central depository. For example, a serial rapist, known as

the "Westside Rapist" terrorized Cleveland in the 1980s. He was eventually convicted of raping 29 women (192). The police had partial fingerprints from several crime scenes, and the perpetrator had a record of prior convictions, but there was no way at that time to connect the prints without a suspect or suspects. Stated another way, there were no "cold hits" before AFIS. Accordingly, when the identification "exception" was judicially recognized, stationhouse fingerprinting did not solve past or future crimes. Consequently, the fingerprint "precedent" cannot be cited without further analysis.

Other Uses: Medical and Administrative Purposes

Some databank statutes do not limit use of DNA profiles or stored samples to criminal identification. For example, one statute authorizes databank samples to be used in medical research, even though informed consent has not been obtained from any of the subjects (48, p. 1491). Somewhat similarly, the Massachusetts statute permits disclosure for "advancing other humanitarian purposes" (193). Although many research uses of criminal databanks may ultimately prove to be ethically and legally acceptable, added safeguards such as mandatory approval by medical review boards are essential (17,19,44,47). The greater possibility that individual genetic information will be identified or released in the course of research also underscores the need for enhanced security for DNA samples and profiles described above, particularly civil remedies.

Military and Medical Records

In the future, one can expect criminal enforcement officials to turn to other repositories of DNA, such as military and medical databanks, to search for matches with crime scene profiles (47,195). Commentators have only begun to analyze the privacy issues raised by government use of DNA for law enforcement when the original biological samples were collected by other entities for entirely different purposes. While such a dramatic expansion of criminal DNA databanks seems susceptible to the legal challenges outlined above, there is currently neither judicial guidance nor academic consensus on whether this type of dramatic expansion to the criminal enforcement artillery will survive constitutional challenge (17,19,21,45,163). Additional legislative prohibitions or limitations seem inevitable if DNA databanks expand in this way (195).

CONCLUSION

DNA databanking offers a powerful tool for crime solution, especially in violent crime cases such as rape. Unfortunately, possible infringements of essential rights to privacy may also be made possible by the collection and centralization of individuals' genetic information. While the courts have begun to consider the constitutionality of DNA databank programs, other privacy concerns presented by the databank statues are likely to evade judicial scrutiny. There is thus need for more anticipatory legislation to ensure that the best of DNA databanks is harnessed and used for the good, without eroding the privacy rights that remain for those whose genetic material is stored in state DNA databanks. As bioethicist Eric Juengist has remarked, "It is ... individuals' 'informational privacy' that is at stake in the prospect of widespread [state DNA databank laws], and it is in those terms that the policy challenge ... should be framed. What should society be allowed to learn about its citizens in the course of attempting to identify them?" (44, p. 63). While important steps have been taken over the past few years to improve state databank laws, work remains to be done.

OUTLINE

INTRODUCTION

Researchers are constantly discovering new linkages between human traits, diseases, or conditions and human genes. The information obtained through the Human Genome Project is expected to be used for human benefit. But should the use of this information be restricted in any way, and if so, by whom? People might be reluctant to gather useful information about their genetic heritage if there is a chance this information will be used to their detriment by others. "Genetic discrimination" has a long history in the United States and is defined as "discrimination against an individual or a member of an individual's family solely on the basis of that individual's genotype" (1). Fears about genetic discrimination could limit the utility of new genetic discoveries.

A number of states have attempted to protect individuals by enacting legislation restricting the use of genetic information by employers, insurance companies, and others (Tables 1 and 2, Appendix). At the same time the federal government has enacted statutes that affect the necessity for, and utility of, state intervention. One federal statute in particular, the Employee Retirement Income Security Act of 1974 (ERISA), has created difficulties for states that wish to regulate the use of genetic information (2). The federal government recognized the difficulties faced by the states and enacted the Health Insurance Portability and Accountability Act (HIPAA) (3). This Act directly regulates the permissible use of genetic information by employment-based plans and authorizes states to engage in additional regulatory action in this area. This article is devoted to examining the roles of ERISA, HIPAA, and state statutes in regulating the use of genetic information. The discussion concludes that federal legislation has provided an important supplement to state regulation of the use of genetic information.

GENETIC INFORMATION

Although the technology for genetic testing has only recently become accessible, genetic information has been available for a long time. People have long understood the general concept of heredity and have been aware that some conditions, such as hemophilia, tend to be inherited within families. The general concept of hereditable conditions gained a new scientific foundation with Watson and Crick's description of the structure of DNA in the 1950s. Since that time scientists have been able to make an ever-increasing number of connections between the structure of an individual's DNA and that individual's traits or the expression of a variety of genetic conditions. What this means, first of all, is that the problems presented by the availability of genetic information are not new. Some genetic information has been available for use, properly or improperly, and with good or bad intent, for much of this century. Individuals with a family history of a known genetic condition have used this information to make important decisions, such as decisions about whether to reproduce or whether to provide health or life insurance for a member of the family.

States have also used this information to sanction the sterilization of individuals based on their genotype. For example, in 1927 the United States Supreme Court upheld the constitutionality of a Virginia statute that allowed the involuntary surgical sterilization of Carrie Buck, a female resident in a Virginia institution for the "feebleminded." In this now infamous case, *Buck v. Bell*, Justice Holmes concluded that "it is better for all the world, if instead of waiting to execute degenerate offspring for crime, or to let them starve for their imbecility, society can prevent those who are manifestly unfit from continuing their kind. . . . Three generations of imbeciles are enough" (4,5). Although modern courts are not likely to uphold state-mandated sterilization programs, this decision vividly demonstrates past misunderstandings about the nature of the hereditability of various traits as well as the misuse of that information to infringe individual rights.

While the availability of genetic information has a long history, the technology used to obtain this information has undergone rapid change. Advances in genetic research have improved the accuracy of attempts to relate the content of one's genetic code with its real life effects. In addition research has created an exponential growth in the number of conditions with an identified genetic correlate. This has enabled scientists to test for the presence of the particular gene or gene combination. Within the next several decades we are likely to have access to over 100 different tests for genetic variations that predispose persons to common diseases such as cancer, cardiovascular diseases, autoimmune diseases, and so on (6).

Table 1. Selected Recent State Legislative Genetic Information Initiatives

State (year enacted)	Type of Genetic Information	Area of Protection	Type of Protection
Alabama (1997)	Genetic test for predisposition to cancer	Health benefit plans (insured, self-insured)	No genetic testing or use of result for coverage or rates
Alaska (1997)	HIPAA-related provisions; genetic information	Health insurers	No discrimination based on health status; health status included genetic information; no preexisting condition unless genetic condition diagnosed
Arizona (1997)	Genetic condition	Life or disability insurance contracts	No coverage or rate discrimination unfair unless actuarial guidelines met
Arkansas (1997)	HIPAA-related provisions; genetic information	Group health plans	Genetic information not a preexisting condition without diagnosis of condition related to the information; no discrimination based on health status; health status includes genetic information
California (1994, 1995, 1996, 1998)	Asymptomatic genetic condition or predisposition	Health benefit plans (insured, self-insured, and MEWA) Disability insurance for medical expenses also regulated	No nontherapeutic use of information; confidentiality protections
Colorado (1994)	Direct tests for presence or absence of alterations in genetic material associated with disease	Health, group disability, long-term care insurance Does not cover life insurance or individual disability insurance	Therapeutic use permitted; no underwriting use in covered insurance
Connecticut (1997)	Information about genes or inherited characteristics derived from individual or family member	Individual or group health insurance	No use for coverage or rate determinations Can refuse to cover or can apply preexisting clause to person with symptomatic genetic disease.
Delaware (1998)	Broad definition of genetic information "about inherited genes or chromosomes, and of alterations thereof, whether obtained from an individual or family member, that is scientifically or medically believed to predispose an individual to disease, disorder or syndrome or believed to be associated with a statistically significant increased risk of development of a disease, disorder or syndrome"	Informed consent and confidentiality Health Insurance	Restricts access to genetic information, except where person consents or otherwise permitted by law Insurers are permitted to have access under some circumstances Prohibits discrimination in access or rates of health insurance based on genetic characteristics
Florida (1997)	Information from genetic testing for asymptomatic persons DNA analyses	Health benefit insurers (insured, self-insured plans) No protections for coverage and rate determinations of life insurance, disability income policies, long-term care policies, or certain other insurance policies Public or private entities performing DNA analyses	Health insurers cannot use genetic information in coverage or rate determination unless diagnosis of disease Other than in statutorily limited situations, public or private entities performing DNA analysis must obtain informed consent of person and result is property of individual

Table 1. ***Continued***

State (year enacted)	Type of Genetic Information	Area of Protection	Type of Protection
Georgia (1995)	Genetic testing for asymptomatic genetic conditions.	Health and sickness plan payers	Therapeutic use only
		Does not cover self-insured plans subject only to ERISA	Confidentiality protection
		Statute does not protect against use in life insurance, disability income policies, long-term care, Medigap, and other policies	
Hawaii (1997)	Genetic information of individual or family member	Health Insurance. Does not apply to life insurance, disability income insurance, and long-term care insurance	May not use genetic info for coverage or rate determinations
	HIPAA provisions		Confidentiality protection
		Group and individual health insurance	Implements HIPAA
Idaho (1997)	Small employer reforms	Small employers	Limits on use of health status
Illinois (1997)	Genetic testing for abnormalities or deficiencies linked to current disorders or susceptibility. No confidentiality protection for determination that person suffers from disease, "whether or not currently symptomatic."	Accident, health insurance policies	Accident and health insurers may not seek or use for nontherapeutic purposes
		Employers	Confidentiality protection
			Individual can release favorable results to insurers for consideration
			Employers may use if consistent w/ADA
Indiana (1997)	Results of genetic tests	Insurers other than life insurers	Insurance companies not entitled to access to genetic test results unless individual gives specific written consent
	Direct genetic screening or testing of individual's genes for defects linked to disorder or susceptibility or damage	Health care services coverage	Non-life insurer may not use individual or family members genetic testing results to determine coverage or rates
	Does not cover detection of genetic disorder through its manifestation		Insurer may consider favorable results released by individual
			Confidentiality protection
Iowa (1992, 1998)	Genetic Testing in Employment	Employers, labor organizations, licensing authorities	No mandatory pre-employment genetic testing; employee can volunteer and give informed consent for genetic testing related to occupational risks
	Small group reforms	Small groups	
			Restrictions on use of health status, including genetic information
Kansas (1997)	Genetic screening or tests	Health insurers, HMOs	Covered entities should not request test or condition insurance on testing; covered entities should not establish rates based on results
	HIPAA -related	Group and individual policies must be renewed without consideration of health status, which includes genetic information	Life insurance, disability, and long term care coverage must set rates based on reasonable risks
			Life insurers not covered

(*continued*)

Table 1. ***Continued***

State (year enacted)	Type of Genetic Information	Area of Protection	Type of Protection
			Group and individual policies must be renewed without consideration of health status, which includes genetic information
Kentucky (1998)	Genetic testing or information	Group or individual health plan; group insurers; disability income insurers	"A group or individual health benefit plan or insurer offering health insurance in connection with a health benefit plan or an insurer offering a disability income plan may not request or require an applicant, participant, or beneficiary to disclose to the plan or insurer any genetic test about the participant, beneficiary, or applicant"
Louisiana (1997)	Genetic information is all information about genes, inherited characteristics, or family history/pedigree expressed in common language	Health insurers, including employee benefit plans Life disability income, and long-term care insurance policies excluded	Health insurers may not use genetic information of individual or family member in coverage or rate determinations Confidentiality protection
Maine (1997)	Genetic tests or results	Employers Health insurers Life, disability, long term care insurers	Employers prohibited from discriminating based on refusal to take genetic test or results of genetic test unless bona fide occupational qualification Health insurers cannot use genetic test results to discriminate Life, disability, long-term care insurers may discriminate only if reasonably related to expected claims experience
Maryland (1997)	Genetic test used to identify alterations in genetic material associated with disease or illness	Health insurance policies or contracts Section does not apply to life insurance policies, annuity contracts or disability insurance policies	May not use genetic test results for coverage or rate determinations Confidentiality protections
Minnesota (1995)	Presymptomatic test of genes associated with genetic conditions or predispositions	Health plan companies Life insurance policies	Health plan companies may not require or use genetic tests in coverage and rate determinations Life insurance companies may require use of genetic test but informed consent and confidentiality provisions apply
Missouri (1998)	Genetic testing and information	Insurers, employers	Insurers cannot require tests or consider results Excludes disability income insurance and long-term care insurance Employers can use genetic information when directly related to job responsibilities Confidentiality protections

Table 1. ***Continued***

State (year enacted)	Type of Genetic Information	Area of Protection	Type of Protection
Montana (1991, 1999)	Genetic condition Genetic information and genetic tests	Life and disability insurance Individual or group insurers	Coverage and rate discrimination permitted only where "substantial" differences in claims likely Insurers may not require genetic testing Insurers may not discriminate in coverage or rates Provisions do not apply to life insurance, disability insurance, or long-term care insurance
Nebraska (1997)	Genetic information	Individual and group insurers	Prohibits discrimination based on health status, which includes genetic information
Nevada (1997)	Genetic information is that obtained from a genetic test to determine abnormalities linked to disorder or susceptibility to disease	Health insurance Disability income and long-term care coverage excluded	Health insurers cannot require test for individual or family members and cannot use results in coverage and rate determination
Nebraska (1997, 1996)	Genetic information or a typical hereditary cellular or blood trait; genetic testing Genetic characteristics are inherited gene or chromosome or alteration thereof scientifically or medically believed to predispose individual to disorder or to predispose to disorder	Employers Health insurance; life insurance and annuities	Employers cannot use genetic information, etc., as basis for discrimination Confidentiality protections Genetic characteristics cannot be used in coverage and rate determinations for health insurance Discrimination in life insurance must be reasonably related to expected claims experience
Nevada (1997)	Genetic information and testing HIPAA	Group and individual health insurers HIPAA Implementation	Health insurers prohibited from requiring genetic tests or from using the results of such tests to discriminate in coverage or rates Long-term care or disability insurance not covered HIPAA Implementation
New Hampshire (1995)	Genetic Testing	Employers, labor organizations	Cannot require genetic testing or use to affect terms and conditions of employment Individual can consent to tests for susceptibility to workplace chemicals if employer takes no adverse actions based on results Genetic tests can be used to determine insurability for life, disability income, or long-term care insurance as part of employee benefit plan

(*continued*)

Table 1. ***Continued***

State (year enacted)	Type of Genetic Information	Area of Protection	Type of Protection
	Genetic information	Health insurers	Cannot require individual or family member to undergo testing and cannot use information in coverage or rate determinations
		Life, disability income, and long-term care insurance	Life, disability income, and long-term care insurers can use information
New Jersey (1996, 1997)	Genetic Information and Testing	Restrictions on testing apply to all "persons"	Informed consent required for most genetic testing
	Employers not permitted to require genetic tests	Special rules for life insurance or disability income insurance.	Commissioner on Banking and Insurance to establish regulations
	Genetic characteristics	Employers	Limits ability of employers to require testing or require access to test results
	HIPAA implementation	Group and individual insurers	
		Group and individual coverage	Prohibits discrimination in coverage or rates based on genetic characteristics
			HIPAA implementation
New Mexico (1998)	Genetic Information Privacy Act	Applies to most "persons"	Genetic analysis prohibited without informed consent
			Life, disability, long- term care entities are exempted
			Prohibits discrimination based on genetic analysis, genetic information, or genetic propensity, except that life, disability income, and long-term care insurers are permitted to make actuarily reasonable adjustments
New York (1996)	Genetic predisposition	Employers	Unlawful for employers to discriminate against individuals based on their disability, genetic predisposition, or carrier status
	Genetic tests, genetic predispositions	All persons; insurance companies	Informed consent and confidentiality required; special rules for consent and confidentiality for insurers
North Carolina (1997)	Genetic information: from individual or family member, about genes, gene products or inherited characteristics	Health benefit plans, including all those where regulation permitted by ERISA	Insurers may not make coverage or rate determinations based on genetic information
	HIPAA amendments	Excluded types of plans include disability income, long-term care, and Medigap coverage	No person corporations, etc., can engage in employment discrimination based on genetic information about the individual or family members
		Persons, corporations, etc.	HIPAA conforming amendments
		Group and individual plans	
North Dakota (1997)	Genetic information	Hospital and medical insurance	Genetic information is not a preexisting condition absent a diagnosis

Table 1. ***Continued***

State (year enacted)	Type of Genetic Information	Area of Protection	Type of Protection
Ohio (1997, repealed effective 2004; replacement provision)	Genetic screening or testing	Health insurers; government self-insurers	Health insurers cannot require testing or use results unless favorable results volunteered by applicant Provision repealed effective 2004; protections for genetic information obtained before 2004 remain
Oklahoma (1998)	Genetic Nondiscrimination Insurance Act; genetic information means result of a genetic test and does not include family history	Health and accident insurance, not disability income or long-term care	Prohibits discrimination based on genetic information "except to the extent and in the same fashion as an insurer limits coverage, or increases premiums for loss caused or contributed to by other medical conditions presenting an increased degree of risk" Insurers may discriminate based on manifestations of conditions Weak confidentiality protections
Oregon (1995, 1997)	Genetic characteristic: gene or chromosome or alteration thereof believed to cause or predispose to disease Genetic information can be about individual or family	Insurance providers include all those subject to state regulation; health providers	Informed consent and confidentiality protections Insurers cannot use favorable genetic tests as inducement to purchase insurance Genetic information cannot be used negatively in hospital and medical expense insurance
Pennsylvania (1996)	PKU and Insurance	Insurance companies	Insurance must cover PKU-related formula
Rhode Island (1997)	Genetic testing	Individual or group coverage, HMOs, nonprofit health corps and insurers	No use of genetic tests or results to affect coverage or rates for health coverage Disability income and long-term care policies not covered
South Carolina (1998)	HIPAA Implementation Genetic privacy act protecting genetic characteristics and genetic information	MEWAs Health coverage	Impermissible "health status" discrimination includes use of genetic information Informed consent and confidentiality provisions; prohibits discrimination in coverage or rates based on genetic information Excludes disability income, long-term care coverage, and other nongeneral health insurance types of policies
South Dakota (1997)	Genetic information and preexisting medical conditions	Individual, group, and small employer policies	Preexisting condition cannot include genetic information unless related condition has been diagnosed

(*continued*)

Table 1. ***Continued***

State (year enacted)	Type of Genetic Information	Area of Protection	Type of Protection
Tennessee (1997)	Genetic information; carrier status, genes that cause or predispose to disease	Insurance providers, but focused on medical or health insurance; excluding life insurance, disability income, long-term care policy and other types of insurance	No coverage or rate discrimination.
			Confidentiality protection
	Questions about family history excluded		Restrictions on ability of insurer or plan to consider health status; health status includes genetic information
	Insurers are permitted to ask questions about health of applicant and family	Small group market, individual and group coverage	
	HIPAA implementation		
Texas (1997)	Genetic information: that derived from genetic test for genes associated with predisposition to disorder	Employers, licensing authorities; group health benefit plans as permitted by ERISA	Discrimination based on genetic information or refusal of testing prohibited by employers, group health benefit plans, and licensing authorities
		Excluded insurance plans: specific disease plans; accidental death or dismemberment; Medigap, works compensation, long-term care, etc.	Confidentiality protection. Insurers may not coerce abortion in pregnant women carrying children with genetic conditions
Vermont (1997)	Results of genetic testing	Business of insurance	Genetic test results can be used where there is a reasonable relationship between the information and anticipated claims experience
	Genetic testing in employment, licensure, and insurance	Employers, licensing authorities, insurers	
			Employers or licensing authorities cannot require or use genetic test results
			Health insurers cannot require testing or use results in underwriting
			Disability or long-term care coverage excluded
Virginia (1996)	Genetic Information	Health insurers	No discrimination in coverage or rates based on genetic information
	HIPAA-related reforms on genetic information and health status	Insurer issuing group or individual coverage	Confidentiality protections
			Disability income insurance excluded
			Genetic information cannot constitute preexisting condition unless diagnosed condition
Washington (1988)	PKU-related provisions	Insurers, HMOs	Coverage of PKU-related formula
West Virginia (1997)	HIPAA implementing provisions	Various health plans	Limitation on use of health status; health status includes genetic information; preexisting medical condition only where genetic condition diagnosed
Wisconsin (1991, 1997)	Genetic test for disease or predisposition	Insurer or self-insured governmental programs	Cannot require testing or revelation of results and cannot use in coverage and rate determinations
	Genetic tests or information	Employment	
	HIPAA-related amendments	Various insurers or plans	Use in life insurance and income continuation insurance must be reasonably related to risks

Table 1. ***Continued***

State (year enacted)	Type of Genetic Information	Area of Protection	Type of Protection
			Employers may not require or use genetic tests; employees may request and provide informed consent for genetic tests related to occupational safety issues
			Genetic information not a preexisting condition without diagnosis of condition
Wyoming (1997, 1998)	HIPAA-related amendments	Group and small employer health plans	Insurers cannot discriminate based on health status; health status includes genetic information; no preexisting condition unless genetic condition diagnosed

Note: The table was first created using a Westlaw search of the state legislative database in Fall 1997. The table was updated with an additional Westlaw search in Fall 1999. The search results were compared with a separate survey published in Ref. (25).

There are at least two sources of genetic information: the general medical records of the individual or his or her family (which may reveal information about genetic disease), and the results of specific genetic tests performed on the individual or his or her family. Policy makers interested in protecting genetic information must regulate both sources. Advances in genetic testing have further complicated the issue by providing information about an individual's susceptibility to particular genetic conditions. An individual may be determined to be a "carrier" of a gene, that is, able to pass the trait on through reproduction but at no risk for expression of a genetic condition. For example, individuals can carry the gene associated with Tay-Sachs without personality experiencing the disease. Alternatively, genetic testing can reveal that a person has a genetic condition or disease ("diagnostic testing"), such as hemochromatosis. It can also reveal that a person will develop a genetic condition at some future point ("predictive testing"), such as Huntington's disease, or that the person is at greater-than-average risk for developing the condition or disease being tested, such as certain types of colon or breast cancer (7).

USE OF GENETIC INFORMATION BY EMPLOYERS, INSURERS, AND OTHERS

Buck v. Bell involved the use of genetic information by the state, which mandated sterilization as a method of protecting the public welfare. But private entities, such as insurance companies and employers, have also been interested in obtaining genetic information. These private parties have an interest in using the genetic information to make decisions about employment, insurance, and other issues. Employers might want to exclude potential employees who present higher health insurance costs or who might be susceptible to workplace injury or illness (8). In the 1970s, for example, employers began screening workers for sickle cell anemia, which led to stigmatization and discrimination against sickle cell anemia carriers in employment (1). Insurance companies selling health, disability, life, long-term care, or other types of policies might want to exclude applicants or raise premiums for those who have higher rates of illness, disability, or premature death (7,8).

Individuals who anticipate these forms of discrimination and social stigmatization will have an interest in restricting access to genetic information. There are some circumstances, however, where an individual might want to release genetic information to employers or others in order to gain more favorable treatment than they would otherwise receive. This discussion is concerned with the state and federal regulation of the use of genetic information by private parties in the context of health, life, and other types of insurance. The central issue in this complex web of regulation is control. Who will control the decision about whether to undergo genetic testing, the individual or some third party such as an employer or an insurer? Who will control access to and use of genetic information: the individual or a third party?

A number of different commissions, working groups, and other organizations have concluded that it is important to restrict access to genetic information. The view of the Task Force on Genetic Testing created by the National Institutes of Health (NIH) and Department of Energy (DOE) Working Group on Ethical, Legal, and Social Implications of Human Genome Research is typical:

> Protecting the confidentiality of information is essential for all uses of genetic tests.... Results should be released only to those individuals for whom the test recipient has given consent for information release.... Under no circumstances should results ... be provided to any outside parties, including employers, insurers, or government agencies, without the test recipient's written consent....No individual should be subjected to unfair discrimination by a third party on the basis of having a genetic test or receiving an abnormal test result. (9, pp. 14–15)

The common belief that the privacy and confidentiality of genetic information must be protected to encourage individuals to undergo testing does not resolve all questions.

Which level of government should become involved in regulating genetic information, the federal government or the states? What uses of genetic information are permissible? When is the use of genetic information "unfair"?

OVERVIEW OF STATE AND FEDERAL REGULATION OF GENETIC INFORMATION

It is important and useful to understand the distinctions between the regulatory authority of the federal and state governments regarding the control of genetic information. The federal government has power over interstate commerce which theoretically could include the regulation of insurance companies and the provision of health and other benefits by employers. Nevertheless, the federal government for many years failed to enact much substantive regulation touching on the problems created by genetic information. Indeed, under the McCarran-Ferguson Act, the federal government has long ceded primary authority over the regulation of the business of insurance to the states (10). Where federal law existed, it tended not to impose substantive standards of conduct regarding the use of genetic information.

Under the Employee Retirement Income Security Act of 1974 (ERISA), the federal government established various requirements for the maintenance and operation of employee benefit plans (2). These federally regulated benefit plans include those in which the employer undertakes to provide medical or health coverage for its employees. But ERISA did not originally regulate the substantive content of those employee benefit plans in any way that impinged on the ability of the employee benefit plan to seek out and make use of genetic information. Other federal statutes, such as the Rehabilitation Act of 1973 or the Americans with Disabilities Act (ADA), prohibited certain types of discrimination by employers and others, but these statutes were not drafted to make clear that they included protections for all types of genetic information or discrimination (11,12).

Thus, for several years, states were alone in regulating access to and use of genetic information in insurance or employment-related areas. Many states enacted specific statutory protections for genetic information as a matter of self-initiated state policy (see Table 1). State legislation in this area was sparked by the knowledge that advances in genetic technology were creating conflicts between individuals, insurers, and employers. Individuals often wanted to know relevant genetic information but then realistically or unrealistically feared discrimination by others (11,13).

The federal ERISA statute governing employee benefit plans created some significant barriers to state regulation (2). ERISA contains a vigorous "preemption" clause. The clause invalidates state attempts to regulate many types of employee benefits, including state efforts to regulate the way in which employers use genetic information in certain employee benefit plans such as in health benefits coverage. Congress appeared to recognize the regulatory vacuum created by the ERISA preemption clause when it enacted the Health Insurance Portability and Accountability Act (HIPAA) (3). This federal statute established substantive guidelines for the use of genetic information in health plans and also explicitly authorized consistent state regulation. HIPAA sparked a new wave of state legislative activity so that now nearly all states have enacted measures governing the use of genetic information in at least some contexts (Table 1).

STATE REGULATION AND ERISA PREEMPTION BEFORE THE HIPAA AMENDMENTS

State Regulation Before HIPAA

States began to be concerned with the use and misuse of genetic information over 20 years ago because of the problems associated with sickle cell anemia testing. These concerns were augmented over time as geneticists began to identify a host of conditions thought to be related to underlying genetic traits. States sought to encourage individuals to use genetic testing services by protecting the voluntary and confidential nature of genetic testing. On the other hand, states recognized that providing access to genetic information for individuals but not insurers could create problems. Is it "fair," for example, to permit an individual who knows she is susceptible to early disability and death, but does not share this information with her insurer, to purchase large amounts of disability and life insurance coverage (7,14,15)? In an effort to deal with some of these problems, states attempted to establish when insurers, or others, should be permitted to gain access to an individual's genetic information and to establish certain domains within which discrimination based on genetic characteristics would be permissible.

As Table 1 indicates, a number of states responded to these conflicts by enacting strong privacy protections for genetic information in the early to mid-1990s. State genetic privacy acts, such as those enacted in California, Georgia, Nebraska, and New York, generally provided strict protections for the confidentiality of genetic information. Some states even provided that a person's genetic information would be the "property" of the individual. Typically an individual could not be tested without giving specific informed consent, and genetic test results could not be released without the individual's consent.

Some states prohibited employment discrimination based on genetic factors. New Hampshire, Nebraska, and New York, for example, prohibit employers from using genetic test results to affect the terms and conditions of employment. These state employment discrimination statutes supplement the sometimes weak protections offered by existing federal statutes.

Some states also sought to regulate the use of genetic information by insurers, particularly health insurers before HIPAA's enactment. California, Colorado, Georgia, Minnesota, Montana, Oregon, and Wisconsin adopted restrictions on the use of genetic testing or genetic information by insurers. Each of these states focused on health insurance, leaving life insurers and other types of insurers relatively free from state regulation.

The early state efforts to regulate the use of genetic information by insurers appeared to be driven by three principles: (*1*) genetic information is a "good"

which individuals should be encouraged to obtain, (*2*) access to medical and health insurance should not be restricted based on genetic information, and (*3*) genetic discrimination in other types of insurance, such as disability income or life insurance, should not be prohibited. The fact that so many states attempted to regulate in this area suggests a high level of state concern about the impact of genetic information on the health insurance market.

State efforts to regulate health insurance were complicated by a complex federal and state regulatory structure. Congress largely delegated the regulation of the business of insurance to the states in the McCarran-Ferguson Act (10). Yet two important federal statutes affected the ability of states to regulate in this area. The first, and most important, impediment to state regulation of the insurance market was ERISA (2). The second relevant federal statute was HIPAA, which amended, ERISA and prohibital certain types of genetic discrimination (3).

Employee Retirement Income Security Act of 1974

ERISA regulates employee benefit plans, including health coverage, disability, and life insurance provided as a benefit of employment (2). The benefit plans covered by ERISA include those in which an employer enters into a contract with another entity such as an insurance company. ERISA also applies where an employer "self-insures," or bears the risk of paying the benefits directly. (Governmental plans, church plans, and a few others are excluded from ERISA regulation.) (2).

About 70 percent of the people who have private health insurance coverage obtain ERISA benefit plans through employment (19). However, most employees who have health insurance through employment are covered by plans that are "self-insured," that is, their employer bears the risk of medical expenses (19).

Until recently ERISA was silent about the employer's ability to take genetic conditions into account in the terms and conditions of his or her employee benefit plans. Nevertheless, the ERISA preemption clause presented a substantial barrier to effective state regulation of genetic information.

Federal Preemption of State Regulation of Genetic Information

Unlike many federal laws, ERISA was drafted with an explicit and broad preemption clause that prevents states from regulating employee benefit plans. The statute states that ERISA "shall supersede any and all state laws insofar as they may now or hereafter relate to any employee benefit plan" (2). The major exception, for our purposes, is the "savings clause," which explains that "nothing in this subchapter shall be construed to exempt or relieve any person from any law of any state which regulates insurance" (2). This provision "saves" state laws regulating insurance from ERISA preemption. However, ERISA makes clear, that in regard to employer self-insured plans, "an employee benefit plan shall [not] be deemed an insurance company ... or to be engaged in the business of insurance ... for purposes of any law of any state purporting to regulate insurance companies" (2). Self-insured employee benefit plans are thus completely protected from state regulation.

The Supreme Court has often been called upon to interpret this complex and confusing provision. In order to decide whether ERISA preempts a state law, the Court must start with the presumption that Congress does not intend to supplant state law (20,21). In evaluating whether the normal presumption against preemption has been overcome, the Court considers whether the state law "relates to" an employee benefit plan. The Supreme Court has said that a state law "relates to" an employee benefit plan if it (*1*) has a "connection with" or (*2*) "reference to" such a plan (22). State laws that "relate to" an employee benefit plan in this fashion are preempted and given no effect because of the ERISA preemption clause, unless an exception to preemption can be found.

Once the Court rules that a state law "relates to" an employee benefit plan and thereby falls under ERISA preemption, it must determine if the law "regulates insurance" and thus escapes preemption under the "savings clause." To determine if a law regulates the "business of insurance," the Court must first consider whether, from a commonsense view, the contested prescription regulates insurance (23). The Court must also consider three factors to determine whether the regulation fits within the "business of insurance," the phrase used in both the McCarran-Ferguson Act and the ERISA: (*1*) whether the practice has the effect of transferring or spreading a policyholder's risk, (*2*) whether the practice is an integral part of the policy relationship between the insurer and the insured, and (*3*) whether the practice is limited to entities within the insurance industry (23).

Under the "deemer" clause, a state law that relates to an employee benefit plan but is "saved" from preemption because it constitutes the state regulation of insurance can still not be applied to self-insured employee benefit plans. A "self-insured" plan — one in which the employer bears the risk of his or her employee's health care costs directly — cannot be treated as an insurance plan and thereby be subjected to state regulation of insurance (20).

ERISA's broad preemption clause has presented a significant barrier to state regulation of the use of genetic information. A large number of states have sought to prevent entities from using genetic information to determine whether to provide health benefits for individuals. California law provides, for example, that genetic information should not be used in making coverage or rate determinations for medical benefits (see Table 1). Since most persons who have private insurance obtain it as a benefit of employment, California's statute is only effective if it is applied to employee benefit plans. Under the ERISA preemption clause, California's statute may be considered state "regulation of insurance" and may be "saved" from preemption (2). This means that the state statute can be applied to insurance companies that sell health insurance to employers for the benefit of their employees. The statute cannot be applied, however, to employers who self-insure their health benefits plans. Employers who self-insure are immune from state regulation under the "deemer" clause of ERISA. It is for

this reason, to avoid state regulation, that many employers provide employee benefits, such as health care coverage, through self-insurance.

The same principles apply to state attempts to regulate the use of genetic information in other areas, such as disability income and life insurance. Under ERISA, states can regulate insurance companies selling these types of benefits and may prohibit or permit the use of genetic information in determining the terms and conditions of the insurance plan. However, states are barred from attempting to regulate the use of genetic information by employers who self-insure a disability or death benefit plan. Consequently most states permit the use of genetic information as an underwriting consideration in life and disability income insurance (24). Indeed, ERISA preemption has little impact on employers who self-insure because state law often permits use of genetic information in coverage or rate determinations for disability and life insurance.

EFFECT OF THE HEALTH INSURANCE PORTABILITY AND ACCOUNTABILITY ACT OF 1996

HIPAA Amendments to ERISA

Although by 1996 many states had attempted to regulate the use of genetic information, the ERISA preemption clause limited the effectiveness of state regulation, since it shielded self-insured employee benefit plans, such as those providing health coverage, from state regulation. In addition, more than half the states had not enacted *any* legislation governing the use of genetic information. Critics were quick to note that state regulation had not been an effective method of restricting improper use of genetic information in health care coverage determinations.

Congress responded to these critics with amendments to ERISA that govern the use of genetic information in many types of health insurance coverage. While recognizing that state regulation is still important, particularly in areas outside employer provision of health coverage, in 1996 Congress amended ERISA to provide protection from genetic discrimination in some contexts.

HIPAA amends ERISA to directly regulate the use of genetic information in several important ways (3). The most serious restrictions are imposed on group health plans. HIPAA prohibits the use of "genetic information" in making eligibility determinations for group health plans, whether the health plan is insured or self-insured. Group plans are also prohibited from charging individual members higher premiums because of genetic information about themselves or their dependents. HIPAA provides that these plans may not consider an individual's genetic characteristics to be a preexisting condition unless the genetic characteristic has given rise to a diagnosis of an actual condition related to the genetic information (3).

Other sections of HIPAA, while not specifically focused on the issue of genetic information, provide important benefits for individuals who have a genetic condition. The statute establishes a "credit" for prior insurance coverage that may be applied to the preexisting limitations period of a new policy. This means that an individual with a diagnosed genetic condition will actually have greater job mobility, since he or she will be able to achieve continuous coverage for medical treatments even after switching jobs (3). The statute also contains some protections that apply to health insurer issuers (including HMOs) and individual health plans. The statute establishes standards for guaranteed availability and renewability, for example, that could prove helpful to individuals who have genetic conditions (3).

Finally, HIPAA does not amend the general ERISA preemption clause but does provide that states may continue to regulate certain aspects of how health insurance companies use genetic information (3). States will monitor the implementation of the federal rules governing insurers and HMOs, for example. States can also enact alternate protections, so long as their efforts do not prevent the application of federal law. Thus states may enact certain measures that provide greater protection to individual enrollees than that under federal law. Most states already have passed state legislation implementing HIPAA's protections in the state insurance market.

Even with HIPAA, there are still big gaps in protection for those concerned about loss of confidentiality and/or genetic discrimination (17). First, HIPAA regulates the "use" of genetic information but does not otherwise protect the creation or privacy of the information. Second, HIPAA focuses federal regulation on group plans; individual health insurance policies are offered lesser protection. Third, even for group plans, HIPAA does not prohibit an insurer from charging higher overall rates for a plan based on genetic information about plan participants.

Current Status of State Regulation

As Table 1 shows, most of the states that now regulate the use of genetic information enacted their legislation during or after 1996, the year of HIPAA's enactment. Most state regulation now focuses on insurance issues. A large number of states attempt to control the use of genetic information by various types of insurers. There are three basic variables that characterize state legislation: the definition of "genetic information," the types of insurers or entities regulated, and the substance of the insurance regulation (25).

The first important variable is the type of genetic information covered under the state statute. States have taken a variety of approaches to defining the types of genetic information subject to statutory protection. Most states focus on the use of "genetic testing" and protect test "results." Several take into consideration the need to protect both the test results of the "individual" and his or her "family members." Louisiana recognizes the need to protect other types of genetic information, such as information about genetic conditions that might be found in the family history or medical records of an individual.

A significant number of jurisdictions, such as California, protect only genetic information about "predispositions" or "susceptibility," while permitting disclosure of information about actual genetic conditions or diseases. Some states, such as North Carolina, seem to protect the full range of genetic information, up to and including a determination that an individual in fact is currently exhibiting the effects of a genetic condition.

The second variable in state regulation is the identity of the entities subject to regulation. As shown in Table 1, states typically have sought to regulate a wide range of insurers and insurance-like entities. Thus state laws focus on health benefit plans, whether insured or self-insured (e.g., see Alabama, California, and Florida). The statutes also attempt to restrict the use of genetic information by health maintenance organizations, preferred provider organizations, and other health insurer-hybrids. State regulatory schemes mention other types of insurance, such as life insurance, disability income insurance, Medigap coverage, and other types of policies.

The third variation in state regulation is the differential treatment of genetic information based on the insurance coverage type. Each state regulating the use of genetic information by insurers has enacted strong prohibitions against use by health or medical insurance entities. A large number of states, however, permit discrimination — or at least "actuarially sound" discrimination — by life, disability income, and other types of insurers. Most of states regulating the use of genetic information in insurance thus have established that discrimination in health or medical benefits is "unfair" while discrimination in other types of insurance is often "fair" and should be permitted (5).

Some of the legislation would doubtlessly have been enacted even without HIPAA. But many of the post-1996 statutes have clear objectives on the implementation of HIPAA-type provisions within the state. Post-HIPAA, state legislation that relates to employee benefit plans will consequently not be preempted so long as it does not prevent the application of federal law (3). Indeed, states can and have considered provisions that would establish standards more protective than those offered under HIPAA.

CONCLUSION

Genetic information is becoming an increasingly important area for state and federal regulation. Most states have already specifically regulated the confidentiality and use of genetic information. There are significant barriers, however, to effective state regulation, including federal preemption under ERISA.

HIPAA's enactment and the subsequent flurry of state legislative activity have been helpful to those concerned about the confidentiality of genetic information and the risk of genetic discrimination. However, commentators have identified the gaps that still remain. It is clear that further federal action must address at least two of these gaps: (*1*) the risk of discrimination in group premiums or rates based on genetic information, and (*2*) the risk of the loss of privacy for genetic information (17). Before the Congress are versions of the Patients Bill of Rights that would protect individuals in group plans from discrimination in the provision of services based on genetic information (26,27). Congress is also considering bills specifically designed to protect the confidentiality of genetic information and to restrict the imposition of genetic testing (28).

New York, New York

OUTLINE

INTRODUCTION

Genetic tests are the means by which individuals may unlock the wealth of information contained in their genetic constitution, and as the understanding and significance of genetic information advances, the scope of genetic testing expands accordingly. However, growth in genetic testing has opened new avenues of commercial exploitation that raise problems with ensuring adequate evaluation of the scientific legitimacy of genetic tests being offered to the public. The Food and Drug Administration (FDA) subjects genetic tests sold as kits to full regulatory review but leaves genetic tests provided as services entirely free from FDA scrutiny. The federal government does not review genetic testing services for the soundness of the scientific claims made for the tests, and there is very little substantive review of genetic testing services at the state level. The issue of whether the current state of regulation and the distinction between test kits and testing services is reasonable becomes more pressing as the genetic testing industry gains momentum.

Like many achievements in biotechnology, developments in genetic testing have been shadowed by concerns about their use and implications: scientists worry how their research will be used, physicians wonder whether the benefits outweigh the harms, and ordinary people face philosophically uneasy choices about whether knowledge leads one to the garden or away from it. The nuanced and weighty problems surrounding the use of genetic technology have been struggling for years toward resolutions that might suggest a basis for practical action. While numerous states have passed laws restricting the use of genetic information (1,2) and a consensus appears to be growing regarding the privacy of genetic information, basic questions about regulating genetic tests themselves remain mired in complex theoretical and scientific controversies. For many years the Task Force on Genetic Testing, an entity organized by the National Institutes of Health (NIH) and the U.S. Department of Energy, provided leadership in the development of national policy on regulating genetic tests. The Task Force produced its pivotal Final Report in 1997 (3) which contained extensive analysis of the regulatory and scientific issues related to genetic testing and provided groundbreaking detail on the economics and practice of the genetic testing industry (3). However, the role of FDA, a natural candidate to lead regulation of the safety and efficacy of genetic tests, was left surprisingly murky in the Report's recommendations. In fact the Final Report did not specify an appropriate candidate to monitor the scientific validity of genetic testing services. This result is remarkable in light of the fact that the Task Force's creation derived in part from an Institute of Medicine report criticizing the disparity between test kits regulated by the FDA and unregulated testing services (4,5). Panel members were clearly attentive to the issue and had questioned publicly the business strategy of marketing tests as services rather than kits specifically for the purpose of evading FDA oversight. Dr. Neil A. Holtzman, chairman of the Task Force, observed, "Companies don't create kits so they can circumvent the FDA regulatory process" (6). Yet the Final Report refrained from proposing an extension of FDA oversight to genetic testing services.

Such reserve, however, may have derived more from the Task Force's consensus style of decision making than from a fundamental objection to FDA involvement in genetic testing regulation. Part of what made the Task Force's conclusions so forceful and well-informed was the diversity of interests represented on the panel, including from the biotechnology industry (3). The Final Report of the Task Force had the distinction of being unanimously approval by its members with no abstentions. However, several Task Force members had openly doubted whether the FDA was the right entity to regulate genetic testing services (3). In fact, as early as April 1997, the Task Force on Genetic Testing "tabled any efforts to come up with a recommendation for the role that the FDA should play in regulating genetic testing" (3). In addition FDA itself showed considerable reluctance in assuming greater responsibility. In her testimony before the House Subcommittee on Technology, the FDA Deputy Commissioner Mary K. Pendergast stated that, "[t]o date, the FDA has minimal involvement with genetic testing," and cautioned that careful weighing on the relevance of further FDA efforts would be necessary:

> If the FDA is to do any of the additional regulating, we would have to evaluate how these concerns fit with other concerns facing the Agency, e.g., product approval and regulation, infectious disease transmission through foods, blood, and tissues, and examine how the harms from inaccurate genetic testing stack up against those other priorities. If additional oversight is mandated, there is the question of resources and how to pay for the oversight (7).

The agency has repeatedly taken the position that it will not exercise jurisdiction over tests marketed as services (8). Another full-length study, which supported the imposition by "federal regulators" (9) of minimum standards for the positive predictive value (PPV) of genetic testing services, came to the following conclusion: "In light of the public and political pressures on the FDA, such regulation might best be introduced through the [Centers for Disease Control], [Federal Trade Commission], [Health Care Financing Administration], or [Department of Health and Human Services] by, for example, modifying [the Clinical Laboratories Improvement Act]" (9, p. 1299).

While the new Advisory Committee on Genetic Testing in the Department of Health and Human Services (DHHS), formed at the recommendation of the Task Force, closely involves FDA in its activities, it is proceeding with the collection and analysis of data on the analytical validity, clinical validity and clinical utility of genetic tests leaving aside, as premature, the issue of the appropriate source and level of oversight (10). The question that remains unanswered is why the distinction between commercial services, which FDA believes it has authority to regulate, and kits makes sense. A Task Force member affiliated with OncorMed expressed the view that FDA did not have the appropriate level of expertise (6), but the criticism applies equally well to the agency's competence in regulating genetic testing kits, whose ranks can be expected to swell in the next few years. According to an FDA official: "At present we estimate that there are, or soon will be, dozens of companies or laboratories offering hundreds of different genetic tests to the public and it is projected that this number will grow substantially" (7). Currently 5,000 genes associated with genetic disorders have been cataloged for the Human Genome Initiative by a group at Johns Hopkins University (11). It appears that amid herculean efforts to collect information, resolve grave social issues, and achieve consensus among the various constituencies in genetic testing, the proposals refrained from charging any particular regulatory body with assuring consumers that the genetic tests being performed as a service, which represents the vast majority of emerging tests, are scientifically valid, despite agreement as to the necessity of such measures (9,12). That is not to say that detailed and fact sensitive proposals were not made to secure the validity and analytical sensitivity of these tests through improvements at the provider or clinical level. With regard to some of the principles, however, it cannot be enough to presume the clinics will regulate themselves, and, perhaps due to political constraints, the Final Report did not specify which regulatory body should enforce the recommendations.

The regulatory standards were introduced presumably to ensure that genetic testing is made available in clinical laboratories whose clinical validity has been established, that is, their positive predictive value (PPV), unless it is collecting data on clinical validity under either an IRB-approved protocol or conditional premarket approval agreement with the FDA.

The task of developing an understanding of how FDA *should* and, from a legal perspective, *could* fit into a coherent and flexible regulatory plan remains open. The efforts of the Task Force and other institutions and professionals have laid the difficult ground work for the development of standards and protocols in the genetic testing community, and a slight shift in perspective could suggest a path to greater clarity in regulations and liability. By focusing on the problem from a test recipient's perspective, the issue becomes remarkably simple. Despite some empirical differences in delivery, the information dynamics from the patient's perspective produce as great a need for protection in the area of commercial genetic testing services as for a test packaged as a kit. Indeed, apparent factual distinctions that may seem important from a regulatory standpoint turn out to be irrelevant when considered from the view of a genetic test recipient. Emphasizing these considerations is quite appropriate in determining the applicability of FDA oversight, furthermore, because the national protection of consumers is the animating purpose behind food and drug legislation even when it encroaches upon the prerogatives of medical practice. Subject to the boundary issues involved in legal jurisdiction (14), FDA is the most logical and efficient choice as the regulatory actor. Nothing in the Final Report or in available information defeats this view or suggests a better alternative. While it is important to recognize the political and institutional constraints that may dissuade the agency from undertaking regulation of genetic testing services, it is equally important to be aware that these external considerations may be charting a course in the wrong direction.

Ensuring public health safety in an age of new biological technologies will undoubtedly subject FDA to evolutionary pressures, but the novelty and complexity of genetic technology should not deflect the agency from its traditional goals and areas of oversight. FDA already has begun to review the early products of genetic technology, and it will doubtless face many more in this millennium (16–18). The use of innovative forms to deliver essentially commercial products should not confound regulation. It is important, however, to make a distinction between commercial testing services that have the character of products and traditional laboratory analysis. A bright-line rule not only serves regulatory goals and eases compliance, but is advisable to stay well within the bounds of federal authority. The dangers of genetic information are profound and warrant the public delegating the resources and mandate to the FDA to ensure that the troubling issues and agonizing choices occasioned by genetic testing are not compounded by poorly developed or even misleading information.

BACKGROUND ON GENETIC TESTING

The potential scope of genetic testing as a commercial enterprise has become increasingly clear over the last decade (19). In 1986 the conductors of the survey found only 118 companies likely to be offering or researching genetic tests, and of those 85 companies responded to the survey. Only 22 were performing or developing tests. In contrast, the 1996 survey found a target audience of 594 biotechnology companies of which 461 responded. About a third of respondents were engaged in genetic testing

activity (3). The once largely academic activity has moved into the marketplace, where more and more companies are realizing that it can be big business. A survey conducted in 1986 found 22 biotechnology companies offering or developing genetic tests, whereas a similar survey conducted ten years later found 147 companies. Tests have been developed for hundreds of conditions (20), including Alzheimer's, colorectal cancer, and melanoma with others such as asthma and even deafness on the horizon (21–24) and according to NIH, more than 450 research programs are working to develop more (21). It should be noted that the press and literature on genetic tests quote a large variety of figures for how many genetic tests have been developed deriving largely from differences in definition. Because thousands of genes linked to disorders have been identified, it would be possible to say that thousands of tests have been developed. In many of these cases, however, the disorder is extremely rare or the linkages have not been established with sufficient generality to justify use in a clinical setting. Nonetheless, the commercial potential of viable tests is considerable. The total DNA diagnostic market is estimated to exceed $6 billion by 2005 (25). Depending on the complexity involved and the number of genes to be screened, a single test may cost anywhere from a few hundred to several thousand dollars (21,26,27) and might be used by millions every year. For example, the most commonly used genetic screening test for phenylketonuria is used on millions of newborns annually (20). The proceeds from even one test could prove very lucrative. Consider, for example, the osteoporosis test being developed by Medical Science Systems, Inc. (28). The company estimated that if 2 percent of all affected Americans, approximately 500,000 people, are tested at $200 each, the market for this one test alone is worth $100,000,000 in revenues (28). MSSI focuses on the national market in estimating the commercial potential of a test. (Also companies such as Myriad, Salt Lake City, Utah, and Genetics and I.V.F. Institute, Fairfax, Virginia, comply with the regulations of jurisdictions as far away as New York in their quest for a national audience.)

Like the rest of the biotechnology industry, however, these endeavors are new and are dependent on recent breakthroughs in science (3). It is a young and dynamic industry (29). According to the Task Force Report, "The companies engaged in testing activities operate in an extremely dynamic environment, frequently undergoing restructuring, forming new partnerships, embarking on new initiatives, or dropping projects" (3, app. III). The various obstacles involved in entering the genetic testing market at this time — regulatory uncertainties, ethical issues, rapid technological evolution, the inherent limit on the utility of a test to once per patient — serve to dampen rapid maturation in this sector (3). Also most single-gene disorders are quite rare and have less market potential, so to earn high profits the tests must involve more common disorders, which often turn out to be more genetically complex (3,30). Investing in research for more common multiple-gene disorders such as cancers and heart ailments is expensive and risky (3), but promises the biggest payoffs in terms of patents and first to market profits. Consider, for example, the unseemly race to patent the BRCA1 breast cancer gene test, which generated a considerable amount of controversy in 1996 (31). Alternatively, a company could commercialize technology licensed from an academic or research institution (3). In either situation an attractive way to reap the full benefits of developing the product and to leverage research and development and production costs is promotion to a national market (28,32). For example, the fee for a single breast cancer genetic test is $2000, for the two genes involved in here ditary nonpolyposis colorectal cancer, $870. The international competition to identify the first breast cancer gene was probably the most publicized scientific "race" of the 1990s. And when the winners — Myriad Genetics, a Utah-based biotechnology company, working with the University of Utah — promptly sought a very broad patent over BRCA1 in 1994, there was considerable disquiet. Opposition came not only from "genetic interest groups," arguing that genes are natural human blueprints which should not be patented, but also from other scientists who had co-operated with the Utah group during earlier stages of the research (31).

This commercial model for test development, however, is of fairly recent origin (26). Most genetic testing still takes place in research and academic settings (33). In the survey of genetic testing discussed above, twice as many nonprofit organizations were engaged in genetic testing activities as biotechnology companies (3). Perhaps more significantly, most of the basic research underlying the science of testing continues to be generated in public and nonprofit institutions and universities through sequencing under the Human Genome Project (HGP) and investigational studies of particular disorders (34–37). A comparison of recent headlines is instructive. Several research centers organized by the National Institute for Alcohol Abuse have found links between specific chromosomal areas and a propensity for alcohol abuse (34). The development of private sector initiatives is part of a general burgeoning of genetic testing research and practice rather than representative of a transition from public to private leadership. Symbolic of the growth of both research and commercial endeavors, a new publication known as the *Journal of Genetic Testing* was recently introduced (38).

What is a Genetic Test?

The landscape for the policy debate on genetic testing takes place against a complex and rapidly evolving scientific background of genetic testing technology. The details and methods used in genetics are complicated, but the general concept of a genetic test is fairly simple. By now the image of DNA as a double helix should be quite familiar (20). DNA stands for deoxyribose nucleic acid. The deoxyribose, in conjunction with a phosphate group, alternately link together to form the backbone of the helix similar to the sides of a ladder. The nucleic acid, of which there are four kinds, projects off the deoxyribose molecule to form the step of the ladder known as the base. Each step in the winding ladder of the helix is called a base-pair, and a person's genetic code contains billions of base-pairs (20). Imagine if the two sides of the ladder were pulled apart, splitting all the steps in half (20). (More specifically 23 human chromosomes contain

about 3 billion base-pairs. Each side of the ladder is a reverse of the other because of the base-pairing.) Each half of a base-pair is called a *nucleotide*. The sequence of nucleotides provides specific directions for the production of all the parts of a living organism. Originally a *gene* was defined as a set of nucleotides that codes for a protein (20), although the term now commonly is used to identify sets of nucleotides that are associated with more general traits. Although variation in human genes is as natural as variation in fingerprints, there are specific variations in some genes that cause or are linked to a genetic disease (20). For example, the common inherited disorder of cystic fibrosis results from mutations or deletions in a transmembrane protein known as cystic fibrosis transmembrane conductance regulator. Thus, locating and cloning a disease gene can be important in determining the molecular pathology of inherited disorders. A genetic test determines whether an individual has a harmful genetic variation or any other specified genetic sequence. At present directly sequencing a gene (20) is a method reserved primarily for finding the gene originally. It is uncommon for a genetic test to simply sequence each person's gene at the relevant location because sequencing has until recently been a time-consuming and expensive process. Increasingly powerful engines for the sequencing of DNA, however, make the prospects of such an approach not only possible, but likely in the future. For example, the Perkin-Elmer's 3700 DNA analyzer, which gained so much notoriety as the engine behind a bid to take HGP private, can analyze thousands of base-pairs a day and sells for $300,000 (39–42).

Causation in Genetic Diseases. There are several relatively high incidence single locus gene disorders such as sickle cell anemia, thalassemia, and cystic fibrosis where genetic diagnosis is now common (4). Of course, identifying a disease-related genetic variation is not always conclusive, nor is failing to identify one. There may be an extremely large number of disease-inducing variations amid many benign ones, requiring extensive clinical follow-up and research. Expression of a gene or genetic predisposition is subject to complex laws of inheritance and the influence of environmental factors (3,29). In addition common disorders such as heart and Alzheimer's diseases are usually multifactorial, which greatly increases the complexity of analysis (3,20,29). Tracing the relative significance of variable genetic and environmental factors is extremely troublesome from a research perspective and impedes conclusive determinations of risk and probability. The complexity of the underlying genetics requires flexibility and sensitivity to situation-specific information for effective genetic testing generally. Indeed, the pace of innovation subjects testing practices to continual change. These conditions, and the technical difficulty level involved, encourages testing to be performed as a service rather than packaged as kits at least in the near and medium term (19).

Future Technology. In the relatively near future it may become possible to screen a larger number of patients more routinely for a larger number of genetic diseases, and to do so for diseases with more allelic variation. For example, the "gene chip," a device with space for up to 409,000 probes, has been developed (44). This new technology is in the final stages of gaining approval for its first commercial use detecting mutations in the P53 gene, which may lead to development of certain cancers. This mutation usually is acquired during the course of a person's life, however, and there currently is no chip-based test commercially available for inherited diseases (44). There is no reason, however, that this technology could not be used to test more cheaply and rapidly for a large number of genetic diseases at once. Additionally the DNA chip may make it more feasible to test for diseases with a large number of different disease alleles such as cystic fibrosis (a three base-pair deletion detectable by a single probe accounts for 68 percent of cystic fibrosis mutations, but the other 30 percent arise from over 60 different kinds of mutations (20,45). Although there are no commercial genetic tests for inherited disorders based on this technology, the chip may be a view into the future of such testing. Given the chip's probable status as a device, it will be a future likely overseen by FDA.

Potential Harms in Genetic Testing

The technical aspects behind genetic testing indicate that use of these technologies may involve considerable uncertainty. Tests for multifactorial inheritance disorders such as Alzheimer's and breast cancer have generated the most concern because the clinical utility of a positive test in a healthy individual is often still unclear at the time the tests become commercially available. For example, a panel of experts has recently concluded that testing for ApoE4, the Alzheimer's "susceptibility" gene, does not provide sufficient predictive value to justify its use outside of research labs (46). While the test improves the clinical diagnosis of symptomatic patients, it is not appropriate for testing at large. These ambiguities and uncertainties, however, probably are not significantly greater than in other medically complex areas of diagnosis. What distinguishes genetic diagnosis from other kinds of complex or controversial forms of testing? In truth, there are many similarities, especially from a medical perspective. Misdiagnosis could lead to unnecessary, painful, and risky treatments (4), and the failure to diagnose might discourage diligence in taking care of the body and seeking medical attention. Imperfect tests in general create difficult choices, suffering, and uncertainty. In fact, when used to diagnose a symptomatic individual, there are probably few differences between genetic tests and other methods of assessing disease. Predictive genetic testing, however, is performed on healthy individuals and even on fetuses in utero. The tests frequently offer only estimates and probabilities of risk, and may become available before the validity and reliability of its predictive value have been established. The genetic diseases for which tests are being developed are generally more dangerous and severe within the range of ailments (2,30), and unfortunately there are rarely effective treatments, much less cures or means of prevention (26). The fundamental and basic nature of genetic abnormality changes the entire dynamic of disease. One's genetic

heritage, unlike a virus, bacterium, or a mutant cell, simply cannot be destroyed or abated (39,47). Genetic conditions, in a sense, are inseparable from the existence and identity of a person, and they can confer potential disease status upon someone with perfect health and no symptoms. The medical realities of genetic diseases form a background for a much broader, and sometimes more troubling, range of social and psychological concerns. The basic character of genetic information brings it to bear on fundamental life choices and understandings in a way that raises unique possibilities of harm to the individual, and perhaps, even to society.

Inherited Breast Cancer. The paradigmatic case and original source of much of the controversy and concern over the commercialization of genetic testing was the discovery and marketing of the BRCA breast cancer gene tests (31). The case provides a good illustration of the issues involved in the commercialization of genetic testing. Normal or wild-type BRCA genes apparently inhibit the growth of tumor cells in breast and ovarian tissue (48). Mutations in the genes may confer a lifetime risk of 80 percent for developing breast cancer and 50 percent for developing ovarian cancer (48). There are many deletions and variations, however, that may appear in a woman's BRCA gene of "unknown significance" (49), and in fact the high correlations to risk cited above are based on specific mutations found in women that were previously determined to be high risk (48,50). The possibility of selection bias compromises the probabilities (51–53). It has been speculated that the risk posed by the BRCA mutation for women with no family history of breast cancer might only be 40 percent or lower (54). Amid this background of uncertainty, and with the drastic measure of a prophylactic mastectomy as the only potentially preventative option, several companies moved to provide BRCA tests commercially (55). The Genetics and IVF. In vitro Fertilization Institute in Fairfax, Virginia, began offering the test to the general public on the theory that women had a right to know about their genetic status (56). Myriad Genetics, in its promotional literature to physicians, suggested that almost everyone could benefit from taking the test (57). Since then a University of Washington study has concluded that women without a strong family history of breast cancer should not worry about getting tested (58). Another study at Leiden University in the Netherlands found that the polymerase chain reaction (PCR) process used in the gene tests was missing about a third of the disease-causing mutations because they were too large (59).

At the center of the confusion and controversy, women were making private, painful decisions about whether to undergo testing despite few medical remedies except for surgically removing both breasts. Parents had to decide for daughters and weigh the benefits of alertness in life to symptoms of the disease against the possibility of ruining her healthy years with depression and apprehension. A woman told that she has a significantly increased risk would have to decide how to react to news reports that having no children or having them late increases the risk of breast cancer (60) and that smoking seems to reduce the risk (61). She would have to contemplate the possibility of passing on the gene to her children and the guilt that might entail. Some of the healthy women who tested positive chose the difficult course of prophylactic double mastectomies and oophorectomies (removal of the ovaries), although breast cancer could still occur in remaining tissue or even in the abdomen or colon (62). Questions remain whether the estimated 2.5 million other American women with BRCA mutations should undergo similar procedures (62). Today new options such as tamoxifen offer women alternative means of prevention and hold promise for future developments (51–53,63). An at-risk woman, however, would still have the burden of figuring out how reducing the risks posed by her particular mutation compares to side effects like increasing the risk of uterine cancer and life-threatening blood clots (64). The result is a biological version of Russian roulette that many women may simply avoid by not playing at all (65).

Dangerous Information. The discussion of breast cancer gives some brief indication of the hard choices and painful consequences that genetic testing can create. Only a superficial sense of these issues can be conveyed here, but it is important to realize the scope of the effects of genetic information. Perhaps the most obvious effect, as well as the most difficult to describe, is that testing positive may be "psychologically devastating" (26). It can cause deep depression or anxiety, and disrupt family relations. Even cases of suicide of otherwise healthy individuals have been reported (4,66). The problems seem most acute with respect to incurable late on-set disorders, such as Huntington's disease, where the utility of testing in light of the lack of treatment has been the subject of considerable controversy (67). Genetic information also substantially affects important life decisions such as whether to have children and even whom to marry (68). Such information may even define personal identity and status within one's community (69).

The broader social implications of genetic testing also are profound. Genetic testing already has begun to enable genetic discrimination by employers and insurers (70,71). The government has started creating databases for the DNA of employees, all military personnel, and criminals (70,71). Prenatal diagnosis provides a means of extending subtle social discriminations to selective termination. In California, the only state keeping track of prenatal genetic testing, 70 percent of women receive prenatal diagnosis (72). It is estimated that at least half the pregnant women in the country do so, and that about half the women who receive a positive test for a serious illness choose selective termination (72). There is little room to be sanguine in these matters. Consider, for example, the recent research indicating the genetic basis of Lou Gehrig's disease (73), and imagine that parents began terminating births of afflicted fetuses. An advanced society might think that the private activity of parents has resulted in a net benefit, but in fact, could the world have done without the likes of Stephen Hawking, or for that matter, Lou Gehrig (74)? An Institute of Medicine study commented:

> The development and widespread use of genetic tests ... raises issues about discrimination and privacy ... that

> people found to possess certain genetic characteristics will lose opportunities for employment, insurance and education. . .. [G]enetic testing raises worries about inequities and intolerance . . . that not everyone will share equitably in the benefits of genetic testing, that some will be stigmatized, and that the beauty of human diversity will be denigrated due to a narrowed definition of what is acceptable (4, p. 30).

In Germany genetic testing already is being used in immigration policies (75), and in the United States suits for "wrongful birth" have been brought against doctors who botched genetic tests indicating disability (76).

The stakes in genetic testing are not only the traumatic personal ones discussed above, but include far-ranging social ones involving democracy, privacy, and delicate notions of human worth. As one commentator has noted, "Although their proponents invariably proclaim that new technologies will bring unprecedented prosperity and freedom, they can also threaten our civic values. What Thomas Jefferson called 'cherished liberty' is not determined by our genes. It is determined by our eternal vigilance" (70). The difficult private and public decisions that genetic information requires, about the power of genetic selection, eugenics, and so on, seem impossible to render. Before individuals and society are asked to go where angels fear to tread (77–80); however, it seems reasonable to ensure at least that the momentous consequences provoked will flow from information sufficient and reliable enough to make a basic scientific determination. It is not easy to advise a parent whether to terminate selectively a fetus that has an 80 percent (or perhaps only 40 percent) chance of developing breast cancer (72) or for society to decide whether to intervene. In fact the only easy thing to say about these troubling and complex issues is that people should not be asked to resolve them based on information with no established clinical validity. It is perhaps the only easy decision to make in minimizing the harms that can result from genetic information. The question remains, however, over who should be responsible for doing so.

HISTORY AND JURISDICTION OF THE FOOD AND DRUG ADMINISTRATION

Though FDA regulates genetic testing kits, it has historically had a policy of not regulating clinical services (82). Before turning to the original reasons behind adoption of this policy, it might be appropriate to explain why the option of restraint might have particular currency with respect to genetic testing. The political climate in which FDA now operates greatly heightens the risks and barriers to undertaking new forms of regulatory oversight. Since 1994 there has been a remarkable shift in public, and especially congressional, attitudes toward FDA. While critical campaigns in the past traditionally centered on the agency's failure to protect sufficiently the public health or to meet fully its statutory obligations with respect to imposing regulations and review (83,84) recent criticisms have focused on excessive bureaucracy and oversight that prevented medical benefits from reaching the public with adequate speed (85,86). Comparisons were made to the availability of new products in European markets (87), and, particularly in the case of HIV treatments, the social cost of standards and requirements for testing and proof of efficacy became the basis for public outrage and demonstrations (88). A newly elected Republican Congress, sensing an opening, concentrated much of its energy on FDA in its campaign to deregulate American business (89–92). The fierce cost-cutting budgetary environment put further restrictive pressure on the scope of the agency's regulatory mandate.

The FDA also has not had positive experiences taking strong regulatory positions in the testing area. Its last few attempts to protect the public from too much self-knowledge proved to be an institutional bellyache. In the late 1980s FDA adopted a complete ban on HIV home testing kits, which came under considerable derision (93–97). Accusations of paternalism were leveled and public health experts argued that without encouraging testing of populations not apparently at-risk, efforts to control spread of the disease would not be effective (98). FDA retreated from its position in 1995 (99). Similar efforts to block the distribution of drug-testing kits also suffered considerable unpopularity (100).

Finally, the agency's lack of enthusiasm may stem from the intuition that regulation of genetic testing is a thankless task. The extraordinary volume of scholarly writings on genetic testing exploring the social and moral implications often include critiques of potential government policies, which writers prophesize will lack nuance and sensitivity to the exploding issues related to genetic testing (101–105). Almost any guidelines that can be produced by the limited resources available will prompt passionate objections and painstaking critiques. While physicians, scientists, consumer advocates and other thoughtful individuals repeatedly declare that some effort to establish validity should be undertaken (2,8,11,12), the general public may still question attempts to limit their access to information, however uncertain the information may be. People might prefer to judge for themselves.

In addition to these present considerations, the policies and possibilities of FDA regulation of genetic testing are shaped by its institutional and jurisdictional history. Its range of administration is formulated according to a legislatively constructed and evolving societal role that is defined by specific purposes and by its position in relation to other guardians of the public health.

Historical Account of the FDA's Mandate

FDA's creation and evolution have resulted largely from successive periods of public crisis (106). Its charter began at the turn of the century when industrialization created an urban workforce dependent on produce and packaged goods transported from rural areas (107). The market proved to be a poor regulator of the quality and content of these goods, and the horrors of mislabeled and adulterated foods became the subject of public outcries and criticism (108,109). For example, food labeled "potted chicken" or "potted turkey" in North Dakota was found by state government officials to contain no discernible amounts of chicken or turkey (108). The first food and drug law was passed in 1906 and was aimed solely at punishing transportation of food and drugs that were adulterated

or misbranded (110). There was no provision for direct regulation of safety and efficacy.

Congress began to entertain the possibility of more expansive regulation during the New Deal, but could not come to an agreement on the issue for many years (107). From the outset there was concern about administrative overreaching into the discretion and business decisions of the industry and fear that regulation would hinder growth (107). The trade-off between preservation of the public health and economic and technological development was immediately apparent. While Congress debated, in 1937 the elixir sulfanilamide disaster struck (111). The product, which had been tested for appearance and taste but not for safety, caused the deaths of almost 100 people. The only federal statutory violation was labeling the product as an elixir, which technically can apply only to alcohol solutions (111). The product was actually a sulfa compound dissolved in diethylene glycol with unfortunately fatal side effects. The manufacturer was not required to test for safety, or even to disclose the fatal ingredients. It was a tragic introduction to the inadequacies of existing legislation, and within a year the basis of modern food and drug law, the Federal Food, Drug, and Cosmetic Act of 1938 (FDCA), was passed (107,112).

In 1962, following the development of powerful new pharmaceutical products, regulation for effectiveness was added to the goals of FDA (107). The amendment was an important step in blending the work of the medical profession with the obligations of federal regulators. While the thrust of the laws continued to be the protection of individual consumers of mass-produced and marketed products, comprehensive regulation of all drugs (not merely for whether people could be harmed but for whether they would be helped) represented a major inroad on medical discretion. Extending FDA guardianship over both the safety and effectiveness of medical devices through the Medical Device Amendments of 1976 continued the assault (108). Congress was aware of the overlap, and specifically provided that effectiveness need only be reasonably substantiated (113). The statute made clear that no interference in medical practice, particularly with respect to the physician–patient relationship, was intended (114). The reluctance to regulate clinical services derives from this historical deference to medical practice.

With each successive wave of technological advancement in various health-related fields, the agency's purview has expanded and adapted to encompass novel issues and risks. Despite political attacks and criticisms of FDA, it will rarely be heard that the agency should be abolished. FDA's necessity has been demonstrated by experience, and despite complaints about the bureaucracy there is a certain efficiency to its existence. By having one national gatekeeper to monitor for potentially harmful drugs or devices, the independent review necessary to secure the public health takes place only once and is rendered in a methodical and dependable manner rather than duplicatively in offices and hospitals with inconsistent results depending on variations in time, access to information, and interest. The public benefits from consistency, standardization of review, avoidance of redundancy, and accumulation of institutional expertise generated by the existence of a central monitoring agency.

Boundaries of FDA Jurisdiction

While a fairly uncontroversial argument can be made that the agency has some authority to regulate the activities of services under the Medical Device Amendments to the FDCA (116), it seems equally clear that its discretion to do so is not unlimited. The question of where to draw the line is a matter of some novelty and ambiguity. There are in fact two separate but related inquiries involved: first, whether the regulation of an apparently intrastate service falls within the constitutional boundaries of federal power, and, if so, whether such power has been delegated by Congress to FDA. The extent to which a historical deference to the medical profession may bear upon proposed efforts to intervene in auxiliaries to clinical practice also must be considered.

Interstate Commerce Clause. FDCA derives its authority ultimately from the interstate commerce clause of the U.S. Constitution (117), which grants Congress the power, "[t]o regulate Commerce with foreign Nations, and among the several States, and with the Indian Tribes" (118). The significance of the clause has undergone considerable evolution as the legitimacy of national power has grown, the most memorable point of departure taking place during the New Deal. During the 1930s President Franklin D. Roosevelt oversaw enactment of a series of laws designed to help the country out of the Depression including the National Industrial Recovery Act. The Supreme Court invalidated the Act and other efforts as unconstitutional in several famous cases including *ALA. Shechter Poultry Corp. v. United States*, 295 U.S. 495 (1935) and *Carter v. Carter Coal Co.*, 298 U.S. 238 (1936). Roosevelt's response was a proposal to change the structure of the court to include one additional justice for each justice over the age of 70 who did not retire. In 1937 there were six such justices. Several key opinions on the Court changed in what has come to be known as "the switch in time that saved Nine." After that time the New Deal vision of national power was vindicated completely, and almost no judicial restraints on the federal commerce power seemed to remain:

> By 1945 the supreme court had come to the position that the primary and perhaps exclusive federalism-based constraints on Congress were imposed by the political process. Although Congress's regulation of the national economy has continued to grow, nearly all of its work falls well within the boundaries set by cases such as *Wickard* and *Darby* (119).

Present jurisprudence interprets the commerce power to permit Congress (*1*) to regulate the use of the channels of interstate commerce, (*2*) to regulate and protect the instrumentalities of interstate commerce, or persons and things in interstate commerce, even though the threat may come only from intrastate activities, and (*3*) to regulate those activities having a substantial relation to interstate commerce (120). FDCA already has been sustained as a constitutional exercise of the interstate commerce power (121–123). In determining the permissible extent of federal regulation of genetic testing, however, the constitutional question warrants preliminary consideration, because under the doctrine of "constitutional doubt"

statutes are construed, if fairly possible, so as to avoid raising a serious question as to its constitutionality (124).

The substantial relation to commerce theory is probably the best basis for regulating genetic testing services. A classic case illustrative of the generous boundaries of that test is *Wickard v. Filburn* (125), the authority of which recently was reiterated by the Supreme Court (120). *Wickard* sustained an implementation of the Agricultural Adjustment Act of 1938 that imposed a wheat quota on a farmer whose wheat was intended entirely for consumption on the farm (125). Not only was the wheat not intended for marketing or distribution out of the state, it was not intended for commercial sale at all. Determining that even the home consumption of wheat bore on the demand for it in the national market, the Court concluded, "This record leaves us in no doubt that Congress may properly have considered that wheat consumed on the farm where grown if wholly outside the scheme of regulation would have a substantial effect in defeating and obstructing its purpose to stimulate trade therein at increased prices" (125). The Court's holding, however, was premised on a specific finding that home consumption substantially affected the economics of the wheat industry. In *United States v. Lopez* the Supreme Court rejected the claim that bearing weapons near schools substantially affected interstate commerce" (120). There clearly are limits to the effects that will support jurisdiction. With respect to commercial genetic testing where samples or patients cross state lines to obtain service for fees or where the company itself has clinics in several states, regulation is clearly well within the bounds of Congress' constitutional power. The activity clearly bears on commerce that is interstate in nature. Even if a test is "home brewed" entirely in state and performed on local residents, it would probably fall within the rule enunciated in *Wickard* and subsequent cases that intrastate activity affecting interstate commerce may be regulated. The Supreme Court repeatedly has sustained regulation of intrastate activity that bears a substantial relation to interstate commerce (120). A more troublesome question arises with respect to programs offered by academic and research centers that are nonprofit. The findings of the Task Force suggest that despite the volume of testing in which such institutions engage, they do not compete significantly with commercial producers and providers (2). If the programs attract patients from out of state then regulation might be supported under the second prong of the commerce power, namely protecting persons in interstate commerce (120). Regulation of solely regional test centers and nonprofit organizations therefore present increasingly marginal constitutional cases for regulation.

Federal Food, Drug, and Cosmetic Act. The more substantial inquiry focuses on the breadth of Congress' delegation of regulatory power to the FDA as it bears on genetic testing. The relevant operating provision in the FDCA is codified at 21 U.S.C. §331, which prohibits:

> (a) The introduction or delivery for introduction into interstate commerce of any food, drug, device, or cosmetic that is adulterated or misbranded.
>
> (b) The adulteration or misbranding of any food, drug, device, or cosmetic in interstate commerce.
>
> (c) The receipt in interstate commerce of any food, drug, device, or cosmetic that is adulterated or misbranded, and the delivery or proffered delivery thereof for pay or otherwise. . . .
>
> (k) The alteration, mutilation, destruction, obliteration, or removal of the whole or any part of the labeling of, or the doing of any other act with respect to, a food, drug, device, or cosmetic, if such act is done while such article is held for sale (whether or not the first sale) after shipment in interstate commerce and results in such article being adulterated or misbranded.

Pursuant to its authority to regulate devices in this section and under other MDA provisions, FDA has asserted repeatedly that it has the power to regulate genetic testing services (126). To support its authority, FDA must identify both a device and the presence of interstate commerce. The language of FDCA is therefore more limited than the constitutional boundaries, regulating activity in interstate commerce rather than activity merely bearing a substantial relation to interstate commerce. The agency has several alternatives to establish jurisdiction: It may premise jurisdiction either upon the materials shipped in interstate commerce from which the genetic test is assembled, on the genetic test itself, or some blend of the two.

Materials Received in Interstate Commerce. FDA's regulation of analyte-specific reagents is an example of regulating ingredients or materials received in interstate commerce (116). Extending regulation to the entire genetic test assembled after the components are shipped in interstate commerce, however, adds a twist. Section 331(k) of title 21 of the *U.S. Code* prohibits adulteration or misbranding of a "device" after shipment in interstate commerce, and the statutory definition of "device" includes "any component, part, or accessory . . . intended for use in the diagnosis of disease or other conditions" (127) clearly encompassing the materials used to assemble a test. A logical and persuasive argument can be made that the components previously shipped in interstate commerce can be "adulterated" within the meaning of Section 331(k) by assembling them into a genetic test that does not conform to regulations prescribed by FDA. A similar reasoning was adopted by the U.S. Court of Appeals for the Ninth Circuit in *Baker v. United States* with respect to the sale of misbranded drugs (128). The court held that Section 331(k) applied where the ingredients were shipped in interstate commerce even though the final manufacture and sale of the drug took place in California (128). The U.S. Court of Appeals for the Eighth Circuit adopted a similar approach to extend regulation to animal biologics that were only distributed intrastate (129). In its argument for jurisdiction under this theory the FDA would be assisted by the long-standing principle in food and drug law jurisprudence that the "high purpose of the Act to protect consumers who under present conditions are largely unable to protect themselves . . . [should not] be easily defeated" (130). Ensuring the public health is a prime example of national power and prerogative, especially where the circumstances are buttressed by other

commercial and interstate elements. The weakness in the approach is that a testing service could theoretically evade regulation by assembling the test from materials which never crossed state lines, even if the service openly and aggressively engaged in national consumer-oriented marketing and served residents from outside the state.

Commercial Testing as Interstate Commerce. Alternatively, jurisdiction may be premised on the genetic test itself if it can be deemed to be an object in interstate commerce. There is some question whether a product technically manufactured and consumed locally may nevertheless, in light of the surrounding circumstances, be an object in interstate commerce. In the past courts have found interstate commerce where the consumer traveled from another state (131) or where information crossed state lines (132), both of which often are involved in providing commercial testing services by test producers. There appear to be no cases, however, where jurisdiction was premised on a device that did not itself at some point cross state lines (133). By providing testing as a service, companies inadvertently have found a means for circumventing the regulation of diagnostics. It is an exception not limited to genetic testing, and generates some disturbing dynamics. Beyond the lack of FDA regulation, it also makes manufacturers no longer dependent on the approval of the medical establishment and allows them to advertise and sell directly to the consumer. Consider, for example, the recent controversy over an Alzheimer's test marketed as a service by Nymox Pharmaceutical Corporation (134). The company ran an advertisement in *TV Guide* implying a conclusive test despite considerable doubt as to the scientific validity of the $400 test (134). A nationally advertised single-test "service," such as the Nymox Alzheimer's test, bears a rather suspicious resemblance to a nationally distributed product, the very object of historical FDA regulation. Adopting the theory that interstate commerce could be created by out-of-state advertising and servicing would require some revision of existing interpretations (135). Courts might be willing to view the test as taking place in interstate commerce under Section 331(a) or (b) if the regulation was restricted specifically to commercial providers who marketed their tests outside the state. Regional services that advertised only to local medical practitioners would provide little basis for regulation. The more interstate elements that are added in defining the scope of those regulated, the more compelling the case for applying Section 331(a) or (b). Using Section 331(a) or (b) seems to better reflect the substance of the activities' interstate nature. However, premising jurisdiction on the test components shipped in interstate commerce and proceeding under Section 331(k) seems a more certain approach under present case law.

Unwarranted Interference with the Practice of Medicine. Although there are dependable grounds for asserting statutory jurisdiction, the FDA must be wary of encroaching on medical practice. While many of the FDA's activities constrain the practice of medicine, such as regulating drugs and screening medical devices (136), there are limits to the permissibility of interference, perhaps even of a constitutional nature. In a very early opinion the Supreme Court stated, "Obviously, direct control of medical practice in the States is beyond the power of the federal government. . ." (139). Although it should be noted that this statement was made prior to the changes in the federal commerce power wrought by the New Deal (119), there is probably still some active residue of the principle remaining today. In *United States v. Evers*, the FDA tried to regulate a physician's use of a chelation drug in treating arteriosclerosis (138). The district court concluded that it was an unwarranted agency intrusion, stating:

> The courts have rather uniformly recognized the patients' rights to receive medical care in accordance with their licensed physician's best judgment and the physician's rights to administer it as it may be derived therefrom (138).

On appeal the U.S. Court of Appeals for the Fifth Circuit declined to endorse this reasoning and affirmed on entirely different grounds (139). The situation involved in *Evers* is quite different than the setting of genetic testing involving commercial labs and regulation of substantive changes in the device rather than merely regulating its medical use. In addition *Evers* reflects somewhat dated, paternalistic notions of the privileges of the medical profession that may have little currency in the modern era of patient's rights. Despite doubts about its authority, however, the reasoning of *Evers* strongly suggests that some care should be taken to avoid encroaching on the practice of medicine in fashioning regulation for genetic testing (140).

THE CASE FOR FDA REGULATION

FDCA arose partly out of a recognition that drug companies and medical products manufacturers, although they assist doctors in saving lives and relieving suffering, are not parties to the Hippocratic Oath. Their motive is profit. Regulation represents a determination that the dangers posed to public health are not sufficiently accounted for in the risk calculus of companies when they introduce products. As revealed in the historical discussion of FDA, the nation learned that lesson through painful experience and since that time has attempted to anticipate potential problems by delegating broad authority that can evolve to cover novel technologies (141,142). There seems to be little disagreement that some authority should determine that genetic tests being offered as services have positive predictive value for the disorder being tested (9,12). In tension with this simple purpose is a broad and varied range of settings in which genetic testing takes place. Any DNA analysis performed at the request of a physician or researcher, whether in a chemical or hospital laboratory including individualized linkage analyses used for diagnosis, can constitute a genetic test. Over 500 laboratories in universities, hospitals, public health departments, and commercial centers perform analysis utilizing innumerable target genetic variations and rapidly evolving test strategies (143). If that is the objective of regulation, it is quite apparent that FDA is not exceptionally suited to such a task. It seems, however, that the dangers generating unique concerns do not arise

in all settings where genetic testing services are provided. Some testing takes place in a research environment or as an extension of medical practice similar to other forms of laboratory analytical services where there has been no general call for regulation. Describing these settings is a helpful prelude to distinguishing precisely the objective of regulating genetic tests. When the goal is carefully identified, the strengths and expertise necessary to its implementation will also become apparent.

Information Dynamics in Genetic Testing

Genetic testing providers may engage in a wide range of activities: researching genetic linkages (144), developing new diagnostic products (28), performing genetic analysis, and serving people directly through clinics (145). To clarify the information dynamics and make the realities of the industry's structure simpler and more immediate, the discussion proceeds by tracing the progress of a hypothetical consumer of genetic testing services through the process. An individual may obtain a genetic test either as part of a clinical research program, through a physician, or directly from a commercial testing service. The fourth option of purchasing a home test kit is not currently available in the United States, although an over-the-counter genetic test for cystic fibrosis was recently introduced in the United Kingdom (146–148).

Patient Participating in Research. Individuals asked to participate in research programs often already have developed the condition or are related to someone who has the condition (4,9). The linkage studies used to identify disease genes are most productive using a familial database and comparing the genes of those who have the disorder with those who do not have it (144). The researchers are necessarily genetic specialists and academics who must comply with human subject requirements and other investigative protocols (9). The potential harms of poor information in this scenario are minimal since the individuals tested are at-risk to begin with, the information is often accompanied by education and counseling (26), and the results are delivered by professionals with the specialized knowledge necessary to explain the significance and experimental nature of the information and who have motive other than commercial profit. Sometimes the results are not even given to the test recipient (4). In addition to taking place in a "protected" setting (26), testing for research purposes yields important social benefits in increased scientific understanding of the human body and produces precisely the kind of information necessary to make medical determinations more reliable.

Requesting Testing through a Physician. There are basically three purposes for which genetic testing might be ordered through a physician. First, the physician might be using it to further the diagnosis and treatment of a symptomatic individual, which in the case of genetic disorders is usually a child (a related case involves presymptomatic testing of a close relative). Second, an expectant mother might seek prenatal diagnosis, or her obstetrician might recommend it based on a family history of previous birth defects. Finally, a physician may recommend it to an individual with a general family history of a condition, or the individual might raise the possibility on his or her own after having heard of the test on the news or even through advertisements.

Diagnosis of a Symptomatic Individual. As discussed above, when genetic tests are used to make or improve diagnosis of a symptomatic individual, the dangers implicated are not significantly different from those occasioned in other types of testing. Because the test recipient presently is endangered by illness, any medically useful information may facilitate treatment and prevent imminent physical harm. The ordering physician, furthermore, is usually a specialist in the particular disorder being tested for and has a special capacity to determine the presence of a valid indication for testing (149) and evaluate the medical implications of a positive result. The case will involve a patient under continuing care whose medical and family history will have been explored in conjunction with the disorder. For family disorders, close relatives who are tested will be subject to similar conditions. Although a high rate of misinterpretation may persist even in these circumstances because of the complexity of genetics (149), these tests generally offer a greater degree of medical certainty as a starting point (149) and physicians who work with genetic disorders are more likely to be able to understand and evaluate genetic information and research (2).

Prenatal Diagnosis. Prenatal diagnosis involves somewhat special considerations, and also blends aspects of the other two cases. In a survey of physicians, obstetricians earned some of the highest marks for genetic knowledge (2). Obstetricians' work exposes them to more genetics, and they are one of the main users of clinical genetic services, including genetic counseling (29). Furthermore, until recently, most prenatal diagnosis utilized the same tests employed by pediatricians and specialists to diagnose symptomatic individuals. To have the test performed, the obstetrician may send a sample to one of the national commercial laboratory services, a regional service or the laboratory at a local hospital, perhaps one with which she is affiliated. Because of the risks involved in prenatal diagnosis (48), the tests remain conservative and focus largely on severe, predominantly single-gene disorders with well-established genetic tests. Commercialization of tests like the one for breast cancer susceptibility, however, may not leave prenatal diagnosis immune. An article noted that "some couples already are asking for [testing] the genes that confer a fifty to eighty five percent breast cancer risk" (72). The Genetics and IVF Institute has responded that they might even do it "after counseling and careful consideration" (72).

General Physician Referral. Primary care providers are likely to be on the frontlines of both demands for genetic tests by patients (150) and advertising by biotechnology companies and national laboratories who develop tests. As one journalist noted, "It's almost a daily occurrence to pick up the morning newspaper and read that scientists have found another gene that causes a medical malady" (26). Furthermore, "Once we find the gene, the stories imply, a genetic cure may be just around the corner"

(26). Most Americans are confident in the ability of their primary care physician to tell them if they are at risk and believe that the family practitioner can correctly interpret a genetic test (151). Unless their doctor has had some previous experience with genetic testing, however, their reliance may be misplaced (150). A 1993 study found that primary care physicians earned low scores on average in a test of genetic knowledge, although there was marked improvement for more recent years of graduation (152). Unfamiliarity with the essentials of genetics makes the primary care provider a somewhat unlikely candidate for ensuring independent review of the clinical utility of a new genetic test. In fact, the media and even advertising may take the decision out of the hands of primary care providers as consumers are persuaded to pursue the test based on these extrinsic sources, and physicians feel pressured not to interfere in the patient's decision making (149).

At present there are only a handful of companies developing new, advanced tests (2). Most are young, aggressive companies "hoping to take the lead in a potentially lucrative field, unconstrained by the complex FDA regulations that beset drug approvals (28,153,154). The rest of the industry is comprised of major diagnostic companies, such as Boehringer Mannheim, Ciba-Geigy, and Johnson & Johnson, and national behemoths in genetic testing services, such as Genzyme, Lab-Corp., Abbot Laboratories, and SmithKline-Beecham, which have been slower to commit resources (153). The existence of the small companies revolves around their venture capital structure, which requires quick turnarounds on profit and creates intense pressure to get a product quickly to market, perhaps even before the test's safety and effectiveness can be established (153). The smaller regional commercial testing centers, such as Clinical Diagnostic Services serving the New York metro area and Laboratories for Genetic Services in Texas, traditionally have offered a more conservative array of genetic analysis but seem to have been expanding in recent years (155). Their advertising is almost exclusively local and is directed at physicians rather than the broader public because of expense considerations. Laboratories affiliated with universities and hospitals generally offer a smaller range of testing, specialize in particular kinds of tests, and rarely advertise their services.

Getting a Test on One's Own. The last consumer is one who has not been invited to be part of a research study and has not been referred for a test by a physician. Perhaps, the individual does not wish to divulge family disorders for fear of insurance discrimination, or he or she is motivated more by curiosity and apprehension than medical necessity. The laboratories at universities, hospitals, and regional commercial services are largely unavailable without a physician referral (155). A few testing services that cater to a nationwide audience, however, have given consumers direct access to genetic testing. A prominent and controversial example is the Genetics and IVF Institute, which permits walk-in testing for BRCA mutations (145). Third-party screening of the test's validity in this scenario obviously would be nonexistent.

Need for Regulation. The need for objective information on the soundness of tests being purveyed is greatest with respect to commercial services marketing tests directly to the public. In these instances, a genetic testing service bears the greatest resemblance to a conventional commercial product. Prior to commercialization of genetic testing, there were established, informal networks for obtaining a test through specialists and other experienced providers. If a test was well-proven, knowledge about the test filtered through the professional establishment to the appropriate physicians. Now, producers promote novel tests directly to all physicians and the public (153). The consuming physician and patient need not have any independent information to obtain access. The problems of misinformation and defective information seem to be most critical where the elements of commercial interest, puffery, ready access by the public, and lack of independent review converge. In fact, the essence of these elements lies in the flow of information, that is, who has it and who depends on it. A negative change in the source of information away from the supervising physician to a financially self-interested company or service may be summarized in one word: marketing. Relying for information on the very parties who have the most to benefit from praising the test, however, obviously leaves a great deal to be desired.

Current State of Regulation

However, the existing framework of regulation focuses not on where the greatest harm may exist, but on whether a test is packaged or performed on site. Providers and developers of genetic testing are currently subject to a patchwork of federal and state regulation based on the form of the activity engaged in rather than the substance. Biotechnology companies who package the test as a kit to be distributed to laboratories and physicians are subject to FDA regulation. Companies and laboratories that deliver the testing as a service, sometimes by accepting samples through the mail, are not subject to any regulations to ensure safety and effectiveness. Instead, only the technical competence of a laboratory's testing is regulated under the Clinical Laboratory Improvement Act. Laboratories also are licensed by the state and voluntarily may undertake limited FDA compliance by setting up Institutional Review Boards (IRBs) (8). Laboratories associated with academic and research institutions are regulated similarly, and usually have IRBs and prescribed human subjects protocols (8).

FDA Regulation of Kits. FDCA as amended by MDA (107) and the Safe Medical Devices Act of 1990 (156) established a comprehensive system to regulate the safety and effectiveness of medical devices. The level of review depends on a device's classification (159). Class I devices are devices that pose no unreasonable risk to health and whose safety and effectiveness can be ensured by general controls (158). Class II devices require specialized controls to ensure their safety and effectiveness (158). Most genetic tests, however, would probably fall into Class III because of their complexity (160,161). Class III devices require submission of a premarket approval application for FDA review unless "substantial equivalence" can be established with a previously approved device through Section 510(k) notification (162). When an application is

received, FDA assigns the product to an examiner who possesses the relevant scientific background to review the application. Although no more than a handful of genetic testing products have been submitted for review (163), the agency already has designated an examiner to specialize in genetic tests (164). Oncor's Inform Her-2/Neu breast cancer genetic diagnostic was one of the first genetic tests to pass FDA review (165). When Oncor first submitted a version of the gene diagnostic kit, FDA rejected the application (166). It was not until after the company "expanded reproducibility studies, set forth manufacturing criteria, and ... develop[ed] a training program for the physicians and technicians using the test" that it was approved for use in predicting the likelihood of recurrence in previously symptomatic patients (166). FDA also requires compliance with good manufacturing practice (GMP) standards, monitors advertising, and expedites clearance by utilizing postmarket control (83). The agency further might condition approval on the company developing a system to ensure counseling or physician consultation (167).

Clinical Laboratory Improvement Amendments. The Clinical Laboratory Improvement Amendments of 1988 (CLIA) were passed to establish minimum quality standards for laboratory testing (168). The Health Care Financing Administration (HCFA), which implements CLIA, reviews some 158,000 laboratories across the country pursuant to the act (169). CLIA sets forth quality standards for proficiency testing, patient test management, quality control, personnel qualifications and quality assurance (170). There is no effort under CLIA's regulatory administration to establish the utility of or the validity of using any particular test. Under CLIA, the laboratory need only demonstrate that its procedures result in accurate and reliable identification of the target, namely, technical competence in test performance (2). Furthermore, much of the review process is conducted through third-party accreditation organizations and programs (171). The scope of review is limited to laboratory procedures and its purpose, to certify labs for payment under federal health plans, is largely administrative.

State Regulation. The states of Washington, Oregon, and New York have laboratory review regulations rigorous enough to qualify them for exemption from CLIA regulation by the HCFA (172). However, only New York undertakes any significant assessment of genetic testing. If a company or laboratory located in New York or providing testing to New York residents wishes to offer a genetic test, it must become certified for the particular test, a process that involves consideration of the quality and effectiveness of the test (28,173).

Choosing a Regulatory Actor

There is thus a sharp regulatory divide between genetic testing kits, which receive the full intensity of FDA review of safety and effectiveness, and widely marketed genetic tests offered as a service, which generally receive no review of safety and effectiveness. It is a regulatory divide not warranted by any significant factual distinctions. A genetic testing recipient requires as much protection from the harms of a proprietary genetic test provided as a service, as a genetic test sold as a kit. If a company promotes a genetic test in interstate marketing directly to the public, the test, even if performed as a service, loses the characteristics of medical practice and carries the hallmarks of commercialization. It is a product being purveyed to the public, and as such, should be subject to the scrutiny of the nation's gatekeeper of medical devices, the FDA. In fact FDA is the only agency whose existing legislative authorization might cover regulation of genetic testing services.

The lack of convincing alternatives emphasizes the appropriateness of FDA oversight. Besides FDA, there is a fairly short list of other serious potential regulators of genetic testing: the Centers for Disease Control (CDC), the HCFA, or the Department of Health and Human Services (DHHS) (8). Both CDC and HCFA are agencies within DHHS (as is FDA). CDC "is responsible for promoting health and quality of life by preventing and controlling disease, injury, and disability" (174). CDC is the nation's prevention center; its efforts are directed primarily at monitoring, researching, and preventing diseases, and cover a broad range of social activities including collaborative projects with either HCFA or FDA (175,176). HCFA administers the Medicare and Medicaid programs and CLIA (177). HCFA's duties in certifying laboratories and reviewing testing proficiency are related to its administration of Medicare and Medicaid and are intended to ensure that laboratories are qualified for the work for which they are being reimbursed, which is similar to its authority to prescribe nursing home standards (178). Finally, DHHS is mentioned not so much to suggest that the department itself undertake regulation of genetic testing, but that a new body within DHHS be created to do so. As an initial matter, it is not apparent that these alternative regulatory bodies have any existing statutory authorization to regulate the clinical validity of genetic testing, which creates a substantial hurdle to effective action and suggests a lack of traditional jurisdiction. Under CLIA, the CDC determines the categorization for tests performed by laboratories, and HCFA reviews their competence. As discussed, however, CLIA does not include the authority to review the quality or scientific validity of a genetic test and focuses instead exclusively on proficiency. However, the public policy question remains as to whether the CDC or HCFA have more expertise and a more appropriate structure than FDA to substantively regulate genetic tests, or whether all the agencies are so poorly suited to the task that a new body should be invented.

HCFA does not appear to have developed particular genetics expertise in its regulation of clinical laboratories (179,180). While it may have a better infrastructure to undertake widespread regulation of many different sites, the clinical validity of a type of genetic test only needs to be established once. Nor does HCFA seem to have familiarity in conducting a substantive scientific review. CDC could be a more promising candidate because of its scientific expertise and prominent historical role in disease control. Setting up a new process for conducting safety

and effectiveness review for genetic testing services under CDC, however, seems redundant because FDA already is implementing similar measures to regulate genetic testing kits. The science and protocols for evaluating a genetic test for clinical utility should not change based on how the test is delivered. Furthermore the issues raised in regulating genetic testing conform to those routinely raised for FDA such as identifying a professional standard, expediting clearance through postmarket controls and tracking, monitoring advertising, and determining equivalence with a previously approved produce.

In fact, the only benefit of choosing another agency or charting a new one comes not from any advantage in scientific qualifications or institutional expertise, but in avoidance of perceived excessive bureaucracy at FDA. This concern, however, may be misjudging the matter. Government review and approval of a diagnostic is inherently bureaucratic. Creating a new organization to undertake the task or assigning it to one with no experience is nothing more than reinventing the wheel and hoping it turns out better this time. Not only is such a course somewhat doubtful in rationale, it is duplicative of existing FDA regulation of genetic testing kits and therefore wasteful of public resources. From the perspective of expertise and experience, it is clear that FDA may most readily provide the regulation called for in genetic testing services.

CONCLUSION

Perhaps the most disturbing aspect of the issues discussed is the immediate need for oversight. FDA is the best positioned agency from the perspective of jurisdiction and institutional expertise to undertake the task, and what it requires is not so much legislative authorization as a social and political mandate. Promptness in action is not only essential in light of the particular circumstances in genetic testing but foreshadows the proficiency of society to address these problems in the future. Commercialization of genetic testing is one of the first challenges presented by the wondrous and rapid developments in genetic technology, and it only can be hoped that the government will prove itself capable of managing the dangers with the energy and foresight necessary to ensure that the public safely receives the benefits of a new era in genetics.

OUTLINE

INTRODUCTION

Privacy is a broad concept. In the legal context it includes at least four categories of concern: (*1*) access to persons and personal spaces; (*2*) access to information by third parties, and also any subsequent disclosure of this information by third parties (the category of concern best captured by the term "confidentiality"); (*3*) third-party interference with personal choices, especially in intimate spheres such as procreation; and (*4*) ownership of materials and information derived from persons (1). Typically statutes characterized as "genetic privacy acts" address a number of these concerns, regulating genetic testing and other means of generating genetic information, limiting access to genetic information, and ruling out certain uses of genetic information by third parties. However, some states have laws that are much narrower. Further, even laws that are broad in terms of the range of privacy concerns addressed may be narrow in scope, targeting a particular industry or type of information keeper. For example, many genetic privacy laws were passed in response to abuses, actual or perceived or potential, in the insurance industry and by employers. Some laws are tailored to problems that arise in the areas of research or law enforcement or family relations.

For organizational purposes, this article is divided into four sections. Each section covers major developments at the state and federal levels, and common (or judge-made) law as well as statutory law, to the extent relevant. Given the range and complexity of the issues, this entry is intended as an overview. For more in-depth treatment, the reader may wish to consult the sources cited in the references.

LAWS REGULATING THE GENERATION, DISCLOSURE, AND USE OF GENETIC INFORMATION

State Laws

Genetic Privacy Laws. At present, the only laws that comprehensively address genetic privacy are at the state level. At least 35 states have some statutory law relating to genetic privacy (excluding laws authorizing creation of DNA banks and databases for law enforcement purposes, which may include privacy protections). See Table 1. The most comprehensive of these laws include general provisions covering genetic testing and the handling of genetic information, accompanied by more focused provisions addressing special concerns that arise in connection with insurance and employment, and in Texas and Wisconsin, occupational licensing.

Most genetic privacy laws cover at least two aspects of privacy, access to persons (for testing) and access to information. See Table 2. About half prohibit genetic testing of persons or samples without prior informed consent, subject to certain exceptions, for example, law enforcement, paternity determination, court order, and anonymous research. In many states the elements of the consent form are specified; standard elements include a description of the test, a statement of the purposes of testing, and the names of the persons or entities to whom results may be released. It is common for laws to contain a statement that genetic information is confidential, or "confidential and privileged," meaning that it is protected from subpoena in a civil proceeding, although production can still be compelled by a specific court order. Disclosure of genetic information to a third party without written authorization or consent is generally prohibited unless an exception applies. The standard list of exceptions parallels the list of exceptions to the consent requirement. Some states also permit disclosure of genetic information for the benefit of blood relatives if the subject is dead (2). Usually the authorization for disclosure must be specific rather than general. Many state laws provide that these legal protections only apply to genetic material or information that can be identified as belonging to an individual or family.

In the area of insurance, a major issue is breadth of application of genetic privacy laws. Many states limit special privacy protections for genetic testing and information to *health* insurance, leaving consumers with few or no safeguards in their dealings with life, disability

Table 1. State Genetic Privacy Laws (as of November 30, 1999)

State	Statute
Alabama	Ala. Code §27-53-1 et seq.
Arizona	Ariz. Rev. Stat. Ann. §20-448.02
California	Cal. Civ. Code §56.17; Cal. Health & Safety Code §1374.7; Cal. Ins. Code §§742.405, 742.407, 10123.3, 10123.35, 10140, 10140.1, 10146 et seq.
Colorado	Colo. Rev. Stat. §10-3-1104.7
Connecticut	Conn. Gen. Stat. Ann. §46a-60
Delaware	Del. Code Ann. tit. 16, §1220 et seq.; Del. Code Ann. tit. 19, §711
Florida	Fla. Stat. Ann. §§627.4301, 636.0201, 760.40
Georgia	Ga. Code Ann. §33-54-1 et seq.
Hawaii	Haw. Rev. Stat. §§431 : 10A-118, 432 : 1-607, 432D-26
Illinois	Ill. Comp. Stat. Ann. §513/1 et seq.
Indiana	Ind. Code Ann. §27-8-26-1 et seq.
Kansas	Kan. Stat. Ann. §44-1002 et seq.
Kentucky	Ky. Rev. Stat. Ann. §304.12-085
Louisiana	La. Rev. Stat. Ann. §22 : 213 : 7
Maine	Me. Rev. Stat. Ann. tit. 5, §19301-02; Me. Rev. Stat. Ann. tit. 24-A, §2159-C
Maryland	Md. Ins. Code Ann. §27-909
Minnesota	Minn. Stat. Ann. §72A.139
Missouri	Mo. Ann. Stat. §375.1300 et seq. (Vernon's)
Montana	Mont. Code Ann. §33-18-901 et seq.
Nevada	Nev. Rev. Stat. Ann. §§629.111 et seq., 689A.417, 689B.069, 689C.198, 695C.207, 695B.317
New Hampshire	N.H. Rev. Stat. Ann. §141-H : 1 et seq.
New Jersey	N.J. Stat. Ann. §§10 : 5-12, 10 : 5-43 et seq., 17B : 30-12
New Mexico	N.M. Stat. Ann. §24-21-1 et seq.
New York	N.Y. Civ. Rights Law §79.1; N.Y. Ins. Law §2612 (McKinney)
North Carolina	N.C. Gen. Stat. §58-3-215
Ohio	Ohio Rev. Code Ann. §§1751.64, 1751.65, 3729.46, 3901.49, 3901.491, 3901.50, 3901.501 (Baldwin)
Oklahoma	Okla. Stat. Ann. §tit. 36, §3614.1 et seq.
Oregon	Or. Rev. Stat. §§659.036, 659.700 et seq.
Rhode Island	R.I. Gen. Laws §§27-18-52, 27-19-44, 27-20-39, 27-41-53, 28-6.7-1 et seq.
South Carolina	S.C. Code Ann. §38-93-10 et seq.
Tennessee	Tenn. Code Ann. §56-7-2701 et seq.
Texas	Tex. Labor Code Ann. §21.401 et seq.; Tex. Ins. Code Ann. §21.73; Tex. Rev. Civ. Stat. Ann. §9031 (Vernon's)
Vermont	Vt. Stat. Ann. tit. 18, §9331 et seq.
Virginia	Va. Code Ann. §§38.2-508.4, 38.2-613
Wisconsin	Wis. Stat. Ann. §942.07

income, and long-term care insurers, among others. Texas is unusual in limiting protections affecting insurance to group health benefit plans (3). Legislation specifically directed at life insurers has been enacted by a number of states, but the protections afforded applicants for life insurance are minimal. Typically these laws require only that informed consent be obtained prior to performance of any genetic testing and/or that any use of genetic information in medical underwriting meet standards of actuarial fairness. Note that state protections are generally considered to be inapplicable to self-funded employer-sponsored benefit plans, including employer-sponsored health and life insurance, due to the operation of the federal Employee Retirement Income Security Act of 1974, commonly known as ERISA (4).

Many genetic privacy laws are silent on the issue of retention of samples (i.e., biological specimens obtained or retained for the purposes of genetic testing). A few states require destruction of samples upon specific request, or after the purpose for which the sample was obtained has been accomplished. The New York law requires that the sample be destroyed at the end of the testing process or not more than 60 days after the sample is taken, unless a longer period of retention is expressly authorized (5). Laws that require destruction of samples typically include exceptions related to research and law enforcement, areas discussed in more detail below.

States also vary in the sanctions imposed for violations of privacy protections. In most states, a violation is a misdemeanor punishable by fine or jail time or both. (A willful violation may be a felony.) Further, a number of states allow individuals to sue for equitable relief, such as an order to stop a violation, and damages, costs and attorney fees (6). The Louisiana law relating to health insurance allows recovery of the greater of actual damages or $50,000 ($100,000 in cases of willful violation) against persons who violate the law by negligently collecting or disclosing genetic information, and the law authorizes treble damages where a violation resulted in monetary gain (7).

Definitional Issues. Whether a law relates to insurance, employment, or has a more general orientation, the choices legislators make in two key areas have significant implications: (*1*) how to define the category or categories of protected material or information, and (*2*) whether and how to address the problem of compelled consent.

State genetic privacy laws typically focus on the generation, disclosure and use of "genetic information," a term that may be linked to a definition of "genetic test" and/or "genetic characteristic." Many states that have genetic privacy laws use one or more of these definitions to limit protections to persons who are presymptomatic or asymptomatic for disease. (The protections in an Alabama law are even more limited, only applying to presymptomatic testing for a predisposition to cancer [8].) From a policy perspective, this limitation may be defensible; it is unclear why persons with diseases that are genetic in origin should be favored vis-à-vis persons with diseases that arise in some other fashion. On the other hand, the "genetic revolution" has blurred many lines that formerly appeared sharp, even creating questions about what counts as a disease. For example, the Illinois Genetic Information Privacy Act provides that results of genetic testing that indicate the person is already afflicted with a disease, "whether or not currently symptomatic," are not subject to the confidentiality requirements of the act (9). This provision suggests that a disease may exist

Table 2. Summary of Key Provisions in State Genetic Privacy Laws (as of November 30, 1999)

Provision	State
General provisions	
Genetic testing generally prohibited without prior informed consent	AZ, DE, FL, GA, NV, NH, NJ, NM, NY, OR, SC, VT
Standard exceptions include law enforcement, paternity determination, court order, anonymous research	
Standard elements of consent form include description of test, statement of purpose(s), who receives results	
Person requesting genetic testing must advise of risk of discrimination	VT
Genetic information confidential and/or privileged	AZ, CA, CO, GA, IL, MO, NY, OK, OR, SC, TX
No release of genetic information without specific authorization	AZ, CA, CO, DE, FL, GA,
Standard exceptions include law enforcement, paternity determination, court order, anonymous research, benefit of relatives (subject deceased)	HI, IL, LA, MD,[a] MO, NV, NJ, NM, NY, OR, SC, TN,[a] TX,[b] VT, VA,[a] WI,[c]
Requests for genetic services expressly protected	DE, HI, LA, KY, MD, MN, MO, NV, NH, NM, RI, VT, VA
Destruction of (identifiable) sample generally required upon request and/or accomplishment of purpose	DE, LA, NV, NJ, NM, NY, OR, TX
Definitions	
Narrow definition of genetic test/characteristic/information:	
• Test (direct) for alterations in genes	CO, IN, KS, MO, OH
• Test for predisposition and/or environmental damage and/or carrier status	AZ, DE, IN, ME, NJ, NM, NY, TX, WI
• Person must be a- or presymptomatic	AL, CA, FL, GA, IL,[d] KY, ME, MD, MN, MT, OK, SC, TN, VT, VA
Genetic information expressly excludes family history	FL, MO, MT, OK, TN
Insurance and employment	
Health insurers prohibited from requiring genetic testing[e]	AL,[f] CA, FL, GA, HI, IL, IN, KY, LA, ME, MD, MN, MO, MT, NV, NH, NJ, OH, OK, RI, SC, TN, TX,[g]
Health insurers prohibited from requesting genetic testing and/or information (some states add "for nontherapeutic purposes")[e]	CA, CO, FL, GA, HI, IL,[h], IN,[h] KY, LA, MD, MN, MO, MT, NH, OH, OK, RI, TN
Employers prohibited from requiring genetic testing (some states add "unless job related" or similar language)	CT, DE, KS, ME, NH, NJ, OK, OR, RI, TX, VT
Employers prohibited from requesting genetic testing and/or information (some states and "unless job related" or similar language)	CT, DE, KS, NH, OK, OR, VT
Sanctions	
Individual right to sue	CA, CO, DE, GA, IL, LA, NV, NH, NJ, NM, RI, SC

[a] Insurance context.
[b] Employment, group health insurance, and occupational licensing contexts.
[c] Employment context.
[d] Provision in Act states that confidentiality protections do not apply if genetic testing indicates that the individual is at the time of the test afflicted with a disease, whether or not currently symptomatic.
[e] Self-funded plans covered by ERISA may be exempt.
[f] Genetic tests for predisposition to cancer.
[g] Group health insurers.
[h] Insurers may consider favorable test results voluntarily submitted by an individual.

purely on the basis of genotype, without any phenotypic manifestation. Another area of variation is whether "genetic information" includes biological materials such as tissue samples.

Some laws specify that only testing or information relating to inherited genes or genetic characteristics is covered, pointing up an ambiguity in the adjective "genetic." Many diseases, including all cancers, can be described as genetic in the sense that they are triggered by altered genes. However, only 5 to 10 percent of cancers are thought to be closely linked to a particular set of inherited genetic defects. Another area of variation is the stringency of the definition of genetic test. Some states limit the term to direct tests for alterations in genetic materials, while others include tests of proteins and other gene products. It is also common to exclude routine medical tests, such as cholesterol tests, human immuno-deficiency virus (HIV) tests, and drug tests from the definition of genetic test.

Genetic tests are not the only source of information about predisposition to disease or disease risk. Some of the first documented cases of genetic discrimination involved inferences from family history (10). Several

states use a broad definition of genetic information that appears to encompass information in a family history. For example, the Connecticut law defines genetic information as "information about genes, gene products or inherited characteristics that may derive from an individual or family member" (11). Louisiana expressly includes family history in its definition of genetic information, while Florida, Missouri, Montana, Oklahoma, and Tennessee expressly *exclude* family histories from protection (12). Finally, a number of states expressly extend privacy protections to requests for genetic services (13).

Compelled Consent. Genetic privacy laws commonly prohibit health insurers and employers from requiring genetic testing as a condition of insurance or employment and from using any genetic information acquired in a discriminatory fashion. Privacy advocates have long argued that these protections are fairly meaningless if insurers and employers can persuade or pressure unsuspecting individuals into submitting to genetic testing or sharing genetic information, or obtain genetic information from other sources. Once a third party has possession of information, it is very difficult to police its use (14).

To address these problems, some states prohibit covered insurers and/or employers from even requesting genetic testing or genetic information (15). Vermont, while not prohibiting requests, requires that the person requesting genetic testing advise the individual to be tested that the results may become part of the individual's permanent medical record and may be material to his or her ability to obtain insurance benefits (16). At least four states prohibit covered insurers from seeking genetic information for any nontherapeutic purpose (17). A Delaware law passed in 1998 makes it unlawful for an employer to "intentionally collect" genetic information unless it can be demonstrated that the information is job related and consistent with business necessity or is sought in connection with a bona fide employee welfare or benefit plan, and laws in Oklahoma and Oregon provide that an employer may not "seek to obtain" genetic information concerning an employee or prospective employee (18). It is unclear whether these laws will have any effect on employer access to health insurance claims data, a major area of concern for privacy advocates.

Generic Privacy Laws. In some states, either by default or design, privacy protections are "generic" rather than "genetic," that is, such protections as exist apply to the general category of medical record or health information rather than to genetic information per se. Generic approaches avoid many of the definitional or line-drawing problems that arise in statutes that seek to single out genetic tests and information for protection. They also avoid stigmatizing genetic conditions by treating them differently (19). However, general laws tend to be fairly weak. Laws providing for the confidentiality of physician–patient communications limit disclosure by providers of health care, but they typically permit blanket releases of information to insurance companies and other third parties. Oregon is one of the exceptions. The state-mandated form for medical record release authorizations requires that sensitive information (HIV/AIDs-related records, mental health information, genetic testing information, and drug/alcohol-related information) be initialed by the patient or legal surrogate in order to be included in the release (20).

The first-generation Insurance Information and Privacy Protection Model Act, released by the National Association of Insurance Commissioners in 1981 and adopted in 10 states, covers areas such as pretext interviews (i.e., attempts to gain information involving a misrepresentation of or refusal to provide identity), disclosure of information practices to applicants and policyholders, the content of authorization forms, access to recorded personal information including medical record information, opportunities for correction of recorded personal information, limitations and conditions affecting disclosure of personal information, and penalties and remedies for violations. It does not block exchanges of sensitive information or describe specific steps insurers must take to minimize the risk of unauthorized disclosure. It also bars any action for defamation, invasion of privacy, or negligence for disclosure of personal information in a manner permitted under the state insurance code, even if the information is false, absent malice or willful intent to injure, and a provision of this nature is common even in states that have not adopted the model law.

A Connecticut law passed in 1999 to prohibit the sale of medical record information and restrict disclosure for marketing purposes, and a similar Maine law passed in 1998, are examples of the next generation of generic privacy laws (21). The Connecticut law has a broad definition of "medical-record information," which expressly includes information obtained from a pharmacy or pharmacist. (However, the definition excludes information that lacks personal identifiers *or* has been encrypted or encoded.) The law requires insurance-related entities that regularly collect, use or disclose medical record information to develop and implement written policies, standards and procedures for its management, transfer and security. These must include limiting access to persons who need the information in order to do their jobs, employee training, institution of disciplinary measures, periodic monitoring of employee compliance, and an additional layer of protection of "sensitive health information," which includes information regarding genetic testing such as the fact that an individual has undergone a test.

The National Association of Insurance Commissioners' Health Information Privacy Model Act, released in 1998 and enacted in at least one state (Montana) in 1999, also protects health information generally rather than singling out genetic information. In the employment arena, an innovative Minnesota law imposes a "job-relatedness" condition on all medical evaluation by employers, and laws in a few other states offer similar protections (22). Massachusetts has a general Privacy Act that authorizes the award of damages as well as equitable remedies for "unreasonable, substantial, or serious" interventions with a person's privacy (23).

Constitutional and Common Law Protections. Genetic privacy may also be protected, generically, under state

constitutions. Several state constitutions recognize a right to privacy (24). The case of *Norman-Bloodsaw v. Lawrence Berkeley Laboratory* concerned unauthorized testing of clinical and administrative workers for conditions including sickle cell trait. Because the employer, a research laboratory, was operated by a California state agency and a federal agency, the workers had claims under the state and federal constitutions, as well as federal antidiscrimination laws. The Ninth Circuit Court of Appeals found that constitutionally protected privacy interests encompass medical information and extend beyond unauthorized disclosure to reach collection of information by illicit means. According to the court, "the most basic violation possible involves the performance of unauthorized tests — that is, the nonconsensual retrieval of previously unrevealed medical information" that may be unknown even to the test subjects (25). The court concluded that genetic conditions are among the conditions that should enjoy the greatest level of protection. Mere consent to a general medical examination and the taking of samples for routine testing would not constitute authorization for these highly sensitive tests.

Common law may be another source of protection and redress. Invasion of privacy is a blanket term for a number of separate claims under common law. The two most relevant to the genetic context are (*1*) public disclosure of private facts, and (*2*) intrusion upon seclusion. In *Doe v. High-Tech Institute*, a case involving unauthorized testing for HIV/AIDS, a Colorado court concluded that a person has a privacy interest in a blood sample and in the medical information obtained from it, and that an additional, unauthorized test can be sufficient to state a claim for relief for intrusion upon seclusion (26). The elements of the claim are intentional intrusion (which need not be physical) upon the solitude or seclusion of another or his private affairs or concerns, and evidence that the intrusion would be highly offensive to a reasonable person. The court in *Doe* commented that in a case of unauthorized testing the intrusion is the interference with autonomy, namely the right to control important health decisions such as whether to undergo testing for a particular disease, condition, or genetic trait. Offensiveness depends on the nature of the specific test and the circumstances under which the test was performed. A law prohibiting a particular kind of testing without consent can serve as evidence of a significant privacy interest.

Ownership of Genetic Information. A few states have statutes that at least obliquely address the question of ownership, the fourth category of concern subsumed under privacy. A section of the Oregon genetic privacy act states that "an individual's genetic information and DNA sample are the property of the individual except when the information or sample is used in anonymous research," but the law also states that this provision "does not apply to any law, contract or other arrangement that determines a person's rights to compensation relating to substances or information derived from a sample of an individual from which genetic information has been obtained" (27). (The Delaware and New Jersey laws contain similar disclaimers.) A 1999 amendment to the Oregon law, effective August 2, 1999, to January 1, 2002, declares any research conducted in accordance with federal regulations for the protection of human subjects "anonymous" (28). Several states have laws that contain general declarations that genetic information is the "unique" or "exclusive" property of the person tested (29). In a much-discussed case, *Moore v. Regents of University of California*, a court rejected a patient's argument that commercial development of a cell line derived from his excised cells amounted to theft, while recognizing that patients have a right to information concerning their physicians' economic and research interests as part of the consent process (30).

Federal Laws

Certain members of Congress have taken an interest in genetic privacy, and bills addressing genetic privacy have been circulating for several years. Most of the genetic privacy bills introduced recently are limited to the health insurance context, although one addresses health insurance and employment. As of May 15, 2000, none of these bills had been enacted. Hence state law remains the primary source of protection for genetic information, although a diverse array of federal laws that are broader in scope may have some bearing on conduct in this area. For example, laboratories that perform genetic testing may be subject to the Clinical Laboratory Improvement Act, and attention is currently being given to confidentiality standards. In the employment context, the Americans with Disabilities Act (ADA) of 1990 regulates the timing and scope of medical examinations conducted by employers. The ADA also requires that employers keep information obtained from medical examinations confidential.

A number of federal laws, as well as bills or regulations under consideration, address the privacy of medical records or health information generally. The Privacy Act of 1974 regulates the handling of health-related information by federal agencies. The Health Insurance Portability and Accountability Act (HIPAA) of 1996 provides protection against discrimination based on genetic information and specifies how genetic information is to be handled for purposes of preexisting condition clauses in group health insurance. HIPAA also mandates further attention to privacy concerns. On August 12, 1998, pursuant to a HIPAA requirement, the Department of Health and Human Services (HHS) published a proposed rule establishing security standards for all electronic transactions involving health information. A proposed rule intended to protect the privacy of individually identifiable health information was published on February 3, 1999. The rule does not single out genetic information for heightened protection. It does provide a framework for regulation of the use and disclosure of individually identifiable health information by health plans, health care clearinghouses, and health care providers that engage in electronic transactions. The rule would not preempt stronger privacy protections at the state level (31). If Congress does not take action, the rule will be issued in final form sometime in 2000 or 2001.

Several bills have been introduced in Congress that would introduce more comprehensive privacy regulation at the federal level, including the "Health Care Personal

Information Nondisclosure Act of 1999" (S. 578), the "Medical Information Protection Act of 1999" (S. 881), the "Medical Information Privacy and Security Act" (S. 573), the "Medical Information Protection and Research Enhancement Act of 1999" (H.R. 2470), and the "Health Information Act" (H.R. 1941). As of November 30, 1999, none had been enacted. Major points of contention include the scope of protected health information (the Medical Information Privacy and Security Act appears to be unique in explicitly including tissue samples) and the level of anonymity required for exclusion, the acceptability of blanket authorizations, rights of minors, preemption of state laws offering greater protections, and the creation of an individual right to sue for violations. Interestingly all provide that protections continue after death.

The U.S. Constitution is yet another source of privacy protection for health-related information. In *Whalen v. Roe*, a case involving a New York law requiring physicians to send copies of prescriptions for certain classes of drugs to the state health department, the U.S. Supreme Court ruled that the privacy interests secured under the U.S. Constitution extend to medical record information (32). However, the court found that the steps taken by the state to protect confidentiality were sufficient to meet constitutional requirements. In *Norman-Bloodsaw*, discussed above, a federal appeals court ruled that the right to privacy extends to genetic testing.

LAWS REGULATING RESEARCH

Basic Regulatory Framework

The Federal Policy for the Protection of Human Subjects (often referred to as the "Common Rule") and other regulations governing human subject research are codified at Title 45 Part 46 of the Code of Federal Regulations. The Office for Protection from Research Risks (OPRR) within the National Institutes of Health has primary responsibility for implementation. Significantly, these regulations only apply to research conducted, supported, or subject to regulation by a department or agency of the federal government. Further, since the term "human subject" is limited to living individuals, biological materials and data derived from deceased persons are not covered. Also, to be covered, research must involve (*1*) intervention or interaction with the individual or (*2*) *identifiable* private information, meaning that the identity of the subject is or may readily be ascertained by the researcher or associated with the information. If neither condition is met, research would not be considered human subject research. OPRR has taken the position that information is identifiable where codes can be broken with the cooperation of others (33). Some research, while covered, may be eligible for an exemption from regulatory requirements. The categories of exempt research include research involving the collection or study of existing data or specimens, if these sources are publicly available or if the information is recorded by the investigator in such a manner that subjects cannot be identified directly or indirectly through identifiers.

For research that falls within the scope of the regulations and does not qualify for an exemption, there are two basic requirements: approval must be given by an Institutional Review Board (IRB) and proper informed consent must be obtained from participants. One requirement for IRB approval is that "when appropriate" adequate provisions are made to protect the privacy of subjects and maintain the confidentiality of data. The consent requirement has aroused more controversy. Traditionally tissues, blood, and other biological materials used for research have been stored and studied without explicit consent based on a waiver provision in the Common Rule. Section 46.116(d) states that informed consent for research can be altered or waived if an IRB finds and documents that (*1*) the research involves no more than minimal risk to the subjects, (*2*) the waiver or alteration will not adversely affect the rights and welfare of the subjects, (*3*) the research could not practicably be carried out without the waiver or alteration, and (*4*) whenever appropriate, the subjects will be provided with additional pertinent information after participation. With the advent of genetic research, some have argued that the risk associated with the use of identified or identifiable data or specimens is no longer minimal and consent should be obtained, particularly where protocols propose sharing information with the source or a third party (34).

In August 1999 the National Bioethics Advisory Commission issued recommendations for the interpretation or modification of existing federal regulations relating to the use of human biological materials in research. The Commission found that use of specimens for purposes other than the purpose for which they were originally collected raises the strongest privacy concerns. Pursuant to the recommendations, even research limited to manipulation of existing specimens, if identified or coded (identifiable), would be judged greater than minimal risk and therefore ineligible for a consent waiver unless an IRB were to find that a particular study adequately protects the confidentiality of personal information and incorporates an appropriate plan for whether and how to reveal findings to the donors or their physicians. Consent forms for research would provide a menu of options; future research uses involving unidentified and unlinked samples would generally be accorded similar treatment, as would identified and coded samples (33).

Turning to the state level, states that have genetic privacy laws often exempt research activities, but only if there is some level of anonymity. Requirements vary, ranging from a requirement that the genetic information used for research be free of all identifiers, to a requirement that the only identifier be a code, to a requirement that the identities of donors not be released to researchers. States may parse the research exemption as an exemption from the mandate to obtain informed consent before performing any genetic testing or as an exemption to the mandate to obtain authorization for disclosure of genetic information to a third party. The Missouri law exemplifies the latter approach: genetic information is confidential and cannot be disclosed without written authorization except for health research conducted in accordance with the Common Rule or health research "using medical archives or databases in which the identity of individuals is protected from disclosure by coding or encryption, or by removing all

identities" (35). Florida's genetic privacy law contains no exemption for research (36).

Like much biological materials research, medical records research has traditionally been conducted without the knowledge of patients, let alone their informed consent. State medical record confidentiality laws frequently permit access to records for research purposes, so long as researchers maintain the confidentiality of identifiable information (37). Minnesota generated much controversy when it passed a law imposing unusually strict requirements on external researchers seeking access to medical records. An executive of a biotechnology company that conducts a large proportion of its clinical trials at the Mayo Clinic reports that this state law has dramatically reduced the medical records available for research, from 97 percent when the law was passed to 70 percent in 1999 (38).

The privacy bills currently under consideration by Congress would permit disclosure of protected health information for health research that satisfies certain requirements, typically compliance with the Common Rule (or the equivalent for the Food and Drug Administration, FDA) or, in the case of existing information, review by an IRB or IRB-like entity. The Medical Information Privacy and Security Act would make all health research subject to Part 46 of Title 45 of the Code of Federal Regulations, whether federally funded or not. The proposed rule on health information privacy, referred to above, would subject all medical records research to scrutiny by an IRB or privacy board, but only with respect to certain privacy criteria (31).

The federal and state laws and regulations that protect research subjects either by requiring consent or by requiring anonymity for health information and biological materials used in research do not address the potential for abuse of information about specific populations. Research involving biological materials that have been stripped of individual identifiers should not produce information that will result in direct harm to particular donors, but it may reveal sensitive information about the groups to which the donors belong.

DNA Banking for Research Purposes

Banking of biological materials for research, and storage of related information, is largely unregulated. DNA banks range from the collections of individual researchers to the extensive stores of the U.S. Centers for Disease Control and Prevention. State public health agencies may also have extensive collections of biological materials and health information (e.g., cancer registries and "Guthrie cards," specimens of infant's blood on filter paper), subject to varying levels of privacy protection. At least four states require that genetic information be destroyed at the completion of a research study or upon withdrawal of the person from the study, unless retention is explicitly authorized. In a controversial move, the Michigan Commission on Genetic Privacy has recommended that the state permanently preserve blood samples of newborns, which were originally collected to screen for rare congenital disorders, for use in research conducted in accordance with the Common Rule (unless parents elect to opt-out of research) (39).

Research and Commercial Development

The potential for commercial development based on genetic research has added another layer to research informed consent. While the court in *Moore* refused to recognize a patient's property rights in a cell line derived from his tissue, it did find that physicians must disclose personal interests unrelated to the patient's health that may affect their judgment and failure to do so may give rise to a cause of action for performing a medical procedure without informed consent or breach of fiduciary duty. In response to the *Moore* ruling, consent forms have been expanded to include explicit permission to retain cells for development with potential commercial value. It is not clear that current laws adequately address issues of commercialization. The Uniform Anatomical Gift Act, adopted in some form by the majority of states, gives the donor the authority to decide particular use of body tissue, while the National Organ Transplantation Act prohibits the sale of human tissue and organs for transplantation. Neither law was designed to address the commercialization of genetic material (40).

Law and Chilling Effects on Research

Some have argued that the new emphasis on informed consent for research use of biological materials and medical records will have a chilling effect on research (41,42). The major concern is that the ethical benefits of obtaining informed consent (e.g., demonstrating respect for persons and for privacy as personal choice) are far outweighed by the burdens to research. Consent requirements mean added time, expense, and paperwork, and selective participation may introduce significant bias into research, detracting from its value. A further concern is the lack of uniformity in state laws. Major research projects frequently cross state lines in order to obtain adequate accrual of subjects.

Research may also suffer due to uncertainty concerning confidentiality protections for data in the possession of researchers. A number of celebrated products liability cases from the 1980s showed the willingness of courts to compel production of research data. For example, in *Deitchman v. E.R. Squibb*, Dr. Arthur L. Herbst was required to produce research data linking adenocarcinoma of the genital tract and exposure in utero to diethylstilbestrol (DES); Herbst was not a party to the case nor was he even being called to testify (43). A provision of the Omnibus Consolidated and Emergency Supplemental Appropriations Act (P.L. 105-277) passed in October 1998 requires that federal agencies make data produced under awards to nonprofit organizations available to the public through Freedom of Information Act procedures. To be sure, individual identifiers are removed before data are released to litigants or requestors, but this does not allay the concerns of researchers and privacy advocates. With expanded capacities to manipulate data, redaction to eliminate obvious identifies may not adequately protect the privacy of individuals and groups. Under the

Public Health Service Act, Certificates of Confidentiality are available for certain types of sensitive research including genetic research. Certificates of Confidentiality, however, only protect against forced disclosure of identifying information about individuals, not forced disclosure of aggregate data.

Other Emerging Issues

The fecundity of biological materials raises two further concerns. Particular samples may have potential for usefulness in future research unanticipated at the time of collection. Should the individual be recontacted for permission to do further research on the sample or is a generic consent to use of the sample in future research sufficient? More pressing, with advancements in genetics, the amount of useful medical information that a sample can yield continues to expand. What is the responsibility of a researcher to inform the donor of the sample if medically significant information is discovered? Since most state laws do not require total anonymization of samples used in research, it is theoretically possible to identify the donor. With the possibility of identification may come a responsibility to inform, but the potential psychological harms and risk of discrimination that accompany unsolicited disclosure or "inflicted insight" must be carefully evaluated. Cases addressing the obligations of treating physicians to disclose information to potentially affected family members (discussed below) appear to be the closest analogue. Subjects might be queried concerning their desire for recontact for further studies and for contact with medically significant information, yet questions of interpretation will remain.

LAWS REGULATING DNA BANKS AND DNA DATABASES

Large collections of DNA samples, and records reflecting the results of analysis of those samples, are assembled primarily for one of three purposes: law enforcement, identification of human remains (chiefly in the military context), and medical treatment and research. This section addresses collections of DNA samples (or "banks") and DNA records (or "databases") related to the first two purposes. Interest in this area has been focused on the first two categories of privacy concern, bodily integrity and confidentiality. In particular, questions have arisen concerning the constitutionality of coercive extraction of DNA samples and subsequent testing, and the adequacy of measures to ensure confidentiality and protect samples and information from misuse by third parties. Although their primary goal is identification of perpetrators of crimes, DNA banks and databases maintained by law enforcement agencies may also contain DNA records of unidentified persons, and, in a few states, relatives of missing persons. Texas also authorizes inclusion of DNA records of "a person at risk of becoming lost" (44).

DNA Collection by Law Enforcement

The collection and analysis of DNA samples for law enforcement purposes is concentrated at the state level, with some coordination through the Federal Bureau of Investigations. All 50 states have passed authorizing legislation. States must meet certain federal guidelines in order to participate in data exchange through the Combined DNA Index System or CODIS, established under the DNA Identification Act of 1994 (45). Recently, controversy has centered on the scope of state collection efforts. State laws usually authorize collection of a sample (blood or a buccal swab) upon conviction of a crime and/or as a condition of parole or release from custody. Many state laws cover juvenile offenders (or children adjudicated delinquent) as well as adult offenders, and they contain no special provision for the expungement of DNA records or samples upon attainment of majority.

Initially the focus was on individuals convicted of sex crimes and other serious felonies, offenses associated with high rates of recidivism and biological evidence. However, at least 14 states have added burglary, a nonviolent property crime, to the list of covered offenses. Further, in 1999, several states considered legislation that would permit the creation of DNA records for felony suspects at the time of arrest, a practice contemplated under a Louisiana law that has been enacted but is not yet effective (46). (Significantly the DNA Identification Act limits entries into CODIS to DNA identification records of persons convicted of crimes, analysis of DNA samples recovered from crime scenes, and analysis of DNA samples from unidentified human remains.) Such an expansion of scope may implicate group as well as individual privacy interests. Given that certain minority groups are disproportionately represented in the prison population, and therefore in DNA databases, these technologies may be more effective in "fingering" members of those groups. This problem is likely to be compounded if all arrestees are sampled. The Attorney General has asked the National Commission on the Future of DNA Evidence to study the legality of taking samples upon arrest.

Inmates challenging state laws on Fourth Amendment unreasonable search and seizure grounds have lost with a fair degree of consistency. For example, in *Boling v. Romer*, the Tenth Circuit Court of Appeals found that obtaining and analyzing the DNA of an inmate convicted of a sex offense is a search and seizure raising Fourth Amendment concerns, but that the search and seizure was a reasonable one in light of an inmate's diminished privacy rights, the minimal intrusion of saliva or blood tests, and the legitimate government interest in the investigation and prosecution of unsolved and future crimes by the use of DNA in a manner not significantly different from the use of fingerprints, that is, for purposes of identification (47). First Amendment free exercise, Fifth Amendment self-incrimination and due process, Eighth Amendment cruel and unusual punishment, Fourteenth Amendment equal protection, and ex post facto clause challenges have also failed. The balancing tests may come out differently, however, when the subjects of collection and testing have yet to be convicted of any crime. It is significant that most state laws provide for expungement of samples and information when a conviction is overturned. The Rhode Island law also provides that all identifiable information and samples be destroyed upon official proof that the subject has been deceased for at least three years (48).

At present the biggest deterrent to expansion of DNA sampling by law enforcement agencies is a lack of capacity to analyze samples, rather than any fear of lawsuits. As of June 1999 the backlog of samples awaiting analysis exceeded 500,000 nationwide (49). In response, states are sending samples to private laboratories, a practice that heightens concerns about security and potential for misuse of data.

The DNA profiles entered in CODIS databases currently consist of 13 DNA loci or markers. These DNA markers were selected for their variability, rather than their intrinsic information value (e.g., links to disease or personality traits). Hence advocates for the use of DNA databases in law enforcement believe the potential for abuse is limited. In this regard it is important to distinguish between the samples stored in DNA banks, which can be used to generate other, more sensitive information so long as they are in existence, and the profiles stored in DNA databases. Given the interest in behavioral genetics, one can imagine the eagerness with which some researchers might pursue access to genetic information concerning this particular subset of the population.

State laws address confidentiality concerns in a number of ways. They typically contain a statement that DNA profiles are not public records. Some laws require custodians of samples or records to implement security measures. The Rhode Island law is one of the more detailed in this respect, requiring that an encryption code be used for access to records, that DNA samples be securely locked with access only by director of health department and head of laboratory, and that all identifiers be removed when samples are provided to third parties for creation of DNA records (50). Some state statutes require the relevant agency to develop privacy standards for laboratories under contract. The California law declares that the computer software and database structures, as well as the data, are confidential (51).

Most state laws mimic the language of the DNA Identification Act limiting disclosure of DNA analysis to criminal justice agencies for law enforcement purposes, in judicial proceedings, and, to defendants for criminal defense purposes. Where personally identifiable information is removed, disclosure is also permitted for population statistics databases, for identification research and protocol development purposes, and for quality control purposes. While the reference to population statistics databases might be interpreted broadly, in this context the term refers to analysis of the frequency of occurrence of genetic characteristics in local populations, a type of research closely related to the identification objective for which the DNA banks and databases have been established. Even so, a few states seem to take a fairly permissive view. A number allow dissemination of statistical or research information if there are no identifiers, and the Alabama law permits the state's DNA population statistical database to be used to provide data relative to the causation, detection and prevention of disease or disability and "to assist in other humanitarian endeavors including, but not limited to, educational research or medical research or development" (52). The Massachusetts law allows release of DNA records for the purpose of assisting in the identification of human remains from mass disasters, assisting the identification and recovery of missing persons, and "advancing other humanitarian purposes" (53). At the other end of the spectrum, Indiana, Rhode Island, and Wyoming expressly prohibit the use of the state collections for the purpose of obtaining information about human physical traits or predisposition for disease (54).

DNA Collection by the Military

The Department of Defense is compiling the world's largest employer-held DNA bank; all inductees and all active duty and reserve personnel are required to provide samples to the military's DNA Specimen Repository. The purpose of the repository is to permit identification of remains, with DNA extracted from samples only as needed. However, concerns have been expressed about possible diversion of the repository to other uses, such as criminal investigation (55). In 1995 a federal district court upheld the sampling program against a challenge on constitutional and other grounds, although the judgment was vacated on mootness grounds after the plaintiffs had been honorably discharged (56).

LAWS REGULATING FAMILY RELATIONS

Disclosure to Potentially Affected Family Members

In the clinical context, a major question has been whether health care providers have a legal and/or ethical duty to disclose genetic information to family members for whom the information may have medical or reproductive implications. There is little direct statutory guidance in this area, and where statutes exist, they tend to permit disclosure rather than mandate it.

The Uniform Health Care Information Act (National Conference of Commissioners on Uniform State Laws, 1985) recognizes several exceptions to the general obligation to keep information confidential. One exception permits, but does not require, a health care provider to disclose information from a patient's record where the health care provider has reason to believe that disclosure will avoid or minimize imminent danger to the health or safety of the patient or another individual. The exception developed out of common law precedents permitting or requiring disclosure in situations where a patient had an infectious disease and the facts were such that the patient could be expected to infect others absent disclosure, or where a patient threatened harm to self or others. The Act has been adopted in only two states, Montana and Washington, and Montana declined to include this provision (57). Other statutes that limit disclosure of health care information fail to address this issue directly, and it has fallen to the courts to define the scope of a legal duty to disclose genetic information.

Judges have grappled with this issue in two cases, *Pate v. Threlkel* and *Safer v. Estate of Pack*, with somewhat different results (58). In interpreting the results, it is important to recognize that both cases were decided at a stage in the proceedings where the court was required to accept as correct the plaintiffs' assertions concerning

the standard of care required of physicians during the relevant time period (and other factual matters). Also the decisions in these cases are binding only in the respective jurisdictions, Florida and New Jersey. Other courts will accord them weight based only on the persuasiveness of the reasoning relative to the law in their home states.

Pate was decided first, with the basic facts as follows: Heidi Pate discovered that she had medullary thyroid carcinoma, an autosomal dominant disorder, three years after her mother received treatment for the same disease. She sued her mother's physicians and their employers, arguing that the physicians had a duty to warn her mother of the risk of genetic transmission and to recommend testing of any children. The Florida Supreme Court ruled that if the standard of care was to warn a patient of the genetically transferable nature of a condition, as Pate alleged, then the intended beneficiaries of the standard would include the patient's children as well as the patient. In other words, the patient's children would be entitled to recover for a breach of the standard of care. However, in light of state laws protecting the confidentiality of medical information, the court found no requirement that a physician warn a patient's children. Rather, the court found that in any circumstances in which the physician has a duty to warn of a genetically transferable disease, that duty will be satisfied by warning the patient. The court believed a more expansive standard would be burdensome and unmanageable.

Safer involved similar facts. Donna Safer's father was treated over an extended period of time for colon cancer associated with adenomatous polyposis coli, an autosomal dominant disorder. Almost two decades after his death, Safer was diagnosed with metastatic colon cancer associated with adenomatous polyposis coli. Safer then sued the estate of George Pack, her father's physician, for Pack's failure to warn of the risk to her health. Two additional facts, taken as true for purposes of the court's decision, were significant. First, Safer's mother testified that on at least one occasion she asked Pack whether what he referred to as an "infection" would affect her children and was told not to worry. Second, Safer contended that careful monitoring of her condition would have provided an opportunity to "avoid the most baneful consequences of the condition," a consideration giving force to her argument that the standard of care in the circumstances was to warn any children at risk.

Examining the precedents, the New Jersey Appeals Court found no essential difference between this case with its "genetic threat" and traditional duty-to-warn cases involving the menace of infection or threat of physical harm. The court concluded that a duty to warn in the genetics context would be quite manageable, commenting that those at risk are easily identified. The court noted the potential to avert or minimize substantial future harm by a timely and effective warning to potentially affected persons. The court failed to state how the duty to warn might be discharged, especially in cases involving small children. The relation of this ruling to confidentiality protections was considered only in the court's concluding speculations about possible complications, such as the existence of an instruction from the patient not to disclose information to family members. The court offered no resolution of this dilemma.

Some states do have statutes that address the question of disclosure for the benefit of family members in very narrow circumstances. For example, a section of the California Welfare and Institutions Code concerning involuntary commitment provides that information pertaining to the existence of a genetically handicapping condition may be released to a qualified professional for purposes of genetic counseling for a blood relative upon the request of the blood relative (59). This can happen either with the consent of the patient or after reasonable attempts have been made over a two-week period to get a response from the patient.

It is important to remember that broad dissemination of genetic information is not an unalloyed benefit to potentially affected family members. In addition to possible psychological harms, family members may face discrimination if genetic information finds its way into their medical records or becomes part of their knowledge base and so must be disclosed on applications for insurance. This could happen without their cooperation where a health care provider shares information without first verifying that family members with to receive it, or where an insurer or other third party stores information concerning more than one family member and fails to prevent information flow. An awareness of this problem appears to explain a New York law that prohibits any person in possession of information derived from a genetic test from incorporating that information into the records of a nonconsenting individual who may be genetically related to the tested individual (60).

Testing of Children

The right of parents to order genetic testing of their children has also provoked some discussion. The issue is particularly vexing where the testing is for an adult-onset condition that cannot be prevented, ameliorated or cured by any action taken during childhood. In such cases it is hard to argue that testing confers any benefit on the child, or any benefit on the parents such as the ability to plan for burdens likely to affect the family unit (as might be the case with an incurable condition manifesting in childhood). The general rule is that parents control medical decision making for their children. The Delaware genetic privacy act expressly states that it "does not alter any right of parents or guardians to order medical and/or genetic tests of their children" (61). An Illinois law addresses a situation in which testing is requested by or ordered for a child and a question arises concerning the proper recipient of the results. The statute requires a health care provider who orders a genetic test for a minor to notify the minor's parent or legal guardian of the results of the test, but only if the provider determines that notification would be in the best interest of the minor and has first sought unsuccessfully to persuade the minor to give the notice (62).

Paternity Determination

The use of genetic testing in the determination of paternity is most analogous to the use of genetic testing in

law enforcement. As in the law enforcement context, testing aims at identification rather than production of information about health or behavior, and similar privacy interests are implicated, namely the interest in being free of unwanted bodily invasion, and the interest in preventing access to or disclosure of personal information. If an individual refuses to submit to paternity testing, the result may be a contempt citation or a presumption that the results would be adverse to the individual. Laws governing genetic testing to determine paternity typically provide that the results of testing are confidential and cannot be disclosed to third parties absent exceptional circumstances. Sample retention is not always addressed. Some laws do provide that if a man is found not to be the father of a child in a paternity proceeding, the man's genetic material must be destroyed (63).

Adoption

Adoption is yet another context in which genetics, privacy concerns, and the law come together. A critical issue here is the extent of adoptive parent and adoptee access to genetic information. State adoption laws typically require preparation of a report of the complete family medical and social history of a candidate for adoption (so long as parental identity is not disclosed), including identification of any known genetic disorders. Ten states require information concerning extended family if available (64). Generally, the adoptive parents, and the adopted child upon attainment of majority, are allowed access to this information. In a few states, where an adopted child has died, genetic information (and other medical information) is available to the spouse of the adopted child if he or she is the legal parent of the adopted child's progeny, and also to any progeny of the adopted child age 18 or older.

Some states create voluntary registries that allow nonidentifying genetic information to flow back *to* birth parents (e.g., notice that the child has been diagnosed with sickle cell anemia, meaning that the birth parents are carriers of sickle cell trait), as well as permitting transfer of additional information *from* birth parents as it becomes available. In Arizona, other biological children of the birth parent can also access nonidentifying information in adoption records upon request (65). In several states, a certified statement from a physician explaining why genetic or other critical medical information should be communicated to adoptive parents or an adopted child, or an adopted child's genetic parent or sibling, is the trigger for an effort by the registry to notify the affected person(s) that the nonidentifying information is available from the registry (66). North Dakota places information exchange within the discretion of the child-placing agency (67).

Opening of sealed adoption records that include identifying information is usually permitted only by court order upon a showing of "good cause." Proceedings to open records have been brought by adopted children seeking to contact genetic relatives as potential donors of tissue or bone marrow for life-saving transplants, or for other health-related purposes. In such cases courts typically apply a balancing test, weighing the interests of the adopted child, the adoptive parents, the biological parents, and society. In *Golan v. Louise Wise Services*, New York's highest court reversed a lower court order that would have permitted an adoptee, seeking genetic information for evaluation of his heart condition, access to the identities of his biological parents. The court found that consideration of the adoptee's well-being alone in cases involving medical problems with genetic implications would "swallow" the state's strong policy against disclosure. The court suggested correspondence through a guardian ad litem as an alternative to unsealing adoption records (68).

Other scenarios put forward by commentators, in which privacy interests may be at odds with other interests, are more speculative, and appear not to be directly addressed under current law. For example, there are concerns about excessive testing of children prior to adoption. Genetic testing or genetic information might also be demanded of prospective adoptive parents, as bearing on their suitability for parenthood. Concerns have also been expressed about the use of genetic information as ammunition in child custody disputes, as affecting the likelihood that a parent will "be there" for a child in the future (10,69).

Postmortem Testing for the Benefit of Family Members

Several states authorize sharing of genetic information with family members once a person is dead. The next logical step is genetic testing of the dead to obtain information desired by family members. Under normal circumstances the next-of-kin usually controls disposition of the body and has the right to consent to or refuse an autopsy (or the use of samples in research). An argument could be made that by extension family members have the right to order genetic testing, although laws prohibiting genetic testing without consent with only limited exceptions might be cited as evidence against such a right. In at least one case, reported in the media, a daughter was given access to a sample of her deceased father's blood for paternity testing. Her mother sued the hospital to try to block testing and lost (70). There appear to be few laws directly addressing this question. A notable exception is a New York law that expressly authorizes genetic testing on specimens from deceased persons if informed consent is provided by the next of kin (71). (Autopsies may also raise the unsolicited disclosure problem, where a pathologist obtains genetic information that may be material to family members in the course of an autopsy and must determine whether to disclose this information to family members.) The Native American Graves Protection and Repatriation Act addresses the issue by stipulating that Native American remains in the possession or control of federal agencies are the property of lineal descendants or tribes and must be repatriated upon request (72).

MISCELLANEOUS

Genetic information is increasingly sought in the context of civil litigation. Defendants in personal injury lawsuits may be eager to prove that injuries resulted from the plaintiffs' genetic defects rather than their own negligent

conduct. As noted above, state laws may declare that genetic information is privileged and hence protected from routine discovery in the investigational phase of a civil proceeding. However, a judge may order testing or disclosure of information if persuaded of its relevance. For example, a defendant in a lawsuit arising out of an automobile accident sought to compel genetic testing of the plaintiff for Huntington's disease, as a possible causal factor, and the court ordered the testing over the plaintiff's objections (73). Colorado law creates a barrier to recovery for injury arising from genetic counseling and screening, prenatal care, labor, delivery, or postnatal care where it can be established that the injury was the result of a genetic disease or disorder (74). A provision of the law expressly permits discovery of medical information concerning the plaintiff and makes this information admissable as evidence at trial. In addition the law allows discovery of medical information relating to genetic siblings, parents, and grandparents of the plaintiff, if the defendant cannot secure voluntary releases and persuades the court of the possible relevancy of the information.

GENETIC INFORMATION, LEGAL, GENETICS AND THE AMERICANS WITH DISABILITIES ACT

MARY R. ANDERLIK
University of Houston
Houston, Texas

OUTLINE

INTRODUCTION

The Americans with Disabilities Act (ADA) is one of the landmark pieces of legislation of the twentieth century (1). Its purpose is to "provide a clear and comprehensive national mandate for the elimination of discrimination against individuals with disabilities" (2). Many people affected by genetic conditions fear discrimination, especially in the areas of employment and insurance. The ADA contains provisions that address disability discrimination affecting the conduct of employers and insurers. However, the protections of the ADA may be of little help to those who believe they have suffered discrimination owing to a genetic characteristic. This is so owing to the restrictive definition of disability in the ADA and other features such as a provision that shelters traditional insurance underwriting practices from challenge under the ADA.

Structural Reasons for Discrimination

It may be helpful to review some of the reasons for genetic discrimination, and the available evidence concerning its prevalence, before proceeding to a discussion of the statute itself. Discussions of genetic discrimination tend to focus on the employment and insurance contexts. This is so because given the current arrangements for financing health care, both employers and insurers have strong financial incentives to discriminate on the basis of genetic information (and other information concerning present or future health status) in order to control costs.

Employment

In the United States, employers frequently play a role in obtaining health insurance for employees. Where an employer assumes responsibility for paying some part of the premiums for experience-rated health insurance or chooses to self-insure, employee health problems have a direct effect on the employer's financial performance. Experience rating means that premiums are set based on the claims history of persons covered under the employer's group policy. For small employers, in particular, one employee with an illness that is expensive to treat can send premiums sky-rocketing, increasing costs to the employer and to other employees. Where an employer chooses to self-insure, the employer bears the burden of any

expenditures for covered medical care and captures the benefit from any reduction in such expenditures. In 1997, 13 percent of all employers had self-funded health plans, and 56 percent of firms with 500 or more employees had self-funded health plans (3). Strategies that self-insured employers might be tempted to pursue to hold down health care related costs include cutting salaries or increasing employee cost-sharing to offset any increases in health care costs, weeding out workers likely to have health problems through hiring and firing processes, identifying conditions that are likely to prove costly and excluding them from coverage (a strategy that is more effective if the health risks of actual employees are known), and dropping health coverage entirely (4).

In addition employers may seek to exclude individuals with above-average susceptibility to a toxin from certain jobs out of paternalistic concern or fear of liability. Another response would be to increase protections (e.g., reduce exposures) for all workers. In the employment context, it is important to distinguish between screening and monitoring. Screening refers to efforts to test applicants or employees for conditions that may render them more susceptible to harm from workplace substances than the average person. The target is the individual, and the goal is to improve productivity and lower workers' compensation and health insurance costs. Monitoring refers to the performance of periodic examinations of employees to identify and assess changes. The target is the active workforce and the goal is to identify workplace risks that can be reduced through implementation of prevention programs (5). Finally, employers may wish to exclude persons with genetic conditions from the workforce based on concerns about attendance and productivity.

Insurance

Insurers, such as issuers of health, disability, long-term care, and life insurance policies, discriminate among insureds and applicants for insurance based on health status due to bottom-line concerns and philosophical commitments. The bottom-line concern may be solvency or profitability. In addition many insurers have a commitment to "actuarial fairness," meaning that policies are priced to accurately reflect risk or expected losses. The forms of health status related discrimination operative in insurance are captured by the term "medical underwriting." Insurers obtain health information in order to decide as a threshold matter whether an applicant is an acceptable insurance risk, and also for use in setting premiums. Insurers can also design benefit packages strategically to limit potential losses. For example, health insurers can exclude certain conditions or procedures from coverage, or they can use "preexisting condition" clauses to eliminate coverage for any health care needs that relate to a condition diagnosed or treated prior to enrollment.

As a justification for these practices, insurers cite the problem of adverse selection. Adverse selection is the disproportionately heavy purchase of insurance by individuals at higher risk for claims than their insurers are aware. When individuals learn that genetic or other factors put them at high risk for disease, disability, and/or early death, they may load up on insurance. If insurers are ignorant of the information concerning risk, they cannot incorporate it into the process of underwriting. As the proportion of higher-risk individuals in an insurance pool increases, payouts will increase, and as payouts increase, premiums for all policyholders will go up. In a voluntary system of insurance, premium increases can be expected to drive out lower-risk individuals, resulting in a further increase in the proportion of higher-risk individuals, and so on. At least for health insurance, the problem of adverse selection could be addressed through universal coverage (6). The preferred solution for U.S. insurers has been to ensure that they have access to any health-related information that may be available to applicants for insurance.

Anecdotal and Survey Evidence of Genetic Discrimination

Although incentives to engage in genetic discrimination are present, the limited evidence available suggests that few employers or insurers systematically collect or use information derived from genetic testing. The expense involved in testing is surely a factor. A government-sponsored survey of Fortune 500 companies in 1989 found that of the 330 respondents, 12 reported conducting current biochemical genetic screening of employees. None reported conducting direct-DNA screening (5). Significantly more employers may solicit family histories containing genetic information.

In testimony before a congressional committee in 1998, a spokesperson for the Health Insurance Association of America stated that a survey of association members found none required genetic testing or solicited information regarding genetic testing as part of the application process (7). Authors of a recent study of genetic discrimination in health insurance concluded that a person with a serious genetic condition who is presymptomatic currently faces little or no difficulty in obtaining health insurance (8). Further over 75 percent of Americans obtain health insurance through their employers or the government and would not be subject to individual medical underwriting (9).

By way of contrast, almost 75 percent of life insurance policies are individual policies (10). As a result the majority of Americans with life insurance coverage are subject to medical underwriting. An individual may be denied life insurance if a family member suffers from a heritable disorder associated with premature death. For example, the practice among life insurers has been to decline to write individual policies for children of people with Huntington's disease until they are over 50 years old (11). Underwriting standards for individual policies of disability-income insurance may be even stricter. A number of researchers have surveyed currently healthy people with known genetic predispositions to disease or family members affected by genetic disorders. These researchers consistently find that a number of respondents report personal knowledge of instances of genetic discrimination in insurance and employment, although the magnitude of the problem is difficult to establish from these kinds of surveys (12).

Investigative reports and lawsuits are another source of information on genetic discrimination. A *New York Times* investigative report on genetic testing in the workplace

in 1980 found that DuPont de Nemours & Co. tested black job applicants for sickle cell trait. DuPont also tested job applicants for two enzyme deficiencies correlated with ethnicity. The purpose, according to the company's medical director, was to determine whether these tests would be of value in protecting the health of susceptible employees. (Another employer, Dow Chemical Company, engaged in genetic monitoring to detect any changes in chromosomal structure that might be attributable to workplace exposures.) Many years later, Lawrence Berkeley Laboratory, one of the national laboratories involved in the Human Genome Project, was sued for testing clerical and administrative employees for sickle cell trait, allegedly without employee consent. In each of these cases, it was unclear how the genetic information was used in decision making. DuPont apparently reassigned a small number of employees based on results of one of the enzyme tests (13).

Although the evidence concerning the actual extent of genetic discrimination is sparse, there is overwhelming evidence that people fear genetic discrimination. Nearly two-thirds of respondents in a 1997 survey reported that they would not undergo genetic testing if employers and health insurers would have access to the results. A 1995 survey found that over 85 percent of respondents were very or somewhat concerned about access to and use of genetic information by employers and insurers (12).

ADA: OVERVIEW

The ADA represents a blending of civil rights law and disability law. Key provisions were influenced by Title VII of the Civil Rights Act of 1964 and by the Rehabilitation Act of 1973 and its implementing regulations. From civil rights law the ADA derives its broad ambition of emancipating people with disabilities from a history of discrimination. From disability law it derives its demand for accommodation rather than simple equality, its mandate of community integration to combat isolation and segregation, and its emphasis on individualized or case-by-case decision making, taking account of the reasonableness of any accommodations requested and the burdens imposed on public and private actors. In addition the ADA reflects the belief that the denial of opportunity translates into dependency and nonproductivity, giving rise to substantial social costs.

The ADA was signed into law on July 26, 1990; most provisions became effective on or before July 26, 1992. Its structure is fairly neat. The law begins with a recital of findings and purposes and a number of general definitions, including a definition of the key term "disability." Each of the first three titles addresses a particular arena in which discrimination may occur. Title I governs employment. It applies to employers with 15 or more employees, excluding the United States and certain private clubs. Title II governs public services and applies to state and local governments and specified transportation agencies. Title III governs public accommodations and services and applies to all private entities with operations affecting interstate commerce. Each of these titles contains a prohibition of discrimination — with some variation in phrasing — and an enforcement provision. A section labeled "miscellaneous provisions" offers guidance on interpretation of the statute generally, and Title IV concerns telecommunications.

The U.S. government is subject to the antidiscrimination mandates of Section 501 of the Rehabilitation Act (14). The Rehabilitation Act also applies to federal government contractors (Section 503) and any entity receiving federal financial assistance (Section 504). Differences between the ADA and the Rehabilitation Act include the language in the prohibitions on discrimination. The Rehabilitation Act prohibits discrimination "solely" by reason of a person's disability (15). Titles I through III of ADA use "because of" or "on the basis of" disability, suggesting that the disability need not be the only factor motivating the adverse treatment (16). Enforcement is another area of difference. The Equal Employment Opportunity Commission (EEOC) is charged with issuing regulations under Title I of ADA and enforcing its provisions, and the Department of Justice is responsible for Titles II and III of ADA. The Rehabilitation Act does not concentrate authority in this manner. For example, the Department of Health and Human Services (DHHS) issues implementing regulations governing its grantees and enforces the law as applied to its own activities and those of its grantees through its Office for Civil Rights. The remedies available under the two statutes also differ. For example, the courts have established that money damages may be awarded under the Rehabilitation Act, whereas this remedy is sometimes unavailable under ADA.

The sections of ADA that are most relevant to the area of genetic discrimination are the definition of disability, the provisions in Titles I and III affecting employment and insurance, and the miscellaneous provisions that address the relationship of ADA to other laws and to insurance. While there are similarities, Titles I, II, and III are not perfectly symmetrical. In particular, a provision of Title I that regulates the collection of medical information by employers has no equivalent elsewhere in ADA. This important prophylactic provision will be discussed first, before consideration of whether and how the ADA might affect genetic discrimination in employment and other areas.

THRESHOLD QUESTION: IS A GENETIC CONDITION A "DISABILITY"?

Statutory Language

The definition of disability is important because the antidiscrimination provisions of ADA protect individuals with disabilities from discrimination based on disability. Under ADA, disability can be established in one of three ways. First, an individual can show that he or she has "a physical or mental impairment that substantially limits one or more of the major life activities of such individual." Second, an individual can show that he or she has "a record of such an impairment." Third and finally, an individual can show that he or she is "being regarded as having such an impairment" (17). Although other provisions of the statute categorically exclude certain conditions from the definition of disability (e.g., transvestitism, pedophilia,

compulsive gambling), the determination of whether a particular condition satisfies one of the three prongs of the definition of disability is generally made on a case-by-case basis.

Under the first prong of the definition, an affected individual might argue that a genetic condition is a physical or mental impairment that presently substantially limits the major life activity of reproduction, or will in the future substantially limit one or more major life activities of the individual. Under prong three, an affected individual might argue that he or she is being regarded as having a physical or mental impairment that presently substantially limits one or more major life activities, or that the anticipated future impairment, whether certain or merely more likely than for the average person, is being imputed to the present as evidenced by the discriminatory conduct of a third party. The strength of the argument will likely depend on the nature of the condition. The adjective "genetic" alone is fairly uninformative for ADA purposes; generally, ADA is concerned with function rather than causation. Commentators have identified at least seven categories of genetic conditions that may merit separate analysis: (*1*) already-expressed severe genetic conditions, such as symptomatic Huntington's disease, (*2*) already-expressed minor genetic conditions, such as polydactyly expressed in an extra finger or toe, (*3*) unexpressed late-onset genetic conditions, such as presymptomatic Huntington's disease detected through genetic testing, (*4*) genetic mutations associated with increased risk of disease (predispositions), such as BRCA1 or BRCA2 mutations detected through genetic testing, (*5*) unaffected carriers of recessive and X-linked disorders, such as carrier-status for cystic fibrosis, (*6*) genetic conditions that are cured or kept under control through treatment, such as phenylketonuria controlled through diet, and (*7*) conditions with a genetic basis that do not limit major life activities but are stigmatized or misunderstood, such as Down syndrome or Tourette syndrome (18). Category 1 conditions should satisfy the first prong of the definition of disability. Category 2 conditions would appear to fall outside the definition of disability (unless they are stigmatized or misunderstood). For the other categories, the outcome is uncertain, although the legislative history and the opinions of administrative agencies and the courts can be mined for insight.

Legislative History and Agency Interpretations

The legislative history of the ADA concerning genetic conditions is scanty at best. On the day the House of Representatives voted on the final conference report, three congressmen entered in the record statements that the law would protect "carriers of a disease-associated gene" from employment discrimination based on speculation about future illness or increased health care costs for carriers or their dependents (18). There is no record of debate on this point. To the extent the issue was thought of at all, then, the cases that came readily to mind for the few genetically minded legislators were autosomal recessive conditions such as sickle cell anemia. This is not surprising, since presymptomatic predispositional testing for diseases such as breast cancer and colon cancer has only recently become widely available.

Reliance on agency interpretations is complicated by the fact that the introductory sections of ADA, unlike Titles I through IV, contain no delegation of authority to a particular agency. EEOC, which has charge of Title I, has produced several documents that elaborate on the definition of disability. EEOC's Title I regulations attempt to clarify certain aspects of the definition of disability, although they do not specifically mention genetic conditions. According to the Title I regulations, a "physical or mental impairment" includes "any physiological disorder, or condition, cosmetic disfigurement, or anatomical loss" affecting at least one of the major body systems. Some examples of major life activities are given, such as caring for oneself, walking, and working. To "substantially limit" is to significantly restrict as to condition, manner, or duration of performance relative to the performance of the average person. Factors to be considered include the nature and severity of the impairment, its duration or expected duration, and "the permanent or long term impact, or the expected permanent or long term impact of or resulting from the impairment" (19). The Title I regulations also present several possible variants of "regarded as" disability; the unifying element is the focus on what the third party's treatment of the individual suggests, rather than on the physical or mental state of the individual. The Title III regulations issued by the Department of Justice are similar to the Title I regulations on these points (20).

Interpretive guidelines receive considerably less deference from the courts than regulations but may still carry some weight. EEOC's interpretive guidance for Title I, published as an appendix to the regulations, affirms the importance of case-by-case determinations. However, it contains some rather unnuanced assertions. It states that the definition of impairment does not include "characteristic predisposition to illness or disease" (21). This suggests that regardless of contextual factors, genetic predispositions to cancer or heart disease are not disabilities protected under ADA — unless the "regarded as" prong of the definition fits the case. On the other hand, EEOC makes HIV infection an example of an impairment that is inherently substantially limiting. Hence, to the extent that a genetic mutation can be analogized to HIV infection, this language suggests a strong case can be made for recognizing the mutation not only as an impairment but also as a disability under the first prong of the ADA definition.

EEOC has also issued a compliance manual for Title I. On March 15, 1995, an amended manual was released that included the following language concerning "regarded as" disability: "This part of the definition of 'disability' applies to individuals who are subjected to discrimination on the basis of genetic information relating to illness, disease, or other disorders. Covered entities that discriminate against individuals on the basis of such genetic information are regarding the individuals as having impairments that substantially limit a major life activity" (22). In the compliance manual, EEOC gives the example of an asymptomatic individual with a genetic

mutation conferring an increased risk of colon cancer; an employer discovers this information after making a conditional offer of employment and withdraws the offer due to concerns about attendance, productivity, and insurance costs. The example suggests that where action is taken on the basis of present fears, the definition of disability is satisfied, even if the fears are about future performance or future costs and even if the fears are not, strictly speaking, unfounded. Although the emphasis in EEOC's interpretation of "regarded as" disability is on myths, stereotypes, and misperceptions, EEOC states that the individual does not have to demonstrate that the employer's perception is wrong, for example, that health care costs will not increase if persons are hired who are at elevated risk of serious illness. (On the other hand, a finding of disability under ADA will not necessarily lead to a finding of liability. As discussed below, a prima facie case must include a showing that discrimination occurred because of or on the basis of the disability. Establishing a violation may be difficult, given that employers are unlikely to document that decisions are being made on the basis of genetic information.) The Department of Justice has not addressed genetic conditions in its interpretive guidance for Title III.

Judicial Opinions

No published judicial opinion addresses whether an individual with a genetic mutation associated with disease, but not yet expressed in symptoms, has a disability under ADA. A number of cases have raised somewhat similar issues. In *Bragdon v. Abbott*, the U.S. Supreme Court held that HIV infection, even in its early stages, is a disability under the first prong of the ADA definition (23). It is important to understand the court's reasoning, since an unexpressed genetic condition may or may not share the characteristics the court found significant in *Bragdon*. First, the court addressed whether HIV infection is an impairment. The court found that given the immediacy of the damage to the hemic and lymphatic systems, the predictable course of the disease, and its severity, an impairment exists from the moment of infection. Next the court concluded that as to the plaintiff reproduction was a major life activity. The court further concluded that the risk of infecting a partner and the risk of infecting a child could substantially limit this activity. Even assuming the risk of perinatal transmission could be lowered from 25 to 8 percent using antiretroviral therapies, the opinion stated that it is not possible to say as a matter of law "that an 8 percent risk of transmitting a dread and fatal disease to one's child does not represent a substantial limitation on reproduction."

Huntington's disease and other similar late-onset genetic conditions would appear to meet the *Bragdon* criteria of predictability and severity. Assuming some damage to a body system could be established prior to full expression, they would likely qualify as impairments from the moment of transmission. The case for genetic mutations associated with increased risk of disease is considerably weaker under the *Bragdon* criteria, since the element of predictability is missing; the same would be true for the category of unaffected carriers. (There is some irony here. Many people are struck by the unfairness where a third-party treats a possibility of disease as if it were a certainty as a risk avoidance measure, but the case for protection under ADA appears stronger where the question is not whether but when a disease will develop.) Genetic conditions would pose risks of transmission to a child analogous to the risk of infection associated with HIV, although the risk to a partner would be absent. For monogenic genetic disorders, the risk of transmission will generally be 25 or 50 percent. Factors affecting the reproductive options of particular plaintiffs, such as the availability of preimplantation genetic diagnosis, would also appear relevant under the Supreme Court's framework for analysis.

The concurring and dissenting opinions in *Bragdon* are of interest as well. Justice Ginsburg, concurring, stated that "[n]o rational legislator ... would require nondiscrimination once symptoms become visible but permit discrimination when the disease, though present, is not yet visible." This reasoning lends further support to a distinction, in the assessment of impairment, between those genetic mutations that inevitably give rise to disease and those that simply increase the risk of disease. Writing for the dissenters, Chief Justice Rehnquist stated that taken to its extreme the logic of *Bragdon* would "render every individual with a genetic marker for some debilitating disease 'disabled' here and now because of some possible future effects." Justice Rehnquist meant this as a warning of a peril to be avoided, but the language could be used by those who favor just such an extension.

In *Sutton v. United Air Lines*, the Supreme Court returned to the definition of disability, focusing on the substantial limitation requirement (24). The case involved two women who suffered from severe myopia but had 20/20 vision with corrective lenses. The court held that what matters for purposes of determining disability is an individual's present state, which includes mitigating measures such as corrective lenses; being "potentially or hypothetically" substantially limited does not suffice. (The court was influenced by a congressional finding, in the introductory provisions of ADA, that 43 million Americans had one or more physical or mental disabilities. The court found this number hard to reconcile with a broad interpretation of disability.) While the holding in *Sutton* would not change the result in *Bragdon*, or an analogous case in which the potential for transmission of a genetic mutation would substantially limit current reproductive options, it does suggest that any argument that a mutation qualifies as a disability under the first prong of the definition due to its anticipated effects will fail. Certainly those with genetic conditions that are cured or kept under control through treatment will have a hard time establishing disability, unless they can show that the side effects of treatment are themselves disabling, or satisfy one of the other prongs of the definition.

Unfortunately for plaintiffs, *Sutton* also puts up a barrier to establishing "regarded as" disability, by suggesting that concerns about an impairment that are sufficient to prompt negative employment action may not be sufficient to establish that the employer is regarding the individual as disabled. Cases decided before *Sutton* had

interpreted the definition of disability to encompass a third party's perception that disability was likely in the future, if that perception influenced present action. In *Doukas v. Metropolitan Life Insurance Company*, a federal district court noted that limiting ADA to perception of present disability would violate congressional intent and "allow an employer to refuse to hire an epileptic as long as the job applicant was not having a seizure at the time" (25). The court in *Winslow v. IDS Life Insurance Co.* found this reasoning persuasive (26). These cases, which concerned mental illness, and analogous cases involving genetic predisposition to disease, might be distinguished from *Sutton* by the unavailability of mitigating measures and the severity of the potential impairment. *Sutton* was, after all, a case about mitigating measures, despite language dismissive of probabilistic calculations and fears about the future as elements in the construction of disability. In *Cook v. State of Rhode Island Dept. of Mental Health*, a case decided under the Rehabilitation Act, the First Circuit Court of Appeals found that an employer's fears about risks associated with the plaintiff's morbid obesity were sufficient to establish perceived disability (27).

Is it good policy to adopt a generous interpretation of the ADA definition of disability and so extend ADA protections to unaffected carriers of recessive and X-linked disorders and individuals with unexpressed late-onset genetic conditions or genetic predispositions to disease? The answer to this question would appear to rest on a careful analysis of the fit between the purposes of ADA and the experience of persons falling within the particular category under consideration. Unaffected carriers of sickle cell trait can point to a history of isolation and segregation. Individuals with a genetic predisposition to cancer can point out that when employers turn them away, their contributions as productive members of society are diminished, perhaps unnecessarily and certainly prematurely. It is worth noting that state antidiscrimination laws may contain definitions of disability which are broader than the ADA's. For example, New York's highest state court has interpreted the New York State Human Rights Law to include "diagnosable medical anomalies which impair bodily integrity and thus may lead to more serious conditions in the future" (28).

COLLECTION OF INFORMATION BY EMPLOYERS

Title I of the ADA regulates medical examinations and inquiries conducted by employers (29). What is permissible varies according to the stage in the hiring process. To make sense of ADA, one needs to view hiring in terms of three stages: a pre-employment or interviewing stage prior to an offer of employment, a pre-placement or entrance examination stage after an offer of employment has been made but before commencement of employment duties, and a postemployment stage initiated with employment duties. The only acceptable *pre-employment* inquiries concern the ability of an applicant to perform job-related functions. Examinations and inquiries are generally prohibited *postemployment*, unless they can be shown to be "job-related and consistent with business necessity." However, two kinds of information-gathering activities relating to existing employees are expressly permitted: (*1*) voluntary medical examinations, including voluntary medical histories, as part of an employee health program, and (*2*) inquiries into the ability of an employee to perform job-related functions.

Employers have the most freedom at the *pre-placement* stage of employment. Title I states that after an offer of employment has been made, but prior to the commencement of employment duties, an employer may require a medical examination (which may include a review of medical records) and may condition the offer of employment on the results. The two limitations on employer discretion in this area are (*1*) all entering employees must be subjected to examination regardless of disability, and (*2*) the medical information obtained in this way must be collected and maintained on separate forms and in separate files, must be treated as confidential, and can be used only as permitted under Title I. Title I permits release of information to supervisors and managers where it concerns necessary work restrictions and accommodations, to first-aid and safety personnel when appropriate if emergency treatment may be required, and to government officials conducting compliance investigations. The same rules concerning separate forms and files, confidentiality, and use, apply to information obtained through examinations and inquiries made of existing employees.

The regulations issued by EEOC explicitly state that employment entrance examinations need not be job-related and consistent with business necessity (30). However, if an employer withdraws an offer of employment based on the results of an examination, the criteria used must not be of a kind to screen out or tend to screen out individuals with disabilities, or must be job-related and consistent with business necessity. This restriction on employer discretion may be hard to enforce, since job applicants who have received conditional offers of employment will often have a difficult time detecting illegal uses of information. An employer is generally not required to share the employer's reasons for withdrawing an offer of employment with the affected individual, and ADA does not alter this state of affairs (18). Some state genetic privacy laws require specific consent for genetic testing and disclosure of results, but absent such legislation, an individual may be completely in the dark concerning the nature or results of any tests conducted or information reviewed as part of an entrance examination.

Once in court, job applicants or employees face several hurdles. They may be met with the argument that only individuals who meet the statutory definition of disability are protected from inquiries and examinations. (As discussed at considerable length above, this test may be difficult to satisfy.) Federal appeals courts in the Eighth, Ninth, and Tenth Circuits (covering the western states and much of the midwest) have ruled that a plaintiff need not be disabled in order to state a claim for the unauthorized gathering or disclosure of confidential information by an employer (31). Plaintiffs alleging a violation of ADA's confidentiality protections may have difficulty showing that the violation resulted in some kind of tangible injury. Further ADA's confidentiality

protections only apply to information collected through pre-placement medical examinations and the kinds of medical examinations and inquiries authorized under the ADA for existing employees. This leaves out medical information in benefit records, for example, medical information contained in benefit request forms. In *Yoder v. Ingersoll-Rand Company*, a federal district court ruled that the confidentiality provisions of ADA did not apply to a physician's statement confirming a diagnosis of HIV/AIDS in a disability benefit request form (32). The court rejected an argument for broader protection based on the general purposes of ADA. Medical information obtained before the effective date of ADA will also fall outside its protections (33). Finally, ADA does not prohibit employers from using general release forms, or soliciting consent to a broad battery of tests, at least at the conditional offer (pre-placement) and postemployment stages. Employers may compile extensive information in connection with voluntary wellness and employee assistance programs (34).

The Lawrence Berkeley Laboratory case, mentioned in the introduction, illustrates some of the difficulties associated with pursuing a remedy for unauthorized genetic testing. The employees in that case sued their employer under Title I of ADA and under other state and federal laws. The employees contended that testing for sickle cell trait and other sensitive medical conditions, allegedly without their knowledge or authorization, violated ADA because the testing was neither job related nor consistent with business necessity. They also advanced claims based on violations of privacy rights under federal and state constitutions. Finally, they argued that in singling out black employees for sickle cell testing (and female employees for pregnancy testing), the defendants violated Title VII of the Civil Rights Act. Title VII prohibits discrimination in employment based on race, color, religion, sex, or national origin. The employees did not allege that any employment-related action was taken on the basis of their test results or that their tests results were disclosed to third parties.

In *Norman-Bloodsaw v. Lawrence Berkeley Laboratory*, the Ninth Circuit Court of Appeals concluded that there is no remedy under ADA for unauthorized testing or testing lacking a job- or business-related justification at the pre-placement stage of employment (35). The court suggested that the only viable claim given the facts would concern a failure to properly maintain medical records according to ADA requirements but that something more than a general allegation of inadequate safeguards would be necessary for that purpose. The court found that the plaintiffs were entitled to a trial on their other claims.

It is important to note that ADA does not preempt state laws that provide greater or equal protections, and plaintiffs may have greater success in pursuing claims for breaches of confidentiality or unauthorized testing or inappropriate inquiries under state law. Title I of ADA must also be considered together with other federal laws affecting employment. For example, the Occupational Safety and Health Act (OSHA) requires medical monitoring of employees who may be exposed to hazardous chemicals. The implementing regulations require physical examinations before workers are assigned to certain sites, including a family history addressing genetic factors, but they do not require genetic testing (36). EEOC has stated that Title I does not halt the performance of such examinations, which might in any event be justified as job related and consistent with business necessity (37).

DISCRIMINATION IN EMPLOYMENT AND EMPLOYER-PROVIDED BENEFITS

Elements of Prima Facie Case and General Defenses

The general prohibition of discrimination in Title I is broadly stated to encompass all aspects of employment (38). So long as an individual with a disability is "qualified," that is, can perform all essential job functions, he or she is protected from discrimination because of or on the basis of the disability with respect to job application procedures, hiring, advancement, discharge, compensation, training, and other terms, conditions, and privileges of employment. Limiting, segregating, or classifying a job applicant or employee in a way that adversely affects his or her employment opportunities or status, and failing to make reasonable accommodations (i.e., accommodations that could be accomplished without undue hardship to the employer), are instances of discrimination, as are failures to abide by the rules concerning medical examinations and inquiries. Individuals with dependents with disabilities are also protected, because discrimination is defined to include the denial of equal jobs or benefits to a qualified individual because of the known disability of an individual with whom the qualified individual is known to have a relationship or association.

Even if a plaintiff makes a prima facie case, that is, establishes the elements of disability and disability-based discrimination, the employer can avoid liability by showing that a particular use of qualification standards, tests, or selection criteria was job-related and consistent with business necessity, and that no reasonable accommodation was possible under the circumstances. Qualification standards may include a requirement that an individual not pose a "direct threat" to the health or safety of other individuals. EEOC's Title I regulations specify that a direct threat is "a significant risk of substantial harm" (to self or others) that cannot be eliminated or reduced by reasonable accommodation (39). The assessment of risk must be based on "the most current medical knowledge and/or on the best available objective evidence." The likelihood and imminence of the potential harm are among the factors to be considered. This fairly stringent standard should preclude employers from making employment or job assignment decisions based on genetic susceptibilities or predispositions to disease, unless the science is good and tests of significance and substantiality are met. ADA does not prevent employers from seeking to understand and reduce hazards in the work environment. Nor does it prohibit the offer of accommodation to an employee with a condition that greatly increases the likelihood that the employee will suffer harm from a particular activity, or become incapacitated in a way that puts others at risk, assuming information about the condition is acquired by legal means. The fall-back defense of "undue hardship"

requires a showing of "significant difficulty or expense," considering the nature and net cost of the accommodation, the financial resources of the facility and the covered entity, the impact of the accommodation on operations, and so on.

Employer-Provided Insurance and the Insurance Safe Harbor

While an employer cannot refuse to hire, or fire, a qualified individual with a disability due to fears about increased health care costs, or exclude the individual from benefit programs available to other employees, the employer is given considerable latitude in the area of insurance. The key provision in this area is what has become known as ADA's "insurance safe harbor" (40). The relevant subsection states that Titles I through IV should not be construed to prohibit or restrict (*1*) an insurer or other entity that administers benefit plans from underwriting risks, classifying risks, or administering such risks in a manner based on or not inconsistent with state law; (*2*) a person or organization from establishing, sponsoring, observing or administering the terms of a bona fide benefit plan based on underwriting risks, classifying risks, or administering such risks in a manner based on or not inconsistent with state law; or (*3*) a person or organization from establishing, sponsoring, observing or administering the terms of a bona fide benefit plan that is not subject to state laws that regulate insurance. (The Employee Retirement Income Security Act of 1974, known as ERISA, prevents the application of state insurance laws to employers' self-funded health plans.) However, ADA states that this provision cannot be used as a "subterfuge" to evade the purposes of Titles I and III.

EEOC's interpretive guidance on Title I addresses medical underwriting and preexisting condition clauses and benefit design issues. The guidance document states that medical underwriting and preexisting condition clauses included in health insurance policies offered by employers are not affected by ADA, except to the extent that practices are found to be inconsistent with applicable state law (21). In the area of health insurance, the Health Insurance Portability and Accountability Act of 1996 (HIPAA) may offer more extensive protections. (HIPAA focuses on group policies, but those with individual polices may benefit to a limited extent from provisions governing the transition from group to individual coverage and guaranteed renewability.) HIPAA *permits* issuers of group policies to impose limited preexisting condition exclusions *but only* if these relate to conditions for which medical advice, diagnosis, care, or treatment was recommended or received within the six-month period ending on the enrollment date. Genetic information cannot be treated as a condition in the absence of a diagnosis of the condition related to such information (41). HIPAA *prohibits* issuers of group policies from excluding an individual within the group from coverage on the basis of a health status-related factor relating to the individual or a dependent. The list of health status-related factors includes genetic information. HIPAA also prohibits variation in benefits, premiums, and contributions for similarly situated group members on the basis of these factors, but neither HIPAA nor the ADA requires that employers offer any insurance at all.

Employers can affect health care costs through benefit design as well as through medical underwriting and preexisting condition clauses. EEOC has concluded that ADA does not prohibit employers from placing limits on coverage for certain procedures or treatments (e.g., visit limits), even if these adversely affect individuals with disabilities, so long as the limits are applied equally to individuals with and without disabilities (21). EEOC offers more extensive comment on health insurance in its Interim Enforcement Guidance on Disability-Based Distinctions in Employer Provided Health Insurance (42), and in the Title I Technical Assistance Manual (37). The guidelines on benefit design would permit an employer to exclude all experimental drugs or procedures from coverage, so long as this restriction is applied evenhandedly to all insured individuals. It follows that employers would have no obligation to arrange for coverage of gene therapy and other interventions still in the research phase. Indeed, EEOC states that broad distinctions that apply to a range of dissimilar conditions and constrain individuals with and without disabilities are not distinctions based on disability. A term or provision is disability-based only if it singles out a particular disability or discrete group of disabilities or disability in general for inferior treatment. Cancers, muscular dystrophies, and kidney diseases are given as examples of discrete groups of disabilities. Genetic disorders, or inherited genetic disorders, would arguably constitute a discrete group of disabilities, meaning that it would not be permissible for an employer or plan administrator to single out interventions targeting genetic conditions for more limited coverage than other conditions. Picking and choosing among genetic conditions might also run afoul of the ADA. In *Henderson v. Bodine Aluminum, Inc.*, a woman with breast cancer argued that an insurer's policy of paying for bone marrow transplants for some cancers, but not breast cancer, violated the ADA. The Eighth Circuit Court of Appeals ruled in her favor, stating that "if the evidence shows that a given treatment is non-experimental ... and the plan provides the treatment for other conditions directly comparable to the one at issue, the denial of that treatment arguably violates the ADA" (43).

Courts are still struggling with the "subterfuge" language in ADA. EEOC's Interim Enforcement Guidance states that this language refers to "disability-based disparate treatment that is not justified by the risks or costs associated with the disability" (42). If an employee can make a prima facie case of discrimination, then EEOC puts the burden on the employer to produce evidence that "the disparate treatment is justified by legitimate actuarial data, or by actual or reasonably anticipated experience, and that conditions with comparable actuarial data and/or experience are treated in the same fashion," or to offer some other acceptable justification for the practice (e.g., that there is no other way to ensure the solvency of the plan or prevent a drastic increase in premiums). This suggests that ADA can be used to challenge underwriting decisions that are based on outdated or inaccurate information about genetics in general or specific genetic disorders, or on myths, fears, or stereotypes that have no basis in science. However,

the phrase "reasonably anticipated experience," common in state insurance laws, does appear to create some room for inference from available data. Also a few courts have adopted a restrictive interpretation of subterfuge, holding that a benefit plan cannot be a subterfuge unless the employer intended by virtue of the plan to discriminate in a non-fringe-benefit-related aspect of the employment relation (e.g., the employer set out to design a benefit plan that would discourage persons with disabilities from applying for jobs) (44).

DISCRIMINATION BY INSURERS

Threshold Question: Scope of Title III

As noted above, Title III of the ADA regulates public accommodations. Rather than a true definition of the term, the statute offers a laundry list of private entities that are covered if their operations affect interstate or foreign commerce. These include an "insurance office, professional office of a health care provider, hospital, or other service establishment" (45). Because insurance is mentioned, individuals who have experienced discrimination in insurance have turned to Title III for a remedy. Resort to Title III is most common where insurance is not provided through an employer (or relief under Title I is unavailable for some other reason). Under Title III, as under Title I, the individual seeking a remedy for discrimination must first establish that he or she is an individual with a disability within the meaning of ADA.

A major point of controversy at present is whether Title III extends beyond access to physical structures to address access to services such as insurance policies. The courts are divided. In its Title III Technical Assistance Manual, the Department of Justice assumes rather than argues for the broad view (46). The evidence offered in favor of the restrictive view includes the many references to "offices" in the list that defines public accommodation and the insurance safe harbor. The leading case for the restrictive view is *Parker v. Metropolitan Life Ins. Co.* (47). In *Parker*, an individual sued her employer and her insurer claiming that a shorter benefit period for mental disability than for physical disability under an employer-provided disability policy violated ADA. The Sixth Circuit Court of Appeals ruled that a public accommodation is a physical place and a disability policy not obtained in an office transaction is *not* a service or good offered by a place of public accommodation. Although it was unnecessary to the decision in the case, the court also concluded that Title III does not extend to the contents (terms and conditions) of insurance policies. *Parker* has been followed by the Third and Ninth Circuit Courts of Appeals, and the Seventh Circuit Court of Appeals has also taken the position that Title III does not apply to the contents of insurance policies (48).

The First Circuit Court of Appeals has presented the case for the broad view. In *Carparts Distribution Center v. Automotive Wholesaler's Ass'n*, the First Circuit reasoned that by including "travel service" in the list of examples of public accommodations, Congress signaled that commercial enterprises not requiring physical entry could be public accommodations (49). The court noted that neither Title III nor the implementing regulations makes any mention of physical boundaries or physical access. Further the court believed it would be irrational, and inconsistent with the purposes of ADA, to conclude that persons who enter an office are protected by ADA, but persons who purchase services over the telephone or by mail are not. As to whether ADA requires scrutiny of the contents of insurance policies, the court found that in some cases, meaningful access to a service requires a change in substance. The reasoning of *Carparts* has been adopted by the Second Circuit Court of Appeals (50).

Other Title III Issues

Even if Title III is found to apply to insurance policies, plaintiffs may have a difficult time prevailing on a claim. The antidiscrimination language in Title III is broad: "No individual shall be discriminated against on the basis of disability in the full and equal enjoyment of the goods, services, facilities, privileges, advantages, or accommodations of any place of public accommodation by any person who owns, leases (or leases to), or operates a place of public accommodation" (51). Administrative methods that have the effect of discriminating on the basis of disability are expressly included. And Title III, like Title I, addresses discrimination based on association with an individual with a disability. However, if an insurer can establish that the actions taken were in accordance with sound actuarial principles, reasonably anticipated experience, or bona fide risk classification, they will likely be sheltered by the insurance safe harbor (discussed above). Construing the Title III antidiscrimination provisions in light of the insurance safe harbor, the Department of Justice has concluded that "a public accommodation may offer a plan that limits certain kinds of coverage based on classification of risk, but may not refuse to insure, or refuse to continue to insure, or limit the amount, extent, or kind of coverage available to an individual, or charge a different rate for the same coverage solely because of a physical or mental impairment, except where the refusal, limitation, or rate differential is based on sound actuarial principles or is related to actual or reasonably anticipated experience" (46). In essence, the Department of Justice and the EEOC have chosen the same middle course.

As in the employment context, it may be difficult for plaintiffs to make a prima facie case because they lack access to key information. The Title III Technical Assistance Manual states that ADA does not require an insurer to provide a copy of the actuarial data on which its actions were based at the request of the applicant (46). Further several courts, including the Third Circuit Court of Appeals, have suggested that allegations of subterfuge do not compel insurers to come forward with evidence to justify their coverage or underwriting decisions (48).

Still a number of plaintiffs have prevailed in lawsuits against insurers brought under Title III. For example, in *Chabner v. United of Omaha Life Insurance Co.*, an individual with fascioscapulohumeral muscular dystropy sued a life insurer for issuing him a life insurance policy at a premium that was considerably higher than the standard

premium (52). As a threshold matter, the court found that Title III applies to insurance underwriting practices. Next the court held that where it is undisputed that an individual was treated differently based solely on his disability, the insurer has the burden of coming forward with evidence that the differential treatment was based on sound actuarial principles or actual and reasonably anticipated experience. The court added that even though the legal standard refers to "anticipated experience," insurers may not engage in speculation; that is to say, underwriting must always have a basis in actuarial data. The court found that in this case the defendant had failed to satisfy its evidentiary burden. As a result the court entered summary judgment in favor of the plaintiff. A recent decision from the Ninth Circuit Court of Appeals may affect the continued validity of the legal analysis in *Chabner* (48), but the facts are representative of the type of case that may become increasingly common as genetic disorders are subject to medical underwriting.

DISCRIMINATION IN PUBLIC PROGRAMS

Although the focus of discussion has been on employment and private insurance, the potential exists for discrimination in many public sector programs. In the ADA framework, public programs fall under Title II, governing agencies of state and local government. Although the bulk of Title II is devoted to public transportation, this title contains a general prohibition of discrimination by reason of disability affecting participation in or receipt of benefits of services, programs, or activities (53). Professional licensing appears to be one area where new developments in genetic technology could give rise to discrimination. Some have noted that there is also considerable potential for genetic discrimination in the public schools. (Private schools would be public accommodations covered under Title III.) It is conceivable that genetic information will someday be used to make modifications to programs to better meet the needs of children with genetic conditions. Genetic information may also be used to segregate children, where an administrator or teacher is persuaded that a certain mutation is associated with behavioral and disciplinary problems, or to attach labels to children that may become self-fulfilling prophecies (54). In these circumstances Title II of ADA could be used to challenge segregation and to combat other damaging practices based on stereotypes or hypothetical risks rather than individualized assessment. The Rehabilitation Act, which preceded ADA, remains available as an additional source of protection against discrimination by entities receiving federal financial assistance.

CONCLUSION

In sum, ADA exhibits the usual limitations of legislation: failure to adequately address situations remote from the experience of its framers, and resort to ambiguous language to achieve consensus. Few of the lawmakers who debated ADA reflected on the significance of developments in the field of genetics for civil rights and disability law, and the text of ADA contains no mention of genetic conditions or genetic testing. Accordingly it is uncertain whether genetic conditions that are known, but presently asymptomatic, are covered under the statute. The extent to which the new antidiscrimination law should change the rules for insurance companies was certainly debated, but the resolution of that debate allowed for a range of interpretations. Indeed, the language of the statute is sufficiently ambiguous to send courts in different directions on the question of whether ADA imposes any constraints on the substance of insurance policies, especially those purchased by individuals. At present, then, there is considerable uncertainty concerning the relevance of ADA to genetic discrimination. ADA is certainly not a comprehensive response to the problem of genetic discrimination. Nonetheless, unless and until comprehensive legislation is enacted at the federal level, ADA will have to serve as proxy for a more complete and considered response, supplemented by the Rehabilitation Act and HIPAA and other federal and state laws. As genetic knowledge increases, and with it the potential for genetic discrimination, the courts will inevitably have to address some of the areas of uncertainty described above. In the not-to-distant future we should have, if not more justice, then at least more clarity.

OUTLINE

INTRODUCTION

Genetic testing is expanding at an accelerating rate (1–5). Genetic tests were first used to screen for or diagnose a hereditary disorder in a given individual. This early testing was based on the determination of abnormal protein products or metabolytes produced by the mutant genes, such as sickle hemoglobin in sickle cell anemia or phenylalanine in phenylketonuria. Subsequently this was expanded to include testing for carriers of mutations with potential expression in subsequent offspring by identification of sequences of deoxyribonucleic acid (DNA) representing the actual mutation, such as sickle cell and cystic fibrosis carrier screening. Most recently it now includes testing for genes which, based on other genetic and environmental interactions, predispose to a wide variety of disorders, such as breast/ovarian cancer (BRCA1 and 2), cardiovascular disease, schizophrenia, and obesity. Genetic tests now include tests for gene products, actual genes, that is, DNA sequences, and abnormalities of chromosomal number and morphology. The field of gene therapy and preventative genetic engineering is just beginning to develop effective interventions.

The broadening of the scope of genetic medicine has not yet been recognized by public policy makers in legislative bodies, public health agencies, and the courts. As a

consequence there is only a relatively limited body of law and regulation that addresses the many unresolved problems this new technology presents.

The legitimate interests of government include protecting the liberty, privacy, health and safety of its citizens, promoting the welfare of the community, and arbitrating disputes between competing values and interests in the society so as to obtain the greatest good for the greatest number with due consideration of minority rights and values. A great deal of interest has been generated and legislation enacted that addresses the issues of the use of genetic information in insurance, employment, and research (6–8). Much of the preoccupation with this issue is due to the unique market-based philosophy applied to health care delivery in the United States. Discriminatory use of genetic information to deny access to or increase the cost of insurance is a symptom of this broader problem, and its importance diminishes greatly in other developed nations where health care is not dependent on employment and is available as a universal social benefit. Discrimination has been discussed in the press and in professional journals for some time and will not be discussed in this article. Rather, we will try to address the neglected issue of ensuring equitable access to genetic services that meet a minimal standard of quality at reasonable cost. The issues of how best to use this new knowledge to alleviate the burden of genetic disorders on individuals and the society requires a response irrespective of the problems associated with discrimination.

PUBLIC HEALTH ROLE

The core functions of public health have been listed by the National Academy of Science Institute of Medicine as assessment, policy development, and assurance (9). Federal and state public health agencies have made only a small beginning in fulfilling these functions in genetic services.

ASSURANCE OF QUALITY GENETIC SERVICES

Licensure

Federal and state healthcare agencies are charged with the general mission of protection of public health, safety, and welfare. One of the major administrative tools used to ensure this general objective is achieved is regulation. This includes regulation of persons and facilities providing services, that is, governmental licensure. A license is an official governmental document that allows the holder to perform certain actions that are prohibited to the general public. It is therefore a restriction of personal liberty. Any legislator who proposes a law that restricts personal liberty needs to convince the legislature and the public that the restriction is necessary to protect the public from a greater harm than the restrictions would impose and that there is no other effective or less restrictive way to prevent the harm. Based on these basic considerations, is there a case for governmental licensure of genetic personnel such as doctoral-level geneticists in cytogenetics, genetic counselors, genetic laboratory technology, genetic nurse specialists, and genetic facilities such as laboratories?

There are different concepts of what evidence would be sufficient to demonstrate public harm. Some would espouse a proactive stance and would be satisfied with evidence that supports a reasonable probability of harm.

Others favor a reactive philosophy and want to "count the bodies," such as document-specific instances of real harm.

PUBLIC EDUCATION

If citizens can protect themselves, there is no need for governmental involvement. There is little reason to believe the public can protect it self. The National Academy of Sciences in 1975 concluded: "It is essential to begin the study of human biology, including genetics and probability, in primary school, continuing with a more health-related program in secondary school.... Sufficient knowledge of genetics, probability, and medicine leading to appropriate perceptions of susceptibility to the seriousness of genetic disease and of carrier status cannot be acquired as a consequence of incidental, accidental, or haphazard learning..." (10). This has been reinforced by the Presidential Commission, the Institute of Medicine, the National Science Foundation, and other public and private groups in the intervening years. However, studies continue to document the low level of scientific literacy in the United States. The public at large is not well informed about genetics and genetic disorders and needs to rely on the services of experts. Five out of six never heard of genetic engineering. Only one-third of college graduates can correctly describe deoxyribonucleic acid (DNA). Surveys of scientific literacy have validated this deficiency (11–16). Erroneous genetic information or misinterpretations can lead to decisions not to get pregnant, terminate a pregnancy, stigmatization, loss of self-esteem, marital or familial disruptions, inappropriate and risky interventions, and the like.

PRIMARY CARE

Can we rely on the usual sources of care to protect the public from unnecessary services while assuring access to appropriate, high-quality services? With respect to genetics, the high probability of harm resulting from services provided by persons without specific training and experience in genetics is documented in several studies of genetic knowledge and practice of nongeneticists, such as, primary care practitioners (17–22). The inclusion of modern human genetics in the training programs for physicians and nurses is a relatively recent event. The number of human chromosomes and their relationship to disorders such as Down syndrome was not known until 1959. Prenatal diagnosis was introduced in the early 1960s. Use of DNA based tests in clinical medicine only began in the late 1970s. There are a large number of practicing physicians who have had little or no genetics in their training. Even after medical schools began to introduce genetics, the hours were minimal and frequently

elective. Few questions on genetics are included on medical licensing or specialty board examinations. The result is a generally unsatisfactory understanding and application of clinical genetics in primary care. This is not a reflection on the dedication and concern of primary care physicians, who could not reasonably be expected to keep up with the explosion of genetic knowledge, but simply a factual description of the current situation.

The occurrence or high probability of occurrence of harm in the absence of access to qualified genetic personnel has been demonstrated and accepted by most knowledgeable professionals who have studied this area, but the questions remains, Is licensing the only or best solution to the problem? What are the alternatives? One alternative solution would be improved education of primary care providers. This is certainly necessary in any event and could contribute to improvement of services but does not appear to be practical or effective as the only response. Primary care physicians have limited time for continuing education and many areas of clinical practice other than genetics are competing for this limited time. In addition they have limited time with their patients. Studies indicate an office visit includes approximately 11 minutes of face-to-face contact with the physician. The average genetic counseling visit is approximately 50 minutes (23–25).

PROFESSIONAL CERTIFICATION

Another alternative is self-certification by professional societies (26). The first effort in certification of genetic counselors was the American Society of Human Genetics (ASHG) program which began in 1979. This was followed in 1980 by the recognition by the American Board of Medical Specialties of the American Board of Medical Genetics (ABMG) with the first certificates issued in 1981 under the auspices of ASHG. Certificates were issued to genetic counselors, doctoral-level geneticists, and physicians. The American College of Medical Genetics (ACMG) was established in 1992 and recognized as a component society by the American Medical Association (AMA). In 1993 the American Board of Genetic Counselors (ABGC) was established to continue the certification of genetic counselors. There are now 1006 medical genetic specialists, 150 Ph.D. medical geneticists, and 779 genetic counselors with board certification in the United States. While this process was a major contribution to the resolution of the problem, it is again not completely satisfactory. The medical specialty is still not listed in telephone directories nor recognized by the majority of third-party payers as one to be included in panels of specialists or listed in directories of providers. Utilization guidelines and reimbursement for services for these specialists are still being developed. Failure to authorize or reimburse for genetic counseling done by nonphysicians has limited the use of genetic counselors and Ph.D. geneticists. Furthermore, in most states, any physician can legally provide genetic services without special training or qualifications or specialty board recognition. This situation allows any physician, nurse, or counselor to be self-designated as a genetic specialist or subspecialist, which is misleading to the public.

FUNDING

Another alternative to prevent harm is the use of federal and state payment for services as a means to require the use of qualified staff in delivery of high quality genetic services. However, this is only effective for those services eligible for state payment and leaves the citizens who are not eligible unprotected. The reimbursement requirements of Medicaid or children with special health care needs are examples of this approach.

LICENSURE

As a result of this analysis, the only effective solution is to legally recognize the training and expertise of genetic professionals by licensure. There are additional arguments for licensure in terms of development of quality genetic services. Frequently quality genetic services require consideration of complex questions of risks, benefits, conditional interpretation, various interventions of varying effectiveness, and the like, in brief, information that would be beyond the reasonable expectation of the scope of primary care. If genetic personnel were licensed, the state could require the use of licensed or otherwise qualified personnel for complex genetic problems in order to maintain the quality of services. The existence of a license would allow genetic counselors as recognized professionals to have some say in governmental policy affecting their field of interest. Licensure would also promote the creation and funding of positions needed for expansion of new genetic services. In order to expand training programs, it is necessary to create a defined pool of positions for the graduates. Licensure would allow the public to specify and request referral to these professionals as recognized by the state.

SCOPE OF PERSONNEL LICENSURE

What kind of genetic personnel need licensure? Physician geneticists are licensed as physicians and only require better recognition and utilization of their specialty board certification. There are a group of doctoral geneticists trained in human clinical genetics who are certified by ABMG as Ph.D. medical geneticists. The laws of most states do not allow such persons to obtain a physician's and surgeon's license, and therefore prohibit their clinical utilization. For example, a cytogeneticist is prohibited from diagnosing chromosome anomalies as the practice of medicine. Provided their clinically related services are limited to their area of training and expertise, provision should be made to legally recognize them as practitioners by certification or licensure. Masters and doctoral level genetic counselors are an essential part of quality genetic services and need to have their practice made legal, including registration or licensure. In the laboratory area there are four subspecialist certificates issued by ABMG: clinical cytogeneticist, clinical biochemical geneticist, clinical molecular geneticist, and clinical biochemical molecular geneticist. The 1997 directory lists 425 clinical cytogeneticists, 137 clinical biochemical geneticists, 143 clinical

molecular geneticists, and 49 clinical biochemical molecular geneticists (27). These are doctoral level categories, and they require candidates to pass an examination in general medical genetics as a precondition to taking the specialty examination. Individuals in these classifications are intended to function as laboratory directors of genetic specialty laboratories. The actual bench-level performance of tests is the job of the laboratory technologist. The complex techniques used by these technologists are not a part of traditional laboratory technology training programs. Recognizing the need for special training and certification in the field of cytogenetics, five California cytogeneticists organized an Association of Cytogenetic Technologists (ACT) in 1975. In cooperation with the National Certifying Agency for Medical Laboratory Personnel (NCAMLP), a national technologist certification program was developed in cytogenetics, which issued its first certificates in 1981.

The field of molecular biology, namely DNA analysis, was largely research oriented until the early 1990s. The California Department of Health Services contacted ACT and NCAMLP and requested a certification process be established in molecular biology. As a result ACT expanded its area of interest and in 1996 changed its name to Association of Genetic Technologists (AGT). NCAMLP responded by establishing a certification program for Certified Laboratory Specialist in Molecular Biology with the first examination given in July 1997. There is no specialty certification for technologists in biochemical genetics at this time.

FACILITIES LICENSURE

Federal and State Licensing Responsibilities

The federal government has not assumed responsibility for licensure of personnel. The basic law regulating laboratory practices, the Clinical Laboratory Improvement Act of 1988 (CLIA), does provide for certain minimum educational and experience qualifications for laboratory directors, technical supervisors, and testing personnel and describes their responsibilities (28). The federal regulations first require a current license issued by the state in which the laboratory is located. The only specific reference to genetics is the area of cytogenetics where the technical supervisor must have four years of genetic training or experience, two of which must have been in cytogenetics. There is currently an advisory committee working on improving the coverage of genetic laboratory personnel. All laboratories must be in compliance with CLIA, including the genetic specialty laboratories. The federal regulations cover areas of staffing, patient test management, quality control, proficiency testing, inspections, and sanctions.

States generally have laws that require licenses for clinical laboratories and laboratory personnel. New York (1972) (29) and California (1995) (30) recognize genetics as a laboratory specialty area. New York defines the qualifications for laboratory director and makes the director responsible for using qualified technologists and maintaining quality control. Specific standards are detailed for cytogenetics (1972), and genetic testing (1990). Proficiency testing and site visits are required. California is currently implementing a similar program. However, in addition California requires licensure of genetic technologists.

LICENSURE CONSIDERATIONS

Public agencies and legislatures, in considering a proposed licensure program, need to collect information in a variety of areas before the full societal impact can be assessed. This includes the numbers of personnel and their professional representation; what segment of the public is served, what is the position of public advocacy groups, is there duplication or competition with existing licenses, what is the nature and severity of harm to be prevented? Are there alternatives? What will licensure cost? What will be the effect on supply? What is the limit on the scope of practice? Are knowledge and skills testable? Are there approved schools to provide training? What is the economic impact?

LEGISLATION AND REGULATIONS

With or without licensure, laws can be passed regulating the provision of genetic services. Legislation has been used in California to regulate prenatal serum screening (31). The state law permits the Department of Health Services to specify standards for vendors participating in the statewide birth defect screening program, which is called the Expanded AFP program. This program is based on the well-documented association of specific patterns of analytes (alpha feto-protein, human chorionic gonadotropin, and unconjugated estriol) with increased risk of birth defects (neural tube defects, abdominal wall defects, Down syndrome, and other chromosomal defects). The law also requires that all women seen before the twentieth week of gestation be provided information about the screening and be offered an opportunity to be screened by the program. If the woman elects to be tested, she signs an informed consent. Specimens are collected and transmitted to the laboratory. Specimens are analyzed in one of eight regional private laboratories under contract to the department. These laboratories use uniform methodology and are subject to daily quality control by the state. All data and laboratory results are communicated to a central computer in Berkeley. All persons who are judged to be high risk by the central computer algorithm are authorized, at no additional charge, to receive follow-up diagnostic services at one of 29 state-approved Prenatal Diagnostic Centers. The follow-up services include genetic counseling, ultrasound examination and, if necessary, amniocentesis, amniotic fluid analysis, and karyotyping. Any facility that meets state standards can be designated an approved vendor. The standards require that the prenatal diagnostic center be directed by a board-certified medical geneticist, that genetic counseling be provided by board-certified genetic counselors, that ultrasound examinations be performed by specially skilled and experienced ultrasonologists, and that amniocentesis, if indicated, be performed by experienced perinatologists/obstetricians. The state

collects a participation fee from third-party payers or from the participant, which covers all operating costs and is used to reimburse vendors. This public–private partnership design has succeeded in providing universal access to high-quality services.

TECHNOLOGY ASSESSMENT

In addition to prevention of adverse consequences of genetic disorders by promotion and regulation of personnel, the state is obligated to provide another kind of protection, namely protection from premature promotion of tests and substandard services that could adversely affect individual citizens or the community at large. This establishes the public health department as the primary technology assessment agency. Technology assessment really is a process of reviewing the scientific evidence and the information and opinions of experts to determine if a given technology should be applied in clinical practice and under what circumstances and conditions.

FEDERAL ROLE

Decisions on the appropriate implementation of any new genetic testing program are currently not centralized (32). There was an Office of Technology Assessment (OTA) established in 1972 to conduct assessments for the Congress. The mandate was broad, encompassing any technological problem, and OTA did publish some studies of heath technologies. OTA was abolished in 1995. In 1989 the Institute of Medicine published a monograph recommending a national technology assessment agency (33). The Congress established the Agency for Health Care Policy and Research (AHCPR) in 1989, but again, it has a broad area of responsibility and has not included many genetic technologies in its reviews. The National Institutes of Health (NIH) has established a mechanism called a consensus conference where a panel hears presentations from experts, reviews the literature, and publishes consensus statements on technologies. The federal Food and Drug Administration (FDA) has been proposed to play this role through their regulation of diagnostic kits and devices (34,35). While they could regulate clinical accuracy and utility, they do not have the authority to regulate the ancillary clinical setting in which the test is used.

STATE ROLE

Given the numbers of technologies being proposed or currently in use without rigorous analysis, all these efforts contribute useful information and should be encouraged. However, it is important to establish technology assessment capacity at the state level since the states play such a critical role in regulation and funding of health care. The legislature of the state of Maryland established a Maryland Commission of Hereditary Disorders in 1973, which reviews genetic tests, but this model has not been adopted by other states. There is a legitimate role for the state regulatory process using input from both experts and the public. The regulations can prohibit unvalidated testing, when the preponderance of evidence indicates that the public either individually or collectively could be harmed, except as part of a research project. The state can impose conditions on genetic testing by regulation when the evidence indicates such conditions are necessary. These conditions might include specialized informed consent, confidentiality, pre- and/or post-test counseling, protective measures, quality assurance requirements, record keeping requirements, availability of diagnostic and intervention resources, and so on. This approach could include use of state accredited or registered personnel who had training essential for the proposed testing program. Finally, once a technology is accepted by the experts and the public using the evidentiary process, the state has an obligation to promote equitable access. This could involve mandating that all public and private payment sources pay for any cost-effective technology, funding screening centers, and conducting public and professional education or outreach with the at-risk public. One example of the states' carrying out this function is the newborn screening for genetic disorders.

PRIVATE SECTOR

In addition to state regulatory practices, most insurance companies and managed care organizations have technology assessment groups. The criteria used by these private groups can be unduly influenced by cost considerations and it is not unusual to find a test accepted by one payer and regarded as experimental and not accepted by another.

PROBLEMS WITH LEGISLATION AND REGULATION

While laws and regulations have undoubtedly saved lives, prevented disease and disability, and increased the value of the goods and services, the potential for regulatory abuse and damage is all too apparent to the public. The arguments made in favor of an expanded activist role for public health in regulation of genetic services could be seriously undermined by failure to avoid the situations that have contributed to the current low esteem accorded the use of this governmental tool. The first error is what is referred to as "agency capture" where the special interest group affected by the regulations controls directly or indirectly the governmental regulators. Regulation should not be used to increase incomes of specialists through unnecessary restriction of services. Licensure laws can be used to exclude qualified providers in order to maintain incomes. Facility standards can be used to monopolize services and improve their economic outcomes. The public and the regulators should be aware of this tendency and should maintain an open public process that remains focused on the goal of assuring universal access to comprehensive high-quality, cost-effective services. While recognizing the contributions and qualifications of such professional groups as ACMG and the National Society of Genetic Counselors (NSGC), the state should remain open to including others, such as pathologists with subspecialty training in cytogenetics or molecular biology and nurses with subspecialty training in genetics

as qualified providers. Special certification of training in hereditary cancer counseling, sickle cell counseling, and cystic fibrosis genetics can be used to create a pool of qualified personnel to implement specific screening programs. Finally, involvement in policy development of the increasingly active groups of individuals and families affected by genetic disorders and the general public can exert a corrective action.

Part of the process of effective regulation is the follow-up of enforcement and monitoring. Simply putting a requirement in a statute or regulation is no guarantee that the system will implement the requirement as intended. Failure to enforce regulations is another factor undermining public confidence in government's interest and ability to represent the public interest. On-site monitoring, chart reviews, records maintenance, reporting outcomes or events, and the like, are required on a continuous basis to ensure uniform application of the law and community-wide implementation. While these add to the burden of regulation they are essential if the benefits of regulation are to be real instead of imagined.

Another problem is the incompetence of some of the regulators. It is difficult to provide in the public sector the kinds of salaries that will be guaranteed to attract the kind of genetic expertise needed. It is important that regulators have access to expert consultants and adopt policies and processes that permit input from a broad variety of genetic and nongenetic professionals, as well as affected members of the public. Qualifications of regulators should include familiarity with the field of genetics, public health, law and administration, and the way the health care system operates. The regulatory agency should have sufficient resources and visibility to be able to develop and implement effective programs and formulate and enforce regulatory standards. The regulations should reflect a consensus of affected parties as to the minimum requirements of currently accepted standards of care, and not utopian efforts to provide cutting-edge technologies to anyone who might possibly benefit.

CONCLUSION

The rapid development of genetic knowledge and technology poses problems, both familiar and novel, for the society. As the representative of the public, the federal and state public health agencies need to be prepared to ensure equitable access to quality genetic testing for high-risk populations. Regulation of personnel and facilities providing testing can play a constructive role in assuring that the inevitable adverse consequences of testing are minimized and benefits are maximized with fair treatment of all the involved parties and interests.

OUTLINE

INTRODUCTION

Have you ever smoked a cigarette or drunk a cup of coffee and felt more alert? Do you know someone who wears a hearing aid and attends better to oral language, thus remembering things better? Do you want your surgeon to be using the latest technological equipment in treating your condition? Should Indian chess players participating in international competition be permitted to consume bramin, which is used widely in their country for cognitive enhancement? Do you believe that electronic technology will play an increasing role in education? Do you think that biological and information sciences will lead to new knowledge that will enhance our ability to pay attention and remember? Do you believe that, particularly at this time in the history of the human race, such enhancements in our ability to think may be especially critical? Do you think wisdom is a desirable individual and social goal?

This article presumes that many readers will answer some of these questions in the affirmative. People already consume products and participate in activities that they believe will enhance their thinking abilities, and they are inclined to seek out the latest advancements in these areas (1). Perhaps this interest reflects the fast pace of life in modern times and the desire for individuals and groups to obtain competitive advantage in the worlds of business and education.

This article examines some of the underlying ethical issues that relate to cognitive enhancement. We will explore these issues after a discussion of what we mean by cognition and by enhancement (2). We believe that interest and activity in this area of life will only increase in intensity in the future.

Cognition

The term "cognition" could perhaps be replaced with the word "thinking." However, clinicians and researchers use the term to refer to a variety of intellectual skills, including attention, learning, memory, language, skilled motor behaviors, and perceptual abilities. In addition it often encompasses so-called executive functions, such as goal setting, planning, judgment, problem-solving, and decision-making.

Most of the literature on cognitive enhancement addresses methods of enhancing either attention or memory through medications. Thus drugs may help one stay awake and attend to stimuli in the environment or remember past or upcoming events better. Undoubtedly, we would be even more excited by cognitive enhancers that improve so-called higher level thinking, such as the executive functions and even wisdom (3). All intellectual abilities depend on adequate arousal. (Note that it is difficult to learn new material when in a coma.) Arousal is intimately related to attentional mechanisms. Another fundamental intellectual task is to selectively attend to important stimuli in the environment and to avoid distraction by those less critical. Interventions that affect the speed of processing, allocation of attention, and accomplishment of complex tasks might be expected to improve higher level decision-making and problem-solving as well.

Cognitive Enhancement

The term cognitive enhancement is usually used to differentiate this concept from enhancement of noncognitive or

emotional abilities. The ability to appreciate and detect the wide range of human emotion both in oneself and in others is also a critical ability that deserves consideration for enhancement. Clearly, alterations in mood, such as depression and anxiety, can impair decision-making and problem-solving. Drugs such as Fluoxetine (Prozac) can help clinically depressed patients, but whether interventions can enhance emotional abilities in normal individuals remains uncertain (4,5). Nevertheless, presumably normal grocery shoppers snap up herbal teas and substances like St. John's Wort in hopes that they can.

The distinction between cognitive and emotional capabilities is somewhat arbitrary. Fundamental psychological functions, such as arousal and motivation, suggest that basic distinctions between thought and feeling deserve scrutiny. However, for this article we will not focus on enhancement of noncognitive abilities, although we will make brief mention of the possibilities of biological intervention in this domain. We should also point out that one of the ultimate goals of enhancement technologies, that is, to improve human wisdom, would undoubtedly involve improvement in both cognitive and emotional skills, as wisdom represents that integration of high-level processing of both thoughts and feelings (6).

Biological Substrates

We are beginning to understand more about the biological substrates of human cognition, opening this as an avenue for the development of enhancement technologies through molecular biology and neurochemistry. Much of this understanding has come from the study of diseases such as Alzheimer disease and other dementias (7,8). Dementia is the medical term for loss of cognitive abilities in more than one domain, and Alzheimer disease is the most common dementia. Alzheimer disease is biologically characterized by the loss of specific populations of nerve cells in association with specific pathological features observable under the microscope. Relating the loss of particular populations of cells to clinical symptoms has been the Holy Grail of clinical pathological correlation in Alzheimer disease and related disorders.

One of the biological systems underlying learning and memory is the cholinergic basal forebrain (9). Loss of nerve cells in this structure, located deep in the brain underneath the basal ganglia, is a substrate for the cognitive impairment found in Alzheimer disease and some other disorders. The basic scientific evidence for this is fairly convincing in terms of the effects of damage to the structure in animals on learning and memory. Drugs that block cholinergic systems can cause memory problems in normal human beings. Most important from a therapeutic point of view, drugs such as Donepezil, which enhance cholinergic function (they are cholinesterase inhibitors that work by blocking the enzyme that breaks down acetylcholine), improve attention and memory in these conditions. Although the effects are moderate in size, they have been definitely and conclusively demonstrated in double-blind placebo controlled studies (8).

There is no specific biological marker to differentiate normal aging from Alzheimer disease. Some degree of dysfunction to the basal forebrain occurs as we all age. A variety of labels (10,11) have been applied to this condition, ranging from benign senile forgetfulness to aging associated memory impairment to the term most commonly used today, mild cognitive impairment. These labels are applied to individuals who are usually older but do not have significant enough cognitive impairment to be considered demented. For example, memory problems rarely affect function in daily life. Thus a variety of trials are underway to enhance memory in individuals who are labeled with these conditions. They are by definition not demented and hence, normal. Therefore these trials really represent attempts to enhance cognition in normal individuals.

In addition to interventions that enhance cognition symptomatically, science is attempting to develop therapies that may slow the progression of conditions like Alzheimer disease that are due to gradually increasing loss of nerve cells in structures such as the cholinergic basal forebrain. A variety of approaches are being used, ranging from antioxidants such as vitamin E, antiinflammatory agents, and compounds that act to enhance the viability of nerve cells, such as nerve growth factors. Trials are also underway to treat patients who have mild cognitive impairment with these agents to delay the onset of Alzheimer disease, which would occur in a significant number of these individuals. Hence two forms of treatment are currently being used in normal people to try to enhance cognition, one symptomatical and the other preventative.

We should hasten to add that the therapeutic targets biologically are more than just the cholinergic system. Neuronal loss occurs in the locus ceruleus, which uses the neurotransmitter noradrenalin and the raphae nuclei, which use serotonin. The clinical consequences of loss of cells in these populations are less clear. However, drugs that act on these transmitters can affect cognitive abilities such as attention, as well as mood (4,12). Antidepressant medications work to enhance neurogenetic and serotonergic functions. For example, drugs such as amphetamine and Ritalin can affect mood and attention in normal individuals, and are used to treat Attention Deficit Disorder in children and adults.

Cholinergic medications may improve behavioral symptoms, namely noncognitive symptoms in dementia. Thus, again, we are reminded that the distinction between things cognitive and things affective is not always easy to determine either at a clinical or biological level. Although biological approaches are promising and growing increasingly so, most of human history has focused on nonbiological approaches to enhancing thinking abilities. Schools have been widely used throughout history to enhance thinking ability in children and adults, although their effectiveness has been under increasing scrutiny. Various assistive devices have been employed, such as the Chinese abacus, which was one of the earliest. Varieties of memory assistive devices have been used probably since the advent of commerce. However, the power of information sciences is increasing as rapidly or perhaps more rapidly than that of the biological sciences, offering other forms of enhancement possibilities for cognitive abilities. As computers and personal digital assistants proliferate and become more intelligent, the symbiosis between individual people and their computers becomes greater.

We have chosen here to focus on both biological and information systems enhancement and their ethical implications, although at first glance they would appear to be quite different. However, devices are currently used clinically in which microcomputers embedded in people control the infusion of biological substances designed to improve cognition (e.g., insulin pumps in diabetics). In principal, as biochips become increasingly sophisticated, enhancement technologies would likely include both silicon- and carbon-based approaches.

THE NATURE OF ENHANCEMENT

The article by Eric Juengst (13) in this encyclopedia provides the framework for our considerations of enhancement. Moreover we have benefited from work focusing on enhancement in sports (14). The area of genetic enhancement and physical enhancement has received more attention (15), for example, in the area of cosmetic surgery (16). Enhancement has been useful to limit the domain of medical practice, as it is usually considered to lie at the fringe of the scope of medicine. However, we will focus on the second meaning that Juengst gives to enhancement, which is the notion of self-improvement. The limiting of the domain of medicine is an interesting area in cognitive enhancement. The success of the medical establishment in identifying Alzheimer disease as a treatable condition requiring medical research and intervention has been noted. Interestingly the nature of Alzheimer disease as a disease is being challenged by the approach to try to enhance cognition in people with so-called mild cognitive impairment. However, we will focus principally on the notion of cognitive enhancement as improvement rather than treatment.

IMPORTANCE OF COGNITIVE ENHANCEMENT

Individual Use Pattern

It seems evident that individual human beings have decided that cognitive enhancement is a goal worth pursuing. Not only do we put considerable energy into going to school, but we also pursue increasingly faster individual computers and frequently take biological interventions ranging from coffee to complementary alternative measures in seeking out enhanced thinking ability. Global expenditures of billions of dollars, far exceeding expenditures on prescription drugs for all conditions, let alone those designed to enhance cognition, demonstrate the importance that individuals assign to this area, as this money is spent out of pocket (17). The range of biological products that have claimed to enhance cognition is enormous (1). Perhaps the most commonly used drug for this purpose worldwide is ginkgo biloba. The scientific evidence that ginkgo biloba helps in any disease state is inconclusive. The evidence that it enhances normal cognition is even weaker.

An entire class of drugs has been referred to as noototropics, meaning mind growth. The original compound, piracetam, has been demonstrated to improve learning and memory in a variety of animal models. Its effects in human beings are limited, however. Yet compounds in the same class such as nefiracetam are under active investigation for treating stroke and dementia. The power of genomics, combinatory chemistry, high throughput screening, and a variety of other approaches available in the industry, make it reasonable to think that more effective medications will be developed in the future, not only for diseased conditions, but for enhancing normal thinking.

Understanding Complex Systems

The stakes for cognitive enhancement go far beyond the individual economic performance of human beings. The human race is facing complex challenges to its very survival (18,19). For example, it seems evident that human beings have had significant impact on their environment and that of other species. A topic such as global warming and the controversy surrounding it illustrates the difficulties that human beings have in understanding the behavior of complex systems, such as our biosphere, and projecting the effects of our behavior in the present onto the state of our biosphere in the future. Computer models can be used to make projections about the viability of life on this planet, and thus we are already using information technologies to help us analyze complex system behavior. It is obvious that if we had biological and information science interventions that could enhance our ability to understand the consequences of our own behavior in the present, this would be a tremendous advancement for future generations. This would be particularly important if the cognitive abilities enhanced were, in fact, executive functions and even wisdom, improving the human brain's ability to model the consequences of present behavior on future states.

Thus we believe that the current interest expressed by individual human beings in enhancement could be reason enough to consider the ethical issues seriously. However, the need to enhance our cognitive abilities to help ensure the sustainability of life on this planet raises the stakes even further. It seems clear to us that thinking through the ethical issues surrounding cognitive enhancement warrants serious consideration.

ETHICAL ISSUES COMMON TO BIOLOGICAL AND INFORMATION INTERVENTIONS

Goals

If the goal of cognitive enhancement using either drugs or computer systems were self-evidently a desirable outcome, then the enhancement of higher level thinking, such as wisdom, would seem to be especially desirable. However, it is quite possible that enhancement of selective areas of cognition would not necessarily result in overall improvement. We already exist in a world in which people find the pace of life rapid. Would a drug that merely improved the ability of an individual to think more things be a desirable product? Would this merely focus attention on quantitative rather than qualitative outcomes? Would we create increased unhappiness by driving people forward to greater and greater productivity? Enhancing cognition might have detrimental effects on

the broader personality. One is reminded of the warning of Spock on *Star Trek*, that there might be sacrifices to be made in the emotional life by enhancement in the cognitive sphere. Surely this is not necessarily a consequence of cognitive enhancement, but it is one worth being aware of. After all, we do live at a time that still celebrates the rational values of the enlightenment. Focusing on enhancing thought without feeling, that is, knowledge without wisdom, might in fact contribute to further self-destructive and society-damaging behaviors.

Costs

Another ethical issue common to enhancement technologies, be they drugs or computers, represents the issue of costs. How much energy should human society place into trying to develop interventions to improve cognition? Of course, this is a difficult question to answer because one can never predict the results of scientific research. If very effective interventions were developed at low costs, this might be desirable. However, it is a daunting challenge to enhance human cognition in any way, and thus societal resources could be invested out of proportion to the likelihood of success.

Justice

The fact that enhancement technologies already do cost considerable amounts of money raises the ethical issues surrounding justice and access (20,21). This topic is already of considerable interest to health care professionals and individuals who have thought about universal access to computer technology. Would the availability of even more effective enhancement technologies increase the already growing distance between the have and have not countries, as well as the have and have not populations within countries?

Risks and Benefits

The introduction of new technologies raises the issue of risks and benefits. Although we have talked mostly about the positive outcomes of enhancement technology, all technologies have potential downsides. Medications to enhance cognition that are given to healthy people would need to have a low chance of significant side effects in order to justify their use. Who would decide what level of enhancement is worth what level of risk? In the United States and in most countries, the regulatory authorities in governments attend to the issues of risk benefit and disease but have limited jurisdiction over enhancement technology designed for individuals who suffer from no illness. Clearly, at a more macro level, the Y2K problem illustrates the risk of dependence on information technology. Will we someday regret that we have become so dependent on computers that human lives can be lost as a result of power failures or other system crashes?

ETHICAL ISSUES RELATING PRINCIPALLY TO BIOLOGICAL INTERVENTIONS

Interventions designed to change the biology of an individual human being present some ethical issues, which if not unique, are at least more obvious in relationship to this form of intervention. We might have included the issue of risk-benefit in this discussion, as various adverse events are more likely to be associated with medications than with the use of computers. However, pills seem to create the ethical issue of an artificial road to enhancement. Steroids taken by athletes are viewed as creating an unfair competitive advantage. While improving athletic prowess through diet, exercise, videotape feedback, and even computer analysis of physical motion is viewed as laudatory, taking pills to improve athletic prowess is not. Thus drug tests are now de rigeur at sporting events, and athletes who are found to have taken performance enhancing drugs are disqualified. Are drugs equivalent to hours of training? Will a cognitive enhancing pill that replaced hours of toil and sweat in a classroom similarly be viewed as some kind of inauthentic perversion (22)? However, distinctions between artificial and natural are actually difficult to make and, if the pills were relatively safe, most individuals might believe that this form of enhancement would be appropriate.

ETHICAL ISSUES RELATIVELY UNIQUE TO COGNITIVE ENHANCEMENT WITH INFORMATION TECHNOLOGY

Clearly computers are a more evident technology that enhances human beings' ability to remember and problem solve. What is clear also is the rapid advance in the intelligence of computers. What are the ethical issues that relate to enhancing human cognition through the use of computers?

Confidentiality

The first issue relates to that of confidentiality (23). Computers enhance human cognition in part by allowing information to be shared more quickly between different individuals, for example, through the use of e-mail. Yet this easy distribution also allows for the possibility that more information becomes available essentially to the entire world. Who has not received an e-mail entitled something like "learn everything about everybody"? Therefore violation of privacy becomes a major concern in using information technology to enhance human thinking abilities.

Computer-Assisted Information Processing

As mentioned in the beginning, in terms of environmental issues, solving complex health and resource problems is becoming increasingly difficult. Within the area of medicine, for example, it is becoming increasingly difficult to know which medical interventions to offer which patients. It is ironic that almost a century after the beginning of so-called scientific medicine, we are now promoting the notion of evidence-based medicine and health care. We need to take seriously the moral obligation to use optimally the information that has been collected to make individual and population health decisions. One approach that has been used as part of that evidence-based medicine is meta-analysis (24). Individual clinical trials often provide useful information

that affects the behavior of clinicians, for example, which drugs to use, in which quantities, and for what conditions. However, many studies are equivocal in their interpretation. Hence the notion arises of examining conclusions that might be drawn by reviewing the entire body of information available about a particular intervention. In other words, meta-analysis synthesizes the results of studies, viewing them not just as individual protocols, but as a sum total acknowledgment in a particular domain.

Meta-analysis has, however, engendered considerable controversy, being described variously as obvious, necessary and wise, or statistical fakery. The controversy can be seen, for example, in the meta-analysis of the effects of secondary smoking, namely smoke inhaled by individuals who do not themselves smoke but who are in the environment of smokers. It seems evident that it is worthwhile examining all the evidence available on a particular topic, such as the effect of passive cigarette smoking, but this must be done in a rigorous way.

Missing Data

A further ethical issue has to do with the availability of all the information about a particular intervention. Academics and drug companies, for different but related reasons, do not like to make so-called negative studies available through publication. Reporting on something when a study does not work cannot advance one's career or one's bottom line. Yet a systematic and important bias is introduced into the domain of knowledge about an intervention if only positive trials are reported. Thus it seems apparent that there should be ethical obligations to publish negative results as well as positive results, or else clinical decision makers will be misled when they review the available literature.

Cognitive Prostheses

The branch of computer science most intimately concerned with cognitive enhancement is artificial intelligence (AI). A recent trend in AI research is toward building "cognitive prostheses," systems that amplify a human problem solver's own thought processes. As used in this context, the term "prosthesis" includes enhancement as well as treatment so that both hearing aids and stethoscopes would qualify as prostheses. The goal of building cognitive prostheses is to enhance the power of even the finest human mind (25). The vision is not to build an all purpose problem solver that makes its user generally smarter but to build a series of special purpose computer tools, each of which symbiotically interacts with its user to solve one particular type of problem. Thus one tool might help a lawyer to plan a more brilliant defense, and another might help a professor to write a more interesting lecture. There is no theoretical limit to the type of cognitive activity that might be enhanced. Clearly, if that activity were itself unethical, such as plotting a perfect crime, then using cognitive prostheses to support it would also be unethical. However, not all of the ethical issues involved are so obvious.

Computer Program Error

One new issue is that of determining who is responsible if the computer makes a mistake. Programming errors in devices designed to administer doses of radiation to treat cancer have occurred and led to human death (26). AI systems are not infallible, and they might conceivably offer bad advice or focus a user's attention away from critical information. While legal responsibility is still solely assigned to human beings, other possibilities for moral responsibility have been proposed for the case in which computers autonomously make bad decisions. One possibility is to think of a computer as an agent, which can be liable for harm, just as human medical assistants can be. Another possibility is to allow that no one may be responsible for faulty judgment rendered by machines. The rationale for the latter position is that the use of truly life-enhancing technology should be encouraged, and blame is clearly discouraging (27).

It has been suggested that the reason responsibility is so hard to assign when computers make mistakes is that the norms for building good computer decision systems are not well understood (28). There are no accepted standard practice guidelines, as there are in medicine, to help determine if system designers and programmers have done everything reasonable to ensure the goodness of a computer system. We must depend on the integrity and skill of system developers to ensure dependable, accurate systems. Fortunately, in symbiotic systems, in which people and computers work together, the human partners may serve as valuable safeguards, recognizing when computer outputs seem dubious.

Symbiosis

Still other issues arise from the symbiotic nature of the relationship between the human user and the computer system. A central goal of AI research is to create machines that think like people. Whether or not that goal is ever fully achieved is open to technical and ethical debate. However, there can be no doubt that great strides have already been made. So it is entirely possible that a cognitive prosthesis could function like a virtual colleague. How will we relate to our virtual colleagues? Will we come to depend on them, feel emotionally attached to them, and even debate ethical issues with them, as we might with real colleagues? If so, will this enhance our professional lives, or merely reduce the social interaction we might otherwise have with real colleagues? What roles will we allow our virtual colleagues to play, and what types of activities will we reserve for human beings?

CONCLUSIONS AND FUTURE DIRECTIONS

In this article, we have reviewed a broad collection of issues relating to human values and hence ethics surrounding the use of biological and information technologies to enhance cognition in normal people. We have tried to illustrate our case by examples of behavior and practice in evidence today. It seems that there are important reasons to try to enhance individual and social intelligence using both drugs and information systems. What issues might we

see emerging in the future if we momentarily take the viewpoint of the science fiction writer?

Cyberspace

First, recall that it was William Gibson who introduced the notion of cyberspace some years ago in his book *Neuromancer* (29). The overlap between biological and computer enhancement was evident in this work, as the protagonists would choose from a wide assortment of stimulants and related biological compounds before "jacking in," that is, creating a direct biological link to the computer network before they immerse themselves in the shared mental space known as "cyberspace." To some extent we are already involved in cyberspace. Multiuser domains are spaces created electronically in which people can interact with so-called avatars, where a visual image can be created and observed to interact with other individuals in that space. It is quite possible to adopt a false identity, even to change age and gender, and to interact in social circumstances that can cause benefit or harm to other participants in this space. Admittedly, the power of interaction in this kind of space is more limited than that envisioned in *Neuromancer*, but it is certainly a start. We are all aware of stories of people meeting on the Internet who either marry or kill each other.

The notion that drug enhancement can be combined with computer enhancement is clearly evident in those of us who brew a cup of coffee before answering our e-mail. The likelihood of direct biological connection to the Internet is also not so farfetched. Already we can wear headphones and goggles that permit us to enter the world of virtual reality generated by computers. From its earliest applications in space exploration and flight simulation, virtual reality has grown to encompass surgical simulation, virtual anatomy for medical education, and artificial threatening environments for use in the psychiatric treatment of phobias (30). Yet the Internet is also full of virtual reality "games" featuring countless fictitious creatures, as well as representations of real people, who have been killed, maimed, or destroyed. Ensuring that this powerful technology is used only for societal benefit becomes a new moral imperative.

It is a small step to recognize in an individual with a cochlear implant or some visual assistive device that involves the interaction between their own individual assistive device and their nervous system to directly connect this device to the Internet. It is not so farfetched to imagine a plug on a cochlear implant that would allow a direct connection to music obtained and downloaded from the Web.

Computers as Moral Players

We will conclude on one, perhaps most distant and yet provocative issue that exists in *Neuromancer* but not in reality yet. We do already meet intelligent entities on the World Wide Web that are not human beings or even the manifestations of live human beings. Many have played a game of chess where the opponent is a computer. At what level of intellectual capacity would a computer have to exist before we would give it moral status? Perhaps the answer to that question is an infinite amount, since moral status is not granted on the basis of cognitive abilities alone.

Yet other types of human abilities are already being envisioned for computers and built into working computer systems. Kurzweil has written a book called *The Age of Spiritual Machines* (31,32), which asks whether emotional and other more affable human abilities can be programmed into a computer. AI researchers are currently building systems that can understand and model human emotions (33). Initial results in the field of affective computing may seem modest. Computers sense human emotions, like frustration, in computer users so that they may better respond to user needs. Virtual animals and cartoon characters are set in virtual worlds, where they act in accordance with their levels of hunger, fear, playfulness, aggression, and desire for affection, rather than according to programmed scripts. However, the research goals are far from modest. Following neurological findings that rational thinking may be affected by too much or too little emotion, AI researchers seek to enhance computers with the abilities to recognize, possess, and express human emotion. Will these new capabilities enhance computers to the point where we might afford them moral status?

Certainly science fiction writers have already addressed this topic. We could be forming the moral relationships between silicon-based information entities and carbon-based entities. Isaac Asimov developed an entire world based on the three principles of robotics that define the moral obligation of intelligent robots towards human beings (34). The first principal of robotics is that robots must not harm human beings nor allow them to come to harm through inaction. Who would determine the three laws of human beings that would govern their behavior toward complex computer systems? Destroying a computer system would certainly cause significant moral harm to human beings dependent on it, but at what point would we raise concern about destroying the computer itself?

Yes, this does seem farfetched, but it is not unrelated to growing concerns in bioethics about the moral relationships between human beings and other biological information processing entities. As concern about the environment continues and the relationships between human beings and other life forms become more fully understood, it seems evident that we should have moral responsibilities to other creatures in our biosphere and to the biosphere itself. We can ask whether we have a greater moral responsibility to a chimpanzee than an amoeba. We can ask whether we have a greater moral responsibility to a chimpanzee than an anencephalic child. We can ask at what point do we have a moral responsibility to a highly complex information system compared to a simple biological entity. Would you be willing to consider that the Internet has distributed intelligence and good moral purpose in its own right, beyond the effects it has on human beings? Would you sacrifice a single amoeba and give it less moral status than a distributed information system being considered for termination? If you are willing to take this moral step, then when in the process of the evolution of a biological and a computer information entity does this moral shift occur, if ever?

Importance Revisited

Life will be very different in the future because biological life itself will be changed, and there will be change in large part because of the availability of human beings to manipulate and create life forms that are biological. The future will be also dramatically different because of our ability to create different information processing entities. In fact the very survival of the human race depends on the responsible use of powerful biological and information technology. Clearly, we should give thought to the ethics of cognitive enhancement now and hope that some of these improvements in biology and information technology will someday assist us in being wiser about the use of technology to enhance human thinking.

HUMAN ENHANCEMENT USES OF BIOTECHNOLOGY, ETHICS, HUMAN GROWTH HORMONE

CAROL A. TAUER
College of St. Catherine
St. Paul, Minnesota

OUTLINE

INTRODUCTION

The appropriate use of drugs that supplement endogenous production of growth hormone (GH) in children and adolescents is the subject of both ethical and medical controversy. From a scientific standpoint, questions about the long-term efficacy of GH treatment for children who are not GH-deficient (GHD) remain unresolved (1–8). Yet GH supplementation is proposed for a variety of indications, ranging from the child who lacks naturally produced GH to the average-height child whose parents want him to star in basketball. A regimen that is clearly therapeutic for some indications is proposed for questionably therapeutic or enhancement purposes in other situations. Can we draw a line between applications that are directed toward appropriate goals for the practice of medicine and those that fall outside its scope? This question raises conceptual issues because of the difficulty of distinguishing "therapy" from "enhancement," professional ethics questions related to defining the goals of medicine, and social ethics questions about what is a just or fair allocation of medical resources. Growth hormone therapy has become a paradigm case for testing theoretical analyses of issues like these.

THE THERAPY/ENHANCEMENT DISTINCTION

Debates on the ethical scope for genetic manipulation often cite the insertion or correction of the growth hormone gene as a test case. In discussions of therapeutic versus enhancement applications of genetic engineering, the manipulation of the GH gene in short to average healthy children is used as a typical example of enhancement engineering. W. French Anderson, pioneer in gene therapy research who advocates drawing a line to preclude enhancement applications, states:

> The most obvious [enhancement] example at the moment would be the insertion of a growth hormone gene into a normal child in the hope that this would make the child grow larger (9, p. 22).

While insertion of the GH gene itself is still a hypothetical possibility, the modification of height that is sought through biochemical GH raises similar questions. Insertion of the gene is a more drastic measure and most likely carries more risks, yet the administration of the drug also leads to questions about appropriate uses of medical technology for purposes that go beyond therapy, or for enhancement purposes. In fact John Robertson cites the presumed right of parents to increase a child's height through injections of growth hormone to support the claim that parents have a similar right to enhance a child's height through gene insertion at the time of conception (10).

Yet while conceptual and ethical debates about the goals of medicine and therapeutic versus enhancement applications of biotechnology continue to cite growth hormone as a test case (10–13), the literature of pediatric endocrinology has become increasingly skeptical of the potential success of expanded uses of GH. As studies of long-term height gains from GH treatment appear to show less promising results than were anticipated from short-term studies, researchers are showing decreased optimism and professional societies are advising great caution in the prescription of GH (2–5,15–19). If these unpromising results are confirmed through long-term controlled studies, then the ethical questions may become moot, at least for the specific case of enhancing height through GH. But the questions will remain, even if transferred to other technologies.

HISTORY OF GROWTH HORMONE

Treatment of children who are deficient in GH began in 1958, when hormone taken from the pituitaries of human cadavers was shown to significantly increase the growth of treated children. A child who does not secrete GH is described as a pituitary dwarf, and if untreated, is not likely to reach an adult height greater than 4 ft 6 in. However, a two-year course of treatment with natural GH required hormone from 50 to 100 pituitary glands, so dosage was limited and selection criteria for treatment were stringent.

In 1985, after some natural GH was found to be contaminated with an infectious agent or the prion that causes Creutzfeldt-Jakob disease, the FDA halted its sale. Two companies, Genentech and Eli Lilly, had developed biosynthetic versions of GH through recombinant DNA techniques. Genentech's drug Protropin was approved in 1985, Lilly's Humatrope soon after. FDA approval, however, was limited to the population of children who had been treated with cadaveric hormone, that is, children with classical GH deficiency or pituitary dwarfism.

The cost of treatment with biosynthetic GH is very high; it is currently estimated to average $18,000 a year, varying with weight of child, dosage, and frequency of injections (range estimated from $10,000 to $50,000 a year) (19,20). The usual course of treatment is four to five years, yielding an average cost per child of $80,000 to $100,000 (21,22).

From a situation of scarcity we have moved to a situation of highly plentiful (but very costly) growth hormone. Thus it has become possible to consider higher dosages, more frequent injections, and a more extended course of treatment, as well as extension to populations other than children with classical GH deficiency, such as girls with Turner's syndrome and children with chronic renal failure, or previous cranial irradiation or craniopharyngioma of the pituitary. In addition GH has been prescribed for children who are very short but who exhibit no definable medical condition or deficiency. While this usage is both ethically and medically controversial, if it were successful it could result in an even more extensive use of GH for healthy children of average height whose parents for some reason wanted them to be taller.

CONTROVERSY ABOUT APPROPRIATE USE OF GROWTH HORMONE

In the United States prescription of GH is primarily in the hands of pediatric endocrinologists, to whom referral is made when there is a concern about growth (20).

But endocrinologists disagree on appropriate criteria for prescribing GH beyond the population with demonstrated GH deficiency (GHD). Some reject the limitation to children with GHD, since scientifically the line between GHD and non-GHD children is by no means bright and clear, and may not even be meaningful (23).

Indications for Prescription of Growth Hormone

Clinical Criteria. It is very difficult to measure endogenous production of GH because secretion is variable or pulsatile rather than continuous. The usual method is provocative stimulatory testing through administration of substances like arginine, insulin, or Levodopa. An alternate approach is labeled physiological: sampling at frequent intervals over a 24-hour period or in a particular situation. There is no agreement on the best method; no measurement is viewed as completely reliable (24). Some authors describe three different diagnoses: complete or classic GHD, partial GHD or GH insufficiency, and non-GHD (25). Others hold that there is no discrete condition that can be labeled GHD but rather a spectrum of disorders involving GH secretion and utilization (23).

Given the pitfalls of trying to differentiate GHD from non-GHD children, some endocrinologists say the problem to be treated is short stature or low growth rate, not simply GH deficiency (26). The latter should not be the only, or even the primary, indication for GH treatment. In this view, the criterion for treating a very short child should be actual responsiveness to administration of GH, demonstrated through significantly increased growth velocity over a trial period.

For short but otherwise normal children, such use is presently experimental. An "off-label" use of a drug approved by the FDA for another population is not illegal. However, short-term acceleration of growth in normal children may not actually be a predictor of long-term gains. The drug might accelerate bone aging and result in a child's reaching the same adult height more quickly (or even a lesser height). Thus an enormous cost and the burdens of three to seven shots a week for four to five years might yield little or no long-term increase in height (2–5,15–17,27).

Current Practice Patterns. A recent national study of pediatric endocrinologists regarding their prescribing patterns showed a wide range of variation in the indications for which these doctors would recommend GH treatment (28). With a response rate of 81.3 percent (434 out of a possible 534), this study provides broad information about current practice. Physicians were given eight scenarios, all representing variations in the clinical status of a 10-year-old boy or girl (sex alternated randomly) whose current height was either 2 or 3 standard deviations below the mean. Other factors that were varied were growth rate, whether bone age was normal or delayed, and predicted adult height. Three price variations were added to each scenario (cost of $13,000/year, drop to $2000/year, drop to $100/year), as well as intensity of family desire or pressure, resulting in 32 different decision situations.

Respondents generally agreed that GH use for non-GHD children has been increasing over the last five years, and almost unanimously agreed that "short stature matters and has dysfunctional emotional impact." But there was lack of consensus regarding the perceived efficacy (both expected adult height and long-term adverse effects) of GH treatment for non-GHD children. Thus there was more agreement on the psychosocial ramifications of shortness than on the scientific and medical evidence, which is presumably the area of these professionals' expertise.

The investigators concluded that GH recommendations are currently based at least partly "on a desire to address perceived impairment rather than on a clear knowledge of patient response [i.e., medical evidence]" (28). External nonphysiological variables such as strength of family wishes and cost are apparently also significant in relation to prescribing decisions. A commentator on this study noted that until we have validation of GH treatment from controlled prospective trials, "the use of GH treatment in non-GHD children will continue to be based on anecdote and emotion rather than fact" (29).

Forces Driving Interest in Expanded Uses of GH

In the United States, thousands of short healthy children are currently receiving GH treatment which is unvalidated (30). A large number of them are part of a study that follows them at least through the period while they are receiving the drug. Genentech, whose drugs Protropin and Nutropin dominated the U.S. market in the early years of biosynthetic GH, provides for all recipients to be part of its postmarketing surveillance program, the National Cooperative Growth Study (31). While approximately two-thirds of the 12,000 children enrolled in the program by 1992 had GH deficiency or another definable medical condition, the remaining third is believed to represent primarily healthy short children (30,31).

The National Institutes of Health (NIH) are conducting several studies, mainly directed toward subject populations that have medical diagnoses, but one to test the long-term effectiveness of GH therapy in very short healthy children (27). (A study similar to the latter is ongoing in Great Britain, the Wessex Growth Study.) The NIH study calls for 80 "short stature" subjects to participate in a double-blind controlled clinical trial, with half the children receiving GH injections three times a week, the other half placebo injections. All children undergo extensive tests and examinations and will be followed to adult height, when the mean heights of the two groups will be compared.

Because of complaints that the NIH study violated ethical and regulatory requirements for research with children, an independent Review Committee was convened in late 1992. While this committee determined that continuation of the study was ethically acceptable, commentators pointed out that this conclusion was reached only by extending ethical norms on research involving sick children to research involving healthy children who were short (30,32,33). Thus the Review Committee's approval of the NIH study suggests that it is appropriate for medical science to seek remedies for

the condition of short stature, even in the absence of an identifiable medical condition.

Four types of forces are driving research programs on expanded uses of growth hormone: desire to resolve uncertainties in clinical medicine, economic interests of the drug companies, consumer demand and family autonomy, and ethical claims related to equality and justice.

Desire to Resolve Uncertainties in Clinical Medicine. The question of whether growth hormone prescribed to short normal children actually results in an increase in final adult height is considered one of the most pressing problems in pediatric endocrinology today. Thousands of short children with no diagnosable medical conditions are receiving GH, but their physicians do not know what the treatment is actually achieving, even at a purely physiological level. This widespread prescription of a nonvalidated (and costly) therapy mandates a research program of the highest rigor, according to many proponents including the NIH Review Committee (1,30).

In addition there is some concern about the safety of long-term use of GH in children who are not measurably deficient. While a history of administration to children with GHD has revealed no significant problems, we are now dealing with a different population (34,35). The dosages being administered are higher than when GH was scarce; and in order to sustain increases in growth rate in non-GHD children, it appears necessary to administer even larger dosages. Two organizations that filed court complaints opposing the NIH "short stature" study focused on what they regard as real risks of harm to healthy children (36,37). While the NIH Committee assessed these risks as hypothetical or insignificant (30), Arthur Levine of NIH defended the necessity for the research by stating that GH "could be dangerous," and its safety in short healthy children needed to be proved (38).

Many clinicians would argue that until the clinical uncertainties about benefits and risks have been resolved, it is premature to worry about what they view as theoretical ethical questions about the goals of medicine and enhancement therapies.

Economic Interests of the Drug Companies. The rationale for the NIH "short stature" protocol states that the prospect of a plentiful supply of GH leads to "the need to evaluate other potential uses for this hormone" (27). Genentech had an "orphan drug" permit for GH which expired in 1992, and Eli Lilly's expired in February 1994. After these two companies lost their protected market in the United States, three other companies, Novo Nordisk, Pharmacia and Upjohn, and Serono developed biosynthetic GH drugs that have been approved for use in the United States. All five companies manufacture drugs approved for treatment of pediatric GHD, and some are also approved for other indications (39). In addition several European manufacturers have shown interest in obtaining FDA approval to market GH in the United States.

In the early 1990s market analysts suggested that extensive competition could drive the price of GH well below the cost of the protected Genentech and Eli Lilly drugs (40). It was even suggested that the cost of human GH might eventually come near that of bovine GH, which is produced by a similar recombinant-DNA process. When the congressional ban on use of bovine GH expired in February 1994, the cost of a two-week injection was $5, or $130 a year (41). However, the price of human GH has remained relatively stable despite new manufacturers and loss of orphan drug status (20).

The threat of loss of market share and a potentially lower cash return on investment would necessarily influence a company to explore additional uses for a product it has developed at great expense. In the case of recombinant-GH, potential uses in adults have begun to be explored and are the focus of numerous research efforts. Studies indicate that adults who are GHD frequently exhibit increased fat mass, reduced muscle mass and strength, smaller hearts and lower cardiac output, lower bone density, and psychological problems, and they appear to have an increased risk of death from cardiovascular disease (42). While there are some risks of side effects, GH replacement therapy for GHD adults has been demonstrated to be beneficial through double-blind, placebo-controlled trials (42,43). This therapy has been approved by the FDA for use with GHD adults as well as to treat AIDS wasting. Estimates indicate that about 70,000 adults in the United States may be affected by GHD, while the current pediatric market includes approximately 40,000 patients (39). Thus expanding the prescription of GH to GHD adults offers the prospect for a highly lucrative market for drug companies.

Nevertheless, there will likely continue to be interest in exploring additional uses for GH with children and adolescents and in extending FDA approval beyond the current indications of GHD, Turner's syndrome, and chronic renal insufficiency (39). Since short stature and abnormally slow growth of a child are observable characteristics and are generally of concern to parents, consumer interest in remedies for short stature will continue to drive research on the use of GH for non-GHD short children.

Consumer Demand and Autonomy. As the public becomes aware of the availability of growth hormone treatment, parents of a short child increasingly take initiative in requesting that it be tried. These parents may be concerned about psychological and social difficulties that may confront a short child in later childhood and adolescence, or about the long-term economic and social disadvantages of being short. Such problems are perceived to be more serious for males than for females; approximately 75 percent of the children in the Genentech collaborative study who do not have specific medical diagnoses are male (31), as are 90 percent of the children enrolled in the NIH "short stature" study (30). But even when classical GHD is included, the percentage of black children treated is only a third of what would be expected given the percentage of black children in the U.S. population, and females with problems are identified only when their deficiency is more extreme than that of males. Moreover, as awareness of the availability of GH treatment increases, data show "an even greater tendency to refer or test males [than] females" (31).

Parental request for testing and for a trial of GH treatment is largely based on a subjective perception of inadequacy, to which the medical system responds. The result is a documented referral bias in favor of testing and treating white male children, even though females, and males of other races, may be able to demonstrate greater need. Moreover there is some evidence that treatment of non-GHD females may result in more significant long-term height gains than treatment of non-GHD males (6,8,16). Given that the risks of therapy appear to be slight and that a short-term growth benefit is likely, parental pressure for GH treatment of a short healthy child, particularly a short boy, may be difficult to resist. Note that the study of prescribing patterns described earlier found that strong family wishes for GH increased the likelihood that an endocrinologist would prescribe it (28).

In this era when patient or parental autonomy regarding medical treatment is a central or even overriding ethical value, the endocrinologist may consider the option of GH therapy a matter of parental choice. Provided that parents are well-informed that for short healthy children the treatment is still experimental with a remote possibility of risk, then their autonomy permits them to choose it. However, thoughtful physicians will also raise issues of possible psychological harm: What if expectations are not reached? Will the child be severely disappointed if the gain is only one or two inches? Does the use of drug treatment in itself suggest to the child that there is something wrong with him or her? (44) After the full range of risks and benefits has been explored, the principle of autonomy may appear to support the prerogative of parents to make the choice of treatment in the interests of this particular child, whom they presumably know better than anyone else does.

Justice: Two Aspects. As the previous section notes, the current allocation or distribution of GH treatment raises questions about fairness or justice in relation to race and gender. Prescribing patterns suggest that this very costly drug is currently prescribed in a way that is discriminatory. Even if the discrimination is purely de facto, resulting from which particular parents and children pursue GH treatment most energetically, still the discrimination and its effects remain.

But a different interpretation of justice has been invoked to support a principled extension of GH treatment and to justify providing it to short healthy children who are not GHD. David Allen and Norman Fost have devised the cases of Johnny and Billy to persuade us that a short non-GHD child has as much right to GH treatment as a GHD child:

> Johnny is a short 11-year-old-boy with documented GH deficiency. . . . His predicted adult height without GH treatment is approximately 160 cm (5 ft 3 in.). Billy is a short 11-year-old boy with normal secretion according to current testing methods. . . . He has a predicted adult height of 160 cm (5 ft 3 in.) (26, p. 18).

Allen and Fost argue that it is unjust and discriminatory to provide treatment to Johnny but not to Billy, solely on grounds that Johnny has an identifiable medical deficiency and Billy does not. If the two boys can be expected to experience equivalent psychosocial problems and to be similarly disadvantaged, both as children and adults, then it seems arbitrary to treat one with GH but not the other.

The NIH Review Committee gave a great deal of weight to the principle of equal treatment, arguing that short non-GHD children suffer the same "functional impairment and psychosocial stigmatization" as GHD children. Therefore it could be unjust to deny them access to treatment simply on the basis of an "imprecise definition of 'deficiency'" (30). On this interpretation of justice it could be discriminatory to deny GH treatment to a child, no matter what his or her medical condition, if the child's short stature is perceived to be disadvantaging, disabling, or otherwise problematic. Authors who have written in defense of the treatment/enhancement distinction acknowledge that this example presents a hard case for them (13).

GOALS OF GROWTH HORMONE THERAPY

Importance of Identifying the Goal of Therapy

In the biomedical ethics literature, attempts to discern a conceptual and ethical distinction between therapeutic and enhancement uses of biotechnology often cite the case of Johnny and Billy, sometimes with discomfort that Billy appears to be as entitled to treatment as Johnny. In the literature of pediatric medicine, the current focus is on formulating a standard of care that has a rational connection with research results (18,19). Here the aim is to develop criteria for the classes of children for whom GH treatment is appropriate, based on studies that demonstrate significant benefits to that class in proportion to risks and costs, both personal and financial.

For either enterprise, the goals for GH treatment must be explicitly identified. Possible goals cover a variety of statistical, therapeutic, pychosocial, and enhancement ends or purposes. Each of these goals presumes a different understanding of the benefit to be provided, and thus each one points to a different way of evaluating whether treatment has been successful. Some of the goals appear to be only instrumental ends, where success requires that their attainment be a means to the attainment of some other more ultimate goal. Thus a rather lengthy list of goals collapses into a shorter set of ultimate goals.

Goal 1. To Increase Growth Velocity or Growth Rate. Some clinicians emphasize potential benefits of an increased growth rate, whether or not GH treatment produces a significant augmentation of eventual adult height (45). A child with measurable GH deficiency (GHD) has a pathology of growth and a physiologically abnormal growth rate. Similarly, it may be argued that a child without measurable GHD but whose growth velocity is measurably abnormal also has a pathology of growth or a growth disorder (46,47). If such a pathology is regarded as a medical condition, then its remediation is therapeutic and falls under traditional goals of medicine.

In their clinical discussion of "disorders of stature," Hindmarsh and Brook advocate using abnormality of growth velocity as the main criterion for considering

GH treatment. It is clinically diagnosable by objective standards. It circumvents the relationship of height to societal biases and is independent of racial or ethnic height differences (48). It is also independent of male–female height differences. This view maintains that amelioration of abnormal growth rate is the correction of a physiological deficiency.

But providing GH treatment to increase growth velocity in a short child may also be regarded as a means to some other goal, for example, to prevent or remedy psychosocial or behavioral problems that short children are thought to experience. However, if increased growth velocity is perceived as instrumental to the achievement of other goals, then its success and legitimacy must be evaluated in relation to those other goals (49). Only if studies demonstrate that psychosocial gains are actually achieved could an increase in growth rate directed toward such goals be defended.

Goal 2. To Increase Eventual Adult Height. The NIH "short stature" study, the Wessex Growth Study, and a number of already-completed studies aim to determine whether short-term gains from GH treatment translate into long-term height gains (2–8,15). For many physicians, parents, and researchers, the increase in growth rate sought in goal 1 is only a means to an increased adult height.

However, while medical science can assess normal growth (or growth velocity), there is really no medical criterion for normal height per se. Height is partly genetic, and is sex, race and ethnicity dependent (as growth rate is not). While it is within the competence of medicine to investigate why a child is not growing and to ameliorate that deficiency, medical science lacks objective criteria for what is a "good" or "healthy" height (13,50,51).

Height is not the sort of thing where one necessarily desires more rather than less, and some people (given goals such as gymnastics or riding race horses) may prefer to be statistically quite short. An increase in adult height through GH treatment, if achievable, is a goal that is necessarily only a means to the attainment of other desired goals. Increased height may be sought in order to avoid perceived psychosocial problems, or because extreme shortness could be functionally disabling, or because shortness is economically and socially disadvantaging within certain contexts. Thus the success of treatment must again be evaluated in terms of whether it achieves its ultimate goals.

Goal 3. To Ameliorate a Perceived Deformity. The NIH study protocol states that extreme short stature is perceived as "a major developmental abnormality" and the Review Committee cites evidence that it results in "psychosocial stigmatization." In relating this problem to traditional medical practice, Lantos, Siegler, and Cuttler note that surgery for deforming congenital anomalies is considered proper and is generally reimbursable. They believe that the short stature resulting from classical GHD is so severe that it is generally viewed as a major deformity, and hence is treatable (21). In most cases, however, the shortness of children who are not GHD is not as extreme.

Goal 4. To Prevent or Treat Psychosocial, Learning, and Behavioral Problems. Studies have suggested that children with very short stature may experience failure in school and have psychosocial and behavioral problems (52,53). For some endocrinologists, preventing or ameliorating these problems is the major goal of GH therapy. Underwood and Rieser recommend that therapeutic goals be defined "in terms of how short-term acceleration of growth would benefit the patient socially and psychologically" (45). Increasing the rate of growth could be instrumental for this short-term purpose even if significant gains in adult height could not be demonstrated.

If the actual or potential psychosocial problems of the patient are definable under the umbrella of mental health treatment (see Ref. 54 for difficulties in such definition), then GH treatment might perhaps be viewed as a therapeutic or preventive means for dealing with them (49). There are precedents in the practice of medicine for the use of drug therapy for behavioral or psychological disorders in children. However, it would be highly unusual to prescribe drug injections to children merely because they were believed to be at risk for such problems, namely for prevention (21). But what about very short children who are actually displaying these problems?

Recent studies show that psychosocial problems are not correlated to shortness per se, but that they are more likely to be related to hormonal deficiencies (2,55,57). Thus in assessing the appropriateness of GH therapy as a means for treating mental health problems, the two populations of GHD and non-GHD children must be considered separately. However, even with GHD children, no one yet is able to claim that we have scientific evidence for the effectiveness of GH therapy in improving their psychosocial functioning (52,58). "There have been no placebo-controlled evaluations of the behavioral effects of GH treatment," according to Richard Clopper (58). Some clinicians decide to prescribe GH largely on the basis of a perception that short children experience psychosocial problems, although there is no solid evidence from research to support GH as a remedy (28,29). If the reason for GH therapy is its supposedly beneficial effect on psychosocial adjustment and school performance, then studies must measure whether these results are actually achieved.

Goal 5. To Correct a Functional Disability. Advocates of GH treatment for short stature stress its functionally handicapping effects, particularly if the shortness is extreme. The NIH Review Committee cited "functional impairment" and "difficulty with physical aspects of the culture" as problems of short people that justified a research program (30). In providing examples to show that very short people are functionally handicapped, authors frequently cite problems in driving a car, and inability to reach shelves, light switches, and elevator buttons. Since children who are still growing are not regarded as handicapped simply because they are not tall enough to do these things, attaining this goal requires that GH treatment achieve an increase in final adult height.

Medical treatment is typically provided when it is effective in remedying a functional disability that

interferes with activities of daily living or that prevents one from earning a living or living independently. The question is: what level of short adult stature can realistically be defined as that sort of disability? Often it would be simpler (and less costly) to modify the environment or the vehicle than to attempt to modify the body of a completely healthy person by means of GH injections. Moreover the criteria currently used to define "extreme shortness" are statistical and have no logical relationship to standard definitions of functional disability. Thus, while the goal of remedying a disability is consistent with therapeutic goals for the practice of medicine, its application to GH treatment of non-GHD children is questionable.

Goal 6. To Remove the Economic and Social Disadvantage of Short Stature. Data show that our society has a bias against short people, particularly short males. Allen and Fost note that "discrimination based on height — heightism — pervades American life," and that shortness "imposes a disadvantage in the competition for schools, jobs, income and mates" (26).

Society's attitude toward short people is a prejudice that often leads to discriminatory consequences. Lantos et al. note that "we do not usually call prejudice-induced conditions . . . diseases" (21). In his analysis of prevention as a legitimate goal of medicine, Eric Juengst argues that this goal should be limited to efforts to defend people from "robust pathological entities [i.e., genuine disease entities], rather than changing their bodies to evade social injustices" (51). In other words, it is not appropriate for medicine to respond to discrimination by modifying the physical characteristics against which society is prejudiced. Other authors describe the use of medicine to respond to society's preference for taller people as social engineering. In attempting to make some people taller, medicine may simply be reinforcing "heightism" in our society.

Goal 7. To Enable Parents to Seek a Preferred Height for Their Children. This goal suggests that any height could be achievable, which is almost certainly incorrect. Ann Johanson, former Director of Clinical Affairs for Genentech, acknowledges that children with normal stature and growth rate are unlikely to gain significant additional height or growth velocity from GH treatment (59). Recently completed studies confirm this hypothesis (2–7,15,60). However, if a safe method of supplementing GH, either biochemically or through genetic manipulation, were shown to cause significant height increases in normal-height children, this goal would represent a pure enhancement use of GH. In the literature specifically focused on growth hormone, no one appears to advocate such enhancement use, even though parents may request it. But discussions of enhancement therapies in general sometimes defend providing them, based on the constitutional right of parents to autonomy and discretion in rearing their children (10).

GH TREATMENT FOR CHILDREN WITHOUT MEDICAL CONDITIONS

The Argument Invoking Equal Treatment

The Case of Johnny and Billy. The only clearly therapeutic goal for GH treatment is to increase or normalize growth rate in children who have a definable medical condition that is related to a pathology of growth. Secondarily this increased growth rate ought to produce an increment in final adult height over what was predicted. But what of Allen and Fost's case of Johnny and Billy? Recall that Johnny and Billy are both short 11-year-old boys, and that each has a predicted adult height of 160 cm (5 ft 3 in.). The difference between them is that Johnny has a documented GH deficiency, while Billy's tests show normal GH secretion. Allen and Fost argue that it is discriminatory to offer GH treatment to Johnny but not to Billy (26).

In applying the concept of justice to this situation, we are invoking the principle that equal cases should be treated equally. Since no two cases are ever exactly alike or equal, we must identify the relevant factors in which similarity is required. With Johnny and Billy, the similarities stated are short stature at present and equal predicted adult heights. Similarities assumed are that shortness will cause them similar psychosocial problems and will disadvantage them equally, and that GH treatment will benefit them equally and carry equivalent risks. If these assumptions are correct, then fairness seems to mandate that the two cases be treated equally in terms of provision of GH. In brief, a non-GHD child predicted to reach the same adult height as a GHD child has an equal right to GH treatment.

Justice entails this conclusion, however, only if the two cases are truly similar in relevant respects. But actual data show that they are different in important and often overlooked ways, so that the principle of equal treatment of similar cases does not apply to these two situations.

Dissimilarities between Johnny and Billy. First, a lack of endogenous GH appears to be linked to physiological and functional consequences in addition in growth. While earlier studies of short-statured children had shown them more susceptible to learning difficulties and academic failure than children of normal height, these studies did not distinguish according to the etiology of the short stature. Newer studies which concentrate on short children with GHD suggest that these children "show significant deficits in several specialized cognitive domains including those requiring complex visuoconstructional skills, orientation in space, long-term memory, and attention span" (61).

Some of this research fails to distinguish children with isolated GHD from children who lack not only growth hormone but are multiply hormone deficient or even panhypopituitary (lacking all pituitary hormones). When these distinctions are made, children with more severe endocrine problems do demonstrate more severe cognitive deficits and psychological disturbances (61,62). But authors of the Michigan longitudinal study, which followed a group of GHD children for seven years, reached a preliminary conclusion that even some children with

isolated GHD "may have cognitive profiles similar to those described as learning disabled" (61,63).

Two studies of the psychological adjustment of GHD adults show that their profiles differ from those of matched controls of equally short stature, and that they are at risk for anxiety and depressive disorders, frequently displaying symptoms seen in patients with clinically diagnosed social phobia (64,65). Again, subjects with multiple endocrine deficiencies appear more vulnerable than those with isolated GHD. But Pine, Cohen, and Brook found that "A blunted growth hormone response to physiologic challenges remains perhaps the best-replicated biological correlate of emotional disorder," while not claiming which is cause and which is effect (66).

In summarizing the results of these studies, Brian Stabler observes that short stature alone is not responsible for the low quality of life of many GHD patients, but that "neuropsychologic functioning is fundamentally impaired in many GHD children." The more deficient in GH a child is, the greater the cognitive and behavioral difficulties, suggesting a "relationship between psychosocial functioning and degree of endocrine deficiency" (62).

On the other hand, studies of the adjustment of short children in general show that their level of social and academic functioning is "reasonably indistinguishable from that of average-statured peers" (55–57). After reporting their study that showed minimal long-term height gains from GH treatment of short normal children, Hindmarsh and Brook concluded:

> It has been alleged that short stature adversely affects children and the short-term effects of r-hGH on height ... might therefore find advocates for this therapy. Neither we nor others have been able to document markers of adverse psychological effects in normal short children (2, p. 16).

Thus short stature is not the primary factor underlying the behavioral, academic, or emotional difficulties of some short individuals. Rather, these problems appear linked to an underlying medical condition of which short stature is only one feature (55). While it may be reasonable to provide GH to Johnny to help him overcome these types of deficits in addition to growth failure, it is unlikely that merely increasing Billy's stature will offer comparable psychosocial benefits to him.

Second, there is skepticism as to whether a non-GHD child could make comparable height gains on comparable doses of GH. While some authors believe that cumulative growth response of non-GHD subjects is comparable to that of GHD patients (67), others cite strongly conflicting data (68). The latter argue that in order to achieve comparable height gains you would have to treat over a longer time period, at higher dosages, with correspondingly higher costs. At some higher dosage toxicity could be expected, possibly leading to side effects such as diabetes.

Recent studies that compare two groups of non-GHD children, one group treated with GH and the other untreated, also come to differing conclusions (2,3,6,7,17). Hindmarsh and Brook found that both treated and observation groups had some increases in final height over that predicted, but that the change in the treated group was not significantly greater than that in the observation group (2).

While studies show that GHD children like Johnny can be expected to make significant height gains through GH treatment, there is no comparable consensus among researchers as to whether Billy could anticipate similar gains, especially in the long term. It is unlikely that an expenditure on Billy equivalent to that on Johnny would bring Billy equal benefits, even in relation to height itself.

Third, the case description makes no mention of the two boys' growth velocities. It is almost certain that Johnny has subnormal growth velocity, while Billy's may well be within the normal range. If so, then the two boys differ significantly with respect to pathological versus normal growth, and Billy would be regarded as developmentally normal.

Fourth, because Billy does not have an identifiable medical or developmental problem, he is apt to be at greater psychological risk as a result of prescription of drug therapy. In his article "Is Taller Really Better?" Douglas Diekema argues that treatment itself may have a stigmatizing effect:

> When we seek to change the height (or physical appearance) of a child, he may perceive that he is incomplete and unacceptable. His peers may have suggested this on the playground. Now his parents seem to have confirmed it through their efforts to make him taller (69, p. 114).

Cosmetic interventions after an illness or accident are "less likely to make the child perceive himself as undesirable," since they restore something that was taken away. Interventions which repair abnormalities that interfere with functional capacity offer the child a benefit for him or herself, not merely in relation to how the child is perceived by others or in comparison with others. But GH treatment aimed solely at changing a child's body or appearance could have adverse psychological effects and do more harm than good (69).

C.G.D. Brook of the London Centre for Paediatric Endocrinology warns doctors who are pressured into providing GH for non-GHD children to be mindful of "the problems of stigmatising otherwise normal children" (60). Billy is at more risk of this stigmatization through the medicalization of his stature than is Johnny, who has a definable medical problem.

Fifth, while Johnny and Billy as individuals may both experience psychosocial problems, Billy's are more apt to be treatable without use of GH. Stabler notes that short individuals who do not have neuroendocrine impairment are very adaptable, and he cannot say whether GH or psychotherapy is more effective in treating them (70). Since Stabler advises that GH should never be given without supplementary counseling or psychotherapy, it would be significantly more cost effective to choose psychotherapy rather than GH plus psychotherapy for Billy. Brook, in noting the lack of evidence that short children suffer psychosocial disadvantage solely because of their stature, as well as the impossibility of testing whether an increase in growth rate would provide psychosocial benefits, concludes:

> It is much more important for a short child to acquire coping skills than to buy [socially unimportant] inches through pharmacological means (60, p. 692).

These five arguments show that in the real world of GH treatment, the given data about Johnny and Billy are entirely consistent with the conclusion that they differ in a number of ways that are relevant with respect to treatment with GH. The fact that GH is provided for GHD children does not entail that it must be provided for equally short non-GHD children.

Short Stature as Disability or Disadvantage

Even if Johnny and Billy are not completely equivalent with regard to the provision of GH therapy, still it may be argued that because of the handicapping effects of very short stature, or the social and economic disadvantages of shortness, it follows that increased height (and hence GH treatment) is a legitimate medical goal for Billy. Even advocates of a restrictive definition of legitimate goals for the practice of medicine generally support treatment to remedy or ameliorate a disability. For example, Sabin and Daniels hold that "the central purpose of health care is to maintain, restore, or compensate for the restricted opportunity and loss of function caused by disease and disability" (54). The application of medical science in order to level social and economic disparities is more controverted. But even the goal of treating "disability" has problems when invoked to justify the extension of GH treatment.

Is Short Stature a Handicapping Condition? Allen and Fost classify extreme short stature as a handicap, that is, "a physical . . . disability that prevents or restricts normal achievement." They suggest that height below the 1st percentile is "likely to be handicapping" (26). (For North American adult males this would be a height about 5 ft 3 in.; for adult females about 4 ft 10.5 in.)

As noted earlier, difficulty in driving a car or in reaching shelves or switches usually can be ameliorated through modification of a vehicle or environment. While it is possible to imagine statures so short that a person is unable to function outside a radically adapted environment, the heights suggested do not appear to be that restricting.

Moreover the appeal to short stature as a functional disability is belied by height criteria that are significantly different for males and females. Since the mean height for adult males is about 4.5 in. greater than that for females, treatment criteria based on these mean heights cannot really be aimed at overcoming a functional handicap. Males and females do not drive different cars according to their sex, nor use different light switches. If a 5 ft 1 in. female is not functionally impaired in activities of daily living, why is a 5 ft 1 in. male?

Much publicity has been given to fatalities allegedly caused by air bags at the time of an automobile crash. More than half of such deaths have involved children, and almost all adult deaths have been women. Evidence indicates that "women of short stature are particularly susceptible to head and neck injuries from air bags" (71,72). Women under 5 ft 2 in. are statistically at particular risk; however, that height, while below the first percentile for males, is well above it for females. Moreover federal crash-worthiness standards call for testing that uses 5 ft 8 in. dummies, the height and weight of an average male. In September 1998 the National Highway Transportation Safety Administration proposed new rules that would require testing to minimize the risks of air bags to infants, children, and short adults. However, comment on these rules was extended to December 30, 1999, and as of early 2000, the rules had not yet been finalized (73). The reason that the driving environment is more hazardous to short people is that safety tests and modifications are premised on drivers' being average-sized males. This example illustrates how the "handicap" of shortness results from the way equipment is tested and designed, not from shortness per se.

Short people must live in the world as it exists at present, however. A careful study of daily life activities and a range of occupational choices might identify a height level below which a person really is handicapped, that is, unable to function without major environmental accommodations. (This height level might turn out to be around 4 ft 6 in.) Such a result would base the criteria for "handicapped by reason of stature" on actual data, rather than on statistical population norms. It might then be possible to consider offering GH treatment to remedy the disability of short stature.

In determining the allocation of treatment, however, the resources that are generally available for the treatment and rehabilitation of people with disabilities must also be taken into account. Fairness requires that equally debilitating handicaps be provided equal resources. Economist Mary Ann Baily suggests that money spent on expanding access to GH could better be used instead to help severely handicapped children through rehabilitative care, training, and high-tech devices, since at present these benefits are "not well-covered by private or public payers" (22).

If we apply Allen and Fost's suggestion that children in the first percentile be considered handicapped, then with about 39,000 U.S. children in the first percentile at any given age, to provide all of them with five years of GH treatment at $18,000 a year would cost over $3.5 billion a year. Compared with the defense budget this amount may seem small. However, total 1996 Medicaid payments for dependent children under 21 were only $17.5 billion, and the 1999 allocation to NIH for medical research for infants and children through the National Institute of Child Health and Development was only $752 million (74,75). Many children in the first percentile may have pathologies of growth or other medical conditions. But for those who do not, the use of scarce resources to provide GH treatment appears to be a low priority in relation to other possible expenditures related to the needs of disabled and sick children.

Should Medicine Remedy the Disadvantage of Short Stature?. Short stature has been shown to carry both economic and social disadvantages. One study suggests that there may be an increased income (height bonus) of

roughly $1150 a year (1999 dollars) per inch of greater height (76). Over a work life of 40 years, the total increment would be $46,000 per inch. If GH treatment were evaluated purely on an economic basis, a gain of two inches or $92,000 through a five-year course of treatment costing $90,000 would just about balance the investment in GH treatment. However, the anticipated increment in income would be gained through an increase in height relative to others who would become comparably shorter and presumably earn less. Thus an individual's interest in greater height is not correlated to a societal interest when medical resources are expended for GH treatment.

Most discussions of the disadvantaging effects of short stature focus on males. Studies show that a 12-inch height reduction is a significant predictor of lower economic status among men but not among women (77,78). (Obesity is a significant predictor of lower economic status for women but not for men.) These data could be taken to mean that women suffer less economically from shortness, and hence the disproportionate treatment of males with GH is not a concern. On the other hand, there is evidence that the typical size difference between males and females plays a major role in the status and income differential between the sexes. One study found that women who are 5 ft 7 in. earn on average the same salary as men who are 5 ft 7 in. (79). A study of the effects of both sex and size on status ranking found, as expected, that both males and people of greater size are perceived as having higher status. More surprisingly, this study found that the correlation between sex and status rank is largely (65 percent) accounted for by the correlation of sex with size, rather than by socioculturally influenced factors (80).

When the practice of medicine engages in trying to make some people (mostly white males) relatively taller, it is not only contributing to the "heightism" of our society. Given the correlations among sex, size, and status, it is also reinforcing discriminatory attitudes in relation to women (and toward people of typically shorter racial and ethnic groups) (79).

Moreover we do not know whether persons whose height is increased through GH treatment acquire the same advantages as people who are taller to begin with (69). Demographic data on adults who were GHD and were treated with GH are limited and often disappointing. Subjects in some studies, while reaching educational levels comparable to the population as a whole, were not comparably employed, married, or living independently of parents (62,81,82). Other studies, however, have identified more positive outcomes (83,84). A well-controlled study at Children's Hospital of Buffalo found a high educational level in previously treated adults, and also a low unemployment rate of 8 percent, at a time when overall unemployment in the area was 9 to 10 percent. None of these adults were experiencing significant emotional or adjustment problems (84).

Thus the data on the effectiveness of GH treatment for overcoming economic and social disadvantages are mixed, and placebo-controlled studies are completely unavailable (58,85). Even for GHD individuals, studies do not provide convincing evidence that GH treatment results in alleviation of the economic and social disadvantages of short stature.

These arguments provide three reasons for questioning the use of GH treatment to overcome economic and social disadvantages: (*1*) We cannot show that it is effective for this purpose. (*2*) Even if it were, providing some persons a height advantage relative to others offers no net benefit to society. (*3*) Not only is there no societal benefit, there is a negative impact through the reinforcement of societal biases and prejudices.

Liberty Rights and Personal Preferences

It could be argued that if an individual has a particular personal goal for which greater height would be an asset, then that individual should have the freedom to seek professional assistance to achieve that increased height. Since physicians, and specifically pediatric endocrinologists, control the prescription of biochemical growth hormone, physicians would necessarily be involved, and their prescription of GH to satisfy personal preferences would be no different from other uses of medical expertise for cosmetic purposes. Arguments about a just or fair allocation of societal resources would carry less weight if the patient either paid for, or contracted with an insurer who would pay for, such treatment.

This argument overlooks the fact that GH treatment to increase height must be provided during the child's growing years, and is most effective when begun early and continued until growth is completed. Hence (almost) all treatment occurs while the patient is a minor and unable to give an autonomous consent. Given the uncertainties about the clinical outcomes and the psychosocial benefits of GH treatment for non-GHD children, as well as the unpromising results of long-term studies, even adults would find it difficult to weigh these supposed benefits against the risks, inconveniences, and costs of years of medical treatment.

The endocrinologist has been designated as the customary gatekeeper for prescription of GH because of the need for a well-informed person to weigh risks against benefits, and to safeguard against the possibility of nonbeneficial (or even harmful) usage (19). Pediatricians, of whom pediatric endocrinologists are a subset, are given authority regarding child health issues because they are regarded as "guardians of and spokespersons for the well-being of children" (86). This charge requires that at minimum they base prescription of GH on evidence from studies and on practice guidelines developed by professional societies (18,19,29). It also requires them to recognize that while adults may choose to utilize medicine to change their bodies according to their preferences, adults (even parents) do not have a right to impose arduous treatment on healthy children simply to change their appearance.

The use of GH to treat short stature per se is a "medicalization" of problems whose sources lie within society rather than the short individual. The search for drug treatment to ameliorate psychosocial problems experienced by the individual patient often overlooks a wide range of other therapies, resources, and supports that are apt to be more effective in dealing with these problems. In fact some practitioners argue that focus on

short stature "is in some ways an obstacle to gaining truly comprehensive care for [short] children" (62).

Moreover treatment that is provided by physicians, even if paid for by individual parents, increases the pressure to expand reimbursement through public funds and through health plans. What is at first regarded as a consumer issue, namely providing what clients want and will pay for, eventually comes to be expressed in terms of fairness: Why should the wealthy have access to a medical treatment that most people cannot afford? History shows that entitlements are often expanded in this way, without other justification.

The use of medical technologies to modify people according to their preferences is apt to increase public concern about emerging genetic therapies. While most genetics researchers and clinicians stress their interest in applying gene therapy only to severe and lethal diseases (9), yet the public can easily be aroused to fear and oppose all interventions that involve genetics. Avoiding the use of GH for what can only be regarded as enhancement purposes upholds a consistent policy of focusing genetic science on therapeutic applications.

Finally, no patient or parent has a constitutional or liberty right to demand any particular medical treatment. Even the right to procreative liberty, a highly protected right in the United States, does not permit one to demand RU-486 as an abortion option, nor to insist on Depo-Provera as a contraceptive before it was approved for that purpose. While parents have a wide range of choices as to how they wish to rear their children, they cannot insist that the medical profession cooperate with whatever plan they may have.

CONCLUSION

The development of recombinant human growth hormone has resulted in a plentiful supply of the GH drug. It has been shown to be safe and effective in improving growth in children who are growth hormone deficient, and is also approved for treatment of girls with Turner's syndrome and children with chronic renal insufficiency. In addition administration of GH has been recognized as therapeutic for GHD adults and is effective to treat AIDS wasting. The question of whether the drug ought to be prescribed beyond these categories, particularly for children who are healthy but short, remains an unresolved question. For many endocrinologists, abnormally slow growth, but not simply shortness, is an indication for treatment, even in the absence of other medical conditions.

The prescription of GH to short but otherwise normal children represents the use of medicine for enhancement purposes. Beyond the as-yet-unanswered question of whether such treatment actually achieves a significant long-term gain in height, there are unresolved ethical questions regarding the appropriateness of directing medical and societal resources to the amelioration of short stature. If amelioration of shortness could be shown to achieve other appropriate goals, such as improvement in psychosocial functioning, there might be justification for the prescription of GH to short normal children. However, studies do not demonstrate that shortness in itself is problematic, and other solutions for psychosocial and similar problems appear to be preferable, especially given the high cost and the burdensome administration of GH treatment.

Because of a variety of factors associated with GH treatment for idiopathic or unexplained short stature, many arguments can be marshaled against allocating medical resources to this form of enhancement. However, these arguments are not necessarily transferable to other biotechnologies in which the enhancement versus therapy debate arises. Exploring these biotechnologies on a case-by-case basis provides one means for clarifying the enhancement or therapy distinction and its ethical implications, or for supporting the position that the distinction is not a helpful one.

HUMAN ENHANCEMENT USES OF BIOTECHNOLOGY, ETHICS, THE ETHICS OF ENHANCEMENT

ERIC T. JUENGST
Case Western Reserve University
Cleveland, Ohio

OUTLINE

INTRODUCTION

In discussions of ethics in biotechnology one frequently encounters the claim that there is an important moral distinction between using biotechnological tools and products to combat human disease, and attempting to use them to "enhance" human traits. Thus people argue that using biosynthetic human growth hormone to treat an inborn growth hormone deficiency is praiseworthy, but not the use of the same product to increase the height of a hormonally normal short child (1). Similarly, while the use of human gene transfer techniques to treat disease enjoys widespread support from secular and religious moral authorities, a line is usually drawn at using the same protocols to attempt to improve upon otherwise healthy traits (2,3). Even those unwilling to condemn the enhancement uses of biotechnology outright almost all concur that ethics demands that therapeutic applications of these tools be given priority for research and development (4). As a result the distinction has been enshrined in biotechnology policies at both professional and governmental levels, and continues to inform much of the public discussion of new biotechnological advances.

Despite its widespread support as a moral divide, however, treatment–enhancement distinction is not easy to characterize conceptually. It often even seems in danger of evaporating entirely under conceptual critiques even before the question of its moral merits is entertained. If "enhancement" is to keep serving as a significant policy boundary, we should at least be clear about just what it demarcates. Examining the multiple ways the distinction is interpreted within the bioethical and science policy literature can help with this clarification, and that is the goal of this entry. Ultimately it will suggest a normative point: that the interpretations that most accurately identify the moral concerns at stake in the uses of biotechnology are those that focus on the uses that would serve to exacerbate, rather than reform, the social injustices that flow from our intolerance for human biological variation.

TREATMENT–ENHANCEMENT DISTINCTION

The treatment–enhancement distinction is usually used in bioethics to argue that curative or therapeutic uses of biotechnology fall within (and are protected by) the boundaries of medicine's traditional domain, while enhancement uses do not, and to that extent are more problematic as a professional medical practice or a legitimate health care need (5). Unfortunately, making the distinction between treatment and enhancement is not without its own complexities. The distinction is explicated in at least three distinctly different ways, which have different merits as boundary markers for medical research and practice. There are accounts that rely on medicine's own understanding of its professional goals, accounts which rely on theoretical measures of "species-typical functioning" that go well beyond medicine, and accounts that turn on particular concepts of disease.

Professional Domain Accounts

One approach to the enhancement/treatment distinction is to define it in terms of the accepted limits of professional medical practice. On this view, "treatments" are any interventions which physicians and their patients agree are useful and proper, while "enhancements" are simply interventions which are considered to fall beyond a physician's professional purview. Thus physician-prescribed physical therapy to improve muscle strength would be considered legitimate medical treatment, while weight-lifting under a coach's supervision to achieve a particular physique would be considered an enhancement. This view resonates well with a number of contemporary social scientific critiques of biomedicine, which suggest that medicine has no natural domain of practice beyond that which it negotiates with society (6). It also provides a simple normative lesson for professionals concerned about their obligations in specific cases: One takes one's cues from the patient's value system, and negotiates towards interventions that can help achieve the patient's vision of human flourishing (7).

Unfortunately, however, these same features also deny this approach the ability to be of help to those attempting to use the treatment/enhancement distinction in order to regulate gene transfer research. Relying on the conventions of professional practice provides no principled way to classify technological innovations as either within or outside medicine's proper domain until after the fact of their acceptance or rejection by the medical community. To the extent that useful "upper-boundary" concepts are required at the policy level — for societies making health care research allocation decisions, for example — this impotence is an important weakness.

Normalcy Accounts

Fortunately another approach to interpreting the treatment/enhancement distinction is framed explicitly as a

policy tool for separating legitimate health care needs from luxury services. The most developed exposition of this view is Sabin and Daniel's endorsement of what they call the "normal function" standard for determining the limits of "medically necessary" (and therefore socially underwritten) health services (8). Sabin and Daniels argue that an appropriate boundary between medically necessary treatments and optional enhancements can be drawn by thinking about how to provide medical services fairly within a population. Following Daniels' earlier work (1,10), they construe health care as one of society's means for preserving equality of opportunity for its citizens, and define health care needs as those services that allow individuals to enjoy the portion of the society's "normal opportunity range" to which their full array of skills and talents would give them access, by restoring or improving their abilities to the range of functional capacities typical for members of their reference class (e.g., age and gender) within the human species. Daniels has specified this definition of health care needs further by saying that the notion of "species-typical functioning" it relies upon is not "merely a statistical notion," but implies "a theoretical account of the design of the organism," that describes the "natural functional organization of a typical member of the species." Any interventions that would take expand an individual's range of functional capacities beyond the range typical for his or her reference class would count as an (medically unnecessary) enhancement.

The "normal function" approach is a sophisticated attempt to define the limits of social obligations to provide health services for policy purposes, and comes close to accurately reconstructing the rationale behind many actual "line drawing" judgments by health care coverage plans and professional societies. Unfortunately, this approach is also semipermeable in an important way for our purposes.

The first serious problem is the problem of prevention. While efforts at generic "health promotion" straddle the border of biomedicine, efforts to prevent the manifestation of specific maladies in individuals are always accepted as legitimate parts of biomedicine, and would be automatically located on the "treatment" side of the enhancement boundary. On the other hand, one of the ways one can prevent a disease is to strengthen the body's ability to resist it long before any diagnosable problem appears. These forms of prevention attempt to elevate bodily functions above the normal range for the individual (and in some cases the species), and to that extent seem to slide into enhancement. Consider the case that LeRoy Walters and Julie Palmer make for including some genetic enhancements within the domain of legitimate medical needs. They start with the paradigm of a nongenetic preventive intervention — immunization against infectious disease — and then drive their genetic truck through the border-crossing it creates:

> In current medical practice, the best example of a widely-accepted health-related physical enhancement is immunization against infectious disease. With immunizations against diseases like polio or hepatitis B, what we are saying is in effect, "The immune system that we inherited from our parents may not be adequate to ward off certain viruses if we are exposed to them. Therefore, we will enhance the capabilities of our immune system by priming it to fight against these viruses.
>
> From the current practice of immunizations against particular diseases, it would seem to be only a small step to try to enhance the general function of the immune system by genetic means. . . .In our view, the genetic enhancement of immune system function would be morally justifiable if this kind of enhancement assisted in preventing disease and did not cause offsetting harms to the people treated by the technique (4, pp. 13–14).

This argument is bolstered by the fact that the technical prospects for such preventive–enhancement interventions already look good, given gene transfer research now underway to treat ill patients in just those ways. Thus the gene therapist summarizes the prospects for using gene therapy in oncology this way:

> Over the next few years, it appears that the greatest application will be in the treatment of cancer, where a number of genes that have been isolated have the potential to *empower* the immune system to eliminate cancer cells. . . .Human gene therapy cancer trials have also been initiated for insertion of the tumor necrosis factor (TNF) gene into T-lymphocytes in an effort *to enhance the ability* of T-lymphocytes to kill tumors. Another approach has been to insert the TNF gene into tumor cells in an effort *to induce a more vigorous immune response* against the tumor (emphasis added) (10).

Another gene transfer protocol already underway 'treats' people with an inherited high risk of heart disease by increasing the number of low density lipoprotein receptors their blood cells carry, enhancing their ability to clear their high levels of cholesterol from their blood before it causes heart disease (11). If it works to reduce their risk of heart disease, why not use it prophylacticly to reduce my more modest risk? Moreover, if human gene transfer protocols like these are acceptable as forms of preventive medicine, the critics ask, how can we claim that we should be "drawing the line" at enhancement?

Disease-Based Accounts

Probably the most common rejoinder to the problem of prevention is to distinquish the problems to which they respond. Treatments are interventions which address the health problems created by diseases and disabilities — "maladies" in the helpful language of Clouser, Culver, and Gert (12). Enhancements, on the other hand, are interventions aimed at healthy systems and normal traits. Thus, prescribing biosynthetic growth hormone to rectify a diagnosable growth hormone deficiency is legitimate treatment, while prescribing it for patients with normal growth hormone levels would be an attempt at "positive genetic engineering" or enhancement (13). On this account, to justify an intervention as appropriate medicine means to be able to identify a pathological problem in the patient; if no medically recognizable malady can be diagnosed, the intervention cannot be "medically necessary," and is thus suspect as an enhancement.

This interpretation has the advantages of being simple, intuitively appealing, and consistent with a good bit of biomedical behavior. Maladies are objectively

observable phenomena and the traditional target of medical intervention. We can know maladies through diagnosis, and we can tell that we have gone beyond medicine when no pathology can be identified (14). Thus the pediatric endocrinologists discourage the enhancement uses of biosynthetic growth hormone by citing the old adage "If it ain't broke, don't fix it" (15). This interpretation is also the one at work in the efforts of professionals working at the boundary, like cosmetic surgeons, to justify their services in terms of relieving "diagnosable" psychological suffering rather than satisfying the aesthetic tastes of their clients (16), and in our insurance companies' insistence on being provided with that diagnosis before providing coverage for such surgeries.

Unfortunately, this interpretation does also face at least two major difficulties. The first problem that any disease-based interpretation of the enhancement boundary faces is, of course, biomedicine's infamous nosological elasticity. It is not that hard to coin new maladies for the purposes of justifying the use of enhancement interventions. By interpreting the boundary of medicine in terms of maladies, this approach puts the power for drawing that boundary squarely in the profession's hands, with the corresponding potential for abuse. Moreover, the preventive powers of a give enhancement intervention can be difficult to disprove, if the targeted disease never manifests itself. Enhancing interventions would have the advantage of the man who claimed his dance was keeping dragons out of Central Park: Until a dragon lands, it is hard to argue that he's not providing a preventive service.

The more important problem, however, is that for practical purposes no matter how the line is drawn, most biotechnological interventions that could become problematic as enhancement interventions would not have to cross that line in order to be developed and approved for clinical use, because they will also have legitimate therapeutic applications. In fact, most biosynthetic biologicals and gene transfer protocols with potential for enhancement uses will first emerge as therapeutic agents. General cognitive enhancement interventions, for example, are likely to be approved for use only in patients with neurological diseases (17). However, to the extent that they are in high demand by individuals who are merely suffering the effects of normal aging, the risk of unapproved or "off-label" uses of these products will be high (18). This risk poses unique regulatory challenges. Even if, for example, the U.S. Food and Drug Administration (FDA) vigorously attempted to regulate genetic enhancement technology, under its current legislative mandate the agency is unlikely to regulate off-label uses of approved products (19). Moreover, given the current regulatory vacuum surrounding the private practice of reproductive medicine, there is little to prohibit the application of these techniques to early human embryos as well, in hopes of effecting germ-line transformations.

This last point is critical for policy purposes, because it suggests that, in countries like the United States, the real challenge to regulation in this area may not be the development of enhancement interventions or "enhancement research" but about the downstream "off-label" uses of gene therapies for nonmedical enhancement purposes. The policy problems then becomes one of controlling access and use of the technologies, not their research and development. Unless laws are changed, regulation of biotechnological enhancements ill fall under the common law — which, given the absence of FDA regulation of off-label uses remains the most potent potential source of legal regulation — will focus on physician malpractice and actions for lack of informed consent. This presents another set of challenges for the law, since the novelty of enhancement technologies will make it difficult for judges and juries to ascertain the reasonableness of physician behavior (19).

These realities have pressed those who would use the treatment/enhancement distinction for policy purposes to articulate the moral dangers of genetic enhancement more clearly. After all, personal improvement is praised in many spheres of human endeavor, and, as purely elective matter, biomedical interventions like cosmetic surgery are well accepted in our society as means to achieving personal improvement goals.

ENHANCEMENT AS A FORM OF CHEATING

There are two lines of thought that have emerged from this recent work. The first focuses on the idea that biomedical enhancements are a form of social cheating. This is the view that taking the biomedical shortcut erodes the specific social practices that would make the analogous human achievement valuable in the first place. Thus some people argue that it defeats the purpose of the contest for the marathon runner to gain endurance chemically rather than through training, and it misses the point of meditation to gain Nirvana through psychosurgery. In both cases the value of the improvements lie in the achievements they reward as well as the benefits they bring. The achievements — successful training or disciplined meditation — add value to the improvements because they are understood to be admirable social practices in themselves. Wherever a biomedical intervention is used to bypass an admirable social practice, then the improvement's social value — the value of a runner's physical endurance or a mystic's visions — is weakened accordingly. If we are to preserve the value of the social practices we count as "enhancing," it may be in society's interest to impose a means-based limit on biomedical enhancement efforts.

Interpreting enhancement interventions as those which short-circuit admirable human practices has special utility for policy analysis. To the extent that biomedical shortcuts increasingly allow specific accomplishments to be divorced from the admirable practices they were designed to signal, the social value of those accomplishments will be undermined. Not only will the intrinsic value be diminished for everyone that takes the shortcut, but the resulting disparity between the enhanced and unenhanced will call the fairness of the whole game (be it educational, recreational or professional) into question. If the extrinsic value of being causally responsible for certain accomplishments is high enough (like professional sports salaries), the intrinsic value of the admirable practices that a particular institution was designed to foster may even start to be called into question (20). For institutions

interested in continuing to foster the social values for which they have traditionally been the guardians, this has two alternative policy implications. Either they must redesign the game (of education, sports, etc.) to find new ways to evaluate excellence in the admirable practices that are not affected by available enhancements, or they must prohibit the use of the enhancing shortcuts. Which route an institution should take depends on the possibility and practicality of taking either, because ethically they are equivalent.

ENHANCEMENT AS AN ABUSE OF MEDICINE

Unfortunately, some of the social games we can play (and cheat in) do not turn on participants' achievements at all but on traits over which individuals have little control, like stature, shape, and skin color. The social games of stigmatization, discrimination, and exclusion use these traits in the same manner that other practices use achievements: as intrinsically valuable keys to extrinsic goods. Now it is becoming increasingly possible to seek biomedical help in changing these traits in order to short-circuit these games as well. Here, the biomedical interventions involved, like skin lighteners or stature increasers, are "enhancements" because they serve to improve the recipient's social standing, but only by perpetuating the social bias under which they originally labored. When "enhancement" is understood in this way, it warns of still another set of moral concerns.

On this interpretation, what makes the provision of human growth hormone to a short child a morally suspicious enhancement is not the absence of a diagnosable disease or the "species atypical" hormone level that would result: Rather it is the intent to improve the child's social status by changing the child rather than by changing her social environment (21). Enhancement interventions are almost always wrongheaded under this account because the source of the social status they seek to improve is, by definition, the social group and not the individual. Attempting to improve that status in the individual amounts to a moral mistake akin to "blaming the victim": It misattributes causality, is ultimately futile, and can have harmful consequences. This is the interpretation of enhancement that seems to be at work when people argue that it inappropriately "medicalizes" a social problem to use Ritalin to induce cooperative behavior in the classroom. In such cases the critics dispute the assumption that the human need in question is one that is created by, and quenchable through, our bodies, and assert that both its source and solution really lie in quite a different sphere of human experience.

This interpretation of the enhancement concept is useful to those interested in the ethics of personal improvement because it warns of a number of moral pitfalls beyond the baseline considerations that the enhancement–treatment distinction provides. Attempting to improve social status by changing the individual risks being self-defeating (by inflating expectations), futile (if the individual's comparative gains are neutralized by the enhancement's availability to the whole social group), unfair (if the whole group does not have access to the enhancement), or complicitous with unjust social prejudices (by forcing people into a range of variation dictated by biases that favor one group over others). For those faced with decisions about whether to attempt to enhance themselves or their children through gene transfer, this way of understanding enhancement is much more illuminating than attempts to distinquishing it from medical treatment, because it points to the real values at stake. Ideally, one should do no gene transfer that will make an existing social problem worse, even if exacerbating injustice would further one's own interests.

On the other hand, protecting these values is difficult in a pluralistic society like ours, since it means developing ways to policing individuals' complicity with suspect social norms (22). Under the historical shadow of state sponsored eugenics programs, our government is unlikely to promulgate lists of acceptable and unacceptable enhancements, even if the intent of the lists are to protect the interests of those who are unenhanced.

Moreover regulatory limits on access to genetic enhancements in the United States could be ineffectual if individuals could obtain enhancements abroad. In the past, we have seen a number of examples of persons circumventing U.S. laws to obtain medical care abroad, including seeking illegal abortions abroad prior to *Roe v. Wade*, purchasing unapproved AIDS drugs (RU486) and other pharmaceuticals abroad and returning with them to the United States (23), and traveling to foreign countries to obtain infertility treatments that were illegal or unavailable in the United States (24). Most nations' ability under domestic legal authority to control offshore access is extremely limited. Another approach would be to try to prevent people from travelling abroad in the first place in order to obtain contraband enhancements. Again, the United States arguably possesses the authority to restrict travel on grounds of national security (25). Would obtaining enhancements abroad amount to such a threat? Even if it did, travel restrictions have been imposed on travel to specific countries; it would be virtually impossible to restrict travel to a country for a specific purpose, if travel were permitted for other purposes.

CONCLUSION

Clearly, all of the ways of understanding "enhancement" as a moral concept that I've reviewed have limitations. However, all these interpretations do seem to be alive and well and mixed together in the literature on the topic. It is not possible to cleanly assign the different interpretations of "enhancement" to different spheres of ethical analysis. But there do seem to be some rough correlations that might be made. Thus the interpretations that contrast enhancement interventions with "treatments" seem most useful where it is the limits of medicine's expertise that is at issue. Whether medicine's boundary is defined in terms of concepts of disease, or in sociological terms as the scope of medical practice, or in terms of some theory of the human norm, this interpretation at least provides tools to draw that boundary. Moreover, all other considerations being equal, the line that it draws is the boundary of medical obligation, not the boundary of medical tolerance. Using

this tool, enhancement interventions like cosmetic surgery can still be permissable to perform as phsysicians, but also permissable to deny. This has important implications for social policy making about health care coverage, to the extent that society relies on medicine's sense of the medically necessary to define the limits of its obligations to underwrite care. Again, all other considerations being equal, this interpretation of the concept suggests that few enhancement interventions should be actively prohibited by society or foregone by individuals, even when they are not underwritten as a part of health care, since there is nothing intrinsically wrong with seeking self-improvements beyond good health.

By contrast, the interpretations of enhancement that focus on the misuse of biomedical tools in efforts at self-improvement seem the most relevant to issues in the personal, rather than professional, ethics of enhancement. Concerns about the authenticity of particular accomplishments are moral challenges to the individual but find little purchase in the professional ethics of biomedicine, with its focus on the physical safety and efficacy of its tools. The primary policy implications of this interpretation are for the social institutions charged with fostering particular admirable practices: Enhancement interventions that offer biomedical shortcuts to achievement force reassessments within those institutions of the values they stand for and the practices they have designed to foster them.

Finally, at the other end of the spectrum, enhancement interventions that seem to commit the moral mistake of trying to address social problems through the bodies of the potentially oppressed do seem to mark a stronger set of moral boundaries for all concerned. For biomedicine, this concept marks an epistemic limit beyond which medical approaches to problem-solving are not only unnecessary but conceptually wrongheaded. For individuals, parents, and society, these kinds of enhancement interventions risk either backfiring by exacerbating the social problems they are intended to address, or being futile, if they merely result in a shift of the normal range for a given social trait. Where the medicalization account of enhancements fits a given intervention, there does seem to be more justification for stronger warnings, protections, or prohibitions across the board, whether the interventions falls within medicine's boundaries or not (26).

ACKNOWLEDGMENT

The research conducted for this article was supported in part by NIH grant R01 HG-1446-02. I am grateful to Tom Murray, Maxwell Mehlman, Erik Parens, and David Smith for useful discussions of the text and many of the ideas presented here.

HUMAN ENHANCEMENT USES OF BIOTECHNOLOGY, ETHICS, THERAPY VS. ENHANCEMENT

OUTLINE

INTRODUCTION

In recent years ongoing practices as well as new or anticipated developments in reconstructive surgery, sports medicine, psychopharmacology, human gene therapy, and emerging areas of biomedical engineering aim at altering the appearance of the body; increasing the efficiency, capacity or productivity of various human functions or performances; and changing features of the personality or mood. Conveniently (if imprecisely) referred to as enhancements, these phenomena, insofar as they are implemented through the institutions and practices of medicine, raise the question of whether their pursuit can be distinguished from the treatment of diseases, and if so, what normative significance, if any, such a distinction has. At stake in this distinction are important ethical and policy issues. As various authors have argued, the distinction between therapy and enhancement is commonly invoked to determine the composition of a basic health care insurance package and to limit the medicalization of human life (1).

THEORIES OF HEALTH, DISEASE, AND ENHANCEMENT

It may seem obvious that, for example, a chemotherapy regimen to treat cancer and a pharmacological agent or (should it become possible) a gene transfer to increase one's powers of concentration fall under radically different categories of intervention. It is natural for many to think of the former as the treatment of a disease and the latter as the enhancement of a capacity. However, there has been significant disagreement over how to account for such a difference and even whether it can be maintained at all in the end. The controversy derives from rival theories of disease in the philosophy of medicine. These include naturalist theories for which disease is a value-free concept grounded in the biological and medical sciences, and normativist theories for which disease is a value-laden concept referring to certain states that individuals (or groups or societies) seek to avoid or overcome. There are strong and weak versions of each type of theory.

Strong Naturalism

The most influential strong naturalist theory is that of Christopher Boorse (2,3). Analyzing what he takes to be the traditional medical understanding of disease, Boorse argues that (*1*) health (or normality) is the absence of disease (or pathology); (*2*) because the medical sciences are based on physiology, pathology is defined with reference to the survival and reproductive competence of the organism as the goals physiology studies (recognizing that other goals, e.g., survival of genes or ecological equilibrium, may be important for other branches of biology); (*3*) a pathology is a reduction of a part-function at any level of the interlocking hierarchy of functional processes (ranging from organelle to cell to tissue to organ to gross behavior) below its statistically species-typical range as determined with reference to the relevant age and sex class. While other theories of disease make use of a statistical range to define normality and pathology, Boorse's emphasis on physiology with its notion of a species design consisting of interlocking functional processes ultimately explained in terms of their contribution to survival and reproductive competence makes him a naturalist.

Boorse's theory has the advantage of enabling one clearly to distinguish pathologies from other characteristics. For example, to cite David Allen and Norman Fost's now-familiar scenario (4), one can distinguish short stature due to human growth hormone deficiency (a part-function operating below the normal range) from short stature as an inherited trait reflecting normal human genetic diversity (assuming that a currently unknown genetic dysfunction is not the cause). Similarly Boorse's theory enables one to distinguish, with James Sabin and Norman Daniels (5), a case of shyness characterized by interpersonal sensitivity and defensive withdrawal due to a bipolar disorder from shyness that simply falls on one end of a normal distribution of social adaptation. Moreover, because many deformities (including harelip and cleft palate) typically involve dysfunction as well as deformity, they may be distinguished from other features (ranging from male baldness to much more severe structural defects) that do not involve dysfunctions. And because age is used as a reference group to determine pathology, dementia among older adults (an abnormal condition) can be counted as a disease while osteoporosis among postmenopausal women (a normal condition) is not. Finally, part-functions operating below the normal range can be distinguished, using this theory, from those operating at the low end of the normal range. For each of these pairs, improvements of the first element in the pair would count as therapies, while improvements of the second element would be considered enhancements.

How would Boorse's theory fare in view of more complex cases? Actual and hypothetical developments in human gene transfer raise the question of how the theory would evaluate the enhancement of certain functions in the course of treating or preventing disease. For example, Juan Manuel Torres describes a multidrug resistance protocol that enhances the capacity of the bone-marrow cells of cancer patients to resist certain side effects of chemotherapy (6). Would this be considered therapy or enhancement? While the protocol involves raising a part-function beyond the normal range, this enhancement (as Torres argues) is simply a necessary part of a procedure aimed at the removal or mitigation of a severe pathology. So long as the various elements or phases of a course of treatment are explained and evaluated in terms of the overall process or its end, there is no reason not to describe the intervention as part of the treatment of a disease. The same reasoning would apply to measures such as immunizations, which enhance an immune function as a necessary condition of preventing specific pathologies.

But what about an intervention such as the one proposed by Leroy Walters and Julie Palmer, which would aim not at a specific pathology but at increasing the capacity of the immune system as a whole to resist pathology more generally (7)? Would this constitute treatment or enhancement?

Nothing in Boorse's theory suggests that the category of pathology in medical science is restricted by the level and scale of the intervention, the complexity of the part-function involved, or the nonspecificity of the pathology. Would enhancing the immune system in this way nevertheless fall under the somewhat dubious category of positive health, that is, a state beyond the mere absence of pathology? Probably not, since such an intervention would not seem to violate Boorse's three criticisms of notions of positive health, namely that such notions lack a clear limit (in this case, autoimmune disorders would establish the limit of improvement), involve trade-offs among incompatible positive goals (the goal in this case still refers to freedom from disease rather than to a positive ideal of somatic good), and are value laden in a way health as the absence of disease is not (8). Boorse's theory, then, seems capable of handling all of these difficult cases. However, in order to cover these cases, it would be more precise to follow Walters and Palmer in distinguishing between health-related and non-health-related enhancements.

A final question for Boorse concerns the distinction between genetic disease and genetic variation. Returning to an earlier example, how would his theory greet the discovery of one or more genetic patterns linked with short stature? The mere existence of such a pattern could simply be an instance of human diversity and would therefore be insufficient for designating that pattern as a pathology. But what if the pattern resulted in a low output or inhibited performance of some part-function that depressed the latter below a normal range? Since disrupted part-functions at any level of the organism count as pathologies, it would appear necessary to describe the condition as such and to consider an appropriate therapy as the treatment of a disease. This example illustrates how genetic knowledge could require one to reclassify as therapies many interventions that would now, on Boorse's theory, be considered enhancements.

Boorse distinguishes sharply between the theoretical level of medical science (specifically, pathology) and the clinical level of medical practice. This raises the question of what normative significance his theory has for policy and medical practice. Boorse recognizes that his is a theoretical and not a clinical concept of disease. On the one hand, many minor, merely local or compensated pathologies (e.g., small benign internal tumors, minor warts or scars, mild cirrhosis of the liver) are undiagnosable and/or have no gross effects on disability, deformity or distress; on the other hand, physicians legitimately perform functions (e.g., childbirth, male circumcision, treatment of osteoporosis) other than the treatment of disease. Moreover he recognizes that diagnostic and therapeutic acts are always subject to the moral criteria elaborated in the bioethics literature; clinical pathology, unlike pathology as a theoretical medical science, is not value free. However, Boorse describes the removal, mitigation, and prevention of pathology as the *core* of medicine while other activities (including enhancement) are *peripheral*: not necessarily illegitimate, but more controversial and lacking the objectivity and urgency of the treatment of pathology. He argues that the treatment of disease constitutes a presumption for clinical medicine because health (biological normality, i.e., absence of pathology) is almost always in the interests of patients and is neutral to most choices of activity and lifestyle. When these conditions fail to hold — when health is not in the interest of a patient or is not neutral with regard to activity or lifestyle — the presumption is defeated and other values may take priority over health.

However, it is doubtful that the treatment of disease constitutes a presumption even on Boorse's own account. The interests or values of the patient, and not the concept of disease, appear to be the normative core of clinical medicine; they determine when and to what extent health is the legitimate goal of clinical practice. Of course, it would be wrong to conclude from this alone that enhancements are justified by the interests or values of patients — that health should not be pursued in some cases does not entail that enhancement should or may be pursued — but there are some cases, such as the treatment of osteoporosis in postmenopausal women, where enhancements clearly should be pursued. It would be odd and even irresponsible to describe these cases as the overriding of a presumption and lacking in urgency and objectivity.

For all of these reasons it is questionable even on Boorse's account whether the objectivity of pathology in the theoretical sphere can simply be carried over into the clinical sphere (even if, as seems likely, biological normality will be the highest priority of clinical practice in the majority of cases). Hence, while Boorse gives a convincing argument for a theoretical distinction between treating a disease and enhancing a trait, the usefulness for policy makers and clinicians of a theory that places treatment of osteoporosis in the same category as facelifts is minimal at best. It says nothing about which health care services should be covered or what limits should be placed on medicalization.

Weak Naturalism

Not all forms of naturalism assume that science requires value- free concepts of health and disease that leave a gulf between medical theory and medical practice. Leon Kass's naturalism differs from Boorse's in two crucial respects (9). First, health is not simply the absence of disease but the wholeness and well functioning of the organism. There are degrees of health, and health can be promoted and maintained even in the absence of disease. The notion of wholeness cannot be captured in a physiological description and, especially in Kass's later essays, involves an experiential oneness of the lived body.

Nevertheless, this concept is still biological. It is manifested in phenomena such as the self-healing and pain-response capacities of organisms, and while Kass describes health as the fitness of the organism for its characteristic kinds of activity, he does not, as normativists do, define health in terms of what individuals

or societies value. The difference between health and mere absence of pathology, the emphasis on wholeness with its abstraction from specifiable part-functions, and the lack of a biostatistical normal range would all seem to encourage Kass to welcome health-related enhancements. His theory would seem especially hospitable to those health-related enhancements (e.g., improving the performance of the immune system) that target the organism as a whole. However, Kass never argues for categorizing any such enhancements under the pursuit of health, and his view of medicine as most properly cooperative with, rather than transformative of, the body's own processes seems to cast a general suspicion on the entire enterprise of technological enhancement (assuming that cooperation and transformation can be consistently distinguished).

Second, Kass formulates a biology grounded on reflection on formal and final causes, thus closing the gap Boorse opened between value-laden medical practice and the value-free science on which medicine is based. No longer limited to physiology with its narrowly focused concern with individual survival and reproductive competence, medicine for Kass is concerned with "powers and desires for work, friendship, love, learning, awareness, mobility, thought and memory, self-command, and the sheer enjoyment of life." Health is not the realization of these goods, but the fitness of the organism for pursuing them. The biology medicine presupposes thus constitutes a broad view of human fulfillment — one that would appear to authorize medicine to extend far beyond the domain of health and disease and would appear to endorse a wide range of non-health-related enhancements. Nevertheless, Kass is highly critical of the use of medicine to fulfill individual preferences or desires, to advance societal priorities or programs, or to alter or replace basic physical processes or social institutions.

The problems with Kass's naturalism follow from the indeterminacy, vagueness, and ambiguity of his major claims. First, it is unclear whether in the end Kass's emphases on degrees of health and on health as wholeness differ significantly from Boorse. Within a biostatistical normal range, there are degrees of difference between those at the higher and lower ends; in this sense health even for Boorse is not *merely* the absence of disease. Health maintenance and promotion, highly commended by Kass, either merely prevent or mitigate disease, or they advance one from a lower to a higher level on a normal range (i.e., they enhance one, in the health-related sense of enhancement). The difference with Boorse seems to be an optical illusion produced by fundamentally different theoretical orientations. Boorse exhibits the modern tendency to treat pathology as basic, with death as its ultimate epistemological and ontological condition. Health is defined negatively, as the absence of pathology, namely normality, a biostatistical notion. Kass aims to recover what he believes is a classical tradition in which health is basic and is not mere biostatistical normality but greater or lesser fitness for the characteristic activities of the organism. Hence what Boorse would simply describe as statistically diverse levels of a single state of being normal, Kass would describe as different degrees of health. Of course, Kass may still wish to distinguish pursuits of higher degrees of health from enhancements by distinguishing those enhancements that cooperate with nature from those that transform nature. But it is not clear what would determine such a distinction. Does it ride on the degree of alteration, on the extent to which the altered capacity exceeds the human average for that capacity, on the type of intervention involved or the technology it employs?

Second, it is unclear whether Kass can distinguish his broad list of functions that constitute health from the desires, preferences, ideals, projects, and effects that for him fall outside the pursuit of health. Kass is aware of the difficulties involved in giving an account of what would constitute a healthy power or desire for, say, work or learning without specifying the particular kinds of work or learning that are the object of individual desires, aptitudes or commitments. But without such a distinction it seems impossible to distinguish the pursuit of health from what Kass must regard as the pursuit of idiosyncracy, or health from enhancement. Health would be relative to the particular activities and goals of individuals, making Kass a normativist. One way out of this problem would be to try to distinguish general purpose interventions — those that improve capacities needed for all or nearly all ways of life — from idiosyncratic interventions that equip one for a limited range of ways of life at the expense of others. However, in addition to problems involved in making and defending this distinction beyond the obvious cases of treating serious disease, its definition of health in terms of ways of life would move Kass into the normativist camp once again.

Third, as Kass's list of human capacities and activities indicates, health can affect almost any human activity or practice. It is likely that enhancement technologies will be increasingly capable of improving "powers and desires" for these capacities and activities indefinitely. Unless, then, he can determine what levels of realization are appropriate for each capacity and what role, if any, medical intervention should play in their realization, the medicalization of these capacities and activities will go virtually unchecked. Finally, even when Kass's reflective biology leads him to approve certain procedures, such as in vitro fertilization (IVF), that are not strictly health-related (IVF does not treat infertility, and infertility, for complex reasons, is not actually a matter of disease and health for Kass) but that fulfill desires that are, according to his biology, natural, he is unsure whether physicians should perform them or not. He seems torn between his conviction that medicine should ideally restrict itself to the pursuit of health and his belief that bringing such procedures under the umbrella of medicine is the best strategy for curtailing their abuse.

In sum, despite his effort to close the gap between the natural and the normative, it is not possible to derive from Kass any clear guidelines regarding basic health care coverage or the limits of medicalization.

Strong Normativism

Strong normativist theories permit a much simpler treatment of the therapy–enhancement distinction because most of these theories deny that any such distinction

can be made in a publicly binding way. H. Tristam Engelhardt, Jr. repeatedly claims that problems become medical problems when (*1*) they appear as a failure to achieve a valued state such as a certain level of freedom from pain or anxiety, a certain level of function, a particular realization of human form or grace, or an expected span of life, and when (*2*) they are problems of a sort that cannot be willed away and are embedded in a web of anatomical, physiological, or psychological causal forces that are open to medical explanation and manipulation (10). This does not prevent Engelhardt from making distinctions among such problems. First, some conditions are likely to be disvalued in nearly all cultures and environments and in light of nearly all human purposes, while others will be disvalued only under some such circumstances. Second, the judgment that a condition is a matter for medicine rather than, say, law or religion will for some conditions (e.g., appendicitis) be a virtually unavoidable judgment, while for other conditions (e.g., alcoholism or criminal behavior) the plausibility of such a judgment will be contested. Third, there are both negative senses of health (the absence of particular diseases, deformities, and dysfunctions) and positive senses (enhancement of capacities, augmentation of pleasures, etc.).

It is natural to refer to the former phenomena in each of these three pairs as treating, describing, or diagnosing a disease and the latter phenomena as involving the enhancement of a trait. But for Engelhardt this could be misleading. To group phenomena under one or the other of these categories merely reflects, respectively, the range of contingent agreements and disagreements concerning which states are and are not disvalued; the purposes and circumstances that make one or another judgment more useful and plausible; and a particular view of which among the diversity of human traits are species typical, normative, and natural. Only within a particular substantive view of the good is it possible to determine which states genuinely constitute values and disvalues; what properly comes under the domains of medicine, law, and religion; and where to draw the line between negative and positive health. It follows that the decisions regarding the composition of insurance coverage and the proper limits of medicalization can be made only within particular communities with their substantive views of the role of medicine in the overall human good.

The plausibility of Engelhardt's account follows from the insuperable difficulties both strong and weak naturalists face in arguing, from within naturalism, for any normatively binding force for their distinctions between therapy and enhancement. Its implausibility follows from its failure to understand the relation of medicine to the sciences of physiology and pathology. In his criticism of Boorse, Engelhardt argues that to define disease in terms of what affects the individual is arbitrary in light of what evolutionary biology tells us about nature's preference for species or genes over individuals. However, Boorse argues that disease is a concept in the medical science of pathology, itself based on physiology, a science which focuses on goals of individual organisms (specifically, on their survival and reproductive competence). It is therefore a mistake to argue that concepts of disease arbitrarily privilege the individual organism over the species. Of course, it is true, as Boorse admits, that the choice medical practice (usually) makes to combat disease rather than to serve the evolutionary fitness of the human species is a normative choice. But this proves only that medicine (as a clinical practice) is normative; it says nothing about disease (11).

Similarly one may, as Engelhardt (on the basis of his views of the philosophy of science and the history of medicine) does, reject Boorse's claim that physiology and pathology are altogether value free, question whether the concept of disease they support can in difficult cases be distinguished as rigorously from other states, as Boorse assumes, and deprive the concept of disease of any normative significance for the practice of medicine — one may do all of this without denying that medicine, on the basis of physiology and pathology, can in principle distinguish disease from other states of the organism. Of course, Engelhardt could concede this and still argue that basic health care coverage and the limits of medicalization must both be established by particular communities. However, with regard to insurance coverage, Engelhardt himself admits that many conditions are regarded with near (though still contingent) universality as disvalues. If so, it is reasonable to assume for purposes of public policy that most serious pathologies would fall under this description and thus be eligible for coverage, while also allowing trade-offs for more highly contested conditions and leaving room for particular individuals and communities to determine the rest (perhaps even in the form of vouchers if one's theory of justice demands, as Engelhardt's does not, a level of public support of health coverage that extends beyond what most people regard as serious conditions).

Medicalization is more difficult. While particular communities could be left to determine for themselves what role medicine should play in their pursuit of what they understand is the human good, it will be necessary for many policy purposes and for purposes of criminal and tort law to make public decisions on the proper domain (whether that of law, medicine, or religion) of conditions such as alcoholism and socially disruptive behavior.

Weak Normativism

Not all normativist theories deny the possibility of public agreement in principle on the distinction between therapy and enhancement. K. Danner Clouser, Charles Culver, and Bernard Gert define a malady (an inclusive term covering what injury, illness, sickness, disease, trauma, wound, disorder, lesion, syndrome, etc. have in common) as a condition of an individual, other than his or her rational beliefs and desires, such that he or she is incurring or at significant risk of incurring a harm or evil (death, pain, disability, loss of freedom, or loss of pleasure) in the absence of a direct sustaining cause (12). Maladies are harms (or significant risks of harm) that are caused in a certain way and that rational persons want to avoid unless they have good reasons not to avoid them. The normative core of this concept is clear in the notion of a harm that one wants to avoid. But unlike strong normativism, the reference to what rational persons want in the absence of good reasons to the contrary stakes a claim to universality. Maladies are disvalued states, but the disvalue is objective,

assuming that the underlying theory of rationality, which Gert develops elsewhere (13), is true.

The notions of harm, significant risk, and absence of a direct sustaining cause all have significance for the distinction between therapy and enhancement. Of their various categories of harm, Clouser, Culver, and Gert devote the most attention to disability. Here they differ from Boorse in two important respects. First, rather than specify age as a reference class against which to evaluate a level of function, they highlight for each ability the stage in normal development when that ability is at its peak. Prior to that stage, to lack the ability is to have an inability; after that stage, to lack it or lose it constitutes a malady. This means that when humans of very advanced age lack or lose an ability (e.g., to walk a certain distance), they suffer a malady even if, say, 98 percent of those in their reference class lack this ability. To attempt to return such individuals to, or to maintain them at, a level of ability that is normal for the species as a whole, regardless of age, is therefore to treat a malady, not to enhance a characteristic. This denial of the relevance of age leads Clouser, Culver, and Gert to classify menopause as a malady, since it constitutes the loss of an ability women normally have.

Second, what counts as lacking or losing an ability is determined by a statistical normal range, but without a concept of species design. This means that a person who develops an extraordinary ability, such as running a marathon in fewer than three hours, and then loses that ability does not suffer a malady (unless her ability is so compromised that it falls below the normal range). It also means that statistical normality, not function, determines which reactions to environmental factors and what levels of risk are maladies. Since nearly everyone tends to become short of breath in a smoke-filled room and to attract mosquitoes, these conditions are not maladies; for the same reason, improving the performance of the immune system would constitute an enhancement.

The concept of a distinct sustaining cause is also crucial for distinguishing maladies from other conditions. For example, individuals whose stature falls below the normal range suffer a variety of discriminatory attitudes and practices. These constitute a distinct sustaining cause of the suffering: when these attitudes and practices are not in effect, the harm disappears. Thus this condition is analogous to the pain that accompanies a wrestler's lock and disappears when the hold is released, and is distinct from a genuine malady such as an allergy, which also involves factors external to the individual but which persists for a period of time even after these external factors are removed.

The harms individuals suffer due to skin color also have a distinct sustaining cause in social attitudes and thus do not constitute a malady. What, then, of the harms individuals suffer due to extreme deformities or disfigurations? Clouser, Culver, and Gert argue that unlike responses to skin color, which are learned responses and vary among societies, responses to these conditions are "universal," spontaneous, and "natural," indeed "like the natural environment." This argument is confusing, but the point seems to be that one may distinguish allergies and severe deformities from short stature and skin color by arguing that responses of the environment to the former are "normal" and intractable, while responses to the latter are variable and alterable. If this is so, the causes of the latter conditions are distinct from the individual in a way that the causes of the former conditions are not. Assuming that responses to deformity can be assimilated to nature in this way (a major assumption), gross deformities and allergies would be maladies while short stature and skin color would not.

While critics of the Clouser-Culver-Gert theory have attacked as counterintuitive or sexist its designation of pregnancy (which involves significant risks of various maladies) and menstruation (which involves pain and discomfort) as maladies (14), the features outlined above also have problematic implications. The problems follow from the effort to distinguish between maladies and normal human variation using the notions of a normal range and absence of a distinct sustaining cause, but without the notions of species design and references classes found in Boorse's strong naturalism. For this theory, procedures aimed at the postponement or reversal of menopause (perhaps no longer an outrageously unlikely prospect) would constitute treatment of a malady, but curing or relieving a mild asthmatic condition that prevents a marathon runner from competing at her previous level would not. A near-universal risk of succumbing to a virus, being statistically normal, apparently would not count as a malady. Gross deformities would count as maladies only if it could be proved that negative responses to them are natural to human beings.

In fairness to this theory, Clouser, Culver, and Gert do not recommend discarding all of the terms for which malady constitutes the commonality. It may be possible, then, to regard the marathon runner's asthma as a disease though not a malady, and its relief or cure as a therapy and not an enhancement. However, this simply raises the questions of how the theory *would* distinguish treating a disease and enhancing a trait and, more generally, what advantage the concept of malady has if it cannot cover admitted instances of diseases with significant effects.

Clouser, Culver, and Gert claim that the concept of malady does have several advantages over rival theories, but this is questionable. Two of the advantages claimed for it, namely the recognition that abnormality is neither a necessary nor a sufficient definition of disease (or related terms) and that malady applies equally to mental and physical conditions, are shared by all of the theories examined here. A third alleged advantage, that the concept of malady could be useful for setting precendents and negotiating borderline cases in determining insurance coverage, is doubtful: It would be an unusual insurance plan that would cover reversal of menopause but not asthmatic conditions of athletes. The fourth alleged advantage would occur if genetic interventions make it possible to enhance properties such as height, intelligence, memory, and strength: They argue that the concept of malady may help determine whether unenhanced (but still statistically normal) levels of these properties constitute deficiencies or not. But any theory that makes use of a normal range will offer this benefit. The more difficult

question is whether these properties are candidates for disease or malady or simply represent human diversity. This question turns not on the differences between malady and disease but on whether it is more plausible to link the normal range to a concept of species design (as Boorse would) or to the absence of distinct sustaining causes.

Finally, Clouser, Culver, and Gert quite plausibly deny that any concept of malady or disease can establish the proper limits of medicalization by determining what medicine should and should not choose to provide. In sum, this theory does not seem to offer, in comparison with other theories, any advantages that would offset its disadvantages.

ARGUMENTS FOR THE NORMATIVE SIGNIFICANCE OF THE DISTINCTION

The foregoing discussion indicates the unlikelihood that a theory of health, disease, and enhancement will succeed in determining which health care services should be covered or what limits to medicalization should be observed. Other arguments begin with a normative principle determined independently of such theories and then attempt to show how the principle requires a distinction between therapy and enhancement, at least in some contexts.

Risk–Benefit, Just Allocation, Discrimination

Two common arguments for distinguishing between therapy and enhancement and for excluding the latter from the practice of medicine refer to the risks of enhancement technologies and the problems they pose for just allocation and discrimination. W. French Anderson (15) and Juan Manuel Torres (16) invoke both arguments to assert the normative force of the line between therapy and enhancement in gene transfer technology, though the arguments and their shortcomings are applicable in other areas of medicine as well. Anderson focuses on the different levels of medical risk involved, respectively, in adding a normal gene to overcome the effects of a nonfunctioning gene and adding a normal gene to increase the productivity of a gene functioning at a normal level, and on the relation of these risks to the likely benefits of each kind of intervention, concluding that only in cases of very serious disease do the benefits outweigh the risks. However, this is only a temporary rationale for a line between therapy and enhancement.

It is reasonable to expect that the enhancement of normally functioning genes will gradually become safe enough that the risk–benefit ratio will increasingly favor at least some uses of gene transfer for non-health-related enhancements, while some uses of gene transfer for the treatment of disease will have unfavorable risk–benefit ratios. In this regard gene therapy will likely resemble every other branch of medicine where lines drawn by risk–benefit ratios cut across the line between therapy and enhancement. Anderson also points to the important and difficult questions of who should benefit from enhancements and how to avoid potentially discriminatory uses of them, arguing that until we resolve these questions we should limit our genetic interventions to the treatment of serious diseases. However, while these are urgent questions in nearly all areas of medicine, our inability to resolve them has not prevented us from intervening into less serious nongenetic conditions without a consensus on who should benefit from such interventions, or from carrying out other interventions and practices that could be accompanied by the discriminatory effects Anderson and Torres cite (i.e., pressure to undergo treatment or to adhere to eugenic goals, exacerbation of the gap between haves and have nots).

Genetic enhancement is neither a necessary nor a sufficient condition for moral problems of these kinds; such problems have occured in the past and present without genetic enhancements, and they need not occur, or even be exacerbated, because of genetic enhancements. It is true that gene transfer technologies could provide new and potentially dangerous occasions for such problems, resulting in discrimination of a much greater magnitude than at present. However, coerced treatment and eugenics would require extensive use of gene transfer in the population, which Torres himself considers highly unlikely, while the odds that gene transfer will expand the gap between haves and have nots more than a nonmedical enhancement such as education already does (with the enthusiastic complicity of many of those who argue against genetic enhancements on these grounds) is just as unlikely.

The Threat to Athletic Competition

Another context in which the distinction between therapy and enhancement is considered relevant is sports medicine. The issue, noted by Dan Brock (17), Eric Juengst (18), Thomas Murray (19), and others, is whether the use of sports medicine for purposes beyond the treatment of injuries destroys the very definition of the activity itself or the significance of the athlete's achievement. However, sports medicine appears to have developed to the point that the line is no longer drawn between therapy and enhancement but between different types and different levels of enhancement. For example, many nutritional supplements aimed at improving the performance of one or another somatic capacity are currently permitted in a number of sports. If effective, these supplements clearly enhance performance; they do not treat an injury or related condition. Of course, other nutritional supplements are banned. But usually this is either because they are deemed to be unsafe, or to have an unfavorable risk–benefit ratio, or because the level of advantage they offer is deemed to be unfair to other competitors or inconsistent with the meaning of the activity, not because they go beyond the treatment of injuries and related conditions. Clearly, then, the distinction between permitted and banned nutritional supplements occurs within the category of enhancements; few among those responsible for the oversight of these sports are advocating a ban on nutritional supplements altogether (if indeed the latter could even be consistently distinguished from ordinary dietary measures).

Fair Equality of Opportunity

Finally, the therapy-enhancement distinction is invoked to determine what medical services a just system of health

care allocation is obligated to provide. Norman Daniels argues that because disease and disability significantly affect the opportunities open to individuals, health care has a central function for justice (20,21). He defines justice in Rawlsian terms of fair equality of opportunity, which requires that opportunity be equal for persons of similar skills and talents (although the resulting inequalities are mitigated by the difference principle in Rawls's theory, which holds that these inequalities must work to the advantage of the least well off) (22). Justice therefore must protect individuals against factors, such as race or sex discrimination and disease or disability, that restrict the range of opportunities that would otherwise be open to persons of similar skills and talents. Justice requires access to health care services that prevent, cure, palliate, or compensate for diseases and disabilities. However, fair equality of opportunity does not require provision of health care services for all conditions that create inequalities of opportunity but only for conditions of disability or disease (i.e., for pathologies).

Daniels's position turns on two points: the principle of fair equality of opportunity itself, and a rationale for including pathologies but not disadvantageous normal human traits in the set of conditions for which society is obligated to provide health care services. Daniels recognizes that his principle of fair equality of opportunity is vulnerable to those who point out that because both pathologies and skills and talents are due significantly, though not entirely, to the natural lottery, they should be treated identically so that either society is obligated to remedy restrictions of opportunity in both cases (social welfarists) or in neither case (libertarians). However, Daniels's arguments against these opponents are largely circular: he repeatedly appeals to certain actual beliefs and practices that reflect his intuitions to criticize other actual beliefs and practices that do not. Moreover, his theory lacks a convincing rationale for excluding disadvantageous traits from fair equality of opportunity. If justifiable, such an exclusion would serve two important purposes: it would keep health care expenses in check (as Daniels notes), and it would help preserve human diversity against the leveling effects of the quest for competitive advantage.

In presenting his case for this exclusion, Daniels quite plausibly draws on Boorse to distinguish pathologies from traits. However, it is not clear why this distinction should matter to fair equality of opportunity. Considering Allen and Fost's example, Daniels observes that short stature has roughly the same effect on equality of opportunity whether it is caused by human growth hormone deficiency (a pathology) or simply reflects human genetic variation. He notes further that in both cases it is equally the result of the natural lottery and equally the object of social prejudice.

Why then should this distinction count for purposes of justice? In defense of the distinction, Daniels simply reasserts his principle of fair equality of opportunity, which (he claims) recognizes from the outset that skills and talents and (he now adds) "other capabilities" are unequally distributed. Styling this view "the standard model" which (he alleges) reflects "our actual concerns" and "our consensus," Daniels in effect tries to salvage the normative significance of the distinction between therapy and enhancement in these cases by pleading that the matter has already been settled in favor of the normativity of this distinction. However, even if this were in fact settled (which it is not), whether the settlement is defensible is precisely what the example calls into question.

Having appealed to an allegedly prevailing adherence to his rule of exclusion from basic coverage, Daniels goes on to undermine the credibility of his own adherence to it by arguing that if an inexpensive treatment for improving the cognitive capacities of children becomes available, there would be compelling reasons — he mentions the enhancement of education, the narrowing of the gap between children at the low end of the normal range and others, and the increase of social productivity — to seek enhancement in this way. Even if one ignores the unlikelihood that such a treatment would in fact realize the second benefit, one must wonder about a theory of fair equality of opportunity that invokes the therapy–enhancement distinction to treat as unequals two individuals who are equally the victims of the natural lottery and social discrimination while it violates that distinction to serve socioeconomic ends and advance the status of persons already in the normal range.

ARGUMENTS AGAINST THE NORMATIVE SIGNIFICANCE OF THE DISTINCTION

Critics such as Kathy Davis (23) and David Frankford (24) seek to show how the therapy–enhancement distinction could, if adopted in the formulation of health care policy, be used by insurers and bureaucrats to deny genuine health care needs on the grounds that they are enhancements rather than therapies. Neither Davis nor Frankford wishes to abandon the distinction, only to ensure that it is applied with context-sensitive judgment. Frankford questions whether such context sensitivity is possible in the policy arena, while the examples Davis draws from the Dutch health care system point to the same conclusion despite her hopes to the contrary.

CONCLUSION

The result of this critical survey is that distinguishing between therapy and enhancement is easier than it is often assumed to be while articulating and defending any normative force for this distinction is more difficult than it is often assumed to be. The implication is that the therapy–enhancement distinction has little if any relevance for determining basic health insurance coverage or the limits of medicalization. With regard to insurance coverage, some procedures that are technically enhancements according to current medical science (e.g., treatment of osteoporosis for postmenopausal women) are almost certainly of higher priority in many cases than some procedures that treat diseases. Fortunately, while the therapy–enhancement distinction does not help in this or in many other cases, it is possible to arrive at a rough agreement on which conditions seriously inhibit almost any way of life, and thus should, in principle, be covered in a basic plan while permitting trade-offs

when there are reasonable disagreements even at this level. If one's theory of justice does not permit all of these conditions to be covered, one may be forced to prioritize these conditions, after the example of the Oregon Medicaid program. If one's theory of justice requires funding basic coverage beyond these conditions, vouchers would enable individuals or groups to determine the composition of this additional coverage in accordance with their views about the relation of various somatic conditions to valued activities or ways of life. Medicalization and the normalization that accompanies it present a more difficult problem. To determine the appropriate limits of existing and emerging technologies will require a view of the ethical significance of the body and its capacities and limitations, and of the place (if any) of the discourses and practices of biomedicine in realizing these capacities and responding to these limitations (25).

OUTLINE

INTRODUCTION

Genetic enhancement, whether in the form of somatic enhancement for adults or for children, genetic selection for enhancement, or germ cell enhancement, may give the recipients significant social advantages. It is impossible at this time to be certain which traits will prove susceptible to genetic enhancement, but they may include physical traits, such as beauty, stature, strength, and stamina,

personality characteristics such as charm, cheerfulness, charisma, confidence, and energy, and mental capabilities, including memory, intelligence, and creativity.

These improvements obviously will be in great demand. But how widely available will the technologies be that make them possible? Some genetically engineered drugs that produce somatic enhancements may be relatively affordable. Others may not. Genetic selection for enhancement in which fetuses were tested in utero might not add much to the cost of performing genetic tests to detect abnormalities or disease (1). This might make it, and the accompanying abortions, the "poor person's" genetic enhancement technique. But any enhancements performed on embryos would be expensive, since they would include the costs of in vitro fertilization (IVF). Currently IVF costs average $25,000, and there would be added costs of the genetic manipulations, which are likely to be substantially greater, particularly when the technology is first introduced.

Genetic enhancement is not likely to be paid for by any public or private health insurance program or policy. This is evident from the lack of third-party payment for cosmetic medicine, which is perhaps the most analogous biomedical technology currently available. The legislation governing the Medicare program contains a general prohibition against paying for "items or services ... which are not reasonable and necessary for the treatment of illness, or to improve the functioning of a malformed body part" (2), and includes a specific exclusion for "cosmetic surgery" (3). States have adopted the same coverage exceptions under their Medicaid programs (4). Private health insurance plans also do not cover cosmetic medicine; the language in the author's high-option Blue Cross policy is typical: "Coverage is not provided for services and supplies ... for surgery and other services primarily to improve appearance or to treat a mental or emotional condition through a change in body form...."

Even if the government wanted to provide general access to genetic enhancement, the cost would prove prohibitive. Widespread access to enhancements such as preimplantation selection or manipulation that depends on access to IVF currently would amount to $120 billion per year for the IVF services alone (5). Somatic enhancement would not be cheaper. A single somatic enhancement in the form of a substance like human growth hormone, which currently costs about $30,000 per child per year (5), would amount to $22 billion a year just to provide to the 1.7 million children who were in the lowest 3 percent of the population in terms of height (6). The figure for multiple somatic enhancements over a number of years for the entire population would be astronomical.

The high cost and the lack of coverage by third-party payment plans, of course, does not mean that no one will access genetic enhancement but only that it will be limited to persons who can purchase enhancement with their own assets. This gives rise to two related problems. The first is inequality, which is also discussed in another entry; the second is unfairness. The issue of fairness would arise at the micro level if genetically enhanced individuals compete for scarce resources against, or find themselves in a conflict of interest with, those who are unenhanced. Genetic enhancement could confer a decisive advantage in competitive circumstances. How should society respond to the potential unfairness?

SPECIAL NATURE OF GENETIC ENHANCEMENTS

In a society whose members believe in the possibility of upward social mobility, people seek to better themselves and their children. They educate themselves and try to obtain the best education they can for their children. They may try to marry "upward," hoping for a mate who will increase their opportunities, social standing, and wealth. They push themselves and their children to cultivate and make the utmost use of their talents.

Many of these efforts take the form of medical or pharmaceutical interventions. People take drugs to improve their athletic and cognitive performance. They subject themselves to surgery to improve their appearance. Some of these activities, such as selecting one's mate, have at least an indirect influence on the genetic makeup of succeeding generations.

Against this background of current enhancement practices, what is so exceptional about genetic enhancement? Society has had plenty of experience coping with the social implications of efforts at self-improvement. While society's response has not always been adequate or successful — witness the difficulties in trying to control the use of performance-enhancing drugs in sports — will the problems created by genetic enhancement be so different that they require special attention?

Of course, even if we felt that wealth-based access to genetic enhancement did not constitute a new kind of threat to social equality, society might still need to respond to it in a vigorous fashion. The additional inequality arising from genetic enhancement, when added to existing sources of inequality, might tip the scales in favor of social unrest. At least, we might well want to monitor the situation closely, and stand prepared to respond if necessary.

Yet in a number of important ways, genetic enhancement does differ from previous sources of inequality and unfairness. Taken together, these differences justify a significantly heightened level of concern, if not outright alarm:

1. The probable high cost of genetic enhancement means that fewer individuals will gain access to it compared to those who can avail themselves of other forms of self-improvement. Twenty million Americans are members of commercial health and sports clubs (7). In 1997, 480,588 persons obtained cosmetic surgery. In contrast, only 39,390 per year obtain IVF (8), and even fewer would be able to afford the additional cost of preimplantation genetic enhancement. Somatic enhancement might be cheaper, but it might still be beyond the reach of many who wished to enhance multiple traits or to produce long-term results.
2. The effects achievable with genetic enhancement are likely to affect some traits that are not highly susceptible to current forms of self-improvement, including

some that are fundamental to personal success. Current self-improvements are limited in scope. One can change one's weight (although usually not permanently); employ cosmetics and cosmetic medicine to improve appearance within certain limits; somewhat increase the ability to cope with loss, failure, and stress; build muscles; develop greater physical, mental, and social skills; and increase reading speed. Genetic enhancement, however, may improve intelligence, cognition, charisma, creativity, energy, cheerfulness, sense of humor, and other characteristics that are arguably central to success and well-being.

3. Persons who are fortunate enough to be able to gain access to genetic enhancements are likely to obtain a much greater and long-lasting advantage than those who employ more traditional forms of self-improvement. Performance-enhancing drugs in sports produce their effects on the basic human phenotype, and the effects, while perhaps enough to win competitions, are relatively modest (9). Although cosmetic interventions change the appearance, they rarely stray from "normal" ranges for physical traits, and with the exception of cosmetic surgery, are often transitory, as any dieter knows. To date, techniques for improving memory and other cognitive functioning do not appear able to significantly increase intelligence or to have a particular profound or permanent effect (10,11). But there is no telling how powerful genetic enhancement can be. It could stretch the limits of desirable human traits considerably, perhaps even indefinitely. For example, there may be no such thing as being "too intelligent." Moreover, enhanced persons can still employ traditional forms of self-improvement on top of their genetically enhanced starting point.
4. Current self-improvement techniques tend to affect at most only a few aspects of performance or appearance at one time. In most cases, people work on one trait — for example, their facial appearance, their weight, their ability to solve puzzles, or memorize facts. Cosmetic polymedicine, while not unknown, is rare (12). Even a professional athlete in full training mode can do no more than exercise and take performance-enhancing drugs to increase strength and stamina, hire a famous coach and perhaps a sports psychologist, and repeatedly practice a skill or routine. Genetic enhancement, on the other hand, may permit wholesale changes in characteristics. Parents with sufficient resources may engineer numerous improvements in their children, and they may purchase multiple somatic enhancements for themselves or their dependents (13).
5. As the result of the ability of genetic enhancement to alter multiple traits in significant ways, genetic enhancements may give people decisive advantages or major success not just in one or two spheres of social activity but in a broad range of social endeavors. This may enable them to cross what Michael Walzer calls "spheres of distributive justice." Imagine the following individual, he says:

> Here is a person whom we have freely chosen (without reference to his family ties or his wealth) as our political representative. He is also a bold and inventive entrepreneur. When he was younger, he studied science, scored amazingly high grades in every exam, and made important discoveries. In war, he is surpassingly brave and wins the highest honors. Himself compassionate and compelling, he is loved by all who know him (14).

   If genetic enhancement made such a person possible, he and his kind would be likely to dominate the rest of society.
6. Finally, unlike most advantages derived from self-improvement, some genetic enhancements — those achieved through genetic selection for enhancement or germ-line engineering — will be incorporated into the genetic makeup of future generations (15). Both the genetic enhancements and the societal advantages that they confer will be inherited, and those who obtain them will comprise a special class within society. Although initially defined by its wealth, this class eventually will come to be characterized by its superior genetic endowment.

In short, genetic enhancement possesses a number of characteristics that raise special concerns for society (16). Some of the objections, like playing God, are metaphysical. Others concern the serious practical consequences for the individual and for society. The rest of this article will concentrate on these two consequences, beginning with the implications for social equality.

THREAT TO EQUALITY FROM GENETIC ENHANCEMENT

Is it fair for some people to have greater genetic advantages than others? This is a question that forms the crux of the age-old problem of "natural inequality" which has plagued philosophers and social theorists at least since the ancient Greeks. If genetic enhancement is unfair, then presumably society should do what it can to rectify the situation, and this engenders the secondary, but equally vexing, problem of what form societal intervention should take and how feasible it would be.

Some philosophers tolerate natural inequality more than others. Meritocrats, for example, welcome substantial inequalities resulting from the distribution of natural talents, pointing to the benefits that accrue to society from the accomplishments of the gifted. John Gardner, for example, objects to what he calls "extreme equalitarianism," which, he states, "ignores differences in native capacity and achievement and eliminates incentives to individuals." In Gardner's opinion, this signifies "the end of that striving for excellence that has produced history's greatest achievements" (17). Others relish excellence as much for its own sake as for what it can achieve. According to Thomas Nagel, "[a] society should try to foster the creation and preservation of what is best, or as good as it possibly can be. . . .Such an aim can be pursued only by recognizing and exploiting the natural inequalities between persons, encouraging specialization and distinction of levels in education, and accepting the variation in

accomplishment which results" (18). Robert Nozick even disputes the idea that the fact that natural assets are arbitrarily distributed in society means that they are not deserved (19).

Philosophers who are morally troubled by inequality, on the other hand, tend to regard it as unjust for some individuals to benefit by virtue of their genetic endowment compared to others who do not fare as well in the genetic lottery (20). These philosophers generally agree that unchosen and unearned advantages and disadvantages must be minimized in order to achieve a more just society. As Rawls states: "It seems to be one of the fixed points of our considered judgments that no one deserves his place in the distribution of native endowments, any more than one deserves one's initial starting place in society" (21; also see Ref. 22).

Although liberal philosophers agree on the goal of rectifying the injustices of the natural lottery, they disagree substantially on how this should be achieved. A basic dispute, for example, concerns just what is to be equalized: "welfare" — that is, some subjective measure of well-being — or "resources" (23,24). Another contentious issue is how much inequality society should tolerate, whether of welfare or resources, in order to assure the production of desired goods. For example, meritocratic, libertarian, and free-market theorists all justify their tolerance for inequality at least in part on the ground that permitting people to profit from the exercise of their natural talents is necessary to induce them to increase the total sum of societal goods. In reaction at least in part to these and other difficulties, many philosophers abandon the quest for absolute equality, whether of resources or welfare, in favor of providing everyone with a minimum level of assets or of well-being, or with "equality of opportunity" (18,25,26).

Despite the gaps and imprecisions in the theory of equality and its application, it does provide at least one clear imperative in regard to wealth-based genetic enhancement: If genetic enhancements are viewed as natural assets, distributed largely by chance, then the principle of equality requires that society attempt to rectify the advantages that they confer, except to the extent that it may be necessary to allow individuals to profit to some degree from their natural talents in order to secure benefits for society as a whole. On the other hand, if genetic enhancements are viewed as "earned" advantages, obtained through diligence and effort, then at least some theories of equality would permit the enhanced individual to retain the additional value created by enhancement.

The easiest case for saying that genetic enhancements were unearned is when they were obtained by children from their parents or other family members. The children have done nothing to entitle them to such advantages; from a moral standpoint, their enhancement is no more than the luck of the draw (27). The interest of equality therefore would seem to justify depriving enhanced individuals of the benefit of enhancements that were installed by their parents or that were purchased with inherited or unearned wealth. Another easy case would be when persons acquired the money to purchase enhancements by immoral means; they too have no moral claim to the benefits.

But what about the person who obtains the necessary funds by dint of the sweat of her brow, without exploiting others or behaving otherwise immorally? This person has a strong claim to be allowed to retain the benefit from her genetic enhancements as morally deserved. Similarly a parent who earned the wherewithal to purchase genetic enhancements for her children in morally acceptable ways may contend that her children ought to be entitled to enjoy the benefits (28).

If we feel obliged to level the genetic playing field even when the advantages of genetic enhancements have been acquired in morally deserving ways, we might base our action on the view that equality is a moral imperative that overrides desert. This rationale no doubt to some extent lies behind schemes that redistribute earned wealth, like progressive income taxation. But the techniques that would be required to level the genetic playing field, as we will see, are far more intrusive than progressive taxation — even when accompanied by aggressive government enforcement. If these methods are to be politically acceptable, they must be premised on more than an abstract belief in the value of equality. They must be based as well on the conviction that genetic enhancement, if left unchecked, would be a grave threat to society. Can this view be sustained? I believe it can.

One of the most important of our societal goals is maintaining a liberal democratic form of government. This goal is directly threatened by wealth-based genetic enhancement: The inequality of social opportunity that results may be so great that a liberal democratic form of government becomes unsustainable, and our political system instead becomes autocratic or oligarchic. This follows from the assumption that a minimum degree of equality is necessary for modern liberal democracy to exist (29). If social inequality becomes too pronounced, liberal democratic political systems become unstable. As one sociologist states:

> Inequality in the distribution of rewards is always a potential source of political and social instability. Because upper, relatively advantaged strata are generally fewer in number than disadvantaged lower strata, the former are faced with crucial problems of social control over the latter. One way of approaching this issue is to ask not why the disprivileged rebel against the privileged but why they do not rebel more often than they do (30).

The characteristics of genetic enhancement that threaten to destabilize liberal democratic government are the features mentioned earlier that distinguish genetic enhancement from other forms of self-improvement: its high cost which may place it beyond the reach of all but the very wealthy, the broad and fundamental nature of the traits that it could enhance, the magnitude of its effects; their multiplicity, the resulting ability to gain advantages in multiple spheres of social activity, and the possibility created by germ-line enhancement that these advantages would be passed on to successive generations.

These characteristics not only give rise to social inequality; more insidiously, they undermine the belief in equality of opportunity. A widespread belief in equality of opportunity is the principal manner in which liberal

democracies accommodate the reality of inequality — that everyone is not equally endowed with natural assets, nor with the same luck or disposition to work hard. In the United States, although most people will tolerate large in equalities in the distribution of resources, the main principle is that everyone have an equal opportunity to these resources (31). As John Shaar notes, the belief in equal opportunity is instrumental in maintaining the prevailing social order:

> No policy formula is better designed to fortify the dominant institutions, values, and ends of the American social order than the formula of equality of opportunity, for it offers *everyone* a fair and equal chance to find a place within that order (32).

Genetic enhancement would create such profound, true differences in ability that they would endow the wealthy with opportunities that are irrevocably beyond the reach of the less fortunate. We have from history other societies with population characteristics similar to those that would be created by wealth-based genetic enhancement. In medieval Europe, individuals were born into their respective classes. Only in rare exceptions were peasants able to obtain education in religious institutions or become apprenticed to a trade, so, they remained found to their station in life (33). In slave-owning societies, people were born into bondage and could be freed only by escape (self-exile) or at the pleasure of their masters. In contempory India the caste system is an example of such a society, and it is a constant threat to the nation's democratic institutions (34).

In short, wealth-based access to genetic enhancement creates not only a moral challenge but a political threat. From a moral standpoint, those who gain enhancement may not have done anything to deserve it. Adults may have come by the means necessary to purchase enhancement in objectionable or morally irrelevant ways — through exploitation or the brute luck of inheritance. Children who are enhanced by their parents are unlikely to have done anything to earn it; this is patent in the case of more remote generations enhanced through prior germ cell manipulations. Yet genetic enhancement poses more than an ethical quandary. Even if the price of genetic enhancement had been earned in a moral sense, the social impact of wealth-based enhancement is likely to be severe. Somatic enhancement alone could so dramatically widen the gulf between have's and have-not's that class warfare would ensue, and the conflict could topple democratic government. Germ-line enhancement could create, quite literally, a master race. The question is whether there is any practical way to prevent this.

PROMOTING GENETIC EQUALITY

In the face of the serious threats to equality represented by wealth-based genetic enhancement, what options do we have to promote equality? One approach would be to "level up." An obvious example is to give everyone access to genetic enhancement regardless of wealth. As pointed out earlier, however, this would be prohibitively expensive.

Even if we decided to divert some enormous portion of the gross national product (GNP) to finance a massive enhancement entitlement program, what enhancement services would such an entitlement program provide? This raises the old argument over resource versus welfare equality. If the objective were to give everyone an equal amount of enhancement resources, those who started out with a more favorable distribution of natural assets would end up better off. If instead we attempted to give everyone an equal or minimum share of enhancement, or an equal or minimum share of enhancement-created opportunity, how would we measure equivalence? Would an extra inch of height be equal to an extra ten points of IQ? The problem would not be solved if we gave everyone an equal share of money and allowed them to purchase whatever enhancements they desired. Logically, unless all enhancements cost the same, those who desired expensive enhancements would be less advantaged than those who were content with cheaper ones — again, the problem of expensive tastes (32). Moreover, since we could not afford to provide everyone with access to the same enhancements that the wealthy could purchase, the wealthy always could stay ahead of the rest of the population. Now we could solve the problem if we gave everyone the maximum amount of enhancements available, but then again we would run into the problem of prohibitive cost. Such problems would plague any attempt to give the unenhanced some countervailing benefit other than genetic enhancements, like money, information, or political power which would level the playing field.

The fact that some people start out with a more favorable distribution of natural assets suggests another approach: subsidize access to enhancements, not for everyone, but for those who were genetically disadvantaged. In other words, bring everyone up to the same level of genetic well-being. This would comport with Rawls's difference principle by improving the fortunes of the least well-off (21). But it runs into the same problems that were just described in attempting to equalize access to enhancements. In addition, allocating enhancements to the genetically disadvantaged would necessitate identifying genetically disadvantaged individuals or groups within the population, and measuring their degree of disadvantage. This would raise serious practical, moral, and political objections. Determining what counts as a genetic disadvantage is similar to trying to identify whether or not someone has a disability — a determination that is controversial, and often appears arbitrary (35–38). Measuring the extent of disability is an even thornier enterprise: Witness the morass that the state of Oregon found itself in when it tried to ration Medicaid services on the basis in part of how much they alleviated disability. Even if we could identify and quantify genetic disadvantage, we would need to establish a "normal" degree of genetic well-being state that the disadvantaged could attain, so we could give them the correct amount of enhancements or money with which to purchase enhancements. But "normalcy," as noted earlier, is highly arbitrary, value laden, and subjective (11). Furthermore it can become a constantly moving target as the distribution of advantages and disadvantages within the population shifts and as

the average level of advantage increases with the number of people becoming enhanced. Finally, any attempt by the government to identify and rectify genetic disadvantage smacks of eugenics, which is politically suspect if not unthinkable.

If leveling up is not a feasible response to genetic enhancement, the alternative is to level down (14). The most straightforward approach would be to prevent anyone from obtaining genetic enhancement. A ban on genetic enhancements could be aimed at a variety of targets. For example, purchasing or possessing enhancements could be made illegal, similar to laws punishing illegal drug use or rules prohibiting the use of performance-enhancing drugs in sports. Another target would be health care professionals and institutional providers such as hospitals and IVF clinics. Congress or state legislators could make it a crime for health care professionals to provide genetic enhancements. Violators would face disciplinary actions by state medical boards, including loss or suspension of their licenses (39). Hospitals and other facilities like IVF clinics that continue to offer enhancement services would lose their licenses, their accreditation, or their ability to receive reimbursements under Medicare and Medicaid. Finally, if genetic enhancements were proprietary products such as drugs or medical devices, the Food and Drug Administration (FDA) could deny marketing approval.

But why wait until enhancements are available before banning their use? Why not prohibit research aimed at developing enhancement technologies in the first place? An analogy is the federal government's ban on federal funding of research on embryos and fetuses (40). Privately funded research could be restricted by penalizing institutions such as hospitals that participate in clinical trials, and by FDA denying permission to ship experimental enhancement products across state lines for purposes of human testing (41).

All of these restrictive approaches have limitations, however. Penalizing people who genetically enhanced their children would trigger intense constitutional debate. Particularly in the case of passive enhancements involving traditional "coital" methods of reproduction, the Supreme Court is likely to apply a strict scrutiny standard under which the right to decide what type of child to conceive or bring to term can be overridden only by a compelling state interest, and then only if the state uses the least intrusive means of regulation. Genetic enhancement accompanying less traditional methods of reproduction, such as IVF, may be entitled to less constitutional protection. However, even then, the courts are likely to take a hard look at overly intrusive government regulation. Somatic self-enhancement, while not raising issues of reproductive freedom, would set the state's interest in promoting equality against the individual's constitutionally protected interest in personal liberty and autonomy, including the right to make life-style decisions that do not harm others.

Those FDA restrictions on the sale of enhancement drug products, biologics, or devices able to survive constitutional challenge as an appropriate regulation of interstate commerce would be hampered by the way in which they are likely to become commercially available: as unapproved or "off-label" uses of products approved for therapeutic rather than enhancement purposes. A genetically engineered drug that enhances cognition, for example, could be approved to treat cognitive impairment, such as the effects of Alzheimer's disease. After it is approved for a therapeutic purpose, people might begin to seek it for unapproved enhancement purposes. The experience with human growth hormone mentioned earlier is a prime example. This genetically engineered drug is approved for use in children with "a lack of adequate endogenous growth hormone secretion," causing short stature (42). Yet parents are reported to be asking doctors to prescribe it for children who are merely short, and there are anecdotal accounts of parents requesting the drug for children who are already tall, in order to enhance their chances of playing competitive basketball (43).

FDA does not effectively regulate off-label uses of unapproved drugs. It merely limits the ways in which the manufacture may promote the drug for unapproved uses. Even if the FDA attempted to prohibit manufacturers altogether from promoting drugs for an unapproved use, enhancement uses would become public knowledge through media reports, the Internet, and word of mouth. Targeting health professionals who provided enhancement products to their patients would present similar obstacles. The FDA presently has no authority to control the prescribing behavior of physicians, who are free to prescribe products for uses which are not approved (44). There is nothing unlawful about a physician prescribing human growth hormone for children for an enhancement purpose which is not indicated on the product labeling. The only effective action the agency can take now is to ban or limit sales of the product altogether — for both therapeutic and enhancement uses. Yet in the case of products approved to treat serious and especially popularized diseases, this would carry an intolerably high political price.

The same problem would beset efforts to prevent research on genetic enhancements from taking place. Consider a ban on research on genetically engineered drugs to enhance cognitive function. Such a ban would be justified, it might be argued, on the ground that developing such a product would give those who used them an unfair advantage in competitions for scarce resources like college acceptances or aptitude-based job slots. But these same products most likely would be useful in treating diseases of cognitive deficiency, such as Alzheimer's and dementia. It is extremely difficult to curtail research on a specific use of a product. In any event there is little point, since, as stated above, once the product is developed for therapeutic use, it can easily migrate to enhancement uses.

Moreover an effective ban on access to genetic enhancements, whether aimed at individuals obtaining them for themselves or their children, or at providers and manufacturers, would require an elaborate enforcement regime. The analogies that best describe what would be necessary are programs to control the use of performance enhancing drugs in sports and the use of illicit recreational drugs. Indeed, the most appropriate government agency for regulating genetic enhancements may not be FDA but rather the Drug Enforcement Agency (DEA). After all, DEA, pursuant to the Controlled Substances Act,

is responsible for enforcing restrictions on access to physiologically active products stemming from societal objections to their use.

Like the war on drugs and the effort to ban drugs in sports, restricting access to genetic enhancements to promote equality is bound to be extremely intrusive and expensive. These precedents were not completely effective. Somatic enhancements in the form of drugs, although perhaps complicated to manufacture, may be easy to conceal. Even enhancements that depended on sophisticated medical procedures such as IVF might be procured if one "knew the right person," the way "back-alley" abortions could be obtained prior to *Roe v. Wade* (45). The overwhelming consumer demand for genetic enhancements is certain to spawn a robust black market. As the experience with abortions indicates, people who are prevented from obtaining genetic enhancements domestically simply will procure them abroad (46).

The most troublesome aspect of enforcing a ban on genetic enhancements is likely to be the difficulty of determining that someone has been illegally enhanced so that they, and/or the person who enhanced them, can be punished. In part, this is a technical problem of detecting the presence of enhancement products or enhanced DNA in the human body. A similar problem plagues attempts to ban performance-enhancing drugs in sports. Athletes and their coaches are becoming increasingly adept at deceiving drug-screening tests. The athletes may use substances such as erythropoeitin that are naturally occurring in the body so that the exogenous enhancement cannot be chemically distinguished (47). Furthermore the athlete may be able to use an enhancement substance to produce a benefit, such as increased muscle mass, and then stop taking the substance sufficiently in advance of a screening test so that its use cannot be detected.

In the case of genetic enhancements, the enforcement problem would be compounded by the difficulty of distinguishing between therapeutic and enhancement uses. As noted earlier, the difference between the two often is not clear. Someone could claim, for example, that an improvement in appearance was necessary to treat feelings of inadequacy, or that an increase in strength or dexterity was preventive therapy in that it enabled them to avoid injury. Furthermore, as has been noted, many genetic enhancements have lawful medical uses. Someone could take human growth hormone in an attempt to become tall enough to play professional basketball, but someone else could take the exact same substance to combat pituitary dwarfism. A ban on enhancements would require a complicated system for distinguishing between legitimate and prohibited activity involving the same products. In addition, banning genetic enhancement in conjunction with assisted reproductive technologies such as those delivered in IVF clinics would require a far more effective scheme of regulatory regime than is currently in place (48).

Yet the strongest objection to banning genetic enhancements has not been mentioned so far: Enhanced individuals not only may personally benefit from their advantages, but they may confer advantages on society. For example, a person whose science ability was enhanced (assuming that this collection of traits was amenable to genetic manipulation) might make important discoveries that would be impossible, or take much longer, for an unenhanced scientist. As noted earlier, even proponents of equality recognize the need to permit a certain degree of inequality in order to increase social benefit. In short, we might want to permit an individual to be enhanced if we expected the ratio of societal to personal benefit to be favorable enough.

Together with the practical limits on the effectiveness of a complete ban on genetic enhancements discussed earlier, the social value of certain kinds of enhanced performance make the goal of a total ban both unrealistic and undesirable. Some people will manage to enhance themselves no matter what it takes, and in some cases we will want people to do so. This leads to several policy suggestions: (*1*) enhancement licensing, (*2*) establising an enhancement lottery, and (*3*) regulating germ-line enhancement.

Enhancement Licensing

In order to permit genetic enhancements to produce desirable social gains, as well as to take some of the pressure off of a regulatory embargo that attempted to prevent the wealthy from purchasing enhancements, we should institute a system for licensing individuals to obtain genetic enhancements on the condition that they employ their enhanced abilities in some predefined manner to benefit society. By reducing the number of people who were enhanced, a licensing program would reduce the degree of social inequality, and the threat that genetic inequality poses to democratic institutions.

The system would be similar to legally enforced professional licensing schemes that give their holders powers and privileges denied ordinary citizens in return for agreements to abide by rules designed to promote social goals and to refrain from behaving in socially undesirable ways. The system also would bear some resemblance to licensing ownership or use of dangerous products such as handguns or automobiles. The administrative costs could be financed by licensing fees.

Such a licensing requirement could be enforced in the first instance against providers of genetic enhancement products or services. They themselves would be required to be licensed as a supplier, which would carry with it restrictions and reporting requirements. (A similar program operates under the Controlled Substances Act to keep track of the prescribing of narcotics and other dangerous drugs.) Individuals who seek to purchase enhancements would apply to a licensing board and would be required to propose the socially desirable purposes for which they seek to be enhanced. Those whose applications are approved would report to the board periodically to provide assurance of satisfactory performance, and their reports would be carefully audited. Licensed enhancements that involved manipulation of DNA would be genetically "tagged" so that lawfully enhanced individuals could be distinguished from those who obtained enhancements on the black market (49,50). Failure to fulfill the terms of the license would be penalized by loss of access to the enhancement or to its benefits. Depending on the nature of the enhancement, the penalty could take the form of being deprived of supplies of

the enhancement product, actual biological reversal of the enhancement, various forms of social handicapping, surtaxes or monetary penalties, and perhaps in cases of egregious violations, such as the use of enhancements to cause serious harm to others, imprisonment. Similar penalties would be imposed on persons who were discovered to have supplied or obtained enhancements without being licensed.

Establishing an Enhancement Lottery

The licensing scheme so far described would be open only to the wealthy, since they would be the only persons who could afford to purchase genetic enhancements. This would perpetuate the inequalities described earlier that would result from wealth-based access to enhancements described earlier. The solution would seem to be to provide some people with access to enhancements even if they could not afford it. One approach would be a government program that subsidizes enhancements for certain persons, perhaps those who, in return for their license, promise to provide the most desirable set of social benefits. But this would embroil the government in an enhancement-rationing program in which it was required to judge the relative merit of different proposals, a task that would raise objections similar to those that have been lodged in the past against health care rationing programs in general (51). On the other hand, such a licensing plan does not raise similar objections because the licensing authority would not compare individuals seeking enhancement but would allow anyone to purchase enhancements so long as they agreed to meet certain minimum social objectives.

A better solution than a rationing program would be to establish a national lottery for genetic enhancements (46). Everyone would be given one chance in each drawing. The winner or winners would be entitled to resources sufficient to enable them to purchase the maximum package of enhancements lawfully available in the private market, although in order to "cash in" their winnings, they would have to become licensed like everyone else who was enhanced. Like the licensing program itself, the lottery could be financed by license fees paid by those who purchased enhancements. Among the advantages of a lottery approach is that its randomness would give continued vitality to the concept of equality of opportunity.

Regulating Germ Line Enhancement

The greatest threat to social equality posed by genetic enhancements is the formation of a genobility — a class of related individuals who achieve and maintain an unassailable grip on wealth, power, and social privilege and who pass their advantages on to successive generations. As discussed earlier, a genetic aristocracy of this sort is antithetical to liberal democratic political systems. If genetic enhancements are obtainable at all, then to some extent the formation of an enhanced class cannot be prevented; persons who were wealthy enough to purchase enhancements presumably would be able to provide their children with greater material advantages than persons who were not enhanced, thereby making it more likely that these children would be able to purchase genetic enhancements in their turn. Yet the formation of such a genobility is far more likely to occur if individuals were permitted to make enhancement changes in their germ lines. Their offspring would inherit these genetic advantages, which they would be able to supplement with additional germ-line enhancements that they purchased, which in turn would be passed on to their children, and so on (52).

The social threat created by the inequality that would result from germ-line enhancement may not readily be mitigated by the licensing requirement that would accompany the lawful acquisition of somatic enhancements. It is difficult to imagine how to ensure that a person's children would abide by the licensing conditions agreed to by their parents. The children could be required to become licensed in their turn (e.g., when they reached the age of majority) on penalty of forfeiting their enhancement advantages, but despite the stipulation that the enhanced individual devote some degree of his or her enhanced capabilities to the public good, being licensed at the age of majority may not be sufficient to counteract the inequality that germ-line enhancements would produce.

The solution then would seem to be to prohibit germ-line genetic enhancement altogether. Conceivably the threat in social equality could be met by banning only those forms of germ-line enhancement involving gene transfer, and not the passive sorts of germ-line enhancement that would occur with genetic selection for enhancement, selective abortion for enhancement, or preconception enhancement. Moreover laws that make it illegal for individuals for enhancement reasons to discover their genetic endowment, to select embryos for implantation, or to abort a fetus, might be more realistic politically than laws that prohibit the alteration of germ cells for enhancement purposes.

A ban on germ-line engineering would raise a host of problems. It might be challenged as an unconstitutional interference with procreative liberty, although the justification that it was necessary in order to preserve democratic liberties from being engulfed by a genetic aristocracy might be deemed a compelling state interest. Detecting when someone had altered germ cells would be difficult and intrusive (53). Nevertheless, a ban may be necessary to promote a minimum level of genetic equality.

UNFAIRNESS

Regardless of the manner in which we attempt to reduce the inequalities that may be created by wealth-based genetic enhancement, some people invariably will become enhanced. A licensing scheme that is vigorously and effectively enforced will go some distance toward offsetting the advantages enjoyed by enhanced persons but not far enough. Enhanced individuals still will be in a superior position compared to unenhanced persons. This raises the question of whether and in what ways society should respond in order to reduce the resulting unfairness.

This unfairness will be felt most acutely when the unenhanced compete with the enhanced for scarce societal resources or when an enhanced individual exerts power over an unenhanced person in a relationship in

which their interests conflict. These circumstances can occur in a large number of settings: between rivals for someone's affection or in interpersonal relationships such as those between boyfriend and girlfriend (and similar relationships between members of the same sex); in contests, including sports, games, beauty pageants, and talent shows; in competition for access to limited privileges, such as admission to academic institutions; in fiduciary relationships, such as those between patients and health care professionals, trustees and beneficiaries, directors and shareholders, attorneys and clients, and insurers and insureds; and in ordinary business relationships, such as those between seller and buyer, landlord and tenant, realtor and purchaser, lender and debtor, manufacturer and consumer, and employer and employee. The object of the competition may be any desirable good: money, jobs, status, affection, sexual favors, political influence, or market power. The relative advantage conferred by genetic enhancement would depend on both the context and the nature of the enhancement: In a test of strength, for example, enhanced intelligence may be of little value. Unfairness could arise either in a zero-sum situation in which the enhanced person obtains benefit at the unenhanced person's expense, or in non-zero-sum situations in which, although both the enhanced and the unenhanced person gain, the share gained by the enhanced person is greater and the share gained by unenhanced person smaller than would be the case if the parties were equivalently advantaged.

All these situations are subject in some fashion to external rules of behavior. They may be formal public laws; legally enforceable private law, such as the bylaws and other governing principles adopted by corporations, partnerships and unincorporated associations; or social norms or customs. How should these systems of rules respond to the potential unfairness created by genetic enhancement? Should the rules treat these differences as if they do not exist or do not bear on the activity? Or should the rules attempt, in some fashion, to level the playing field? If one person possesses an advantage over another, should the rules permit her to profit from it at the other's expense? Although it would be fascinating to consider nonlegal responses based on social norms and customs, the focus of the rest of this article will be on legally enforceable rules, that is, on public and private law.

If we attempt to level the genetic playing field in response to genetic enhancement, what would our options be? Basically there are the same two approaches that we examined in the previous section in discussing how to reduce genetic inequality: Either we decrease the advantages of those persons who were genetically enhanced, or we improve the lot of those who were not. In short, once again, we can level "up" or "down."

Leveling up would entail giving those who were not genetically enhanced some countervailing benefit. This could be money, professional advice, information that was hard to come by, or any other desirable resource that would help level the playing field. It could be a preference in access to a scarce resource, such as an affirmative action program. Yet, it is difficult to conceive of how this approach would work in the context of personal interactions. Would an unadvantaged person be permitted to draw on some public store of resources to place her on the same level as the enhanced person? Obviously this could not be a store of genetic enhancements, since that would contradict the basic assumption that we cannot afford to provide genetic enhancement to everybody. Yet, the same problem of scarce resources would plague any other subsidy, monetary or otherwise: It would cost too much to put the unadvantaged on the same level as the enhanced.

A less expensive alternative might be to level up only those who were the most disadvantaged relative to the enhanced. This would resemble laws prohibiting employment discrimination against persons with disabilities (54). The effect of these laws is to require employers to subsidize persons with disabilities so that in competitions for employment they can match persons who are not disabled. Only disadvantaged employees or applicants for employment receive this benefit, thus leveling the employment playing field.

This approach is intuitively appealing. By focusing on improving the lot of the worst off, it moves in the same basic direction as Rawls's difference principle. Yet it would produce odd results if it were applied to a more realistically complex society in which some people are enhanced, some (the unenhanced) are merely "normal," and some are disadvantaged: If through access to countervailing benefits, the disadvantaged are truly brought up to the level of the enhanced, they would pass those who previously had been neither advantaged nor disadvantaged. The formerly unadvantaged now would constitute the disadvantaged. In short, unless everyone is made equal, or the distribution of countervailing benefits is a once-only event, a policy of benefiting the worst-off would create an infinite regression. There will always be a group that is disadvantaged or unadvantaged and that riskes being treated unfairly by the enhanced — and also, under a genetic "affirmative action program," by the formerly disadvantaged who have been leveled up.

This leaves the other option of "leveling down." Since we cannot prevent some people from obtaining genetic enhancements for themselves or their children, unfairness might be avoided by preventing them from taking advantage of their enhancements when competing with the unenhanced or exerting power over them.

Some idea of the ways in which we might level down the genetic playing field can be obtained by reviewing how rules currently respond to the potential unfairness inherent in interactions between advantaged and unadvantaged individuals. Here, instead of advantages conferred by genetic enhancement, society is concerned with natural or acquired advantages such as youth, beauty, size, strength, endurance, intelligence, memory, creativity, information and knowledge, experience, social status, money, and personal power. If we examine current public and private law rules, we see a number of ways in which they attempt to level the playing field by leveling down these sorts of advantages:

1. Competition that is arguably unfair is sometimes prohibited. A private law example is the ban on the use of performance-enhancing drugs in sports

competitions (55). Another sports example is weight classes in certain competitions such as rowing and wrestling. In these competitions, athletes who have an advantage in weight are precluded from competing with those who weigh less.

Banning competitions between advantaged and unadvantaged individuals is not confined to sports. A public law example is the prohibition against insider trading in securities. Here the advantage is information that is not available to the public about a corporation whose stock is publicly traded. The law attempts to deny those who possess this information any financial gain from it. The advantaged individual is given the choice of either disclosing the information or not trading stock in the company.

2. The rules permit a transaction to take place only if the person with the advantage forfeits it by sharing it with the unadvantaged. An obvious example is information possessed by one party in certain business transactions, such as when the advantaged person knows that "disclosure of the fact would correct a mistake of the other party as to a basic assumption on which that party is making the contract" and nondisclosure would be a failure to act in good faith and "with reasonable standards of fair dealing" (56). Presumably such transactions are not prohibited altogether because it is sufficiently inexpensive to enforce the forfeiture rule and there is a sufficiently high possibility that, given adequate enforcement of the rule, the result will be fair.

   Similarly in some cases the person with the advantage is handicapped so that the advantage is removed. This occurs, for example, in horse racing where jockeys who weigh relatively little are deprived of their advantage literally by having to carry weights. Better golfers are also deprived of their advantage by removing strokes from the score of other golfers.

3. The rules do not prohibit the competition but allow the unadvantaged to avoid the outcome if it seems too unfair. The doctrine of unconscionability in contracts is such a rule, which applies to advantages in the form of information or market power (57). Another example is the fiduciary rules that permit a court to a void a transaction by a trustee of a trust if the result would be unfair to the beneficiaries (58).

4. The rules sometimes level the playing field by eliminating the arm's-length nature of the transaction. The advantaged person is permitted to engage in the transaction but not allowed to employ the advantage in such a way as to take advantage of the other party. This is the result, for example, of fiduciary rules that mandate the fiduciary's undivided loyalty towards the entrustor and prevent the fiduciary from serving an interest other than the beneficiary's (59).

On the other hand, the rules could make no effort to level the playing field, and legislators could ignore or even to celebrate the advantages that some people have over others. With the exception of affirmative action programs, for example, admissions criteria at selective educational institutions do not adjust applicants' accomplishments in light of their background or abilities. A person applying to Harvard with an IQ of 120 competes with applicants with IQ's of 160; the fact that an A in AP Calculus or a high score on the Scholastic Aptitude Test (SAT) achieved by the person with the 120 IQ is a far greater accomplishment than the same grade achieved by the person with the 160 IQ is irrelevant. Many athletic competitions force athletes to compete with those who are advantaged by being younger: older baseball and basketball players must compete with those considerably younger, some straight out of high school. Shorter basketball players are not allowed to shoot from stepladders, and there are no professional leagues for players of "normal" height. In football the slight take the field at their own peril.

This raises the question of whether the unfairness problem raised by wealth-based genetic enhancement simply should be ignored, as it seems to be in the case of college entrance criteria and in certain sports settings. What would justify ignoring the problem?

In many cases the fact that the rules ignore advantages, or certain advantages, is probably arbitrary, coincidental, or an historical artifact of no theoretical significance. In horse racing, for example, jockeys' weights are equalized on the premise that it is the quality of the horse and the jockey's horsemanship that should matter. There are no weight categories in football because that is just not how the game was conceived. Organized chess competition does not prohibit the use of cognitive enhancers such as nicotine or stimulants because the organizers simply never thought of it (E.C. Johnson, Assistant Director, U.S. Chess Federation, personal communication, October 4, 1995).

Nevertheless, we can posit several principled reasons why it may be inappropriate to deprive genetically enhanced individuals of their advantage in specific transactions or relationships: (*1*) loss of societal benefit from the enhancement, (*2*) difficulty in detecting enhancement, (*3*) difficulty in distinguishing between enhancement and effort, (*4*) nonenhancement advantages, (*5*) public intrusion into private affaires, and (*6*) transaction costs.

Preventing the Loss of Societal Benefit from the Transaction

An enhanced scientist, presumably enjoys personal advantages by virtue of being enhanced; she otherwise might not have been admitted to MIT, for example, or be able to earn a fortune from her patents. But despite the unfairness to unenhanced persons who applied to MIT or tried to develop patentable inventions, we might forgo trying to strip her of her personal benefits. By allowing her to benefit personally, we encourage people like her to purchase scientific enhancements so that society could reap the benefits. (This might well be the justification for not leveling the playing field in terms of intelligence in the case of admissions to institutions of higher learning.)

An example of a societal benefit that might be a sufficient reason to permit enhanced individuals to retain personal benefit are reductions in the costs of accidents. A naturally talented automobile mechanic might be expected to make safer repairs than someone with less talent,

and therefore might be entitled to a hiring preference over someone who lacked her natural talents. The same might be said for an enhanced automobile mechanic. The argument becomes even more compelling in the case of persons responsible for the safety of large numbers of people: airline pilots, railroad engineers, operators of nuclear power plants, and the like.

Difficulty of Detecting Enhancement

Systems of rules might have no choice but to ignore the unfairness created by competitions involving enhanced and unenhanced individuals if enhancements cannot be detected. This is a severe problem in attempting to prohibit the use of performance-enhancing drugs in sports. The earlier discussion of licensing catalogued the difficulties of detecting enhancement and the potential solutions.

One further approach to the detection problem might be to permit unenhanced individuals to assert a rebuttable presumption against persons they interacted or competed with whom they believed were enhanced. Unless persons against whom the presumption was asserted could establish that they were not in fact enhanced, the rules would proceed to level the playing field (e.g., by having courts undo the deal, or penalizing the person presumed to be enhanced for participating in a prohibited competition). Inability to produce proof of lack of enhancement would satisfy the burden of proof that the person was enhanced. This would encourage the enhancement industry itself to develop a workable tracking and record-keeping system.

Distinguishing Between Enhancement and Effort

Arguably society should focus its leveling efforts on advantages derived from genetic enhancement, rather than on advantages obtained through personal effort. Otherwise, the effect will be to discourage effort, leading to sloth and loss of social benefit. As noted earlier, however, it may be difficult if not impossible to distinguish between achievements that are earned and achievements that result from enhancement. Accordingly, it might be argued, the rules ought to ignore genetic enhancement.

Yet genetic enhancement may be a sufficient social threat that it is appropriate to level playing fields regardless of this risk. Indeed, society often deprives people of plainly earned advantages in order to promote equality or fairness. Though not without its critics, progressive income taxation transfers earned wealth to achieve a more just distribution of resources. Weight categories in sports are enforced regardless of whether an athlete's size is the product of diet and exercise or steroids. Fiduciary law requires individuals with superior information to disclose it to beneficiaries, clients, and patients, even though the information may have been obtained through great effort. Similarly an enhanced person automatically might be required to disgorge her advantage (of information, market power, etc.), even though she obtained some or all of it through her own efforts. Alternatively, as mentioned before, the fact that someone was enhanced could establish a rebuttable presumption that any advantage related to the enhancement was due to the enhancement rather than to effort.

Nonenhancement Advantages

Just because someone is not genetically enhanced does not mean that they lack sufficient resources or talents to compete fairly with someone who is enhanced. The unenhanced person may possess great wealth, or have some special store of knowledge, or have access to the best advisors. Leveling the genetic playing field may exacerbate unfairness if it focuses on genetic enhancements to the exclusion of these other types of advantages. If society attempted to correct for all differences between people, however, there would be no end to societal interference.

On the other hand, as discussed earlier, the advantages conferred by genetic enhancement could be so great that it would be appropriate to single them out for remediation. Moreover, where enhancement merely creates a rebuttable presumption of unfairness, the enhanced individual would be free to prove that her enhancement advantages are equaled or outweighed by nonenhancement advantages possessed by the complaining party.

Intrusiveness

Given the difficulties of detection and differentiation described above, any attempt to level the playing field would invite public intrusion into highly personal affairs. To rebut an inference of enhancement, for example, people would have to reveal their personal and medical history, including particularly sensitive information relating to their genetic makeup and their reproductive activities.

If the stakes are high enough, however, we seem to be willing to require people to compromise their privacy rights. For example, athletes must submit to physical examination and to yield samples of bodily fluids for testing, often under nearly public conditions. Given sufficient concern for maintaining privacy and the confidentiality of sensitive personal information, and so long as the least intrusive means were employed to decide if someone were enhanced, the cost may be justifiable.

Transaction Costs

Leveling the genetic playing field is liable to be costly. Forums, advocates, and referees would be required to resolve fairness disputes. Black markets, both domestic and foreign, would need to be policed. The specter of a "war on genes" is not an attractive one. Yet again, the threats posed by genetic enhancement might well be worth the cost of leveling.

In short, there seems to be no obvious reason why we would ignore the unfairness created by wealth-based genetic enhancement, except in situations like preventing accidents or achieving scientific breakthroughs in which the ratio of social to personal benefit clearly demonstrated a substantial net benefit to society, or in situations in which the costs of leveling were deemed to be greater than the costs of unfairness. In all other cases, one or more of the leveling techniques listed earlier would be appropriate, depending on the circumstances.

LEVELING THE GENETIC PLAYING FIELD

Although our overall objective is to minimize individual unfairness caused by interactions between enhanced and unenhanced individuals, at same time, we want to maximize the societal benefit from individual enhancements. This raises the question of how to respond when the two objectives are incompatible, namely when individual unfairness can be prevented only by sacrificing societal benefit.

The answer depends on the nature and magnitude of the unfairness and of the forgone societal benefit. Ultimately public policy should favor preventing unfairness if the cost of unfairness is deemed to exceed the expected societal benefit. Conversely, a substantial amount of societal benefit should be sought at the expense of a relatively small amount of individual unfairness. The more substantial the unfairness, and the more equal the costs of unfairness and societal benefits tend to be, the more emphasis should be given to correcting the unfairness of the transaction.

For example, suppose that we are reviewing applicants for scarce medical research funding. Successful research is expected to yield significant societal benefits. Applications are submitted by both unenhanced individuals and individuals enhanced in ways that significantly increase their chances of research success. All other things being equal, we ought to award funding to the enhanced individuals. If the impact on the unenhanced individuals' careers is deemed significant enough, however, consideration might be given to mitigating the unfairness, such as by allocating a certain amount of funding for them alone (a sort of "unenhanced persons' affirmative action program"), or by favoring applications involving both enhanced and unenhanced investigators.

As suggested by the approaches described above to leveling the playing fields, there are a number of techniques for mitigating genetic unfairness. Some of these techniques are more costly than others, both in terms of implementation costs and in terms of forgone social benefit. The enhanced individual might be required to share with the unadvantaged person the advantage created by enhancement. At a minimum, enhanced individuals would have to disclose that they were enhanced. In a business transaction an enhanced party who by virtue of their enhancement has obtained superior information could be required to disclose that information to the unenhanced party. Sharing might be a preferred mitigation technique where a transaction is expected to yield societal benefit because it encourages the enhanced party to engage in the transaction by allowing that party some degree of personal benefit.

If sharing is impractical, such as in zero-sum situations, or if the implementation costs of sharing are too great compared with the expected societal gain, unfairness might be mitigated instead by handicapping the enhanced party. For instance, in contests, including athletic competitions, the enhanced individual could be put at a disadvantage, such as being given a longer distance or a harder question.

Another technique worth considering is allowing the interaction to take place but permitting the unadvantaged party to apply to a court or an administrative agency to challenge and overturn or adjust a result if it is too unfair. This flexible, posthoc approach might be appropriate where the unfairness costs and societal benefits of a transaction were difficult to predict in advance. Business deals might be candidates for this approach, for example, particularly those in which the advantages enjoyed by the enhanced party, such as market power, could not, like information, be shared, and in which the particularities of transactions made the application of a priori handicapping rules too inexact. Making outcomes voidable also saves the costs of intervening in every transaction; only those results that seem too unfair will be reviewed.

An interesting option is to eliminate the arm's length nature of transactions between enhanced and unenhanced individuals. Like fiduciaries, the enhanced would be made responsible for the welfare of the unenhanced, a sort of genetic noblesse oblige. As in true fiduciary relationships, this could decrease the costs of monitoring the behavior of the enhanced by substituting a system of sanctioned trust for a regime of direct external controls. It also would encourage the unenhanced to interact for their benefit with the enhanced, facilitating resulting societal benefits (60).

Finally, if no significant social benefit were expected from an interaction, it could be prohibited. An alternative to handicapping enhanced athletes, for example, would be to forbid them from competing against athletes who were unenhanced. Such a competition might be allowed only if the costs of enforcing such a prohibition were great compared to the unfairness.

Los Angeles, California

OUTLINE

INTRODUCTION

This article outlines some of the moral, legal, and general policy difficulties societies and individuals will face if technological enhancements via germ-line and somatic mechanisms become possible (1). It identifies and analyzes some of the conceptual structures necessary to explain the nature of these difficulties, suggests some alternative basic scenarios — such as greater or lesser scarcity of technological enhancement resources, impacts on how we perceive each other, different remediation patterns — and then maps and reverse-maps the projected technological developments against the value and legal structures. It also describes and comments on what many see as the most critical threats and promises, from our present value standpoints, of the anticipated changes, as well as on what might be the fate of these very standpoints themselves. The idea of enhancement is compared to other processes of human change, principally to the familiar forms of self-progress and the practices of treating disorders, injuries, and the like. Questions are raised about the very significance of these distinctions as rational *authorizing* and *limiting* tools that might guide us in distinguishing among permissible and impermissible interventions, and among obligatory and nonobligatory ones.

The moral and legal issues are explored primarily by way of the concept of equality. Some of the classic and (possibly) novel difficulties in the equality analyses include matters of access to and distribution of technological resources; the possibility of increased socioeconomic and political stratification that may be irreversible; the effects of a technological enhancement regime on the ways in which we view each other (as planned and assembled objects or as persons? some blend of these or other attitudes?) and on the viability of present views about equality and its relationship to justice, fairness, autonomy, utility, and ideas of merit, virtue, and desert. Considered in the discussion of our notions of merit, virtue, and desert is whether they are to be reconstructed or abandoned. Distributional criteria and, more generally, different egalitarian arguments based on different visions of equality are sorted, and there is a brief exploration of how the structure of our democratic institutions might be altered by responses to particular distribution patterns of merit attribute enhancements — in particular, by adopting a plural voting system of the sort envisioned by John Stuart Mill. Different forms of remediation or prevention of inequality and of affirmative promotion of equality are briefly touched on. At the end there is a brief review of some issues arising under the United States Constitution: If technology changes as many anticipate, the acute moral and policy issues will eventually be vetted and disputed within the legal system.

MEANINGS OF ENHANCEMENT

Mapping Meanings of "Equality" onto Meanings of "Enhancement," and Vice Versa

To explain how equality may be affected by technological enhancement requires some account of the meaning of "enhancement"; a review of the intimidating complexities of the equality analysis, including equality's relationship to other basic values; and an examination of how varying understandings of the concepts of enhancement and equality affect each other.

This article outlines a bi-directional mapping of differing versions of equality and projected forms of enhancement against each other. Different ideas of equality may lead to different valuations of enhancement, and the reverse. An initial task is to distinguish different equality arguments, and this rests, in part, on asking the now-familiar question, *What* is supposed to be equal to *what?* An obvious example of variant meanings of equality is suggested by the tension between equality of opportunity in its several forms (2) (certain ex ante positions are to be set equal) against equal-outcome standards (certain ex post positions are to be set equal). These opposing pulls are especially vivid when considering the possibility of, say, major enhancement of intellectual abilities. Equal opportunity understood as rights against interference by others with access to enhancement resources may yield unequal outcomes that track and intensify existing inequalities in wealth, income, status, and power. Diminishing returns in the value of increments in ability may set in slowly, thus prolonging the incentive to continue adding increments to intellectual talents, further deepening inequalities in power and social status. As a given form of enhancement becomes widespread, its value to a particular individual may shift from enabling her to tower over others to enabling her to avoid being towered over. For some traits, then, the more widespread the enhancement, the more urgently the less able need it in order to avoid losing more and more ground to more and more persons. At some later stage, relative interpersonal positions may be unchanged, although "absolute" performance capacities are amplified. An equality of outcome standard, on the other hand, would require major centralized intervention either to narrow the ability gaps among persons, or at least to preserve their relative standing. In the latter case, equality of outcome would encompass — not flat-out equal abilities — but preserving the status quo ante concerning the relative "distance" between persons. Of course, egalitarian maneuvers might involve redistribution of traditional goods and services, either in addition to or instead of enhancement opportunities (3).

Technological Expectations; Germ-Line and Somatic Enhancements

Current directions in technology clearly justify assuming for argument's sake that we will be able to influence significantly the development of our targeted traits as compared with what life's lottery (genetic or environmental) might otherwise have presented. The apparently successful germ-line alteration that resulted in superior learning

ability in mice illustrates the point nicely (4). In earlier experiments, mouse embryos assimilated rat genes coding for growth hormone, producing some large mice that themselves bred several hefty offspring. The important point to take from these results is that even complex polygenic and multifactorial traits such as intellectual ability or size may be heavily influenced by a given gene (5): Not all genes and environmental factors are equal — some may have outsize or disproportionate effects (6). The accompanying point, of course, is that similar outcomes in human beings may be quite far off, if they are possible at all.

One distinction requires immediate attention — that between *germ-line* and *non-germ-line* techniques for altering traits in a specific possible or existing person. (Selective breeding would alter the distribution of traits in a population but not in a particular individual.) The latter include genetic alteration of somatic (body) cells ("gene therapy"); such alteration does not affect gametes (mishaps aside) and so does not affect one's descendants. Nevertheless, because "gene therapy" and the development of substances directly affecting gene operations require extensive knowledge of genetic mechanisms, all these modes of enhancement will be mentioned here.

The Idea of Enhancement

In General. For convenience, "enhancement" and "augmentation" are used interchangeably, although the latter might also suggest "extension" or "supplementation" (e.g., a springier vaulting pole). Standing alone, the term "enhancement" will refer to technological enhancement, not to socially and legally accepted processes of self-improvement — say, gradually increasing one's strength by lifting weights, or improving analytical skills through study. Many observers view the results of such accepted measures as "internally" rather than "externally" or "unnaturally" generated changes that compromise claims of personal, meritorious achievement (7). In fact these varying paths toward superior traits will generally be intertwined, further complicating our analysis.

Here are three basic families of overlapping questions concerning the meaning of "enhancement." Who is to be enhanced and why? What is to be enhanced and why? What counts as enhancement and why?

What Is the "Unit of Enhancement"? We need to ask first *who* or *what* is to be enhanced. A possible person presently in the form of an early embryo, or as-yet-unjoined gametes? A particular living person or group? The present or future human race?

What Is Enhanced? Traits, attributes, and characteristics are the targets for enhancement, but to what do these terms refer? Behavior patterns? Physical appearance? Tissue structure? Molecular arrangements — such as genomic structure — and biochemical processes? Competitive performance? Predispositions to develop particular physical or mentational conditions? And which of these targets should be selected for improvement? What role does culture play in characterizing and valuing traits, and how might this track genetics? A culturally valued trait may rarely have a clear genomic correlate.

What Counts as Enhancement? The two most discussed issues are, first, whether and how to distinguish permissible forms of enhancement (practice, pumping iron) with impermissible forms (ingesting memory-aiding substances, altering the germ line of one's children — technological fixes or shortcuts generally); and, second, whether and how to distinguish between enhancement, on the one hand, and repair of "defects" or injuries or control of disorder, on the other. As to the latter, a major reason for insisting on the treatment/augmentation distinction is the belief that it provides limits on an enhancement imperative that might seem to be utterly unbounded. This is not without cost, however: We risk devaluing and stigmatizing those with "imperfections" of various sorts. In any case, resource constraints may impose severe limits on the extent to which the "treatment model" and the "enhancement model" will be "lumped."

Enhancement of Merit and Wealth-Attracting Attributes (Resource Attractors). Traits plainly vary in importance. Those strongly favored for whatever reason — special abilities, health, appearance, personality, culturally preferred predispositions — are critical variables affecting the distribution of life's rewards, including social and political status, income and wealth, praise, mating opportunities, and prizes. The moral and conceptual foundations of merit and desert judgments are complex (8) and cannot be plumbed here, but it is vital to see that "merit attributes" are often (but not necessarily) "resource attractors" — they are distributional criteria of sorts, whether in market, centrally directed, or other economic systems. The close coincidence of these ideas permits some interchangeable use. Suppose, now, that we can enhance these distributional criteria through technological alteration. Those persons already in a position to draw substantial resources may sharply augment their resource-attractiveness — possibly in a self-accelerating cycle that draws increasing wealth and power to the enhanced persons. In at least a metaphoric sense, then, one's very "merit" is increasing — one's "merit basis" is "stepped up" — thus amplifying one's claim for still more of everything, including still more merit. The resulting risks of increased and more inflexible social stratification are obvious (9). (The risks seem lessened when enhancement is temporary and must be repeatedly renewed — a point to retain throughout this discussion.) One existing parallel is the distribution of educational resources, particularly advanced and specialized higher education. Another is wealth itself: One needs it to get more of it, and even to keep what one has. Here the intersection of equality with justice and fairness considerations is obvious. (A close comparison and ranking of these values is not possible here.)

"Repair of Disorder" as Distinguished from "Enhancement"; Disorder versus Enhancement Models for Justifying Trait Alteration. If a pathological condition is successfully treated, we are unlikely to describe the restorative process or its result as "enhancement" unless the intervention appears to go beyond "canceling out" the disorder and induces a "nonnatural" condition that masks or displaces the impairment rather than restoring the patient's

ex ante personal baseline. If the improvement is justified by a supposed medical need, however, complaints of unequal distribution of enhancement resources may be blunted, although complaints about unequal access to medical resources may continue. In many cases the two models are partially "merged" — for example, measures to increase immunity or other resistance to certain disorders or conditions.

More generally, equality issues concerning enhancement will not just vanish when a disorder model is invoked. For one thing, reliance on a disorder model will not go unopposed. One can question the moral relevance of the distinction between disorder- and enhancement-based justifications for distribution: If an egalitarian imperative requires remedial measures, then — resource scarcity aside — what difference does the therapy-enhancement contrast make if one's relative position will be improved either way? One can also note the difficulties in distinguishing between the two in various other cases. For example, repair of a fracture might make one less vulnerable to future fractures, leaving one in effect stronger than before the injury. And, as we saw, germ-line or somatic manipulations that make one less vulnerable to, say, infectious diseases straddle the treatment/repair versus enhancement distinction. An oft-mentioned example of these difficulties is the use of human growth hormone. Its administration as treatment for short stature caused by pituitary or other disease is more readily accepted than its use on short persons not suffering from a height-impairing disorder — although from the short person's viewpoint, it may make little difference what accounts for his fate (10). The latter use is often seen as technological enhancement — although of a socially handicapping trait (11) — rather than treatment. Of course, whether something is a treatment at all rests on whether it is directed at a disorder, disease, injury and the like, and this may again depend in part on cultural habits and existing environmental conditions: What are socially (un)acceptable moods, or prevailing attitudes toward persons of very short/tall stature? Does the society's current "physical plant" (e.g., lots of stairs, few elevators) contribute to the limitations of persons with particular conditions? Still more, the treatment/enhancement distinction might be viewed as immaterial to the more general goal of "normalization" (12) — a concept overlapping, but distinct from, that of enhancement. But the standard of "normalization" may rise with enhancement or treatment, and the notion of relative handicap — or even disorder — may thus expand, with unfortunate consequences for the "handicapped."

Despite problems with the systematically murky treatment/enhancement distinction, however, it is far from meaningless (12).

Enhancement, Illicit Transformations, and Compromise of Identity, Merit, and Desert; the Paradox of Perfectionism; Effort and Merit. The traits a given culture most values at a particular time — say, intelligence (13), strength, and the capacity for diligent effort — are (1) the main targets of traditional improvement efforts such as training and practice and (2) arguably the most sacrosanct against technological tampering (14).

So the very traits selected for improvement are precisely those whose "artificial" ("nonnatural," "identity-compromising," "externally induced") augmentation is the most suspect. Indeed, if the wrong paths are taken, we may not even *count* the result as "improvement" or the accomplishment as (fully) merited. The very status of merit attributes may be impaired when they are technologically refashioned to extend beyond one's preexisting natural baseline, as augmented by traditional effort. But traditional baseline methods of self-alteration are not only *not* banned, they are *required* by perfectionist/progress ideals. (Whether such personal obligations accompany social obligations to assist individual perfectionism, of course, depends on the content of the ideal, and in turn on underlying basic value conceptions.) The upshot is that bettering ourselves in *inappropriate* ways does not "perfect" us — it lessens us. Thus, more is less. A possibly connected idea is that dispensing with effort as a critical component of achievements and improvements might "cheapen their value and cheat the social practices in which they play a role" (15).

As a rough intuitive matter, enhancement also raises troubling images of compromised personal identity, and thus of assignments of credit or rewards. If technology threatens identity, it also threatens the moral and political relevance of merit and desert. In turn, where merit/desert ascriptions are undercut, equality constraints become more muddled than usual. To assign greater rewards to those of greater merit than to others does not — on *some* views of equality — breach equality standards, and indeed may be required by them. If we cannot say who won the race, we cannot fully justify our assignment of prizes.

The capacity for effort at self-improvement or anything else seems to be a merit attribute, so this deserves some additional comments. We often prize *trying*, which we commonly view as under our control, as much or more than native endowments, many of which seem arbitrarily fixed. The results of traditional forms of striving are thought to be consistent with a stable identity. Now, the capacity to try is thought to be influenced by genetics and noncontrollable aspects of environment, as are other merit attributes. The talent for struggle is itself subject both to technological and nontechnological improvement (an infinite regress of trying?). How should we morally rate an increased capacity to exert diligent effort when the capacity is itself altered technologically? Isn't this as questionable as alterations of supposedly "fixed" traits such as intelligence, and of incrementally improvable traits such as strength? (One thinks of steroids in athletics here.)

It is also possible, in context, to view technological enhancement of endowments — including the capacity for effort — as itself reflecting a kind of praiseworthy effort. An increment in powers of memory, for example, may be unearned but nevertheless possess intrinsic value and instrumental value, as where it aids air traffic controllers in keeping up with the ever-increasing flood of data.

Demand for Enhancement Resources; Economics. The scale of demand for such resources depends on many

variables that cannot now be clearly identified and measured. These variables include the nature of the enhancement, its monetary costs and perceived medical risks, the deterrence or incentive effects of gatekeepers and their standards (physicians as well as bureaucrats may keep the gates because of medical risks), cultural variables (whether technological enhancement is (dis)favored in general or for specific traits will obviously affect its level of use), interpersonal pressures (also influenced by culture), links and interactions among different traits, and personal preferences. Different forms of technological enhancement may of course fare quite differently in the market (16).

Any stable economic unit requires supply and demand equilibrium for any commodity, and this presupposes diminishing returns for incremental distributions. Diminishing returns will no doubt set in at some point for distributions of "increments in merit," but as noted, this onset may be quite late in the game (as with many medical resources generally). You may not value yet another hotdog, but you can always stand to be smarter. There may even be expanding returns at various distributional stages. To make modeling and prediction still more difficult, different assemblies of merit traits may interact in unpredictable ways in the market; some traits will reinforce or "potentiate" each other, some will impair each other, some increments can substitute for others, and so on. Finally, recall the impact of extent of social use: Being highly intelligent is less valuable when all are highly intelligent, yet there may be as much or more pressure to consume enhancement resources even if solely to maintain one's position.

COMPETING VERSIONS OF (IN)EQUALITY

A Thought Experiment Not Far Removed from Reality

This exercise is meant to illustrate differences in specifying what is to be "equalized" through distribution (2,17). If the egalitarian goal is to attain $X = Y$, what might X and Y be and what does "=" mean?

Suppose we have a mechanism (e.g., drugs, somatic gene "therapy," or germ-line alteration) that can significantly enhance one's mental abilities. There are many possible distributional schemes for the enhancing techniques. The distributees might be individuals or possible individuals in early embryonic or even dissociated gametic form. The distributive mechanism might be central direction by government, markets, or kinship and other interpersonal relations. The effects of the technology, for good or ill, are likely to vary among persons. Sophisticated models will take account of the variability, but simplifying assumptions concerning uniform efficacy are appropriate for now. For example, one might assume that we will see the same per-dose linear increments in a given ability for all persons, or that effectiveness is a direct or inverse function of preexisting ability — the abler one is, the greater or lesser the increment. It is also helpful to leave aside the fact that mental abilities come in many varieties as well as strengths and that their recognition and status may vary among cultures. The particular regulatory or licensing schemes that would implement the distributive plan are not discussed here. Whatever the schemes are, for oneself, one's children, or some group, the licensing procedure must embrace either a substantive criterion or some objective mechanism such as a lottery or queuing (neither of which is entirely "objective").

Market Distribution. Free market exchange implements a sort of equality of opportunity based on ability to pay (including insurance and borrowing power). There is an extensive literature on the moral foundations of markets, including commentaries on the role of characterizing existing distributions of goods and bads as just or unjust, and on the impact of "preinstitutional desert" and fairness in promoting realization of legitimate expectations, but this is left aside here (18). "Enhancement" might be financed through health insurance mechanisms, particularly where the procedure can be viewed as treatment for disorder, defect, or injury, or at least as ambiguous (recall the example of immunological augmentation). (19) Here, a *ratio* is equalized across persons: *dose/financial resources-economic power*. As for nonmarket distribution via central direction, we might consider —

Centrally Directed Distribution of Equal "Doses" to Everyone. This is a simple, ham-fisted sort of equality. It suppresses individual variations and thus bypasses questions of need, merit, and utility. The ratio of dose to threshold status as a person is the same for everyone.

Distribution in Proportion to Need. What is equalized is the ratio of *dose to need*. "Need" itself is a disputed concept for several reasons, including the fact that many asserted needs are based on one's *relative* status within a population, that need exists in degrees, that it is afflicted with the difficulties within the treatment/enhancement distinction, that it may be linked to nothing more than one's preferences or goals, and that it may be unclear what follows from an ascription of need: Are there duties not to interfere with anyone's trying to meet their needs, or government duties to provide assistance? If need rests on having a recognized disorder or injury, then only the afflicted receive doses — e.g., the demented or persons with Down syndrome. It is unclear how to apply a "need" standard to statistical "outliers" who are not disordered but nevertheless are handicapped by their distance from the median. And need may, as suggested, be task related: Did Einstein "need" enhancement to make progress on a unified field theory?

The fact that one's needs may be based on being relatively worse off, whether in natural endowments or in environmental circumstances, requires special attention (20). Well-known political and moral theories call for measures of "redress" because many of the worse off are seriously disadvantaged. Rawls's difference principle, for example, suggests distribution of resource-attractors to equalize the dose/need ratio — where need is linked to relatively low status (21). The difference principle, however, can also be viewed as threatening other visions of equality, as well as values of autonomy, justice and fairness. Redistribution entails interference with

autonomy, and is arguably unfair in allowing some persons (the worse off) to reap the full benefits of their native abilities while preventing others (the better off) from doing so. Of course, a central question is "redistribution of *what?* The existing stock of wealth? Opportunities for enhancement?

Distribution in Proportion to "Social Utility." The ratio equalized here is dose to social utility. The social utility of some distribution pattern might be inversely *or* directly related to the distributee's relative ability, without regard to whether disorder underlies his or her low-end status. Distribution to those handicapped by low intelligence might reduce the need for social services. As for the very talented, think of encryption specialists trying to break an enemy's code (suppose that the British "Enigma" program hadn't cracked the German code in World War II?). Only those on the "edges" of human ability would become licensees. One might even expect pressures on government to require certain workforce groups, if not everyone, to use enhancement resources, though enforcement might be quite unpleasant — not to mention immoral and unconstitutional (e.g., violations of the Thirteenth Amendment).

Distribution in Proportion to Preexisting Merit. There are "native" ("endowed") merit attributes such as mental abilities, physical agility, and the capacity for diligent effort. There is also "acquired" merit based on accomplishment, good works, and developed skills and aptitudes. [The division between the two is hazy (8,53–68,109–131).] Here the ratio equalized is *dose to merit*. On this standard, the answer to "Who merits (more) merit?" is simply: those who *already* are highly meritorious. This sharply contrasts with a view of equality that sees natural variation in aptitudes as something to be overcome rather than presupposed as a suitable basis for distributing life's rewards (21).

Distribution in Proportion to Intensity of Personal Preference. The criterion here is how badly one wants something — including enhancement itself as a major facilitator for success generally. Extremely (pathologically?) intense preferences might be viewed as needs. Preferences and their intensities may also be regarded as a form of merit. We admire persons whose "desire to win" is strong enough to overcome serious odds.

Distribution to Achieve Equality of Outcome. Here, doses are distributed so that all have equal intelligence, however this level is chosen. There is no unitary concept of intelligence, and the task of equalizing all recognized forms of intelligence (22) seems far-fetched, but this is a thought experiment, after all. This rather open-ended outcome standard may entail that everyone be as intelligent as the previously most intelligent, or that the more intelligent are affirmatively impaired (they receive "negative doses") to reduce their status (23) while the less intelligent are upgraded. If the desired uniform ability level is Φ, the ratio equalized is the absolute value of *dose effectiveness to distance from* Φ (including positive and negative doses). The driving force here might be the alarming idea that equality requires or is aided by making persons as identical as possible. On the other hand, "equality of outcome" may refer to identical proportional increases, leaving everyone's position in the "pecking order" the same. Of course, these different forms of equal outcome are in general quite different, and they bear only an uncertain relationship to more comprehensive forms of equality of outcome — income or wealth, social standing, political power, and so on.

Distribution by Lottery. In an effort to bypass the immense difficulties in applying the ideas of equality, fairness, and justice, some have recommended distribution of scarce resources via lottery (24). Perhaps in this sense lotteries represent a form of being "unprincipled on principle" (25). In any case, the suppression of interpersonal differences entailed by lotteries (once the lottery's constituency is defined) is both the *point* of resorting to them and the chief *objection* to them.

Randomization schemes cannot be properly denounced on egalitarian grounds without a theory of equality that explains why equalizing over one field rather than others (e.g., doses, dose/merit, or other ratios) reflects or produces "true equality," or at least a preferable form of equality. If a satisfactory equality theory is unavailable, values other than equality must be invoked. As it stands, lotteries serve some visions of equality and rationality and contravene others. On one view, lotteries promote equality because all who qualify for the lottery (qualifying itself raises serious equality issues) have an equal chance of winning it, *despite* their varying personal characteristics. Indeed, it is precisely the attention to these varying individual traits that constitutes for lottery supporters a violation of equality: These interpersonal variations — rather than basic personhood itself — are to be *suppressed*. On the other hand, some will receive the resource and others will not, *without a "substantive" reason.* This situation is arguably irrational and thus a violation of equality standards, possibly under prevailing views of personhood and its entailments.

Equality Wars: Conflicting and Concurring Versions of Equality and Inequality; Remedies for Inequality; Equality, Enhancement, and Respect for Persons

In General: Equality of Whom or What and with Respect to What? What *do* we assert in saying that $X = Y$? 'X' and 'Y' might designate persons, groups, opportunities or prospects held by persons or groups; means for taking advantage of opportunities to achieve one's goals; specific outcomes (wealth, victories, etc.); social or moral status; political power; rights as persons (26), without regard to differing traits; traits characterizing different persons; ideas, conceptual systems and philosophies; and overall ("net") personal or group merit or social worth despite differing traits.

Each possibility rests on concepts that are themselves difficult to penetrate, and are likely to reflect serious political and philosophical differences. To assert equality of noninterference rights — such as free speech, free exercise of religion — is far from asserting equality of

means, opportunity, or prospect in securing audiences or places of worship (2). And these differing equalities may hold drastically different positions of respect and commitment among different persons and groups within a society, and from society to society. "Fundamental" noninterference rights are protected under the U.S. Constitution. Affirmative ("welfare") rights generally are not, even when directed toward increasing or preserving equality. The rejection seems to be founded partly on autonomy grounds, and partly on rival views of equality: Redistribution entails that some receive unearned rewards and others do not, and different persons will be allowed to keep different proportions of their wealth or income. The flags of equality, fairness, and justice are carried by all sides here — a point that is retained throughout this discussion.

One could raise parallel questions by asking about the meaning of the equality operator "=." Is it an assertion of fact (Arnold's strength is equal to Sylvester's), and if so of what sort? Is it a moral or political claim about equal rights or entitlements, and if so to what? Does it reflect an ideal both of the *threshold* equality of persons without regard to their differences and of how they should be treated? If we say persons are equal because they are all equally persons, why is undifferentiated personhood the right level of abstraction rather than personhood qualified by particular (dis)favored traits? If we say that the political power of (person)(group) X "equals" that of (person)(group) Y, we may mean they have equal numbers of votes, or equal power to elect candidates of their choice, or equal power to influence government policies (a particularly obscure claim), or any of several other options. It is not clear that we can justify our choice of "meaning" here via reference to equality alone, without reference to justice, fairness, autonomy, and utility — even if equality is not fully "reducible" to any of these other values or to some subset of them.

Equality and the Special Status of Merit Attributes. Judgments about an individual's merit are often relied on as a fundamental ground for sorting people — specifying certain (in)equalities among them — and for acting on these characterizations. The governing moral intuition (perhaps not in all cultures) is that outside the domain where only threshold personhood counts, persons are to be judged on their relative merits, and not on "arbitrary" personal characteristics or relationships. It is difficult to formulate a coherent theory for sound application of the epithet "arbitrary." For example, is it arbitrary — and thus perhaps morally improper — for individuals to search for a mate solely within their principal social group(s), which may be defined in part on the basis of ethnicity, race, religion, or national origin?

But comparative merit judgments are also criticized because, among other things, they produce unequal outcomes and may rest on unjust features of the status quo. More distribution of resources that strengthens one's measure of merit may expand and reify existing inequalities — even if it remains unclear whether artificial enhancements would be recognized as merit claims.

Valuation of Equality. As Temkin asks: "Is equality really desirable? And what kind of equality should we seek — that is, insofar as we are egalitarians, should we want equality of opportunity, primary goods, need satisfaction, welfare, or what? ... When is one situation *worse* than another regarding inequality?" (17, p.3).

The question of what "equality" means is distinct from the question whether it is desirable or valuable — although the two inquiries are linked in complex ways: Assignment or recognition of meaning often involves value analysis. There is, to be sure, an oddity in asking about the value of equality or of any "basic" value. How can one "value" basic values when these basic values represent the very terms in which value is defined and assessed? However paradoxical this may seem, we characteristically rank-order our values and assess them with respect to each other. But this is a matter for a comprehensive enterprise in moral theory.

Rectifying Inequalities. Plainly a major issue in genetic enhancement is whether it should be used to rectify inequalities by affirmatively creating equalities — and if so, how. Suppose that we reach a rough consensus on the preferred meaning of "equality" in various situations. There nevertheless may remain significant differences over appropriate measures to rectify or prevent inequalities. For example, if A's cache of goods is v but B has more, holding w, is A intrinsically worse off when B acquires still more but A continues to hold v? (17) From an equality standpoint, is it better to achieve equality by raising A's holdings from some outside source or transferring some of B's holdings to A? Or to enhance A's aptitudes and let him, on his own, try to overtake B? Should we worry more about inequality between certain groups than inequality within those groups (17)? Rectifying existing or past inequalities may implicate procedures that *themselves* may violate specific conceptions of equality — such as transfer payments. Such redistributions arguably impair the right to reap the benefits of one's natural gifts, as amplified by skills acquired through effort. As mentioned, they entail that some persons — those less well off — can acquire additional resources earned by others, and perhaps can keep a larger proportion of what they earn than can others.

"Rectifying" Differences. A population consisting of a single human clone (in the collective sense) might have equality problems, but the problems would surely be rather different from (but not necessarily lesser than) ours. A rather drastic (and perhaps technologically impossible maneuver) would be to make as many persons as identical in major respects as possible. The costs (from our present framework) in reduction of cultural and physical diversity and the loss of multiple perspectives in human endeavors seem very difficult to bear, although the radical transfiguration of human life makes them hard to assess. And, of course, the resource costs might be prohibitive. The point here is simply to observe that "difference" does not entail "inequality" in any sense relevant here, and few are on the stump for technological erasure of human variation (27).

Equality and the Morality of Inclusion and Exclusion. One might select among competing ideas of equality by appealing to a preferred morality of inclusion — of lumping by appealing to commonalities. The point of this brief reference is to emphasize two observations. Some may see the "technology of perfection" as allowing displacement of chance variations by planned similarities: We will all be perfectly equal because we will all be equally perfect. However, the very emphasis on perfection may impose serious burdens on those viewed as disabled or handicapped (3).

Is Equality "Empty"? Perhaps the indeterminacies (a term left undefined here) or conflicts *within* the idea of equality cannot be eased by further analysis of equality. There seems to be no overarching notion of equality to appeal to in all contested cases. The tensions may be irresolvable (17), though occasional consensus on certain matters may be attainable.

This is the central idea behind the claim that equality, at least in many important circumstances, is "empty" — a vacuous concept (28). The emptiness claim is roughly that the egalitarian maxim, "treat persons (dis)similarly situated in (dis)similar ways," cannot be understood and followed without a substantive moral/political theory of (dis)similarity that cannot itself depend on equality. We need, on this view, a theory with normative content to tell us what difference a difference ought to make. Equality alone does not tell what characteristics or actions (or anything) to "lump" as relevantly similar, nor what to "split" or suppress as relevantly different. For example, if government action permits some speech and restricts other speech on the basis of content, we cannot tell whether a constitutional or moral equality principle has been breached without a substantive free speech theory.

Equality and Other Values: Conflicts and Connections

It is often said that in many circumstances, equality, autonomy, fairness, justice, and utility (or any subgrouping) conflict. The nature of the conflict of course depends on the versions of equality and other values under review (29). A standard example is affirmative action. Distributing benefits on the basis of racial, ethnic, or gender criteria entails reduction of opportunities — a form of reduction of liberty and autonomy — for those without the relevant characteristics, and imposes forms of personal association on unwilling persons. These processes and outcomes conflict not only with particular views of equality, but with those of fairness, justice, autonomy, and utility (29,31). On any given set of views, justice may dictate what egalitarian maneuvers to prefer — say, that equality of opportunity, in justice, requires some degree of access to enhancement resources either via noninterference rights or via positive entitlements. Or some states of affairs or actions may be viewed as unjust because of a violation of some equality standard. (There are level-of-category problems in listing "basic" values. Not everyone would place these values on the same plane of moral reality or discourse. "Justice as fairness," for example, presupposes that at least certain versions of fairness are criteria for a higher-order concept, justice. Such difficulties cannot be further addressed here.)

Distributional Equality Generally; Distribution That Transforms the Distributees; Distributional and Nondistributional Equalities

Distribution and Personal Transformation. Distributional equality concerns who gets what, why, when, and how under any given system for distributing scarce resources. It addresses matters both ex ante (e.g., who gets the "merit-enhancing" commodity) and ex post (e.g., who gets what rewards — including still "more merit" — after the distribution and, at least in part, as a result of it). This ex ante, ex post distinction is particularly important given the possible "transformative" effects (left undefined here) of the distribution of enhancement resources. Augmentation may change the structure of the distributional game by disproportionately enlarging the distributee's resource-drawing power — ratcheting it up so that it is hard to undo. One might argue that all distributions "transform" the recipients and that there is no sharp distinction between the transformative effects of education or training, on the one hand, and of technologically augmented intellectual or physical functions, on the other. This is obviously true, but the absence of clear borders marking a distinction does not of itself trash the distinction.

Equality and Reduction, Mere Use of Persons, and Objectification: Some (Largely) Nondistributional Problems. Suppose that we believe a practice of enhancement reflects and generates excessive concern with the measures of specific traits and thus "reduces" persons to the (often commercial) value of these traits. This reduction is intimately connected with the processes of "mere use" and "objectification" of persons — their devaluation or descent from persons to "objects." A person who is (at least partially) objectified, reduced, and subject to mere use has thus suffered an egalitarian loss. (If everyone were reduced or objectified, however, there might be equality among the objects.)

ENHANCEMENT AND ITS EFFECTS ON (IN)EQUALITY; (NON)DISTRIBUTION OF ENHANCEMENT RESOURCES; REGULATORY CHOICES

Nondistribution Options: Nonallocation at the Macro Level; Restrictions on Manufacture, Distribution, and Use; Black Markets; Paternalism and Community Self-Protection

In General. There are many commodities that we think, for whatever reason, should not be distributed widely, if at all. To limit distribution, we can avoid allocating resources to the creation of such evils. If this fails, we can enact prohibitions or lesser regulations concerning distribution and ultimate use, although this may risk greater loss of control because of the rise of black markets. For example, prohibitions or severe restraints on use of enhancement resources may compound their risks by inhibiting safety controls such as physician guidance.

Whatever we decide about use of the commodity, the selection of the best regulatory mechanisms to implement our preferences remains open (31). Resolving this may

require empirical inquiries to inform the moral, legal and policy options. Certain arguments frequently offered to justify nondistribution require attention because they bear on equality.

Nondistribution to Protect Those Who Prefer Non-use: The Perceived Risk of Greater Inequality as a "Coercive" Factor; Technology-Driven Demand for Greater Skills and Thus for Enhancement. People often do things they would rather avoid because, if they don't, they fear others will gain advantages over them. One might say that doing so reflects a "straitened preference"—it is what they want only under adverse, dispreferred circumstances. This is not necessarily bad: A child averse to learning to read may find a "second-best" reason to do so when advised that "all the other kids are doing it." Similarly the risk of falling behind in athletic activities may drive some otherwise unwilling competitors to steroids or other supposed enhancers. Although one can dispute the claim that this is rightly called "coercion" via excessively strong incentives, a strong sense of pressure in some form on the unwilling is likely. In some contexts this matter is easily put aside: Many athletes and students do not wish to practice, study, train hard, or diet, but few speak of coercion in these contexts. One must compare such standard efforts with, say, ingesting memory-or muscle-enhancers to shorten the task. Some pressure to do the former is widely considered desirable—possibly obligatory under some circumstances; not so with the other. Few complain of coercion in these contexts, partly because the general endorsement of such self-improvement counts against applying pejoratives such as "coercion" or even "undue influence." Still the wide use of these characterizations suggests that something is believed to be amiss in the choice situations in question.

More generally, pressures favoring enhancement of living persons, fetuses, and possible persons are likely to grow. There is some evidence of technology-driven increases in the demand for "human capital" as reflected in investment in education and training (32).

Paternalistic Nondistribution to Protect Persons against Physical or Psychological Harm; Autonomy versus Autonomy. Enhancement measures, whatever their efficacy, carry risks of adverse effects. Of course, the nature, incidence, and seriousness of such effects—perhaps even whether they are in context adversities at all—is largely unknown. One justification for nondistribution may thus be pure paternalism (a term left undefined here) (33). Another justification, suggested above, reveals autonomy's internal tensions: promoting autonomy by reducing "coercive incentives" (34) to use disfavored commodities. But a broad interpretation of "coercive" may impair the autonomy of those wanting to use the suspect resources and who knowingly assume their risks.

An Equality Argument against the Preceding Nondistribution Arguments. Those seeking access to enhancement resources may of course also offer an important equality argument: They are denied equality of opportunity to better themselves and are relegated to an inferior status as against their superiors, whose natural gifts are as arbitrarily deemed meritorious as are the enhanced attributes.

Nondistribution to Reinforce Equality Values and to Avoid Devaluation of Life and of Effort; Ambiguities of Identity.

The Lombardi Effect: Winning Isn't Everything—it's the Only Thing (35); Paradoxes of Reduction and Valuation; Reduction as Compromising Equality. We learn in part from observing and interpreting social practices, and the societal risk here lies in the "lesson" or "message" that athletic victory is worth serious bodily or mentational harm. [A 1984 poll of uncertain rigor reported that Olympic athletes would accept death at an early age in a Faustian exchange for guaranteed gold (36).] If the practice is banned, getting caught and sanctioned is also perceived as a risk. However, it is the ban itself that is in question here. Note also that to characterize the risk as "mere" (as in "risking life and limb for mere athletic victory or for show") pressupposes certain value premises. One might urge, for example, that in a nation besieged by enemies on all sides, the supposedly adverse lesson about winning at all costs is useful for national self-defense by reinforcing a warrior state ideal.

To the extent the victory-is-all lesson is learned (by observers and the competitors themselves), it may reflect and constitute a reduction of human value to a single function or goal—athletic or other competitive success. Such devaluation bears on equality. Those persons who are reduced (a concept strongly linked to "mere use" and "objectification") are seen as less worthy than others, and thus unequal to full-valued persons. The enhanced—if that appellation survives—may be viewed as (partial) artifacts of *lesser* merit who leapfrogged over their associates and competitors. If so, it may be the *enhanced* who require protection from the unenhanced (37). (In that event, resulting inequalities of distribution would not be perceived as reflecting true differences in personal worth, and artificially enhanced talents would not be seen as lessening or devaluing the natural talents or acquired skills of others.) The value of enhanced persons will have collapsed into a narrow range of traits based on their prospects of victory. This supposed reductive risk carries us to the next difficulty.

Troublesome Links Among Enhancement, Value Reduction, and Positive Valuations; Role of Risk-Taking; "Person Perception". Value reduction by focus on specific traits or accomplishments is intricately linked to valuing persons positively—viewing them as meritorious and deserving of our high regard. We value persons not only because of the traits that define their threshold value as persons, but because the strength of those traits distinguishes them from others. How does this differ from "reducing" them to their traits? If we cannot say, the contrast between reduction and positive valuation seems empty. Suppose that an athlete says "winning is the only thing and is worth my life." Does this reflect "reduction" and lesser status—in her own eyes or the eyes of others? Or, on the contrary, supervaluation and greater status? Or some combination? The more general question concerns how we indeed perceive each other as particular persons—an issue not only for moral and political theory and practice, but for continuing work in cognitive psychology.

The answers, if any, may depend partly on cultural baselines. The United States for example, is not about to ban football or boxing because they risk severe permanent injuries or death. But *incremental* risks beyond a traditional baseline may be rejected because they reflect inappropriate trade-offs: All risks are justified if winning is everything or the only thing. (Think of escalating boxing to fights to the death.) Such a view arguably reflects a debasement of the value of life in the eyes of the audience and in the competitors' own eyes. (This particular argument would of course not directly apply to "magic bullets" — zero risk but effective enhancers. But there may nevertheless be possible adverse effects of extreme focus on the traits needed to win.)

As for risks undertaken for intellectual enhancement — such as a dangerous, possibly fatal drug that greatly augments memory — the situation is unclear and may depend on cultural circumstances affecting the comparative valuation of traits (e.g., intellectual as against athletic abilities). In Frank Herbert's *Dune*, rival feudal houses far in the future relied on resident "Mentats" — "wizards" of a sort — who amplified their preexisting exceptional intelligence with an addicting "spice." They evidently were judged *both* on their initial baseline abilities and the level of their enhanced abilities — the latter probably being a partial function of the former (38). Perhaps they were also judged on the skill with which they enhanced themselves and on their courage in facing risks. In this sense, at least a sliver of their "endowed" merit endured. Given their culturally imposed duties, what they did can be characterized in context as praiseworthy effort rather than merely as deriving an unearned benefit. Moreover their work would continue to reflect effort and struggle if, partly as a result of their enhancement, the complexity of their tasks increased (14); those who can do more complex work are likely to have it presented to them. Still, as suggested, artificial enhancement may not be viewed as meritorious enhancement at all. Indeed, from this standpoint, the more revered an attribute is, the more it is corrupted through technology's manipulations, and the more degraded is the "enhanced" person.

Avoiding the Social Devaluation of Effort. This category embraces both paternalistic and nonpaternalistic reasons for nondistribution of "elite-creating resources." As suggested, a possible (perhaps inaccurate) impression conveyed by a visible practice of enhancement is that the enhanced are getting a free ride (or at least a reduced-cost one). So, it is argued, enhancement entails getting too much bang for the buck — cheating of sorts — even if done in the open. If effort is devalued, merit judgments are distorted, and so are our judgments concerning the (in)equalities holding among competitors. (The claim that merit evaluations are "distorted" presupposes some preferred baseline from which to measure distortion.) What are we to make of the fact, for example, that some students, relying on their own gifts as aided by work, are disadvantaged in college-entrance examinations as against "artificially" or "unnaturally" able persons? To avoid this inegalitarian disadvantage and the disruption of prevailing norms, would a student need a license reflecting that she had not been enhanced before the exam? (Or might it be the other way around — "nonenhanced need not apply"?) Of course, one may question the sanctity of prevailing norms, but within reason, communities have some defeasible moral and legal right to maintain the major features of their normative systems (39).

Devaluation of effort might also (paradoxically?) arise from enhancing the very capacity or inclination to make efforts: Some may view the result as external to one's character — an outside supplement that carries no merit with it. Some authorities, for example, say that steroids may expand one's capacity to exert efforts before reaching exhaustion (40).

More on Threats to Identity; Confused Attributions; Effects on Equality Judgments.

1. *Altering living persons.* Recall the distinction between germ-line alteration and gene therapy or other somatic treatment on living persons, fetuses, and embryos. In dealing with living persons, some aspects of equality concern assessing the fairness of returns on effort and of rewards for one's native endowments — particularly when effort and endowment are combined. Such judgments obviously require identifying and comparing persons. Enhancement may confuse notions of personal identity in at least two ways. It may create ambiguity as to the "source" of one's performance — whether it is "internally" generated and thus causally attributable to that person, or the result of "external" artificial augmentation and thus "attributable" to an outside source. If the latter, then the person in question "didn't do it." The judgments of merit and desert underlying the distribution of rewards will also be confused.

   Moreover, enhancement may, by altering personal traits, appear to interrupt the continuity of human identity, which in other circumstances endures despite gradual, historically acceptable change. In both situations equality appraisals — at least in extreme cases (not yet at hand) — may be distorted or even meaningless. Who or what is equal to whom or what? Who won the fight? Should an enhanced Mentat transplanted from a Dune world be eligible for a chaired professorship or the Nobel Prize? (Data, an android in *Star Trek: The Next Generation*, was ultimately awarded the Lucasian Chair — the same Cambridge chair held by Sir Isaac Newton.) Should he be rewarded only if all other candidates had similar enhancement opportunities?

   Do major trait changes truly compromise personal identity — say, a sudden escalation of intelligence from average to extraordinary (41). After all, one's "baseline" identity doesn't really disappear: The new one is built on it, and all new identities will continue to differ sharply from each other. One can well imagine, as suggested, educational institutions debating whether their admissions criteria should exclude augmented persons as not "truly meritorious" unless their natural abilities ex ante — their "enduring merit" — would have secured their admission. Should we compare and rate

persons only on the basis of endowments pre-enhancement? Or is this irrelevant history? Even if pre-enhancement merit remains relevant, the "locked-in" resource-accumulations made possible by accelerating returns might be viewed as going far beyond fair rewards for ability — assuming that *that* distributional criterion is believed sound.

2. *Altering germ lines.* Identity problems may take on a different form when one considers the genomically enhanced — through alteration of early embryos or of gametes — as well as those who were enhanced somatically. The latter can be further divided into persons enhanced in utero, as embryos in vitro, or as young children, or adults. Our sense of self-identity, autonomy, and personal worth may differ sharply depending on our knowledge of the nature and timing of our enhancement, and on the reasons for it. Knowing that one's genome was altered will not necessarily have the same impact as knowing that one's physiology was altered. There will also be differences depending on the timing of the somatic changes — principally whether pre-memory (where the person would know herself only in her enhanced — and, to her, "native" form) or within memory. In any of these variations, think of children asking their parents just why their "natural identities" were tampered with or even changed, whether genomically or somatically. Was a potential person (the *un*enhanced entity) adversely affected because its existence was blocked and replaced by "another" person deriving from the altered entity (42)?

Equality Impacts of Technological Enhancement: More on Distributional Options

In General: Enhancement That Alters the Bases for Distributing Benefits and Burdens. As we saw earlier, the "equality impacts" of distributing anything depend not only on matters of fact but on what notions of equality are used. In turn this may determine what "units" or entities are being compared and targeted for what forms of "equalizing" with respect to what distributable entities. We may be addressing existing or future persons, families, groups, and so on, with respect to equalizing income, wealth, social status, legal and political rights, and opportunities of many sorts, and so on (2).

We now need also to distinguish between distribution of the resources needed for enhancement, and distribution of all other commodities. Distribution of enhancement resources changes the game by altering the criteria for resolving distributive claims; this "feedback" may be far more striking than the distribution of education and wealth.

Do Disorder/Treatment Models Blunt Equality-Based Objections to Enhancement Distributions? — Treatment as Restoring Equality Rather Than Distorting It through Enhancement. The connection between disorder models and equality was suggested earlier. If one's relative incapacity is disorder based, health care may restore normality. (It may also create it for those congenitally disordered by raising them to a "normality baseline.") This is less likely to be viewed as a suspect form of enhancement, at least where the disorder and matched treatment are well-recognized as such. Indeed, such medical intervention may be thought to *promote equality* by reinstating equality of opportunity, undistorted by adverse medical conditions (3,15). In other respects, it may worsen equality conditions through pressures to move affected persons to normality. This may downgrade "alternative lifestyles," with adverse effects on various groups — those within the deaf culture, for example. There will, nevertheless, be strong pressures to expand the boundaries of the disorder/treatment model in order to secure insurance or other forms of payment. Of course, the greater the expansion of coverage of various "medical conditions" and of persons, the higher the price of insurance, and the greater the exclusion of lower income groups.

But enhancement not justified within a disorder model is likely to be seen as impairing equality in several ways. One is by distorting "nature-based" equality of opportunity resting on native endowments as elevated by customary forms of self-improvement. Another is by interfering with the unequal but arguably justified outcomes of competitive pursuits (43). (This is of course heavily dependent on the reigning political philosophy.) On the other hand, suppose that enhancement becomes legal, its use disclosed, its price relatively low, and its efficacy roughly the same for all. Then, whatever other objections would remain, inequality concerns, though remaining important because of existing and enduring positional differences, would be partially muted. Of course, other moral issues about enhancement would endure.

However, if variations in natural endowments were thought irrelevant to merit and desert, the point of distinguishing treatment from augmentation would largely be lost, except for clear medical need. As Daniels puts it, if one rejects the "standard model" that takes the distribution of abilities as given, then "the distinction between treatment and enhancement has no point, at least where enhancement is aimed at equalizing capabilities (43, pp. 124–125)."

Enhancement and the Demise of Merit; Person Perception Again; Interpersonal Comparisons of Merit, Desert, and Equality; Entrenchment of Elite Blocs (New or Old); Racial, Ethnic and Gender Dimensions of Enhancement.

In General. Perhaps the very idea of merit would largely "drop out" if the use of enhancement resources were widespread and comprehensive, surviving, if at all, only when applied to judging skill in arranging for and using such techniques. (If we also do not deserve the traits we each received From Above, what meaning does "merit" have other than a thin estimate of economic worth?) Assuming such "no-merit" assessments are made, they are likeliest when living persons are augmented by medical/surgical means, including somatic cell gene therapy or "genetic pharmacology." But our more immediate target is to trace possible effects of such enhancements on different forms of equality: social equality; political equality; equality of opportunity (broken

down into matters of means, prospect, and so on (2,44)); group equality; and the roles of merit and need in making equality judgments. Although these broad and rather clumsy categorizations of equality can carry us only so far, they are useful starting points.

"Social equality" rests partly on the differing frameworks for "person-perception" (44) we use to appraise each other — and ourselves. Perhaps the genetically enhanced would perceive themselves — and be perceived by others — as "superior" in any of several senses: possessing greater intrinsic merit (even if artificially elevated by humans) and hence desert for various rewards; being more useful to society — and so more worthy, in both moral and nonmoral senses; and belonging to an elite group holding substantial political power. Perhaps this elite group would be the successor to an established powerful group; or it might constitute a new kind of elite based on genetic or other augmentation.

Another concern relates to the formation of blocs defined by the particular nature of the enhancement. People regularly sort themselves into groups defined roughly by the strength of particular traits: the more intelligent, the more physically fit, the more nerdy and so on. Enhancement of these traits might solidify these groups and strengthen their political and economic power. Their continued existence as discrete and enduring entities is suggested by how they differ from, say, political parties in the United States.

More generally, if distribution of expensive enhancement resources followed a market or preexisting merit path, existing socioeconomic distances would be enlarged and less bridgeable. This might reinforce adverse views about various ethnic and racial characteristics. Because of the self-reinforcing nature of distributions of "merit" — of the very grounds for distribution generally — the creation of entrenched elites may be hard to reverse. (If traits involving regard for others were so distributed, it might seem odd to speak of unbridgeable distances.)

Threats to Equal Respect for Everyone's Common Personhood: Enhancement as Intensifying Concern with the Strength of Specific Traits, Leading to Reductionism Generally and to Devaluation Resulting from One's Reduced Standing. Some equality judgments may involve a sort of "suspended belief" concerning the extent of interpersonal differences. One reason technological enhancement seems more unsettling than familiar forms of self-improvement is that it calls attention more specifically to the enhancing agent's target traits. Why such enhancement is more salient than long-term, gradual advances is an issue for cognitive psychology, particularly as it bears on person-perception. In any event, our common personhood may be overshadowed by a more intense focus on interpersonal differences. Our moral value *as persons* may be partially displaced by our increased value *as bearers of certain traits in certain measures* (14). To *plan* a person's traits suggests that those traits, as augmented, reflect his primary or even his only value — "value" here meaning social utility. This reduction, as suggested, is affiliated with the ideas of mere use of persons (in violation of the second formulation of Kant's categorical imperative) (45), objectification (46), and related processes. (The nature of this affiliation will not be investigated; it is not necessary to specify which of these notions are criteria for the others or inferences from the others, and they are taken as more or less substitutable here.)

Threats to the Valuation of Persons with Conditions Generally Viewed as Disabling, Particularly Those Who Decline Measures — "Therapeutic" or "Enhancing" — to Eliminate (or Improve) the Condition or Prevent It in Others. There are conditions that, in some cases, are not viewed as disabilities but as enablers. The best-known example is that of deaf persons, at least within what has come to be known as the deaf culture. If they decline measures to enable them to hear — assuming effective measures became available — they might be severely called to task, particularly if they continue to press for special social services. If parents, deaf or hearing, decline these measures for their children, they may be criticized even more severely. These measures — the limiting case of "normalization" (as compared to "assimilating" or "mainstreaming") may, as Silvers puts it, "devalu[e] alternative or adaptive modes of functioning" (12, p. 112). Still more, there is controversy concerning the moral propriety of terminating pregnancies when the developing fetus is believed *not* to be affected by a form of hereditary deafness. Moves to make this more difficult for deaf couples may also be viewed as devaluing deaf culture.

Forms of Regulation; Markets and Other Procedures; More on Equality's Internal Conflicts.

Natural Differences. There are obvious natural and acquired differences among persons, although their significance and even their recognition may rest both on competing moral frameworks and on cultural variables (18). Not all differences — assuming they are perceived at all — count as inequalities. In some cases, cultural variation may be of modest significance. Persons born without limbs, for example, will have difficulty in moving independently from place to place, and this is obviously a crucial ability for most persons in most cultures. But just how well such persons fare depends heavily on variations in familial and general social practices affecting those impaired in this and other ways.

Where differences are recognized as significant, however, one must inquire into their moral status how they should be dealt with. The differences might be taken as given and their effects left to the workings of decentralized market, kinship, or other private arrangements. Or, communities might try to improve matters from an egalitarian perspective, viewing the fact of major interpersonal differences as "natural wrongs" or injustices (17,18). Any effort to displace the market would of course take us into a different phase of moral and policy analysis: establishing criteria for distributing resources, including enhancement resources, and specifying procedures to verify that the criteria have been satisfied by prospective recipients (native endowments, accomplishments, prospects, interpersonal connections, etc.). Any choice of distributional regime — market, nonmarket or mixed — necessarily involves contested moral issues. The "genetic supermarket" (Nozick) may be efficient (21,47) in some sense, but it does not bypass foundational problems.

Recall that the developing technologies involved here are "reflexive" in the sense that they are meant to alter and enhance its consumers, and access to such resources is likely to roughly track prevailing distributions of economic or political power. This changes the normative terrain considerably because each distribution changes any static models we have been dealing with by (possibly) sharply changing the criteria for each successive set of distributions. We can no longer rest on assumptions that major human traits change only gradually, if at all (48).

Janus-Faced Equality. Technological enhancement provides some opportunities to even out nature's hierarchical roughness. It also creates the possibility of worsening it, as emphasized above (1,37). If such leveling is indeed a community moral obligation on egalitarian (and other) grounds, a ban on enhancement — when used to promote rather than impair equality — might violate a principle (corollary to some forms of equality) mandating rectification of specified inequalities through certain mechanisms.

But such apparently egalitarian rectification efforts would require centralized intervention into distribution of enhancement resources. Enabling the have-lesses to move closer to the have-mores might thus *itself* violate some aspects of equality — and of autonomy, fairness, justice, and utility — through coercive redistribution. As we saw earlier, some would lose more of what they earn than others, and some would receive unearned benefits while others would not.

In any case, it is unlikely that any distributive scheme would "level out" human traits. And few — from current perspectives — would think it desirable, morally or otherwise.

A Review: Inequalities Compounded; the "Matthew Effect" and Terminal Social Stratification: The Problem of "Who Merits Merit?" Again. The rich get richer, the poor get poorer, ... and the smart get smarter? Why not? The well-educated already more easily qualify for still more education, often to the exclusion of the less-educated (49). "For unto every one that hath shall be given, and he shall have abundance: But from him that hath not shall be taken away even that which he hath" (Matthew, 25:14–30). (Merton coined the phrase "Matthew Effect" in referring to allocation of resources in scientific research.)

Distribution of scarce resources is of course a classic problem for economics, ethics, political theory, public policy, and just plain politics. But the distribution of enhancement resources, as we saw, raises special issues. Enhancement almost inevitably targets merit attributes — which are generally wealth-attracting resources.

The relevance of the Matthew Effect is obvious. The distribution of resources for enhancing "merit" claims for distribution, as we saw, involves a sort of feedback loop: It alters the very ground on which the initial distribution is made, generating a multiplier effect. Under such conditions Thomas Jefferson's "natural aristocracy" of "virtue and talents" is replaced by an artificial aristocracy of technologically enhanced abilities (50).

Of course, if the idea of merit does not survive the new age of technological alteration, "Who merits more 'merit'?" becomes doubly a nonsense question. Not only are we unable to increase our merit artificially, but merit itself is gone as a relevant moral category. Even if all or some characteristics lose all or some of their status as merit attributes, it seems likely that enhanced intellectual and physical powers, unevenly distributed, will continue to attract wealth and resources. Business, after all, is business: Intelligence counts for scientific research; heft counts for football; attractive faces and bodies draw attention and money — whether or not we talk about merit. The demise of merit, moreover, may not dispatch the view that we are nevertheless "entitled" to the fruits of our varying natural *or* enhanced abilities — whether we "deserve" any of them or not. In any case, the outcome of decentralized distribution of resource-attractors, as suggested, might ratchet up social, economic, and political stratification, and the hierarchical structure of community life generally. At least this is a potential outcome if distribution is based largely on decentralized mechanisms, such as markets, kinship, or old-boy/girl networks.

Enhancement and Interpersonal Desert: Time Scales, Life Plans, and Social Stability.

Enhancement of Living Persons within Their Respective Memories. We are accustomed to the gradual acquisition of merit earned by effort, resulting in gently escalating desert Sudden, major alterations in attributes, particularly merit attributes that help define one's identity, aren't associated with ordinary persons; Western culture links "shape-shifting" to mythological para-human creatures. But part of the very point of technological enhancement is to shorten the time span and reduce the effort needed to strengthen one's attributes beyond their endowed "maximums," and to gain the resulting incremental rewards. Such sudden changes in individual capacities may present major difficulties to a transformed person, to those around her, and to society generally (41). Our choices about life style and life plan have always depended strongly on presuppositions about our attributes — both assets and deficiencies — and their general stability (a stability consistent with their gradual elevation or deterioration). Suppose, however, that someone of modest talents and accomplishments rapidly becomes abler. Would she think that she *deserves* more of life's rewards because her abilities have sharply increased? How would she acquire these rewards? The newly intelligent or memorious (51) can't just saunter onto the grounds of Acme University and demand entry and possibly displacement of their (new) inferiors. Or can they?

Perhaps the spreading self-awareness of new powers — and the spreading fears of those stuck where they are — will provoke political and social instability. A somewhat distant analogy would be the sudden emancipation of large numbers of slaves or indentured servants who had been denied education and other resources needed to flourish as free persons. Think also of the comparatively rapid (if incomplete) change in the status of women in the United States and elsewhere. Virtually every aspect of equality would be challenged by technological enhancement. In particular, the nature of the contests between different forms of equality may also change. The perennial war between forms of equality of opportunity and forms

of equality of outcome may be intensified by the limited availability of enhancement resources that greatly enlarge one's prospects, and by the growing "distances" between the enhanced and the unenhanced.

There is thus a two-stage egalitarian problem: determining who gets "merit-enhancing" resources, and determining what collective or individual responses to make when faced with the escalating demands of the newly enhanced. These *nouveau intelligent* do not suddenly enter the fabled set of fully qualified rocket scientists. (Memory and skills transfer is not discussed here.) But they will argue that they have joined the set of persons immediately entitled to further education and training, and, within a short time, to appropriate forms of employment and their attendant rewards. It is too early to say whether it will make any difference whether they frame their claims by relying on merit and desert or on economic and social utility.

Other Enhancements. Questions parallel to those just raised arise with those whose genomes were altered, or possibly whose traits were revised during embryonic development (but without genome changes) or fetal development or in early childhood. Our responses, however, may be different. All of these persons are likely, in different ways, to look upon themselves as identified with traits they have had "wired in" for as long as they can remember. Moreover, for whatever it is worth, they cannot themselves be accused of having tried to evade or soften the struggle for self-improvement and to reap unearned benefits. Those enhanced as adults or older children, however, will be able to compare their attributes "before and after" enhancement, and those who affirmatively opted for enhancement might be blamed for such (partial) evasions.

Again, it is unclear how limited-access institutions such as educational facilities and desirable employment opportunities could quickly adjust, even over one or two generations, to a sharp escalation of merit claims for entry. A further complication is that some forms of labor may become even more disfavored than they are now among more educated groups — cleaning/sanitation, simple but hard labor, some forms of blue-collar work, and various low-skilled personal-service functions. Other things remaining fixed, however, the shortage of supply for such labor would raise its wage rate, which presumably would draw applicants willing to trade (temporary?) embarrassment for an enlarged income. (But then, their services might then be too expensive for many consumers, especially among the unenhanced.)

Both Groups in the Long Run. The questions just raised also apply to long-run considerations, and here matters become still more speculative. How would we forecast shifts in attitudes and beliefs about interpersonal comparative valuations? We do not know how we will value (or reduce) each other when merit traits are significantly malleable.

Still we are not entirely at sea and can make at least minimalist projections. One would think that with escalating demand for the (possibly) superior services produced through stronger merit attributes applied to increasingly more demanding tasks, investment would gradually yield institutional responses: more educational facilities, more complex mental and physical competitions, and new technologies enabling disfavored lines of work to be done more by machines and less by persons. This would generate greater incentives and pressures for still further personal enhancement, new stages of institutional response, and so on. It is hard to say where diminishing returns and equilibrium would set in. Recall also that one effect of the greater salience and strength of merit attributes might be to amplify the social, economic, and political importance of the enhanced traits: enhancement efforts would be likely to require major investments of all kinds, both financial and emotional — and people want returns on their investments. The result would be still greater emphasis on interpersonal differences.

One theoretical possibility should be kept in mind for analytical purposes, however unlikely it may be: With broad access to similarly effective agents, there might be little *relative* interpersonal change, even though everyone's individual performance level was raised. But this would also represent a major source of pressure for social and economic revision: Nearly everyone will be abler, more insistent on appropriate rewards for ability, and more concerned about the responsive formation of new institutions to satisfy their new levels of talent. The sluggishness of social and political responses to the claims of those with newly enhanced attributes may contribute heavily to various forms of social instability. And some instabilities might well arise because of negative shifts of attitude both toward those with clearly defined disabilities or handicaps and those who are unenhanced (or not successfully enhanced) and find themselves ever-lower in relative standing.

Equality of Groups and Blocs: More on Social Stability. One uncontroversial point is that groups and communities play major roles in social and political life and, partly as a result of this, in the formation of one's sense of identity and self-regard. Matters of interpersonal equality are thus conceptually linked both to intergroup and intragroup equality — and both realms of equality are affected by prevalent views on merit and desert.

Humanity has generally sorted itself into groups, and some existing groupings are defined by observed or supposed differences in merit traits and accomplishments. Indeed, in a distributional system based entirely on the purest notions of merit, with the arbitrariness of prejudice, stereotyping, corruption, fraud, and coercion largely absent, one could infer that resulting differences in attainments, rewards, and status are based entirely on differences in abilities or other merit or wealth-attracting resources. Perhaps this just replaces one set of "arbitrary" criteria (old-boy/girl networks, ability to pay, kinship preferences) with another (genetic and environmental lotteries), but this is another issue. In any case, this somewhat intimidating prospect has been addressed in several well-known (and controversial) works (52). If realized, we would in theory lose our excuses for failure (e.g., "politics did you in"). Our relative status would rest on "the merits" and unambiguously reflect our attributes, perhaps as in Mensa, whose membership is chosen (in

theory) on the basis of pure ability rather than interests or accomplishments. Once again, we face a raising of the borders between existing groups, and possibly the creation of new entrenched factions.

Still, we do not know whether any given pattern of enhancement would inspire social/political instability. Much may depend on whether, despite the greater gaps between individual and groups, the lot of the worst off is nevertheless improved (53). If the size of the gap between the better and worse off is great enough, the overall risks of instability may go up even if the resources of the less well off increase. Our notions of poverty seem to involve ordinal rankings as well as the cardinal value of one's holdings.

Political Equality Imperiled: In General.

Shifts in Political and Moral Ideals; Widespread Use and Low-Cost Access. It seems that many prospective parents now prefer the genetic lottery and are eager, or at least willing, to accept whatever they receive from it. We often eschew planning even where it is possible to plan, preferring vagueness and uncertainty to precision and predictability. Perhaps a partial explanation for this is fear of responsibility when things go awry or simply not as planned, or confusion over what to select. Beyond this, such preferences seem linked to what is perceived as a defining element of personhood: We envision persons as creative and autonomous, not bounded by fixed life plans imposed on them. Nonpersons have none of these attributes. Neither natural nor assembled objects possess them, and other living things seem too far off the mark to justify such characterizations (54). But competitive pressures may inspire many parents-to-be to seek greater precision of outcome in their reproductive plans, and (possibly) to rigorously enforce these plans on their offspring. Fear of an unenhanced child's eventual reaction to discovering that she is disadvantaged might well play a role here. (The parents in most cases cannot respond by telling the child that she had no alternative existence. The selfsame embryo from which she developed could have been isolated and altered, or her traits could have been changed after birth.)

Assume that the longer-term results of these pressures and of economies of scale are nearly universal low-cost successful efforts to enhance. Equality complications attributable to enhancement would be then be greatly attenuated, though not entirely removed (and standard equality problems would likely endure). From this particular egalitarian perspective, if not others, the more technology and the wider its use, the better.

However, where there are large-scale distributional inequalities, there is a risk of (irreversible?) erosion of equality's status. Equality could be adhered to (if at all) only in the sense of preserving the abstract idea of equality of opportunity: no affirmative blockade interfering with one's right to use her preexisting intelligence and wealth to secure more intelligence and wealth, for herself and for her existing or future offspring, and to reap the benefits of her enriched capacities — and so on down the dynastic generations.

How might this shift our ideals? Institutions and practices, by their very existence and visibility, "communicate" ideas and impressions, and these may have learning effects (55). Of course, what is "learned" depends on what is perceived or understood, and might be reshaped by responsive public debate.

Segmented Society. One feature of a world with both genetically and nongenetically enhanced persons might be a more rigorous division of labor, perhaps of the sort envisioned by Plato in his *Republic* (56). After all, if we take the trouble to (re)assemble our offspring with certain "engineered" traits, they had better do what we planned, right? Equality analysis here is of course beset with factual and normative/conceptual uncertainty. On the one hand, the escalation of technological complexity combined with enhancement might lead to greater division of labor and social stratification. On the other hand, enhanced persons might form a world with less rigorous division of labor because they become polymaths and jacks-of-more-than-one-profession.

Still, it is conceivable that regardless of how rigorous the division of labor is, political and social equality of a sort may hold. Different professions, trades, and occupations, and the varying aptitudes underlying them, might be viewed as equally worthy — an "equality of the enhanced." The "alphas" may be viewed as equal to the "betas," though their augmentations (via the germ line or the living body) and life work may be entirely different.

But this is nothing to count on. It is also plausible to expect that equality is largely "read out" where (from our present perspective) it is most applicable and most needed. The more entrenched the social stratification becomes, the greater will be the need for corrective notions of equality and of "remediation," but the less likely it is that there will be influential partisans for equality in any sense.

A More Equalized Society Instead? As suggested, enhancement resources might be distributed in ways that promote equality in several forms, consistently with whatever divisions of labor are implemented. Distribution might rest on need, where "need" is linked to enhancing equality of opportunity, perhaps vindicated by some degree of social assistance. Moreover every person might be considered to have a stronger claim to augmentation than his immediate "superiors" in preexisting attributes, giving him the right of first refusal for the next set of resources. And, as we saw earlier, where different traits are enhanced, the "net equality of the differently enhanced" may hold — as equality of "overall" merit. Finally, greater equality might be pursued by familiar redistributive or other social measures that are not directed toward trait alteration. So there is a slight possibility of a "more equalized" society. But this possibility should now be vetted through the lens of democratic theory.

More on Political Equality Imperiled: Democracy and Governance.

Enhancement and Democratic Theory: Millian Plural Voting and the Attenuation of Democracy

1. *Kinds of democracy: Is one-person, one-vote a defining characteristic of democracy?* What are and should be the effects of sharp differences in human

characteristics on matters of political governance? If we are not in fact equal to each other in deliberative ability, judgment, and drive, why do we all have equal voting power in the sense that when casting ballots in general elections, no one's vote counts for more than another's? We are not equal in our knowledge of the issues, our abilities to assess competing arguments, the nature and intensities of our preferences, our capacities to contribute to our social and economic system, our stakes in the outcomes of particular government policies, or even in our interest in participating in public affairs. And enhancement technologies may amplify these differences.

Yet for most of us, "democracy" seems to be all but definitionally connected with the maxim "one person, one vote." Unless this maxim holds, there is on this view no true democracy. Is this definitional link indeed appropriate given our vast interpersonal differences? Not all political thinkers have thought so. As Thompson summarizes John Stuart Mill's discussion of plural voting:

> The principle of competence expresses Mill's belief that a democracy should give as much weight as possible to superior intelligence and virtue in the political process (57).

Mill thus did not think that equal votes among electors was essential to democracy or for promoting the public good — quite the contrary. He endorsed plural voting (though perhaps with later reservations and possibly as a temporary measure) in which individual citizens had votes proportional to their "individual mental superiority" (58,60). The number of votes per elector would thus be a function of his or her revealed competence. Mill discussed occupational success, test results, and educational status as criteria for assigning more than one vote (59, pp. 475–476)

For Mill, plural voting is one method, among others, for furthering the principle of competence (57). His idea of competence is complex, however. It is not addressed simply to intelligence, but to skills (57), since highly intelligent persons might lack skills needed for sound governance. His vision of ideal competence also includes "moral competence." Education seems to be not just a proxy for competence, but partly constitutive of it. (One supposes that it might be a proxy for native ability.) Finally, Mill qualified his recommendations by recognizing that participation values were in tension with competence values (59,60).

The link between Mill's competence principle and human enhancement is clear. Genetic engineering, for example, has long stimulated fears that enhancement would threaten democracy — at least in forms demanding equal votes for all electors. Sinsheimer has asked, "Could ... deeper knowledge of the realities of human genetics affect our commitment to democracy (61)?" If mere knowledge of the physical bases (both genetic and nongenetic) of the differing endowments underlying Millian competence can threaten democracy, one might well expect that the vivid reality of the huge gulfs between the enhanced and the unenhanced would represent an even greater threat.

But the nature of the threat to democracy must be specified. This is no simple task, given the fact that "democracy" may take quite different forms, and that the status of the one-person, one-vote standard as the premier form of democracy is a question at issue. All forms of democracy are linked by the idea that the governed — or some portion of them — are to have a significant say in what affects them, and that this voice is to be broadcast by some form of majoritarian aggregating of votes on important matters. This voice is an obvious component of autonomy, which is in turn an essential ground of democracy, and it is not simply advisory or merely a request for redress coming From Above. It is to be decisive within significant domains, although it may be subject to principled constraints derived from constitutions or other sources of law. What constitutes an "important matter" is of course hugely uncertain, but clarifying it is unnecessary here.

Return now to the question that opened this section: Why is the political equality that is implemented by one-person, one-vote accepted in the face of individual differences? Dahl raises a parallel question:

> [I]f income, wealth, and economic position are also political resources, and if they are distributed unequally, then how can citizens be political equals? And if citizens cannot be political equals, how is democracy to exist (30, p. 326)?

(Dahl is describing conflicting theoretical perspectives, not necessarily endorsing any.)

2. *Applications to an age of enhancement; one-person, one-vote.* A system of equal votes at the ballot box is far from ensuring "equal" political influence or equality in anything. Think, for example, of the suppression of group preferences in at-large voting districts (62). Nevertheless, in its own way, one-person, one-vote implements equality both practically and symbolically. If effective enhancement is feasible, might equal-vote democracy (somewhat paradoxically) be the preferred form of political governance *because of* — rather than despite — greater interpersonal differences? After all, even though we are not equally *able*, we may be more or less equally *affected* by particular government policies, and, whatever the unequal impacts, they are not uniquely correlated to ability. To respond that impacts on the less able count for less than impacts on the more able is to presuppose a far different theory of the equality of persons *as* persons than is now held, at least in many quarters. Still, the idea that all persons are equally affected by a given kind and degree of adversity might itself be under siege in an enhancement age.

It seems unlikely that unequal allocation of votes would be seen as a realistic, efficient, and benign recognition of differences in ability, native or augmented, or of the varying impacts of political policies. It will probably be taken, correctly, as reflecting deep disrespect for those allotted fewer votes (63). And no doubt, many of those with more votes — and some with fewer — will believe that disrespect is justified given the substantial gulfs in resource-attractive or merit traits.

There are, of course, conceptual issues and "exceptions" to the one-person, one-vote standard. That standard is arguably attenuated by many institutions, such as the U.S. Senate, where states have equal votes whatever their respective populations, or special voting units such as water districts, where votes are allocated on the basis of varying rates of use or on other variables.

But in general elections, at the ballot box level, plural voting is excluded from most modern ideas of democracy. Mill himself did not necessarily endorse it over other techniques for enhancing the influence of competent elites (57,59). He seemed well aware of the substance of the Matthew Effect: Those with excess voting power may draw increasingly disproportionate shares of rewards (48,65) and possibly still more voting power, in an extended cycle. He did not endorse the ' "blind submission of dunces to men of knowledge." ' (57, p. 85) As mentioned, he also strongly emphasized participation values in democracy, which help to control government and to educate the participants, making them more competent (57). As Thompson describes Mill's resolution of the tension:

> Just as the educative benefits of participation partly justify the extension of participation, so the educative value of superior competence partly justifies the influence of a competent minority (57, p. 79).

But participation to promote competence will not necessarily save the day for one-person, one vote — particularly in an age of enhancement, with its increased and entrenched gulfs in ability, as discussed next.

Enhancement and Democratic Governance. Plural voting is a long way from dictatorship or other autocracy, but it is nevertheless likely to be taken as inconsistent with the idea of equality of persons *as* persons (60). One might thus question the seriousness of enhancement's challenge to democracy by recalling that we now maintain democratic ideals *notwithstanding* the *present* perception of *very* wide interpersonal differences. A major rationale for maintaining the one-person, one-vote regime is to prevent further consolidations of power that leave persons with inadequate access to basic commodities and opportunities.

But our commitment to democracy — and/or to various sociopolitical conditions that enable democrats to implement their commitment — might be fragile nonetheless

> Equality of control is an unstable equilibrium. Differences in knowledge, skill, opportunity and activity create inequalities of control; these in turn tend to generate further differences, which create further inequalities. [Note how this may be compounded in still further cycles by enhancement.] Hence the struggle to maintain a polyarchal organization ["[t]he main sociopolitical process for approximating (although not achieving) democracy . . ."] is never won; indeed, it is always on the verge of being lost (65, pp. 41, 282).

Enhancement and Participation. Representative democracy is not just a matter of voting rights and voting power, and elections do not confer unreviewable, irreversible delegations of authority to representatives or officials. Ideally it entails genuine opportunities for participation, in order to promote its underlying ideals of autonomy and equality, in one form or another. The sort of narrowly defined "efficiency" promoted by restricting voting and governing to superior elites is not part of the democratic canon (47). Participation is a troublesome concept to interpret: There is speaking one's piece before the appropriate representatives and government officials, there is *influencing* their exercises of power, there is having access to relevant information and ability to comprehend it, there is being a plausible candidate for office as a representative or for appointment to public office, and so on. All these aspects of democratic participation may be affected by enhancement, whatever mode of distribution of enhancement resources is selected. One's greater or lesser abilities may expand or contract one's audience, or ability to communicate with politically powerful persons and groups, or relative deliberative skills, or capacity to quickly grasp the issues of the day, or ultimate influence. Moreover, in republics we delegate responsibility for governing to others, partly from the sheer need for division of labor, partly because we want government to be run by persons capable of doing so soundly. To be nonenhanced — that is, to be relatively less capable — may be to risk exclusion from government office.

As suggested, however, the prospect of enhancement may not be fatal to egalitarian democracy, either in political theory or in fact.

First, the arguments about allocating votes as a function of competence may be somewhat misdirected. Democracy, again, is in part about having a say in what affects one. But as we saw, how much something affects you may have little or no connection to your varying competences. Moreover, to justify plural voting on our understanding of democracy, we need a moral premise concerning the proper relationship between one's political power and one's particular circumstances — including not only one's competence but one's vulnerabilities to harm under government policies. Within our present political framework, the premise is not confirmed. Representative democracy may contemplate an ideal of superbly qualified electors and even more superbly qualified representatives, but the ground for democracy is not the superior decision-making competence of the people and their delegates, as opposed to despotic rulers or elites. It rests *generally* on the unfairness and injustice of impairing autonomy by subjecting people to policies, conditions, and interactions that seriously affect them when they do not have a

voice in the matter, at *some* important level of choice. We cannot order the President to cease bombing the principality of Lower Paregoric, but we can select the President — via electors we vote for. And the ground for *equal-vote* democracy, as we saw earlier, rests partly on the unfairness of giving unequal power to persons whose vulnerabilities are likely to be quite similar, whatever their mental and physical aptitudes. Thus, the "equally affected" argument may overpower the "superior contribution" argument. Nevertheless, the possibility remains that our current notions of equal vulnerability and impact will change as enhancement technologies develop.

To turn matters around, one might urge that under given circumstances it is the *enhanced* whose participation is at risk — particularly if they are a numerical minority. But even if they are endangered by their "suspect" status, plural voting may not be the best mechanism for protecting them as compared with a strong regime of individual rights. Of course, that regime may also be impaired by a hostile majority of the nonenhanced.

Second, egalitarian democracy might survive even within the Millian framework because the available enhancements might not be seen as affecting competences relevant to democratic governance. It is not clear, for example, that moral competence can be affected in any but the most slapdash way by genetic engineering — although the possibility of doing so should not be entirely dismissed (66).

Third, as a matter of theory, it is unclear how a competence criterion for ballot power can be assessed entirely independently of certain background moral issues concerning, say, the fair/just/egalitarian distribution of goods and services. With enhancement, the "ability gulfs" between persons are themselves a partial function of preexisting wealth differences. Depending on what forms of distribution of enhancement resources were in place, these wealth differences would be unjustifiably ratified and reified by plural voting. Because Millian competence is empirically tied to wealth, which may be morally irrelevant, to defend plural voting on competence grounds thus begs some questions of moral evaluation concerning distribution and its underlying issues of equality and fairness.

Superior competence, in this context, thus remains a murky concept. Indeed, as Singer observes, "Mill himself said, later in life, that [plural voting] was a proposal which found favour with no one. The reason, I think, is not that it would obviously be unfair to give more votes to better qualified people, but rather that it would be impossible to get everyone to agree on who was to have the extra votes" (67).

Fourth, even if technological enhancement did affect relevant forms of competence, those who remain unenhanced are not "incompetent" in any sense, including Mill's. A loss of relative standing in ability or depth of learning does not entail deliberative incompetence. "Competence," at least for present purposes, arguably concerns attaining a certain threshold at least as much as it concerns the distance between oneself and others, though the two are connected. In this respect it is similar in structure to "personhood." Here a Millian might respond that enhancement could simply elevate the accepted competence threshold for qualifying as a voter, establishing a new minimal baseline for competence — but this still would not make the case for supernumerary votes.

Fifth, far from being inconsistent with equal-vote democracy, the increasing gaps between persons make it all the more desirable to retain that voting system, as suggested earlier. The less endowed and less enhanced are not likely to suspend pursuit of their own interests, despite their new relative dimness. Although the better endowed might be better able to protect themselves, given their superiority, a possible result of plural voting might be dangerous instabilities, partly because of the perceived risk of — and actual — aggrandizement of resources by the elites. The greater the fear of such risks, the more that departure from equal voting will be seen as sending us down a steep, greasy slope emptying into an abusive oligarchy — run either by the numerically inferior enhanced or by the unenhanced, each fearing domination by the other. In such a world, not only is equality compromised, but so also are all other basic values.

Turn now from equality to autonomy. (This in turn will shortly return us to equality.) What will become of *it* if enhancement is institutionalized to some degree? In parallel to the dismissal of the respect owed to the less gifted, one might urge that not only do they deserve fewer rewards, their autonomy is of lesser worth. From contemporary liberal perspectives, however, basic autonomy is not tied to one's measure of abilities, unless it falls below the general competence threshold, however defined. Yet, just as we make interpersonal comparisons of "worth" in various senses, we may in fact think that autonomy as exercised by different persons may decline in value with the declining *relative* competence of these actors. This view may have still greater pull where enhancement is practiced. Perhaps if autonomy for all is to be protected, some sort of equal-vote democracy is necessary to preserve it. As we saw, democracy might remain preferred partly because of the posited inequalities, not despite them. Still, defenders of plural voting or rule by an elite are likely to suggest that, precisely because of the elite group's superior competence, autonomy and even equality itself are better promoted by what seems like an inegalitarian system (29). It is thus hard to deny that participatory/autonomy values are at elevated risk in an enhancement context.

Sixth, perhaps the most obvious defense of equal-vote democracy is that it may be instrumental in promoting opportunities to obtain the very enhancement resources that inspired this debate about democracy's requirements — a continuation of enhancement's potential role as "remediation" of natural inequalities. There is certainly no assurance that the elites will look out for anyone's interests but their own, except on the doubtful assumption that they will also be moral elites with a strong egalitarian or altruistic bent. It bears mention at least once in this entry, despite the point's familiarity, that the result of superior competence may be greater and more successful evil.

Finally, plural voting defenders will, sooner or later, make the simple-sounding argument that there is *no*

threat to equality in an enhancement age. Equality, after all, concerns the similar treatment of similarly situated persons and the dissimilar treatment of dissimilarly situated persons. If the more able are relevantly different from the less able, treating them differently is not only not inconsistent with equality, it is required by it. The obvious response, which can only be summarily stated here, is that this claim presupposes a large set of unconfirmed and strongly contested moral propositions.

Social Changes in Attitudes Concerning Equality, Self-Regard, and Community: Symbols, Communication, and Learning. The operation and observation of our social institutions and practices generate learning effects. Present conceptions of equality and other values may eventually confront a world where long-standing assumptions about the relative stability of traits and character will be loosened. This emergence of a world in which human traits are far more controllable than now may, as suggested, drive changes in our attitudes about the demands of equality and fairness generally, and merit and desert in particular. These value shifts may occur for several reasons. For example, the consolidation of political power into hierarchies (whether or not reflected in plural voting) may result from the distribution of enhancement opportunities to those already holding wealth and power. Hierarchical institutions and practices may generate self-perpetuating learning effects through citizen participation or observation. People may come to perceive themselves and their social stations differently, perhaps as fully locked in. Enhancement may spur an increasingly intense focus on traits and their comparative measures, and magnify their apparent social and commercial value. True, we might still think that traditional enhancement enhances but that technological enhancement reduces. But whether the latter will indeed *reduce* persons to the social value of their enhanced traits or *elevate* them in a morally relevant sense is not now predictable.

CONSTITUTIONAL CONSIDERATIONS IN BRIEF

Constitutional Frameworks

In the United States, government regulation of use and distribution of enhancement technologies must be tested against claims of violating implied "fundamental liberty interests" under the due processes clauses of the Fifth and Fourteenth Amendments. (As for equal protection considerations, see the discussion below.) Federal action must also be tested against express and implied limitations on the powers of the federal government. Mention of some constitutional considerations is thus called for, and constitutional argument structures are in any event useful in discerning and addressing some of the most important issues generated by enhancement.

The right to procreate, as articulated in *Skinner v. Oklahoma* (68), might be taken to encompass at least certain forms of germ-line engineering or fetal manipulation, although the strength of such rights is open to serious question; the U.S. Supreme Court may be forced to consider a hierarchy of procreational liberty interests, each imposing a greater or lesser burden of justification for government regulatory maneuvers. The recently emerged practice of prenatal and preconception screening for disorders, which is likely to be protected as a major adjunct to procreational autonomy, might suggest parallel protection of affirmative intervention to forestall the disorders via germ-line or fetal alteration. Nevertheless, the issue is uncertain, partly because of the differences between "standard" (if technologized) reproduction and anticipated future forms: *having children at all* is not the same as *having children in certain ways, or of certain (arranged) sorts.* It is one thing to leave matters to unrevised sexual recombination, and another to affirmatively determine the traits of a specific individual.

Somatic trait augmentation — at least for competent adults — arguably ought to have greater constitutional protection than parental choice to manipulate the germ line or alter fetal development because the affected party is the decision maker. Nevertheless, it is more challenging to describe the constitutional terrain because there is no clear, recognized conceptual bin in which to place it. (Compare "procreational autonomy.") There is no general constitutional liberty or "privacy" interest embracing a right to do what you will with your body, although some commentaries, scholarly and nonscholarly, might suggest otherwise. There are recognized liberty interests of sorts in refusing various forms of medical treatment and in "personal security," which are likely to extend to forced administration of enhancement techniques, medical or nonmedical. But these doctrines do not settle matters of noninterference with voluntary use or positive assistance in securing access.

This is not to say, however, that a persuasive case cannot be made for protecting the decision whether to enhance one's basic merit attributes as an important feature of the liberty protected by the Fifth and Fourteenth Amendments; it is much too simple to assert that such textually unmentioned rights are impossible because no long-standing "tradition" protects it. There is in fact a tradition of substantially free choice in making use of changing methods of instruction, training and general pedagogy for the purpose, among others, of self-improvement. It might well be thought to extend presumptively to control of mental functions and of bodily physiology generally. [Because of the logical link between mental functioning and communication, a First Amendment argument for fair access to intellectual enhancement resources — as well as the right to refuse such resources — might also be crafted (69).] One might also urge that the liberty interest in shaping the nurture and education of one's children encompasses enhancement. The interpretive maneuvers underlying these constitutional arguments are complex and entertaining; they are described briefly below. If serious enhancement arrives on the scene, however, arguments of these sorts are certain to be offered in opposition to restricting access to augmentation services.

Under the logic of constitutional protection of liberty interests, if any of these characterizations of a right to

noninterference with enhancement decisions are successful, governments will have to justify their prohibitions and their regulatory systems generally. The weight assigned to the liberty interest will, in theory, determine how heavy these burdens of justification will be. Government will at a minimum have to identify serious interests that may be compromised by attempted or successful augmentation — for example, avoiding injuries to existing or possible persons. It will also, in theory, have to defend the precision of its means for protecting these interests. Imposing a major burden of justification on government action, for whatever reason, is the core component of a judicial decision path known as "heightened scrutiny." In recent years the U.S. Supreme Court has recognized liberty interests that apparently draw an "intermediate" level of scrutiny, rather than the maximum "strict scrutiny" standard (70), and with technological change it may well have to construct still more levels of calibrated protection.

Paths of Constitutional Interpretation

It is especially difficult to project future constitutional analysis when the transformative processes in question seem so far removed from traditional paradigms and historical understandings — assuming these matters remain constitutionally relevant. Tradition, history, original intent, and lexical understandings at the time of framing continue to be viewed as important and perhaps decisive interpretive criteria (separately or in some combination) for both explict and implicit liberty interests, although some cases have been offered as counterexamples (71). Those arguing that enhancement falls within a strongly protected liberty interest — whether as an aspect of procreational liberty, a right of personal development, or a right to control our mental and physical functions — will have varying difficulties making their case. If their characterization is rejected by the courts, then the government's burden of justification is very weak — a minimal rationality test that constrains far less than use of the term "rational" would suggest in everyday language. The difficulty in constitutional characterization of an interest is greatly compounded when the asserted interest reflects an innovation that does not seem to fit existing categories. Thus, determining whether reproductive ventures involving germ-line engineering are included within a strongly protected liberty interest will, as with any form of legal characterization, involve (inter alia) comparisons to exemplars of what is or is not protected. Partisans then characteristically state whether the interest proposed for special protection is "too far removed" or "distant" from the archetype. (This vastly oversimplifies huge interpretive issues.) The problem, however, is that the supposedly defining features of the models offered may be contested. Is the process of creating a person who didn't exist before a sufficient condition for calling the process procreation — either in common discourse or in constitutionalese? Or must the person have been created by human sexual recombination rather than asexually? Or must the person not only be the result of sexual recombination but of sexual recombination *simpliciter* (where we simply rely on the genetic lottery and avoid affirmative trait-changing, though possibly using prenatal and preconception screening, possibly followed by abortion or nonconception)? If we do not know what defines the standard example, we cannot tell how "far" we are from it. As things stand, prohibiting prenatal or preconception screening would seem to impermissibly burden procreational rights, but this does not show that forbidding germ line alteration — even for enhancement rather than disorder prevention — is also be impermissible. How "far" is affirmative genetic change in persons-to-be from prenatal or preconception testing in aid of deciding upon abortion or nonconception? All are forms of "genetic control," but germ-line alternation is vastly different, at least when viewed through prevailing constitutional frameworks. When biological technologies separate and rearrange life processes in ways not contemplated by our existing concepts, the interpretive difficulties we already face may be greatly amplified.

For now, it is enough to say that human procreation has come to vary along several overlapping axes. They concern technological facilitation of gamete union (e.g., in vitro fertilization); social arrangements (within or outside marriage; collaborative — e.g., surrogacy; use of gamete banks, whether or not for eugenic purposes); whether the efforts involve asexual methods (cloning); technological mechanisms for trait prediction; and technological mechanisms for positive control or influence over traits. It seems plausible to think that procreational autonomy extends as a *presumptive* protection — in full or near full strength to technological facilitation of gamete union (subject to limited health and kinship regulations), to procreation regardless of marital status (subject to certain protection-of-marriage limitations), and to prenatal or preconception screening for disorders, defects, or injuries. This presumptive protection might be overcome by compelling or important countervailing interests. Broader protection of collaborative procreation, and for which participants, is less certain, although strong coverage is likely for gamete donation or sale (at least for a modest price to avoid charges of "economic coercion") by persons within or outside the intended nuclear family. The constitutional fate of human cloning is seriously in doubt because of the perception by many that asexual reproduction is a truly radical departure from standard procreation, and does not belong within protected constitutional categories. Although germ line enhancement within sexual reproduction is a striking departure from standard reproduction because of its partial nullification of the genetic lottery, it seems likelier than cloning to be assigned some serious presumptive protection, at least within a disorder model. (Cloning may not go entirely unprotected, however.) As noted, however, the strength of "compelling" or "important" governmental interests can in theory override the individual rights claim, if the regulations are carefully tailored to further those interests so as to reduce intrusions on constitutionally protected interests.

Constitutional Equality Standards

There may also be questions concerning the status of the enhanced or the nonenhanced as members of discrete, identifiable groups at risk for discrimination and

exploitation. If so identified, classifications concerning the group may be treated as "suspect" to some degree under the Fourteenth Amendment's equal protection clause and the Fifth Amendment's implied parallel protection. This will again trigger heightened scrutiny and, in theory, impose a nontrivial burden of justification on government action. If this "suspectness" characterization fails, the government is likely (but not certain) to prevail (72). The point here is that many egalitarian claims find little or no purchase within the constitutional framework of equality, which offers strong protection against certain forms of discrimination (racial, ethnic, gender, etc.), modest protection against certain forms of classificational irrationality involving vulnerable groups (it is hard to predict which groups will be considered vulnerable), and for all practical purposes no protection for any other form of classification. In egregious cases of abuse or manipulative control over enhanced or unenhanced persons, however, one might claim violation of the Thirteenth Amendment (banning slavery) or the Nobility Clause (Article I, §9) (73). Both provisions are heavily inspired by considerations of equality.

Congressional Powers

Congress has an uncertain range of powers to promote constitutional rights under Section 5 of the Fourteenth Amendment (and parallel provisions in other amendments), subject to Supreme Court control. If any group — nonenhanced or enhanced — seems especially put upon, Congress may consider remedial legislation (perhaps as a form of "affirmative action") (37). Congress also retains considerable powers to protect or promote constitutional rights under the commerce clause, and the taxing and spending powers.

CONCLUSION

Dealing with technological enhancement and its impact on basic values is beset with the usual problems associated with value analysis — vagueness, ambiguity, "open texture," indeterminacy, and collision with other values. But these problems are aggravated because the new powers seem to undermine assumptions concerning our understanding of these values. Determining just how crucial these assumptions are to the tasks of moral and legal evaluation of enhancement technologies forms a major portion of the analytical work required.

The most obvious assumption being tested, of course, is that we are severely limited in altering native traits — including our most valued merit attributes and resource attractors — by the constraints of our individual genetic endowments and by the very nature of familiar and slow-working tools of self-improvement: study, training, practice, effort, self-discipline.

It now appears, however, that technological intervention via the germ-line and somatic mechanisms will eventually allow us to alter, at least in certain ways, the limits of what we now view as relatively fixed potentials for improvement. Today, with extended study and practice as he grows up, Forrest Gump can learn to make change, to balance checking accounts, and to do some algebra, but quantum gravity will forever elude him. Later, perhaps such limits will no longer hold: evidence of the possibility of serious and accelerated trait changes seems to be growing. Does one's merit, virtue, and ultimate desert rest only on traditional paths toward personal progress?

HUMAN ENHANCEMENT USES OF BIOTECHNOLOGY: OVERVIEW

ROBERT WACHBROIT
University of Maryland
College Park, Maryland

OUTLINE

INTRODUCTION

There is little doubt that the most controversial issue regarding biotechnology is the prospect of employing it for the purpose of human enhancement. The following discussion is intended to serve as a roadmap to the various questions and topics raised by the prospect of enhancement, with special emphasis on the conceptual issues. A detailed examination of the ethical issues is the topic of another article.

We will begin by examining the so-called demarcation problem: What is enhancement and what is it being contrasted with? We will then survey some of the types of modifications that lead to enhancement. Although the primary modification people have in mind is genetic, it is worth looking at nongenetic modifications — biotechnological and nonbiotechnological — in order to place the concerns with genetic modification in a broader landscape. Finally, we will examine some general approaches for assessing genetic enhancement.

THE DEMARCATION PROBLEM

Enhancement modifications are typically defined alongside therapeutic modifications. A therapeutic modification is one that brings a trait that was below a recognizable, specieswide norm up to that norm. (The term "traits" is meant in its broadest sense, including physical attributes, mental or physical abilities, dispositions, and capabilities.) As a first approximation, we can characterize an enhancement modification in contrast as one that is a nontherapeutic improvement. The norm referred to here is the one that separates conditions of health from those of disease. The distinction between enhancement and therapy is therefore linked to the distinction between health and disease.

Two important points should be raised about this linkage. First, while the various proposed theories of health and disease yield corresponding accounts of what enhancement and therapeutic modification means, controversies and obscurities in the former will translate into the latter. Problems with particular theories of health will have counterparts in problems with the corresponding account of enhancement modification. Indeed, skepticism about there being an objective contrast between health and disease will translate into a corresponding skepticism about the distinction between enhancement and therapy. Consequently the health/disease distinction is of limited use in *explaining* the enhancement/therapy distinction. None of this, however, undermines the link. The first distinction will be as clear and useful as the second. Thus, while it is true to say that therapeutic modifications attempt to treat disease whereas enhancement modifications attempt to improve a trait that is not diseased, there can be considerable debate over whether a particular modification therefore constitutes an enhancement and why.

Perhaps the most debated issue regarding theories of health and disease is whether or not the distinction — what constitutes the norm — is value-free: Is the judgment that someone is diseased — that someone's condition falls below a norm — an objective discernment of a biological state or a value judgment? Is a particular condition a disease independent of whether we think it is bad or undesirable? Can a condition be a disease in one culture and not in another? Although this dispute is not particularly salient in discussions over enhancement, these discussions have typically proceeded with the idea of the norm being fixed and not relative to individuals or cultures. If what constitutes enhancement varies with individual or culture — if enhancement is in the eye of the beholder — then it is not clear that we can sensibly articulate an (ethical) issue about enhancement as such. Nonrelativistic conceptions of normality tend to favor objective theories of health and disease, though that still leaves considerable latitude over how to conceive of normality, from statistical conceptions (1) to biological conceptions (2). Nonetheless, objective conceptions are not the only kind of nonrelativistic conception of normality. Norms that are recognized to be arbitrary and conventional can still frame the issue, as discussions over the problems of enhancements in sports demonstrates. Indeed, even a normative conception of norms could be invoked, as long as the relevant values are themselves understood to be nonrelativistic.

The second point to note is that acknowledging the link between health/disease and enhancement/therapy can suggest that the latter is a medical matter. Ethical issues regarding enhancement modification should then be seen in terms of the ethics of medicine and the professional duties and responsibilities of health professionals. As plausible as this suggestion may be, we need to distinguish at least theoretically between questions regarding the ethics of enhancement modifications and questions regarding the ethics of physicians performing enhancements modifications — for example, whether a particular enhancement modification is ethically objectionable from whether it is unethical for a physicians to perform such a procedure. It may well be that the answer to the second determines the answer to the

first — for example, that the ethical questions regarding enhancements comes down to questions about the role morality and professional ethics of physicians, but a claim like that requires more of an argument than pointing to the connection between the enhancement/therapy distinction and the health/disease distinction (3, Introduction).

An immediate challenge to any account of the enhancement/therapy distinction is the presence of apparent borderline cases or exceptions to the classification scheme. These fall into two classes.

One class of cases is modifications that, strictly speaking are enhancements, but whose purpose is to respond to (the threat of) a disease. For example, a modification that improves people's resistance to particular diseases beyond the normal capacity would count as an enhancement but its purpose would be disease prevention and so arguably therapeutic.

A different class of borderline cases or exceptions arises from an ambiguity in the idea of "normal traits." It can mean a trait whose appearance and function is normal, but it could also mean a trait whose appearance, function, *and* development is normal. Moreover normality itself often refers to a range within a trait rather than to a sharp line. Thus, imagine two people, both of whose height is five feet. While the first person has short parents, the second has tall parents but suffers from a growth disorder. Both people have a height that falls within the normal range, but the second person's height is the result of a disease. A modification that brought the second person's height from five to six feet would be a modification within the normal range *and* a response to a disease (4).

Both types of cases indicates that a classification scheme generated by outcomes *and* by purposes is a scheme driven by one too many criteria. Since there is no direct line between outcomes and purposes, we should not be surprised if there are cases that fit each criterion differently. Which criterion we should use will depend on what we are trying to classify. If we are trying to classify modifications, then outcomes would be the better choice; if we are instead trying to classify practices or aims, then purposes might be a better criterion. Using both criteria is inevitably confusing in that not only can the same procedure and outcome be associated with different purposes but the same event often is shaped by multiple purposes. Ambiguities in classifying particular cases will inevitably arise. (See Juengst's article in Ref. 3 for a discussion of various other alternatives and their problems.)

The point about normality not being a sharp line raises an important distinction within the category of enhancement modifications: There could be modifications that raise a trait above the norm and there could be modifications that raise a trait from one point within the normal range of that trait to a higher point in that range. This suggests that the classification of modifications should be tripartite: therapeutic, intranormal, and (proper) enhancement. Nevertheless, we should note that many commentators understand enhancement to mean any improvement of a normal trait, thereby collapsing the second and third categories. Cosmetic surgeries, which can often be regarded as intranormal modifications, are thus placed in the same category as genetic modifications to create superpeople. Whether fewer distinctions or categories is better will depend on how the issues are analyze and whether one classification clarifies matters more than the other. As we will suggest below, it is better to keep intranormal modifications, which are differences of degree, distinct from enhancements proper, which are differences of kind.

TYPES OF MODIFICATIONS

Biotechnology covers a range of technologies and procedures, many of which could conceivably be employed for enhancement. Drugs could be designed to interact with the body's chemistry in such a way as to alter behavior, biological functioning, structure, or affect. Even without introducing drugs, special procedures — such as transfusing a person with their own blood or "blood doping" — can affect traits or behavior. But the most discussed enhancement technology is one in which a person's genome is altered.

It is an empirical question which traits can be enhanced by modifying an individual's genes. And it may turn out that enhancing certain traits requires not only genetic modifications but also certain alterations in the individual's environment. That is to say, a particular genetic modification might not by itself bring about an enhanced trait; it might give the person a capacity to developed the enhanced trait whose realization demands a special exercise regime, diet, or other efforts. The idea of genetic enhancement technologies therefore does not rest on an assumption of genetic determinism — that a genetic alteration alone is sufficient to bring about a particular trait. While a popular image of genetic enhancements is that of some magic-wand transformation in which the person is a passive recipient, the matter can be more complex. Realizing a genetic enhancement might involve hard work. This point will become important later when we consider assessments of enhancements.

Genetic modifications are often separated into two kinds — somatic and germ line. The difference is whether the particular genetic modification affects the individual's gametes so that the modification can be passed on to the individual's offspring. The object of a somatic modification is a modified individual, but the object of a germ-line modification is a modification that becomes part of the individual's legacy or inheritance. In saying that there are these two kinds of genetic modifications, we are *not* claiming that of any particular genetic enhancement there is a somatic version and a germ-line version. That is entirely an empirical matter. It may well be that certain kinds of enhancements can only be done as somatic while others can only be done as germ line. For example, a modification may only be somatic because it interferes with the individual's ability to reproduce. A modification may only be germ line because the only feasible way of delivering the modification to all the relevant cells requires inserting the modification in the few cells of the embryo stage, which would then likely affect the individual's germ cells. Although the distinction between somatic and germ-line modification is conceptually clear, it may not be applicable everywhere.

Nevertheless, many commentators find the distinction useful. It is reasonable to assume that somatic

enhancements are simpler as far as ethics and public policy is concerned. Germ-line enhancements appear to raise all the issues of somatic enhancement and then some. And so it would seem that we should first examine the acceptability of somatic enhancements and only after settling that should we proceed to an examination of germline enhancements. This strategy however is difficult to sustain if we allow for the possibility that enhancements might not stand or fall as a group. If we are open to the possibility that some enhancements might be acceptable and others not and we acknowledge that some enhancements may have only a somatic or a germ-line version, the strategy of considering first the somatic case and then the germ-line case may not always be applicable. Some enhancements might as a matter of technology not have a somatic version.

(Of course there is one way of ensuring a genetic enhancement is not in effect germ line — combining the modification with one that also renders the individual infertile. But this possibility is probably not worth dwelling on: It is difficult to conceive of a case where, as a matter of ethics or public policy, an enhancement would be acceptable but only if the individual agrees to sterilization.)

ASSESSING ENHANCEMENTS

There are two broad approaches to determining the acceptability of an enhancement: the assessment can be based on what the enhancement is — the product — or on how the enhancement is achieved — the process. We will briefly provide an overview of the questions each of these raise in turn, leaving a more detailed discussion of the ethics for a separate article. For this entire discussion, we will be assuming that the modification is safe and effective so as to target our inquiry on the acceptability of the enhancement modification itself rather than on side issues regarding the acceptability of risky biotechnological procedures.

Product Assessment

Recall the earlier contrast between enhancements, properly called, and intranormal modifications. An assessment that focuses only on products will pass on intranormal modifications, since there is presumably nothing wrong with the result of an intranormal modification, at least at the level of the individual. For example, there is nothing wrong in itself with being six feet tall, so an intranormal modification that renders a person six feet tall cannot be unacceptable because of the result.

Confining ourselves therefore to only proper enhancements, the first kind of product assessment is directed at trade-offs the modification allegedly imposes. For example, suppose that a modification enhances a people's memory capacity but with the result that the speed in accessing memory is considerably slower. Or suppose that an enhanced memory capacity results in greater irritability. How should these trade-offs be assessed? Should it be a matter of individual choice or public policy?

A second kind of product assessment is directed at the "humanity" of the modification. According to this approach there is something wrong in itself and not because of alleged trade-offs in having a particular trait enhanced beyond what is (normally) human. Indeed, because of the enhanced trait, the individual might not be regarded as human. The problems arising from the various racial and ethnic divisions of humanity might well carry over to this new kind of division. In addition some people might regard enhanced individuals as an insult to the integrity of the species or, seen religiously, an insult to God's creation. How should these concerns be addressed in a pluralistic society?

A third kind of product assessment is directed at the widespread use of enhancements. Even if there is nothing wrong with any particular enhancement use, problems arise when many people or certain sectors of the population primarily make use of this enhancement. For example, suppose genetic enhancement of memory were possible and it resulted in memory-enhanced individuals being significantly more successful in several aspects of life. If only the wealthy had access to this technology, genetic enhancements would create or exacerbate troublesome inequalities. But even if the technology were made available to everyone, problems could arise. The desirability of some traits arguably rests on their not being common or widespread; if everyone is a blonde, then blondes will not have more fun. Furthermore people who do not want to be enhanced might nevertheless feel under some considerable pressure to avail themselves of it because many other people are doing so.

Process Assessments

When the issue becomes the process, then intranormal modifications are as much a subject for examination as enhancements, properly called. Indeed, it might be argued that we only need to examine intranormal modifications: If an intranormal modification is unacceptable from the standpoint of process, it would seem that extending that modification to the point of enhancement would also be unacceptable from the standpoint of process. The obverse would also seem to be true, though we should emphasize that acceptability from the standpoint of process does not entail acceptability from the standpoint of product.

The first kind of process assessment is directed at the suggestion that using biotechnology to effect an improvement is wrong because it is artificial. This concern need not be one that crudely equates natural with good and nonnatural with bad, raising concerns even about ordinary medical interventions. The worry here is a "commodification" of certain traits, and the people who have them, because of their being made to order, so to speak. This type of assessment is often linked with the concern about the humanity of the modification mentioned above.

The second kind of process assessment arises from a concern that using biotechnology in order to effect an improvement undermines the value of the improvement. The value we place on certain achievements may depend on the struggle and effort required to achieve them. If they could be made effortless — at least on the part of the individual — and common, we might well cease to value them. As we noted earlier, some (genetic) enhancements may only result in enhanced capacities; realizing them may still require effort, discipline, and luck on the part of the individual. Is the kind of effort relevant to the value we place on certain achievements?

The third kind of process assessment is directed at the suggestion that using biotechnology to enhance people is not the sort of thing physicians should do. The values or aims of the medical profession are held to be incompatible with performing enhancements. This can be a parochial concern in that a judgment that physicians should not perform enhancements leaves the question of the ethics of enhancement untouched. One can consistently be a supporter of capital punishment and yet hold that physicians should not be involved in either administering lethal injections or making the official pronouncement of death. In order to make this type of assessment have broader significance, one must argue that any profession that provides enhancements has suspect aims or values.

HUMAN GENOME DIVERSITY PROJECT

HENRY T. GREELY
Stanford University Law School
Stanford, California

OUTLINE

INTRODUCTION

The Human Genome Diversity Project (HGDP), first proposed in 1991, has thus far been responsible for more controversy than research. It has raised many of the same concerns as the well-established Human Genome Project (HGP) but at the level of human groups rather than that of individuals. As of the date of this article, the future of HGDP remains uncertain, but it is certain that the study of human population genetics, with its implications for human groups, will continue. The history of HGDP and the discussions of ethical, legal, and political issues it has stimulated are a source of useful lessons in either case, lessons about the complexity of social consequences of genetic research on human groups.

HGDP

HGP plans to publish the nucleotide sequence of the human genome in the next few years. The underlying point to HGDP is that there is no one human genome; instead there are about six billion existing human genomes, one for every living member of *Homo sapiens*, each of whose genome is separate and at least slightly distinct from all others. (Even monozygotic, "identical," twins, who make up under 1 percent of our species will show some genetic differences caused by mutations during development.) HGDP seeks to create a resource for studying this diversity. Its goals, which are set out most clearly in the report of its founding meeting in September 1993 in Alghero, Sardinia, include collecting and preserving genetic samples from approximately 500 different human populations around the world, performing some genetic analysis of the samples, and making both the results of those analyses and portions of the samples themselves available to interested researchers (1). HGDP, and the scientists behind the project have pursued these goals with limited success since 1991.

Scientific Background

The human genome is made up of approximately three billion base pairs of DNA, spread over 46 chromosomes. Individual human genomes do not vary by much. Genomes from two people, from anywhere in the world, vary on average at about one base in a thousand along any given stretch of their DNA. Within the regions of the genome that code for protein, the variation is closer to one in ten thousand. Most human genetic variation falls in regions of the genome that have no known function. Variations in these regions may be completely without consequence. Even variations that fall within the coding region of genes may be unimportant, either because they do not change the protein product, as when a single nucleotide substitution does not change the amino acid coded for, or because they change in the protein product in ways that make no apparent difference — that do not change the individual's phenotype. Other variations will affect the person's phenotype: in ways that may be negative, such as a genetic disease; in positive ways, such as increased resistance to a disease; or in ways that, as far as can be seen, are neutral, such as eye color.

The consequences of these variations will often depend on the individual's environment; having one copy of the gene for sickle cell anemia may cause mild health problems but provides some protection against malaria. In areas where malaria is rare, it may be a disadvantage; in areas where malaria is common, an advantage. The study of variations in individual genomes that have phenotypic consequences is the traditional study of human genetics.

If humans did not vary genetically, classical genetics could not see anything. Hair color, eye color, blood type, strongly genetic diseases — all these genetic traits are linked to the existence in individuals of genetic variations.

Particular genetic variations, or genetic "markers," are not distributed randomly among the world's peoples. The percentage of any human group with a particular genetic variant, or marker, may differ from the percentage in another group. The genetic contribution to skin coloration, for example, clearly varies among humans in ways that correlate, albeit imperfectly, with culturally defined ethnic groups. The same is true of other genetic variation, some of which has observable consequences, such as blood types, and most of which does not. The study of the patterns of genetic variation among human groups is called human population genetics. After the rediscovery of Mendel's work at the beginning of the twentieth century it became possible to study human variation at the genetic level even though human genes, at that point, remained abstractions. The key was to find some observable physical characteristics that were inherited in the manner described by Mendel and hence, presumably, determined by genes. By observing the variations in those characteristics, one was observing variations in the underlying genes.

This research began around 1915 with studies of the prevalence of ABO blood groups in different populations (2,3). And different patterns were discovered (4). Type A blood was most common in Northern Europe (although not found in a majority of the population even there). The peoples of Southern and Eastern Europe had a higher percentage of type B blood than those of Northern Europe, although, again, only a minority of them had type B blood. Native Americans overwhelmingly carried type O blood. The classification of humans into different *biological* groups based on their observable physical variations had been undertaken in Europe at least since Linneaus began biological classification of animals in the eighteenth century. The usual result was "scientific proof" that Europeans were "biologically superior." Human population genetics, which appeared to offer a way of classifying human groups based on characteristics that were not environmental, could be enlisted into such an effort. Thus some Nazi propaganda talked of the importance of blood type A Nordic peoples holding back the flood of blood type B blood from the "inferior" peoples of south and east.

In fact, over time studies of human genetic variation using classical markers have revealed that humans are not genetically very distinct and that most of the variation that exists is found within human populations. An estimated 85 percent of all human genetic variation exists within populations; only 15 percent reflects statistical differences between populations (5,6). Where differences among groups exist, they are usually *not* in the presence or absence of particular variations, but in their frequency. These differences are the products of statistical analysis and meaningful only for the groups, not for the individuals within them. For example, all human populations seem to include some members with each of the ABO blood types: O, A, B, and AB. Around the world, the A blood type is found in about 30 percent of humans. In some populations, particularly in the Americas, it is found in only a few percent. Among Armenians, it is found in just under 50 percent of the population. Any one person with an A blood type is highly unlikely to be Armenian; any one Armenian is more likely than not to carry some other blood type. If, however, 50 percent of a town of 3000 people have the A blood type, the inference that most of the town is Armenian — or made up of people related to the Armenians — may be worth investigating.

For most of the twentieth century, a shortage of classical genetic markers — phenotypical variation that is inherited in a Mendelian manner — limited direct empirical research into human genetic diversity. The theory of population genetics, however, both human and nonhuman, fruitfully expanded through the middle of the twentieth century. Then, the finding by Avery that genes were made of DNA and the discovery by Watson and Crick of the structure of DNA led ultimately to an era where much more genetic variation was much more directly observable through analysis of variations in the DNA itself. This not only allowed examination of more genetic traits but permitted for the first time the examination of genetic variation in regions of the genome that had no effects on phenotype. As these regions contained the vast bulk of human genetic variation, the ability to study such variation was greatly enhanced.

Such studies could have many uses. Perhaps the most interesting would be to provide additional evidence concerning human history and evolution. It will rarely be the case that one bit of genetic variation will be very informative, but by analyzing the patterns of variations in many different locations in the genome, population geneticists can, in some cases, estimate the closeness of the relationships between human groups. Eventually they may be able to generate a "phylogenetic tree," showing the relationships between human populations as putative descendants of common ancestors. This kind of information could be used as evidence of human migrations. The evidence can be used for very general questions, such as testing the "Out of Africa" hypothesis of human history, or for very narrow ones, such as exploring the history of the Japanese. The migrations studied might be recent, as in the Native American movements to the Great Plains after the acquisition of the horse made bison a more easily exploited resource. They can be more distant, such as, perhaps, the spread of Polynesians through the Pacific, Bantu-speakers through sub-Saharan Africa, or Indo-European speakers through Europe. In some of these cases, the evidence may be negative, showing that these changes in culturally defined groupings involved changes in cultures but did not result from migrations of genetically related people, which would itself be an interesting finding. Or the migrations can be still more distant, such as the evolution and spread of humans across the globe from their African origins.

This general approach of using variations to trace history is neither novel nor foolproof. The same kind of approach has been used to trace the history and changes of different texts, the development of languages, and, with molecular and nonmolecular evidence, the evolution of many different living things. This phylogenetic approach

may prove particularly difficult with humans, who did not separate into reproductively isolated populations. Genetic variations have flowed between human groups prodigiously in the last few centuries; it is certain that some level of gene flow between many groups has long existed. Today's culturally defined "populations" may not have substantial genealogical, and hence genetic, connections (7,8). The absence of such connections, though interesting on its own account, would undercut the historical value of population genetics (and, as noted later, cause some ethical problems). Genetic evidence of history and evolution is one line of evidence, to be considered with historical, ethnographic, linguistic, archaeological, and other kinds of evidence. It is, in the abstract, no more or less powerful or accurate than any of the others. But it does offer a different, and independent, line of evidence, which is of great interest.

The study of human genetic diversity has other uses. It may be used to answer some questions in cultural anthropology, such as patterns of marriage in the caste system in India. It might be used to test more general propositions in population genetics — after all, we know far more about the history and mating habits of *Homo sapiens* than we know about *Drosophila* in the wild. Or it could be of some help in biomedical research. If, for example, a variation in a "candidate gene" is identified as linked to a particular disease, the ability to check the prevalence of that variation in a population where the incidence of the disease is known might provide useful hints for further research.

A final, and more symbolic, value concerns the definition of the "normal" human genome. Genetic variation within the human species is small — especially variation that clusters along population lines — but it does exist. If "the" human genome were defined by the genetic variations most common in the countries where HGP is taking place, it would greatly overrepresent people of European ancestry, who make up less than 20 percent of the world's population. Variations not found in those of European ancestry, even if common around the world, might be viewed as "abnormal." For example, the ability to digest lactose, the sugar found in milk, is very rare among adult mammals. Among humans, most North Americans, and most Northern Europeans, can digest milk well as adults, but that ability is not common in the rest of the world's humans (9). Adult lactose intolerance is considered an abnormal condition in the United States, even though it is found in most humans. A specieswide resource of human genetic variation could help counteract similar parochial misunderstandings of the human genome.

Human genetic variation can serve these goals only if it is known. Current efforts to study it run into the so-called empty matrix problem (5,10). Genetic variation has been studied in many populations around the world for most of the twentieth century, either as classical genetic markers (like blood types) or, more recently, as DNA variations. But genetic variations that have been examined in one population will not have been analyzed in others, so those populations cannot be compared. Additionally, for many populations the samples examined were quite small. Human population geneticists ideally would like to have a large number of samples from a large number of populations, all analyzed for the same large set of genetic variations. It was this desire that led to the birth of HGDP.

HGDP Forms, 1991 to 1993

HGDP's parents were two population geneticists: Luca Cavalli-Sforza at Stanford and Allan Wilson at University of California, Berkeley. Their discussions of the "empty matrix" problem took on new life at in the early 1990s when the Human Genome Project began operating. They conceived the idea of HGDP as an important, and relatively inexpensive, supplement to HGP. With Charles Cantor, Robert Cook-Deegan, and Mary-Claire King, they wrote the first call for the project, published in *Genomics* in 1991 (10).

Wilson's illness and subsequent untimely death from leukemia in July 1991 prevented him from playing a large role in the project, which had an important consequence for its shape. Wilson and Cavalli-Sforza had taken very different views over HGDP's sampling strategy. Wilson had wanted to sample on a grid basis, taking a certain number of randomly chosen people from each of a series of squares laid down over a world map. This sampling method was used by population geneticists studying wild populations of drosophila or other nonhuman species. Cavalli-Sforza was more interested in sampling based on existing populations, both for logistical reasons and for the information such sampling could provide about population history. Cavalli-Sforza might well have won this argument in any case, but Wilson's death ensured that result (1).

The nascent project began to attract other supporters, from anthropology as well as genetics, and from overseas as well as from the United States (11–13). Sir Walter Bodmer, then President of the Human Genome Organisation (HUGO), appointed a committee to study the idea of a Human Genome Diversity Project in 1992. Cavalli-Sforza chaired the committee (1).

In early 1992 the American members of this committee — Cavalli-Sforza; Marcus W. Feldman, a population biologist from Stanford; Kenneth K. Kidd, a geneticist from Yale; Mary-Claire King, a geneticist then at the University of California at Berkeley (and now at the University of Washington); and Kenneth M. Weiss, a physical anthropologist at Pennsylvania State University — received funding from the U.S. federal government for planning HGDP (1). The funds, amounting to about $55,000, came from the National Science Foundation (NSF), the Department of Energy (DOE), and from two parts of the National Institutes of Health (NIH): the National Institute for General Medical Science and what was then the National Center for Human Genome Research (now the National Human Genome Research Institute). The committee used the planning funds to sponsor three workshops: one at Stanford in July 1992, one at Penn State in October 1992, and one at NIH in February 1993.

The first planning workshop focused on collection methods. In considered what kinds of samples would be needed and how many samples should be obtained from each population. A crucial issue at this stage was whether the project should collect DNA samples or lymphoblast cell-lines. DNA, purified from blood or from samples

scraped from the interior of the cheek, was easy to process and inexpensive, but would provide only a small amount of DNA from each participant. The latter, white blood cells transformed by viral infection to have an indefinite life span, were more expensive and technically more difficult but held the promise of an inexhaustible supply of DNA from each sample. The workshop recommended a combined strategy of acquiring a small number of cell-lines from each population along with a much larger set of DNA samples (1,14).

The second planning meeting focused on anthropology and sampling strategy. Anthropologists met at Penn State to discuss what anthropological questions could be addressed by a resource of human genetic diversity and what *kinds* of populations would be most useful to sample. The participants talked about wanting to get samples from populations that represented major linguistic groups in a region, that had interesting cultural or linguistic aspects, or that could be used to answer specific anthropological questions. They also noted the value of collecting samples from isolated populations that were rapidly disappearing as distinctive cultures, largely through assimilation. These populations they referred to as "isolates of historical interest." Using these guidelines, the workshop divided into groups based on geographical specialization, with orders to produce a list of 500 populations as examples of the types of populations such a project might want to sample. The workshop felt that the list would be useful in demonstrating to funding agencies that the project thought through these sampling issues. [In the event, the anthropologists did not get their list below 700 populations (1,15).]

The third workshop, held for two and a half days in February 1993 at NIH, had three parts. The first day was returned to issues of sample types and the debate over cell-lines. The second day was devoted to a discussion of ethical and human rights issues raised by the project (16,17). On the third morning, the project organizers met with representatives from possible federal funding sources, including NSF, DOE, and several institutes of NIH. The morning started under a cloud, as the previous evening had featured President Clinton's first State of the Union address, in which he stressed the importance of reducing government expenditures. It did not get better for the project organizers, as the federal funding agencies listened to their plans for HGDP with interest but made no commitments.

In September 1993, HGDP held what became its founding meeting, in Alghero, Sardinia. This four-day meeting was supported by the remaining funding for planning workshops, with additional support from the Porto Conte Research and Training Laboratories Foundation, the European Commission, the Soros Foundation, and HUGO Europe. The researchers gathered at this meeting agreed on an organization and a substantive outline for HGDP (1).

The organization was to work at two levels. An international executive committee, affiliated with HUGO, would exercise oversight over the entire project. Thirteen members were appointed to this committee, from four continents. The international executive committee could have subcommittees and would, the meeting decided, establish at least two: one on informatics and one on ethics. Both the fund-raising and the actual operations of the project were to take place at a regional level, run by committees made up of scientists living and working in those regions. The regions were envisioned as having continental or near-continental scale.

The substantive work for these committees was to fall into three main categories: collection, preservation, and analysis (with subsequent data base entry) of DNA samples. The project adopted as an interim goal the collection of samples from 500 different human populations. Using the number of distinct languages as a rough proxy for the number of populations, this would be a sample of around 5 to 10 percent of human populations. The samples from each participating population were to include about 15 cell-lines and many more samples of purified DNA. Basic ethnographic information, derived from a standard questionnaire, would also be obtained from each individual providing samples.

These samples would then be preserved at repositories. The group at Alghero concluded that there should be more than one repository, in order to provide backup storage for samples, and that regional repositories should be considered. Samples of DNA from the repositories would be provided at cost to qualified researchers on request. What qualifications were necessary was not entirely settled, but the intent was to prevent the wide spread of these samples to cranks.

The samples were also to be the subjects of analysis, at the repositories and elsewhere. The repositories were expected to analyze samples for a standard set of markers. Researchers who accepted samples from the repositories were to do so subject to a condition that they return the results of their analyses of the samples to the repositories. The analysis of the samples was to be placed into a database by the project, which was also to be open to all qualified researchers.

The Alghero meeting endorsed an estimate that, worldwide, the project would take about five to seven years and cost about $5 million to $7 million per year. By the end of 1993, regional committees had formed in North America, South America, Europe, and Africa, while organizing efforts had begun in Oceania. The structure for HGDP proposed at the Alghero meeting was adopted by HUGO in January 1994. But attention had already been drawn to HGDP and opposition had started to build. For the rest of the decade, HGDP would make very little progress.

HGDP Stalls, 1994 to 1999

HGDP began to attract press attention in the 1992 planning workshops. The October 1992 workshop at Penn State in particularly was featured in *Science* magazine, where one of the sidebar stories had the inflammatory headline about "Endangered Populations" (18). Press attention brought less welcome attention, notably from a nongovernmental organization headquartered in Canada called the Rural Advancement Foundation International (RAFI) (19). RAFI had begun in the 1970s as a nonprofit group focusing on developing world agriculture, largely

in opposition to the so-called Green Revolution. Over the years RAFI had become concerned about what it termed "bio-piracy," collections of plant material from developing regions by Western seed and pharmaceutical companies. These collections, RAFI and others charged, were often used to produce new products with no financial or other sharing with the peoples from whom the plants had been taken. Starting at a Pan American Health Organization meeting in spring 1993, RAFI began to spread the word among nongovernmental associations concerned with indigenous peoples that HGDP was another, deeper attempt at bio-piracy, taking, this time, not indigenous people's plants but their own human genes (20). RAFI took the sample list of populations, compiled at the Penn State workshop in October 1992, and publicized it on the Internet as HGDP's "hit list" (21). This caused understandable concern to groups that suddenly read of themselves as the "targets" of an international genetics project from whom they had never heard.

RAFI also tried to tie HGDP to examples of what it claimed was bio-piracy by the U.S. government. In September 1993, RAFI protested a patent application filed by the United States on a white blood cell (lymphoblast) cell-line derived from a woman from the Panamanian Guaymí people. The cell-line was infected with a human retrovirus called HTLV-2, which made it interesting as a source for virus and viral antibodies. In October 1995, RAFI protested against a patent that had been granted to the United States for a cell-line derived from the white blood cells of a man from the Hagahai population in Papua New Guinea. This cell-line contained a related human retrovirus, HTLV-1. In both cases RAFI won. The United States abandoned the Guaymí cell-line patent application and abandoned the Hagahai cell-line patent application. In both cases RAFI tried to connect HGDP to these applications, claiming, in the Hagahai case, that "The thin veneer of the HGDP as an academic, non-commercial exercise has been shattered by the US government patenting an indigenous person from Papua New Guinea" (22,23).

RAFI's actions sparked a surge of condemnations of HGDP by various nongovernmental organizations, including some representing, or purporting to represent, indigenous peoples (One writer has counted 13 such resolutions (24); another, earlier article had a list of 11 (25).) Opposition to HGDP came from organizations concerned about indigenous peoples, about patent rights and the developing world, and about genetic technologies more generally. Most of the condemnations were taken after hearing only from opponents of the HGDP and they often demanded that the Project, which had not yet begun any collections, stop or reverse its work. Thus, for example, in 1994 the Foundation for Economic Trends, founded and controlled by Jeremy Rifkin, a well-known opponent of biotechnology, formally petitioned NIH to cease all of its (nonexistent) funding for the HGDP's collecting activities (26).

At least in part as a reaction to this activist opposition, the HGDP's North American Committee decided to spell out its ethical positions more fully. This was not the first time HGDP had discussed ethical issues. It had sponsored a full-day workshop on these issues at NIH in February 1993 (16). The organization's founding meeting in Alghero, Sardinia in September 1993 included a discussion of ethics and required that the International Executive Committee create an ethics subcommittee (1). The meeting's report devoted several pages to ethical concerns. It classified as major concerns collection issues, intellectual property; racism, xenophobia, and hypernationalism; and public understanding. The report included 10 proposed ethical guidelines that the meeting had accepted:

1. The HGD project and its participating researchers must always respect the human of the sampled individual and the cultural integrity of the sampled population. . . .
2. Informed consent is both an ethical imperative and a legal requirement. The HGD project must satisfy both conditions. . . .
3. Researchers should actively seek ways in which participation in the HGD project can bring benefits to the sampled individual and their communities. Examples of such benefit include health screening, medical treatment or educational resources.
4. One way to avoid bringing harm to the sampled individuals or their communities is by protecting the confidentiality of those sampled and, in some cases, of their entire community.
5. Although very unlikely, it is neverless [sic] possible that the results of the HGD project may lead to the production of commercially beneficial pharmaceuticals or other products. Should a patent be granted on any specific product, the project must work to ensure that the sampled population benefit from the financial return from sales.
6. Human history — and the human present — is full of racism, xenophobia, hypernationalism, and other tragedies stemming from beliefs about human populations. In the past, some of those tragedies have been perpetrated by, or aided by, the misuse of scientific information. All those involved in the HGD project must accept a responsible to strive, in every way possible, to avoid misuse of the project data.
7. Many people in the world have, at best, a limited understanding of human genetics. Some fear the consequences of human genetic research, in part because of the limits of their understanding. To scientists involved in the HGDP project, such fears may not seem justified or even, in some cases, fully rational by the concerns are very real of the people involved and they must be addressed. It is essential that a worldwide "public awareness" program is included within the project to educate people about its aims, methods and results.
8. Inevitably, the ethical issues faced by the project will evolve over time. The issues must therefore be kept under continual review. The widest possible consideration of the issues should be encouraged.
9. The transfer of technology to developing regions of the world, which is an integral part of the

proposed project, should contribute positively to the development of self-sufficiency in these regions. The help given should not be superficial and of only short-term usefulness.

10. There should be a feed-back of information to populations that participate in the HGD project, most especially about any aspect of the project in which a particular interest had been expressed.

The report from the Alghero meeting was not published until early 1995, and even then, it received little attention. It also became clear to the North American Committee that the project, at least in North America, needed a more concrete position on a number of ethical, legal, and social issues. As a result, in 1995, using funds provided by a grant from the John D. and Catherine T. MacArthur Foundation, the North American Committee developed its own draft "Model Ethical Protocol for the Collection of DNA Samples" (27). The Model Ethical Protocol was largely completed by the fall of 1995 (17). It was posted on the project's Web site in 1996 and published in a law review in 1997. As discussed in more detail below, the 15,000-word Model Ethical Protocol offers detailed guidance on many aspects of DNA collection for HGDP. It introduced two particularly significant innovations into this kind of research: the concept of "group consent" and the use of contracts to give participating populations some control over subsequent uses of their materials and derived data. The Model Ethical Protocol has been adopted by the project's North American Committee to guide collections in North America; it has not adopted by the project overall.

The ethical, legal, and social issues raised by HGDP began to be discussed outside HGDP and its opponents. UNESCO's International Bioethics Committee heard discussion of HGDP in the fall of 1994 and appointed a committee to study the issue. That committee, chaired by Dr. Darryl Macer, gave a mixed report in November 1995 (27–29). HUGO, which had appointed the original HGDP committee in 1992 and had adopted the Alghero meeting's recommendations in 1994, asked its Ethical, Legal, and Social Implications Committee to study the issues raised by the project. The Committee, chaired by Professor Bartha Knoppers, considered the project at an October 1995 meeting and produced a set of ethical principles, subsequently adopted by HUGO, on both HGP and HGDP (30). The ethical issues of HGDP were discussed at a workshop at Mt. Kisco, New York, in November 1993 (sponsored by the Wenner-Gren Foundation), at conferences at Stanford in November 1995, and in Montreal in September 1996 (31), at the meeting of the International Association for Bioethics in San Francisco in November 1996, at the annual meeting of the American Association for the Advancement of Science in February 1998 (32), and at a conference at the University of Wisconsin-Milwaukee in February 1999 (33), among other venues. Gradually a literature began to build about the ethical, legal, and social issues raised by HGDP specifically and by human population genetics more generally.

While the ethical (and political) conversation about the project was moving forward, the project itself was largely stalled for lack of funding. The project's organizers, having rejected the idea of any commercial funding, looked primarily to the U.S. government for funds. (HUGO itself never had sufficient funds to consider supporting HGDP and, in fact, has struggled to sustain itself.) The early interest shown by that government, including a largely favorable congressional subcommittee hearing in April 1993 (34), did not translate into substantive funding. DOE's part of HGP made clear quite early its lack of interest in HGDP. NIH was less immediately dismissive. Its portion of HGP, the National Human Genome Research Center (since 1997, the National Human Genome Research Institute) acknowledged the eventual importance of studying genetic variation but did not choose to invest any funds in HGDP. The National Institute for General Medical Science, which seemed more open to HGDP, also failed to fund the project. Only NSF, and in particular, its program in physical anthropology, was encouraging about funding HGDP. The entire annual budget for the physical anthropology program at NSF in the mid-1990s, however, was only about $2 million. It could only fund HGDP if it received a major infusion of funds.

As they had done a decade earlier with HGP, the federal agencies with the most interest in HGDP decided to ask the U.S. National Research Council to report on the idea of the project. The National Research Council, the report-writing arm of the U.S. National Academy of Sciences, National Academy of Engineering, and Institute of Medicine, requires funding for its reports. The NSF, NIGMS, and the office of the Director of the NIH agreed in late 1994 to contribute about $400,000 to fund an NRC committee report on HGDP in the expectation, shared by HGDP advocates, that the Committee's report would either launch or bury the project. The Committee's report, which was finally released in November 1997, did neither.

In the event, the NRC committee was not appointed until early 1996 (35). Chaired by prominent geneticist Dr. Jack Schull, the 17-member committee included three ethicists, Professor George Annas, Dr. Eric Juengst, and Dr. Katherine Mosely. The committee held public meetings in April, July, and September 1996 at which both organizers and opponents of HGDP spoke. In November 1996 it began its deliberations, which took 12 months to yield a report. The report, when published, satisfied neither the proponents nor the opponents of the project — and may have confused many of its readers. The world's two leading scientific magazines, *Science* and *Nature*, reported on the committee's work with diametrically opposite headlines: "NRC OKs long-delayed survey of human genome diversity," claimed *Science* (36), while *Nature* wrote "Diversity project 'does not merit federal funding'" (37), (a headline *Nature* later retracted) (38).

The committee's chair, Dr. Schull, ended up writing correction letters to *both* journals (39,40), but, in fact, the committee's report seemed to provide, in different sections, support for both journals, particularly as diversely interpreted by some committee members. The committee stated that the plans for HGDP were too vague to be the subjects of a specific evaluation, and as a result it would

evaluate the overall concept. It concluded that although there were serious reasons for ethical concern, the federal government might fund such research but only through U.S. researchers who would be subject to U.S. rules on protection of human subjects. The overall message of the long-awaited NRC report was so equivocal, however, that it failed to achieve its sponsors' overall goal — to provide a clear verdict, up or down, on HGDP.

As of early 2000, HGDP — proposed in 1991 and organized in 1993 — remains largely unfunded. Its committee structure has in large part withered. The annual meetings of its International Executive Committee proposed at Alghero in 1993 became, as a result of lack of funds, one meeting in London in September 1994 and one meeting as part of a Cold Spring Harbor conference in October 1997. The North American Committee has remained active as a committee, thanks in part to the funds provided by the 1994 MacArthur grant. HGDP Regional Committees in Southwest Asia and in China, with local funding, have collected some DNA samples from their regions. The South American Committee disbanded and the others are inactive.

The NSF provided some funding for HGDP-related activities in 1997, when it awarded about $600,000 in grant funding for "pilot projects" on various issues related to the HGDP. These funds were explicitly not to be used for collecting DNA. Some continued interest in HGDP and its goals has been sustained by two conferences at Cold Spring Harbor Laboratories on Human Evolution, in October 1997 and April 1999. And, in 1999, HGDP has agreed with the Centre pour l'Étude du Polymorphisme Humain (CEPH) in Paris that CEPH will store 1000 cell-lines from existing collections and make DNA samples available to qualified researchers, thus advancing some of the goals of HGDP.

Outside HGDP the subject of human genetic diversity has become of greater interest. In 1998 the NHGRI, with the end of the sequencing phase of the HGP in sight, created an initiative to use samples from diverse populations to search for "single nucleotide polymorphisms," or SNPs. These SNPs are expected to be useful for locating genes of medical interest, and NIH sought to create a resource of SNPs in the public domain before private firms patented too many of them. (A consortium of pharmaceutical companies and foundations has embarked on a similar effort, again with the goal of putting SNPs in the public domain (41).) The NIH samples, selected from Americans of European, African, Asian, and Native American ancestry, are available from a public repository but with no identifying ethnic information, even at the continental level (42). In fact, investigators taking samples from the repository are required to promise that they will not attempt to identify the ethnic background of the person who gave the sample (43).

Meanwhile, human population genetics continues to be done, for anthropological and other purposes. Recently published research has used the analysis of DNA samples to provide evidence about the origins of Native American (44), Japanese (45), and Chinese populations, among others (46,47). But the empty matrix problem remains — there still exists no broadly derived set of human DNA samples that have been analyzed for a standard set of markers. And no special ethical oversight exists for the ongoing efforts to collect samples for the study of human population genetics.

ETHICAL, LEGAL, AND SOCIAL ISSUES RAISED BY HGDP

As a large-scale genetics research project, aimed at collecting DNA samples from thousands of people, HGDP has raised most of the issues that are raised in similar research. These concerns include, among other things, ensuring the confidentiality of individual information, avoiding undue inducements for research subject participation, the use of previously collected samples, and dealing with the possible return of medically significant information to research participants. The wide variety of cultural backgrounds of anticipated participants in HGDP makes resolving those issues unusually complex, but the basic problems are the same ones faced by any research related to human genetics. Answers to those problems are the same ones faced by any research related to human genetics. Answers to those problems in any context may be contentious, but the HGDP's answers, as proposed in the Alghero report and especially in the Model Ethical Protocol, are unusually detailed but not extraordinary (27). One difficult area not covered at length in the Model Ethical Protocol is the use of previously collected samples, an issue that remains as vexing and complicated for HGDP (48) as it does for medical research more generally (49,50).

The issues unique to the HGDP arise from the nature of the "research subjects" of HGDP: not primarily individual humans, but human groups. The group nature of this research that makes the ethical, legal, and social implications of HGDP so fascinating and so difficult. It also makes the proposed solutions to those issues, particularly the North American Committee's requirement of "group consent," complex and controversial, in some respects perhaps more controversial than the research itself.

Group Concerns

A host of concerns have been raised on behalf of the populations that might participate in the project. Although many different issues are involved, they all fall into two main categories: fears that genetic information will harm the groups that take part and concerns that the groups will be financially exploited with respect to their genetic resources. These concerns have, not surprisingly, been raised largely on behalf of indigenous groups that have suffered from oppression and continue to exist under European domination. Thus the concerns have been raised most actively by groups speaking for Native Americans throughout the Western hemisphere, Australian aborigines, and the Maori, the Polynesian minority in New Zealand. Although the concern about exploitation seems to exist in some other settings, the fears of harm are strongest among the populations with the least power.

It is worth noting that HGDP does not intend to sample solely populations that are indigenous, small, or powerless.

Its goal is to collect a roughly proportionate sample of the world's human populations. Some of them will be small; on the other hand, the Han (ethnic Chinese) are a population of great interest to population geneticists, and they make up about 20 percent of all humans. Thus much of the intended work of HGDP could be achieved without sampling the populations that might be most concerned about the project.

Direct Harms. Critics of HGDP have argued that the project could bring a wide range of harms to participating populations. These range from harms to the population's cultural, to harms in its members relationships to the broader society, to political costs. Each is discussed below.

Two kinds of possible cultural harms have been suggested. One is that participation in this kind of project may violate either a particular group's culture or, more broadly, general indigenous norms (51–54). It has been argued that the assertion of domination and control over nature implicit in modern science is, in itself, antithetical to indigenous cultures. More specifically it is also claimed that some aspects of the DNA collection process will violate cultural norms, such as those that may relate to the treatment of blood or hair. The great degree of variation in human cultures makes it prudent to be skeptical of claims of "universal" cultural norms for indigenous peoples, but certainly some groups will hold such views.

A second type of cultural harm looks instead to the results of the project. Some indigenous activists have argued that scientific evidence from HGDP, by contradicting local cultural histories and origin stories, may undermine the authority and power of the culture. Thus many Native American populations have oral histories that place their origin in American locations. Genetic evidence that the ancestors of Native Americans migrated to the Western Hemisphere from Siberia could shake community members' faith both in that origin story and in the entire culture (51). Supporters of the project counter that these claims need to be examined carefully. Anthropologists have long argued, based on many lines of evidence, that Native Americans migrated to the Western Hemisphere from Asia. HGDP might add some evidence to that conclusion, but its supplemental effect seems unlikely to be great. In addition, it is urged, many people have shown a great ability to disregard scientific evidence that conflicts with their origin myths. In the United States, which provides support for extensive research into the evolution of modern humans, over 40 percent of the population continues to believe that humanity was created in the Garden of Eden about 6000 years ago. Finally, one may question whether cultures necessarily want to preserve their myths unchanged. Nonetheless, in some circumstances this may be a realistic threat to a population's culture.

Those concerned about HGDP also point to broader social harms revolving around concerns about discrimination. As is the case with individuals, groups might be considered genetically susceptible to particular diseases or conditions. This could lead to discrimination against group members in employment, insurance, or other social activities. It might stigmatize the group or support a racist belief in the group's inferiority.

HGDP's supporters use several arguments to try to undercut this criticism. First, HGDP is not looking for disease-related genes; it will focus on random markers that will not reveal this kind of information. Second, the relevance of these concerns they depend crucially on a population's situation. Commentators have discussed in detail the possible and actual existence and significance of discrimination in insurance and in employment in the United States. (And, in the American context, the motivation for employment discrimination often stems from the employer's payment of health insurance costs (55).) In societies where every individual is guaranteed health coverage — which comprise all wealthy countries other than the United States as well as some middle- and lower-income countries — this discrimination becomes irrelevant. In some traditional societies where Western medicine itself may be unavailable, both health insurance and employment discrimination may be irrelevant.

More fundamentally, though, supporters of the project contend that discrimination fears exist in an individual context because genetic information might reveal something about risk that cannot otherwise be known. At the level of human populations, genetic analysis would not often provide that kind of information. Such an analysis might indicate that from genetic causes, the Irish have several times the average levels of the genetic variation that, when an individual inherits two copies of the variant, causes the genetic disease phenylketonuria. It would not indicate which Irish people were at risk and which were not. And, more important, the levels of these risks will already be known directly from public health statistics and epidemiological research. One does not need to know the distribution of genetic variations associated with disease to know disease rates in populations; those rates can be examined directly. It is conceivable that for some disorders, cases linked to genetic variations will have differences from nongenetic cases that would be important to insurers or employers. One could hypothesize that for example, breast cancer cases related to mutations in BRCA1 were less easily and cheaply treatable than other breast cancers. In that case, knowledge that a population had an unusually high rate of those mutations might be relevant. But, for the most part, the prevalence in a population of genetic variations linked to disease will add nothing to the risk information already available from observation of the disease incidence.

The issue of stigmatization is more complicated. Project supporters point out that it is hard to think of examples any populations that are stigmatized because of higher rates of disease. Europeans have higher than average rates of cystic fibrosis, many Africans and Southeast Asians have higher rates of hemoglobinopathies, Ashkenazic Jews have unusually high rates of Tay-Sachs disease. Alcoholism may be one of the few examples of a disease or condition that has stigmatized some populations, such as Irish, Russians, and Native Americans. Again, one might think that if a population is going to suffer stigmatization because it carries disease-associated genetic variations at an unusual level, then it would already been stigmatized for having a high rate of the disease itself. The fact that

the cause is genetic, though, might lead to a higher social impact. The concept of "genetic essentialism" — the idea that one's genes are one's essence (56,57) — could lead people to believe that a population with a high rate of genes associated with a disease is somehow inherently flawed, or more flawed, than a population with a low rate of that genetic condition. Of course, every population is likely to have somewhat higher and lower genetic risks for different diseases, but one might focus on a particularly stigmatizing disorder, such as schizophrenia. On the other hand, a genetic explanation might have opposite effects. If a higher rate of disease in a population is believed to be genetic, the individuals suffering from the disease may be viewed more favorably on the theory that the disease is not the result of their actions. (This relies on the general popular assumption, often false, that diseases with genetic "causes" do not also have, in the same individual, environmental "causes.") This issue has been interestingly discussed in the context of a possible genetic association with sexual preference (58); whether a conclusion that a population's higher rate of a condition has genetic roots would increase, decrease, or leave the same any stigma attached to the group because of the condition is unclear.

The asserted political harms vary. One set of concerns revolves around land claims. If rights to land are affected, legally or politically, by the history of a population's occupation of the land, genetic evidence that the population migrated from elsewhere, or direct evidence from ancient DNA that a different population occupied the land in the past, might have some political relevance (8). Project supporters argue, on the other hand, that few if any peoples are thought to be truly indigenous to any location — under current thinking about human evolution, only some African groups could even possibly make that claim. In many regions of the world, migrations and changes of homeland have happened within historical memories — in too many places, within the living memories. For legal and political significance, the relevant time frame is important; it is hard to imagine many situations where DNA evidence would have current relevance. And, if it were, it might be thought as likely, in a given situation, to favor a population's claims as to harm them. But if one takes the view — which might be quite reasonable for some subordinated populations — that the dominant culture will twist any new "scientific" evidence to its political benefit and your detriment, this concern becomes more understandable. Even if genetic evidence is not directly relevant, it might be used to weaken the political standing for some land claims. This fear of this kind of general political effect may be one of the sources of the controversy over the so-called Kennewick man, an ancient skeleton found in the northwestern United States that some allege has "European" features.

Also related to land claims, concrete or broad, is a possible concern about membership. Some worried that an outside government might impose a genetic test for membership on the population, adding and subtracting members without the group's consent.

Critics of HGDP cite the possibility that genetic variations might be used for biological warfare against sampled populations as yet another political concern. Project supporters claim that such ethnically targeted biological warfare seems scientifically implausible for two reasons. First, the enormous overlap in genetic variations between populations would mean that such a weapon would not affect many in the targeted group and would affect many outside the targeted group. The twentieth century has seen all too many more discriminating and "efficient" methods for genocide. Second, scientists do not know how to kill a cell based on variations in its genetic material. If they did, all infectious disease organisms and all tumors could be handily defeated. Nonetheless, some recent publications have fed this fear (59–61).

Exploitation. Issues of exploitation of participating populations are somewhat different from those of direct harms to those populations. These concerns focus on the possibility that participating populations might be robbed of something of value as a result of the project — "their genes" (20). This view is fed by the great interest, popular and financial, in biotechnology. It is also exacerbated by stories, which can reach the level of myths, about past "victims" of predatory commercial biotechnology, such as the tale of John Moore's spleen (62) or the patent applications for cell-lines derived from indigenous Panamanians and Papuans. There are also parallels, close and distant. The term "bio-piracy" was coined, apparently by RAFI, to describe the use of plants and plant genes from the developing world by commercial firms from the developed world for pharmaceutical and agricultural profit. HGDP may have appeared just an extension of that process to human genes. More generally, though, many indigenous cultures have suffered from exploitation by outsiders in recent history. The slogan that "You stole our land, you stole our resources, and now you want to steal our very genes" has power. Finally, this fear of exploitation flourishes as a result of limited understanding of human genetics. People are ready to believe that their population has its own "genes," let alone its own special variants of human genes. From the identification of a gene in a small number of people, to an understanding of its function, to its application as a profitable pharmaceutical may appear an easy series of events to the outsider. The idea that one's group has "special genes" of great value and power is also a flattering one. For all these reasons people concerned with indigenous groups or, more broadly, the developing world might conclude that HGDP was an effort to exploit the commercial value of human genes from outside the developed world — after all, if those genes did not have value, why would anyone look for them?

The reality is less financially promising and more complicated. Populations do not have unique "genes," although they may have an unusually high (or low) percentage of certain variants of human genes. Identifying a genetic variation as associated with a disease (or with protection from a disease) is a long and complicated process, requiring extensive medical as well as genetic work with individuals and their families, both affected and unaffected with the disease. The jump from the discovery of a disease-related variation to a commercial product is enormous and has rarely been made. None of these activities has any relationship to HGDP. The

project has disclaimed any commercial interests, backing, or connections. But, as critics of the project point out, scientists with commercial connections would, under HGDP's initial plan, have access to samples and data collected by HGDP.

In fact, neither a renegade HGDP nor scientific third parties would be likely to be able to derive information with strong medical, and hence commercial, value from the HGDP samples. HGDP will not obtain the kind of medical data about participants that would be necessary to make the samples it collects useful for this kind of medical research. Without knowing which participating individuals had diabetes and which did not, for example, research into connections between genetic variations and diabetes is not possible. HGDP's organizers have stated that some information of value to medical researchers might be created by the project. For example, if a researcher had identified a "candidate gene" for a particular disease, HGDP's resources might be able to tell her whether the high risk variant was more or less common in populations with known epidemiological risk. But this kind of information seems likely to have little direct commercial value — it will neither prove nor disprove a genetic connection but might narrow the possibilities. Thus HGDP has consistently evaluated the likely commercial value of the samples and data it collects as quite low. It has not, however, been able to rule out the faint possibility that some samples or data could end up having commercial value for some third party user of the information. It is this indirect and unlikely contingency that could give rise to concern about the financial exploitation of participating populations.

HGDP's Responses to Group Concerns

HGDP has been aware of some of the group concerns raised by its research since at least early 1993. It tried to address many of them in the Alghero meeting and report. Some of its solutions in that report include respect for the cultural integrity of participating populations; the resolution to protect individual and, in some cases, group confidentiality; and the renunciation of commercial connections; and, when appropriate, a sharing of financial benefits. The Alghero report expressly recognized that "the ethical issues faced by the Project will evolve over time" and called for their continual review. The most detailed such review from within the project has come from the North American Committee and its Model Ethical Protocol. This document accepted, for North American HGDP work, two broad responses to group concerns: group consent and contractual restrictions on subsequent uses of samples and data. Its idea of group consent has spawned nearly as much controversy in ethical circles as HGDP itself — and more academic literature.

Group Consent. The Model Ethical Protocol requires that where feasible, those collecting DNA samples in North America for HGDP obtain not only the informed consent of individual participants but also of their population (27,63). This collective consent is to be sought from the group's "culturally appropriate authorities," as defined by the group itself. Where permission is denied, the project would not accept any samples from members of the population. The protocol recognizes that such consent will not be feasible for groups that do not have an authority structure, like Irish-Americans or Ashkenazic Jews. In those cases it requires full discussion within the direct community in which the collection is to be done — the local town or religious or cultural association — as well as dissemination of the facts about the planned study broadly to those who identify with the group to enable them to try to influence their colleagues to participate or not in the project.

The North American Committee put forward several arguments in favor of group consent. At the most basic level, its claim is that human population genetics research, by its very nature, has the population as its subject as well as the participating individuals from that population. Every member of that population may be affected, positively or negatively, by the results of the research and thus the population, collectively, should have a chance to decide on its participation. Just as individual informed consent lets people decide whether a particular medical procedure or research project meets *their* balance between costs and benefits, under group consent the group as a whole could hear about the possible harms discussed above and decide whether to take those risks. If a group decides that HGDP involves too great a risk of cultural disruption, negative land claim evidence, or any other harms, it will simply not participate. Individual informed consent is also justified as respecting the autonomy and personhood of the patient or research subject. Group consent acknowledges the cultural reality of ethnic groups. This may have particular force with populations that have been dominated by others. By seeking and respecting their decision, one respects their cultural autonomy. This kind of respect may be welcome by almost any group, but is particularly appropriate with Native American tribes in the United States. Legally, federally recognized tribes are sovereign governments existing in a complex political relationship with the federal government. Culturally non-Indian peoples often do not recognize that legal reality. By expressly giving them a chance to say no to the research with their populations, whether or not conducted on the reservation and hence within their political jurisdiction, the Model Ethical Protocol would uphold and extend that autonomy. And, as HGDP seeks to sample only about 5 to 10 percent of the world's human populations, many groups can decide not to participate without jeopardizing the project's goals.

This idea of group consent is not new. Ethnographers and epidemiologists have long known that the kinds of intensive studies they conduct in the field often require, as a practical matter, a great deal of community consensus building and the approval of those with authority, formal or informal, within the group. In the United States many federally recognized Native American tribes, which are sovereign governments within their reservation boundaries, have in recent years established their own institutional review boards for assessing research proposed on the reservation (64). The idea of collective approval is new to some areas of research, but not to all. In its August 1999 report on the use of human biological materials, the United States National Bioethics

Advisory Commission recognized the significance of group interests and the possible value of group consent, but noted that current law regulating human subjects research does not require that these collective issues be addressed (50).

Group consent has precedents, but it also has problems, both practical and philosophical. Perhaps the largest problem, and one that fits both categories, revolves around the definition of the "group" whose consent is required. Eric Juengst has argued that this is a fatal flaw (8,65). Genetic information about one Navajo village, for example, may have implications all Navajos, on the reservation or off. It may also say something about other speakers of languages in the Na Dene language family, which is spread widely in western North America. It could demonstrate something distinctive about all Native Americans. Or it may have no implications for any groups larger than the individuals involved. Until the research is completed — along with complementary research on other populations — the scope of its effects cannot be known. If the justification of group consent is to have the approval of those who may be affected by the research, it cannot succeed. The relevant group, which would be population defined by a relative closeness of genetic relationship, cannot be defined in advance other than to say, based on the existing knowledge of population genetics, that it does not coincide perfectly with any culturally defined ethnic group.

Juengst's criticism is clearly correct, though its impact is not as clear. Defenders of the group consent can argue that although the definition of the relevant group will never be perfect, it will be a good start. The Model Ethical Protocol says that researchers should determine the relevant group in consultation with the community with whom they are working. If they view a larger grouping as necessarily involved in the research, then it should be so involved. Using the relevant community's own definition upholds, at least, the autonomy justification for group consent even if it does not fully encompass the consent of those affected. Juengst suggests replacing group consent with consideration of group interests during individual consent. Thus, rather than ask the group for consent, individuals asked to participate in the research would be told that the research may have implications for specific groups they belong to and that they should consider those implications when deciding whether to participate. This kind of directed consideration could play a useful role, although it too would be imperfect. The particular individuals approached for the research might not reflect well the concerns of the larger community. And the process of consent — the discussion and debate — may well be much broader (as well as longer and more arduous) in group meetings than in individual informed consent sessions.

Group consent has been subject to a number of other concerns, as well as arguments about the significance of the problem it attempts to solve (66–68). The determination of the "culturally relevant authorities," whose approval will be required may prove difficult (69). Federally recognized Indian tribes, in the United States and in Canada, have governmental structures that will provide a starting place for such authorities. Other communities will not usually have formal governments and finding any "culturally appropriate authority" may be difficult. Even recognized Indian tribes may have a variety of nongovernmental structures claiming authority. If there is a dispute within the population about which people or organizations have authority, how should researchers resolve it? This may be particularly difficult if participation in the research becomes, itself, a divisive issue within the population. One can even imagine one faction using the researcher's acceptance of them as authoritative as a weapon in a power struggle within the group. In some cases, where the structure of authority is sufficiently unclear, researchers may have to walk away from the research entirely. Other criticisms are less pragmatic. Juengst has suggested that group consent is suspect because it asks cultures to become complicit in research that may harm them, which seems a strained way to view giving choices to groups (67). Presumably the interests of the groups would not be better served by a process that imposed research on them whether they liked it or not. Some researchers, including some on the North American Committee, have been troubled that group consent would deprive individuals of their "right" to take part in research on the basis of the group's fears, even if the individuals had removed themselves from the group. Finally, it has been pointed out that the logic of group consent may extend uncomfortably far. Traditional research on human genetics uses "groups" made up both of people suffering from disease and of families. Should disease organizations or extended families also be accorded the power of group consent (63)? The issues raised by a group consent requirement are indeed broad, so broad that it has not been formally adopted yet by any HGDP regions other than the North American Committee. And a Canadian effort to revise their codes of research ethics, though initially proposing a strong "group consent" requirement, removed the discussion from their final version, leaving only a short section on special issues in dealing with the native peoples of Canada (70).

Some have argued that the process of group consultation and discussion should be required even if strict group "consent" is not sought. In a series of articles, Morris Foster and coauthors have argued for a form of "community review," which involves the community where the research is proposed without formally requiring community approval (71–73). Foster has combined this approach with a model agreement for regulating the rights of communities that agree to be the subjects of research (74).

One other response to the risks of group harms deserves mention. Foster has at least occasionally suggested that the identities of populations participating in genetic research should be hidden (33). If no one knows what group provided the samples, the information cannot be used against them by outsiders: in employment, insurance, or politics. (The internally derived harms, such as the undermining of the population's culture, could still occur.) HGDP proposed a limited form of this response, through "fuzzing" the precise identity of a participating group. For example, rather than identify a specific village, perhaps even by use of the global positioning system, HGDP could say that the samples came from a village within a broader region. Of course, withholding information about the group's identity may have its own bad consequences,

both for science, which may not proceed accurately without sufficient specificity, and for the group, which could lose some benefits of the research it not identified. Besides, if the level of group anonymity were too great, it would render impossible some of the historical research that is a key purpose of HGDP. Nonetheless, some amount of group anonymity is a protective tactic that should be considered in this kind of research — and perhaps should itself be a subject of discussion in the consent process, group or individual.

Contractual Defenses against Exploitation. The founding meeting of the HGDP endorsed the idea that participating populations should share in the financial gains, if any, resulting from the HGDP. Its report states: "Although very unlikely, it is neverless [sic] possible that the results of the HGD Project may lead to the production of commercially beneficial pharmaceuticals or other products. Should a patent be granted on any specific product, the Project must work to ensure that the sampled population benefit from the financial return from sales" (1). The Alghero report, however, provided no suggestions for how the Project might ensure such a result.

Again, the Model Ethical Protocol sought to implement that principle. It did so through the medium of contracts (27). HGDP plans to operate both DNA sample and cell-line repositories and a database containing the analyses of HGDP samples. Samples and information in both facilities would be available to qualified researchers. The Model Ethical Protocol states that those facilities should only allow access to researchers who agree, by contract, to restricted commercial uses of the information they obtain from the repository or database. Contracts governing this kind of access, called "materials transfer agreements" in the case of samples and "database access agreements" for the computerized information, have long existed, initially to protect the repositories and databases from liability. The Model Ethical Protocol would expand those agreements to provide that all of the HGDP's samples and information could only be used in ways consistent with terms and conditions limiting their use. These terms and conditions, the protocol suggests, would usually be set by the participating population as part of the process of group consent. Thus a population might choose to forbid any commercial use or any patenting of their samples, the information, or products derived from the samples or information. Alternatively, it might authorize such uses on the payment of a specified royalty to the group or on the completion of a subsequent express written agreement. Or it might allow any uses. Anyone who wanted to use samples or information provided by that group would have to agree to abide by its terms.

Like group consent, contractual limitations on commercial use also have problems, both in their inception and in their implementation, but, unlike group consent, both the idea and its problems have been little discussed. At least four topics need to be raised. First, the topic of possible commercial gains would need to be discussed very carefully in the group (or individual) informed consent. Otherwise, the (very faint) hope of financial rewards might unfairly influence a group to participate in research. Undue inducements to participate in human subjects research are not allowed; despite the researchers' disclaimers, a group might wrongly believe that it has a strong chance of becoming wealthy from its "gene royalties," which, as the researchers would recognize, would be very unlikely ever to exist. Second, some default standards would have to apply to populations for which group consent was not obtained because it was infeasible. These standards would not only have to determine what would be a "fair" return but would also have to consider the problem of who should receive or spend any such sums, as, by definition, no "culturally appropriate authority" would exist for a group from which no consent was sought. Third, attention would have to be paid to who could sue to enforce these contractual clauses. The population might have the best incentive to sue, but it would have poor access to information about the use of its materials and often poor access to the legal system. HGDP would have better access to both but less incentive to protect the population's rights. Finally, would these contractual clauses actually be enforced? Although the status of DNA as "property" remains unclear, there seems no reason to think that courts would not enforce this kind of contract. The main problem is whether anyone would recognize that a pharmaceutical company had started marketing a product based, at least in part, on research done many years earlier using some HGDP samples? This kind of enforcement problem could be enormous, but it might find a solution in the very structure of the pharmaceutical market. Bringing a drug to market is a very long and extremely expensive proposition, costing in the United States an average of several hundred million dollars. The existence of even a possible claim that such a product breached a contract with HGDP and participating populations might throw such a "cloud on the title" of the pharmaceutical company as to ensure that it would not proceed without negotiations.

Racism

In the nineteenth and early twentieth century, the biological sciences, including the newly born field of genetics, helped legitimize and reinforce racism by providing "scientific proof" of the inferiority of disfavored human groups (75–77). This history, shameful to contemporary geneticists, combines with the continued persistence of racist stereotypes to make genetic research into "racial" or ethnic characteristics still politically and ethically charged (78–80). HGDP risked being caught in these controversies around the genetics of race. Although its organizers denounce the idea that human races have *any* biological or genetic meaning, let alone that one "race" is genetically "superior" or "inferior" (6), the project's very name emphasizes that it is looking for genetic differences — and its research agenda makes it clear that those are differences between human populations. The jump from talking about "populations" to being seen as talking about "races" is short. This issue affected HGDP in at least three different ways.

First, some critics accused HGDP of being itself in the thrall, consciously or not, of nineteenth-century visions of genetically defined races. Its plan to compare the patterns of genetic variation frequencies of different culturally defined human groupings was seen as reflecting

a belief by the project organizers that such "pure" groups, or, in a term used by the project itself initially, population "isolates" really existed (81–84). Critics viewed this as both scientifically naive and socially harmful. Even structuring the project around an examination of these culturally defined populations would, in their view, necessarily bias the results. From this perspective, Allan Wilson's "grid" plan of sampling had great benefits. Second, other commentators pointed out that even if the HGDP organizers held a scientifically correct vision of the limited connection between cultural groups and genetic populations, the public did not (8). HGDP, by even looking at genetic differences between group, would reinforce for the public the ideas that such differences existed and that they were important. Finally, HGDP organizers themselves recognized that, however meritless scientists considered "scientific racism," the project's results could be misused for racist ends. In an event used at the time of the greatest discussion of this point, Bosnian Serbs might seize on some slight genetic variation between themselves, as a group, and Bosnian Muslims, as a group, and claim "scientific" support for ethnic cleansing.

The project's supporters disclaimed any belief in genetically "pure" populations, let alone in genetically defined human races. They countered that, although culturally defined groups were not the same as genetically defined populations, they were often genealogically more closely related to each other than to outsiders. Thus the statistical analysis of patterns of genetic variation between different groups had led to useful results in prior research. Further they called the Wilson grid plan impracticable — after all, which one person would represent the genetic variations found in New York or in San Francisco? And, they urged, because the project's data would all be public, the data could be analyzed by those skeptical about the sampling strategy to detect any bias that might exist. The project's organizers admitted the second and third risks: the unconscious reinforcement of a false concept of "genetic race" in the public mind and the possibility of racist or nationalist misuse of the project's data or findings. To counter those problems, the organizers called both for general education and for "ready response teams" of scientists prepared to refute false claims (1,27). The project's supporters went farther and argued that HGDP's results would make "scientific racism" even more untenable by demonstrating the great genetic similarities among humans. This response drew its own reply, accusing HGDP of exaggerating the effects its findings would have in countering racism (7).

One other claim, at least related to racism, has been advanced against HGDP. Its opponents argue that it did not take indigenous groups seriously and did not include them in its planning. This, it is urged, reflects anything from racism and colonialism (51,52), to a scientific arrogance toward research subjects (7). HGDP's organizers respond that indigenous peoples were not excluded from the project planning and point, among other things, to numerous meetings with indigenous groups and to two Native Americans on the project's North American Committee. It is true, though, that at least in North America, the project decided not to emphasize contacts with indigenous activist groups. Instead, it decided to focus its contacts on people living in native communities, after the project was funded to begin collection and so concrete measures could be discussed. It would, in that way, build connections with the very people whose participation in the project it would seek. And it would avoid encounters with political activist groups, often distant from the Native American communities, whose opposition to the project was viewed as highly likely. Whether this strategy was wise remains unclear, particularly when the funding that would have allowed concrete contacts with local communities — and, the project had hoped, would have provided examples of successful collaborations — did not arrive.

FUTURE OF HGDP

HGDP's future remains unclear. As of early 2000, no funding for substantive work had yet been received from the U.S. federal government. No DNA samples have been collected under the auspices of HGDP except in China and in Southwest Asia, with local funding to those regional committees. Discussions are under way for the creation of general repository for some genetic samples, but no database for the results of analysis of HGDP samples had been created. The project continues to inspire controversy, among some ethicists, some nongovernmental organizations, and some indigenous groups. It also continues to inspire its organizers' hopes. Only time will tell whether it thrives or shrivels.

Whatever happens to HGDP, the future of studies of human genetic variation seems quite clear. The kinds of isolated, individual studies that have been going on for 80 years are continuing and expanding. Perhaps more important, the importance of genetic variation for understanding genetic links to disease is increasingly recognized. Once HGP completes sequencing "the" human genome, two next steps seem obvious: determining the function of the identified genes and understanding the consequences of the variations found in the six billion human genomes. Already NIH has created a resource of 450 DNA samples from ethnically diverse residents of the United States to be used to find SNPs (single nucleotide polymorphisms). This kind of variation is mainly important to provide landmarks in the genome; other examples of human genetic variation will almost certainly be of medical and scientific interest. In the long run, as the studies of genetic variation for nonanthropological reasons get broader, the samples and data that HGDP seeks to gather may appear from other sources.

This kind of future, however, would be a continuation of the past. Unless DNA samples were available for analysis or were analyzed against a standard set of markers, the empty matrix problem that led to the organizers to propose HGDP would continue. And supporters of the project argue that the ethical, legal, and social concerns would be heightened, not diminished, by the end of HGDP. Rather than having a project that insisted on compliance with certain ethical standards, DNA collection and research would continue to be done in hundreds of different laboratories, using many different sets of ethical rules. Opponents, on the other hand, can hope

that communities can more effectively resist many small laboratories than one worldwide "project." And they may believe that an end to HGDP will lead to protections better than those HGDP claimed, unconvincingly to them, to plan to impose. One way or another, the issues will remain as relevant. Whether they would be as visible and as fully debated in the absence of a formal HGDP is, at best, unclear. But, whether it ever is completed or not, HGDP and the controversy around it has at least helped illuminate the complex issues — ethical, legal, social, and political (85,86) — raised when human genetics moves from the individual or family to the population.

ACKNOWLEDGMENT

Professor Greely has been associated with the HGDP since 1993 and chairs the Ethics Subcommittee of the Project's North American Committe. In that role he was the principal author of that Committee's Model Ethical Protocol.

OUTLINE

INTRODUCTION

At least theoretically, medicine has benefited and continues to benefit from the participation of sick or healthy volunteers, in human research. Medical practice and research are inseparable elements of modern medicine. Yet, despite the unprecedented success of

medicine and biotechnology in the second half of the twentieth century, human subjects research remains associated with the atrocities committed by Nazi doctors during World War II (1), the dreadful biological warfare experiments conducted by the Unit 731 of the Imperial Japanese Army (2), not to mention the infamous radiation experiments conducted and/or financed by the U.S. government and by governments of other countries (i.e., UK, Switzerland) at the height of the cold war (3). As Jean Bernard, the first chairman of the French National Ethics Committee, has said "Human experimentation is morally necessary and necessarily immoral." The high hopes and expectations in the constant progress of medicine, as expressed by the growing efficacy and quality of health care, have not overridden the fears of society that human beings could be or are being grossly abused for the sake of science. As noted by Jay Katz in the introduction to his comprehensive case book on human experimentation: "When science takes man as its subjects, tensions arise between two values basic to Western society: freedom of scientific inquiry and protection of individual inviolability" (4, p. 1). The primary goal of the regulation of human experiments is indeed to ensure protection of the rights and welfare of human subjects.

As in many other fields of medical practice today, there is a clear shift toward legal regulation (5). By way of national and international legislation, a growing number of detailed guidelines must be followed by all participants in research activities; this means investigators, sponsors, monitors, ethics review boards, research institutions (hospitals, universities, etc.), local and national authorities. The complex regulatory framework is aimed both at protecting the interests of the persons participating in research and at ensuring the quality of the research's results will meet with general public approval, indeed, that the research is "necessarily moral." Before considering in more depth the basic rules that apply to human subjects research as they are presented in international codes, we will review the nature and scope of current research. It is also important to understand how these rules evolved historically as well as the underlying ethical, professional, and legal issues.

It is against this background that the basic principles of research in human genetics should be examined. Of particular interest is the emergence of international ethical norms governing human genetics in the area of human subjects research in biotechnology (6). Positions and proposals have emanated from international and regional bodies such as the United Nations Education Science and Culture Organization (UNESCO), the World Health Organization (WHO), the Human Genome Organization (HUGO), the Council of Europe (CE), the European Commission (EEC), and the Latin American Human Genome Program (PLAGH). We will limit our discussion to the last decade and demonstrate that in the gradual evolution of ethical norms governing human subjects, the area of human genetics research is witnessing a movement from general principles to more refined and complex approaches, sometimes in contradiction with one another. Moreover, because of the personal, familial, and social nature of genetic information, some controversial areas of application are "gen-ethics," which test the founding ethical principles governing human subjects research. The immediate conclusion to be drawn is that the increasing multiplicity, complexity, and specificity of ethics in human subjects research may well lead to losing sight of the fundamental ethical principles, if not undermine them.

NOTIONS AND TERMINOLOGY

Ties Between Medical Practice and Research

In the now classical essay "Training for Uncertainty," Renée Fox analyzed the process by which medical students learn to cope with their uncertainty which, by and large, remains the main (if not only) certainty in medical knowledge. Indeed, the proportion of medical care which relies on solid scientific or empirical evidence varies from only 10 to 50 percent depending on the authors (7). Three basic types of uncertainty can be identified:

> The first results from incomplete or imperfect mastery of available knowledge. . . . The second depends upon limitations in current medical knowledge. . . . A third source of uncertainty derives from the first two. This consists of difficulty in distinguishing between personal ignorance or ineptitude and the limitations of present medical knowledge (8, p. 20).

The first and third types of uncertainty can be limited by the proper selection, training, and continuing education of physicians, while the second type calls for research and the collection of empirical data. Research appears in the latter sense as a means to limit uncertainty and to acquire new, generalizable knowledge. Paradoxically, newly acquired knowledge is per se a source of uncertainty as it often raises more questions than it answers. The constant quest for new knowledge and the expected progress that should result from it is indeed an intrinsic element of scientific thinking (9).

Without elaborating on this point further, it is important to note that research is the basis of medical knowledge, and it is an activity that should be better promoted to give everyone the chance to benefit from it. Even if the recent history of medical research has been full of scandals and abuses, the positive dimension of research is beginning to be accepted. There has been a dramatic change in the general perception of research especially since the 1980s. The major change came from the AIDS epidemic which caused the gay community to put pressure on the scientific community and the government authorities to funnel research into that area. Feminist groups have also successfully promoted the idea that women should no longer be systematically excluded from research protocols, which formerly biased results. Finally, developing countries have asked to receive more support in research activities that are specific to their needs.

Distinctions Between Medical Practice and Research

In 1974 the U.S. Congress created the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (the Commission). Its primary

task was to establish "the boundaries between biomedical and behavioral research involving human subjects and the accepted and routine practice of medicine" (10). After extensive consideration of the topic, the Commission concluded:

> For the most part, the term "practice" refers to interventions that are designed solely to enhance the well-being of an individual patient or client and that have a reasonable expectation of success. The purpose of medical and behavioral practice is to provide diagnosis, preventive treatment or therapy to particular individuals. By contrast, the term "research" designates an activity designed to test a hypothesis, permit conclusions to be drawn and thereby to develop or contribute to generalizable knowledge (expressed, for example, in theories, principles and statements of relationships). Research is usually described in a formal protocol that sets forth an objective and a set of procedures designed to reach that objective.
>
> When a clinician departs in a significant way from standard or accepted practice, the innovation does not, in and of itself, constitute research. The fact that a procedure is "experimental," in the sense of new, untested or different, does not automatically place it in the category of research. Radically new procedures of this description should, however, be made the object of formal research at an early stage in order to determine whether they are safe and effective. Thus, it is the responsibility of medical practice committees, for example, to insist that a major innovation be incorporated into a formal research project.
>
> Research and practice may be carried on together when research is designed to evaluate the safety and efficacy of therapy. This need not cause any confusion regarding whether or not the activity requires review; the general rule is that if there is any element of research in an activity, that activity should undergo review for the protection of human subjects (11, pp. 2–3).

This characterization of medical practice and research makes three basic distinctions. First, the primary goal of practice is to enhance the health and/or the well-being of an individual patient. By contrast, the investigator's goals include those of the research itself. He or she is somehow a double agent whose two masters are research and practice. Even where one does not behave contrary to the interests of one's subjects, the investigator does not act exclusively in their interests. Levine speaks in this regard, of "practice for the benefits of others" (12) which includes not only research with human subjects but also organ or tissue donation, vaccine programs, and participation in the training of health professionals. Second, the doctor–patient relationship is highly personal in the sense that all the activities of the practitioner should be based exclusively on the specific needs and interests of the patient. By contrast, an investigator must strictly follow the procedures fixed in the research protocol. Third, research should be based, in principle, on a written protocol defining its purpose, goals, and means. This research protocol is essential in assessing scientific validity at every step of the research process. It is necessary not only to guarantee the quality and reliability of the research results but also to protect the human subjects against unnecessary and unpredicted risks and burdens.

Questionable Terminology: Therapeutic Research

In 1984 Taylor and his colleagues published an enlightening study analyzing the reasons physicians tend to avoid including all eligible patients in relevant research (13). Of particular import was their discovery that only 27 percent of participating physicians maximized inclusion. The authors cited the following as the most common reasons for this finding:

> (*1*) concern that the doctor–patient relationship would be affected by a randomized clinical trial (73 percent), (*2*) difficulty with informed consent (38 percent), (*3*) dislike of open discussions involving uncertainty (22 percent), (*4*) perceived conflict between the role of scientist and clinician (18 percent), (*5*) practical difficulties in following procedures (9 percent), and (*6*) feelings of personal responsibility if the treatment were found to be unequal (8 percent) (13, p. 21).

This research points out the uneasiness of doctors acting as investigators to the detriment of their role as healers. If the term "therapeutic research" helps physicians to better accept their ambivalent role, it is a source of confusion for the patients–subjects. Research and therapy are fundamentally different. It is contradictory to speak of "therapeutic research," and this term should be avoided (14). The term is ambiguous as it implies some therapeutic benefits for the research subjects, regardless of the fact that benefits are, by definition, hypothetical. It creates confusion about the exact role of physicians involved in research activities who do not clearly disclose the fact that in the research setting they are not acting as healers but as investigators. By the term "therapeutic research," the physician is inviting the patient to participate in research, and the emphasis is on his or her latter role rather than the former. The patient may not be aware of this fact, that he or she is involved in research and that a valid consent is needed.

Categories of Research with Human Beings

The activities covered by the expression "human subjects research" are in fact very broad. A first distinction can be drawn from the term "human subjects." Does it refer solely to research with persons, meaning a person between the moment of birth and the instant of death or should it be extended to research done on fetuses and embryos as well as on human cadavers? Research with fetuses and embryos is, in principle, treated separately from research with human subjects. In general, vulnerable groups are provided special attention and protection in the regulation of research. This is the case for children, psychiatric patients, and prisoners. Minority members are also subject to specific regulation, not only to protect them from research risks and abuses but also to ensure that they have access to research protocols specific to their needs. In summary, the regulation of human subjects research varies according to the vulnerability of the group of subjects involved as well as the nature and degree of expected risks and discomfort.

Concerning the nature of research risks, a distinction should be made between (*1*) clinical research, namely research done "at the bed side," implying direct contact

between the research subjects and the investigator, (*2*) epidemiological research which is based on medical data usually collected for other purposes than the research itself, and (*3*) research on biological material of human origin. Human subject research usually refers to clinical research and the regulation of research is generally designed to address the specific problems raised by this type of research. Yet there is increasing attention being directed toward the two other types of research. Epidemiological research raises particular problems for the respect of privacy and confidentially. Its regulation is linked to the problem of data protection. It also provides directives on the way to collect and assess the informed consent of the subjects. Research on biological material lies somewhere in the middle, depending on whether the material being used has been collected for research purposes. We will see that the development of gene therapy and the mapping of the human genome feed a growing concern about how to regulate this type of research.

ETHICS, PROFESSIONAL RULES, AND LAW

After World War II, 23 doctors, physicians, and high ranking officials of the Ministry of Health in the Nazi government were brought before an international court founded under the principles of public international law. During this trial, which was held in Nuremberg, ten basic principles to be followed in the conduct of research were enumerated. This became known as the Nuremberg Code. Yet there has remained uncertainty as to the Code's specific nature whether its principles are ethical, legal, or both. The Nuremberg Code is usually presented as the first international code of ethics in the field of research. It has had tremendous influence on the codes and rules that followed especially in the drafting of the Declaration of Helsinki adopted by the World Medical Association in 1964. One question remains unanswered, however, at least for the medical profession. Is it strictly a codification of ethical principles or is it legally binding? Interestingly most lawyers would agree on the legal nature of the Nuremberg Code (15), while physicians would rather consider it an ethical code.

Historically two sets of rules dealing with human research had been promulgated earlier in Germany, and they were, to some extent, more detailed than the Nuremberg Code. They are the 1900 Directives to the Directors of Clinics, Out-Patient Clinics and Other Medical Facilities formulated by the Prussian Ministry of Religious, Educational, and Medical Affairs and the 1931 Guidelines on Innovative Therapy and Scientific Experimentation of the Reich Minister of the Interior. These rules were either simply not applied by doctors or were applied in such a confidential way that they could hardly be considered as the expression of a common practice by the medical profession. The Nuremberg Code was also largely inspired by guidelines published only a few months earlier by the American Medical Association. But while the judges who elaborated the Nuremberg Code felt that they were only codifying or summarizing the common rules of the medical profession, physicians have long refused to admit that this intrusion in the regulation of their research activities had any legal consequences. By coining the Nuremberg Code as an ethical code, they were emphasizing that it had no binding force, and therefore that its application was open to interpretation. Its only binding force was derived from the fact that it was to be considered as the expression of the state of the art by the professionals. From the beginning of modern regulation of human research subjects, rules were confined by the medical profession to the restrictive scope of professional ethics. Such interpretation was necessary, if not indispensable, to maintaining the independence of the researchers from any unwanted intervention by lawyers and the legislature.

We agree with Dr. Leo Alexander when he states: "The Nuremberg Code covers all these contingencies in a much more specific manner than subsequent formulations such as the Helsinki Resolution (sic)" (16, p. 396). In fact the first goal of the Helsinki Declaration was not to protect the freedom and rights of the human subjects but rather to allow the continuation of human experimentation: "Because it is essential that the results of laboratory experiments be applied to human beings to further scientific knowledge and to help suffering humanity, the WMA has prepared the following recommendations. . .." This difference in apprehending the regulation of human subjects research whether it is viewed in a legal or in a medical perspective should be better acknowledged. To a great extent there is a misunderstanding about the fact that when there is no specific legal norm, one should apply the general principles of the law. In short, the absence of statutory laws does not mean the absence of law. This has created the illusion that "ethical codes" were filling a lacunae in the law, while they were only making the regulatory framework for research more complete and precise.

INTERNATIONAL CODES IN THE REGULATION OF HUMAN SUBJECTS RESEARCH

Introduction

The regulation of human subjects research is characterized by myriad national and international rules that can be qualified as ethical, professional, or legal. Two of the most preeminent of these norms have already been mentioned, namely the Nuremberg Code and the Declaration of Helsinki. Concerning the latter, it should be noted that it was revised in 1975 (Tokyo), 1983 (Venice), 1989 (Hong Kong), and 1996 (Somerset West). Other documents of reference at the international level should also be cited: Article 7 of the United Nations Covenant on Civil and Political Rights (1966), the International Guidelines for Biomedical Research Involving Human Subjects first adopted in 1982 and revised in 1993 by the Council for International Organizations of Medical Sciences (CIOMS) in collaboration with WHO. The so-called Belmont Report issued in 1978 by the U.S. National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research should also be mentioned. It defends a conception of bioethics that has greatly influenced modern ethical reasoning and is based on the balancing of four basic ethical principles: the principles of justice,

respect for persons, beneficence, and nonmaleficience. This is only a short list of the existing guidelines (18). There are guidelines that concern specific types of clinical trials, for instance, the Declaration of Madrid adopted in 1996 by the World Psychiatric Association or the various guidelines for good clinical research practice (19) primarily designed for drug trials such as the WHO Guidelines for Good Clinical Practice (GCP) for trials on pharmaceutical products (1995) (17) and the "International Conference on Harmonisation" (ICH) Guideline for Good Clinical Practice (ICH–GCP). Other guidelines have only a regional scope, for instance, the Nordic Guidelines for Good Clinical Trial Practice (1989), or the present draft European Union Directive on Drug Trials (20) as well as the CE Convention on Human Rights and Biomedicine (21), not to mention the numerous national laws and codes of ethics. To complete this broad picture of the regulation of biomedical research, two observations still need to be made: First, these codes and guidelines, such as the Declaration of Helsinki and the CIOMS guidelines, are being regularly revised; second, if some of these codes and guidelines should be considered as mainly ethical and/or professional norms, others, such as most of the GCP guidelines, are more or less statutory rules.

Even if guidelines and laws are very heterogeneous, a consensus emerges from them all on some basic requirements regarding the protection of human research subjects during clinical trials. Among theses, the most commonly identified are the following:

- Review of the research project by a competent ethics review board (ERB)
- Fair selection of the human research subjects (special protection of vulnerable population)
- Free, informed consent of the human research subjects
- Respect for the privacy of the human research subjects and for the confidentiality of clinical data
- Favorable balance of harms and benefits
- Compensation for research-induced injury
- Sound, scientific design of the research based on sufficient data from previous nonclinical and clinical studies
- Qualification and experience of the investigator
- Adequacy of the resources available (time, staff, facilities, finances)

These norms are the core elements of all regulation concerning the protection of human research subjects. To better understand the nature and scope of the aforementioned codes, we propose to analyze them in light of the rules of informed consent and ethical review mechanisms. This will also serve as an occasion to clarify the specific links as well as discrepancies between these codes.

Informed Consent

There are few texts like the 'Nuremberg Code' that express with such strength and precision the principle of informed consent freely given by human subjects. It is worth quoting *in extenso*:

> The voluntary consent of the human subject is absolutely essential. This means that the person involved should have legal capacity to give consent; should be so situated as to be able to exercise free power of choice, without the intervention of any element of force, fraud, deceit, duress, overreaching, or other ulterior form of constraint or coercion; and should have sufficient knowledge and comprehension of the elements of the subject matter involved as to enable him to make an understanding and enlightened decision. This latter element requires that before the acceptance of an affirmative decision by the experimental subject there should be made known to him the nature, duration, and purpose of the experiment; the method and means by which it is to be conducted; all inconveniences and hazards reasonably to be expected; and the effects upon his health or person which may possibly come from his participation in the experiment.
>
> The duty and responsibility for ascertaining the quality of the consent rests upon each individual who initiates, directs, or engages in the experiment. It is a personal duty and responsibility which may not be delegated to another with impunity.

It is interesting to note that the first version of the Declaration of Helsinki, adopted in 1964 by the World Medical Association and claiming a relationship to the 'Nuremberg Code', does not mention the rule of informed consent among its basic principles of research ethics. Furthermore, though it provides that the informed consent of human subjects should be obtained before beginning a study with no direct therapeutic benefit, the Helsinki Declaration only requires that "if at all possible, consistent with patient psychology, the doctor should obtain the patient's freely given consent after the patient has been given a full explanation" (23, p. 473).

This wording seems to admit the possibility of applying the therapeutic privilege in the field of clinical trials. By therapeutic privilege, we mean the physician's ability to withhold some information from a patient based on the rationale that it could be detrimental for the patient. Such an interpretation contradicts the first principle of the 'Nuremberg Code'. It has been partly abandoned in the later versions of the Helsinki Declaration, the 1996 version stating clearly that "in any research on human beings, each potential subject must be adequately informed.... The physician should then obtain the subjects' freely-given informed consent, preferably in writing." Yet a 1999 proposed revision raises some serious concerns as it would allow a waiver of written informed consent if the ethics review board determined that the research risks are slight or if the procedures to be used in the research are customarily used in medical practice without informed consent (24). If adopted, this would represent a step backward for the respect of the principle of free and informed consent of the human research subjects (25).

The respect of the human subject's autonomy, and thus of the principle of informed consent, is also a cornerstone of the CIOMS guidelines. Of particular interest is the fact that the CIOMS guidelines recognize that the Declaration of Helsinki is "the fundamental document in the field of ethics in biomedical research," and a copy

of the 1989 version of this text can be found in their annex. Nevertheless, they differ on several points, in particular, on the requirement of the subject's informed consent. Guideline 8 of the CIOMS guidelines which deals with the question of research involving subjects in developing communities provides that: "every effort will be made to secure the ethical imperative that the consent of individual subjects be informed. . . ." Yet, in the commentary following guideline 8, it states: "For example, when because of communication difficulties investigator cannot make prospective subjects sufficiently aware of the implications of participation to give adequately informed consent, the decision of each prospective subject should be elicited through a reliable intermediary such as trusted community leader. In some cases other mechanisms, approved by an ethical review committee, may be more suitable." Thus, after stressing the need to respect individual informed in accordance with the basic principle I, 9 of the Declaration of Helsinki as amended in 1996, the CIOMS guidelines open the door for a broad exception in case of research conducted in developing countries (26). Which norm should apply in a given situation? Should it be the first principle of the Nuremberg Code, the basic principle I, 9 of the Declaration of Helsinki, and also guideline 1 of the CIOMS guidelines, or on the contrary, guideline 8 of the CIOMS guidelines interpreted in light of its commentary? The situation becomes more complicated by the fact that the CIOMS guidelines do not make explicitly reference to the Declaration of Helsinki. To what extent then should the new amendments of the Declaration of Helsinki be taken into consideration by someone referring to the CIOMS guidelines? Such questions arise for many other codes and guidelines that refer to the Declaration of Helsinki or to the CIOMS guidelines, if not to both (27).

In short, the great variety of rules of conduct concerning the protection of human research subjects at the international level does not always contribute to a better understanding of what ethical rule should finally prevail in a given situation. The need for a more effective coordination of these numerous codes is a growing concern, especially at a time several of them are being revised. The very existence of so many documents of reference raises some questions on their role and objectives. As stated by Jay Katz concerning ethical codes of conduct more than 30 years ago:

> The proliferation of such codes testifies to the difficulty of promulgating a set of rules which do not immediately raise more questions than they answer. By necessity these codes have to be succinctly worded and, being devoid of commentary, their meaning is subject to a variety of interpretations. Moreover, since they generally aspire to ideal practices, they invite judicious and injudicious neglect. Consequently, as long as they remain unelaborated tablets of exhortation, codes will at best have limited usefulness in guiding the daily behavior of investigators (28).

If these codes are still relevant for the diminishing number of countries and regions of the world where there is presently no statutory regulation of clinical trials, there is concern about their effectiveness, especially in view of their built-in contradictions. In the near future, it is foreseeable that the issue will become more a matter of the proper training of all participants in clinical trials, the investigators, members of ethical review boards, and the human subjects. The existing codes could then be regarded more as a source of inspiration than of regulation. The need to frequently revise the codes to meet the demand of the research would be less important than the need to assess that everyone involved in research with human subjects is working according to high ethical standards. The question then would be not so much revising the codes but ensuring that the fundamental ethical principles that underlie them are effectively implemented.

GENETHICS

The continuing drive to greater levels of specificity has led to the proclamation of "gen-ethics," which is quickly moving toward more detailed "gen-policies." Some examples of the latter are the legal status of DNA, DNA banking, patentability, genetic research involving children, and, confidentiality. Before turning to specific "gen-policies," we will review the common interpretation of the ethical principles discussed in the first part of this article within the context of human genetics. Broadly speaking they are autonomy, privacy, justice, equity, and quality, all relating to respect for human dignity (29).

Autonomy

The principle of autonomy has found its most recent expression in UNESCO's 1997 Universal Declaration on the Human Genome and Human Rights. The simple yes–no of participation has moved to include not only the notion of free and informed consent to participation [Article 5(b)] but also the choice to be informed or not of the results [Article 5(c)]. The probabilistic nature of most predictive genetic information (to say nothing of its personal, familial, and social nature) requires that the expression of individual autonomy include this choice. The problem with this new approach, however, is that little is known of how much information must be communicated for this right to be exercised. Would too much information unduly restrict or undermine the "right" not to know, and too little that of a truly informed consent not to know? Another addition to the second requirement of consent is that of requiring a specific consent for the banking of a DNA sample, often collected and conserved in the past without such consent (30). Only newborn screening for treatable disorders constitutes a valid exception to individual informed consent according to WHO (31). Finally, another "new" consent appears in the preamble to the European Directive on the Legal Protection of Biotechnological Inventions (32). The preamble states that a patent application on an invention using human biological material of human origin must be from a person who has had the "opportunity of expressing [a] free and informed consent thereto, in accordance with national law" (para. 26). While laudatory in its transparency, the weakness of this formulation lies in the latter part that refers to national law. This

is because only few national laws have addressed the issue of payment to DNA "donors," although this may be covered by human tissue gift legislation that does not specifically exclude DNA from its mandate. No law specifically requires an explicit consent to eventual commercialization (33). Furthermore it remains to be seen if such consent will be necessary for each possible commercial application (impossible?) or whether a simple notification will suffice and, if so, constitute a preliminary condition of participation.

Privacy

Two genetic-specific interpretations of the principle of privacy merit mention here. The first is the increased emphasis on the confidentiality of genetic information especially as concerns third parties (owners and employers). Article 9 of the UNESCO Declaration maintains that exceptions to the confidentiality of genetic information can only be prescribed by law, thus excluding individual consent. Indeed, this could be because consent to access by insurers and employers is not totally free. Thus WHO has proposed: "Genetic information should not be used as the basis for refusing employment or insurance. Exceptions would have to be legally defined (34). The formulation found in the European Convention on Biomedicine (21) specifying that genetic tests should only be performed for "health purposes" (Article 12), that is, medical indications, is particularly enlightening. Yet, if this information is in the medical record due to participation in research, an individual applying for insurance or employment will certainly have "consented" to access to such confidential information. Hence the importance of keeping participation in genetic research out of the medical record.

Finally, WHO's 1997 Proposed International Guidelines (31) and HUGO's Statement on DNA Sampling: Control and Access (30) make a specific exception for professional disclosure to at-risk family members for serious, treatable, or preventable conditions where the patient or research participant refuses to do so. This issue merits further discussion.

Justice

The principle of justice includes the notion of distributive justice, and in the context of genetics this involves not only living persons (e.g., vulnerable populations) but also future generations. Both the inclusion and protection of vulnerable populations in genetic research is reinforced through the requirement of a legal authorisation by a third party and a direct benefit to the incompetent person or, in the absence of the latter, only research of minimal risk Article 17 (2)(ii) (22). Ironically, this protection, while necessary, may inadvertently create indirect discrimination on economic grounds. This is because only those with the legal foresight and financial wherewithal to provide in advance for such a legal mandate specific to research can be included. Thus a competent person would have to undertake the legal procedures to name a future legal representative with a mandate specifically for participation in research. It goes without saying that in the absence of this advance mandate, it is very difficult (emotionally and financially) for family members to deliberately have an incompetent family member legally declared incompetent so that person can benefit from participation in research!

As for the interests of future generations, Article 24 of the UNESCO Declaration mentions that germ-line therapy, which could irrevocably affect future generations "could be contrary to human dignity" (35). This addition was only added in July 1997 when the government representatives met to approve the Declaration prepared by the IBC. The Declaration of Manzanillo would not grant legal representatives the power to authorise interventions in the human genome but would entrust such decisions to a neutral body (Principle 6(e)).

In contrast, neither the 1997 Proposed International Guidelines of the WHO nor its 1999 Draft Guidelines on Bioethics refers to germ-line therapy. As mentioned, the Declaration of Manzanillo (1996) would establish a "neutral" multidisciplinary authorizing body to consider such requests (Principle 6 (d)) (37). This is a subject that should be at the forefront of public debate, or as was the case with cloning, legislation will be inadequate (due to hasty preparation), too comprehensive, or unduly restrictive.

Equity of Access

Both the Declaration of Manzanillo and the WHO Proposed International Guidelines stress the need to respect equity of access to services, that is, access according to need and not economic means. Closely related to the principle of justice, this principle could also serve as the ethical underpinning for the concept of benefit-sharing first found in HUGO's statement on the Principled Conduct of Genetic Research (33). Likewise the 1997 Proposed International Guidelines by WHO maintain that if genetic knowledge leads to the development of "a diagnostic test or new therapies, equity requires that the donors, or the community generally, should receive some benefit" (31). Finally, while not specifically mentioning the principle of equity or access to genetic research or testing, UNESCO's Universal Declaration does provide in Article 12 that the "benefits" of advances in biology, genetics and medicine should be available to all (35).

Quality Control

Building on the principle of "basic science" of the Helsinki Declaration (25), the emergence of the notion of competence and quality control as a prerequisite for permitting research in a given area is a welcome development. Both HUGO in its 1996 Statement on the Principled Conduct of Genetic Research and WHO's 1997 Proposed International Guidelines see the provision of quality control through accreditation and surveillance of laboratory services. Requiring a medical indication for access would also serve to limit the number of tests being offered or advertised by those not trained in the all-important communications or counseling areas. With the advent of predictive testing, counseling takes on extraordinary importance. Still missing, however (and this is not unique to genetics research) are the quality control

aspects (e.g., monitoring/surveillance), once a protocol has been approved.

In short, the translation of general ethical principles governing human research to human genetics has led not only to their further refinement but, at least as a leitmotiv, to their amplification. Indeed, in the area of consent, the emergence of the right not to know, of the need to obtain consent for DNA banking, and perhaps to patenting, if not at least to eventual commercialization, are welcome developments. The principle of the privacy of one's genetic makeup while reinforced as concerns employers and insurers is nevertheless severely tested by the legitimate needs of at-risk family members. In contrast, overprotection of incompetent research subjects in the requirement of a legally recognized representative for research purposes may discriminate against certain families and those with late-onset genetic conditions. Finally, the last two principles, of equity and quality, merit further definition in the context of genetic research. It would be salutary, to say the least, if it was the fear of abuse of testing and misuse of genetic information that has led to the further development of guidelines in this area, since quality control and ongoing surveillance and monitoring are problems endemic to all research.

GEN-POLICIES

The specific translation of ethical principles into gen-ethics further contextualizes into policies concerning issues, such as, the DNA banking, patenting, research involving children, and confidentality. At this more specific domestic level, the interpretation of gen-ethics is less harmonious. Diversity is a cultural and political fact, and it raises problems for multicentered, international trials.

Status

The issue of the status of human genetic material has both ethical and legal significance. Ethics are involved because status distinguishes the human "source" from other elements of the body or products used in research. This is especially evident in the "common" or "collective" characterization at the level of the whole human genome and that of "familial" even at the level of the individual. The law is involved because of the classical division between persons and things (37).

The characterization as "common heritage" at the collective level can influence the treatment of human genetic material in international trade and patenting disputes. The characterization as "familial" can serve to sensitize researchers and research participants to the familial implications of genetic testing. Such distinctions form the underpinning for the construction of an ethical framework that is not solely individualistic in nature, although the choice to participate in research or to be tested must necessarily remain so.

DNA Banking

Nowhere has respect for individual choice based on personal values blossomed more than in the options offered in the context of DNA banking. From the blanket yes or no of a decade ago, participants are now not only offered the choice to be part of disease-specific or more extensive research collaboration, to have their DNA anonymized or destroyed, or to set limits on length of storage, but are also warned of socioeconomic risks (e.g., employment/insurance), possible stigmatization, and commercialization. It is interesting that regardless of the status of the human genetic material (property or person), the same choices are offered.

Theoretically any person with a property right, as proposed in the model Genetic Privacy Act of the United States, must either renounce future financial interests or claim a benefit. Absent an extremely rare genotype, the latter approach would not be practical. The time it takes for a discovery, an invention, and possible profits usually spans a decade and involves thousands of participants in different countries. Only recently has there been any move to simplify and standardize DNA banking choices (38). More interesting is the suggestion (albeit with some dissent) by the National Bioethics Advisory Commission of the United States to allow participants to agree to other future research without further specification (39). This recommendation does not require anonymization as a condition of such an open-ended choice. Last, the international Ethics Committee of HUGO has proposed notification for the anonymous use of genetic material removed as part of routine care (30). This evolution is significant in that the "reification" and "sacralization" extremes in DNA banking policies seem now to have reached a compromise that respects individual choice but does not accord a higher status to DNA than to the person.

Patenting

UNESCO's Universal Declaration on the Human Genome and Human Rights epitomizes both the ethical and legal positions concerning the trend toward the commercialization of genetic research around the world. Article 4 maintains that "the human genome in its natural state shall not give rise to financial gains" (35). While genetic material in its natural state cannot be bought or sold, this should not be confused with the issue of patentability. As the 1998 European Directive on the Legal Protection of Biotechnological Inventions stated (Article 5):

> 1. The human body, at the various stages of its formation and development, and the simple discovery of one of its elements, including the sequence or partial sequence of a gene, cannot constitute patentable inventions (32).

Nevertheless,

> 2. An element isolated from the human body or otherwise produced by means of a technical process, including the sequence or partial sequence of a gene, may constitute a patentable invention, even if the structure of that element is identical to that of a natural element (33).

This ruling is buttressed by two international instruments that bear mentioning. Both the General Agreement on Tariffs and Trade (GATT) agreement and the North American Free Trade Agreement (NAFTA) include the

ethical filter of excluding inventions whose commercial exploitation would be contrary to public policy, a criterion also found in the European Patent Convention of 1973 (40).

Nevertheless, despite both the potential of this ethical filter and the clarification provided by the European Directive, it was not until 1999 that the U.S. Patent and Trademark Office stated that applicants should "explicitly identify a specific and substantial utility." Therefore, for genes and gene products, there is a need "to specify an immediate and identifiable benefit to the public" (41). Such clarification is necessary because patent applications on sequences and on genes have been seriously hampering research and possible therapeutic applications (33).

Genetic Research Involving Children

The earlier discussion of the principles governing the inclusion of vulnerable populations, such as, incompetent adults, raised the issue of potential discrimination by automatic exclusion in the absence of a "legally" appointed representative. When guidelines do not differentiate between incompetent adults and children, the same issue of possible exclusion occurs with children. In the majority of legislation or policy statements, the parents are legal guardians by law. Thus, while the potential inclusion of children is possible (and may even lead to overparticipation), provided their best interests are served by parental authorization, the door is not completely open. Indeed, not only the best interest criterion but also the notions of benefit and risk come into play.

As concerns benefit, the requirement is that in principle, some therapeutic benefit must be expected as well as a favorable risks–benefit ratio. Even in the absence of direct benefit, when the results are "capable of conferring benefit to other persons in the same age category or afflicted with the same disease or disorder or having the same condition ... [and] entails only minimal risk and minimal burden" [Article 17(2)] (21), the research may proceed. This is important in that many genetic conditions are specific to childhood (43) and the automatic exclusion from research would seriously harm both affected children and those potentially at risk. Indeed, overprotection (43), while an understandable reaction to the abuses of the past or even as a precautionary measure when faced with "genetic" unknowns, is becoming a major ethical issue. That being said, there are specific limitations on the genetic testing of children in the absence of available treatment or prevention. These limitations include no testing for the benefit of other family members or for carrier status, nor for late-onset, susceptibility, or predictive purposes.

These restrictions, however, imply the availability of a test, whereas most research aims to find a gene that is either a cause or a determinant among other factors. Thus, in theory, the restrictions above would apply in the situation where DNA is taken with a view toward developing tests that situate the issue within the wider realm of the legitimacy of genetic testing for carrier status or prediction, in general, and where there is no therapeutic potential (prevention, reproductive information, or treatment). It is here that anonymity (removal of all identifiers with some clinical and demographic information remaining) of DNA samples taken in research involving children might best serve their interests and still respect the above-mentioned principles. Samples that cannot be traced can still serve the pediatric community writ large. When the child reaches maturity/majority and treatment becomes available or even reproductive genetic information, the choice to be tested will be an autonomous and informed one.

Confidentiality

Equally sacrosanct to the principle of consent is that of confidentiality. The principle of confidentiality has acquired greater importance in human genetics where the risk of socioeconomic discrimination and stigmatization could take hold. Yet genetic information is at once personal, familial, and social. This raises two further thorny issues: the protection of genetic information in the research setting and disclosure to at-risk family members. The first remains to be settled, and the second is slowly emerging into a consensus.

Currently the protection of genetic information in the research setting is no different from other research findings. When relevant to treatment or prevention, genetic information is placed in the medical record. But in the absence of such medical significance, patient consent is sought for inclusion in the medical record. Indeed, because of the sensitivity of genetic information, most research records are kept under secure conditions. Increased legislative protection of medical records is needed before this practice will change. Any eventual "normalization" of genetic information as medical information depends on such legislative protection. As genetics is integrated more into mainstream medicine, it may well force this issue of medical confidentiality (45).

On disclosure to family members in the situation where an at-risk family member refuses to warn another member, there has been some international agreement about the ethical obligations, although the law is not clear. Drawing on the notions of genetic material or information as familial, on the obligation to rescue, on professional ethics, or on a legal basis for disclosure, the consensus can be summarized as follows: (*1*) if the patient has repeatedly refused to warn an at-risk identifiable family member, (*2*) if that member is at high probability of a serious disorder, and (*3*) if the disorder in question can be prevented or treated, the physician could ethically breach confidentiality but is not legally obliged. At a minimum, however, such disclosure could be considered a legal privilege or a defense to an accusation of breach of confidentiality (45). It goes without saying that the normalization of genetic conditions and information may well solve this serious dilemma of breaching medical confidentiality and allow families to be less stigmatized and more open.

CONCLUSION

The 1997 Universal Declaration on the Human Genome and Human Rights maintains in Article 12(b) that "Freedom of research, which is necessary for the progress

of knowledge, is part of freedom of thought. . . ." (35). There is no doubt that freedom is fundamental to progress and it should be protected and promoted even in a controversial area like human genetics. Still the therapeutic and intellectual benefits of research are challenged by the ethical principles put in place to ensure that voluntary participation is kept in balance with risk–benefit ratios. The major issue of today might well be not that of adding more "rules" but rather constructing the processes and structures that allow us to remember and to realize the basic principles in the first place. The ethical principles should hold true (whatever their translation into more specific policies) in all scientific domains. Like basic legal principles, the ethical foundations of research have survived the test of time. The procedures in place for the implementation of ethical principles must be developed and observed in this time of rapid scientific upheaval.

HUMAN SUBJECTS RESEARCH, ETHICS, AND RESEARCH ON CHILDREN

LORETTA M. KOPELMAN
Brody School of Medicine at East Carolina University
Greenville, North Carolina

OUTLINE

INTRODUCTION

Research with children as subjects can help them individually and collectively. Those who participate can benefit through access to programs or treatments otherwise unavailable to them. In addition research can be socially useful to gain better information about children's diagnoses, therapies, and prognoses. Without research with children as subjects, science cannot address children's unique needs, conditions, or reactions. Doctors may be reluctant to prescribe therapies tested only on adults for children, and insurance companies may refuse to pay for their use because safety and efficacy has not been shown for children. Insufficient information can result in undertreatment of children's conditions or unexpected adverse drug reactions.

What should be done, however, when it is socially useful to conduct a study that will provide extremely worthwhile information, yet some of the children will not be helped and might even be harmed? Should we say that a child's well-being always takes precedent, even if the harm to the child represents only a slight inconvenience, and the information to be gained is urgently needed? On the other hand, what risks are too great to be tolerated, and how should we assess and balance potential harms and benefits? For example, some genetic research involves screening people for certain conditions by taking a small blood sample. While this carries almost no physical risk, a variety of psychosocial harms could befall the participants. Testing may reveal many things people would prefer to remain unknown. They may find that the person's biological father is not the person everyone supposes or detect diseases that are likely to occur later in life. People may find that they are likely to get a late-onset disease like Huntington's disease, schizophrenia, breast cancer, Alzheimer's disease, and so on, and their lives will be changed forever by the test results. Even though they are entirely healthy and can do nothing to prevent the disease, a positive test for one of these late-onset diseases may expose them to prejudice and discrimination. They may be stigmatized, finding people unwilling to marry them, give them jobs, or insure them. Who should decide when children should participate in these or other studies and what standards should be used to base these decisions?

CHANGING ATTITUDES ABOUT RESEARCH PARTICIPATION

Until recently, research was regarded as a dangerous activity and certain vulnerable groups, especially children, were often excluded from studies for their protection. Because children were kept out of studies, however, they often could not obtain untested or experimental therapies, or investigational new drugs (INDs). Such restrictions were criticized as unfair for unjustly excluding some groups from receiving needed care and treatment. For example, regulatory obstacles including federal and state rules restricted the use of untested drugs such as AZT on children with AIDS until some of the rules were changed. However well meaning, these protective measures kept many children with AIDS from getting the only drug that could help them (1). In some cases people's best chance for good medical care is through participation in trials and access to these INDs.

Another issue of justice arose from the practice of automatically excluding certain groups, such as women and children, in order to make the subject population homogeneous. Investigators sometimes restricted those whom they allowed in studies to make it easier to analyze results. People of different ages, races, ethnic groups, or genders sometimes react to interventions differently because of their unique cultural, biological, or behavioral variations. The more homogeneous the subjects, the easier it is for investigators to analyze findings. It also helps hold down costs because studies with similar people require fewer subjects. This practice, however, made it difficult to generalize the findings of studies to other groups. For example, test results of drugs used to treat depression on white, middle-class men might not apply to other groups, especially children, because the causes of depression vary.

While children and adults often have the same diseases, if studies are not done with children, it is uncertain if the results apply to them. Yet they are often treated with the same drugs. The American Academy of Pediatrics concluded that only a small number of drugs and interventions used on both adults and children have had clinical trials performed on pediatric populations. Moreover a majority of drugs on the market have not even been labeled for pediatric populations (2). The National Institutes of Health (NIH) found that 10 to 20 percent of research inappropriately excluded pediatric populations (3). Insufficient information about products can result in undertreatment of children's conditions and adverse drug reactions, because clinicians must choose between prescribing drugs that do not have good information about safety and efficacy, or using therapies that are potentially less effective. Careful studies show that drugs commonly used among adults sometimes harm children, and this could not be discovered until testing was done on this population. For example, Chloramphenicol, a common antibiotic, caused many deaths in neonates because their immature livers were unable to tolerate it (4). Including children in research, then, may provide opportunities for the individual child, as well as benefits for children as a group.

In recent years, federal agencies tried to address problems of inappropriate "protection" and inadequate testing of pediatric drugs and interventions. The NIH adopted a policy that "children (i.e., individuals under age 21) must be included in all human-subjects research, conducted or supported by the NIH, unless there are scientific and ethical reasons not to include them. This policy applies to all NIH conducted or supported research involving human subjects. . ." (3, p. 2). Justification for excluding children from the research would be that the topic is irrelevant to children's health and well-being, that legal or regulatory restrictions exist prohibiting the inclusion of children, that information about them is already available, or that a separate study for children would be inappropriate due to the rarity of the condition in this population, the few number of the children who would be affected, or because there is insufficient data to include them.

In addition the Food and Drug Administration (FDA) (5) now requires drug manufacturers to develop information to help provide better care and treatment of children, especially data regarding the most frequently used pediatric drugs. Like the NIH, the FDA requires manufacturers to test interventions on pediatric populations unless they show that the research would be unlikely to be useful to the treatment of children in any great numbers, or that including children in studies would be impractical, unsafe, unlikely to be unsuccessful, or otherwise unreasonable.

MORAL ASSUMPTIONS

In discussing what sort of research should be permitted using children as subjects, several assumptions are generally made (5). First, competent adults have responsibilities to ensure that children are not abused, neglected, exploited, or denied access to basic care. Second, different policy solutions regarding children should be evaluated in terms of their adherence to primary moral values. Among the most important of these are beneficence (what will benefit children), social utility (what will fulfill some social good), and justice (what is fair). Policies are judged superior when they are likely to benefit children and ensure that they are not exploited. Good standards fairly promote children's interests, well-being, and opportunities to flourish, as well as help children to develop their potential to become empowered and self-fulfilled. Promoting children's well-being and helping them develop their potential as self-determined individuals demonstrates a concern for their welfare and a willingness to address inequalities of the "natural lottery" (the inequalities caused by nature such as the inherited intelligence or diseases) and "social lottery" (the inequalities caused by social factors such as environment or illness that also affect intelligence and abilities).

To introduce the complexity of the moral issues and disputes about children's research, consider two examples. In each, important values must be ranked in order to assess what ought to be done. These values include the importance of pursuing knowledge, respecting people's rights, protecting minors' well-being, and conducting socially needed research.

Case 1

Dr. D, an endocrinologist, first met Martin two years ago as a happy-go-lucky 6-year-old when his concerned parents brought him to Dr. D's office. Martin was extremely short for his age, in the lower 2 percent for height, with a projected adult height of 5 feet 3 inches. The doctor concluded this is a normal genetic consequence of the boy's parents' short stature. They wanted their son to escape the discrimination they had suffered and sought to get growth hormone therapy for him. They were disappointed to learn they could not afford the $20,000 a year or more for up to 10 years that it would cost for this intervention. They had no insurance to cover such matters. Dr. D told them about a double-blind placebo controlled study at the NIH. In this study all the children receive injections three times a week until they reach their full height, perhaps 10 years later. Half the children get the growth hormone, but half get only a placebo (salt-water) injection, resulting in approximately 1000 injections over the years. The children are brought to NIH each year with expenses paid for, and have physical and psychological examinations, nude photographs, and X rays. Martin's parents enrolled him in the study because he has a 50 percent chance of getting the growth hormone. Two years later they return sad and frustrated because Martin, who hates the injections, is still in the lower 2 percent for height and has undergone no growth spurt. The study is underway to test the theory that the children getting the growth hormone will be taller as adults. While clinicians did not know if final growth is affected, they do know if someone has not had a growth spurt, it is unlikely he is getting the growth hormone. Dr. D suspects if he tells the parents this, they will remove Martin from the study. What should Dr. D say when the parents ask if Martin's lack of a growth spurt means he is probably not getting growth hormone but is in the control group getting injections of salt solution?

This case raises issues about the sometimes divided loyalties of clinicians toward the patients in studies, and about how they balance gaining information by supporting the study and acting in the best interest of the subject. The child, although short, was perfectly happy initially but is now sad perhaps because he thinks he needs treatments for his shortness. Having the opportunity to be in the study has arguably harmed him by making him feel there is something wrong with him that needs to be "fixed" by medicine. The general problem is whether doctors' obligations to their patients change when they are enrolled as subjects in research studies. If the physician's first duty is to act in the patient's best interest, and to be truthful, then perhaps Dr. D. should tell the parents that he does not believe that their son is getting the growth hormone because he has had no growth spurt. He knows that if many subjects withdraw from the study this could cause problems for the investigators and even undermine the study.

Case 2

Dr. M is a pediatrician who's taking care of Barbara, a healthy 12-year-old. Her paternal grandfather died of Huntington's disease after a long and debilitating illness where he became increasingly demented and unable to control himself. Barbara, who was horrified by her grandfather's decline, tells her parents she wants to enroll in a research project in which they test people who may get this inherited condition. She longs to know if she is free of this genetic condition and "like everyone else" or has to plan her life to do things she wants before she reaches middle age. Her father does not want to be tested, although he understands that if his daughter has a genetic predisposition for Huntington's disease, then he does as well. He agrees to her being tested because it is important to her but prefers not to know the test results. While she and her parents agree that she should be tested, her pediatrician, Dr. M, and the genetic counselors strongly object to testing her or recommending her as a research subject for this study. They cite policies barring minors from testing for late-onset genetic conditions (6) and have effectively opposed the investigators who would like to include minors in their study. The clinicians oppose late-onset testing and research with minors because they argue that if children test positively for diseases such as Huntington's, they may feel differently about themselves, suppose they are already sick when they are not, find it harder to get jobs or health insurance, and face other psychosocial risks of harm. Should restrictions be placed on parental authority to assess what is in their child's best interest and to give consent for their child to be tested or participate in studies?

The case raises concerns about parental consent, minor's assent, and genetic testing and screening. Especially difficult to assess are the harms and benefits of testing for diseases that will appear many years later. Who should decide whether testing should be done for these "late-onset" conditions? Are some studies too risky to permit minors to participate, even if the parents consent? Many adults handle information of late-onset disease badly, and this could cause children even more harm. Who should assess the potential benefits and psychosocial harms such as loss of self-esteem, bias, prejudice, and discrimination in employment or insurance? While many policies bar minors from testing for late-onset disease, some parents object to such interference with their authority to decide what is best for the children. Should late-onset disease testing be prohibited on minors, or left to the judgment of parents about whether it is in her best interest to get this testing? In addition, what role should older children have in making decisions? In case 2, the parents and the 12-year-old wish to have the child participate in research, but the clinicians strongly object. If the minor is 17 or on the threshold of full civil rights, her views might carry more weight. As children get older their views gain increasing moral importance.

The transition from dependence to independence is gradual in childhood. Infants should be fully protected, while well-adjusted minors on the verge of majority have a justified claim to understand and express themselves in actions affecting their lives. As children become older and can comprehend more, they should participate in important decisions about their lives, including whether they will serve as research subjects. The problem of whether to include children in decision making becomes acute when children are neither clearly incompetent nor clearly as competent as most adults. For this reason the children's assent is sought as they mature.

As with competent people, the ethical basis for research policy with persons lacking capacity to give informed consent concerns promoting their self-determination, fair treatment, and well-being. The difference is that children cannot be expected to promote their own self-interests. Consequently we have to consider when others, usually parents, will be permitted to consent to have their children participate in research.

CONSENSUS ON INFORMED CONSENT

The right to consent for treatment or research is a civil right, and people must achieve a certain degree of maturity before they gain it. As a matter of administrative convenience an arbitrary age such as 18 is selected as the time when a person is assumed to be sufficiently mature to be granted full civil rights. Until minors reach the age of majority, adults generally have legal authority to make decisions for them. Guardians have this authority because they are usually best suited to protect, identify, and act in children's best interest, and foster development to the point at which children can take responsibility for themselves. Yet guardians do not have an unqualified right to control their children's destiny, and their approval of research projects is insufficient to include minors in research.

A moral, legal, and medical consensus now exists that the competent, free and informed choices of adults must generally be followed in devising treatment plans or enrolling them or their children as research subjects (7,8). Ideally, people who are patients getting standard or experimental care share decision making with physicians as part of an ongoing process, where doctors clarify options and make recommendations. When the subject or patient is a minor, their parental consent is sought. Yet parental views do not carry the same weight when the consent is

given for dependents and the professionals believe that the choice for a minor are abusive or neglectful.

There is a moral, legal, clinical, and regulatory consensus about how to understand the meaning of informed consent. To give informed consent, persons must (*1*) have had disclosed to them all information material to the decision, (*2*) understand or comprehend the information disclosed, (*3*) act or agree voluntarily, (*4*) be competent to act or make the decision, and (*5*) authorize or consent to the procedure, act, or intervention (9). Overcoming this presumptive duty to gain informed consent may be accomplished by demonstrating that the study or treatment constitutes a well-established exception to the duty to gain consent. Incompetent patients cannot give informed consent, so this is a well-established exception. Other morally and legally valid exceptions include medical emergencies, public health emergencies, and patient's waiver of consent (8).

Unlike competent adults who can generally decide what constitutes their own best interest, children need others to protect them. For this reason children are not authorized to decide if they will participate in research. Children are vulnerable subjects. Potential research subjects are called "vulnerable" if they lack capacity to give informed consent or are likely to be coerced or manipulated to participate. Children and those severely impaired by mental illness or retardation are typically regarded as vulnerable because they lack capacity to give informed consent. (Others such as institutionalized subjects, prisoners, the poor, those desperately ill, members of the military, students, hospital staff, and laboratory assistants may be called vulnerable because, while able to give informed consent, they are vulnerable to coercion or manipulation.) The informed participation of vulnerable subjects is problematic, and enrolling them in research protocols often requires special justification or safeguards.

FOUR DIFFERENT POLICY INITIATIVES

There are several important research policy options offering different approaches to balancing what is fair, most protective of incompetent people's well-being, and most respectful of whatever self-determination they have or may develop (5,10). These four policies represent different regulative ideals because they balance these primary values differently and because they offer different authority principles (stating who decides) and guidance principles (substantive directions about how decisions should be made). The remaining discussion will be focused on these options.

Let Surrogates Decide Using Their Own Values

One policy allows guardians to give consent for children under their care as they do for themselves, without any additional restrictions. If they can consent for themselves to take part in a research program testing for late-onset genetic diseases (see case 2 in the discussion above), then, according to this policy, they should be able to authorize this for their children. Guardians are typically knowledgeable and concerned, defenders argue, and society should intrude as little as possible into the privacy of family life. Since guardians have the authority to make such life-shaping choices as to their child's religion and schooling, then, according to this view, guardians should also determine whether or not their child should participate in research.

Early in the twentieth century, it was assumed that guardians had almost unqualified rights to control their children's futures until adulthood unless they were emancipated through military service, marriage, or independence (11). One reason for this policy was that minors were judged incompetent to make rational decisions, so complete adult direction was regarded as necessary to help them develop their potential. Parents, usually the father, had this right. No consideration in the courts was given to minors' emergent rationality, hopes, or plans. Their views were not material to a decision, unless they were emancipated. It was considered unnecessary and irrelevant to find out, for example, how the child wanted to be treated (12).

In addition, minors were thought to virtually belong to their guardians until they reached the age of 21 (11). When there were disagreements about the treatment or placement of a child and the dispute went to the courts, the courts' role would be to decide who "owned" the child, since that person had authority to make decisions. It was a great tragedy if the guardian was abusive or neglectful, and as a result a child died or was maimed for life, but the courts took the view that the decision maker, usually the parents, had a right to decide (12). The attitude was that competent persons had a right to make even an unfortunate decision for themselves and their wards, and there was little to be done beyond trying to persuade them to act otherwise.

Critics began to challenge this position in the late nineteenth century, when a major legal and social shift occurred and as children's interests were increasingly considered when choices were made about them. They were granted entitlements to be protected from abusive or neglect as well as liberties independent of their parents. More recently this included setting research policy restricting when children could participate in studies, even if parents wanted them to be in the research. In addition the child's assent was sought as a precondition of research participation.

Guardians now have authority insofar as they promote the well-being of those under their care, and prevent, remove or minimize harms to them. Volunteering to put oneself in harm's way to gain knowledge may be morally admirable. Volunteering to put another in harm's way is not admirable, and may violate the guardian's protective role. Consequently this first policy option — to let parents decide as they would for themselves — is rarely defended today. Its echoes, however, may be heard in case 2, discussed above, where parents resent state restrictions on research with minors.

Nuremberg: Require Consent for All Research

Another policy requires consent from competent persons to enroll them as research subjects. This view is found in the first written international research code, the Nuremberg code (13). Composed at the end of World War II, the

Nuremberg code stands as a international response to the horrible, involuntary medical studies done by the Nazis in which many people, including children, were killed or permanently maimed. The Nuremberg code states: "The voluntary consent of the human subject is absolutely essential." It goes on to define consent in a way that has become fairly standard, as requiring legal capacity, free choice, and understanding of "the nature, duration, and purpose of the experiment; the methods and means by which it is conducted; all inconveniences and hazards reasonably to be expected; any effects upon his health or person which may possibly come from participation in the research" (13, pp. 181–182).

The Nuremberg code was a response to invasive, harmful and sometimes-deadly studies done on unwilling subjects. If taken as a general code for research (and it may not have been intended as such), this policy excludes subjects who lack capacity to give informed consent. The reason sometimes given for adopting this policy is that it violates people's rights of self-determination to use them in research if they cannot give consent for themselves to participate.

One difficulty with this policy is that research for children and other people who cannot give consent will stop and, consequently, so will advances in their care. Children have unique medical problems, and the results from studies with adult subjects may be inapplicable to children. Adults cannot be used to test the safety and efficacy of drugs for childhood schizophrenia, or for premature infants with respiratory distress and infections. To test the safety and efficacy of many standard, innovative, or investigational treatments for distinctive groups, some members of the groups have to be subjects.

The initial justification for excluding persons who lack capacity to give informed consent for research is to honor their rights and protect their welfare. This restriction, however, may prohibit studies that benefit children. Some are denied access to projects or investigational therapies that could help them as well. All children are denied good information about their conditions because there are no results applicable to pediatric populations. Thus it may not promote their welfare, individually or collectively, to forbid their participation. In addition participation in controlled research does not always violate the rights of persons who lack capacity to give informed consent. By excluding persons who are unable to give consent from relatively safe studies that advance knowledge or provide therapeutic benefit, children's needs and opportunities are not given full consideration. This policy would exclude all children from being enrolled in any research, however low the risk of harm. Naturally it would disallow studies outlined in each of the two cases mentioned earlier. More troubling is that it would not permit even safe therapeutic studies. A dying child could not, for example, obtain an experimental drug that might save her life.

Helsinki: Only Therapeutic Research Without Subject's Consent

A third policy option holds that persons who lack the capacity to give informed consent may be enrolled only in therapeutic studies. This view is represented in the next major international code for research to follow the Nuremberg code, the World Medical Association's Declaration of Helsinki. It states: "In the case of legal incompetence, informed consent should be obtained from the legal guardian in accordance with national legislation" (14, p. I, 11). The incompetent person must agree as well, when able to do so. It allows research with incompetent people, but "...only to the extent that medical research is justified by its potential diagnostic or therapeutic value for the patient" (14, p. II, 6). If, however, the medical research is nontherapeutic, then: "The subjects should be volunteers — either healthy persons or patients for whom the experimental design is not related to the patient's illness" (14, p. III, 2). People who cannot volunteer therefore cannot be subjects in nontherapeutic studies.

This policy option distinguishes clinical or therapeutic research (studies seeking generalizable knowledge but intending to provide medically acceptable therapy for the individual) from nontherapeutic biomedical research (studies seeking generalizable knowledge but not intended as therapy to benefit the individual directly). Therapy is designed to benefit the person, so drawing the line at therapeutic research for people who lack the capacity to give informed consent might seem a good solution.

This approach has difficulties. First, classifying research as either therapeutic or nontherapeutic may be misleading and arbitrary. Studies often have features that are not routine therapy such as extra procedures, tests, or visits to the doctor. Second, important medical research may hold out benefits other than therapy to subjects. Small children who are not patients may enjoy participating in studies where they are asked to do such things as stack similar blocks or identify animals from sounds that they made. Older children might, for example, enjoy an outing to a research facility or find the study interesting in itself.

The Helsinki policy, however, forbids nontherapeutic studies, even though some are important and safe. For example, it is very important to learn if children are developmentally delayed. But to determine this, investigators need to establish a normal range against which to compare results. This standard is obtained by collecting data from many children about their height, weight, vision, hearing, and so on. These children are not sick, so the studies cannot be regarded as therapeutic, and therefore on this policy cannot be permitted even if they are extremely important and safe.

Third, the distinction between therapeutic and nontherapeutic studies focuses on direct benefits to the individual. Yet nontherapeutic studies may indirectly benefit persons unable to give consent. When these studies obtain valuable information about them as a group, and involve little or no risk, it seems problematic to prohibit them. As we indicated, standards of typical growth and development help all children yet require testing on large numbers of normal children to generate data that help distinguish developmental delays or impairments in children from normal growth and development. If children ride tricycles, it is not research; if investigators observe when and how they do it to make generalizations about children, it is research that may not be burdensome to the child.

The Helsinki policy is controversial then because it excludes many important, low-risk studies. It also excludes, of course, the research studies suggested in two cases discussed above. In case 1 the child is normal, not sick, so this is not a therapeutic study; in case 2 no therapy is planned.

The initial justification for excluding persons who lack the capacity to give informed consent from nontherapeutic research was to honor their rights and protect their welfare. Safe, nontherapeutic research, however, seems neither unfair, nor a violation of the rights or welfare of people who lack the capacity to give consent. Failing to do safe, but important, studies might be unfair and violate their rights and welfare, since it fails to consider all their needs. Thus, when nontherapeutic studies are not potentially harmful or inconvenient and when the subjects want to participate, it is not clear that their rights and welfare are always violated or that they are treated unfairly.

U.S. Rules, CIOMS and Other Guidelines: Assess the Ratio of Likely Harms to Benefits

A fourth approach allows research with incompetent persons if it holds out benefit or does not place them at unwarranted risk of harm, discomfort, or inconvenience. To try to balance the social utility of research with respect and protection of incompetent people, this option stipulates that the greater the risk, the more rigorous and elaborate are the procedural protection and consent requirements. The U.S. federal government (15, §46.404–7) reflects this policy option in its codes for research, involving children as well as adults. The Council of International Organizations of Medical Science (CIOMS) (16) and health policy groups in other countries have also adopted this general approach (10).

There are advantages to focusing directly on the benefits and harms of procedures or interventions in distinguishing the permissibility of research. It avoids the three problems discussed earlier concerning other options. It offers special protections for vulnerable subjects but permits some research with children as subjects. It also allows that there may be benefits other than therapy to consider in assessing potential harms and benefits to children participating in studies. It does not make the sometimes troubling distinction between therapeutic and nontherapeutic research in order to determine which studies are acceptable for children as recommended in the Helsinki approach. As we saw above, classifying studies as therapeutic or beneficial can be misleading or arbitrary. It can be arbitrary because studies have potential harms unrelated to this classification such as extra tests or visits. It can also be misleading if people assume therapeutic studies are always safe or beneficial. Calling something "therapeutic" may hide potential harms, disadvantages, or other nonbeneficial features, creating an inappropriate bias for participation that would be revealed by careful risk assessment.

In contrast, the fourth policy option focuses on risk assessment to balance the social utility of encouraging studies with the protection of people's rights and well-being. It stipulates that, whenever possible, the incompetent persons should give their assent or affirmative agreement to participate.

In using the likely harms to benefit calculation, the U.S. regulations specify four categories of research with children (15). As risks increase, the regulations require increasingly more rigorous documentation of appropriate parental consent, children's assent, direct benefits to each child, and benefits to other children with similar conditions. Local Institutional Review Boards (IRBs) can approve studies only in the first three categories.

The *first* category permits research with no greater than a minimal risk provided that the study makes adequate provisions for consent from at least one parent and the child's assent. The *second* category of research permits approval of studies with greater than a minimal risk if the risk is justified by the anticipated benefit to each subject, the risks in relation to these benefits are at least as favorable to each subject as available alternatives, and provisions are made for consent from one parent and the child's assent. The *third* category permits research with a minor increase over minimal risk that holds out no prospect of direct benefit to the individual subject where the study is like the child's actual or expected medical, dental, psychological, or educational situation, is likely to result in very important information about the child's disorder or condition, and provisions are made for parental consent, typically consent from both parents, and the child's assent. Investigators using this category might be permitted to conduct, for example, additional lumbar punctures on children with leukemia to help study their disease. Consent from both parents is required if practicable.

Research that cannot be approved under the first three categories might be approved under a *fourth* category if it presents a reasonable opportunity to understand, prevent, or alleviate a serious problem affecting the health or welfare of children, and the study is approved by the secretary of the Department of Health and Human Services (HHS) after consulting with a panel of experts about the study's value and ethics and determining that adequate provisions have been made for the parental consent, typically consent from both parents, and the child's assent. Using this category, investigators might, for example, gain approval to conduct studies on normal, healthy children intended to prevent expression of late-onset genetic diseases. In the United States, IRBs cannot approve studies that have more than a minor increase over a minimal risk which do not hold out benefit for the children. As Table 1 shows, IRBs must seek approval from the federal government to conduct them.

Unfortunately, this fourth policy leaves key terms poorly defined and consequently allows broad interpretations about what risks of harm are warranted. The pivotal concepts of "minimal risk" and "a minor increase over a minimal risk" are problematic. The regulations state: " 'Minimal risks' means that the risks anticipated in the proposed research are not greater, considering probability and magnitude, than those ordinarily encountered in daily life or during the performance of routine physical or psychological examinations or tests." (US 45 CFR46 102i) (15).

Table 1. U.S. Regulations Requirements for Research with Children

Research Category	Risk-of-Harm Category	Requirement for Children's Participation
I (46.404)	Minimal risk	1. IRB approval 2. Child's assent, and 3. Informed consent from at least one parent or guardian
II (46.405)	More than minimal risk, with prospects of direct benefit for each subject	1. IRB approval 2. Child's assent 3. Informed consent from at least one parent or guardian 4. Risk justified by anticipated benefit to each subject, and 5. Anticipated benefits to each subject at least as favorable as that presented by available alternate approaches
III (46.406)	More than minimal risk, without prospect of direct benefits to each subject	1. IRB approval 2. Child's assent 3. Informed consent from both parents or guardians 4. Risk represents a minor increase over minimal risk 5. Likely to yield generalizable knowledge about child's disorder or condition that is important for the understanding or ameliorating of disorder or condition, and 6. Intervention or procedure presents experiences to child that are reasonably commensurate with those in child's actual or expected medical, dental, psychological, social, or educational situations
IV (46.407)	Research not otherwise approvable	1. IRB approval 2. Child's assent 3. Informed consent from both parents or guardians 4. IRB finds that research presents a reasonable opportunity to further the understanding, prevention, or alleviation of a serious problem affecting the health or welfare of children, and 5. Study gains the approval of the Secretary of HHS after consultation with a panel of experts in pertinent fields and following opportunity for public review and comment

Source: CRF **45**, 46, 404–7 (1991).

The first part of the definition is vague because daily risks include dangers from riding in cars, flying in airplanes, and living in a world filled with nuclear and conventional weapons. How well do we know the nature, probability, and magnitude of these "everyday" risks and why should they serve as a baseline to estimate minimal research risk? Depending on where one lives, daily risks can be life-threatening. It seems considerably easier to determine that having a 4-year-old stack blocks is a minimal risk study than to determine the nature and magnitude of whatever risks people normally encounter (10).

The second part of the definition seems to set a standard for physical interventions that have a minimal risk. The test is whether the activity is like that of a routine examination. Accordingly, IRB or Research Ethics Committee (REC) members may not approve as minimal risk research with such procedures as X radiography, bronchoscopy, spinal taps, or cardiac catheterization because they are not part of routine examinations. IRBs and RECs, however, can approve studies which have a minor increase over minimal risk, and some of these procedures have been approved as having only a minor increase over a minimal risk. Without standards for risk assessment, how effective are these guidelines? Not surprisingly there are considerable differences of opinion about whether procedures such as lumbar punctures, multiple placebo injections, arterial punctures, and gastric and intestinal intubations are regarded as risky (10).

Moreover this definition of "minimal risk" and subsequent judgments about what constitutes a minor increase over minimal risk offers no guidance about how to assess psychosocial risks. These include invasion of privacy, breach of confidentiality, labeling, and stigmatization. In "routine" visits doctors and nurses "ordinarily encounter" discussions of family abuse, sexual preference, and diagnoses that could affecting people's abilities to get jobs or insurance. As we saw in our two examples, these can be grave risks.

Freedman, Fuks, and Weijer (17) respond that identifying everyday risks we all encounter is not difficult, although it may be hard to quantify them. Yet they acknowledge the potential problem of using different standards for subject inclusion because of intercultural variation regarding "everyday risks." Their solution is to promote "intercultural ethics" where the norms of *all* the cultures participating would have to be honored to conduct any crosscultural studies. Clearly, however, this proposed solution has not been adopted. This is obvious from the multinational AIDS research conducted in developing countries but funded by nations that would not be able to conduct them in their own countries because they violate research policy. Nations from North America and Europe,

especially the United States, supported this research and tried to justify it in terms of local standards and conditions. There is an ongoing debate over permitting greater consideration of local standards or conditions (18,19).

Second, their assumption that a consensus exists regarding what paradigms to use in assessing the crucial upper levels of justifiable risks of harm also seems unwarranted. There are considerable differences among pediatric experts, in both treatment and research settings, about how to assess the risk of such procedures as lumbar punctures, multiple placebo injections, venipunctures, arterial punctures, and gastric and intestinal intubations (20). Investigators and others have concluded that better standards of risk assessment in children's research need to be formulated (21,22,10). More recently this lack of consensus and regulatory guidance within the research community was extensively discussed in testimony before National Bioethics Advisory Commission (NBAC) recorded in "Regulatory Understanding of Minimal Risk" where members of NBAC agreed this was a problem (22).

The fourth approach represented by the U.S. research rules, CIOMS regulations, and those of other countries seems to many to balance the need to protect the rights and welfare of people who lack the capacity to give informed consent with the need to encourage research. It may, however, be popular because it is so vague that it permits different understandings of what constitutes acceptable risks of harm to them. Each of the other three policy options, although flawed, offer clear guidance about what is permissible. This is not the case with the fourth standard, and debates arise about how to use this policy in certain cases.

DEBATES ABOUT BALANCING HARMS AND BENEFITS

The general acceptance of the fourth policy alternative, with its attendant ambiguities about what constitutes a warranted risk of harm, has engendered disputes about how to understand and balance harms and benefits in permitting research involving children. Recall that in case 1, the parents focus on what is best for their child, and they balance their views about what helps him against the harms that will fall to him if he is in the study but does not get the growth hormone. It is not unreasonable for parents to want to improve their child's life, using the values they think most important. Martin's parents are willing to take risks to have him avoid the discrimination they faced because they are short, but unwilling to have him suffer without a chance of some advantages. If they decide there are insufficient benefits to him from being in the study, then the harms from the hundreds of placebo injections, inconvenience, medicalizing of his shortness, and so on, tip the balance and, using their values, justify taking him out of the study.

The investigators, however, might consider a different set of values, harms, and benefits. They might want to consider not just the harms and benefits to a few people in the study but to all people in the future who might take this drug. Investigators might want to emphasize the virtues of keeping one's bargains of staying in the study until the end. Investigators sometimes stress the long-term benefits of their research in possibly developing new and better therapies in the future. On the other hand, if we speculate on possible long-term benefits from a not yet developed therapy, then we probably should also consider and balance them against the possible long-term harms from it as well. This calculation becomes further complicated because it is hard to factor in special interests, biases, prejudices, and wishful thinking. In addition, if open information makes those in one arm of a study want to withdraw, one must question if there is a genuine balance of harms and benefits in the other arms of the study.

The research rules give little guidance about what goals to use to determine harms and benefits and how to balance them. For example, in case 1 it is crucial to determine the benefits of a good study against the harms to the child, including getting so many placebo injections, and the long- and short-term harms to the doctor–patient relationship. How do we establish the different goals and assessments about harms and benefits? One might conduct an opinion poll about this. If so, what groups should be surveyed? Should they be among parents, doctors, short parents, investigators, or the general public? Clearly we can influence the results of the opinion poll by the group we pick to survey.

Different goals and assessments of harms and benefits are also apparent in case 2, where the parents mean well and want to help their child find out if she has a late-onset disease, hoping, of course, that she will find out that she does not. Unlike case 1, where parents can withdraw their child from a research study, in case 2 they want to get their child into a study if that is the only way that they can get her tested for a late-onset disease. There are different assessments of harms and benefits, with the investigators, parents, and the potential subject minimizing the importance of the predicted harms from testing for Huntington's disease and the pediatrician and genetic counselor refusing to accept their assessment.

These debates arise because reasonable and informed people of good will have different goals and views about what constitutes a harm and a benefit, and about how to rank or balance them. In addition they have different expectations of the future. In what follows, two areas of debate about goals, benefits and harms are discussed: (*1*) distinguishing treatment, prevention, and enhancement, and (*2*) research to develop germ-line gene therapies.

Distinguishing Treatment, Prevention, and Enhancement

New genetic technologies create problems about how to use them. One proposal is to distinguish treatment, prevention, and enhancement and permit use of these new techniques only to prevent or treat medical conditions like sickle cell disease; but not to enhance normal people's height (as in case 1) or their beauty, strength, and intelligence, and the like. On this view we should simply prohibit development of new technologies for the purposes of enhancement. Yet this viewpoint is questionable. In some sense to prevent or treat a disease already enhances one's life, making it difficult to say how these distinctions should be determined. For example, putting fluoride in

the water enhances people's lives by reducing dental pathology. Treating infectious diseases also enhances lives by making people better and preventing others from getting sick. Since such enhancements are not controversial, it appears there are no principled objection to enhancement understood as the prevention or treatment of disease. On the other hand, making normal children taller, as in case 1, is more controversial because shortness is not a disease like dental pathologies or infections. Martin's parents understand the projections are that he will be only 5 feet 3 inches, and while possibly agreeing that shortness is not a disease, they see this is a disadvantage for a man in our society.

Some enhancements are even more controversial than those aiming to bring someone into normal range of height so he will escape discrimination, as the parents in case 1 desired. For example, some enhancements seek to give people special advantages. For example, parents might wish to improve their son's opportunities to become a professional basketball player and are disappointed to learn their child's projected height is only 6 feet 3 inches. They want him to get growth hormone so he can have a better chance of becoming the next Michael Jordan. Many people might object to this use of technologies on several grounds. First, not everyone has access to this technology, so it is unfair for some to get this advantage. Second, if everyone had access to the technology, no one would have the sought-for advantage. It is not possible to enhance the height of all short, normal children because no matter what resources are used, there would still be children in the lowest 2 percent for height. Third, it exposes the child to some risks for controversial or questionable motives. Finally, it is a poor use of an expensive technology when there is so much need in the world. The debate continues over what limits should be placed on parental authority, investigators, and the use of state funds to develop, test, and use new technologies for enhancement, especially where they involve possible harms to the child.

In trying to resolve the debate by prohibiting these technologies for enhancement but permitting them for prevention and treatment, consider the following example. Two boys have a projected height of 5 feet 3 inches. One has short parents, while the other has a tumor. Should one be refused growth hormone therapy because it would constitute enhancement, while the other gets it because it is treatment? Some would argue they both should get the therapy so they both can reach normal height, gain a normal opportunity range, and escape the social disadvantages from prejudice (7). Some might object, however, to either of them getting it, not on the ground that this may be enhancement rather than treatment but because both are in the normal opportunity range for height; they might agree if either child's projected height were far less.

Trying to settle the debate in terms of someone's normal opportunity range raises difficult problems about what constitutes a normal range, as well as the limits of social obligations to find the money to get children to some norm (23). Some might object to giving children a very costly drug using state money when they have a projected heights of 5 feet 3 inches, since being 5 feet 3 inches is not, in their view, abnormal. That is, most options are still open to people with a projected height of 5 feet 3 inches. Many women get along perfectly well at this height, finding no great hardship in being 5 feet 3 inches. Moreover, if the problem is social prejudice, we should fix that, not the child, especially given the great needs to use state resources for basic health care for children. Little girls with Turner syndrome have extremely short stature if they do not get growth hormone, so public funds are routinely used in treating their short stature with growth hormone. Arguably, if any child were projected to have such short statue as these girls, they too should have the growth hormone. But some uses of these new technologies seem like cheating. The use of anabolic steroids, for example, to enhance athletic performance is prohibited as seeking unfair advantage over competitors.

Ultimately, resolution of these debates may involve factors other than finding precise delineations of enhancement, prevention, and treatment. Not only is it very difficult to draw clear lines between them but, in the end, some believe it may not be very important (7). What may be more important is whether it permits someone to gain a normal opportunity range, without undue risk of harm, at a cost society can afford (7,23). The issue may turn on how we rank values and on the balancing of potential harms, benefits, and costs.

Research to Develop Germ-Line Gene Therapies

Human germ-line therapies are controversial because they might modify traits that offspring would inherit from parents. They can be beneficial for all, for example, by curing a condition such as sickle cell disease for patients and their descendants. Or, they might harm the person and subsequent generations. How do we assess the goals and potential harms and benefits of research that could harm not only the individual but his or her offspring? The debate also raises issues about the proper moral restraints on science. Eric Juengst (24) summarizes arguments regarding the goals and potential benefits and harms in developing germ-line gene therapies. The first is its potential to be medically useful. Research into germ-line gene therapy will develop ever more therapies and techniques to cure conditions, rather than merely treat the symptoms. Second, developing these techniques may be the only effective way to treat some of these conditions when palliative or symptomatic therapeutic interventions are unavailable. Third, such measures may be efficient in that by developing germ-line gene therapies, one would prevent the transmission of diseases between generations and therefore avoid treatments for many others in the future. Finally, many resist limiting these therapeutic techniques on the ground that it is an unwarranted restriction of scientific freedom. The federal regulations delineate the limits of research involving human subjects, and if research falls within these regulations, it is unreasonable to limit free inquiry.

On the other hand, there are arguments opposing development of germ-line gene therapy techniques, especially with children as subjects. The first is the unknown, unexplored, and unpredictable risks to the persons and their offspring. Given the uncertainty of these risks of harm, there is no way to determine exactly

whether the harm–benefit ratio would be justified or not. A second issue concerns the problem of whether we are developing techniques for therapy or for enhancement. As we discussed earlier, it is difficult to distinguish between medical and nonmedical uses of these techniques. Third, some object that since these techniques could harm future generations as they try to perfect the development of these techniques, they would be putting future individuals, who gave no consent, at risk. Fourth, there is the issue of the allocation of resources. It would be costly to develop these new germ-line gene therapy techniques, and some argue that we have higher social priorities. Finally, some are concerned that we would change the germ line for all time by these techniques, altering inheritance intentionally and perhaps capriciously.

To conclude, research involving children can foster different and important values including benefit for the children who are subjects, medical advances, prudent use of public resources, health care planning, and public health. With more information, better diagnoses, treatments, and prognoses, as well as informed consent, are possible. In some cases, however, these values can conflict, posing difficult choices on how to acknowledge people's rights, protect their interests, gain good information, and do what is useful socially. Different research policies offer different solutions on how to balance these values, and these policies have their own different strengths and weaknesses. Solutions were judged superior when they fairly promote children's well-being and opportunities to develop and flourish.

HUMAN SUBJECTS RESEARCH, ETHICS, COMPENSATION OF SUBJECTS FOR INJURY

TERRENCE F. ACKERMAN
University of Tennessee
Memphis, Tennessee

OUTLINE

INTRODUCTION

Participation in clinical research sometimes results in pain, physical disability, or even death for human subjects. For several decades scholarly commentators, medical researchers, and government advisory committees have debated the advisability of establishing a national program to provide compensation for injured research subjects. The

substance of this debate has focused on several critical questions. What is the basis and extent of society's moral obligation to compensate subjects for research injuries? Does the incidence and magnitude of research injuries justify the establishment of a national compensation program? What are the essential components of a morally acceptable and practicably workable compensation plan? Disagreements about our moral obligations, the paucity of empirical data about research injuries, difficulties in devising a workable system, as well as the press of other public priorities, have thwarted any clear social consensus on the merits of a compensation program. Nevertheless, the unavoidable fact that some persons are injured in medical research for the benefit of society has sustained the policy controversy.

SOME INITIAL DISTINCTIONS

In exploring the issues regarding compensation, several distinctions are crucial to the analysis. First, it is important to distinguish research injuries for which subjects possess legal means for securing redress and those for which legal recourse is not available (1,2). Injuries may occur as a result of researcher negligence when subjects have not been adequately informed of the risks involved or when due care has not been exercised in protecting them from risks. In these instances injured persons may bring civil suits for damages against investigators. In other limited cases, such as workers' compensation for federal employees, persons injured in research may use existing administrative mechanisms for securing compensation. By contrast, most research injuries occur without any fault on the part of researchers. There are several reasons. Most interventions employed in clinical research, such as chemotherapy or tissue biopsy, possess a definite risk of harm even when competently performed. Oftentimes the use of new drugs or medical devices results in harm that could not be anticipated based on prior knowledge. Moreover, many research subjects have diseases or disabilities that result in a heightened susceptibility to the harmful effects of medical interventions. Yet very few research institutions have formal compensation programs. As a result the debate about compensation has focused on research injuries that occur without researcher negligence and for which no redress is legally available.

Important to the contours of the debate is a second distinction between therapeutic and nontherapeutic research procedures (3). Therapeutic research procedures are performed in order to benefit the individual subject, as well as to produce generalizable knowledge. For example, administration of a new drug in a randomized clinical trial comparing it to standard treatment is a therapeutic research procedure. By contrast, when a medical intervention is performed solely to produce generalizable knowledge, without being intended to benefit the subject, it is a nontherapeutic research procedure. For example, serial venipunctures performed to profile the pharmacokinetics of a new drug in healthy volunteers constitute nontherapeutic research procedures. This distinction is crucial to disputes about the limits of the moral obligation to compensate injuries, the extent of the need for a program, and the practicality of any scheme for identifying compensable injuries.

A third distinction concerns the reasons for which subjects participate in clinical research. Some may participate primarily to promote their own interests. Other subjects may participate in research studies primarily to contribute to the welfare of society. This distinction cuts across the prior one between therapeutic and nontherapeutic research procedures. Most subjects enter trials of therapeutic procedures to secure personal benefits, especially the opportunity to receive a new treatment that may be more efficacious or safe than existing therapies. But participation in a clinical trial may offer no special advantage, as when investigators are comparing the efficacy and safety of two standard treatments. On the other hand, subjects who participate in studies involving only nontherapeutic research procedures anticipate no medical benefit. Yet in many cases they may receive an attractive payment for their participation. An important point of contention is whether personal sacrifice for the common good is a necessary condition for a valid claim against society for compensation of injuries.

A final distinction concerns the difference between medical research that is undertaken at the behest of society and research not similarly sanctioned. In the former category there is research conducted by employees of the federal government, such as physician-investigators employed by the National Institutes of Health (NIH). In addition much medical research in the United States is supported through grants from the federal government to investigators working in public and private academic institutions. There is also considerable medical research conducted by private medical companies required by regulations of the Food and Drug Administration (FDA) for the development of new drugs and medical devices. Whether medical research is federally conducted, supported, or regulated, it is commissioned through the official agencies of society. By contrast, considerable medical research is funded through private sources, particularly charitable foundations. While such research contributes to the common good, it is not officially sanctioned. An important issue is whether an obligation to compensate injuries should be limited to subjects in research sanctioned by the official agencies of society or should extend to all research that contributes to the common welfare.

HISTORY OF THE COMPENSATION DEBATE

Between 1945 and 1965 annual expenditures of the NIH increased exponentially from $701,800 to $436,000,000. This increase reflected an exploding confidence of the American public that medical research could yield enormous advances in the prevention and treatment of disease. By 1960 governmental support for clinical research sustained a vast infrastructure of research programs at medical colleges in the United States.

Despite the proliferation of medical research employing human subjects, there was only sporadic discussion of issues related to the rights and welfare of human subjects. Although the ethical guidelines for the conduct of human

research formulated at Nuremberg were considered relevant to the American enterprise, it was generally believed that the moral conscientiousness of individual investigators was sufficient to assure that subjects were adequately protected. The absence of public reports of research injuries reinforced the informal approach.

This public and professional confidence began to unravel in the 1960s with a series of revelations about studies in which persons were uninformed that they were subjects and/or exposed to unjustifiable risks of harm (4). Public concern was awakened after severely deformed infants were born to mothers who took the sedative thalidomide during pregnancy without being aware of its investigational status. This tragedy helped solidify support for the 1962 Harris-Kefauver Amendments to the Food, Drug and Cosmetic Act, which included the requirement that informed consent be secured from prospective subjects for the testing of investigational drugs. In 1964 it was revealed that two New York physicians, while studying cancer immunology, had injected live cancer cells under the skin of elderly, debilitated patients without their knowledge. This was followed in 1966 by the publication, in the *New England Journal of Medicine*, of Henry Beecher's paper, "Ethics in Clinical Research," which described 22 studies published in leading medical journals that involved the exposure of subjects to unjustifiable risks of harm (5). Finally, in 1972, front-page newspaper articles detailed the infamous Tuskegee Syphilis Study in which 400 poor, black males in Alabama suffering from syphilis had been left untreated for 40 years to study the natural history of the disease (6). Medical research was now acknowledged to involve palpable human costs.

These developments fostered a growing recognition that adequate protection for the rights and welfare of human subjects required the creation of formal social controls over clinical research. Beginning in 1966, the Public Health Service (PHS) established protective mechanisms involving two main components (7). First, human research activities conducted or supported by PHS were required to undergo prior review by committees established at each institution engaging in clinical research. Second, these committees were to approve research only if adequate provision was made for securing the informed consent of subjects or their legally authorized representatives and only if the risks were justified by the anticipated benefits to subjects and others. These essential elements of social control were refined over the next decade and a half, assuming much of their present form by 1981 with the implementation of the recommendations of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (hereafter, the National Commission) (8).

At the same time, a third mechanism of social control was being explored in the legal and medical literature: no-fault compensation for injured research subjects. Some early commentators viewed compensation as a means of fulfilling a societal obligation to those injured in contributing to the common good (9). Initially, however, compensation was often conceptualized as a mechanism for controlling risks (10,11). Compensation programs funded by research institutions would encourage more careful scrutiny of the risk/benefit profile of proposed research studies and would necessitate closer surveillance of the safety of subjects during their participation. Moreover, if injured subjects were fully compensated for medical expenses, lost wages, and related expenses, society would be forced to acknowledge the full costs of medical research.

Beginning in the 1970s a series of government advisory committees formally examined the compensation issue. With the strengthening of other mechanisms for controlling research risks, these groups began to focus on the moral obligation of society to compensate research injuries. For example, the Tuskegee Syphilis Study Ad Hoc Advisory Panel in 1973 endorsed the concept of compensation as follows:

> No policy for the compensation of research subjects ... has been formulated, despite the fact that no matter how careful investigators may be, unavoidable injury to a few is the price society must pay for the privilege of engaging in research which ultimately benefits the many. Remitting injured subjects to the uncertainties of the law court is not a solution (12).

Based on this rationale, the committee recommended establishment of a no-fault compensation program for injured research subjects. Similarly NIH accepted this rationale in three proposals submitted to the Secretary of Health, Education, and Welfare (HEW) in the early 1970s for implementation of a no-fault compensation program administered by the government for injuries sustained in research supported by federal funds. However, acceptance of these proposals was considered premature. Their fiscal implications had not been assessed, alternatives to a federally administered program had not been explored, and the need had not been clearly established (13).

These shortcomings in prior proposals prompted the Secretary of HEW in 1974 to create a task force to examine in greater detail "whether and how to compensate subjects injured in the course of research." The HEW Secretary's Task Force on the Compensation of Injured Research Subjects (hereafter, the HEW Secretary's Task Force) conducted an 18-month study in which it elicited papers on the ethical and legal aspects of compensation, commissioned an empirical study on the extent of research injuries, and consulted with officials from the insurance industry regarding the feasibility of a compensation program underwritten by private companies. In its final report, the Task Force strongly endorsed the proposition that society has a moral obligation to compensate injured research subjects (13). Moreover it maintained that this obligation extended to subjects of both therapeutic and nontherapeutic research procedures. While the Task Force report recommended that subjects in research conducted by PHS be included under the provisions of the Federal Employees Compensation Act, it suggested that compensation for subjects in PHS-supported research be provided by the research institutions receiving financial support. A similar recommendation was made regarding compensation for subjects of research on new drugs and medical devices regulated by FDA.

Although the recommendations of the Task Force were endorsed in June 1977 by the National Commission, they were not readily embraced by the research community (14). This hesitancy did not focus on the ethical argument. Rather, widespread concern was voiced regarding the ability of research institutions to secure private insurance which met their needs for protection, while also not imposing costs or limitations on coverage that would thwart valuable research. These concerns were reflected in the report of the Task Force itself, which found private insurers extremely reluctant to consider compensation coverage, given the diversity of research institutions, studies and subjects, as well as the absence of actuarial data on which to formulate premiums.

While the controversy continued regarding the practical contours of a compensation program, the National Commission addressed the issue from another standpoint. In its report on institutional review boards, the Commission outlined those items of information that a reasonable person in the prospective subject's position would need to know in deciding about participation in research. The Commission proposed that a reasonable person would need to know whether medical treatment and compensation is available in the event of injury (15). In January 1979, this recommendation was adopted by the Department of Health, Education, and Welfare (DHEW), which now required that, for research involving more than minimal risk, institutions receiving federal funds for research must inform prospective subjects regarding the provision of medical treatment for injuries, the availability of monetary compensation, and the identity of the appropriate individual to contact in the event of injury (16). This requirement of informed consent disclosure remains in effect today.

With the substantive issue of a compulsory compensation program still unresolved, the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research (hereafter, the President's Commission) decided in 1980 to undertake a fresh investigation of the issue. In developing its recommendations, the Commission reviewed papers on the ethical and legal issues, reports on the few existing compensation programs, an analysis of the risks of common research procedures, and assessments of alternative program designs (14). The conclusions it reached were more narrowly drawn and tentative than those of the HEW Secretary's Task Force. The Commission affirmed that society has an obligation of justice to compensate injured research subjects. However, it considered this a prima facie obligation that might be outweighed by other duties of social justice if the need for a program was negligible or the costs of administering it were disproportionate to the need. Moreover the Commission restricted the scope of the obligation to injuries incurred as a result of nontherapeutic research procedures. With respect to therapeutic research procedures, the Commission found little evidence that subjects who seek therapy in the research setting expose themselves to risk exceeding that presented in the nonresearch setting. In addition the Commission asserted that distinguishing excess injury in subjects who are seriously ill patients posed administrative burdens that could not be justified in light of the relatively weaker moral claim to compensation for injuries resulting from therapeutic research procedures. The Commission also identified numerous practical aspects of administering a program whose appropriate form could not be settled without some limited experience in implementing such a program. Lastly, the Commission believed that insufficient data on research injuries existed to establish a compelling need for a program. Based on these factors, the Commission recommended that the (now) Department of Health and Human Services (DHHS) conduct "a small, controlled experiment to determine whether a formal program is needed and, if so, the most fair and efficient means of providing compensation." The report of the President's Commission was conveyed to President Reagan in June 1982. In an era marked by shrinking federal programs, no action was taken on its recommendations.

In the intervening years the issue of compensation for research injuries has been revisited only once at the federal level. In 1995 the Advisory Committee on Human Radiation Experiments issued its report on radiation research on human subjects sponsored by the federal government and conducted during the period 1944 through 1974 (17). The Advisory Committee recommended that the federal government financially compensate subjects or next of kin in cases where the government deliberately withheld information from individuals or families regarding the nature of the research. It also recommended compensation for subjects who were physically injured in studies involving either no prospect of direct benefit to the subjects, or the use of controversial interventions that were misrepresented as standard practice. However, the Advisory Committee did not examine general issues regarding implementation of a no-fault, federal compensation program for injured research subjects.

MORAL BASIS OF COMPENSATION

Moral arguments favoring compensation of injured research subjects follow two strategies. Some proponents have argued that establishing a compensation program will have consequences that improve the overall cost–benefit ratio of clinical research. Other analysts have contended that compensation is owed to injured research subjects as a moral right, regardless of its beneficial consequences. This moral right reflects the obligation of society to justly distribute the benefits and burdens of cooperative social activities like clinical research.

The view that a compensation program is justified by its cost/benefit consequences was articulated by early theorists who viewed it as a mechanism for the social control of research (10,11). Several potential benefits of no-fault compensation were envisioned. One is that compensation would encourage investigators to engage in less dangerous research, because the costs of compensating injured research subjects would be drawn from the total funds available for research. Also reduction of risk in planning research would be facilitated by accumulating data regarding the compensation cost profile of common research interventions used in specific subject groups. In

addition compulsory compensation would encourage the allocation of more resources for the early identification and treatment of injuries incurred by subjects. Another goal achieved would be increased public support for the research enterprise, deriving from awareness that appropriate resources are devoted to the needs of injured subjects. Moreover, availability of compensation would encourage participation in research by persons who might demur in the absence of protection against personal loss. Finally, a compensation program might facilitate the conduct of some clinical research that is unusually risky but promises significant advances in medical knowledge. Thus, on this view, society ought to provide compensation for research injuries because it will lead to safer research, encourage societal support and participation, and facilitate the conduct of some risky but highly promising studies.

There are serious shortcomings in this approach to grounding a societal obligation to provide compensation. One problem is that the argument depends on unproven factual assumptions about the incentives for researchers and subjects created by a compensation program. For example, the argument assumes that the availability of compensation would increase recruitment of subjects, even though there is no evidence that persons now decline participation due to the absence of this guarantee. Similarly the claim that research will be practiced more safely if compensation costs are included in the total funding for studies presupposes that current review mechanisms and the conscientiousness of investigators are inefficient in minimizing risks. A second problem is that the incentives created by a compensation program may depend on its exact administrative configuration, and particular schemes may inconsistently both promote and undermine specific goals cited. For example, if a federal compensation program is financed through funds separate from research budgets, it may have little deterrent effect on investigators contemplating the use of risky research procedures. At the same time, greater public awareness about research injuries might discourage research participation, irrespective of the availability of compensation. A third problem is the most decisive. While the incentives of a compensation program may decrease the total harm caused to human subjects and encourage public support for and participation in clinical research, the moral claim of injured subjects against society is valid even if these beneficial consequences are not realized. That is, it is the injury itself that seems to trigger the obligation to provide compensation. Therefore the moral basis of the obligation to compensate injured research subjects must reside in considerations other than the valuable consequences of a compensation program.

The second major approach to delineating a moral basis for compensation proceeds from this important insight. This view asserts that compensation is owed to injured research subjects as a matter of social justice. According to one common interpretation, justice requires that the benefits and burdens of certain cooperative social endeavors be distributed in ways that give all persons an equal opportunity for a good life. When persons are injured in these activities, compensation may help to restore the equality of their opportunity vis-à-vis other members of society.

A crucial question is what cooperative social endeavors create this obligation of justice. In a position that strongly influenced both the HEW Secretary's Task Force and the President's Commission, Childress argues that three features of an activity create a societal obligation of compensatory justice (18). First, the injured party has accepted or has been compelled to accept a position of risk. Objective risks that the party would not otherwise have encountered are created by this position. Second, the activity is for the benefit of society, although any particular person's motives may not be to benefit society. Third, society, through its government or agencies conducts, sponsors or mandates the practices in question. For example, these conditions obtain with respect to persons who serve in the military forces and create an obligation to compensate service-connected injuries. They also apply to the injuries incurred by some research subjects.

Several crucial points should be noted about the scope of the obligation of compensatory justice as specified by Childress. The obligation to compensate research subjects is triggered by the injury without regard to negligence by investigators. Compensation should be provided on a no-fault basis. In addition the obligation to compensate pertains to injuries derived from assuming a position of objective risk that benefits society. The subject's motives to secure a promising new treatment or to receive an attractive cash payment are irrelevant to the right of compensation for injury. Moreover, the obligation to compensate applies to injuries associated with both therapeutic and nontherapeutic research procedures, because both involve a position of risk for the benefit of society. Lastly, the societal obligation to injured subjects applies only to cooperative endeavors officially conducted, supported or mandated by society. Thus research conducted or supported federal agencies, or regulated by FDA are covered by the obligation of compensatory justice. Research privately supported or conducted is not officially endorsed by society and does not create a societal obligation to redress the injuries of subjects.

Despite its intuitive appeal, there are two serious difficulties with this argument. The first relates to the role of consent by prospective subjects to participation in research. When persons knowingly and freely participate in cooperative ventures possessing a risk of harm, other parties are not normally held responsible for injuries that materialize without negligent behavior. This notion is captured by the maxim, *volenti non fit injuria*—there is no injury to one who consents. Moreover, as required by current federal regulations, prospective subjects must be advised as to the availability of compensation. If subjects accept participation in research knowing that it is not available, then their consent is secured with disclosure of the information that a reasonable person would need to know. The choice to participate without this guarantee would seem to relieve any prima facie obligation to redress resulting injuries.

Some commentators respond that the actual process of informed consent is too imperfect to absolve society's obligation to compensate research injuries. The report of the President's Commission delineates some of these

imperfections (14). One is that in some research the risk profile of interventions is not yet established. Prospective subjects must decide about participation without being aware of the nature of unknown or unanticipated risks. In addition experimental evidence suggests that persons tend to discount the importance of substantial harms with a very low probability of occurrence. Finally, it is difficult to convey to prospective subjects a full appreciation for the ways in which specific injuries might be harmful to their interests. In light of these imperfections in knowledgeable decision making, it might be argued that subjects do not really intend to waive their security against the personal losses imposed by injuries.

The argument from imperfections in the consent process is badly weakened by its paradoxical implications. As Engelhardt has pointed out, we are asked to imagine a consent process in which the decision making of prospective subjects is adequate enough to validate their decision to participate in research but not adequate enough to validate their willingness to forgo compensation for injuries (19). Yet the decision to expose oneself to the injury in the first place does not seem to require less ability to comprehend facts and to deliberate about their consequences than the decision to accept research participation without the promise of compensation. Thus, if prospective subjects have sufficient capacity to competently decide about participation in research, they are also competent to accept participation without compensation for injuries.

Another response to the argument that consent relieves the obligation to compensate focuses on the morality of the request rather than the validity of consent (20). We may grant that knowing and willing agreement by subjects relieves society of its obligation. Nevertheless, it may be morally wrong of society to even make such a request. If justice requires that subjects be compensated for injuries incurred in officially sanctioned medical research, then society should not be free to ask persons to forgo compensation. The request for a waiver of this right should be limited to situations in which weightier obligations constrain the use of societal funds for compensation. While persons should be free to decline compensation after they have been injured, society must make the offer as a matter of compensatory justice.

A more serious problem with Childress' argument for the obligation of compensatory justice relates to its scope. For Childress the obligation to compensate research injuries is triggered when persons assume a position of risk in activities that benefit society and are sanctioned through its official agencies. Injuries resulting from both therapeutic and nontherapeutic research procedures are compensable. Likewise injuries are compensable whether the primary motivation of subjects is to contribute to the interests of others or to promote their own interests. The essential difficulty is explaining why the assumption of risk triggers an obligation to compensate injuries when subjects' participation is premised on the judgment that the risks are outweighed by anticipated personal benefits. If subjects are not making a sacrifice for society, then compensation for their losses is not owed them as a matter of justice. The scope of the obligation must be restricted to circumstances in which the positional risk is assumed without the anticipation of offsetting personal benefits.

An example illustrates the problem (21). The federal government sponsors a national lottery to fund educational programs. These programs contribute to the general welfare. Participants in the lottery assume a position of risk. As a cooperative social enterprise, the lottery satisfies the three conditions for compensation of injury cited by Childress. If a losing participant has purchased so many tickets that he faces financial ruin, it follows that he ought to be compensated for his losses. If this implication is unacceptable, then it appears that the scope of the obligation to compensate injuries as sketched by Childress is too broad.

The same difficulty arises with regard to clinical research involving the evaluation of therapeutic interventions (22). Childress assumes that subjects are placed at special risk by participation. However, it is generally agreed that it is not morally permissible to undertake a trial of a new therapy unless prior evidence suggests that it is likely to be at least as efficacious and safe as alternative treatments acceptable to the subject. Moreover, because shortcomings in the efficacy and safety of standard treatments provide the stimulus for evaluating new therapies, it is usually the case that preliminary evidence suggests that the new treatment may be superior. In addition treatment in the research context often includes more intensive monitoring and nursing care for subjects. In many research centers there are also more numerous and specialized ancillary personnel available, including allied health professionals, social workers, and psychologists. Lastly, new treatments being investigated are often provided without charge to the subjects. Thus subjects assume a position of risk to secure overriding personal advantages associated with participation. If there is no sacrifice involved in the subject's participation, then an obligation of compensatory justice does not apply in the event of injury.

Most commentators have assumed that the same factors do not apply to injuries resulting from nontherapeutic research procedures. Subjects injured by these interventions cannot anticipate commensurate medical benefits. If justice requires that the impact of these burdens be ameliorated, then it is appropriate to redress these injuries. But even here, the motivation of subjects complicates the moral equation. In some cases subjects participate in research involving nontherapeutic procedures to secure an attractive payment. Rather than being an act of sacrifice, participation reflects a calculation of overriding personal benefit. Nevertheless, in many cases, research involving nontherapeutic procedures does not involve payment for participation, and subsequent injuries to subjects create the societal obligation to provide compensation.

If many subjects do not incur special risks, then the obligation to compensate injuries is more narrowly circumscribed than envisioned by Childress and the HEW Secretary's Task Force. However, there are ways to blunt the force of this argument. First, the risk–benefit profile of a new therapy undergoing evaluation is, *ex hypothesi*, not yet clearly established. Although preliminary evidence may suggest that it will be at least as favorable as

alternative treatments, the new therapy may prove inferior in a controlled clinical trial. Second, there is always the danger that unknown or unanticipated risks of new therapies will emerge during or after the conduct of clinical trials. Participating subjects expose themselves to these uncertainties that are not present in the nonresearch setting. Third, for subjects who incur injuries in excess of what might be anticipated in the nonresearch setting, it can be maintained they have clearly made a sacrifice that contributes to the general welfare of society. If these considerations are decisive, then the obligation to compensate research injuries should cover therapeutic as well as nontherapeutic interventions.

Even if the argument for an obligation of compensatory justice is compelling, it establishes only a prima facie societal obligation to compensate research injuries. There may be other societal needs, or other obligations of social justice, which have moral priority in the use of limited societal resources. Thus the case for compensation may depend on the extent of the problem of research injuries, as well as the importance of this problem relative to other pressing social needs.

EXTENT OF RESEARCH INJURIES

In the period right after World War II, medical research was frequently depicted as a perilous enterprise exposing subjects to grave risks of harm that would not otherwise be encountered. However, this assumption was not based on empirical data about the frequency and magnitude of injuries. Even today there is only one large descriptive study of injuries in clinical research and the accumulated experience of a few small compensation programs. Available information raises serious questions about whether the frequency and magnitude of research injuries establishes a compelling need for a national compensation program.

A large empirical study was performed by Cardon and colleagues for the HEW Secretary's Task Force (23). Data were compiled by telephone from 331 investigators conducting research on 133,000 human subjects. Overall, injuries were reported in 3.7 percent of all subjects. Eighty percent of these injuries were classified as trivial by the investigator, while nearly all the remaining were temporarily disabling. Permanently disabling and fatal injuries together accounted for about 1 percent of the total injuries.

Separate analyses were performed for therapeutic and nontherapeutic research procedures. Of 39,216 subjects undergoing therapeutic research procedures, 10.8 percent were reported injured. Trivial injuries were incurred by 8.3 percent of subjects and temporarily disabling injuries by 2.4 percent, with less than 0.1 percent suffering either permanently disabling injuries or death. In actual numbers, 13 subjects were permanently disabled and 43 died. Of 93,399 subjects undergoing nontherapeutic research procedures, 0.8 percent were injured. Trivial injuries accounted for 0.7 percent of all subjects, temporarily disabling injuries 0.1 percent, and permanently disabling injuries less than 0.1 percent. Only one subject was permanently disabled, and there were no fatalities.

The investigators also determined that injuries resulting from therapeutic procedures were clustered in clinical trials of cancer therapies. These trials accounted for 37 of 43 fatalities, 9 of 13 permanently disabling injuries, and 648 of 937 temporarily disabling injuries. Except for these cancer trials, there were few serious and/or irreversible injuries reported. Moreover, investigators were asked to enumerate actual injuries, without regard to whether the same results might have been expected from treatment in the nonresearch setting. This point is significant with respect to research on cancer treatments. Standard treatments for cancer carry substantial risks of disabling injuries or death. The study design did not permit investigators to determine whether the frequency and magnitude of injuries in cancer trials was greater or less than expected in the nonresearch setting.

Finally, investigators broached the question of how the risks of harm to subjects undergoing nontherapeutic research procedures compare to the risks of everyday life. Annual rates of accidental injuries that are temporarily disabling, permanently disabling and fatal, per 100,000 Americans, were found to be about 50, 2, and 0.6, respectively. Rates for the same types of injuries in approximately 93,00 research subjects were 37, 1, and 0. If the average duration of participation in research employing nontherapeutic procedures is 3 days, or 1/100 of a year, then these rates do not seem significantly greater than the risks of everyday life.

The President's Commission also reviewed data on research injuries from existing compensation programs in the United States. McCann and Pettit analyzed data from the University of Washington for 1972 to 1981 during which an estimated 356,000 subjects were covered by the university's compensation program (24). In the year prior to initiation of the program, 10 out of 14,942 subjects (0.07 percent) experienced adverse effects. None were partially or permanently disabled, and no deaths were reported. For the first eight years of the compensation program, 144 out of 356,000 subjects (0.04 percent) experienced temporary disability, none were permanently disabled, and two died. In addition a report was received from the Quincy Research Center in Kansas City, Missouri, whose subjects were covered by a workers' compensation program (25). The data covered 2596 normal volunteers and 2478 patients. Clinically adverse events resulted in the hospitalization of 1.43 percent of patients and 0.2 percent of normal volunteers, while fatalities occurred in six patients and no normal volunteers. Analysis suggested that no deaths in the patient group, and only 7 of 36 hospitalizations could be related to the research interventions. Finally, the Commission reviewed the results of the drug testing program using normal volunteers in Michigan prisons for the years 1964 to 1976 (26). The authors reviewed 805 protocols involving 29,162 research participants. They reported that 64 subjects experienced adverse reactions (0.2 percent), but there was only one permanently disabling injury and one fatality (in a patient receiving a placebo). Thus data from these research programs corroborate the findings of Cardon and associates that serious research injuries are very infrequent.

An important policy issue is whether the extent of research injuries is sufficient to transform a prima facie moral obligation to offer compensation into a legitimate social priority. As outlined earlier, the moral argument for compensating research injuries is most compelling with regard to subjects harmed by nontherapeutic procedures. However, the evidence generated by Cardon et al. suggests that the frequency and magnitude of injuries resulting from nontherapeutic procedures is no greater than the risks of accidental injury in daily life. The moral argument for compensating injuries caused by therapeutic procedures is less compelling, because subjects often accept the risks of harm to secure the offsetting benefits of therapy in the research setting. Here the Cardon study found a greater frequency and magnitude of injuries to subjects. Nevertheless, these injuries were clustered in cancer treatment trials, and no attempt was made to determine whether the extent of injuries exceeded that anticipated in the nonresearch setting. Thus available empirical data does not provide convincing evidence that the prima facie obligation to compensate injured subjects should be a social priority.

The President's Commission concluded that existing evidence was insufficient to establish a compelling need for a national compensation program (14). In recommending experimental, pilot programs for compensating injured subjects, the Commission indicated that gathering more comprehensive data on the extent of research injuries should be a crucial component of this endeavor. In this way the data necessary to an informed social policy decision on the relative need for a compensation program could be generated.

ELEMENTS OF A COMPENSATION PROGRAM

Even if the moral argument for compensation is persuasive and the prevalence of research injuries significant, numerous questions remain regarding the design of a morally acceptable program. A leading question involves how compensable injuries are to be defined. The challenge is to isolate those harms to subjects that exceed what would have occurred if they had not participated in research. With regard to nontherapeutic research procedures, the resolution is relatively straightforward. Any injuries that are reasonably related to the interventions should be compensable. Because the procedures are performed for reasons unrelated to the welfare of subjects, any injuries suffered would not have occurred but for their participation in the research.

The problem is considerably more complex in dealing with therapeutic research procedures. Subjects undergoing therapeutic procedures are patients. As patients, they may incur harms from the progression of their disease. In addition, even if they do not participate in a research study, they receive treatments that may cause harm. Therefore it becomes difficult to specify which injuries would not have occurred but for participation in research.

In its recommendations, the HEW Secretary's Task Force proposed the following criterion for compensable injuries:

> Human subjects who suffer physical, psychological, or social injury ... should be compensated if (*1*) the injury is proximately caused by such research, and (*2*) the injury on balance exceeds that reasonably associated with such illness from which the subject may be suffering, as well as with treatment usually associated with such illness at the time the subject began participation in the research (13).

Although intuitively plausible, application of the "on balance" test in the clinical setting presents at least four serious problems. These problems are well-illustrated by clinical trials of cancer treatments, where physical injuries often occur (22).

First, it is frequently not possible to determine whether the disease or the treatment has caused an identified harm. For example, in treating acute leukemia, both the leukemic process and chemotherapy may suppress bone marrow function in a way that disposes to serious infection or bleeding. Second, the "on balance" test relies on a distinction between investigational and standard treatment. However, in some forms of disseminated adult cancer, no standard treatment of choice has emerged. It may not be clear with what treatment an investigational therapy should be compared to determine excess injury. Third, the "on balance" test requires comparison of the overall frequency of various harms and benefits associated with research and conventional therapies. But it is uncertain how to compare incommensurable harms and benefits. For example, does compensable injury occur when an investigational chemotherapy for bone cancer increases the median length of survival by four months but involves a higher incidence of acute hearing loss and severe nausea and vomiting than standard therapy? A final problem is that all chemotherapies for disseminated cancer involve serious risks and fail to achieve remission in a definite percentage of cases. Thus, although the harm–benefit ratio of an investigational therapy in a series of subjects may be less favorable than with standard treatment, it is not possible to determine whether the outcome for a particular subject has, "on balance," resulted in more harm than standard treatment. Thus the President's Commission found that this test for identifying compensable injuries posed "enormous burdens of administration" that could not be justified in light of the less compelling moral claim to compensation of subjects undergoing therapeutic research procedures (14). Of course, if compensable injuries are restricted to nontherapeutic research procedures, these problems are avoided.

A second important issue involves the types of injuries for which compensation will be provided. The HEW Secretary's Task Force recommended coverage for physical, psychological, and social injuries. However, DHEW's interim rule restricted informed consent disclosure regarding the availability of compensation to physical injuries. The President's Commission argued that compensation should focus solely on physical and psychological injuries. The Commission defined "social" injuries as harms to subjects' reputation, personal relationships, or legal status resulting from unauthorized disclosure of personal information gathered in research. It suggested that problems

related to confidentiality could be handled effectively in the prospective review of protocols (14).

The moral analysis of the obligation of compensatory justice provides some guidance in selecting relevant categories of injuries. The principle of justice requires that all persons have equal opportunity to pursue their life plans. Categories of injuries are pertinent if failure to compensate them might seriously compromise the opportunity of injured subjects vis-à-vis other persons. Serious and irreversible physical injuries obviously satisfy this criterion. Likewise serious psychological injuries, such as increased frequency of clinical depression resulting from an experimental drug for bipolar affective disorder, may substantially impair the opportunity of subjects to pursue their life plans. Moreover, even if we restrict "social" injuries to unauthorized disclosure of confidential information, there is no reason in principle to make these injuries ineligible for compensation. Injuries to reputation, personal relationships, or legal status may gravely impair the ability of persons to pursue their goals.

Nevertheless, compensatory justice constitutes only a prima facie societal obligation. Other requirements of social justice, or other compelling social needs may present weightier moral demands on limited resources. These limitations may necessitate that the relative burdens imposed by different categories of research injuries be ranked for funding priority. If the frequency and magnitude of "social" injuries is far less significant in abridging the opportunity of subjects to pursue their life plans, then compensation for these harms may not achieve funding priority.

A third crucial component in the design of a compensation program concerns the nature and extent of benefits for compensable injuries. Benefits might include medical care for injuries, lost wages, monetary awards for pain and suffering, and death benefits for survivors. At present, some academic institutions and pharmaceutical companies provide short-term medical care for injuries incurred by research subjects. With few exceptions, other benefits are not provided.

Our understanding of the obligation of compensatory justice also provides guidance in determining relevant types of benefits. The function of compensation benefits is to restore any deficit in the ability of injured subjects to pursue their life plans compared to citizens who are not injured in research (20). This suggests that benefits should be provided to redress any negative consequences that flow from a compensable injury and that impair the ability of injured subjects to pursue their life plans. These negative consequences obviously include the costs of short-term and long-term medical care, earnings lost due to time in treatment and residual disabilities, as well as loss of income support for families in the event of the premature death of subjects.

However, monetary awards for pain and suffering are more controversial. On one hand, it is clear that pain and suffering may result from compensable injuries and may seriously erode the capacity of persons to pursue their goals. On the other hand, there are practical difficulties in devising a benefits schedule for pain and suffering. One problem is that degrees of pain and suffering can differ substantially for different persons with similar compensable injuries. Another is measuring the pain and suffering experienced by specific individuals. A third problem is that, when pain and suffering is genuinely disabling, much of its harmful impact will be ameliorated by benefits for items such as the cost of medical care and lost wages. Isolating the residual impact of pain and suffering is exceedingly difficult. These problems have led some commentators to suggest that providing compensation for pain and suffering poses insuperable administrative burdens. Nevertheless, one simple solution would be to provide a fixed percentage of the other total benefits as a payment for pain and suffering. This would avoid the administrative complexities of individual determinations, while acknowledging the obligation to rectify its harmful consequences (27).

The status of compensatory justice as a prima facie societal obligation also affects selection of the types and amount of benefits. Other obligations of social justice may limit total government funds that are properly allocated to the compensation of injured subjects. As a result there may be overriding moral reasons for limiting the types or amounts of benefits for injured subjects. Once again, such limitations would require establishing priorities among the types of benefits to be provided.

Another relevant variable in the design of a compensation program concerns the scope of covered research activities. According to Childress, the societal obligation of compensatory justice arises only for research done at the behest of society, as sanctioned through official government agencies (18). This condition reflects the notion that society should redress sacrifices that it compels or encourages for the common good. In accepting this proposition, the HEW Secretary's Task Force recommended that a compensation program cover injuries to subjects in research conducted or supported by the federal government. It also recommended that FDA consider legislation to require compensation in research conducted under regulations for testing the efficacy and safety of new drugs and medical devices (13). The President's Commission agreed that the societal obligation to offer compensation is strongest when the nexus between the government and the research activity is closest. However, the Commission recommended that the pilot compensation program include only research conducted or supported by the federal government, while requesting voluntary participation by private research institutions conducting FDA-regulated research (14). Thus research funded by private philanthropic organizations is not covered by the societal obligation of compensatory justice in the view of either advisory body.

This conclusion can be challenged by reconsidering the factors that determine whether research is conducted with the official sanction of society (1). Privately funded, non-regulated medical research may produce generalizable medical knowledge. The results are typically published in peer-reviewed, academic medical journals. The information is available to other investigators in designing their own research studies. Insofar as the use of these results is permitted in designing research conducted, supported or regulated by the federal government, it might be concluded

that these privately funded research studies are officially sanctioned by society. If this argument is compelling, then equity requires that subjects injured in privately funded medical research be covered by society's obligation of compensatory justice. Legitimate worries about the prospective social control of such research could be addressed by extending the use of institutional review boards to all human subjects research occurring within the United States.

A final critical design variable concerns the source of funding for the compensation program. There are two basic alternatives: governmental or nongovernmental funding. A federally funded program would likely be administered by a government agency, although an alternative might involve provision of funds in research grants for institutions to secure private insurance. Nongovernmental funding would involve statutory or regulatory standards for compensation programs, with research institutions being required to provide benefits through self-insurance, private insurance, or cooperative insurance pools. Some combination of funding might also be possible, with research institutions securing basic coverage for compensation benefits and the government providing backup insurance against catastrophic losses.

There are complex issues regarding what funding mechanism would permit the most efficient and effective administration for a compensation program (28). The moral implications of these alternatives are more limited. If the moral justification for a compensation program lies in its beneficial consequences, then alternative funding mechanisms may create incentives that differentially impact on achievement of these goals. For example, if a compensation program is justified as a mechanism for controlling exposure of subjects to risks and for encouraging surveillance of their safety, then a program in which research institutions purchase private insurance is more likely to provide incentives for safe practice. The costs of coverage for research institutions will depend partly on their success in limiting the frequency and magnitude of compensable injuries to subjects. An alternative moral justification for redressing research injuries is based on a societal obligation of compensatory justice. In this case the primary goal is to ensure that benefits are provided to injured subjects. Funding by the government rather than research institutions is more likely to encourage investigators to assist subjects in identifying compensable injuries and securing adequate benefits. If investigators must worry about institutional expenditures for compensation provided through private insurance, then incentives to discourage legitimate claims are created. The modest level of claims in the few compensation programs funded by research institutions suggests that cost consciousness inhibits advocacy for subjects with compensable injuries.

SUMMARY

Although initial discussions of compensation for research injuries were stimulated by research whose conduct violated the rights or welfare of subjects, subsequent focus has been on injuries occurring without negligence. Numerous government advisory panels have accepted the moral claim that society has an obligation to compensate human subjects for injuries incurred when they assume a position of risk in officially sanctioned research activities contributing to the common good. Despite the intuitive plausibility of this proposition, implementation of a national compensation program has been stymied by a series of vexing issues. The applicability of the obligation to subjects injured by therapeutic research procedures has been widely challenged. A compelling need for a federal program has never been clearly established. Complex issues arise in defining compensable injuries, determining appropriate benefits, clarifying the scope of covered research, and designing a suitable funding mechanism. Implementation of federal regulations for the prospective review of research protocols has substantially reduced incidences in which the plight of injured subjects has received public attention. In an era of shrinking federal programs and without public perception of a palpable need, the prospects for a national compensation program are not promising.

OUTLINE

INTRODUCTION

Our current understanding of human genetic disease is a direct result of family studies research and the explosion of genetic technology over the last half-century. The benefits of this research have been enormous, and range from the discovery of specific genes causing common diseases, such as cancer or heart disease, to a deeper understanding of the mechanics of how environmental factors interact with the human genome or set of genes. However, these advances in genetic technology often alarm the lay public. Indeed, one harsh view is that scientists "have given no more thought to the potential social applications of genome mapping and sequencing than Victor Frankenstein had given to the consequences of creating his monster..." (1, p. 660). Nevertheless, a revolution in biomedical technology and genetics has taken place in recent years, so that genetic studies based on family research are now the mainstays of biomedical research.

The genetic revolution now enjoys governmental support through the Human Genome Project (HGP) (2), a large international effort to sequence and map each of the 24 human chromosomes as well as to understand the underlying genetic variation and function of the genome (3,4). Indeed, HGP is a monumental undertaking that seeks to unravel the human "genetic code" discovered only 47 years ago by Watson and Crick (5). Francis Collins, the current head of the National Human Genome Research Institute (NHGRI) in the National Institutes of Health (NIH) describes HGP as the "single most important project in biology and the biomedical sciences — one that will permanently change biology and medicine" (3).

Both supporters and detractors of HGP predicted that this undertaking will have unprecedented effects on the social fabric of the human community (1). In response to these concerns, the analysis of the ethical, legal, and social implications of this new genetic knowledge has become a vital component of HGP. According to Eric Juengst, the

first chief of HGP's Ethical, Legal and Social Implications (ELSI) branch (italics added):

> . . .the Human Genome Project represents geneticists' growing ability to explore human heredity. It thus generates a wide range of charged questions about how our society's genetic explorations should proceed and how their results should be used. These questions include a set of *unresolved issues regarding the conduct of research involving human subjects*. While these issues predate the Human Genome Project and would continue to exist without it, they are becoming increasingly important as genomic tools and *genetic strategies become pervasive* in biomedical research (6, p. 401).

Juengst and others have thus identified two essential themes for human genetics research (6,7). First, researchers who conduct genetic studies will face new ethical challenges that will require the implementation of specific strategies in the study protocol addressing these issues. Second, because more common diseases and traits will be studied in the future, genetic research will increase in scope and complexity (6,8).

Many human genetic studies such as gene-searching projects sponsored by HGP are based on the analysis of the family group. These are collectively known as pedigree or family studies and are an integral component of modern genetic research. Family pedigree studies were previously considered to have little, if any, inherent ethical conflicts by researchers in the field because the studies were often based on observations of a rare condition in a small number of families. In joining a proposed research study, these families were eager to discover the genetic link to their condition, and often worked closely with the research team. The potential impact of this research on such rare conditions was limited to a few families with these unusual disorders. In contrast, present day family pedigree studies are often focused on the familial nature of common diseases and are conducted on a national and international scale. Thus these studies can potentially impact many more people in communities across the country. Contemporary family pedigree projects are a hybrid between standard epidemiological research and molecular analysis of gene function, in which large numbers of individuals and their family members are enrolled to identify genes that cause human disease.

A crucial difference between family pedigree studies and other biomedical research lies in the collection and analysis of information on family groups rather than unrelated individual volunteers (9). Epidemiologic protocols analyze clinical information on a large number of cases, and thus the risks and benefits of these studies stem from the potential impact on an individual volunteer. In contrast, in family pedigree research, the information gained from one family member can lead to consequences for other family members (6,9). Holtzman and Andrews further argue that genetic research "is different because it often involves testing, and thus *creates* genetic information about individuals and groups that did not exist before" (10). Thus the ethical issues arising from family pedigree research may be inherently more difficult for researchers in the biomedical community. This difficulty may stem from the lay public's view of genes and heredity. Henry T. Greeley, professor of law at Stanford University writes:

> Rightly or wrongly, many people are convinced that genes are special, that they contain and reveal a person's, or a people's, essence, which has enormous value, spiritual and commercial. This exaggerated emphasis on the importance of individual genetic variation makes human genomic research particularly sensitive (11, p. 625).

Participating in genetic research can have significant psychosocial consequences for research volunteers (10). By simply enrolling in a pedigree research study, participants may experience unforeseen psychosocial anxiety and depression. These feelings stem from concern over the propensity to develop a disease, potential genetic discrimination, and the consequences of medical decisions based on perceived risk for disease (6,7,10). Human geneticists who study rare monogenic disorders have recognized these psychosocial issues for many years (12). Current and future researchers aided by the enormous growth in genetic research will focus on common disease processes. In this way a greater proportion of the general population could potentially learn they are at risk for health problems because a relative participated in a family pedigree study. Thus the potential for unforeseen harm to participants and their family members will increase, as genetic family-based studies become more prevalent.

The explosion in the number of family pedigree projects has generated a lively debate in the biomedical community as to the proper ethical conduct of genetic research. Most ethicists agree that the Belmont Report defines the moral guidelines for researchers who enroll human subjects in biomedical research. The three overarching principles contained in this document are respect for persons, beneficence, and justice for human subjects (7,13). However, the authors of the Belmont Report did not specifically address issues relating to use of genetic material and the potential impact of family pedigree research. Several organizations, such as the American Society of Human Genetics (ASHG), the National Bioethics Advisory Commission (NBAC), and the Institute of Medicine have recognized the need for a standardized policy for the conduct of genetic research (14–18). The Institute of Medicine's Committee on Assessing Genetic Risks summarized the relevant ethical principles for genetic research subjects and recommended "vigorous protection be given to autonomy, privacy, confidentiality and equity" (15).

Using unconfirmed research findings in medical decision-making is also a major ethical concern for genetic researchers and has prompted several policy statements by interested groups (17,19). This issue gained national attention in the mid-1990s when BRCA1, the first susceptibility gene for early-onset breast cancer was identified and cloned (20). Most researchers and lay persons viewed the application of genetic markers to forecast the risk of future disease as a positive advance in biomedical sciences (21). However, some groups felt that health decisions based on unsubstantiated genetic research without confirmatory clinical trails could be harmful. Recognizing the uncertainty arising from the

use of the new genetic BRCA1 research results, ASHG strongly advised (italics added) "it was *premature* to offer population screening" for BRCA1 gene testing (17). This issue has been raised with other gene discoveries, such as the ApoE link with Alzheimer's disease, since the health implications of genetic research are not limited to breast cancer research (22). Most authors now recommend that genetic results should ideally be provided within the context of clinical care after the health implications are studied, although the pressure to hasten the transition of new genetic findings into the medical arena is pervasive (17,23,24). The blending of scientific discoveries with the potential health benefits of the new research represents a potential conflict for human genetic researchers, who are then cast in the dual role of healer and scientist.

The time is long past when scientists were able to conduct genetic research involving individuals and their families isolated from the ethical and social impact of the research process and eventual findings of the study. In discussing the transition of research findings to patient care, Ray White from the University of Utah states:

> Human geneticists have a problem. Finally, after years of effort, we are beginning to resolve and identify the genetic components of a number of genetically transmitted disorders and predispositions. On the eve of this scientific triumph, however, at a time when we should be delivering this new knowledge to affected individuals, we have instead discovered that this delivery is compromised by social, economic, and ethical issues (25, p. 173).

It is thus imperative to incorporate ethical strategies into all aspects of study design. These strategies should consider the ascertainment of subjects and family members, information supplied to study participants, control and databasing of study data, disclosure of results, publication of data, and communication among researchers.

This article addresses the many ethical dilemmas faced by genetic researchers who perform family pedigree research. There is a growing realization that conflicts arising from family studies will be encountered in other types of genomic research projects. These genomic studies explore a variety of genetic topics such as the translation of genetic discoveries into clinical practice or analyses of genetic variation between specific human ethnic groups and subpopulations (26). Thus equal attention to the medical and psychosocial impact of the genetic research must continue in parallel with the exciting biomedical and genomic research of the future.

GENETIC RESEARCH ON HUMAN POPULATIONS

A major goal of genetic research is to understand the hereditary factors that cause human disease. Studies based on the family unit have been essential to this research over the last half-century and will continue to form the foundation for future investigations (27). Several older methods, such as twin and family pedigree studies, were developed before the introduction of molecular technology, emphasizing the notion that important genetic information can be gleaned from an individual's family history alone. Geneticists then developed sophisticated study methods, such as linkage analysis and marker association studies, to exploit newly discovered molecular markers for the analysis of family information. While the types of analyses and research goals differ, a common feature of these study methods is the collection and statistical analysis of a trait, or phenotype, in multiple family members. Although most biomedical genetic research focus on specific disease process, the amount of clinical information gathered from each family member and the extent of the family history is variable for each study design (Table 1). For example, twin studies gather complete information about both twins but may not collect information about other relatives. In contrast, family pedigree or linkage studies collect clinical information about many members in the extended family.

Twin studies have been used extensively by researchers to support or refute the genetic nature of a specific disease process or physical attribute, such as height. This method compares the prevalence of a disease in identical or monozygotic (MZ) twins and in fraternal or dizygotic (DZ) twins. Since MZ twins share 100 percent of their genetic material, it is logical to expect that both members of an MZ twin-pair would develop the condition if an underlying gene causes the disease. However, both members of a DZ twin-pair would be less likely to be affected as they only share about 50 percent of their genes. This approach is the basis of a 1991 twin study demonstrating a strong genetic component for the development of asthma (28). MZ twins participating in the study both suffered from asthma or allergies 80 percent of the time compared to 0 percent of the DZ twin volunteers. This asthma study illustrates that genetic information can be gained from the analysis of phenotypic and family information alone, since the researchers did not analyze genetic material from the twin participants.

The risk of a family member developing a specific disease can also be estimated from family-based studies without the analysis of DNA markers. One example of the clinical usefulness of family information is from the

Table 1. Types of Human Studies Used by Researchers to Determine the Genetic Component of Human Disease

Study Design	Human Subjects	Use of Family Information	Use of Genetic Material
Twin	Monozygotic and dizygotic twins	Minimal	No
Segregation analysis	Multigenerational families	Extensive	No
Linkage analysis	Multigenerational families	Extensive	Yes
	or		
	Relative pairs (i.e., sibling pairs)	Immediate family members	Yes
Molecular epidemiologic	Individual cases and nonrelative controls	Minimal	Yes

National Polyp Study, a multicentered clinical trial that examined family history as a risk factor for colon cancer (29,30). The study showed that a family history of colon cancer and colon polyps increased the risk of developing colon cancer two- to threefold over cases with no family history of the disease (30). This study compared the trait in question in affected persons to the occurrence of the trait in biological family members. Importantly, the results from this study were then used to develop risk profiles for colon cancer, illustrating the far-reaching effect of genetic research in clinical practice.

Researchers use the twin and family history study methods to investigate whether hereditary factors play a role in a particular condition, but these studies cannot be used to establish a pattern of inheritance based on Mendel's laws. Family pedigree studies are required in order to determine whether a trait is segregating in a specific pattern of inheritance in the pedigree. Most hereditary conditions typically follow an autosomal dominant, autosomal recessive, X-linked dominant or X-linked recessive pattern, although nontraditional patterns have been described. In order to determine the inheritance pattern or segregation of a gene or trait in a family group, researchers must rely on studies of the extended family (27). An essential ingredient of such studies is the construction of a family tree from the proband or other informants that includes detailed information about affected and unaffected family members over several generations. The research group then uses this multigenerational information to examine whether a gene is responsible for the trait segregating in the affected kindreds. This type of study, called segregation analysis, is a genetic epidemiological research method designed to measure the likelihood, or chance, that a hereditary factor causes the trait or disease in question (27,31). Because entire family groups are analyzed, segregation analysis can determine the inheritance pattern of a disease. This type of study is often the first piece of evidence tying hereditary factors to a disease process. For example, segregation analyses of several hundred families with breast cancer in the female relatives first suggested the existence of a gene or genes responsible for familial breast cancer (32). On the basis of these studies, researchers were then able to estimate that the gene would be carried by 1 in 500 individuals and would be transmitted as an autosomal dominant trait to other family members (33,34). Likewise segregation analyses showed that a major gene segregating in high-risk families most likely caused Hirschsprung's disease, a form of congenital megacolon (35).

Neither twin studies or segregation analyses are used to identify the exact gene causing a particular disease. However, the chromosomal location for the disease-causing gene can be found when family pedigree information is jointly analyzed with genetic markers, or molecular signposts, from multiple members of a family (36). This powerful genetic method is called linkage analysis because statistical tests are used to "link" the disease exhibited by affected family members to known molecular markers found at regular intervals along each human chromosome. These markers are now easily analyzed in a small sample of genetic material, or DNA, from the person being tested. Since the researchers know the chromosomal location of each marker, the disease-causing gene can be "mapped" to a specific genetic region. Linkage studies, otherwise known as mapping studies, rely on the ability to distinguish between a chromosomal region inherited from one's father and the same chromosomal region inherited from one's mother. The strength of this type of study stems from the ability to track these genetic regions between the parent and child within the family. One of the important advances in molecular technology has been the development of highly informative molecular markers for genetic mapping studies that allow the researcher to distinguish the paternal and the maternal copies of a particular genetic region.

Up to 400 separate genetic markers can be used to blanket the entire genome for mapping studies searching for disease causing genes. The markers can be used for candidate gene analysis or whole scale genome scan. Candidate gene analysis is used when the researcher suspects a known gene causes the disorder. The researchers must also know the chromosomal location of the suspected gene, and will test markers that are physically close to the suspected gene. In contrast, a genome scan is used when the location of the gene or genes is not known. These scans test numerous polymorphic markers diffusely located across the entire genome, resulting in the generation of enormous numbers of genotypes derived from each individual and family group.

Several computational methods are employed for linkage analysis each differing in the amount of family information required for the study. Thus the family groups used for linkage analysis range from large multigenerational kindreds to a smaller number of relatives, such as the affected sibling pairs method (31,36). Contemporary family pedigree linkage studies are thus very complex and require experts from a wide variety of disciplines in order to be successful (9). Model-dependent linkage analysis has been very successful in identifying the genes causing many diseases, such as cystic fibrosis, breast cancer susceptibility, and Huntington's disease. In this study design, clinical and genetic information on multigenerational families are studied under assumptions of monogenic autosomal recessive or autosomal dominant inheritance. The results are provided in a log of odds (LOD) score that signifies whether the genetic region is linked or unlinked to the disorder under study. Model-independent methods have also been developed that analyze the genotypes of pairs of family relatives, such as sibling pairs, or parent–child pairs. LOD expresses the chances that a marker is associated, or linked, to the phenotype under study. LOD scores of greater than three signifies that a particular marker has 1000 to 1 odds of occurring by chance alone and is generally used as evidence for linkage. A LOD score of negative 2 or less is generally accepted as evidence against linkage, and LOD scores between 3 and negative 2 is considered unclear for linkage (36).

The components of a linkage study are diagramed in Figure 1 and consist of family recruitment, molecular laboratory, and statistical analysis groups. The recruitment

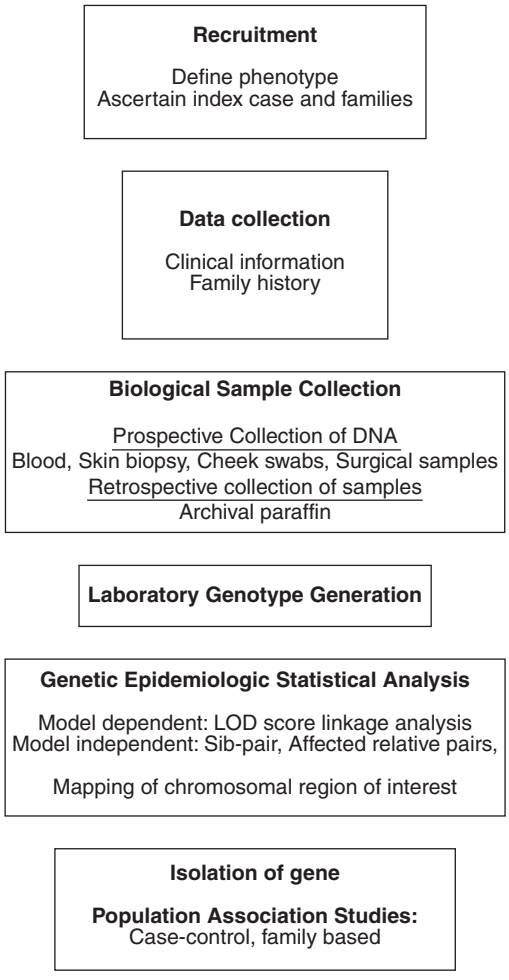

Figure 1. Components of a genetic pedigree or linkage study.

component includes experts in family contact, medical information retrieval, and sample collection. The laboratory component includes technical experts in sample processing and molecular analysis. Experts in genetic epidemiologic methods then carry out the linkage analysis in the statistical analysis component. All these components must be coordinated so that the medical, family, and genetic information can be used to identify disease-causing genes. The common feature of family pedigree linkage studies is the analysis of clinical information and blood samples from several family members in order to assess whether a genetic region is linked to the disease under study.

After a linkage study identifies a possible chromosomal location of a disease-causing gene, the gene is then isolated and identified with more refined genetic techniques and analysis, including positional cloning and sequencing (37). A full explanation of these techniques is beyond the scope of this chapter, except to note that genes are analyzed by a number of technologies. One method, called *DNA sequencing*, determines the exact order of the chemical building blocks, or nucleotides, of the gene. DNA sequencing also allows the researchers to identify genetic changes in an individual compared to the usual sequence found in the general population. Some of these changes are true deleterious mutations in the genetic code, in that the normal function of the gene is altered in the person carrying the mutation (37). However, other gene changes, called *polymorphisms*, may not have real functional significance. Polymorphisms in DNA sequences are very common and are thought to have little impact on human diseases.

Determining whether a gene change is a deleterious mutation or a polymorphism is a common problem for genetic researchers. If a potential polymorphism or mutation is found in a putative disease-causing gene, researchers use several techniques to determine the true effect on gene function. One of these techniques is to study multigenerational families with the disease to test whether the gene change correlates with the phenotype of affected individuals. A second method for researchers to study the phenotypic effect of a potential mutation is to perform molecular association studies examining the occurrence of the genetic marker in larger populations. The goal of these studies is to correlate the potential mutation in groups of unrelated affected and unaffected individuals (38). While most molecular epidemiologic studies do not use information about family relatives, these studies collect and analyze biologic samples for DNA analysis. Molecular epidemiologic studies illustrate the expanding role of genetic techniques in biomedical research, which can be used to provide information about disease-related risks in clinical practice. As knowledge about the human genome increases, future studies will focus on the interaction of several genes as well as the interaction of specific genes and environmental influences as necessary steps for disease development. Thus the methodology and technology of genetic research will become more complex in the future.

Accurate family data and information is the first necessary step in understanding human hereditary. As HGP nears its goal of determining the exact DNA sequence of the human genome, gene identification will be streamlined so that the causal genes will be identified at a faster rate in the future. Indeed, many genes will be identified without knowledge of the biological function or role so that researchers will continue to rely on family participation to understand the gene function in the population. Thus, with the advent of DNA markers for linkage analysis and genomic research, family studies have become the workhorse of modern genetic discovery. While future genetic research will continue to study rare monogenic disorders, the research focus will shift to include the study of genes that contribute to more common diseases, such as cancer, diabetes, cardiovascular disease, and aging. In this way family pedigree studies will then become more pervasive in the biomedical community (6).

POTENTIAL HARMS FOR SUBJECTS ENROLLED IN FAMILY PEDIGREE STUDIES

The wealth of information derived from genetic research is unprecedented and has given the biomedical community many new tools to understand and treat human disease. Genetic studies are no different from other forms of biomedical research, in which the benefits should outweigh

the potential harms to each volunteer. However, as Phillip Reilly notes, "that gene-discovery studies posed the threat of genetic discrimination — that there is a risk of *informational harm* associated with participating in studies that elicit genetic information from which one might infer health status" (39, p. 683). This "informational harm" is different from the usual physical harms that may result from participation in other types of biomedical research, such as clinical trials of new treatments or drugs. Informational harm from genetic research may cause emotional or social difficulties for research volunteers, including the impact of new genetic knowledge on health risks, family dynamics, and possible social stigmatization. Participants in genetic family pedigree studies are also at risk for unintended consequences of the research process. These unintended consequences can include misidentified parentage, learning private information about a family relative, having a research sample entered in additional studies without their knowledge or consent, or finding risk for additional diseases not part of the initial study (9,10,40).

Genetic Discrimination

Genetic discrimination is viewed by the general public as a major threat for individuals who enter genetic research studies (39). In particular, there is concern that genetic information obtained through the analysis of human tissue samples could be used to discriminate against individuals by insurers or employers (41). While the fear of stigmatization has generated a national debate on genetic privacy, it should be noted that few studies have scientifically examined this issue (14,42,43). In one of the first studies to document the occurrence of employment stigmatization and insurance abuse, Billings and colleagues reviewed 41 separate instances of discrimination submitted by genetic professional and patient advocacy groups (44). These authors defined genetic discrimination as "discrimination directed against an individual or family based solely on an apparent or perceived genetic variation from the 'normal' human genotype" and concluded that genetic discrimination is found in many social institutions (44). This report was controversial, as representatives of the health insurance industry argued that the number of discrimination reports were relatively small compared to the thousands of policies issued every year on a national basis (45). Other groups felt the reported instances of discrimination were primarily anecdotal and unsubstantiated by the authors, or that the cited examples did not conform to the authors proposed definition of genetic discrimination (46).

Nevertheless, the level of concern about potential discrimination is very high as shown by a 1997 study of over 1000 geneticist and primary care physicians, who reported over 550 instances of employment or life insurance refusal (43). This report echoes the sentiments of 332 members of the genetic support groups affiliated with the Alliance of Genetic Support Groups (47). This survey documented that up to 43 percent of respondents felt they experienced some form of discrimination by health insurers, life insurers, and employers, including refusal of life or health insurance or employment denial. There is also concern over genetic discrimination on an international level, as evidenced by a similar survey of genetic support groups in the United Kingdom. This survey found that one-third of the study respondents had difficulty when applying for life insurance compared with 5 percent of the control participants (48). The respondents who perceived themselves as suffering from discrimination reported that they experienced rate increases or outright refusals for insurance.

It must be remembered that the public's fear of genetic discrimination is not unfounded, as past abuses and stigmatization based on eugenics and physical disabilities are a matter of public record (1). In the United States these abuses ranged from the forced sterilization programs for persons with physical disabilities to the ill-advised sickle cell anemia screening program for African-Americans (15,49). Holtzman and Rothstein point out that the sentiments of the eugenic movement in the early part of this century still resonate in today's social institutions (50). In fact a 1998 U.S. government report estimated that 15 percent of employers plan to inquire into the genetic status of employment applicants (14). Thus the fear of marginalizing individuals on the basis of their unique genotype prompted policy review and recommendations on a federal level. Several governmental working groups and special commissions have been established to formulate specific policy agenda items relating to the social impact of genetic information (14,51). One of the first working groups was the Task Force on Genetic Information and Insurance sponsored by NIH and Department of Energy (42,51,52). NIH charged this group with studying the social implications of genetic discrimination by health insurance companies. Their 1993 report warned "people will be asked to provide information about their genetic risks to insurers" (51). The Task Force also noted that the risk of losing health insurance coverage for "preexisting" conditions may prevent people from obtaining predictive genetic information that could be used to improve the health and welfare of the person and family.

The Task Force concerns were based on the health insurance risks for people with a genetic condition or a family history of the disease, and most instances of documented discrimination have followed genetic diagnoses made in the clinical setting. However, some authors have suggested that study volunteers might also be required to disclose results from genetic studies in the research setting (53,54). Thus genetic information gained through voluntary participation in a family pedigree study might place the subject at risk for economic harm. This is an issue of *distributive justice* according to Thomas H. Murray, who writes that:

> Human genetics is, from this perspective, a science of human inequality. The principal ethical problem created by such scientific pronouncements of human difference is the task of reconciling such differences with our central moral, political and legal commitments to treating people as equals. That is, we must reconcile the ever-increasing evidences of human inequality with our vital commitment to moral equality (55, p. 80D).

For the research community it is essential to recognize the potential harms of genetic discrimination due to the scientific process. Researchers should develop appropriate study protocols to alert research participants to the possibility of informational harm. However, the magnitude of this risk is currently unknown, and may be part of an "urban myth" (56). A recent abstract presented to the plenary session of the 1999 ASHG national meeting found little evidence for genetic discrimination in a review of applications to 143 health insurance agents (57,58). In addition the study found no indication that insurers were using genetic information for health prediction and risk stratification. However, there have been no systematic surveys of the underwriting practices of life or disability insurance providers, hiring practices of employers, or services provided by social agencies such as housing or adoption. Thus the extent of insurance and employment discrimination based on genetic grounds is currently unknown. The research community must remain vigilant as to the potential economic and social harms to their study participants from inadvertent or premature disclosure of results from genetic studies.

Impact of Susceptibility Gene Identification

Pedigree linkage studies have been very successful in identifying genes responsible for human disease. Physicians are now able to use newly developed DNA tests to diagnose a suspected genetic condition, illustrating one of the benefits of genomic research. One important example in which a gene-based test has supplanted older biochemical testing is RET gene testing for multiple endocrine neoplasia type 2 (MEN2) (59). Gene carriers of this autosomal dominant condition have a 90 percent chance of developing medullary thyroid cancer, a potentially lethal cancer that can strike in childhood and early adulthood. Ninety-five percent of all cases of MEN2 are caused by deleterious mutations in the RET gene. A highly accurate DNA test for MEN2 is commercially available and has replaced the older biochemical calcitonin test used to diagnose this disease. DNA testing can be now offered to healthy at risk family members to determine if they also have a RET gene mutation. RET gene testing also illustrates the benefits of family pedigree research, in that genetic scientists used information from family pedigrees to identify a gene causing lethal thyroid cancer, paving the way for a simple medical test for the entire community. It should be remembered, however, that in order for such studies to be successful, many human volunteers donated their clinical information and blood samples to scientists studying MEN2. In addition volunteers helped the researchers to develop the clinical standards of care before the test could be provided to the general public.

While RET gene discovery is a clear example of the benefits of gene discovery, it is important to recognize that genetic tests are not absolute predictors of health or disease (40). This notion is in stark contrast to the commonly held view of genetic determinism, which suggests a person's genetic makeup is an unalterable blueprint for the future. Genetic determinism ignores the interaction of multiple genes, or environmental factors in developing disease (6,40,60). In addition proponents of this view neglect the underlying uncertainty about the health risks associated with susceptibility genes, in that the risks are more probabilistic in nature rather than an unequivocal link to the development of disease (6). The probabilistic health risks are true even for highly accurate gene tests, such as RET testing for MEN2 where most, but not all, gene carriers will develop thyroid cancer.

An additional reason that a person's genetic code can not be equated with a predetermined outcome comes from an understanding of the mechanism of action for deleterious genetic mutations. A deleterious mutation alters the expression of a single protein product produced by the cell. However, the cell may have several pathways that provide the same function, so that the effect of the deleterious mutation can be masked by the normal proteins encoded by other genes. Thus a one-to-one correspondence between gene mutation and phenotype, which is termed the *genotype–phenotype correlation*, is rarely seen for common conditions due to the complexity of the biological cellular pathways encoded by the genome. As such, disease-causing mutations will usually produce a recognizable phenotype. However, other gene changes, termed *susceptibility genes*, act to increase the propensity for the development of disease. Environmental factors are thought to interact with susceptibility genes to cause a specific disease. Thus the phenotypic effects of most genetic alterations falls somewhere on a continuum of risk for disease rather than an absolute cause of disease.

While categorizing mutations as disease-causing or susceptibility-causing is helpful in describing the potential effect of gene mutations, these labels are overly simplistic and thus are poor predictors for clinical disease. For example, individuals with neurofibromatosis type 1 (NF1) harbor a deleterious "disease-causing" copy of the NF1 gene on chromosome 17 (61). However, when the clinical phenotype of individuals with NF1 are compared, some exhibit the typical skin neurofibromas as teenagers, while others never develop this type of skin manifestation (62). This variation of clinical phenotype is known as *variable expression* of the gene and is thought to be a result of the interaction of the NF1 gene with unknown genetic or environmental factors. Nevertheless, the NF1 gene is fully penetrant. In other words, 100 percent of individuals who carry a deleterious NF1 gene mutation will exhibit symptoms of this disorder to some degree. However, because of variable expression, persons carrying a deleterious NF1 gene may exhibit very mild to severe health problems.

In contrast, other susceptibility gene mutations, such as mutations in BRCA1 and 2 breast cancer genes, will increase the propensity to develop breast, ovarian, or other cancers. Researchers estimate that between 50 and 85 percent of female BRCA1/2 gene carriers will develop breast cancer at some time in their lives, compared to general population risk of approximately 10 percent (63). In other words, since BRCA1/2 gene mutations are not fully penetrant, up to half of female gene carriers will remain cancer free and will be unaffected by their constitutional genotype. Other changes in genes, such as metabolic polymorphisms, are associated with minor functional effects of the protein product and can have

mild to moderate effect on the risk for disease. One well-known example is the CYP gene family, which is associated with differing ability to metabolize drugs and medications and other ingested compounds. Several studies have shown metabolic polymorphisms are linked with an increased rate of cancers due to the differing metabolic rates encoded by the different CYP genes (38,64). Most experts caution against the use of such polymorphisms for risk prediction, but the pharmaceutical industry has recognized that these polymorphisms will be important in drug development and have invested heavily in this area of pharmocogenetics (65).

Identifying disease-causing genes will continue to be enormously beneficial in the clinical setting. However, in the research setting, there is a growing recognition that gene identification can have harmful effects on participants and their families. Researchers may find themselves in a situation in which the very success of the project can have a negative impact on the participating individuals and family members. The major liability of pedigree studies stems from the inference of health states from the untested genetic discoveries. Volunteers may receive preliminary and unproven health information about a specific genetic marker, since the necessary follow-up studies on the function and clinical impact of the newly discovered gene have yet to be conducted. Thus there is a potential for research volunteers to receive preliminary, incomplete, and potentially harmful information from participating in pedigree research projects. In addition participants may never learn about important future developments in clinical trials or may learn about important health risks months to years after entering a study. It should be noted, however, that there is little evidence documenting harm to volunteers from genetic research at this time.

Volunteers for genetic pedigree studies are thus participating in the first step of scientific discovery in which there is a potential for finding disease-causing genes. However, since genetic mutations cause a wide range of phenotypic effects, researchers must use discretion when deciding whether to disclose preliminary study results to volunteers. In some cases the participant may wish to be informed about their genetic result prior to the completion of clinical trials. The researchers may also wish to share the experimental results with certain participants believing that more harm would come from withholding research results (6,66). Disclosing research results is a difficult dilemma, placing the researcher's duty to nonmaleficence in conflict with the subject's autonomy. The potential uses of genetic testing for disease prediction was the overriding concern of the researchers who released premature BRCA1 genetic results to a young woman intending to undergo a prophylactic mastectomy based on her family history of breast cancer (66). After being informed of her genetic research results, she found that she did not carry the family's high-risk gene mutation and was able to avoid prophylactic surgery. Before providing her with these results, the researchers weighed the potential psychosocial harms of releasing untested preliminary information with the harm of undergoing an unneeded medical procedure. The researchers were also concerned about alleviating the anxiety associated with genetic risks for disease. Anxiety and concern about health risks are well-recognized among family members at risk for Huntington's disease, Alzheimer's disease, and familial cancer syndromes (67).

Other researchers have cautioned that experimental findings from genetic studies should not be disclosed to the research subjects. The Children Cancer Group declined to disclose individual genetic research results to the physicians and parents of children enrolled in a genetic study of the p53 gene and childhood osteosarcoma (68). The p53 gene had been identified as the cause of cancer in families with the Li-Fraumeni syndrome in which multiple family members with osteosarcoma, leukemia, adrenal carcinomas, and other tumors (69). After careful consideration, this group chose to publish the genetic test results only in aggregate, as originally planned. They cited the lack of proven clinical utility of constitutional p53 gene mutations in nonfamilial cases, the potential for stigmatization and discrimination, and the subject's age as minors as factors in their decision. This group and other authors are concerned that predictive knowledge can be emotionally burdensome and can stem from knowledge of the family history as well as known carrier status from genetic testing (6,70). Thus the potential harm to research subjects from genetic knowledge cannot be neglected, and must be weighed when researchers are confronted with requests to divulge genetic research information.

Unintended Consequences of the Research Process

The problem of unexpected detection of new or secret information is also a concern for researchers who conduct family pedigree studies. The discovery of such knowledge by the researcher is an "unintended consequence" of the scientific process since this information is not related to the research goals of the study. This unexpected information can surface as a result of molecular analysis of the family blood samples and generally involves the inadvertent discovery of information that may not be known by all members in the family. For example, a serious, yet unintended, finding in genetic research is the discovery of mistaken parentage for a study volunteer, such as in nonpaternity or secret adoption. Since linkage analysis is dependent on distinguishing the maternal and paternal copies of each genetic marker, researchers can easily identify inconsistencies in the family when tracking the marker from parent to child. In this way the transmission of genetic markers is followed through subsequent generations and a family secret could potentially be discovered. While discrepancies in genetic markers can result from laboratory sample mix-up or other technical mistakes, a significant proportion is due to nonpaternity.

The rate of nonpaternity is estimated to be between 2.8 and 28 percent depending on the population group under study (71–73). While accurate figures are not known, it is not uncommon for researchers to confront this situation in family pedigree studies. Juengst outlines the dilemma of such a nonpaternity discovery for a research team studying a rare skin disorder (70,74). Subsequent publication of the pedigree revealed inconsistencies in the parental

genetic markers showing nonpaternity in two children in the kindred. Reilly also described a situation in which nonpaternity was discovered in a gene–mapping family study (75). Following discussion with outside consultants, the researchers decided that they would not disclose this sensitive information to the family. In addition this group chose to omit the details of parental inconsistencies in a subsequent publication (75).

Another unintended research finding is the discovery of a genetic mutation associated with a risk or susceptibility for a disorder that is distinct from the original focus of the study. In this way a person may be surprised to find that they are at risk for unforeseen health problems. In fact this type of incidental finding has occurred in genetic studies of common health problems, such as cardiovascular disease, as well as studies involving rare disorders, such as Hirschsprung's disease. Greely summarized this complicated aspect of genetic research by stating:

> One gene may be associated with multiple diseases. Therefore, a person who takes a genetic test to learn something about one disease may end up with information, possibly unwanted or harmful, about another disease (22).

Cardiovascular researchers have known for years that carriers of some forms of ApoE, a lipid transporting protein in the circulating blood stream, moderately increases the risk for heart disease. Many people underwent ApoE screening on a research and clinical basis to determine if they were at a greater risk for cardiovascular problems. In 1993, a surprising association was made between the APOE gene and the risk for Alzheimer's disease, where APOE4 carriers were two to three times as likely to develop dementia later in life. Individuals who accepted ApoE testing in the context of their cardiovascular health then discovered, perhaps unwillingly, information regarding their risk for Alzheimer's disease later in life (reviewed in Ref. 22).

A similar dilemma occurred when researchers attempted to isolate the genes involved in Hirschsprung's disease, or congenital megacolon. As early as 1982 families with Hirschsprung's disease and a rare form of medullary thyroid cancer were identified (76). Medullary thyroid cancer is one of the cardinal features of MEN2 and can develop in young children or in early adulthood (59). As previously discussed, the gene responsible for MEN2 is the RET gene located on human chromosome 10. In 1994 linkage studies based on families with multiple cases Hirschsprung's disease found that one of the genes causing this disease was localized to chromosome 10 at the same location as the RET gene (77,78). Further studies confirmed that mutations in the RET gene were also responsible for some familial cases of Hirschsprung's disease (79,80). Volunteers in Hirschsprung family studies were identified to be at risk for a lethal form of thyroid cancer in addition to the childhood form of megacolon. Thus the APOE and RET gene discoveries were complicated by the unexpected detection of an increased risk for more than one disease process, each with different health implications.

Entire subpopulations can also be identified to have unforeseen health risks as an unintended consequence of the research process. One example of this is the identification of three founder mutations in the BRCA1 and BRCA2 genes in the Ashkenazi Jewish families with breast and ovarian cancer. Population studies subsequently found that three specific mutations, 185delAG and 5382insC in BRCA1 and 6174delT in BRCA2, are carried by about 2 percent of all Ashkenazi Jews regardless of a history of cancer in the family (81). Female carriers of any one of these mutations have a 50 percent chance to develop breast cancer as well as a 20 percent chance to develop ovarian cancer over their lifetimes. The effect of this gene discovery on people with Ashkenazi Jewish ancestry has been immense, since an entire ethnic subpopulation learned that certain members are at a higher risk for cancer (42,82). Because of the high prevalence of these founder mutations, some feel that strong consideration should be given for genetic testing for breast cancer risk based on Ashkenazi Jewish background. Others feel stigmatized by this discovery. Thus, because of family pedigree research and gene discovery, the autonomy and decision making for individual members of this subgroup was subverted. The unexpected detection of disease-causing genes will become a prominent issue for genetic research, as gene discovery in identifiable populations will become more prevalent in the coming years (26).

Breeches of Confidentiality

Researchers using clinical and genetic material from human subjects have a duty to respect autonomy and privacy of each participant (14). As previously discussed, this becomes problematic when the context of the study is the family unit in that "family secrets" such nonpaternity or private difficulties can be inadvertently disclosed to other family members, co-investigators, personal physicians, or employers (6,83). Since genetic linkage studies are generally multifaceted (Fig. 1) and composed of several discrete areas of expertise, the possibility of inadvertent disclosure through the process of the study is a distinct possibility. For example, recruiters for genetic studies may ask, with the participant's permission, to gather medically related materials from the subject's personal physician and medical file. Researchers conducting a linkage study for colon cancer susceptibility genes learned that a subject's personal physician noted in the subject's medical chart that the patient was "in a genetic study for colon cancer" (84). This illustrates the dissemination of information about study volunteers due to the interaction with healthcare workers rather than from the results or knowledge directly gained from the study. Likewise the research team may include identifying information about the participants in reports and data analysis generated by the study, leading to the suggestion that only some investigators in the research project team should have access to sensitive materials.

Once several family members enter a family pedigree study, considerable care must be taken to ensure that medical or genetic information of one family member is not accidentally revealed to other relatives. Researchers must keep in mind that individual family members expect their information to remain confidential, since there may be " family secrets" shared with only a few members in the

kindred (9,83). Psychiatric research is one area of genetic research in which inadvertent disclosure is a concern as the clinical data collected on family members may include potentially stigmatizing information. Clinical information is not always freely shared among family members and can include the severity of psychiatric symptoms, alcohol or drug abuse, or criminal activity. Indeed, researchers may have to share background information about the proband when enrolling other family members in a family pedigree study. Thus some information may not remain private. Juengst notes, for example, that it is particularly difficult to approach a distantly related family member about enrolling in a psychiatric linkage study without sharing the fact that someone in the family is affected with a psychiatric disorder (6). In these cases Shore and colleagues feel that "Subjects will need to be informed, when agreeing to participate in genetic research, that their relatives may also be asked to participate as subjects. It should be made clear to psychiatric patients whose relatives will be contacted exactly what information about a subject will be provided to those relatives" (83).

Family registries and databases of genetic material are rapidly increasing in number. NBAC estimates that over 282 million specimens of human biological materials are currently stored in the United States, illustrating the magnitude of potential genetic information available to researchers (14). These databases contain sensitive genetic information that could be accessed by nonresearch team individuals, such as computer hackers, or social and governmental agencies requesting information. Simply removing names or social security numbers as identifiers may not guarantee that the data will remain anonymous or unidentifiable, since electronic databases are proliferating at a fast pace (85). Schulte and Sweeney point out: "Although the records of government-sponsored or funded studies will be maintained according to the Privacy Act of 1974 (P.L. 93-579), this does not ensure that records will never be disclosed" (86). For investigators accepting federal funds for specific research projects, the Privacy Act permits the release of identifiable research information in some circumstances. Particularly relevant for family pedigree studies, researchers may be obliged to respond to a court order seeking information that would be used to protect the health and safety of other persons. Thus the law can require that the investigator disclose confidential information (19,53,86).

In light of this potential ethical conflict between the duty to ensure the privacy and confidentiality of volunteers and a federally mandated court order to divulge sensitive information, Earley and Strong suggest that genetic researchers use a little known Certificate of Confidentiality (53,87). NIH established the certificate as a means to provide protection for federal research projects investigating the extent of illegal drug use in the 1970s. The 1974 and 1988 amendments expanded the certificate protection to cover other research including mental health research and genetics (87). It is important to note that the Certificate does not provide protection to individual participants in biomedical research. Rather, the Certificate protects the investigators from being compelled to disclose results to outside interests. The Certificate is issued to the principal investigator and provides protection for the life of the study. In most cases the Certificate can be extended beyond the funding cycle for the project. To date, there are no published studies addressing the efficacy of the Certificate of Confidentiality for protecting the privacy of participants in genetic pedigree, linkage, or biomedical studies. Thus it is unclear whether these Certificates will provide adequate protection for investigators or their research subjects.

Breeches of confidentiality and privacy can also occur through the publication of family pedigrees when the researchers report their results to peer-reviewed journals or to other investigators. A unique aspect of family pedigree studies is that each subject's clinical and genetic information is analyzed within the context of his or her family. The pedigree diagram is a valuable tool allowing an investigator to convey phenotypic and genotypic information while maintaining the biological relationship between each research subject in the family. The pedigree also includes such personal information such as age, gender, and birth order of the family members. Importantly, the pedigree diagram is a visual aid enabling the reader to quickly assess the mode of transmission of a disease gene, DNA marker, or trait (88). Recently concern for maintaining the anonymity of families in publications containing pedigree diagrams has been raised because of the comprehensive nature of the information (89,90). This concern has increased within the last few years partially due to the expanding interest and education of the lay public in the field of genetics. Increasing access to research articles via the Internet may also be a contributing factor (91).

In the past, journal editors have treated the publication of pedigrees similarly to the publication of traditional case studies, by simply withholding the names of the subjects depicted in the pedigree diagram (88). However, concerns have been raised that a pedigree diagram depicting the family structure with a description of the disease could pose a risk to the privacy and confidentiality of the participating family (88,90). Publication of such information may adversely impact the members of the kindred in several ways. Pedigree diagrams often contain medical and social information that is highly personal and may be not have been shared with other family members. As discussed earlier, instances of "paternal genotype inconsistencies" included in published pedigrees have caused repercussions within the family under study (6). Additionally pedigree diagrams can indicate medical illnesses, reproductive history, and adoption status of the family members (90). Publication can thus result in the disclosure of private information to the proband, other family members, or outside acquaintances. Furthermore, if genotypes are included in the pedigree diagram, information regarding disease status, carrier status, or disease susceptibility could be unintentionally communicated to the study participant and family members. In addition Byers and Ashkenas concluded that there is a remote possibility of discrimination through the inadvertent disclosure to third parties such as insurers or employers (89). Such disclosure directly violates the study volunteer's right to privacy, regardless of the level

of harm. However, it is unclear whether such disclosure to a third party is a substantial risk at this time, since no published studies have directly examined this question.

Future Use of Research Samples

By collecting medical and family information along with a blood sample, most family pedigree and linkage studies also serve as a repository of genetic material, in which most of the individuals are related in family units. The genetic material used in family pedigree research is usually DNA taken from the volunteer's white blood cells, but it can be DNA from immortalized cell lines, buccal swabs, or paraffin embedded tissue from surgical samples. In most cases the DNA samples are from living individuals who provided their consent to the investigators to use their sample when enrolled in the study. Researchers may also use genetic material from tissue from deceased family members, since adequate amounts of DNA can be removed from surgical samples stored in hospital pathology departments. Since DNA is very stable when properly stored, it is possible for scientist to use the DNA samples for ancillary studies, or for unrelated studies long after the primary study is completed.

Using research samples from previous genetic studies is a common practice, since family pedigree projects will often have unused genetic material at the completion of the initial study. Some investigators stress that such repositories are extremely valuable for future scientific discovery, in which the cost of replicating the collection would be prohibitively expensive (92). In addition others have vigorously protested limitations on studying DNA from archival and family DNA banks, fearing that scientific progress will be impeded if previously collected samples cannot be used in future projects (93–95). However, ethicists and consumer groups suggest that participants may not realize that a sample of their genetic material could be used in future research projects that study other disease processes. Participants may not understand that their sample will remain part of a larger collection of genetic material, since research samples are not routinely destroyed at the completion of the project. Thus the future use of biologic materials has become a controversial and contentious topic among researchers, clinicians, ethicists, and patient advocacy groups (14,16,94,96–98).

The fact that tissue collected for genetic research may be used in future studies complicates the researcher's ability to protect the participant's right to autonomy and privacy. For example, study participants in one survey raised concerns that the previously collected sample could later be included in a research project that the participant would not have supported, such as fetal research or cloning experiments (99). In addition the subsequent research projects may yield clinically relevant information from material from DNA banks or other tissue sources. In this case the participant would be unprepared for information about risk for other severe but preventable disease, since he or she would not have been aware of this possibility when enrolling in the initial study (6,83). Concerns have also been raised about the potential for misuse of genetic information and the possibility of lost health insurance or employment opportunities resulting from unanticipated genetic research on previously collected DNA (38,50,98).

In light of these concerns, it is important to note that two surveys have shown a high proportion of participants enrolled in genetic research studies are willing to have their sample used in future research projects. Lewis and colleagues reported a survey of 416 subjects enrolled in a colon cancer linkage study demonstrating a very small percentage (<3 percent) of respondents refused to allow their sample to be used for future unrelated genetic studies (99). These individuals were primarily concerned about privacy and confidentiality of their personal information if their sample was used in this fashion. Fifty-one percent of the remaining participants allowed their sample to be used if their confidentiality was maintained, while 46 percent indicated that they wanted the researchers to contact them to learn more about the subsequent research before permitting future use. A second survey of 263 subjects enrolled in three separate genetic protocols sponsored by NHGRI found similar results (100). Four percent refused further use of their DNA sample, while the overwhelming majority allowed their sample to be used either after being recontacted (73 percent) or after stripping personal identifiers from the sample (26 percent) (101). The results of these studies indicate that the vast majority of research participants are willing to allow their DNA sample to be used in future research, although potential discrimination is a concern for most participants.

The pace and complexity of human genomic research will continue to grow in the near future and benefit the entire community. However, numerous volunteers in family pedigree studies will be potentially exposed to genetic discrimination from the results or conduct of the study. These harms can simultaneously affect the individual volunteer and their family during the life of the study as well as in the future. The potential harms include confidentiality, genetic discrimination, clinical impact and unintended consequences of gene discovery, and the future use of DNA samples. Thus researchers need to address these issues as they conduct family pedigree studies.

PROFESSIONAL CHALLENGES FOR THE CONDUCT OF RESEARCH

While the exciting advances in molecular technology promise a better understanding of many common diseases plaguing humankind, a consensus among researchers, bioethicists, and legal experts on the ethical dilemmas posed by pedigree studies is noticeably absent (6,8,10,22). Several prominent genome scientists have openly called for the development of standardized policies for pedigree and genome research (3). Some of the proposed policies have been controversial, and may place additional burdens on the research team in the time and resources required to conduct the research project (101). Others have responded that the duty of the researcher is clear and that "ethical research is good quality research" (102). Since one of the inherent ethical conflicts in family pedigree research stems from the blending of basic bench science with the potential use of unvalidated tests for clinical health decisions, each research group should establish protocols

Table 2. Policy Areas for the Conduct of Genetic Family Studies

1. Recruitment and ascertainment
2. Privacy and confidentiality of medical, family, and genetic information
3. Disclosure of experimental results
4. Future use of DNA
5. Informed consent

that are specific for the genetic condition under study. There are five basic areas that the research community should address in developing such policies for genome research (Table 2) including recruitment, confidentiality, disclosure of results, future use of DNA samples, and informed consent.

Recruitment and Ascertainment

Identifying eligible participants who have the correct family structure for a specific study is one of the most important aspects of family pedigree research. Many recruitment issues are no different than other human subjects research, in that subjects should be informed about the goals of the study, what participation entails, and the risks and benefits of entering the study. The NIH Office for Protection from Research Risks (OPRR) published an Institutional Review Board Guidebook in 1993 listing the guidelines for protecting human research subjects (103). While the Common Rule as outlined in the Federal statutes clearly state that human subjects research must be approved by each institution's Institutional Review Board (IRB), it has only been recently that additional guidelines have been put in place for genetic pedigree studies (103, p. A58; 104). Recognizing the unique position of recruiters for genetic studies, the OPPR guidebook states that "The familial nature of the research cohorts involved in pedigree studies can pose challenges for ensuring that recruitment procedures are free of elements that unduly influence decisions to participate" (103).

Recruitment protocols for family-based studies are more complex that those used for standard epidemiologic research projects, since each family member, although biologically related, must be separately enrolled in the study. Thus it is important to recognize that the recruitment process can exert undue pressure on family members to enroll. Pressure can come from the research team, since the study actively searches for kindreds with multiple members affected with the disease under study as these families provide more genetic information to the project (6,9). Coercion can occur within the family unit, especially if a volunteer expects that his or her family will directly benefit from the results of a study. "Thus the pressure of compelling familial relationships may simply replace the researcher's influence in recruiting potential subjects" (6, p. 407). Some researchers suggest approaching families in large groups or through organizations like support groups and allowing interested members to contact the researcher if they wish to join the study. This may serve to increase the autonomy of some people's decision. However, as Juengst points out "...family members may actually feel less free to demur in large group settings, and lay-led support groups vary in expertise, understanding, and objectivity" (6, p. 407).

Consensus has not been reached on how IRBs should require researchers to protect the privacy interests of family members. OPPR suggests that researchers might collect only publicly available facts about family members, such as names and addresses, from the proband (103). Although Juengst acknowledges that obtaining detailed medical and family pedigree information from probands "...is a practice so traditional as to be ethically invisible within the community," he suggests that researchers should follow OPRR's suggestion to collect only publicly available information about family members from probands, and then "...convert this tree into a genetic pedigree by soliciting relevant health data from each relative directly" (6, p. 405). However, this recruitment practice will place additional burdens on the research team to gather this information within the research budget allocated to the project.

Pedigree studies will use many sources for referral, such as support groups, health care providers, clinics hospital databases and family members previously enrolled by the study group. Cohen and Wolpert describe several methods of family enrollment and caution that people may pressure their kin to enroll in the study (9). They also suggest that one family member must first inform other members of the family about the study and provide permission for the recruiters to separately reach each member. The researcher then contacts the family member to further discuss the project and offer participation. Other recruitment strategies in the future will be to use data from family registries that have been developed for research. One such Quebec registry for familial Alzheimer's disease developed a recruitment strategy that relied upon local health care professionals as well as leaflet advertisements in hospitals and clinics (105). This group also developed ethical guidelines for the conduct of the entire research project, incorporating protections for family members and incapacitated adults. Researchers must also determine whether minor children or incapacitated adults should be enrolled in a family study (6,9). Parents enrolling their child must use substituted judgment for the child and not be influenced by other family concerns. Thus specific protections should be in place to include the minor child's assent to join the study.

Ensuring and Maintaining Confidentiality

As previously discussed, researchers have a duty to uphold the privacy and confidentiality of participants in family pedigree research, including medical information and DNA genetic results. Pedigree studies pose additional challenges for the researcher to ensure that the data remains confidential, to prevent private information about some family members from being inadvertently disseminated within the extended pedigree, and to limit potential breeches in confidentiality through the process of publication (7,9,70). Standard approaches have been developed for coding and tracking health and genotype information for study enrollees to aid in managing confidential information (9). While there are

no federal laws that guarantee protection of genetic data, the Certificate of Confidentiality has been proposed to protect researchers from being compelled to submit genetic data to outside agencies (16,53). As previously noted, this protection is afforded to the researcher and not to the research participant. Again, there are no specific guidelines on this issue from OPPR or another regulatory agency, although patient advocacy groups have proposed that similar protections be developed for research subjects (19,96). The National Action Plan on Breast Cancer (NAPBC) focused on developing specific strategies to ensure privacy for participants in genetic studies (19). Stating that "privacy protections for experimental research data in which health care is not delivered should exceed the protections established for medical records" and recommended that identifiable genetic research data should not be included in a person's medical file.

Researchers should guard against providing identifiable data to the public at large through the publication of pedigrees. Representing the family medical history in a pedigree format is an essential part of data for publication but could possibly disclose the familial condition in an identifiable format. Thus a practice of altering pedigree information has been developed to provide anonymity for the family members, although it is debatable whether it affords true protection and may undermine the scientific validity of the study (70,89). OPRR recommends that written consent be obtained from participants as to the release of personal information (103). However, there may be no reason to assume that all family members depicted in the diagram had enrolled in the study (89). The International Committee of Medical Journal Editors (ICMJE) issued guidelines in 1995 for protecting the privacy of research subjects in scientific publications, and recommended that "Identifying details should be omitted if they are not essential, but patient data should never be altered or falsified in an attempt to attain anonymity" (88,106).

Disclosure

The genetic revolution has enabled researchers to locate disease-causing genes which as paved the way to the development of new genetic tests for clinical care. While these advances benefit the entire community, the individuals who donated their clinical and genetic material to family pedigree researchers may wish to know their personal study results. As previously discussed, these research results are experimental, and may not be clinically valid for health concerns. Indeed, the research genetic test result may be technically inaccurate, as these tests are performed in the research laboratory rather than in the clinical laboratory (15). NAPBC also points out that research laboratories have a higher tolerance level for inaccurate experimental results than do clinical laboratories (19). Thus falsely negative or falsely positive test results could be provided to a research volunteer.

Federal regulations in the form of the Clinical Laboratory Improvements Amendments (CLIA) of 1988 were enacted to codify the specific requirements for clinical laboratories providing test results that will be used in clinical management of patients (107). CLIA standards help ensure sample integrity and clinical validity of the test results. While the CLIA statute was developed for all type of laboratory tests, there are limitations in the requirements for testing and monitoring genetic testing (108). Nevertheless, these standards apply to all laboratories that test samples for clinical decision making including research laboratories that supply genetic tests for rare disorders at no cost (15). Thus researchers may be in violation of the CLIA statute when disclosing test results to their participants or to clinicians caring for the subject.

The Institute of Medicine report on genetic testing noted that research laboratories may offer the only available genetic tests for rare disorders, since it is impractical for general clinical laboratories to develop tests that would be infrequently used. The authors of this report recommended the establishment of a central repository and genetic CLIA approved laboratory to offer these tests to patients and family members. Other research groups, such as the newly formed International Gastric Cancer Linkage Consortium, have instituted specific protocols for offering genetic testing to research participants (109). This group recommended that clinical genetic counseling be offered to family members in which a mutation in the E-cadherin gene is found in research subjects. E-cadherin is cellular adhesion molecule and persons with constitutional deleterious mutations are at risk for an aggressive form of gastric cancer. In addition the consortium arranged to have the experimental research findings validated by a CLIA approved molecular laboratory. Thus individuals and their family members will be able to learn their research results while the risk of inaccurate test results are minimized. Several groups have developed guidelines as to the proper avenue of disclosure of research information to volunteers. For example, the ASHG strongly recommends that research results only be communicated "by persons able to provide genetic counseling" (13).

NBAC recognized that disclosing results to research subjects is controversial (14). In a 1999 report the commission recommended that disclosure should occur only where the findings are scientifically valid, have significant health implications for the subject and a treatment is available for the disorder in question (14). The authors of this report also assumed that disclosure would be a rare circumstance for the researcher, although this may not be true for researchers who identify highly prevalent genetic changes for a common disorder. Patient advocacy groups, such as NAPBC, feel that research participants should have access to experimental findings, except when the results have unproven clinical validity. They also recommended withholding research data when the results could harm the subject, interfere with the study, or cause harm to another individual (19). Mac Kay suggests that results should not be disclosed to research volunteers as "a more equitable way of dealing with the possibly conflicting views of family members as well as avoiding the problems of information whose reliability is not yet established" (7, p. 489). However, it is important to recognize that many subjects will be interested in their personal genetic results. Thus, researchers must specifically address whether experimental information

will be provided to their study volunteers and, if so, how disclosure will take place.

Future Use of Samples

One of the most difficult issues for genetic researchers is the development of an ethical framework for the future use of the DNA samples collected for the research study. Members of the research community have hotly debated specific guidelines for research using previously collected or archival tissues, since the future use of genetic material was not considered when many of these repositories were established (14). Most authors recommend contacting and obtaining the subject's consent for research on projects that require the use of specific personal identifiers (67). An alternative approach would be to use samples from retrospective DNA repositories as long as the sample is anonymized and stripped of all identifiers (102).

Several organizations and consumer groups have made recommendations for the future use of genetic samples. In a 1996 policy statement ASHG classified biological samples into one of four groups (16). First, " anonymous" biological samples are defined as samples that were originally collected without any specific identifiers from the person who donated the sample. Thus, linking an anonymous sample to the original source is impossible. Second, "anonymized" samples are defined as samples which were initially collected with specific identifiers, were subsequently stripped of all these identifiers. Anonymized samples are thus irreversibly removed from any link to their source, except that the samples can remain linked with clinical, pathological, and demographic information as long as the amount and type of this linked information does not breech anonymity. Third, "identifiable" samples are linked to sources by a confidential code developed by the original investigator. While a member of the original research team can decode these samples, the person's identity can not be revealed to persons outside of the study. Fourth, "identified" samples are those tissue samples associated with the participant's name, hospital number, or pedigree location and are available to the researchers. Hospital pathology departments are an example of repositories of identifiable tissue samples. A similar classification for research samples has been proposed by NBAC, where samples are categorized into unidentified, unlinked, coded and identified samples (14).

The ASHG report on informed consent for genetic research made several recommendations regarding future use of biological samples. Regarding permission to use the sample in other unspecified studies, this group stated "...It is inappropriate to ask a subject to grant blanket consent for all future unspecified genetic research projects on any disease or in any area if the samples are identifiable in those subsequent studies." This group also recommends that researchers ask the volunteer to "indicate if unused portions of the samples may be shared with other researchers." The report also recommended that the subject should indicate whether subsequent researchers should "receive their samples as anonymous or identifiable specimens" (16).

Several other groups have made recommendations for future use of research samples. In general, most groups agree with the OPRR guidelines calling for researchers to "obtaining consent from the participants for any use of the data (and samples) that is not strictly within the original uses to which the participants agree" (103). Clayton and colleagues made further recommendations, by suggesting that researchers inform the subjects "about the scope and potential consequences of the projects" (98). These authors also suggest that subjects should be asked if they are wish to have their sample anonymized, as well as if they would allow their sample to be used by investigators outside the institution or outside the original research project. The American College of Medical Genetics (ACMG) guidelines propose that researchers request permission for future use of the sample from the volunteer at the time the sample is collected (97). This group also recommended that researchers develop a specific policy about whether subjects will be recontacted if permission to use the sample in the future was not obtained at the time the sample was collected.

Informed Consent

The ethical complexities of genetic research studies prompted one ethicist to write that the "steps to obtaining consent from members of a pedigree can be tortuous" (7). However, the evolving duty of the genetic researchers has been recently described:

> In sum, the people whose genetic and clinical data will be essential for the next phase of human genomics research need to be treated not merely as "subjects" but more as (somewhat limited) partners. Researchers must realize that these people have interests beyond safety; ethicists must recognize that, when well informed, they have the right to participate even in broadly defined research. The goal of this approach is not to prevent research but to prevent research subjects from feeling cheated, powerless, misled, or betrayed (22).

Most researchers recognize that a trusting relationship with the study volunteers is essential for the success of the entire project. Indeed, it is through the informed consent process that such a relationship is first developed. In this way the informed consent process is more significant than the signed document detailing the proposed research and can be a blueprint for the ethical conduct of the research to be performed. Hence the study protocol should include detailed plan for informing the volunteer about the study and obtaining consent prior to enrollment.

Since family pedigree research involves the collection of clinical information and biological samples on multiple family numbers, these studies fall under the Common Rule, which requires that human subjects research supported by federal agencies be reviewed by an IRB (104). NBAC extended this recommendation for IRB oversight for all human subjects research, regardless of federal support (14). The ASHG statement on informed consent for genetic research encouraged researchers to develop procedures to obtain informed consent for both prospective and retrospective studies (16). In addition this report suggested that specific protocols be developed for maintaining confidentiality, disclosure of expected

Table 3. Elements of Informed Consent Document for Family Pedigree Studies

1. Purpose of study
2. Participation is voluntary
3. Costs and/or reimbursement
4. Benefits of participation
5. Disclosure of experimental results
7. Risks or informational harm from participating
8. Ensuring confidentiality: "Certificates of Confidentiality"
9. Future use of DNA sample

and unexpected experimental data, and deposition of samples.

The elements to be included in the investigator's informed consent document should follow standard formats with special additions relevant to genetic studies (Table 3). As with all human subject research, informed consent requires that the consent document be written in language understandable to average readers. It must also include a description of the project and the purpose of the research. The potential participant must be given the option of withdrawing from the research at anytime without penalty. The researcher must also identify any costs related to participating in the project and include an estimate of the amount of time. In addition to these points, informed consent documents must also contain information on benefits, disclosure of results, risks, confidentiality, and future use of samples. Researchers who are composing consent documents for genetic family pedigree studies must pay particular attention to these components to insure that participants are informed of the potential harms specific to genetic studies (103).

Researchers must clearly state that there may be no direct benefits for the participant or family members. However, as discussed previously, researchers must also indicate whether experimental results will be communicated to study volunteers. If the research team is planning to withhold results, the informed consent document should indicate that no research results will be given to the participant. On the other hand, if the research team is planning to share experimental results, the disclosure protocol should be explained to the participant in advance. In this case additional costs that may be incurred by the participant, such as CLIA laboratory confirmation or genetic counseling, should be included in the consent document. In addition to the physical risks that may be incurred in the genetic study the risks associated with "informational harms" must be disclosed (16,39). As previously discussed, these include potential psychological harms from learning preliminary health information directly from the study, or from new and unintended information which may not be related to the initial focus of the study. IRB guidelines state: "Prospective subjects should be informed during the consent process that the discovery of such information is possible" (103). Identification of nonpaternity or undisclosed adoption in a family is another unintended consequence of genetic studies that may cause psychological harm to participants. ASHG recommends that researchers consider including a statement in the informed consent document that mistaken parentage will not be disclosed (16).

A description of steps that will be taken by the researcher to protect the privacy of the study participants should be included in the informed consent document. Most volunteers will want to know that personal information or study results will not be disclosed to third parties, including employers, insurers, and family members, unless there is written consent from the participant. If the researchers follow the ASHG recommendations and obtain a Certificate of Confidentiality, a brief description of the protections it affords should be included in the consent form (16). The researcher should describe how confidentiality will be maintained if the research results or the family pedigree will be published. In regards to publication of family pedigrees, the ICMJE guidelines state: "Identifying information should not be published in written descriptions, photographs, or pedigrees unless the information is essential for scientific purposes and the patient (or parent or guardian) gives written informed consent for publication" (106). This requires the consent of all family members depicted in the pedigree, which can be a daunting task for researchers. Finally, researchers must clarify use of the samples in future research. Many groups have made recommendations about the use of genetic samples for future genetic studies, and most groups agree with the recommendation of the 1995 ASHG report that it is inappropriate to ask a participant to provide unrestricted consent to the future use of a sample when the risks of the future project are unknown (16).

Successful family pedigree studies are dependent upon the generous donation of clinical information, family information and biologic samples by volunteer participants. Recruitment of potential subjects for genetic studies requires a trusting relationship between the volunteer and researcher. Thus the protocol that a researcher develops for the informed consent process is a major component of the study; it will require policies addressing the potential benefits and risks specific to genetic studies. In order to continue the enormous success of the genetic revolution, researchers must develop guidelines that will ensure the ethical code of conduct for their genetic studies.

HUMAN SUBJECTS RESEARCH, ETHICS, INFORMED CONSENT IN RESEARCH

NANCY E. KASS
John Hopkins University
Baltimore, Maryland

OUTLINE

INTRODUCTION

It is only in the latter half of this century that significant intellectual and regulatory attention has been devoted to human subjects protection. In response to isolated, but horrific, examples of unethical research studies, codes of ethics for human subjects research were developed, regulations were passed, and standards of informed consent were established. And yet as often is the case, while this branch of ethics has made tremendous progress in just a few decades, new challenges continue to emerge. It is the purpose of this entry to provide a brief history of human subjects protections, to describe specific elements of informed consent as they apply to research, and to discuss specific examples in which upholding standards of informed consent remains particularly challenging.

HISTORY OF HUMAN SUBJECTS PROTECTIONS

The Nuremberg Code of 1948 usually is considered the first code of research ethics (1). This Code grew out of the Nazi war crime tribunals, during which descriptions had been revealed of experiments conducted on concentration camp prisoners. These experiments, conducted through force and coercion, studied such questions as how long humans can be immersed in ice water before dying of hypothermia, the effects of ingesting poisons, and the effects of being injected with viruses. The Nuremberg Code, intended to guide all future research with humans, was developed as part of the judgment in *United States v. Karl Brandt* et al. (1a). Given the context out of which the Nuremberg Code emerged, it is not surprising that its first stipulation

is that "the voluntary consent of the human subject is absolutely essential" (1, p. 181). It elaborated that the subject should have the legal capacity to consent, should be able to exercise free choice without any coercion or deceit, and should have sufficient knowledge and understanding of the experiment to enable an "enlightened decision." Ensuring that the consent is voluntary and informed is the "personal responsibility" of the investigator. The Code further states that the experiment should be expected to yield important results for society that cannot be obtained through other methods, should be based on previous animal research and a knowledge of the problem, should avoid all unnecessary physical and mental suffering and injury, should not be conducted when there is a priori reason to believe death or disabling injury will result, should not involve a level of risk that exceeds the importance of the problem, should be conducted only by qualified persons, should guarantee that the subject has the right to stop participating at any point, and should be terminated early should there be reason to believe that the experiment is unduly risky.

Shortly afterward, in 1953, the clinical center of the National Institutes of Health (NIH) opened. The NIH clinical center is a research hospital, funded by the federal government, where all "care" provided to patients is part of a research protocol. When the clinical center opened, the NIH decided to require informed consent of healthy volunteers who entered studies, but not of patient-subjects, who were presumed to have reason to want to participate in clinical research (2). Nonetheless, this was one of the first times that an entity of the U.S. government required informed consent for any type of human subjects research.

The first code regarding the ethical conduct of research put forth by a professional medical body was from the World Medical Assembly in 1964 (3). The Declaration of Helsinki, as it was called, echoed many of the tenets of the Nuremberg Code but included additional elements of relevance to doctors who conduct research. It reminds doctors that despite the importance of conducting research, "the health of my patient will be my first consideration." It adds that the responsibility for the welfare of the subject always rests with the investigator and not with the subject, despite the subject having given voluntary consent. Further, "concern for the interests of the subject must always prevail over the interest of science and society." The Declaration further states that experiments not conducted in accordance with the proposed ethical requirements should not be considered publishable regardless of their scientific findings, and that the doctor should be particularly "cautious" if the subject is in a dependent relationship with him or her, in which case a different member of the research staff should obtain consent from the subject.

In the 1960s and 1970s several events in this country brought attention to human subjects research and the abuses that potentially can be associated with it. The Willowbrook hepatitis study was conducted from 1956 to 1970. The Willowbrook School, where this study occurred, is an institution for mentally retarded children. There were poor sanitary conditions at the school, and most children contracted hepatitis A at some point after being sent to live there. Researchers wanted to study the natural history of hepatitis A and the possibility of creating a vaccine for the disease. They decided to inject children who were newly admitted to Willowbrook with the strain of hepatitis that was rampant there. The "study" was justified by saying that the children probably would have become infected anyway and that, scientifically, more can be learned about the natural history of the disease if it is known precisely when the child became infected.

In 1963 the public became aware of experiments conducted at the Jewish Chronic Disease Hospital in New York. The Jewish Chronic Disease Hospital was an institution for elderly, chronically ill adults. In the experiments, residents of the hospital were injected with live cancer cells without their knowledge or consent. The experiments were justified by arguing that these patients would have died soon anyway.

In 1966 Henry Beecher, a well-respected Harvard physician, published in *The New England Journal of Medicine* an article that has become one of the classic pieces in research ethics (4). Beecher, who earlier had called for "a long, straight look at our current practices" (5), now conducted a review of articles published in top medical research journals. In the article he described 22 articles gleaned from medical literature of the time in which ethically questionable practices had been involved. Among his examples were placebos being substituted for an established treatment without patient-subjects' knowledge, studies of vulnerable subjects, and/or studies with a high degree or risk relative to benefit. Dr. Beecher's article received considerable attention, in great part, because his examples were drawn from *published* and therefore well-sanctioned research, and also because he implied that the research described was not necessarily unrepresentative nor unusual.

In response to this series of events, the United States Public Health Service established guidelines for research in 1966 (6). These guidelines required that each institution conducting human subjects research funded by the U.S. Public Health Service establish an Institutional Review Board (IRB) that would review projects in advance. The IRB would determine whether (*1*) the rights and welfare of study subjects are protected, (*2*) the methods to obtain informed consent are appropriate, and (*3*) the risks and potential benefits of the investigation are clear, and the potential benefits outweigh the risks (6). Therefore research review was to be prospective decentralized, based at the researchers' institution, and required to include informed consent.

In 1971 the public's attention turned to yet another horrific example in the history of research ethics. The Tuskegee syphilis experiment had been conducted by the American government from 1932 to 1972 (7). In this example, the Public Health Service was studying the natural history of syphilis. They chose as their subjects poor, black men from the rural south, 400 of whom had syphilis and 200 of whom served as controls. None of the men were told that a study was being conducted. Rather, they were led to believe that the government doctors were providing medical care for them, something

that poor, rural men were eager to find. When certain diagnostic procedures (e.g., spinal taps) were conducted for research purposes, the men were told that they were receiving treatment, and when efficacious antibiotic treatment became available in the 1940s, these men were denied therapy. The justification given for the study was that researchers simply were observing the disease that men already had, and since most of these men had no access to care, not providing care was no worse than what they already would have experienced. This study violated all ethical requirements of research, in that the men were not told they were participating in research and consequently could not provide meaningful consent. The research itself was unreasonably risky, particularly after penicillin became available; and the research singled out certain segments of the populations who were the poorest, were from a racial minority, and experienced none of the study's benefits. After press reports in the early 1970s exposed the horrors of the Tuskegee study, the Department of Health, Educations, and Welfare (DHEW) appointed the Tuskegee Study Ad hoc Panel to review the study, as well as to review the Department's policies for the conduct of human subjects research (8). The panel noted that, although DHEW guidelines had been in place since 1966, it was a journalist, rather than a review committee, that brought the conduct of this study to light. (for further discussion, see Ref. 9). The panel recommended that the Tuskegee study be stopped immediately, and also that a permanent body to regulate human subjects research be established by Congress. While such a proposal was introduced before Congress (9). it was not successful. However, two other responses to this decade of research exposes were successful: New regulations were promulgated by DHEW designed to build upon and strengthen the 1966 guidelines, and the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (National Commission) was established (10).

The National Commission, in existence from 1974 to 1978, was charged by Congress to investigate the ethics of human subjects research, particularly research with vulnerable populations, such as prisoners, children, and mentally disabled adults. In addition to producing 17 separate reports on research with each of these populations, the National Commission created The Belmont Report (11). *The Belmont Report* laid out three principles of bioethics to help examine the ethics of any research endeavor that involves human subjects, principles that remain extremely influential in contemporary bioethics: beneficence, respect for persons, and justice (for further discussion of these principles, see Ref. 12). Briefly, beneficence requires us to look out for the welfare of others. In the context of research, this means that harms to potential subjects must be minimized, and balancing of harms and benefits must occur. Respect for persons requires us to treat individuals as autonomous agents and, when persons have diminished capacity, requires us to protect them from harm. Therefore this principle requires us to respect the decisions and judgments of others, even if we may disagree with them. It is out of the principle of respect for persons that we are required to engage in a process of informed consent with research subjects. Justice requires us to be fair in the distribution of research burdens and benefits. Because of justice, we cannot disproportionately target vulnerable populations for enrollment in research to bear its risks, nor can we allow only those who are well-to-do and sophisticated to reap the benefits of research participation.

The 1974 DHEW regulations in many ways formalized the 1966 PHS guidelines that had required IRB review at local research institutions. The regulations went further, however, by delineating the elements that must be included in the informed consent process conducted with research subjects. These elements will be described below. All institutions that receive federal funding remain subject to these regulations. In 1975 the original regulations (Subpart A) were supplemented by another set of regulations (Subpart B) pertaining to research with pregnant women and fetuses. In 1978 Subpart C was added, providing regulations for the conduct of research with prisoners, and in 1983 Subpart D was added to provide oversight for research with children. In 1991 fifteen other federal agencies adopted Subpart A to apply also to their own research, calling it "The Common Rule." *The Common Rule* is in existence today, providing a common set of regulations for almost all federal agencies that either sponsor or conduct human subjects research in the United States.

Clearly, attention to the adequacy of human subjects protections usually has occurred in the context of a specific example that raised concern. The most recent such instance prompted the creation of the President's Advisory Committee on Human Radiation Experiments (ACHRE). ACHRE was formed in 1994 in response to allegations that radiation-related research was conducted on Americans between the 1940s and 1970s (during the cold war) without the participants' knowledge or consent. The Advisory Committee investigated these allegations and their extensive surrounding history. Moreover ACHRE did work examining the ethics of contemporary human subjects research, understanding that accusations of past abuses would raise questions in the minds of Americans about how much trust ought be put in current research practices and to establish a basis in fact on which to make recommendations for change in the future. Among ACHRE's recommendations were that research ethics training should be required of all research students and trainees, and that competency in research ethics should be required of all individual and institutional federal research grant recipients (9). Further ACHRE recommended that IRBs develop mechanisms to allocate their time more appropriately to riskier and more complex research, that information provided to patient-subjects clearly distinguish research from treatment, and not overestimate potential benefits. ACHRE also recommended that oversight of research be improved and that sanctions be created for those who do not comply with federal regulations (9, pp. 524–526).

Mention also should be given to the code that addresses specifically the conduct of human subjects research in the international setting. Put forth by the Council for International Organizations in the Medical Sciences

(CIOMS), the CIOMS guidelines were established in 1982. Among its provisions were that community consent, while often appropriate and necessary to obtain, cannot serve as a substitute for individual consent, and that research must be responsive to the health needs of the community in which the research occurs.

ELEMENTS OF INFORMED CONSENT

This section will describe both the specific elements of informed consent as delineated in the Common Rule and also will provide broader discussion of concepts inherent to the theory of informed consent. Informed consent has a history in medical practice that precedes but clearly influences its history in research. The clinical history starts with a series of cases at the beginning of the twentieth Century brought by patients who had not given their *consent* to certain procedures. Later in the century are cases brought by patients for not having been adequately *informed* about the procedures to which they were providing consent. In 1906, in *Pratt v. Davis*, a doctor performed a hysterectomy on a woman without her consent (13). The defense had been that when a patient enlists a doctor or surgeon's services, the doctor is given "implied license to do whatever in the exercise of his judgment may be necessary." The defense was rejected, and the case was decided in the patient's favor. Perhaps the most famous case on consent was *Schloendorff v. Society of New York Hospitals* in 1914 (14). In this case the patient had given consent for exploratory abdominal surgery but had specifically requested no further surgery. The surgeon, upon finding a fibroid tumor during the surgery, had gone ahead and removed it. One of the justices ruling on the case, Judge Benjamin Cordozo, wrote in his historic opinion, "Every human being of adult years and sound mind has a right to determine what shall be done with his own body; and a surgeon who performs an operation without his patient's consent commits an assault, for which he is liable in damages." The next fifty years brought a series of cases that led to a new requirement of patients also being informed. A landmark case, perhaps because it coined the phrase "informed consent," was in 1957, *Salgo v. Leland Stanford Jr. University Board of Trustees* (15). In this case Martin Salgo had undergone translumbar aortography which resulted in permanent paralysis, a known potential risk of the surgery. Mr. Salgo sued physicians for failing to warn him that a potential risk of the procedure was paralysis. The court found, in the patient's favor, that physicians had a duty to disclose "any facts which are necessary to form the basis of an intelligent consent by the patient to proposed treatment." This evolved into a requirement that all issues that would be pertinent to a patient when making a decision — such as the nature, consequences, risks, benefits, and alternatives to a proposed treatment — be disclosed before a patient makes a decision.

Extrapolating to the research context, informed consent requires both informing the research participant about the research and obtaining the participant's consent. *Informing* a participant requires disclosing pertinent information and ensuring at least some threshold level of understanding. Of course, fulfilling the former is considerably easier than fulfilling the latter, and consequently significantly more attention in the literature and the regulations exist concerning disclosure. For *consent* to occur, the participant must be competent and must make the decision voluntarily. The concepts of disclosure, understanding, competence, and voluntariness will be discussed below.

Disclosure

While understanding is what ultimately is required for valid informed consent, it is typically through disclosure that a research subject learns enough about the research project to understand it. If, indeed, a research subject were to understand the research other than through disclosure (e.g., through a video tape or from prior familiarity with the research), then substantially less disclosure would be necessary. Most discussions of informed consent, however, rightly assume that subjects know little about the research before they enter into a research relationship. Consequently the regulations governing human subjects research (the Common Rule) lay out in detail the elements of informed consent that must be disclosed (16):

1. A statement that the study involves research, an explanation of the purposes of the research and the expected duration of the subject's participation, a description of the procedures to be followed, and identification of any procedures that are experimental.
2. A description of any reasonably foreseeable risks or discomforts to the subject.
3. A description of any benefits to the subject or to others which may reasonably be expected from the research.
4. A disclosure of appropriate alternative procedures or courses of treatment, if any, that might be advantageous to the subject.
5. A statement describing the extent, if any, to which confidentiality of records identifying the subject will be maintained.
6. For research involving more than minimal risk, an explanation as to whether any compensation and an explanation as to whether any medical treatments are available if injury occurs, and if so, what they consist of, or where further information may be obtained.
7. An explanation of whom to contact for answers to pertinent questions about the research and research subjects' rights, and whom to contact in the event of a research-related injury to the subject.
8. A statement that participation is voluntary, refusal to participate will involve no penalty or loss of benefits to which the subject is otherwise entitled, and the subject may discontinue participation at any time without penalty or loss of benefits to which the subject is otherwise entitled.

Ruth Faden and Tom Beauchamp, in their book on informed consent (17), discuss that potential subjects want

to know information that is *material* to them. The federal regulations are based on assumptions about what would be material to most persons when considering participation. Faden and Beauchamp remind us, however, that certain additional details about a project may be important for a given individual, whereas they may be irrelevant to others. For this reason it is important that in addition to providing the basic elements of disclosure, there also be the opportunity for an informed consent discussion in which potential subjects can raise additional questions. Faden and Beauchamp note that information that is material is not necessarily information that is required for the *decision*, but rather it may be important for the potential subject to feel s/he has a good understanding of the research. For example, it may be important to a potential subject to know whether study hours can be arranged at night, even if the potential subject knows that s/he will participate regardless of the answer.

Understanding

It has been written that "assent to [research] given by a [subject] who actually has not understood disclosed information is not valid authorization" (18, p. 59). This reminds us that while adequate disclosure in most instances is necessary for there to be understanding, it in no way guarantees it. Many factors can contribute to inadequate understanding of research. Investigators may use jargon or language that is difficult for potential subjects to understand (19–21). Subjects who also are patients may be anxious about their medical condition and unable to focus on the specific information provided. Information also might be provided quickly and in large amounts, with little or no time for discussion, such that subjects simply cannot remember or integrate all they were told. Sometimes the words used in research are qualitative and vague. Nakao and Axelrod (22) as well as Fetting et al. (23) found imprecision in many terms used to describe research risks and benefits (e.g., "rare," "infrequent"), and recommend that numeric estimates be used when possible. In their review Silva and Sorrell report many factors that influence comprehension of research information (24). Several studies report that often too much information is given, and that subjects better understand the research when smaller amounts of information are provided. Who delivers information can also be relevant. Muss et al. found that more information about chemotherapy side effects was retained when risks and benefits were described by personnel other than the doctor (25). Not surprising, higher education is associated with greater comprehension of informed consent information (25). Understanding also is unavoidably compromised by lack of experience with a situation. That is, it can be difficult for subjects to imagine how they would react to a certain side effect until they have experienced it. While not a guarantee of understanding by any means, most commentators recommend using some measure to assess subjects' understanding of what they have been told before embarking on the research. This includes not simply seeing whether they can recall what are the study procedures but, at least as relevant, if they can recall what the *purpose* of the research is.

One area where understanding about research may be particularly challenging is clinical research. Here patient-subjects often enroll because of a hope that the research will be of medical benefit to them personally. This can result in research subjects losing sight of the fact that the study is investigational, the intervention has not been shown to be a valid medical treatment, and the purpose of the activity is not primarily to treat their own medical condition. Given that many clinical research investigators also are physicians, it can be easy for patient-subjects confuse clinical research participation with medical care. Studies have demonstrated that some proportion of patients enrolled in research do not understand, or at least, do not remember, that they are enrolled in research. Riecken and Ravich found that 28 percent of patients enrolled in research studies through Veterans Administration hospitals were not aware of their participation in research, despite having signed consent documents, remembering that the intervention had been explained to them and believing that they had been given sufficient information (26). The rate of unawareness dropped the longer patients were enrolled in studies, and patients were more likely to be unaware of their participation if a staff member other than the investigator had explained the study. Penman et al. similarly found that nearly one-fourth of patients receiving investigational chemotherapy did not recall that it was investigational (27).

Yet more subtle clouding of the boundary between treatment and research is demonstrated by many patients who are perfectly aware that they are participating in research but nonetheless view the research as a treatment intervention to improve their underlying disease state. This clouding is critical to issues of informed consent, since a key tenet of informed consent is understanding by the patient (17,18), and a key element of understanding in clinical research is appreciating what is meant by investigational.

Some years ago Appelbaum et al. described this threat to understanding as the "therapeutic misconception" (28). Appelbaum et al. report a psychiatrist approaching a patient to consider participating in a research study. The patient responds, "Yes, I'm willing to do anything that might help me." The patient further says that he understands what is meant by the trial's randomized placebo-controlled design but then goes on to say that he believes *he* will receive the study medication most likely to help him.

Competence

In order for informed consent to be valid, the person providing consent must be considered competent to consent. When a person is *not* competent to consent, a surrogate must consent on the subject's behalf, and IRBs usually engage in a higher level of oversight. That is, there is even greater scrutiny of the risk–benefit ratio, with an assumption that individuals who cannot understand the research in which they will be participating cannot be subject to as much risk as could a person who fully understands. A key principle in discussion of competence here is that individuals are not necessarily uniformly

competent or uniformly incompetent. Rather, the relevant question is whether the individual is competent to understand what is required of him or her by participating, and whether the individual is competent to exercise autonomous decision-making capacity in consenting to enroll. Individuals, for example, may be able to understand that they are being asked to be in research and what would be required of them, while having no recollection of what day of the week it is or who is President. Conversely, some individuals may function well in day-to-day activities but have no understanding of who doctors or researchers are, and cannot comprehend an informed consent discussion. Discussion concerning three specific populations whose full consent often is impaired — children, persons in emergency situations, and persons of limited decision-making capacity — will be provided below.

Voluntariness

Faden and Beauchamp write that "a fundamental condition of personal autonomy is that actions ... are free of ... controls on the person" (17, p. 256). Persons may be *influenced* in their thinking (e.g., by family members, information, or doctors), which ethically is quite consistent with valid informed consent, in contrast to being *controlled* by others (e.g., they are being forced or coerced), whereby they are not acting autonomously. In research, potential subjects may be most likely to feel "controlled" by others if they believe that other opportunities are dependent on their participation. For example, if a patient believes that her doctor will not treat her as well if she refuses to participate, then her decision cannot be considered voluntary. Similarly, if parole comes more quickly to prisoners who agree to participate in research, their decisions about participation may not be fully voluntary. All research consent discussions and forms must therefore emphasize that access to other opportunities will not be affected by potential subjects' decisions about participation. IRBs may decide that certain recruitment strategies are unacceptable because they would raise questions of compromised voluntariness. For example, professors may be told that they cannot solicit research participation from their own graduate students, or physicians from their own patients; in the latter case another physician can seek consent from patients, but the patient's own doctor may be perceived as exerting too strong an influence. Generally, the law "has long recognized a consent or refusal coerced by threats or manipulated by misrepresentation [to be] invalid" (12, p. 163).

CHALLENGES TO INFORMED CONSENT: SPECIAL POPULATIONS

Children

Tension exists when conducting research with children. On the one hand, children are assumed to be unable to fully appreciate the consequences of their actions, and therefore are not considered to be fully autonomous for the purposes of consenting to research. On the other hand, there are conditions that uniquely affect children, or affect children in ways that are different from how they affect adults, and therefore the medical or psychological care of children cannot be improved without research. Concerns based in justice dictate both that children not be used in research when fully competent adults could provide the same answers, yet also that children as a class not be denied the benefits of research knowledge. That is, children as a class ultimately are harmed if they are treated with drugs that never have been tested properly for safety, efficacy, or dosing in children. Consequently children can be used in research ethically only when the research question relates uniquely to them or if it is not greater than minimal risk research. Further, given that children cannot fully consent, we require a higher standard of beneficence. It is assumed that more protection for their welfare should be provided, with IRBs being more paternalistic than they are with competent adults. When children are approached for participation, it is required both that their parent or guardian sign written permission and that the child "assent" at an age-appropriate level. That is, researchers are required to explain certain relevant pieces of the research to the child in language the child will understand to see if the child is willing to participate. This assent undoubtedly will not include all information about the research. It may be as simple as saying to the child, "to learn more about your health, we would like to take some blood from your arm and ask you some questions. We're asking all the kids who come into the clinic today to do this. It's OK if you decide you don't want us to do this. Is it OK with you for us to do this?" In certain instances where the research in expected to be beneficial for the child, parents may overrule a child's lack of assent.

The Departments of Health and Human Services (DHHS) regulations regarding human subjects research were amended in 1983 to include Subpart D, "Additional Protections for Children Involved as Subjects in Research." The regulations define assent as a child's "affirmative agreement to participate in research. Mere failure to object should not, absent affirmative agreement, be construed as an assent" (29). The regulations say that minimal risk research with children is ethically acceptable, assuming that permission from parents and assent of child have been obtained. Research involving greater than minimal risk is allowed only if the risk is justified by anticipated benefit, if the benefit anticipated is at least as great as that offered by alternatives to participation, and if assent and permission are obtained. Research offering more than minimal risk and *not* offering direct benefit to the individual subjects is allowable only if the risk anticipated is minimally more than the risk the child would have experienced through his or her illness or through ordinary medical treatment, and if the expected generalizable knowledge is clear. Research involving more than minimal risk over what the child otherwise would experience, with no anticipated individual benefit, is unlikely ever to be approved. To be approved, the Secretary of DHHS would need to determine, after consultation with "a panel of experts in pertinent disciplines, for example, science, medicine, education, ethics, law, and following opportunity for public review and comment" (30) that the research is

expected to yield great understanding for the treatment of prevention of a serious problem affecting the health or welfare of children, that sound ethical principles are otherwise followed, and that permission and assent are obtained. Two other changes have occurred recently with regard to inclusion of children in research. The NIH issued "Policy and Guidelines on the Inclusion of Children as Participants in Research Involving Human Subjects" in 1998 (31). The policy mandates that research conducted or funded by the NIH include children in all studies unless there are scientific or ethical reasons to exclude children (for further discussion, see Ref. 32). The Food and Drug Administration (FDA) passed similar regulations in December 1998 requiring manufacturers of new and marketed drugs to evaluate the safety of those products in pediatric patients if the product is likely to be used in children (33).

Emergency Consent. In October 1996 the Federal Register published for the first time a waiver to informed consent requirements when conducting research in the emergency setting and when certain conditions apply (34). The regulations apply to Subparts A and D of the federal human subjects regulations (i.e., research with adults and with children) but not to Subparts B and C (research with pregnant women/fetuses and research with prisoners). The rationale for the new regulations was similar to rationales for wanting to be more inclusive of other populations of persons with limited decisional capacity: While it is imperative that the welfare and interests of individual vulnerable persons always be protected, it also is important that interventions that potentially might help such persons be tested and identified. Consequently, where research questions uniquely affect persons in emergency situations, it is sometimes appropriate, in balancing risks and benefits, that research be conducted. The conditions laid out in the new requirements include that eligible patients must be in a life-threatening condition, the available (nonexperimental) treatments are unsatisfactory, there is a need to collect scientific evidence to test new interventions, and an authorized representative for the patient cannot be found in the short time frame required. The investigators are required under the new waiver to document their efforts to find the patient's representative before enrolling the patient without consent. Further there must be procedures in place to inform the subject or his/her legally authorized representative, at the "earliest feasible opportunity," of the subject's inclusion in research and relevant details. If the trial remains ongoing at the time when the subject becomes aware, or the family is contacted, they have the right to terminate participation immediately. It also is required that the relevant IRB approve both the research activity and the waiver of consent. The waiver states explicitly that when appropriate, placebo-controlled trials are allowable under the new policy.

While in general, there has been considerable support for the emergency waiver, some have taken issue with the specific language included that could, again, lead to a misunderstanding about the distinctions between research and treatment. Jay Katz, for example, objected to the insinuation in the new regulations that emergency research has therapeutic intent for the individual patient: "In its emphasis on therapeutic benefits, the FDA obscures the fact that some of the permissible research activities either hold out no promise for therapeutic benefit or are so vaguely defined that potential therapeutic benefit can be inferred when research is the predominant intent. . . . Research must be stripped of the therapeutic illusion which misleads patient-subjects into believing that they are receiving the most advanced and beneficial treatments available, when instead they are being asked to serve the interests of science. . . . Research is not treatment" (35).

Other Persons With Limited Decision-Making Capacity

It is in many ways surprising that except for research with children and with persons in emergency situations, there are no federal regulations governing research with persons with questionable capacity to consent. Instead, it is left to IRBs to determine whether the research ought to go forward and whether consent and other safeguards are sufficient. Again, the challenge when evaluating research of this nature is wanting to enable more knowledge to accrue in this area, which clearly will benefit persons with mental disabilities, yet not wanting to compromise the interests of the individuals who participate in the studies. In order to determine if the participant can provide consent for him/herself, investigators should devise a method for evaluating whether participants have the ability to "understand, appreciate, and reason about the experimental situation" (36). Where they cannot, someone else must give permission on their behalf. Moreover, again, assent to whatever degree is possible, must be sought. If the potential subject will not assent, generally speaking, s/he should not be included in the research. Exceptions sometimes are made when there is clear likelihood that individual benefit would come to the participant as a result of enrolling, but given that research is by definition testing the efficacy of interventions, this may be difficult to prove. When deciding on behalf of someone else, two different standards can be used. If the person with limited decisional capacity previously had capacity, and had made relevant preferences known, then a substituted judgment standard can be used, meaning that the surrogate is simply voicing what s/he believes are (or previously have been) the wishes of potential subject. In contrast, if the subject has never had relevant capacity, then a best interest standard must be used. Essentially a caring person charged with the responsibility of guardianship for the subject decides what is best for the subject, based on how much anxiety it could provoke, its safety and invasiveness, and expected benefits and burdens (36,37). The obligation remains throughout the study to monitor ongoing effects in order to determine whether the subject's participation should be stopped at any time.

Persons With Serious Illnesses

As described earlier, a challenge for researchers is conducting research with persons with serious illnesses. These persons often are vulnerable by virtue of their illness. They may be so eager to participate in anything

that they, rightly or wrongly, believe may help them, that their judgment may be clouded. Moreover physician-investigators who sincerely care about the well-being of their patients, may encourage their patients to participate in research of unknown or little value because they too do not want to admit that few other options remain. While participation of such persons also may occur for altruistic reasons and while research in certain circumstances requires the participation of such persons, IRBs and investigators must be sensitive to these vulnerabilities, vulnerabilities that are not recognized the way being a prisoner, a child, or a person with limited decisional capacity routinely are.

Studies have been done that highlight how persons with serious illnesses often overestimate the benefit they could get from the research and/or forget or ignore altogether, as described earlier, that the research intervention is investigational. For example, Penman et al. found that the primary reasons 144 cancer patients accepted investigational chemotherapy were trust in their physician and belief that the treatment would help (27), and that one-quarter of the patient-subjects interviewed did not recall that the chemotherapy was investigational. Cassileth et al. documented that respondents describe research in different terms depending on whether they are speaking about research generally or their own participation. Patients and members of the general public reported that people generally should participate in research, in order to benefit others and increase scientific knowledge, but that they themselves would participate primarily in order to help "get the best medical care" (38). In a study conducted by the Advisory Committee on Human Radiation Experiments, cardiology and oncology outpatients who had been research participants said in closed-ended interviews that they viewed research as a way to help others (76 percent) and joined to get better treatment (67 percent) and because the research gave them hope (61 percent) (39). When interviewed in greater depth using more open-ended questions, however, these patients with serious illnesses reported that they joined research studies either because their doctors had recommended it, or because they believed they would gain additional medical benefit. For example, one patient-subject said, "When you reach that stage . . . and somebody offered that something that could probably save you, you sort of make a grab of it, and that's what I did" (40).

Concern about patient-subjects' vulnerabilities ought be most acute in the context of Phase I trials where the chance of personal medical benefit is minimal at best (41–43). Studies with patient-subjects enrolled in Phase I research, however, echo other findings. Rodenhuis et al. interviewed 44 patients who had agreed to participate in a Phase I cancer trial. They report that for all patients who participated in the study, "the hope for stabilization, improvement, or even cure of their diseases was the major motivation" (44). Further they report that doing *something* seemed to be of psychological benefit to patients in and of itself: "By continuing to receive medical attention and some form of treatment, they were able to cope with their incurable diseases and deny or postpone more easily the realization of impending death." Daugherty et al. asked patient-subjects enrolled in Phase I cancer research specifically whether they *expected* therapeutic benefit as a result of participation (45). Twenty-two percent of patients said they believed they would receive therapeutic benefit from their participation.

Genetics Research Informed Consent

Increasingly, researchers are conducting genetic research that raises new issues related to genetics research informed consent. Among these are issues surrounding use of stored tissue samples, the challenge of learning uninterpretable information, the potential for learning information about others who did not consent to the research, the potential for learning potentially harmful or damaging information, and the potential for risk to communities as well as to individuals.

Stored Tissue Samples. Tissue samples that are obtained from individuals, either as part of a research study or as part of clinical care, can be stored indefinitely. As such, previously collected samples of blood, particularly those that can be linked to certain demographic and clinical characteristics of the source individuals, are of great interest to other researchers. The ethics question becomes when and under what circumstances those samples may be used by future researchers for purposes quite unrelated to those for which they originally were collected and for purposes never disclosed to source individuals. The concern is that material risks to individuals can occur when genetic information about them is shared (see the discussion below); moreover, gathering information about someone that does *not* result in material harm still can wrong them if it is done without their knowledge and consent. In deciding individual cases, it is important to examine for what purposes consent originally was obtained from the source individuals and whether future researchers want the samples to remain identifiable. Many persons believe that it is inappropriate for individuals ever to be asked to provide blanket consent for all unknown future purposes if the samples remain identifiable (46). Rather, individuals may be asked willingness to provide consent for focused future purposes of their identifiable samples (e.g., future studies also related to Alzheimer's research). Bartha Knoppers has developed a core list of elements to include in a consent discussion when DNA samples will be stored (47). She suggests that individuals be required to agree or disagree with specific uses of data, including, for example, whether to undergo diagnostic tests, whether to permit consultation of their medical records, and whether to be contacted if genetic disorders are identified. Alternatively, samples may be stripped of identifiers. When samples are made anonymous, most ethics concerns disappear, since most risks and harms to individuals can never occur. The use of anonymous samples requires that the samples already existed when the new research plan was proposed and that it is impossible to go back and link samples to identifiable persons (48). Generally, when genetic information is anonymous, the potential benefits of scientific research

are thought to outweigh the risks to individual integrity even without permission from the source individuals.

Uninterpretable Information Learned through Genetic Research. Genetic testing, particularly in its early stages, often is probabilistic, rather than predictive, in nature. Through genetic research, markers may be identified that are associated with certain conditions, but their presence does not guarantee that the individual will become clinically affected, nor will all clinically affected persons possess the marker. Rather, additional markers and/or environmental factors will need to be identified that increase the predictive value of the genetic tests. This fact poses the challenge of, first, explaining complex probabilities to research participants who are more accustomed to extremely sensitive and specific diagnostic tests, and, in addition, determining when the level of uncertainty is so great that it is inappropriate to provide genetic testing results conducted in research to research participants. Indeed, some research at the initial stages of identifying a genetic marker may be considered far too premature to provide information to subjects. Researchers should consider the implications of ambiguous information before the study is initiated and determine *in advance* whether or not research test results will be made available to study subjects. If researchers determine that the results will not be made available, this must be communicated very clearly to subjects during the informed consent process. If results are to be made available, it is best to have a genetic counselor provide and interpret the information to subjects (46). Occasionally researchers may find themselves in the position of having informed subjects in advance that no information gained through the research would be disclosed, but then coming to believe that the information has greater clinical relevance than anticipated. Deciding whether to change disclosure procedures from that which was originally described is a difficult decision and should be made on a case-by-case basis with careful consideration and consultation from others, such as the IRB (49).

In addition to information being of questionable predictive value, there may be little to do as a result of learning it. There are many genetic conditions for which tests now are available yet for which there are no good treatments. It must be highlighted to research participants in such circumstances that the individual benefit to gaining the information (should it be disclosed) is psychological, rather than clinical. Further, when information will not be disclosed, it must be made clear that the purpose of the study is *not* to provide clinical benefit to the individuals who enroll. That is, the study may be conducted in order to compare the prevalence of a marker among different populations, or to determine the sensitivity and specificity of a recently developed test. Ellen Wright Clayton et al. (48) discuss possible legal liability from knowing information about a person that is not disclosed; she suggests that the risk of this is small if truly clinical decisions would not have been made differently had access to the information been available. It must be remembered that in some instances, however, the information *is* of clinical value to the individual or his/her relatives. In such instances, if researchers have a threshold level of confidence in the validity of their data, research participants should be given the choice of whether to learn the information discovered about them through their participation. Further, given that subjects often expect to be told information learned about them, or expect that hearing nothing means that no abnormalities were found, researchers must be very clear in circumstances in which research findings are not disclosed that this does not in any way reveal whether or not a marker was identified for that person.

Potential for Learning Information About Others without their Consent. Inherent to genetic information is that it usually is hereditary, and usually reveals at least some amount of information about other members of one's family. The type of study often conducted to identify a genetic marker is called a pedigree study. In pedigree studies researchers do genetic analyses of blood samples of many members of an extended family known either to be affected or unaffected by a hereditary condition in order to identify a genetic marker that exists uniquely among the affected individuals. Although researchers seek the consent of as many family members as possible, some cannot be found, and others refuse to participate. The awkwardness arises that through the testing of those who *do* provide consent, researchers may de facto learn genetic information about individuals who were not involved in the study. For example, an adult child may refuse to be in a study in which both of her parents agreed to participate, and the child's makeup is inevitably knowable; or one parent may refuse to participate while the other parent and children consent, again inevitably revealing part of the genotype of the parent who refused participation. It is up to IRBs and researchers to determine whether this ability to identify individuals, which ultimately is an invasion of their privacy, is acceptable, taking into consideration the sensitivity of the information revealed. In rare instances, pedigree studies may only be allowable when all members of an extended family agree to participate. Again, it is the role of genetic counselors, acting on behalf of investigators, to make this knowledge clear to participants in the informed consent process before a pedigree or family study is initiated.

Issues of family identification and confidentiality also become relevant in the context of research presentation and publication. While it always is true that research findings must be presented in ways that do not reveal the identities of the individuals who participated, researchers may forget that simply deleting names of individual research subjects does not guarantee anonymity. Pedigree studies may reveal the identities of individuals if, for example, the disease is rare and the family has other unusual characteristics (e.g., it includes triplets), and/or if the town in which many of the family live is identified in the report. It also is possible that individuals reading a published pedigree in a medical journal will recognize the family described as their own and will learn genetic information about other members of their extended family. There is great debate about whether it is ethically and scientifically appropriate for researchers to modify the

pedigree slightly in published reports in order to make the family no longer identifiable, for example, by randomly adding a few family members to the tree who never existed.

Gathering Potentially Harmful or Damaging Information, and Issues of Confidentiality. The information gathered through genetic testing may put individuals at risk of psychological or material harm. Individuals differ greatly in how they react to information that they often can do nothing about it. While some individuals find the knowledge beneficial, others may be made more anxious and upset about something over which they have no control. To the degree possible, counselors should try to walk individuals through different scenarios and try to determine how they think they would react to different types of information before they decide to be in studies in which disclosure could occur.

Moreover, impaired access to certain opportunities, such as health or life insurance and employment, may result as a consequence of participation in genetic research (50). While this rarely is due to researchers' negligence in maintaining confidentiality — and indeed some researchers have Certificates of Confidentiality from the federal government to provide additional confidentiality protections (51,52) — information can become available to insurers in other ways. For example, an individual may mention to her personal physician that she is enrolled in the pedigree study. If the physician makes a note of this in the patient's medical record, the information — even if the test results are not documented — could cause a red flag for insurers who might for other reasons be examining the patient's medical record. In such an instance, the insurer might insist on obtaining a copy of the research records before determining whether the individual was eligible for health, life, or disability insurance. Also persons applying for individual health, life, or disability insurance policies might be asked on a general health question about any medical testing or adverse findings of which they are aware. There is not clear consensus concerning whether information that individuals did not obtain through the clinical setting and was not obtained out of clinical concern must be disclosed to insurance companies in this context.

In some studies researchers bill health insurance companies for genetic testing conducted as part of the research. Obviously this alerts companies to the fact that the testing was done and, usually, that the individual is from a family of higher than average risk of disease. It may be appropriate for researchers, out of respect for the welfare of their participants, not to bill insurance companies in this manner.

A further potential harm arises from learning unanticipated information. While uncommon, it sometimes happens when conducting genetic testing that information that was not sought or anticipated becomes apparent. For example, researchers may become aware of mistaken paternity or of anomalies in the sex chromosomes (e.g., XXY genotypes). This often is troubling to researchers who are caught completely off guard and wonder if they have a responsibility to share the information with participants. In general, it is best for researchers to make it clear in advance that such incidental information will *not* be shared with participants. The exception may be information that researchers, *in consultation with others*, believe holds clinical relevance to the individual would lead the individual to act differently in some relevant way were he aware of it.

Information of Relevance to Communities, in Addition to Individuals. Often specific communities are targeted for genetic research. This may be a community of family members, or it may be an ethnic or religious group (e.g., Ashkenazi Jews), or it may be a group defined by where it lives, such as research conducted as part of the Human Genome Diversity Project, which seeks "information on human genetic diversity, the origins and migration of human populations, and genetic factors related either to resistance or susceptibility to disease" (53, p. 7). In such contexts, risks and potential benefits to communities must be considered, and a person or persons able to provide consent on behalf of the community must be identified. It has been suggested that a fourth principle of bioethics is needed to supplement those described earlier, a principle of "respect for communities" (53). Risks to communities from genetic research are real, since even research that strips samples of individual identifiers often still identifies the sample by "kindred, locality, or ethnicity" (54). In the past, material harms came to persons with sickle cell trait (rather than disease) as a result of being identified (54), and harmful stereotyping or self-perception can result from sweeping conclusions that sometimes are made in research. Foster et al. suggest a process of "communal discourse" to supplement and inform individual informed consent (54). This would occur through public meetings with representatives of the community in which opinions and suggestions are sought and communicated to investigators. Moreover, consulting an advisory board through the duration of the study can be helpful in ensuring that two-way communication remains ongoing.

In terms of recommendations, researchers should engage in an extensive consent discussion and dialogue with potential participants before and, often, during the research. All practical and procedural issues must be covered (amount of time required, purpose of results, etc.). Moreover, a genetic counselor should try to "walk" potential participants through different scenarios to try to discern how they would react to hearing ambiguous or probabilistic information. As a practical matter, given the risks to confidentiality that exist, investigators should apply for a certificate of confidentiality in genetic studies and also should minimize the likelihood that information they learn through studies can become part of the medical record. This means maintaining separate research and clinical records, not filing claims with health insurance companies for tests conducted solely for research purposes, and counseling participants about circumstances that might lead to information about them becoming part of their medical record.

CONCLUSION

Research as an enterprise has grown exponentially in the last several decades, and the field of research ethics has

grown with it. It is unfortunate that it takes examples of unethical practice to prompt us to develop appropriate guidelines and regulations, but the standards we currently have certainly are far more likely to protect the interests of potential subjects than was true decades before. As more research is conducted in the areas of genetics and incapacity, surely the field of research ethics similarly will move forward. In the meantime there is no better protection for subjects than a conscientious and humble researcher, who is aware that he or she may be easily misunderstood, and who is aware that the welfare of the subject always is of greater importance than any particular research question.

HUMAN SUBJECTS RESEARCH, ETHICS, PRINCIPLES GOVERNING RESEARCH WITH HUMAN SUBJECTS

ROBERT J. LEVINE
Yale University School of Medicine
New Haven, Connecticut

OUTLINE

INTRODUCTION

In 1974 the United States Congress passed the National Research Act (Public Law 93-348) which established the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (hereafter, the National Commission). This Commission was charged by Congress to "identify the basic ethical principles which should underlie the conduct of ... research involving human subjects (and) to develop guidelines which should be followed in such research to assure that it is conducted in accordance with such principles...." The principles identified by the National Commission were published in 1978 in its *Belmont Report* (1). This document proved to be highly influential; its principles provide the basis for virtually all commentary on the ethics of research involving human subjects. Moreover these principles have been adopted in major international documents that contain guidance for the ethical conduct of research involving human subjects such as the Council of International Organizations of Medical Sciences' (CIOMS) *International Ethical Guidelines for Biomedical Research Involving Human Subjects* (2).

The guidelines developed by the National Commission were published in a series of reports (3). They have been adopted by the U.S. federal government as the regulations for the protection of human subjects and have also influenced the development of policy in many other nations.

The National Commission defined the basic ethical principle as "a general judgment that serves as a basic justification for the many particular prescriptions for and evaluations of human actions" (1, p. 4). Such a principle is taken as an ultimate foundation for any second-order principles, rules, and norms; it is not derived from any other statement of ethical values. The National Commission identified three basic ethical principles as particularly relevant to the ethics of research involving human subjects: respect for persons, beneficence, and justice. The norms and procedures presented in regulations and ethical codes are derived from and are intended to uphold these fundamental principles. As the National Commission observed in an early draft of the *Belmont Report*:

> Reliance on these three fundamental underlying principles is consonant with the major traditions of western ethical, political and theological thought represented in the pluralistic society of the United States, as well as being compatible with the results of an experimentally based scientific analysis of human behavior... (3, p. 18).

Thus, in the National Commission's view, these principles pertain to human behavior in general; it is through the development of norms that they are made peculiarly relevant to specific classes of activities such as research and the practice of medicine.

Some of the language used by the National Commission may imply an endorsement of one or another foundational ethical theory. For example, the term "respect for persons" suggests a reference to Kantian theory. It is clear, however, that the National Commission did not embrace any such theory (3). As observed by Abram and Wolf:

> Aware of Kantian (deontological), utilitarian, and Aristotelian traditions, for instance, the commission nonetheless refrained from relying on any one of them for the legitimacy of its conclusions. Agreement on a fundamental moral system was not sought or needed (4).

Although these authors discussed the President's Commission, they made it clear that it was patterned after the National Commission, which similarly refrained from relying exclusively on any particular moral system.

ETHICAL PRINCIPLES

Respect for Persons

The principle of respect for persons was stated formally by Immanuel Kant: "So act as to treat humanity, whether

in thine own person or in that of any other, in every case as an end withal, never as a means only." However, what it means to treat a person as an end and not merely as a means to an end may be variously interpreted. The National Commission concluded that:

> Respect for persons incorporates at least two basic ethical convictions: First, that individuals should be treated as autonomous agents, and second, that persons with diminished autonomy and thus in need of protection are entitled to such protections (1).

An autonomous person is "...an individual capable of deliberation about personal goals and of acting under the direction of such deliberation" (1). To show respect for autonomous persons requires that we leave them alone, even to the point of allowing them to choose activities that might be harmful (e.g., mountain climbing) unless they agree or consent that we may do otherwise. We are not to touch them or to encroach upon their private spaces unless such touching or encroachment accords with their wishes. Our actions should be designed to affirm their authority and enhance their capacity to be self-determining; we are not to obstruct their actions unless they are clearly detrimental to others. We show disrespect for autonomous persons when we either repudiate their considered judgments or deny them the freedom to act on those judgments in the absence of compelling reasons to do so.

Clearly, not every human being is capable of self-determination. The capacity for self-determination matures during a person's life; some lose this capacity partially or completely owing to illness or mental disability or in situations that severely restrict liberty, such as in prisons. Respect for the immature or the incapacitated may require one to offer protection to them as they mature or while they are incapacitated.

Beneficence

The principle of beneficence is firmly embedded in the ethical tradition of medicine. It is commonly said that the first principle of medical ethics is "Do no harm." This principle is often stated in Latin, *primum non nocere*, which translated literally means "first (or above all) do no harm." Moreover this statement of principle is commonly and incorrectly attributed to Hippocrates.

Parenthetically, the closest approximation of this statement that can be found in the Hippocratic writings is in the book entitled *Epidemics*: "As to diseases, make a habit of two things — to help, or at least to do no harm" (5). If the first principle of medicine were truly "above all, do no harm," this would rule out virtually all medical therapy; almost all therapies present to the patient a risk of injury. The statement from *Epidemics* is much more compatible with the modern emphasis on trying to achieve a favorable balance of harms and benefits.

In the Hippocratic Oath, the principle of beneficence is expressed in several statements such as:

> I will apply dietetic measures for the benefit of the sick according to my ability and judgment. ...I will neither give a deadly drug to anybody if asked for it, nor will I make a suggestion to this effect.

In biomedical research the leading ethical codes such as the World Medical Association's Declaration of Helsinki enjoin the physician-investigator not only to secure the well-being of individuals (research subjects and patients) but also to develop information that will form the basis of being better able to do so in the future. And, according to the Nuremberg Code, the risks of research must be justified by "the humanitarian importance of the problem to be solved by the experiment."

The National Commission defined 'beneficence' as follows:

> The term, *beneficence*, is often understood to cover acts of kindness or charity that go beyond strict obligation. In this document, beneficence is understood in a stronger sense, as an obligation. Two general rules have been formulated as complementary expressions of beneficent actions in this sense: (*1*) Do no harm and (*2*) maximize possible benefits and minimize possible harms (1).

The first of these two "general rules" proscribes the deliberate infliction of serious injury on an identified individual for research purposes. That is, one may not impose a 100 percent probability of disabling injury on a human subject with no justification other than to solve a research problem (6). "Do no harm" as envisioned by the National Commission does not mean "above all, do no harm." Rather, it permits exposing research subjects to a statistical probability of harm if such exposure is justified in terms of the anticipated benefits, among other considerations (3).

The second general rule of beneficence calls upon investigators to design all of their work so as to maximize the probability and magnitude of benefit to individual research subjects as well as to society. It further requires investigators to minimize the probability and magnitude of injury to subjects and of harm to the interests of human collectives (3). Among the ethical norms that are grounded primarily in the second general rule are the requirements for good research design and competent investigators (3) and the requirement for a favorable relation of risks to anticipated benefits (3, pp. 37ff).

Some authors argue that separation of these two general rules into two fundamental ethical principles, beneficence (do good) and nonmaleficence (do no harm), would tend to decrease confusion (7). For the present purposes, however, it is more convenient to treat beneficence as a single principle; it is generally necessary to consider harms and benefits in relation to each other.

Frankena identifies four obligations that derive from the principle of beneficence (8); listed in decreasing order of ethical force, these are:

A. One ought not to inflict evil or harm.
B. One ought to prevent evil or harm.
C. One ought to remove evil.
D. One ought to do or promote good.

Statement A is a straightforward articulation of the National Commission's first general rule, do no harm (also known as principle of nonmaleficence). Few, if any, would argue that the injunction against inflicting harm or evil

is not at least a very strong prima facie duty. Statement D, by contrast, is not regarded generally as a duty or obligation but rather, as the National Commission pointed out, an exhortation to act kindly or charitably. Statement D becomes a duty in the strict sense most typically when one consents or contracts to be bound by it. Physicians, for example, pledge themselves to act for the benefit of patients. Similarly, researchers who accept public support for their work assume a contractual obligation to promote good by contributing to the development of new knowledge. Moreover, without regard to funding, when one invites human beings to participate in activities that expose them to risk of injury, it is generally necessary to offer them in return something they find valuable; in the context of research involving human subjects, the most generally acceptable item of value that can be offered is a promise to pursue benefits either to the individual subjects or to others with whom they feel a bond of kinship (3). Such promises are made explicit in the process of informed consent. In the light of these considerations the National Commission determined that investigators who performed research involving human subjects incurred a strict duty or obligation to do or promote good.

Justice

Justice requires that we treat persons fairly and we give each person what he or she is due or owed (3). Justice is either comparative or noncomparative. Comparative justice is concerned with determining what a person is due by weighing his or her claims against the competing claims of others. Noncomparative justice is concerned with identifying what persons are due without regard to the claims of others (e.g., never punish an innocent person). The concerns addressed by the National Commission under the rubric of justice are exclusively concerns of distributive justice, a type of comparative justice. This article follows the National Commission in using the term "justice" to mean "distributive justice."

Distributive justice is concerned with the distribution of scarce benefits where there is competition for these benefits. If there is no scarcity, there is no need to consider just systems of distribution. Distributive justice is also concerned with the distribution of burdens, specifically when it is necessary to impose burdens on fewer than all members of a seemingly similar class of persons.

Justice requires a fair sharing of burdens and benefits; however, just what constitutes a fair sharing is a matter of considerable controversy. To determine who deserves to receive which benefits and which burdens, we must identify morally relevant criteria for distinguishing unequals. Various criteria have been proposed (9). Is it fair for persons to be treated differently on the basis of their needs? Their accomplishments? Their purchasing power? Their social worth? Their past records or future potential?

There are those who argue that the fairest distribution of burdens and benefits is precisely that which creates the most benefits for society at large. This is the classical utilitarian argument, which harmonizes the principles of justice and beneficence by stipulating that there is no conflict. To create goods is to do justice; just institutions act so as to produce the greatest good for the greatest number. The National Commission rejected this formulation because it does not accord either with Western concepts of the fundamental equality of persons (e.g., before the law) or with the very strong tradition that interprets fairness to require extra protection for those who are weaker, more vulnerable, or less advantaged than others. This latter interpretation is reflected in such disparate sources as the injunction in the Judeo-Christian tradition to protect widows and orphans, the Marxist dicta "from each according to ability; to each according to need," and more recently, Rawls's contractual derivation of principles of justice (10).

The National Commission's interpretation of the requirements of justice is embodied in one of its statements on the relevance of this principle to the problem of selection of subjects:

> [T]he selection of research subjects needs to be scrutinized in order to determine whether some classes (e.g., welfare patients, particular racial and ethnic minorities, or persons confined to institutions) are being systematically selected simply because of their easy availability, their compromised position, or their manipulability, rather than for reasons directly related to the problem being studied. Finally, whenever research supported by public funds leads to the development of therapeutic devices and procedures, justice demands both that these not provide advantages only to those who can afford them and that such research should not unduly involve persons from groups unlikely to be among the beneficiaries of subsequent applications of the research (1, pp. 9–10).

Each of the three basic ethical principles identified by the National Commission is intended to have equal moral force. In this way the ethical system differs from those that have a single overarching superprinciple such as "justice" or *agape*. It further differs from those that assign priority to principles — to rank them in order of moral forcefulness — to resolve disputes engendered by conflicting requirements of two or more principles (10). The three principles give rise to norms that often create conflicting requirements. For example, the principle of justice, as articulated by the National Commission, creates requirements that are incompatible with some of those created by its principle of respect for persons (3). Similarly norms derived from the principle of beneficence inevitably engender conflicts with those arising from the principle of respect for persons. Implicitly, then, the National Commission also endorsed the notion of prima facie rules; these are rules that are binding unless they are in conflict with other stronger rules or unless in specific situations there is ethical justification for overriding the rule's requirements (3).

ETHICAL NORMS

An ethical norm is a statement that actions of a certain type ought (or ought not) to be done. If reasons are supplied for these behavioral prescriptions (or proscriptions), they are that these acts are morally right (or wrong).

Statements of ethical norms commonly include the words "should" or "ought," but in some cases there are stronger terms such as "must" or "forbidden." A typical statement of an ethical norm is: Research should be conducted only by scientifically qualified persons. The behavior-prescribing statements contained in the various codes and regulations on research involving human subjects may be regarded as variants of five general ethical norms (11). There should be (*1*) good research design, (*2*) competent investigators, (*3*) a favorable balance of harm and benefit, (*4*) informed consent, and (*5*) equitable selection of subjects. In addition a sixth general ethical norm appears in some international guidelines: (*6*) there should be compensation for research-induced injury. The purpose of these ethical norms is to indicate how the requirements of the three fundamental ethical principles may be met in the conduct of research involving human subjects.

Because statements of the ethical norms in codes and regulations tend to be rather vague, they permit a variety of interpretations; it is sometimes difficult to know exactly how to apply them to particular cases. When faced with such uncertainty, it is generally helpful to look behind the norm to examine the fundamental ethical principle or principles it is intended to uphold or embody. Accordingly, the discussion of each ethical norm will call attention to the fundamental ethical principle or principles it is designed to serve.

Good Research Design

> The experiment should be so designed and based on the results of animal experimentation and a knowledge of the natural history of the disease or other problem under study that the anticipated results will justify the performance of the experiment (Nuremberg 3).
>
> Biomedical research involving human subjects must conform to generally accepted scientific principles and should be based on adequately performed laboratory and animal experimentation and on a thorough knowledge of the scientific literature (Helsinki I. 1).
>
> [S]cientifically unsound research on human subjects is *ipso facto* unethical in that it may expose subjects to risk or inconvenience to no purpose (CIOMS 14, commentary).

These are typical expressions of the ethical requirement that research must be sufficiently well-designed to achieve its purposes; otherwise, it is not justified. The primary purpose of this norm is to uphold the principle of beneficence. If the research is not well designed, there will be no benefits; investigators who conduct badly designed research are not responsive to the obligation to do good or to develop generalizable knowledge that is sufficiently important to justify the expenditure of public funds, to impose upon human subjects risks of physical or psychological harm, and so on.

This norm is also responsive to the principle of respect for persons. Persons who agree to participate in research as subjects are entitled to assume that something of value will come of their participation. Poorly designed research wastes the time of the subjects and frustrates their desire to participate in a meaningful activity.

Competence of the Investigators

> The experiment should be conducted only by scientifically qualified persons. The highest degree of skill and care should be required through all stages of the experiment of those who conduct or engage in the experiment (Nuremberg 8).
>
> Biomedical research involving human subjects should be conducted only by scientifically qualified persons and under the supervision of a clinically competent medical person. The responsibility for the human subject must rest with a medically qualified person . . . (Helsinki I.3).

This norm requires that the investigators be competent in at least two respects. They should have adequate scientific training and skill to accomplish the purposes of the research. The purpose of this component of the norm is precisely the same as that requiring good research design; it is responsive primarily to the obligations to produce benefits to society through the development of important knowledge. It is also responsive to the obligation to show respect for research subjects by not wasting their time or frustrating their wishes to participate in meaningful activities. In addition investigators are expected to be sufficiently competent to care for the subject. The Declaration of Helsinki, as an instrument of the World Medical Association, is addressed only to medical research. Therefore, it places responsibility with ". . .a medically qualified person." The Nuremberg Code, on the other hand, is addressed more generally to research; consequently, it does not call for medical qualification.

Competence to care for the subjects of most clinical research requires that at least one member of the research team be responsible for observing the subject with a view toward early detection of adverse effects of his or her participation or other evidence that the subject should be removed from the study. The investigator should have the competence to assess the subjects' symptoms, signs, and laboratory results. There should further be the competence to intervene as necessary in the interests of minimizing any harm, such as by prompt administration of an antidote to a toxic substance.

Balance of Harms and Benefits

There are normative statements in the ethical codes and regulations that require a favorable balance between harm and benefit. Without such a favorable balance there is no justification for beginning or continuing the research.

> The degree of risk to be taken should never exceed that determined by the humanitarian importance of the problem to be solved by the experiment (Nuremberg 6).
>
> Biomedical research involving human subjects cannot legitimately be carried out unless the importance of the objective is in proportion to the inherent risk to the subject (Helsinki I.4).
>
> Risks to the subjects [must be] reasonable in relation to anticipated benefits, if any, to subjects, and the importance of the knowledge that may reasonably be expected to result (CFR. 46. 111a(2)).

There are additional norms in codes and regulations that call for vigilance on the part of those conducting

or supervising the research. At any point along the way, the balance of harms and benefits may become unfavorable; under these circumstances the research should be terminated.

> During the course of the experiment the scientist in charge must be prepared to terminate the experiment at any stage, if he has probable cause to believe ... that a continuation ... is likely to result in injury, disability or death to the experimental subject (Nuremberg 10).
>
> The investigator ... should discontinue the research if in his/her ... judgment it may, if continued, be harmful to the individual (Helsinki III. 3).
>
> Where appropriate, the research plan makes adequate provision for monitoring the data collected to insure the safety of the subjects (CFR. 111a (6)).
>
> An IRB shall have authority to suspend or terminate approval of research ... that has been associated with unexpected serious harm to subjects (CFR. 113).

The requirement that research be justified on the basis of a favorable balance of harms and benefits is derived primarily from the ethical principle of beneficence. In addition a thorough and accurate compilation of the risks and hoped-for benefits of a research proposal also facilitates responsiveness to the requirements of the principles of respect for persons and justice. A clear and accurate presentation of risks and benefits is necessary in the negotiations with the subject for informed consent. Similarly such a compilation of burdens and benefits facilitates discussions of how they might be distributed equitably.

Ethical codes and regulations require not only that risks be justified by being in a favorable relationship to hoped-for benefits but also that they be minimized.

> The experiment should be so conducted as to avoid all unnecessary physical and mental suffering and injury (Nuremberg 4).
>
> The IRB shall determine that ... risks to subjects are minimized: 1) By using procedures which are consistent with sound research design and which do not unnecessarily expose subjects to risk, and (ii) whenever appropriate, by using procedures already being performed on the subjects for diagnostic or treatment purposes (CFR. 111a (1)).

Informed Consent

Principle I of the Nuremberg Code provides the definition of consent from which the definitions contained in all subsequent codes and regulations are derivative:

> The *voluntary* consent of the human subject is absolutely essential.
>
> This means that the person involved should have *legal capacity* to give consent; should be so situated as to be able to exercise *free power of choice*, without the intervention of any element of force, fraud, deceit, duress, over-reaching or other ulterior form of constraint or coercion; and should have sufficient *knowledge* and *comprehension* of the elements of the subject matter involved as to enable him to make an understanding and enlightened decision. This latter element requires that before the acceptance of an affirmative decision by the experimental subject there should be made known to him the nature, duration, and purpose of the experiment; the method and means by which it is to be conducted; all inconveniences and hazards reasonably to be expected; and the effects upon his health or person which may possibly come from his participation in the experiment [*emphasis supplied*].

Thus the consent of the subject in order to be recognized as valid must have four essential attributes. It must be competent (legally), voluntary, informed, and comprehending (or understanding).

It is through informed consent that the investigator and the subject enter into a relationship, defining mutual expectations and their limits. This relationship differs from ordinary commercial transactions in which each party is responsible for informing himself or herself of the terms and implications of any of their agreements. Professionals who intervene in the lives of others are held to higher standards. They are obligated to inform the lay person of the consequences of their mutual agreements.

According to the President's Commission, "Although the informed consent doctrine has substantial foundations in law, it is essentially an ethical imperative" (12, p. 2). The President's Commission refers repeatedly to "ethically valid consent" and in this way reflects a perspective differing with that of federal regulations, which refer to "legally effective informed consent."

The requirement for informed consent is designed to uphold the ethical principle of respect for persons (3, pp. 95ff). It is through informed consent that we make operational our duty to respect the rights of others to be self-determining, namely to be left alone or to make free choices. We are not to touch others or to enter their private spaces without permission. As stated by Justice Cardozo, "Every human being of adult years and sound mind has a right to determine what will be done with his own body..." (13, p. 526).

Privacy and Confidentiality

Closely related to the norms calling for informed consent and minimization of risk are the requirements found in ethical codes and regulations that protect privacy and confidentiality. Privacy is "the freedom of the individual to pick and choose for himself the time and circumstances under which, and most importantly, the extent to which, his attitudes, beliefs, behavior and opinions are to be shared with or withheld from others" (14). In general, investigators are not permitted to intrude into individuals' privacy without their informed consent. When an informed person allows an investigator into his or her private space, there is no invasion.

"Confidentiality," a term that is often and incorrectly used interchangeably with "privacy," refers to a mode of management of private information; if a subject shares private information with (confides in) an investigator, the investigator is expected to refrain from sharing this information with others without the subject's authorization or some other justification.

The ethical grounding for the requirement to respect the privacy of persons may be found in the principle of respect for persons. The ethical requirement for the maintenance of confidentiality of private information is grounded in the norm calling for the minimization of harms. Breaches of

confidentiality may result in such social injuries as loss of personal autonomy, valued relationships, or eligibility for insurance or employment. Moreover, maintenance of confidentiality is essential to the successful practice of various professions; for example, sick people would not consult physicians unless they were confident that their private information would be kept secret (15).

Equitable Selection of Subjects

> Individuals ... to be invited to be subjects of research should be selected in such a way that the burdens and benefits of the research will be equitably distributed. Special justification is required for inviting vulnerable individuals ... (CIOMS 10).
>
> [T]he IRB shall determine that.... Selection of subjects is equitable ... (CFR. 111a (3)).

This requirement is derived from the principle of justice, which requires equitable distribution of both the burdens and the benefits of research. Until the 1970s codes of ethics and regulations were relatively silent on this matter; however, the preamble to the Nuremberg Code reflected an concern with issues of social justice. It pointed out that the "crimes against humanity" were particularly egregious in that they were perpetrated on "non-German nationals, both prisoners of war and civilians, including Jews and 'asocial' persons" Implicit in this statement is the perception that because these subjects were not considered persons in the full sense of the word, they were not accorded the respect due to fully enfranchised persons. As a consequence principle I of the Nuremberg Code established the high standards for consent discussed earlier. When thoroughly honest offers are made to fully autonomous persons, they are presumed capable of defending their own interests and of selecting themselves as research subjects. Because the Nuremberg Code does not entertain the possibility of involving less than fully autonomous subjects, no requirements for their selection are provided.

Ethical codes and regulations in the field of research involving human subjects project an attitude of protectionism. Their dominant concerns are the protection of individuals from injury and from exploitation. There are important historical reasons for this protectionistic attitude. These documents were written with the aim of ensuring that there would never be a repetition of atrocities like those committed by the Nazi physician-researchers, calamities like the thalidomide experience, or ethical violations like those of the Tuskegee syphilis study. In recent years society's perception of biomedical research has shifted dramatically. Now, largely as a consequence of the efforts of the AIDS activists, biomedical research is widely perceived as benign and beneficial (16).

In the era of protectionism, which lasted from the mid-1940s through the mid-1980s, those who wrote policy for the protection of research subjects interpreted the principle of justice to require protection of vulnerable or disadvantaged persons from bearing an unfair share of the burdens of serving as research subjects. Since the mid-1980s, as a reflection of the shift in society's attitude toward research, policies and practices are being revised; the same principle of justice is being interpreted to require assurance that the vulnerable and disadvantaged will enjoy equitable access to the benefits of participation in research.

Populations who were excluded previously because they were considered vulnerable include children, women who have the biological capacity to conceive, and members of racial and ethnic minorities; in recent years federal policies have been revised to require adequate representation of each of these populations in research (17).

Compensation for Research-Induced Injury

> Research subjects who suffer physical injury as a result of their participation are entitled to such financial or other assistance as would compensate equitably for any temporary or permanent impairment or disability. In case of death, their dependants are entitled to material compensation. The right to compensation may not be waived (CIOMS 13).

During the 1970s commentators on the ethics of research reached a consensus that subjects who are injured as a consequence of their participation in research are entitled to compensation. The ethical arguments to support this entitlement are grounded in considerations of compensatory justice (18). Compensatory justice consists in giving injured persons their due by taking account of their previous conditions and attempting to restore them. Sometimes it is possible to literally restore injured persons to their previous conditions, such as through medical therapy for the research-induced injury or illness. On other occasions, when literal restoration is not feasible, a monetary substitute is about the best we can do. Most discussions of compensation for research-induced injury focus on the provision of monetary substitutes in cases in which there is temporary or permanent disability or death.

In the commentary under its guideline number 13, CIOMS notes:

> In some societies the right to compensation for accidental injury is not acknowledged. Therefore, when giving their informed consent to participate, research subjects should be told whether there is a provision for compensation in case of physical injury, and the circumstances in which they or their dependants would receive it.

The United States is one society in which the right to such compensation is not acknowledged. Federal regulations require that prospective research subjects receive:

> an explanation as to whether any compensation and an explanation as to whether any medical treatments are available if injury occurs and, if so, what they consist of, or where further information may be obtained ... (46.116a).

PROCEDURAL NORMS

Ethical codes and regulations contain, in addition to the substantive ethical norms, descriptions of procedures (procedural norms) that are to be followed to assure that investigators comply with the requirements of the substantive norms. The most important general procedural requirement that is relevant to all research

involving human subjects conducted in the United States is the review by an Institutional Review Board (IRB).

Federal regulations require that research involving human subjects be reviewed and approved by an IRB before it may be initiated. The criteria for approval are to ensure that plans are adequate for compliance with each of the substantive norms other than those calling for good research design and competent investigators; responsibility for these determinations is assigned to other agents or agencies (19). In other countries the same assignment is issued to research ethics committees or research ethics boards (20). Article I.2 of the Declaration of Helsinki requires only that the "experimental protocol ... be ... transmitted for consideration, comment and guidance to a committee independent of the investigator and sponsor...." CIOMS guideline 14, by contrast, requires "review and approval by one or more independent ethical and scientific review committees."

Another general procedural requirement (general in that it is designed to ensure compliance with all of the substantive norms) is concerned with the publication of the results of research that appears to have been done unethically. US federal regulations are silent on this issue. There are differing positions in the international documents:

> Reports of experimentation not in accordance with the principles laid down in this Declaration should not be accepted for publication (Helsinki I.8).

CIOMS offers the following commentary under Guideline 15:

> Refusal to publish the results of research conducted unethically ... may be considered, as may refusal to accept unethically obtained data submitted in support of an application for drug registration. However, these sanctions deprive of benefit not only the errant investigator or sponsor but also that segment of society intended to benefit from the research; such possible consequences merit careful consideration.
>
> publication of reports of the results of research ... should include, when appropriate, a statement that the research was conducted in accordance with these guidelines. Departures, if any, should be explained and justified....

There are also specific procedural norms such as the requirement for documentation of informed consent which is designed to ensure compliance with the substantive norm that calls for informed consent.

VULNERABLE PERSONS AS RESEARCH SUBJECTS

When the federal government published its first proposals to develop regulations providing additional protections for especially vulnerable populations of research subjects, it designated them as persons having "limited capacities to consent" (3). The choice of this label highlights the nature of the fundamental problem in justifying their use as research subjects. Because the Nuremberg Code identifies voluntary consent as "absolutely essential," it is clearly problematic to involve subjects who lack free power of choice (e.g., prisoners), the legal capacity to consent (e.g., children), or the ability to comprehend (e.g., the mentally infirm). (Another term commonly used for "those having limited capacities to consent" is "the special populations.")

The National Commission concluded that persons having limited capacity to consent are vulnerable or disadvantaged in ways that are morally relevant to their involvement as subjects of research (3). Therefore the principle of justice is interpreted as requiring that we facilitate activities that are designed to yield direct benefit to the subjects and that we encourage research designed to develop knowledge that will be of benefit to the class of persons of which the subject is a representative. However, we should generally refrain from involving the special populations in research that is irrelevant to their conditions as individuals or at least as a class of persons. Respect for persons is interpreted as requiring that we show respect for a potential subject's capacity for self-determination to the extent that it exists. Some who cannot consent can register knowledgeable agreements (assents) or deliberate objections. In most instances the assent of an individual who cannot consent must be supplemented by the permission of that individual's parent or guardian (in the language of federal regulations, the "legally authorized representative").

To the extent that the capacity for self-determination is limited, respect is shown by protection from harm. Thus the Commission recommends that the authority accorded to members of the special populations or their legally authorized representatives to accept risk be strictly limited; any proposal to exceed the threshold of "minimal risk" requires special justification.

The reports of the National Commission on each of the "special populations" were followed by the promulgation of federal regulations providing "additional protections" for the fetus and pregnant women and for human in vitro fertilization (IVF); for prisoners, and for children (3). Regulations also were proposed for "those institutionalized as mentally disabled" but these have not been promulgated as final regulations (3).

Federal regulations also require:

> Where some or all of the subjects are likely to be vulnerable to coercion or undue influence, such as persons with acute or severe physical or mental illness, or persons who are economically or educationally disadvantaged, appropriate additional safeguards (should be) included in the study to protect the rights and welfare of these subjects (46.111b).

CIOMS, in the commentary under guideline 10, provides an extensive list of the types of persons who may in certain circumstances be considered vulnerable.

ARE THE BASIC ETHICAL PRINCIPLES UNIVERSAL?

The question of whether the basic ethical principles are universal will elicit radically different responses from adherents of ethical universalism than it will from the cultural pluralists. The tension between these two positions has existed since classical times and it is unlikely to be resolved in the foreseeable future (21).

Ethical universalists believe there is a universal set of ethical principles that are applicable to all human beings regardless of their situations in particular cultures. The task of the moral philosopher, then, is to *discover* those universal principles that apply in all times and in all places. Variations across cultures indicate that some societies are ahead of others in the degree of "moral progress" they have accomplished (22).

Ethical pluralists, by contrast, recognize that all ethical principles are developed in the course of discussions held within particular cultures and that these discussions necessarily reflect the unique histories and other circumstances of particular cultures. On this view ethical principles are *invented* rather than discovered. Pluralists further acknowledge the inevitability and recognize the legitimacy of variation across cultures of ethical norms and principles.

This debate has practical import in the increasingly common circumstances in which research protocols are designed by investigators and sponsors in technologically developed countries and then carried out in developing (or underdeveloped) countries or communities. What if there are differences in ethical values in the two cultures? Whose ethics should apply?

It has been argued that there should be a compromise between the two extremes (21). Some ethical principles seem to be universally valid. For example, there is a universal proscription against inflicting injury on a person without justification. But what counts as justification in various societies differs substantially. The principle of respect for persons, when stated at a sufficient level of abstraction, enjoining people to treat persons as ends and not merely as means, is universally applicable. However, when this principle is elaborated to require that all persons are to be treated as self-determining, it loses its relevance to some cultures in which individual self-determination is less highly valued than it is in the United States.

American universalists would argue that persons in such cultures must be educated; they must be taught to value self-determination as much as we do. Some might add that they must learn to value and protect the right to be self-determining or else they will remain vulnerable to exploitation by those who have decision-making authority. Pluralists counter this argument by pointing out that the society seems functional as it is; if we impose on it our ethical standards, it may have a destructive effect on the culture. Furthermore we should show respect for a society by allowing it to be self-determining.

The CIOMS *International Ethical Guidelines* reflect what may be a satisfactory compromise position, holding that some ethical standards are universal while recognizing the legitimacy of some degree of ethical pluralism. These guidelines set forth procedures to be followed when research is initiated and financed in one country (the external sponsoring country) and carried out by investigators from the external sponsoring country in another country (the host country) involving as subjects residents of the host country:

> In short, ethical review in the external sponsoring country may be limited to ensuring compliance with broadly stated ethical standards, on the understanding that ethical review committees in the host country will have greater competence in reviewing the detailed plans for compliance in view of their better understanding of the cultural and moral values of the population in which the research is to be conducted (Commentary under guideline 15).

OUTLINE

INTRODUCTION

Background

The development of the technology of in vitro fertilization (IVF) during the 1970s by Edwards, Steptoe, and colleagues (1,2) made possible the first systematic study of the live, developing human embryo from fertilization onward. At the same time the relatively low success rates of IVF increased demand for more systematic research on fertilization and embryo development. Together these factors have made the issue of embryo research increasingly important in law, ethics, and public policy. Embryo research is also one of the most controversial issues in biomedical ethics and law today. Wherever it has been discussed, there have been significant disagreements about the moral status of the embryo and what constitute legitimate reasons for putting it at risk.

DEFINITIONS

Embryo

The term "human embryo" is used in many ways, some opposed to one another. In ordinary speech it is used to refer to the developing human being following conception. As defined in medical literature, the term is usually applied more strictly to the product of conception from the end of the second week after fertilization to the end of the seventh or eighth week when the fetus is said to exist (3). Before two weeks, the terms zygote (the one-cell conceptus), morula (= mulberry), and blastocyst are used for the developing entity in its various stages.

In the context of ethical and legal discussions of the human embryo, the term usually refers to the product of conception (zygote, morula, and blastocyst respectively) during the first two to three weeks of development outside the womb. Normally this means an embryo that has been created by IVF, although it can also refer to a fertilized ovum that has been flushed from a uterus shortly after conception and kept alive in vitro for purposes of study. The defining features of this entity are its existence ex utero and its early stage of development, usually before or just up to the first processes of cellular differentiation, tissue formation, and the appearance of rudimentary bodily form. In both respects, embryo research differs in U.S. law from fetal research, which typically involves an embryo or later stage fetus in utero or following

abortion (4). In the mid-1980s the term "pre-embryo" was introduced for the human embryo at the earliest stage of development (5), although some have objected to it as possibly finessing the discussion of complex moral questions (6,7).

The National Institutes of Health's (NIH) Human Embryo Research Panel used the term "preimplantation embryo." This is accurate since the embryo involved in research has not yet been transferred back to a womb for implantation and, in current research, is also at the earliest or "preimplantation" stages of development. However, since implantation normally begins at 6 to 7 days in vivo, it is possible that, as our ability to sustain embryos in vitro progresses, some human embryo research, as defined here, will involve "preimplantation" embryos in the first sense (embryos that have never implanted in a womb) but not in the second sense (embryos that are less than 6 to 7 days old).

Conception/Fertilization

Further complicating the definition of the embryo is the question of what is meant by the term "conception" or "fertilization." The embryo is not regarded as coming in existence until after sex cells have joined at conception/fertilization, but conception/fertilization occurs over a period of time (8). It spans a period of at least 22 hours from the sperm's initial contact with the outer membrane (*zona pellucida*) of the egg to syngamy, the alignment on the mitotic spindle of the chromosomes derived from the male and female pronuclei (9). The first appearance of a new diploid nucleus within its own nuclear membrane occurs only after the first embryonic cell division (cleavage) three or more hours later, and the first activation of paternal genes occurs only after the second cleavage division, 12 or more hours later. A specific research program beginning with conception/fertilization therefore might involve gametes or an embryo, depending on which definition of conception/fertilization is accepted and where the cutoff point for the study is established following the admixture of sperm and egg.

In legal jurisdictions where embryo research is banned or stringently controlled, this definitional matter can be of great importance. Although the issue is often ignored in most legislation, two jurisdictions exhibit contrasting approaches. Australia's state of Victoria does not define fertilization, but its law banning human embryo research permits an exception for research "from the point of sperm penetration prior to but not including the point of syngamy" (10). Britain's Human Fertilisation and Embryology Act is quite specific, defining the embryo as present only when fertilization is complete at "the appearance of a two cell zygote" (11). These two items of legislation evidence how it is possible to select different moments in the process of fertilization. The Australian legislation also shows how important this definition can be in determining whether some types of contraceptive research aimed at blocking fertilization are permitted (12). For the balance of this discussion, fertilization will be taken to mean sperm penetration of the egg, since this is the reference point used in most chronological accounts of embryological development.

Human

The term "human" in the definition of the embryo also raises questions. Should a parthenote, an ovum artificially stimulated to begin the earliest stages of cell division, be considered a human embryo in this sense? Is an animal-human hybrid resulting from the fertilization of a human by a nonhuman gamete a *human* embryo? Are chimeric or transgenic embryos, involving the admixture of human and nonhuman embryonic cells or human and nonhuman genetic material, human embryos? Is a cloned embryo, one produced by the insertion of a nucleus from one cell into an enucleated egg cell, a human embryo (13)? Many persons who object to embryo research will predictably find research involving these other forms of embryos to be morally offensive. Current U.S. law, for example, prohibits federal funding for research on parthenotes as well as human embryos created by cloning. For this reason, research on embryos resulting from parthenogenesis, cloning, or transgenic manipulations involving nuclear human DNA should probably be considered under the heading of human embryo research.

Description

As defined, the human embryo involved in research, ranges in size from a one-cell fertilized ovum to an embryo of several thousand cells. In the words of Jones and Tefler, "The recurring motifs of embryonic development are: gradually decreasing potentiality, increasing determination and differentiation, and increasing complexity and interaction. This development occurs smoothly rather than in quantum leaps and its object is the transformation of a single fertilized ovum into a complex organism" (14, p. 45). During the earliest cleavage stages, the cells (or blastomeres) exist in a small, loosely packed mass. Each cell is undifferentiated and totipotent: taken from the cellular mass, it has the capacity to develop on its own into a full human being. Twinning can occur spontaneously at this stage, and the removal of one or more blastomeres does not interfere with the embryo's normal development. As the number of cells continues to increase, some specialization occurs. The outer layer of cells forms the trophectoderm, which at implantation give rise to the tissues that begin formation of the placenta (15). Inside the outer layer of trophectoderm cells, fluid accumulates to form a cavity, the blastocoele, and the resulting entity at 4 to 5 days following fertilization is called a blastocyst. By 6 or 7 days, when implantation normally has begun in vivo, the embryo consists of approximately 100 cells and is roughly 130 μm in diameter. Outer or trophoblast cells surround an inner group of about 20 to 30 undifferentiated cells.

One week later, by 14 days development, two fluid-filled cavities have formed, the amniotic sac and yoke sac, with a two-layered embryonic disk about 0.5 mm in diameter between them. The cells of this disk, now about 2,000 in number, remain undifferentiated. At this time the process of gastrulation begins with the appearance of the primitive streak and the establishment of left-right, head-tail orientation (16). From this point onward, the embryonic disk is committed to forming a single individual with twinning no longer possible unless two

primitive streaks have formed (17). Over the next 3 days, cells migrate to form three layers within the embryo and become pluripotent rather than totipotent: They are able to form broad categories of specialized tissues and organs but no longer an entire individual. At 17 days the primitive nervous system begins to develop with formation of the neural plate that soon develops into the neural tube. By the beginning of the fourth week of development, the neural tube closes and begins to differentiate into distinct regions of the nervous system.

In the two weeks from fertilization to the appearance of the primitive streak, therefore, the human embryo as discussed in this context is marked by very small size, the absence of bodily form, and (with the exception of placental material), the lack of differentiated tissues, organs, or a nervous system. In all these respects it differs from the postgastrulation embryo and the fetus. Currently it is not possible to sustain a human embryo in vitro until the point of gastrulation, so embryo research, as discussed here, usually refers to an undifferentiated entity of this sort. This may change in the future. Some kinds of embryo research that have been proposed, such as research to find genetic or biochemical markers for gastrulation, may extend human embryo research into the third week of development.

WHY CONDUCT HUMAN EMBRYO RESEARCH?

Limits of Animal Models

Many features of embryological development have been conserved in the course of evolution. It is now known that among vertebrates the basic principles of embryonic development, and even the genes regulating it, are similar. This means that much valuable research can be done on animals without the need to use human embryos. Nevertheless, there are significant limits to animal models. Early rubella vaccination research in monkeys indicated that the vaccination did not cross the placenta, yet subsequent research showed otherwise, rendering the vaccine unsafe for human use (18,19). Subtle matters like these can have dramatic effects on the safety of drugs or procedures when findings based on animal models are applied to human beings. From a scientific perspective some human embryo research is therefore necessary.

Assisted Reproduction

There are many areas where human embryo research can be of value. One, already suggested, is research aimed at enhancing the efficiency and safety of assisted reproductive technologies (ARTs). Despite nearly 20 years of clinical utilization and some strides forward in improving success rates, the expense and emotional toll of these procedures are enormous (20–22). Multiple safety concerns have also been raised. When used on healthy women, the drugs that stimulate development of multiple follicles only rarely have serious immediate side effects, but there is an unresolved controversy about the long-term impact of multiple cycles of superovulation on a woman's health, particularly cancer risks (23–25). Little is known about the effects of these drugs on the ova or embryos subjected to them, although it has been suggested that they may be implicated in the high rates of chromosomal anomalies (aneuploidies) found in human occytes used in IVF (26).

The need to transfer multiple embryos to enhance the chances of a pregnancy carries considerable risks in its own right. In Europe and the United States, IVF has resulted in an epidemic of higher order multiple births with its associated toll of miscarriage and prematurity (27). A better understanding of normal embryological development and improved ability to identify "implantation competent" embryos can help reduce the need for multiple embryo transfers. Because of a lack of resources for coordinated multi-center studies of assisted reproductive techniques, some newer procedures like Intracytoplasmic Sperm Injection (ICSI) have been introduced with little or no previous research into their safety for the resulting offspring. One recent study indicates that there is a slight but significant increase in the rate of spontaneous sex-chromosome anomalies among children born as a result of ICSI as compared with the general neonatal population (28). Here, as elsewhere, studies utilizing human embryos can help answer safety questions and improve the success rates of existing procedures.

Embryo research may also lead to entirely new methods of assisted reproduction. One promising set of technologies involves the cryopreservation of immature oocytes (or of ovarian tissue) followed by in vitro maturation and fertilization (29–32). Currently, multiple follicles must be matured in vivo, exposing a woman to the potent drugs used for this. Such stimulation is hazardous to women with polycystic ovarian disease, estrogen sensitive cancers of the breast, or other estrogen-sensitive disorders (31). If oocytes could be matured in vitro, these risks could be eliminated. A host of new donor sources of ova might also be made available, including women who would not wish to be exposed to stimulatory medication. Research on cryopreservation of ova is currently underway (32). Its development, along with in vitro maturation, would provide new reproductive options for women facing cancer treatments or other impediments to the future utilization of their eggs. All these promising techniques require human embryo research involving fertilization and verification in vitro of normal development.

Implantation Research

Many pregnancies fail because fertilized ova never implant in the womb. Improved understanding of the complex process of implantation can help improve pregnancy outcomes for many infertile women. Embryo research in this area can also assist our understanding of related biological processes. Implantation involves the penetration of host tissues by a rapidly growing and highly invasive foreign body. Close analysis based of the growth factors and gene expression associated with implantation can advance our understanding of similar processes that occur in cancer and tumor metastasis. Improved insight into how both fertilization and implantation occur can also lead to new techniques for preventing them. This promises development of improved contraceptive methods.

Normal/Abnormal Development

Embryo research can advance our ability to recognize key events or processes associated with normal or abnormal development. Many serious birth defects and genetic disorders that express themselves months or years following birth have their beginning in the earliest phases of embryogenesis, when cells are rapidly dividing and the basic plan of the body is being established by the operation of genes that act for only short periods of time. It is well known, for example, that viral diseases like rubella can have a devastating effect on early development. The recent discovery of the important role of folic acid deficiency early in pregnancy in contributing to neural tube defects is another example. Embryo research aimed at deepening our understanding of the patterns of normal and abnormal development may thus lead to new preventative measures or therapies.

Genetic Diagnosis

Human embryo research can help improve the newly developed technology of preimplantation genetic diagnosis (PGD). This involves coupling an IVF procedure with genetic biopsy of a single cell (blastomere) from each of the resulting embryos. It permits parents whose offspring are at risk for a genetic disease to avoid transferring embryos that exhibit the mutation or abnormality (33). Although currently much more expensive than other prenatal testing techniques like chorionic villus sampling (CVS) or amniocentesis, PGD offers parents an alternative to later term genetic abortion which is needed to avoid a birth when CVS or amniocentesis are employed.

Cell Differentiation

Human embryo research can contribute to our understanding of the complex processes of cell differentiation and can lead to new techniques for tissue transplantation and repair. Mouse research has already led to the development of techniques for producing in that species immortalized, pluripotent embryonic stem cell lines (34). In this research the inner cell mass of fertilized embryos is dissociated into single cells and dispersed into another dish with a rich culture medium. The embryonic cells continue to grow rapidly and indefinitely. Because of their low immune competence and pluripotentiality, they might be inserted back into other embryos or more mature individuals to replace defective or missing nerve, blood, skin, bone, and germ cells. Recent research by James Thomson and others suggests that this technology can be applied to the development of immortalized, canonical human stem cell lines (35,36). Somewhat differently, nuclear transfer or cloning technologies at the embryonic level have been shown to be an efficient means of introducing altered genes into every cell of the resulting organism. Employed by Wilmut and others to develop the transgenic sheep Polly, this technology also holds out the prospect of new gametic or embryonic gene therapies that might eliminate the need to discard embryos or genetic abortion (37). Human embryo research remains the essential precondition for the development and clinical deployment of all these technologies.

LAWS AND REGULATIONS

Other Countries

A review of existing national laws and regulations reveals significant disagreements about the acceptability of research involving embryos (38,39). Norway prohibits all research on fertilized ova (40); Australia's states of Victoria (41) and Western Australia (42), Austria (43), Germany (44), and Switzerland (45) forbid all embryo research other than that aimed at enhancing the survival of the embryo being studied or used in an IVF procedure. These restrictions rule out research on embryos remaining from infertility procedures that are otherwise destined to be discarded. French law specifies that research "may not be harmful to the embryo" (46), while Denmark permits embryo research only when its purpose is "to improve in vitro fertilization in order to bring about pregnancy" (47). Spain permits research employing nonviable embryos remaining from infertility procedures (48), while Sweden permits embryo research in very general terms (49). Italy and Greece have virtually no legislation in this area (39).

Britain's legislation, the Human Fertilisation and Embryology Act 1990 (50), is the most extensive and most permissive, including a provision allowing the deliberate fertilization of ova for research purposes. Similar legislation was proposed in Canada but much more stringent rules were subsequently enacted (51,52). European disagreements about embryo research are reflected in article 18 of the Convention on Human Rights and Biomedicine of the Council of Europe. This seeks to accommodate very diverse positions on embryo research by calling vaguely for "adequate protection of the embryo" when it is used in research. The convention does, however, explicity prohibits the creation of embryos for research purposes only (53). Because of its different legislation on this matter, Great Britain has entered a reservation against this article, rendering it inapplicable in that country.

Areas of Agreement

Despite the differences there are some broad areas of agreement in this legislation. These include strict requirements of informed consent for gamete or embryo donors; discouragements or prohibitions on the commercialization of gametes or embryos; and widespread prohibition of cloning, the creation of animal-human hybrids or chimeras, or the transfer of human embryos to animal wombs. Where embryo research is permitted, as in Britain and Sweden, a 14-day time limit on such research has been imposed. Several countries have also established special regulatory bodies that must approve or license human embryo research protocols. Britain's Human Fertilisation and Embryo Authority is an example. Arising out of the extensive debate occasioned by the Warnock Committee Report (54), it is charged with the extensive oversight of infertility clinics and the licensing of specific embryo research programs.

U.S. State Law

In the United States only 10 states have legislation on embryo research, nine of them very restrictive (55).

Louisiana's law defines the embryo as a "juridical person" and states that it is to be used in research "solely for the support and contribution of the complete development of human in utero implantation" (56). Federal courts have raised questions about whether this kind of restrictive legislation violates the constitutionally protected right to privacy, and there are also questions as to whether it opposes the right to freedom of expression (as this pertains to scientific research) (57), but the matter has not yet reached the Supreme Court.

Early Federal Initiatives

At the national level there have been significant regulatory and legal initiatives. In the late 1970s, shortly after the development and introduction of IVF, a special body, the Ethics Advisory Board (EAB), was formed by an act of Congress to review and provide guidance for federally funded research on the human embryo. In late 1979 the EAB issued its report containing a broad permission for such research under federal auspices subject to guidelines and limitations indicated in the report and to be implemented by the Board itself (58). However, before the EAB's recommendations could be put into effect, there was a change in adminstrations. During the Reagan and Bush years, funding for the EAB and nominations to its membership, were halted. The legal requirement of EAB approval of all such research and the absence of an EAB created a de facto moratorium on funding for embryo research in the United States.

Human Embryo Research Panel

In June 1993 Congress passed legislation nullifying the earlier requirement of EAB approval (59). To provide ethical guidance for this area, NIH established a special body, the Human Embryo Research panel. Beginning work in January 1994, the Panel held five monthly meetings in Washington open to the public and issued its report in September of that year (60). In broad terms, the report's recommendations paralleled existing legislation in Great Britain and proposals under consideration in Canada (51). Responding to its charge, the Panel divided research into three areas: (*1*) acceptable for federal funding, (*2*) unacceptable for federal support, and (*3*) warranting additional review.

In the first category the Panel placed research aimed at enhancing the safety and efficiency of infertility procedures, at preventing disease conditions arising during prenatal development, and at improving our understanding of the human embryo. Permitted research was governed by a series of stringent guidelines. They included the requirements of demonstrated scientific validity and merit, informed consent on the part of gamete or embryo donors, a prohibition on the purchase or sale of gametes or embryos, and a 14-day age limit on the use of embryos in research.

The category of research that was unacceptable for federal funding included research on embryo cloning (whether by splitting existing embryos to multiply the number of genetically identical embryos, or by somatic cell nuclear transfer to replicate an existing individual) where transfer to a womb was intended; research involving the fertilization of fetal oocytes with intent to transfer; parthenogenesis research where transfer was intended, and the creation of animal-human chimeras. Among those items placed in the category of warranting additional review were cloning by embryo splitting and the use of fetal oocytes where no transfer to a womb was intended.

Subsequent Developments

Among the most controversial of the Panel's proposals, but paralleling existing regulations in Great Britain, was a permission to fertilize oocytes for research purposes without the intention to transfer. Late on December 2, 1994, following a morning meeting in which the Advisory Council to the NIH director unanimously accepted the Panel's report, President Clinton issued a directive overruling this recommendation. Eventually this limited dissent from the Panel's recommendations was overtaken by congressional initiatives barring federal funding of any embryo research that threatened the embryo's survival (61). In May 1999, in the wake of several new research reports showing the possibility of establishing canonical embryonic stem (ES) cell lines from human embryos, the National Bioethics Advisory Commission, once again recommended establishing federal support for human embryo research (62).

Thus the United States during this period has exhibited roughly the same polarization of opinion and legislation on this issue as has occurred in Europe. In one important respect, however, the United States differs from Europe, including Great Britain, where regulations govern all research on the embryo. In the United States, federal legislation and guidelines affect only federally funded research. To date, there has been no federal legislation prohibiting or limiting research with private funds.

ETHICAL ISSUES

Range of Views

The legal turmoil over human embryo research reflects deep ethical disagreements. Foremost among these is disagreement about the moral status of the human embryo in the earliest stages of development. At one end of the spectrum of opinion are those who regard the embryo as fully a human being meriting all the protections due any other human research subject. This position has been publicly defended by the Roman Catholic Church (63,64). At the other end of the spectrum are those who see the embryo as meriting little or no protection and who believe that the primary consideration in human embryo research is whether it benefits or harms adult human beings or children. Someone holding this view, for example, might argue that if embryo research could improve contraceptive alternatives for women or reduce the risks of current methods, then it is not only morally permitted but morally required. Between these polar positions lie those who, for different reasons, accord the embryo some measure of moral respect and believe that any kind of harmful research on the embryo requires stringent moral justification. This issue of the moral status of the

preimplantation embryo is at the center of these debates. The question becomes on what grounds a being or entity achieves moral status.

Genetic Individuality and Moral Status

Some who defend the full moral status of the embryo answer this question by focusing on the embryo's possession of what they regard as the essential biological criterion of humanness in a moral and spiritual sense: a diploid human genome with the inherent and active potential to develop on its own, under normal conditions, into a child or adult human being (65,66). Those who hold this view believe that biological humanness in this sense represents a "bright-line" distinction providing maximum protection for all who are human from possible abuses that may come about if humanness is defined in less determinative ways (67).

Biological Problems

The full moral status view, although seemingly clear, is challenged by biological knowledge on several fronts. One problem has to do with the so-called moment of fertilization, which marks the cherished bright line separating embryos, as protectable, from gametes that are regarded as having no greater moral status than other expendable bodily tissue. Strictly speaking, there is no single "moment" of fertilization but a series of events — a process. This raises the question of whether references to biological phenomena really do provide the bright lines that defenders of this position seek.

A second problem has to do with the realities of twinning and recombination. In a small number of cases, single embryos spontaneously split into one or more embryos, resulting in the birth of monozygotic (identical) twins if the pregnancy proceeds to term (68). Different embryos also sometimes combine to form chimaeras containing one or more fused genomes (69). For some ethicists and theologians, these rare but naturally occurring events challenge the notion that the appearance of a single, discrete genome following fertilization is the marker for moral and spiritual individuality (8,70). The possibility of twinning and the fact that most cells of the early embryo develop into nonembryonic supporting tissue also lead some to question whether we can speak of the early embryo as a single "being" with the "potential" to develop into an adult person (71). Others question whether the high degree of human intervention necessary for IVF procedures does not efface any distinction between embryos and gametes in terms of their "inherent" potential to develop to maturity (72). The fact that cloning technology renders any cell in the body able to become an embryo further complicates the position of those who stress the presence of a diploid genome and raises further questions of what "potentiality for development" means in this context.

Finally, the clarity of this biological view is troubled by the very large proportion of embryos — estimates are as high as two thirds to three quarters of all fertilized ova (73,74) — that do not successfully implant in the womb. If the likelihood of development to term, an important consideration on some accounts of potentiality (67), takes a significant upward turn as gametes becomes an embryo, still another increment in likelihood of birth takes place at implantation. This raises the question of whether this point, or perhaps the later establishment of individuality at gastrulation (after which twinning cannot occur), is not the better "bright" line on which to base protected humanness.

Personhood Views

In addition to these biological challenges, critics of the position that locates full moral protectability at fertilization also offer many objections of a philosophical nature, some of which also appear in the context of the abortion debate. The issue, some of these critics contend, is not biological humanness but moral "personhood." By this they mean the status of being a moral subject worthy of all the rights and protections normally accorded human beings (75). They point out that some individuals who are biologically human (e.g., adults who are brainstem dead or anencephalic infants) may not be persons in a moral sense and may ethically be treated with less than equal respect. It is also possible that in the future we will encounter intelligent life forms that are not biologically human but that nevertheless are persons in a moral sense.

Those holding this view tend to espouse a variety of distinct, but sometimes overlapping, positions regarding the qualities that are needed for personhood. Some believe that highly developed qualities, such as consciousness and a sense of self are needed (76–78). Others stress the beginnings of brain activity or brain function, arguing that if the cessation of brain activity at the end of life is an appropriate marker of death, it should also be a marker for the commencement of moral personhood (79–82). Still others point to sentience, the ability to experience pain (83,84). Although those adhering to the brain activity or sentience views may come to a less permissive position on early term abortion than those holding the consciousness view, all those holding these views tend to agree about the status of the early embryo, whose lack of differentiated nervous system tissue makes it unreasonable to regard it as capable of feeling or thinking.

Symbolic Concerns

Complicating this typology of positions, are the views of those who believe that the significant moral issue here is not the status or rights of the embryo so much as the implications of its treatment for society as a whole. Some who hold this view fear that funding embryo research creates a "slippery slope" that could lead to undermining current protections for human subjects in research, erode respect for persons with disabilities, or encourage eugenic practices (85). Others emphasize the symbolic importance of the embryo, rather than its intrinsic moral claims, and ask how its treatment (or mistreatment) might affect respect for life generally (86,87).

PUBLIC POLICY

The status of the embryo and the question of what degree of respect it deserves are difficult to settle partly

because they involve intensely personal matters of moral conviction or religious belief. Where law or public policy is concerned, however, debate must focus primarily on those considerations that are appropriate for setting policy in a religiously and morally pluralistic democracy. As one writer puts it, "law is not really concerned with the enforcement of morality but rather with providing a framework of peace and order within which people may exercise their personal liberty ... and make their own personal moral choices and engage in what John Stuart Mill calls their own 'experiments in living' " (88, p. 149).

Public Reasoning

This context imposes limits on what can be brought to public debate about issues significantly affecting the lives, welfare, and basic liberties of citizens. The philosopher John Rawls argues that basic public policy in such contexts must employ "public reasoning" that is understandable in terms that are not dependent on particular religious, theological, or philosophical perspectives. It should appeal "only to presently accepted general beliefs and forms of reasoning found in common sense, and the methods and conclusions of science when these are not controversial" (89, p. 224). From this perspective, religious teachings that are unable to sustain themselves without resort to special metaphysical premises belong to the realm of private decision and should not direct public policy where basic matters of citizens' welfare and liberties are concerned.

Two considerations qualify this conclusion. One is that some religiously based views can be articulated in terms of widely shared moral values. When this is done, and the arguments are persuasive, there is no reason to set aside a view merely because it originates in a religious context or is held by a community of religious believers. Second, even when a religious position cannot commend itself to a wider society, it is good public policy to respect this view to the extent that doing so is compatible with the protection of public healthy and safety.

Policy Analysis

Because there is no clear consensus on the moral status of the embryo itself, the most relevant arguments surrounding embryo research from a public policy perspective have to do with the indirect and symbolic impacts on society and people's respect for the sanctity of human life. Will using embryos in research start us down a slippery slope and contribute to the neglect or injury of other protectable human subjects? Will use of embryos lead to a "cheapening" of the value of human life? Will embryo research damage the way we regard human parenting or diminish the protection we accord our young? These questions are all enormously difficult to answer. If we keep in mind that similar questions have been raised with the advent each new reproductive technology, we see how marked this whole area is by deep, if largely speculative, concerns.

On one side of the balance, therefore, are a set of hard-to-assess symbolic concerns to which we might add the very determined opposition of a large number of citizens, some influenced by personal religious beliefs. On the other side is the great promise human embryo research holds out for reducing illness and improving human health.

Policy Conclusions

Taking all these considerations into account, and trying to balance the avoidance of immediate harms against symbolic and other concerns, expert panels like the Warnock Committee, the NIH Human Embryo Research Panel, and Canada's Royal Commission on New Reproductive Technologies have all recommended permitting embryo research under stringent control and limitations, including a 14-day time limit. Apart from Great Britain, however, these expert public assessments have had little impact. Political opposition to embryo research, some of it influenced by religious views or traumatic national experiences with biomedical research and eugenics, as in the case of Germany, has had more effect than the kind of moral analysis and public reasoning employed by expert panels (90).

SPECIAL QUESTIONS

Those who accept the possibility of embryo research must resolve a series of additional ethical questions. Substantial consensus exists about the answers to some of these questions, while others remain very controversial.

Time Limits

As mentioned above, one area in which there has been widespread agreement is the need to set a limit, usually 14 days, on the time during which research can be conducted after fertilization. Since embryo development in vitro usually proceeds more slowly than in vivo, this ensures that embryos used in research have not entered the phase of gastrulation and have not yet developed the primitive streak. It is important to note that the 14-day limit should not be misconstrued, as it has sometimes been (91), as a statement about the definitive commencement of moral personhood at this time. Rather, those who accept this limit usually hold that the embryo cannot definitively be held to be a person before this point, although they may disagree about the time when personhood or enhanced protectability is subsequently established. It is also taken as a reasonable compromise between the moral claims surrounding the embryo and the needs of researchers.

Understanding the 14-day point as a reasonable but not necessarily absolute limit, the NIH Human Embryo Research panel urged that some research beyond this point (in vitro) be permitted in exceptional circumstances when the goal was to assist in the identification in the laboratory of the appearance of the primitive streak. Some who regard the beginning of gastrulation as a morally definitive step would not agree with this exception. Others see exceptions of this sort as propelling us down a slippery slope leading to the abuse of other vulnerable research subjects (85).

Intent to Transfer

Many believe that the question of whether or not researchers intend to transfer an embryo to a uterus is of great moral consequence in evaluating research proposals. Where transfer is in prospect, another class of human subjects becomes involved: children born as a result of these procedures. Since born children are recognized in law and ethics as having a right to protection from injuries inflicted before their birth, this means that researchers must demonstrate that manipulations of the embryo impose no greater risks than would be encountered in a normal pregnancy or, where the purpose is helping a couple have a child, of accepted assisted reproductive procedures. If also means that new assisted reproductive techniques should not initially be applied to human embryos that are to be transferred with the aim of establishing a pregnancy. Before transfer is considered, intermediate studies should be conducted on human embryos that are not intended for transfer. This approach was adopted by Steptoe and Edwards in their initial development of the clinical protocols used today in all IVF programs throughout the world (92,93). Risks to children born as a result of cloning procedures also played a large role in the U.S. National Bioethics Advisory Commission's June 1997 recommendation of a five-year legal prohibition of all attempts at cloning a human being (although the Commission did not at that time bring under review the existing ban on federal funding for the embryo research that would be needed to reduce these risks) (94).

Philosophical Complexities

There are interesting philosophical complexities associated with this high standard of safety for research involving embryos that are to be transferred. Some have argued that a child who would not otherwise exist cannot be morally wronged by procedures needed to bring it into being, even if these same procedures seriously impair its health or well-being (95,96). Without these harmful procedures, it is contended, the child would not have been and, at least up to the point where the harm is not so great as to make it reasonable to wish to not be alive, the child cannot morally complain about its treatment. Those who accept this argument might permit research on embryos for transfer that jeopardizes the well-being of a resulting child if this is the only way that the child can be brought into being.

Not everyone accepts this line of reasoning. Some doubt that being brought into existence should be reckoned as a benefit, and maintain that it is always the obligation of parents (and those who assist them in having children) to strive to ensure that the child has a healthy start in life (97,98). Fortunately these issues do not have to be resolved to establish public policy in this area. Governmental agencies supporting research are chartered to promote public health and to protect the welfare of children and other vulnerable subjects involved in research. Such agencies therefore have good reason to insist on the most stringent guarantees of safety where research anticipates transfer of embryos to a womb.

These protections are less important where transfer is not intended and the embryo is destined to be discarded in any case. It is useful to note here a difference between embryo research and fetal research. In U.S. law, fetuses intended for abortion are accorded the same level of moral protection in research (a requirement of no harm or minimal harm) as fetuses that are intended to be brought to term (99). However, it is not inconsistent to treat embryo research differently because fetal research poses a special set of problems. If researchers were permitted to perform harmful studies on the fetus of a woman intending abortion and she subsequently changes her mind and insists on continuing with the pregnancy, this would create a situation of unavoidable harm for the resulting child because it is ethically unacceptable to force her to terminate the pregnancy. A similar conflict situation cannot arise where embryo research is involved.

Donor Rights and Donor Sources

Donors of the gametes or embryos used in research are an important moral constituency whose rights and welfare must be respected. Three considerations shape thinking in this area: the requirement of informed consent, concern for the impact on family and the succession of generations in the use of certain donor sources, and the implications for society when financial incentives create a market in gametes or embryos used in research.

The requirement that researchers obtain the full, free, and informed consent of those who donate their reproductive material for research purposes means, among other things, that consent must be specific to the type of research proposed. Because donors can reasonably find one kind of embryo research morally acceptable and another repugnant, general consent to the use of gametes or embryos is not appropriate. Behind this requirement of specific consent lies the understanding that gametes and embryos are different from other bodily tissues. They contain the possibility of and association with people's dreams of offspring. Some individuals might be willing to donate reproductive material where transfer is intended, hoping to directly assist others to start a family. Other donors might be unwilling to see children of theirs raised outside the context of their family but would be willing to donate gametes or embryos for research not involving transfer. Despite their different feelings in this regard, all donors have the right to freely understand and consent to how their reproductive material is used in research.

Because oocyte donation for purposes of embryo research now requires follicle maturation in vivo, these procedures are also not without risk to the donor. Although these risks are routinely accepted by women who wish to donate oocytes to an infertile couple, some believe they are disproportionate to any benefits in research contexts where no transfer to a womb is anticipated. The NIH Human Embryo Research Panel came to this conclusion, although it permitted such donation by women about to undergo pelvic surgery who were properly informed about the additional risks of drug stimulation and superovulation. If and when embryo research goes forward in the future, Institutional Review Boards and other groups assigned to assess research risks will have to balance the values involved in permitting donation (including respect for donors' wishes) against the specific

risks to donors and their vulnerabilities to coercion or pressure from researchers or physicians. The clinical IVF context merits special attention in this regard. Although women undergoing treatment for infertility are a constituency that has a significant stake in the benefits arising from embryo research, this context also creates special pressures that run counter to the requirement of full, free, and informed consent. Among these are the hope (or promise) of price reductions or additional support from one's treating physician in return for gamete or embryo donation.

Concern for the impact on family and the succession of generation suggests limits on donor sources. For example, although the use of cadavers as sources of oocytes might be appropriate for research where no transfer is intended (assuming that the women or her appropriate surrogates consent), this source raises many questions where transfer is intended. Among other things we can ask whether it is ethical to bring a child into the world whose genetic mother is deceased. Apart from the psychological risks of this practice, the child conceived in this way is possibly cut off from access to the deceased parent's medical history. Similar questions arise in connection with the idea of using aborted female fetuses as a source of oocytes for in vitro fertilization and embryo research. No only does this undermine the idea of donor consent (a problem not entirely eased by the consent of the abortus's mother to the use of her fetus in this way), it also implicates embryo research in the abortion and fetal tissue debate. Where transfer is intended, it raises the disturbing prospect, in terms of our ideas of generational succession, of the birth of a child whose genetic mother was aborted. For all these reasons, at least where transfer is intended, this donor source is best avoided.

Commercialization

It is also wise for government agencies involved in funding embryo research to avoid creating a market in gametes or embryos used for this purpose. In the United States substantial commercialization already exists in the area of egg or embryo donation, but payment for gametes or embryos used in embryo research poses special problems. Introducing government funding for the purchase of eggs or embryos would create a large source of revenue that might be particularly attractive to poor women, a constituency largely untouched by present commercial practices. In view of the special risks associated with egg donation and the deep symbolic importance of reproductive material, the purchase and sale of eggs and embryos is a practice that could tarnish the whole field of embryo research. This does not preclude the compensation of donors for their expenses in participating in a research program.

"SPARE" VERSUS "RESEARCH EMBRYOS"

Moral Issues

Probably the most vexing ethical issue in embryo research is the question of whether it is ever appropriate deliberately to fertilize oocytes for research purposes when there is no intention of transferring the resulting embryos (100). The alternative to such "research embryos" is to utilize only "spare" or "surplus" embryos remaining from infertility procedures. Although many who regard the embryo as a fully protectable being would object to the use of even surplus embryos in research, some who place substantial moral weight on the early embryo believe that spare embryos can ethically be used, since most are destined to perish anyway. This position has been subjected to multiple criticisms (101). For example, it is not clear why the fact that surplus embryos might otherwise continue in storage or be destroyed warrants their use in research. Those who believe the embryo is fully a moral person may therefore be unable to sustain a distinction between spare and research embryos and may be required by their position to oppose all embryo research.

Some who oppose the creation and use of "research" embryos base their views less on harm done the embryo than on symbolic concerns, believing that it is objectionable to use potential persons in such an instrumental way. These arguments, too, raise many questions. Among them are the question of why it should be regarded as acceptable to create more embryos than can be transferred in an IVF procedure but impermissible deliberately to create embryos for research purposes. Whatever the reasons behind it, opposition to the creation and use of "research embryos" is widespread and cuts across familiar political lines, drawing criticism even from those who accept embryo research generally (102).

Scientific Issues

In practical terms, there are many reasons for wanting to develop embryos for research purposes only. In many types of research existing surplus embryos cannot be used. Limiting research to spare embryos, for example, precludes most research involving study of the process of fertilization, since spare embryos have already been fertilized. Similarly research on in vitro oocyte maturation and oocyte cryopreservation would require fertilization and surveillance of the resulting embryos to establish the efficacy and safety of these procedures. It is true that if fertilization is defined as occurring at some point *after* the penetration the egg by the sperm, some of this research could go forward without being regarded as "embryo research" in a technical sense. This points up the importance of these definitional matters. Nevertheless, in many cases demonstrating the safety of new techniques will require the observation of the resulting embryos for some period of time.

Embryos developed in vitro during infertility procedures, often derived from older eggs, also evidence high rates of chromosomal abnormalities that may explain their inability to implant (103,104). This means that surplus embryos are a less than ideal population for broad classes of research on normal embryo development, and their use may actually produce misleading findings in many studies. To the extent that research requires a "normal" embryo population, whether for direct study or as controls, some research embryos may be needed. For all these reasons, the stakes here are high. Those who believe that

embryos merit significant moral protection will not be persuaded that these benefits justify the deliberate creation of embryos for research purposes only. However, those who oppose this idea of "research embryos" on symbolic grounds, or merely because it strikes them as offensive, will have to reexamine their opposition in the light of its longer-term and possibly important negative impact on medical progress.

CONCLUSION

Human embryo research provides a vivid illustration of the way emerging scientific and medical capabilities are continually challenging the application of established ethical ideas and norms. Despite the elaboration of a significant body of ethical and legal rules governing the use of human subjects in research, new reproductive technologies have brought to the fore an entity, the early human embryo, whose existence raises basic questions about who is a human subject and what should be the limits of the research enterprise. The political turmoil surrounding embryo research is a sign of the difficulty and troubling nature of these questions. Few areas of scientific inquiry evoke so many emotions and differences of opinion. Although prohibited in many European nations and deprived of federal funding in the United States, research involving the human embryo continues. New scientific developments that arise from embryo research or that require it will predictably sustain public interest in this scientific and ethical frontier and stimulate continued debate.

OUTLINE

INTRODUCTION

Adult individuals characterized as vulnerable usually are persons who, for a variety of reasons, are incapable of protecting their own interests. Biomedical research subjects may be considered vulnerable because of illness, mental disorder, or particular circumstances (1). In general, individuals are recognized as vulnerable when they are cognitively impaired, or when their circumstances subject them to intimidation and exploitation, thereby limiting their freedom to exercise autonomous choice. Some persons with mental disorders are prototypical of individuals who are recognized as especially vulnerable. Not only is their decision making compromised by illness, but often they also are socially disadvantaged and devalued for reasons of poverty, institutionalization, or stigmatization. Historically, vulnerable and devalued populations, often unwittingly, were forced to serve as research subjects in studies not relevant to their own conditions, but which benefited the health of more privileged members of society. Yet measures designed to protect these populations have come to be seen as overly exclusionary and unjust. Indeed, populations judged vulnerable are now considered to be at risk of being relegated to a class of persons for whom little or no therapeutic benefit may be available. Exclusion may reinforce their vulnerability. However, powerless and impoverished persons may be especially vulnerable to the popular therapeutic misconception that research protocols provide beneficial treatment. Inability to adequately engage in the process of voluntary and informed consent — for whatever reasons — raises the research subject's degree of risk and vulnerability. Increased regulatory protections that provide for research anticipatory planning, surrogacy, independent health care supervision, and other safeguards may allow vulnerable research subjects to be enrolled in studies that address their conditions while shielding them from exposure to harms and wrongs.

VULNERABLE POPULATIONS IN BIOMEDICAL RESEARCH

Among persons with mental illness there are those who share at least four characteristics that are considered prototypical of other devalued and vulnerable populations. First, their disorders put them at risk for loss of decision-making capacity. Second, they are likely to be poor. Even though persons may be afflicted with mental disorders regardless of socioeconomic level, there is a significant association between poverty and serious mental illness due to the incapacitating effects of the disease itself (2). Third, they are little understood, often demeaned, and unjustifiably feared. Stigma is a significant and widespread feature of mental disorders (3,4). Fourth, like other undervalued populations who are regarded as less important than more powerful and privileged members of society, they are at increased risk of being exploited in research. Abuse of human research subjects has long been associated with members of socially devalued populations. During World War II, a euthanasia program implemented by Nazi physicians killed thousands of patients in German mental hospitals, and set the stage in the concentration camps for the infamous human

subject research on little valued groups like jews, gypsies, and homosexuals (5). Such eugenics programs also were proposed in the United States. A 1942 article in the *American Journal of Psychiatry* suggested killing retarded children (6).

Members of socially devalued groups are singularly vulnerable to exploitation in human subject research. Persons in such groups are more likely to be poor, to be welfare patients, to be in need of health care services, to be high users of institutional facilities like hospitals, group homes, jails, and prisons, to lack social support networks, and, in the United States, to have limited access to health care services. Such populations are apt to be both oppressed and exploited because society discounts them. Their well-being, their rights, and their welfare are disregarded by the society in which they live (7).

Some of the most egregious research studies have targeted specific groups of persons who were considered, in some way, to be inferior. The notorious Public Health Service Tuskegee Syphilis Study, which began in the 1930s and continued for 42 years, used poor and uneducated African-American men as study subjects. The researchers compared the health and longevity of an untreated syphilitic population with a nonsyphilitic but similar population. These men did not even know that they were in a study. They were never told that they had syphilis, nor were they given appropriate medication for their disease when it became available. In 1956 researchers took young residents at the Willowbrook State School who were severely developmentally disabled children, and deliberately infected them with isolated strains of the infectious hepatitis virus. And, another study in 1963, at the Brooklyn Jewish Chronic Disease Hospital dying, impoverished, senile, elderly were — unbeknown to them — deliberately injected with live cancer cells (8).

Genetic Research with Vulnerable Populations

In general, genetic research is minimally physically invasive and does not involve hazardous procedures. Vulnerable populations and the general public may encounter similar kinds of issues in genetic research. Nonetheless, the discrete ethical, social, and legal concerns inherent in genetic research may have greater impact on vulnerable populations. Disorders identified by genetic research are distinctive because they affect not only individuals but also groups of related persons, and groups of unrelated persons. Genetic information about an individual may reveal particular or probabilistic information about his or her living relatives, dead relatives, and future unborn offspring (3). When disclosure of genetic information occurs, individuals, their families, and their ascriptive groups may be affected by a loss of privacy, breaches of confidentiality, familial conflict, and by psychosocial harms.

Studies that make specific comparisons between racial and ethnic groups or involve behavioral genetics may be used to stigmatize and discriminate against members of such populations (9). Genetic information may affect the ways such individuals, their relatives, and their cohorts are viewed by others. On the positive side, knowledge of genetic information relevant to the biological basis of a disorder like Alzheimer's disease appears to have helped dispel myths and reduce stigma associated with the condition. However, some vulnerable and devalued populations, like persons with mental disorders, who already may suffer stigma identified with their disorders and experience unfair discrimination in housing, employment, or insurance, may endure even more intolerance and prejudice. Commentators suggest that strong protections of privacy and confidentiality should be developed in order not to add to the burdens of already disadvantaged groups (3).

Subject Selection Predicament — Exclusion or Inclusion?

A protectionist stance that shields vulnerable groups from research participation may deny them the benefits garnered from scientific research that are available to other disease populations. Paradoxically, such exclusion may reinforce their vulnerability. According to commentators, when diseases that affect women, minorities, and other undervalued populations are not addressed by research, knowledge that could rectify prevailing ineffectual or harmful routine medical care is never produced (10,11). Even though women (and particularly pregnant women), minorities, and children have been systematically excluded from biomedical research, U.S. federal policies have encouraged the research participation of all societal groups. There has been a continuing pressure to increase fair access to, and opportunity to participate in clinical trials (12). Indeed, there has been a paradigm shift in the way enrollment in research trials is viewed since acquired immunodeficiency syndrome (AIDS) was first identified in 1981 (13). Participation in research trials previously had been considered as unavoidably risky and burdensome.

Historically devalued populations, like prisoners and persons with mental disorders, served as subjects and bore the brunt of biomedical research with no forthcoming advantage to themselves or to the populations that they represented, while the more powerful members of society reaped the health benefits gleaned from the research (9,14). Thus vulnerable research subjects were seen as inherently needing protection and an exclusionary model of protection came to be employed. But with the emergence of AIDS this traditional model of protection for selection of human subjects for research trials was transformed. The energetic advocacy of AIDS activists for inclusion in research protocols, and the subsequent clamor of advanced cancer patients to gain admittance to cancer trials encouraged a tight connection between research and treatment. Research came to be seen as a pathway to better medical care for individuals and their particular disease populations. Currently a more expansive and inclusionary model is advocated and greater weight is given to sharing the benefits of research.

Perils of the Therapeutic Misconception: Making the Distinction Between Clinical Treatment and Biomedical Research

Another kind of hazard for vulnerable populations may lurk in a standard that argues for wider inclusion in research trials. Persons who suffer from disabling and

damaging diseases, for which no cure exists, understandably are desirous of relief. However, individuals whose incapacitating diseases may be inadequately treated are likely to be susceptible to the popular therapeutic misconception that research protocols provide beneficial treatment, whether or not there is any prospect of benefit. Indeed, such persons may be especially vulnerable if they are powerless and impoverished members of devalued populations (15).

The distribution of healthcare services in the United States is unequal. Participation in a research protocol for some people may be their only way to gain access to an essential therapy that addresses their particular condition. For example, many persons with mental disorders have no or only inadequate access to any mental health care service due to discriminatory and inequitable health insurance policies that anachronistically differentiate between "physical" health and "mental" health and deny parity. Persons in such circumstances may be willing to bear the risks of research when it appears to offer a prospect for beneficial treatment (12). But biomedical research is not clinical treatment. In clinical treatment the patient's welfare and "personal care" is the physician's first consideration (16). In contrast, in biomedical research the investigator's primary purpose is to develop or contribute to generalizable knowledge, not to benefit any particular research subject (17). The distinction between clinical practice and biomedical research often is misunderstood by research subjects (18). When the demarcation lines are blurred between patient and subject, between physician and investigator, and between treatment and research, patient-subjects are likely to believe, as is the case with treatment, that the research is designed to directly benefit them.

According to Jay Katz, the misconception has grown out of the recent practice of conflating the role of the physician with the role of the research investigator. Physicians who also are investigators compound the potential subject's confusion. It has become common practice for physicians to enroll their patients in their own research studies. Many patients enrolled in such studies believe that they will be the beneficiaries of effective treatments, even though there may be minimal or no likelihood of benefit. Patients misconstrue their physician's invitation to take part in research as a treatment recommendation (19). Patients trust their physicians and permit them to hold enormous power; in exchange, patients expect their physicians only to serve their therapeutic needs (20).

Because the language of many consent forms fosters the belief that a therapeutic benefit will be forthcoming, some commentators propose that the research community take measures to help potential subjects appreciate that they are unlikely to benefit from research participation (21). Other writers express concern that if the therapeutic misconception is not adequately dealt with during the informed consent process, subjects are likely to feel that they have been deceived and public trust of researchers, and the health care system in general, may be eroded. They recommend that a trained, neutral educator provide information about the study and advise subjects when it might not be in their best interests to take part in the study. Additionally these writers suggest that the therapeutic misconception may be lessened if investigators emphasize the substance of the disclosure, explain the scientific methodology, and maintain an ongoing consent process (22).

IMPACT AND INFLUENCE OF INTERNATIONAL CODES, U.S. REGULATORY POLICIES, AND BIOETHICS COMMISSIONS ON RESEARCH WITH VULNERABLE SUBJECTS

International Codes

The central tenet of the Hippocratic Oath — the primary obligation of physicians is to benefit their patients — has prevailed for more than 2400 years in Western clinical medicine. This fundamental ethic recognizes the patient's potential for vulnerability and thus requires that physicians act solely on behalf of their patients' best interests. However, because in biomedical research the scientific method requires that the researcher engender generalizable knowledge, the needs and interests of the vulnerable subject may be compromised. Thus the clinician's obligations to the patient stand in direct conflict with the researcher's duties. These incommensurable goals were rendered potentially compatible by the first set of international research principles, the Nuremberg Code. By making mandatory the voluntary informed consent of all research subjects, the Code strove to shelter the research endeavor (23). The authors of the Nuremberg Code — by employing the moral principal of respect for autonomy — established two kinds of freedom for competent research subjects; the freedom not to be interfered with by others, and the freedom to make their own choices (24).

The Code's dominant principle, "The voluntary consent of the human subject is absolutely necessary. This means that the person involved shall have the legal capacity to consent," was delineated in response to the cruel research conducted by Nazi doctors on prisoners who, because of their circumstance, were not in a position to give their consent, whether or not they were competent (25). Special protections for mentally ill persons, which allowed for proxy consent, were specified in a final memorandum by the chief medical advisor to the Nuremberg judges but were not included in the final document (26). Thus the Code's affirmation of the primacy of consent effectively excludes many persons with disorders affecting their decision-making capacity from participation in drug trials and other sorts of research.

The international codes and regulations that were developed after the Nuremberg Code have attempted to reconcile society's twin responsibilities to adequately protect vulnerable research subjects and to ensure that vulnerable populations receive the benefits of research. The various drafts of the World Medical Association's Declaration of Helsinki, first issued in 1964, endeavor to move along and ease the consent requirements via the mechanism of a legal guardian for persons who lack capacity to consent to research. The Declaration classifies research as "therapeutic" and "nontherapeutic." But the Declaration seems to forbid the enrollment of incapable

subjects in research protocols that do not offer subjects the probability of direct benefit. Research that advances generalized knowledge solely for the benefit of others only may be carried out with volunteers (27).

Another document, the *International Ethical Guidelines for Biomedical Research Involving Human Subjects*, which considers, among other concerns, research involving persons who are incapable of giving adequately informed consent, was issued in 1993 by the Council for International Organizations of Medical Sciences (CIOMS) in collaboration with the World Health Organization (WHO) (28). In the case of incompetent subjects, the CIOMS/WHO guidelines allow for proxy consent: Informed consent may be obtained from a legal guardian or other duly authorized person. The investigator, however, is directed to obtain the consent of each subject to the extent of the subject's capabilities, and also to always respect the prospective subject's refusal to participate in "nonclinical" research.

Evolution of U.S. Policies for Protection of Vulnerable Human Research Subjects

Existing federal regulations provide special protections for research subjects regarded as vulnerable. These regulations apply to research involving children, fetuses, pregnant women, human in vitro fertilization, and prisoners (1). When the federal regulations were first promulgated, special protections for persons, then described as mentally infirm and institutionalized, were proposed but never enacted into law. Although the regulations mention that additional safeguards must be included in the study to protect the rights and welfare of mentally disabled persons, these directions do not (*1*) elucidate criteria, methods, procedures, or limitations to the research design; (*2*) specify the particularities of informed consent processes, or of appointments, powers, and education of surrogate decision makers; (*3*) describe appropriate pathways between the research study and the subject's ongoing clinical care; or (*4*) make provisions for aftercare health arrangements that may be required when the research is concluded (29–31). How did this state of affairs come about?

During and following the Second World War, this country's medical and behavioral research expanded and flourished unchecked, for the most part, by any supervision. Reports of numerous and varied research scandals were exposed (32). Initially the federal government was slow to react despite the efforts of a few members of Congress and some government scientists (33). The government's own Public Health Service's Tuskegee Syphilis Study continued unrestrained until exposed in a 1972 newspaper article. Only then did a flurry of congressional activity occur regarding human research subject protection. In May 1974, regulations protecting human subjects became effective. These regulations raised to statutory status the National Institutes of Health (NIH) Policies for the Protection of Human Subjects, which were first issued in 1966. Forty-three days later Congress created the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research. Because of concerns about the use psychosurgical experimental procedures like pre-frontal lobotomy over which no peer group or federal regulatory body was in a position to regulate, decisionally impaired persons were among the special populations the National Commission was expected to consider (34).

The National Commission in its classic document, the Belmont Report, advanced the principle of respect for persons as autonomous agents, recognized that persons with diminished autonomy are entitled to protection, and applied this basic ethical precept to the process of voluntary and informed consent, as the first principle appropriate to the conduct of research (17). Thus the National Commission echoed the primary tenet of the Nuremberg Code. However, the National Commission allowed a less restrictive approach to involving incapable subjects in research. In its 1978 Report and Recommendations, *Research Involving Those Institutionalized as Mentally Infirm*, the National Commission recognized that indirect harms are likely to occur should research involving persons with mental disorders be forbidden:

> [S]ince some research involving the mentally infirm cannot be undertaken with any other group, and since this research may yield significant knowledge about the causes and treatment of mental disabilities, it is necessary to consider the consequences of prohibiting such research. Some argue that prohibiting such research might harm the class of mentally infirm persons as a whole by depriving them of the benefits they could have received if the research had proceeded (35, p. 58).

This opinion signaled a critical development in the conceptual framework for addressing the moral issues relevant to human subject research in general and to vulnerable human subjects in particular. The National Commission moved away from the position that procedures that hold no prospect of direct benefit to the noncompetent subject are not morally permissible (36). Instead, the National Commission was persuaded by the view that when risks are not unreasonable everyone, with or without decision-making capacity, has an obligation to benefit society, and that within the scope of that obligation research may be acceptable (37). This position allowed for the weighing or balancing of moral interests. The overlapping goals of benefiting the class of incapable persons, while at the same time safeguarding incapable individual subjects from unacceptable harm could be satisfied by balancing the risk of harm with the likelihood of benefit (38).

The National Commission recommended that researchers not involve vulnerable populations in research that was unconnected to their conditions as individuals or as a class of persons. They proposed a ranking of research classifications that instituted to a more precise degree substantive and procedural standards for research protocols involving more than minimal risk to incapable subjects. The National Commission appreciated that not all persons with mental disorders are incapable of giving voluntary and informed consent. They also recommended a process that allowed incapable subjects to assent or object with a simple yes or no when asked about their choice about being enrolled in a study. However, the National Commission was concerned about the vulnerability of this population and advised that when

research protocols involved greater than minimal risk, that institutional review boards (IRBs) be allowed to use their discretionary judgment to appoint a consent auditor to oversee and guarantee the adequacy of the research protocol's consent process. Only in greater than minimal risk research protocols where there was no prospect of direct benefit for the subjects should the presence of consent auditors be compulsory. Because incapable adults lack the legal guardian that most children have, the National Commission suggested it might be necessary for a court-appointed guardian to approve research participation.

The U.S. Code of Federal Regulations reflects many of the National Commission's other recommendations involving populations regarded as vulnerable such as children, pregnant women, and prisoners. Yet the recommendations in its report on *Research Involving Those Institutionalized as Mentally Infirm*, were never transposed into final regulations. In 1978, after the work of National Commission had been completed and the Commission was dissolved, the proposed regulations were published in the Federal Register. The Department of Health, Education and Welfare (now known as the Department of Health and Human Services) regulation writers significantly altered the original recommendations and inserted proposals that were more demanding. They suggested that a consent auditor monitor all research including that which involved no more than minimal risk (39). There was a strong negative response from those who perceived that such regulations would significantly limit valuable research. Human rights advocates had another perspective and voiced concern that clinicians, researchers, and IRBs might not adequately respect the interests of persons with mental disorders.

The next bioethics commission, the President's Commission for the Study of Ethical Problems in Medicine and Biomedical Research, which was established in 1980 by Congress, insisted in 1981 and again in 1983 that the proposed regulations be made official. The Secretary of the Department of Health and Human Services (DHHS) countered that the proposed rules produced a "lack of consensus," and furthermore that the "basic regulations on human subjects research adequately respond to the recommendations made by the National Commission to protect persons institutionalized as mentally disabled" (40). Despite the Secretary's judgment, as of this writing, it is generally agreed that the Code of Federal Regulations does not provide adequate guidance for research with adult persons who have disorders involving some degree of cognitive impairment (30,41–43).

Recent Efforts to Establish Appropriate Safeguards for Vulnerable Subjects

The Advisory Committee on Human Radiation Experiments (ACHRE) was created in 1994 by the President in response to concerns about possible past unethical research conduct by the U.S. government and institutions funded by the government. ACHRE was charged not only to "tell the full story about [human radiation research] to the American public," but also to "examine the present, to determine how the conduct of human radiation research today compares with the past and to assess whether, in light of this inquiry, changes need to be made in the policies of the federal government" for the protection of human subjects in research (44, p. 1).

Among the contemporary research protocols examined by ACHRE were four studies involving diagnostic imaging with cognitively impaired adult subjects. ACHRE's final report noted that in these studies, where subjects' movements were severely restricted, there had been no discussion in the documents or consent forms with the subjects about the implications of these potentially anxiety-provoking conditions. The ACHRE report also mentioned that there was no discussion of the subjects' capacity to consent or evidence that appropriate surrogate decisionmakers had given permission for the subjects' participation. According to the report:

> The question of whether or under what conditions adults with questionable decision-making capacity can be used as subjects of research that offers no prospect of benefit to them is unresolved in both research ethics and regulation. When such research puts potentially incompetent people at greater than minimal risk of harm, it is even more ethically problematic (44, p. 707).

Moreover ACHRE voiced concern in regard to the current system of research oversight. "Without guidance from the federal government, and perhaps regulatory relief, IRBs may not have the flexibility necessary to concentrate their efforts where subjects are in greatest need of protection — on the proposals that pose the greatest risks to subjects" (44, p. 819).

The DHHS Office of the Inspector General (OIG), which conducted a broad inquiry into current IRB practice, reached similar conclusions. According to the 1998 OIG report, IRBs have vulnerabilities that threaten their effectiveness in protecting human subjects (45). The OIG report drew attention to the fact that IRBs rarely conduct ongoing review of active research. Such lapses in oversight may have particularly serious implications when research protocols involve vulnerable subjects who have limited capacity for decisionmaking and thus a limited ability to protect their own interests.

> . . . [This] is a serious national issue because it compromises. . . [the IRBs'] protection of human subjects. It inhibits their capacity to identify and address situations where unacceptable risks emerge, or research results prove to be too favorable to continue, or protocol stray beyond approved limits. It also inhibits their capacity to ensure that the subjects have sufficient understanding of the risks they may incur in the research process (45, p. iii).

In October 1995 the National Bioethics Advisory Commission (NBAC) was established by executive order. The first meeting took place in October 1996. The immediate charge to NBAC was to respond to the ACHRE recommendations to focus on the protection of the rights and welfare of human research subjects. Primary among other tasks, NBAC was to complete the National Commission's unfinished business to consider how ethically acceptable research may be conducted with human subjects who suffer from mental disorders that may affect

their decision-making capacity. The NBAC report and recommendations, *Research Involving Persons with Mental Disorders that May Affect Decisionmaking Capacity*, was published in December 1998 (46). Specifically, the NBAC report "focused its attention on those who may be primarily considered for research because it is their particular mental disorder that is being studied" (46, p. 5). The report identified four types of limitations that may be experienced by persons with mental disorders:

> First, some individuals might have fluctuating capacity, what is often called waxing and waning ability to make decisions, as in schizophrenia, bipolar disorders, depressive disorders, and some dementias. Second, decisionmaking deficits can be predicted in some individuals due to the course of their disease or the nature of the treatment. Although these individuals may be decisionally capable in the early stages of the disease progression, such as in Alzheimer's disease, they have prospective incapacity. Third, most persons with limited capacity are in some way still able to object or assent to research, as in the case of more advanced Alzheimer's disease. Fourth, persons who have permanently lost the ability to make nearly any decision that involves any significant degree of reflection are decisionally incapable, as in the later stages of Alzheimer's disease and profound dementia (46, p. 10).

NBAC commissioners were concerned with the lack of specificity in the federal regulations in regard to safeguards that should be included in research protocols to protect the rights and welfare of adult subjects with illnesses involving some degree of cognitive impairment. Problems surrounding the informed consent process with vulnerable or potentially vulnerable subjects, and challenging moral concerns in regard to research design, distinct to this population, were addressed. Because decisional impairment, some forms of attention deficit, and incapacity may occur more often among "some people with certain mental disorders than in the general population" (46, p. 58), the commission recommended that IRBs require, in studies that pose more than minimal risk, that a qualified professional, independent of the research, assess the person's capacity to consent, even when the potential subject appears to have capacity for decision making. However, the NBAC report allowed for less formal capacity assessment approaches to be used if the researcher can establish good reasons for doing so.

The report also elaborates upon the concept of anticipatory research planning, and elucidates and expands the role of the legally authorized representative. The concept of obtaining a subject's consent to research participation in advance had been examined in 1989 by the American College of Physicians (47). And in 1996 new regulations adopted by the Food and Drug Administration (FDA) and National Institutes of Health (NIH) clarified rules in regard to research involving incapable subjects in emergent and life-threatening situations in emergency settings, and fostered the concept of research anticipatory planning (48). The new rule yields a narrow exception to federal informed consent requirements and permits research to proceed when it is not feasible to get informed consent from a potential subject or the subject's legally authorized representative. The rules allow researchers to obtain a waiver when they cannot reasonably obtain consent in advance or at the time of the subject's enrollment. The regulations also expand the definition of a family member to encompass "any individual related by blood or affinity whose close association with the subject is the equivalent of a family relationship" (49). By supporting the concept of consent in advance and opening up the meaning of "family relationship," these regulations are relevant to and provide guidance for research in general involving cognitively impaired persons (50). It should be noted that NBAC commissioners did "not endorse the idea of authorizing third parties to enroll incapable subjects in research involving greater than minimal risk without the prospect of direct medical benefit" (46, p. 63). For research protocols falling into this category, where subjects have not given specific consent in advance, NBAC proposed that the Secretary of the DHHS create a national panel to review individual protocols that cannot otherwise be approved.

During the 18 months of deliberation that preceded the NBAC report, the commissioners heard testimony from former research subjects, their families, IRB members, and researchers who described their experience with protocols involving subjects with mental disorders. From these public discussions the commissioners learned that certain types of protocols may be expected to escalate subjects' symptoms, relapse, and suffering. The NBAC commissioners reviewed a small selection of such research protocols and consent forms that recently had been conducted in the United States. According to the findings from this brief review, NBAC recommended that IRBs pay special attention and "heightened scrutiny" (46, p. 56) to protocols that incorporate an ethically controversial design. The report identified such studies as those "that are designed to provoke symptoms, to withdraw subjects rapidly from therapies, and to use placebo controls" (46, p. 64). NBAC proposed that in any such studies judged to be clearly critical to the development of scientific knowledge, IRBs, who according to current regulations have the authority to continue observation of approved studies, should exercise that prerogative in studies where subjects may be at risk of relapse.

Ethically Controversial Research Design

Use of placebo in medication trials involving persons with schizophrenia has drawn considerable attention to the ethics of research design. Persons with mental disorders involving decisional impairments, such as schizophrenia and major depression, are likely to suffer painful symptoms that can be life-threatening to themselves or others. Nowadays many of these symptoms can be well controlled by medication. Thus the ethical question arises as to whether it is ever appropriate to withdraw medication from individuals who rely on a specific medical therapy for their continued good health. Even though placebo controlled randomized clinical trials (RCT) generally are judged to be the gold standard for evaluating therapeutic efficacy, the use of placebo controls in RCTs have in certain circumstances come to be viewed as morally problematic. In particular, trials that enroll persons who have cognitive impairments that may affect their decision-making capacity raise serious ethical concerns (51). Such

persons may not adequately understand the concept of a RCT and may be especially confused about the distinction between research (which is to advance and generate generalizable research findings) and clinical treatment (which is to advance the welfare of particular patients). Indeed, as the recent ACHRE studies indicate, persons who were considered to be competent also suffered from the therapeutic misconception and had difficulties distinguishing medical research from clinical treatment (44, p. 761).

There are a variety of opinions regarding placebo use in research protocols. Some supporters of placebo use, including the U.S. Food and Drug Administration (FDA), consider that in the majority of trials with investigational drugs placebos may be necessary in order for the study's conclusions to be reliable (52). Another commentator agrees that the use of placebo controls in RCTs can be highly valuable in certain circumstances, but also points out that such RCTs may be used more often than is necessary (53). In another paper this commentator acknowledges that even when potential subjects are adequately informed, rational individuals are unlikely to agree to participate in RCTs (54). Some writers posit that despite the methodological difficulties, standard therapy should be used as the control in new drug investigations where subjects are at risk for relapse (51). The NBAC propose the employment of three criteria for excluding prospective subjects in placebo arms of studies: (*1*) when "an individualized assessment reveals that certain patients would be at high risk for relapse if a current or prospective therapeutic regimen were discontinued"; (*2*) when "a washout period would not be contemplated for these patients if they were not enrolling in the study"; or (*3*) when "standard therapy has previously proven to be effective" (46, p. 56).

Nevertheless, because unanticipated circumstances can occur, danger may remain for some persons who do not fit the exclusionary criteria and are capable of consenting to participate in drug-free research, challenge studies, or long-term protocols. Subjects who have fluctuating or prospective decision-making impairments whose symptoms are apt to increase are likely to be particularly vulnerable to the exigencies of high-risk protocols. Thus, when symptoms worsen, such individuals may no longer have the capacity for decision making that they were capable of when they initially were enrolled in the study. Such subjects are at risk of becoming vulnerable at precisely the point in a study when they most need to understand, to be aware of, and to make judgments about the use of safeguards — such as their right to withdraw from the study — that have been put place for their protection. Some commentators note that a person's autonomous and voluntary choice to enroll in a research protocol, secured by an informed consent document, by itself may not provide a sufficient safeguard against risks of harm (12,55).

For vulnerable subjects at risk for loss of decision-making capacity, there are other means by which they may provide protections for themselves. According to a number of commentators, anticipatory planning in the form of research advance directives provides not only a mechanism by which potential subjects may choose and appoint surrogate decision makers to act on their behalf should they lose their ability to make decisions for themselves, but also an important method of respecting individual choices. The prior authorization of the surrogate decision maker, and the precise delineation of appropriate subject protections, may make the employment of research advance directives desirable for subjects who may be competent to consent when a study begins, but who may lose their decision-making capacity while participating in the protocol (21,29,46,47,56,57).

RESEARCH ANTICIPATORY PLANNING

Genealogy of Research Advance Directives

In the United States there is some familiarity with anticipatory planning for end-of-life health care. The concept of anticipatory planning was embraced in order to encourage competent individuals to make autonomous choices, in the present, about the medical treatment they would or would not want should they, in the future, lose their capacity for health care decision making. It was hoped that such planning would prompt and enhance a dialogue between doctors and their patients, aid patients to be better informed, and foster the appointment of surrogate decision makers. In truth, this kind of advance planning was seen as a way to forbid heroic measures in the event of a terminal illness (58). However, the employment of such advance directives has been far less successful than numerous bioethicists had at one time anticipated (59,60). Notwithstanding this lack of success, there appears to be a burgeoning interest in psychiatric advance directives. Psychiatric advance directives and advance directives for end-of-life health care are shaped by the same concept — anticipatory planning for a time when the principal may no longer have the capacity to make treatment decisions. But the two kinds of documents differ in substance. The document attentive to end-of-life health care mainly addresses circumstances immediately preceding a singular event — the principal's death. In contrast, the document created for psychiatric treatment endeavors to secure, for a specific population of individuals, a good life (61). Psychiatric advance directives are intended for persons who already have experienced the sort of crisis that they anticipate may recur. Thus they are able to use their past experience to better plan for their needs in similar situations in the future.

The research advance directive is a direct descendant of advance directives for end-of-life care, and has been strongly influenced by the psychiatric advance directive (29). Commentators suggest that substantive and procedural research advance directives, which allow for specific instructions and the appointment of legally authorized representatives (surrogate decision makers), may afford a method to provide protection for some vulnerable research subjects. Research advance directives may be particularly suitable for potential subjects whose decision-making capacity may change during the course of the research. Such persons already may have experienced fluctuating periods of decision-making incapacity or are in

the early stages of progressive diseases like Alzheimer's, dementia, and Huntington's disease. Although research anticipatory planning has been little employed, the concept has been discussed and considered since the 1980s (62,63). In 1996 the FDA and the Office for Protection from Research Risk (OPRR) endorsed the concept of advance informed consent for emergency research (49).

There are critical distinctions between the three types of directives. The end-of-life advance directive was designed primarily to refuse treatment — in the United States the right to refuse treatment appears to be fundamental. In contrast, the purpose of the psychiatric advance directive is both to reject *and to elect* treatment — yet the right to demand treatment is not protected. The research advance directive introduces another kind of anomaly. Such documents, unless carefully regulated, could be used to authorize interventions that may not benefit the research subject. The American College of Physicians in their 1989 position paper, anticipate such a circumstance and propose that these directives may be abrogated if the research would unreasonably endanger the subject's welfare (47). The NBAC commissioners strongly urge that such documents should not be prepared as a blank check for future protocols without regard to risk and benefit:

> Prospective authorization cannot be a "blank check" for research participation.... NBAC limits valid Prospective Authorization to a "particular class of research" and then only if the potential subject, while capable, understood the "risks, potential direct and indirect benefits, and other pertinent conditions" of this particular class of research (46, p. 61).

Healthy elderly persons who participated in a Canadian study were concerned about the use of research advance directives. They believed that procedures and treatment not envisioned at the time the directive was prepared should be prohibited (57). Because the author of the document could inadvertently direct the surrogate decision maker to be an agent in harming them, other commentators also advocate that limits be set on what the principal may request. These commentators recommend that the surrogate decision maker may never — under any circumstances — overrule the principal's objections to participate in the research or any section of the research. Furthermore they suggest that should the subject lose capacity for decision making and be at risk of harm due to some aspect of the study itself, the surrogate is obligated to overturn the subject's instructions and to withdraw the subject from the protocol (64). Yet, other writers argue that because the surrogate's obligation is to implement the principle's wishes, the subject's withdrawal only may occur should the study itself has changed substantially (65).

Unanticipated Circumstances and the Appointment of a Surrogate Decision Maker

Research by its very nature is an activity designed to test a hypothesis and is characterized by uncertainty. Always there is the possibility that unanticipated circumstances will occur. The real prospect of future unknown situations prompts some commentators to argue that research advance directives should only be valid if subjects personally chose, and record, their selection of a surrogate decision maker (21). Some writers believe that if advance directives are to adequately safeguard the principal, the appointment of appropriate and reliable surrogates may prove more important for protection than the principal's ability to give detailed instructions (66,67). Findings from a study on ethical aspects of dementia research reveal that more than half of the study's cognitively impaired patients had the capacity to designate a surrogate decision maker, even though they did not have the capacity to understand a detailed protocol. According to the study's researchers, these patients were capable of identifying surrogates whom they trusted (68).

In 1987 the NIH Clinical Center developed a durable power of attorney mechanism for surrogate decision making in research with persons who were at risk for becoming decisionally impaired. Because surrogate decision makers only assume surrogacy responsibilities during the period when subjects lose their decision making capacities, some writers propose that surrogates participate with prospective subjects in the informed consent process and also co-sign the consent form. Thus surrogate decision makers would be educated about the protocol along with the potential subjects and consequently be privy to the subjects' concerns and wishes in regard to their research participation. According to these writers, surrogate decision-maker participation in the informed consent process may put to rest apprehensions on the part of researchers in regard to sharing the subject's medical information and also bypass the need to pinpoint when services of the surrogate might be required (69).

Nevertheless, there may be obstacles that impede the appointment of an appropriate surrogate decision maker. A designated surrogate, even though well trusted by the principal, may not be capable of doing the job adequately. Some surrogates may not properly pursue a subject's best interests. Who should decide if an appointed surrogate is "appropriate"? One writer suggests that this should not be a judgment made by the researchers alone. This commentator proposes that researchers and IRB committee members educate proxies on the correct ethical standards to be used when making decisions about a decisionally incapable person's research participation (70).

Capacity to Engage in Anticipatory Planning

Making judgments about another person's decision-making capacity may be problematic (70). Society appears to be unable to agree on the degree of impairment it is willing to countenance before it deems that a person lacks adequate decision-making capacity (71). Nonetheless, all potential human research subjects are presumed to be capable of making decisions for themselves, unless there are specific reasons and conditions that lead to the belief that a capacity assessment is required. A careful appraisal of each prospective subject's clinical condition, particular circumstances, and the design of the research protocol are necessary factors in capacity determination. Decision-making capacity customarily is considered to be task specific. A person may lack decision-making capacity in one area but have capacity to make decisions in other areas.

Evaluating a potential subject's capacity typically has consisted of subjective judgments. Now, however, there are beginning to be some tested approaches for assessing capacity to consent to research more objectively (72,73). Many persons with mental disorders whose capacity may fluctuate will have intermittent periods when they have decision-making capacity. It is morally correct, and also usually possible, to approach such potential subjects about participation in relevant research at a time when they are competent.

When consent to participate in research is obtained in conjunction with a research advance directive for persons with limited or fluctuating periods of capacity, or with prospective incapacity, the immediate "task at hand" for such potential research subjects is to understand the concepts involved in anticipatory planning. Commentators consider that capacity to prepare an advance directive is distinct from the capacity to consent to treatment, to research, or even to complete a testamentary will (74). These writers propose that potential subjects should be able to grasp and understand that their consent to participate in a specific research protocol, made in the present, constitutes their agreement to take part in a study that will occur over a specified and perhaps extended period of time. In other words, subjects should be able to discern that some of their choices made in the present may be acted upon in the future. Subjects also should be aware that some of their decisions, when relevant, may involve their agreement to medical procedures. Furthermore potential subjects should clearly appreciate that their appointed surrogate will make decisions for them, should they at a future time while participating in the research protocol become incapable of making decisions for themselves (74). Other commentators maintain that subjects should comprehend that whatever they may have recorded in their research advance directive, that with — or without — decision-making capacity, they may object and withdraw from the study (64).

Research Risk Assessment Ambiguities That Reinforce Need for Anticipatory Planning

Specifying criteria and developing policy that assists people to make accurate judgments about risks of harm in research protocols continues to be difficult. The National Commission's 1978 *Belmont Report* acknowledged this problem but did not resolve it: "It is commonly said that benefits and risks must be 'balanced' and shown to be 'in a favorable ratio.' The metaphorical character of these terms draws attention to the difficulty of making precise judgments" (17, p. 7). Assessments of risk of harm in research protocols must attempt to measure the harm's duration, consequences, potential damage, and how the harm might be considered from a subjective point of view. Even though certain types of risks may be precisely and objectively quantified, many risks of harm only may be qualified because they may be of a more subjective kind (75). It is this tension between objective and subjective considerations that makes it so difficult to fashion procedures and policy that do "justice to the equal importance of all persons, without making unacceptable demands on individuals" (76, p. 5).

The phrase "minimal risk" was advanced by the National Commission as an attempt to establish a baseline measure, and it is the standard used in current U.S. federal regulations. "Minimal risk" is defined as meaning "that the probability and magnitude of harm and discomfort anticipated in research is not greater than those ordinarily encountered in daily life or during the performance of routine or psychological examination" (1, §46.102i). Many commentators recognize that this definition is ambiguous. Writers question whether the "harm and discomfort" is that which may be encountered by healthy people in their everyday lives, or whether ordinary "harm and discomfort" is meant to describe that which may be endured in the daily lives of any population of research subjects who have a particular condition or disease. Some writers propose that if the definition of minimal risk is bound to a subjects's disease or condition, it may be easier to more accurately evaluate the level of risk (77). Others argue that in order to appreciate the meaning of minimal risk in the research context, it must be examined in its specific employment (78). The National Commission in its 1978 report on *Research Involving Those Institutionalized as Mentally Infirm* suggests that the "IRB may determine that prospective subjects who are institutionalized as mentally infirm are likely to react more severely than normal persons to certain routine procedures; in such instances, the procedures present more than minimal risk to the subjects" (35, pp. 8–9).

Making judgments about the risk of harm in research protocols is imprecise. A commentator recommends that when research involves vulnerable or potentially vulnerable subjects, investigators and research institutions must be held to a high standard. Not only must the scientific and ethical justifications be especially sound, but researchers should specify what extra safeguards will be put in place to protect subjects' rights and safeguard their welfare (43). In protocols involving greater than minimal risk, research advance directives may provide a practical way to specify safeguards and guarantee protections for vulnerable subjects. Commentators posit that when a legally authorized representative co-signs the consent form along with the potential subject who is competent, not only is the potential subject's autonomy respected but all parties — the subject, the researchers, and the surrogate decision makers — acknowledge the stipulated protections that must be complied with during (and in some cases after) the study period (62,69).

CONCLUSION

Biomedical research involving human subjects is a distinct kind of undertaking and is essentially different to the routine practice of medicine. In order for research with vulnerable subjects to be ethically permissible, this difference should not only be clarified, but special procedural protections should also be employed. However, the concept of protection for research subjects should no longer mean that vulnerable populations must be excluded from research participation. Rather, protection should

signify that a constellation of safeguards are provided that will guarantee the rights and welfare of all subjects enrolled in studies. The assurance that such protections will be put in place may allow vulnerable populations to volunteer and participate in research protocols designed to study their particular conditions without fear that they will be subjected to research abuse.

HUMAN SUBJECTS RESEARCH, ETHICS, STOPPING RULES FOR RANDOMIZED CLINICAL TRIALS

OUTLINE

INTRODUCTION

"Stopping rule" is a term that refers to a statistical criterion for termination of a randomized clinical trial (RCT). Typically stopping rules are based on p values, namely the probability that an observed difference between two arms of a RCT (presumed under the null hypothesis to be equal in efficacy) with regard to an outcome measure would have occurred by chance. When the difference in outcomes appears quite large at some interim point in the trial, such that this probability is extremely small, one might conclude that the question of whether the two arms have equivalent effects can be answered definitely in the negative, and the trial can be terminated at that point. Although they are called stopping rules, they are for good reasons usually treated as "stopping guidelines," criteria for giving serious thought to ending a RCT before its planned termination date.

Stopping rules are generally developed only for primary outcome measures, which, in turn, are almost always expressions of efficacy. A typical stopping rule might be represented in the following way for a particular interim analysis: We will consider recommending that the trial be terminated if at the second interim analysis

the difference between arm A and arm B with regard to the primary outcome measure is significant at a level of $p < 0.0005$.

Responsibility for monitoring the data developed in the course of conducting a RCT is often assigned to a data and safety monitoring board (DSMB), especially when the trial is evaluating treatment effects on mortality or major morbidity. DSMB members have access to data regarding safety and, when appropriate, to efficacy; such data are kept highly confidential and neither the sponsors nor the investigators are permitted access to them. The DSMB generally conducts periodic assessments of the data regarding the outcome measures (*interim analyses*); one of its major responsibilities is to decide, based on the previously specified stopping rule, whether to recommend to the steering committee (or other group having the responsibility and authority to take such actions) that the RCT be terminated or modified.

The ethical functions served by stopping rules are related to the fundamental ethical principle of beneficence, a formal statement of which was provided by the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research: (*1*) Do no harm and (*2*) maximize possible benefits and minimize possible harms (1). Skillful design and implementation of stopping rules maximizes benefits by increasing the efficiency of clinical trials. When efficacy is demonstrated before the planned termination of a RCT, the therapy that was found effective may be provided to its intended beneficiaries that much earlier. Efficiency in a different sense is also served by conserving resources that would have been wasted by continuing expensive and unnecessary clinical trials. Effective use of stopping rules also serves to minimize harms by reducing the time of exposure of research subjects in the control arm to the ineffective or less effective therapy.

STATISTICAL APPROACHES TO DATA MONITORING

Sequential Designs

When data are reviewed on multiple occasions over the course of a study, the chances of observing a statistically significant result ($p < 0.05$) on at least one occasion can be substantially greater than 5 percent. This results from having multiple opportunities to observe the event of interest, thereby increasing the overall chance of ever observing the event. To take a more everyday example, the chance of drawing the ace of spades from a complete deck of cards is 1 in 52, but the chance of drawing the ace of spades at least once if one draws one card each day for 10 days is substantially greater than 1 in 52.

McPherson, writing in the *New England Journal of Medicine* nearly 30 years ago, showed that, in a case in which there was no difference in outcomes between the treatment and control groups, the probability of ever observing a difference significant at the 0.05 level was actually about 14 percent if the data were reviewed a total of 5 times, and about 19 percent if there were 10 interim reviews (2). Thus, if the risk of a false positive finding (or type I error) is to be kept under 5 percent for the experiment as a whole, statistical designs that preserve the 5 percent level of error (or 1 percent, or whatever other level has been predetermined as appropriate) must be employed.

Study designs that provide for interim analyses of accumulating data while maintaining the overall type I error at the desired level are called *sequential designs*. The simplest approach to preserving type I error in a sequential design is to determine the number of times one wishes to examine the accumulating data during the course of the study, and to then determine the threshold significance level that, if applied at each interim analysis, would lead to a type I error of 5 percent for the experiment as a whole. This problem was studied by Pocock, who showed how to calculate these values (3). For example, he showed that if there were to be a total of five analyses, a p-value of 0.0158 would have to be used at each analysis in order to ensure that the false positive rate for the entire study did not exceed 5 percent. A problem with this approach, however, was the difficulty in interpreting the final analysis when the significance level fell between the threshold of 0.0158 and the nominal value of 0.05. However mathematically correct the threshold value was, it was disconcerting to declare a study with a final p-value of 0.03 as a nondefinitive result because of the number of times the data had been reviewed prior to the final analysis.

A few years later O'Brien and Fleming at the Mayo Clinic developed an alternative design that provided for varying threshold levels as the study proceeded (4). In this design the first interim analysis is performed using an exceedingly small threshold value. At each successive interim analysis the threshold value is increased by a modest increment. This design allows the final threshold value to be close to the nominal value of 0.05. Using the same example as above, with a total of 5 interim analyses, O'Brien and Fleming showed that the following sequence of threshold values would produce an overall type I error rate of 5 percent: 0.0000005, 0.0013, 0.0085, 0.0228, and 0.0417. This design was appealing because it decreased the chance of stopping the study very early, when most investigators would want to be especially conservative, and also decreased the chance that the final "correct" analysis (based on a p-value of 0.0417) would lead to a different conclusion than a final analysis based on the nominal 0.05 level of error.

More recently a number of variations on the O'Brien-Fleming design have appeared. Perhaps the most important is that developed by Lan and DeMets (5), who showed that type I error could be preserved even if the number of interim analyses to be performed were not specified at the beginning of the study. These statisticians recognized that ensuring patient safety sometimes required that additional interim analyses beyond those that were originally planned, and it was important to be able to maintain the validity of study conclusions about efficacy in those circumstances. They introduced the concept of an *alpha-spending function* that specifies how rapidly the type I (alpha) error is to be used up (or "spent") but does not require the number of analyses to be determined in advance. Thus the incorporation of spending functions into the sequential analysis of clinical trials has provided added flexibility without jeopardizing the control of the type I

error level. O'Brien-Fleming designs that incorporate Lan-DeMets alpha-spending functions are probably the most commonly used type of sequential statistical designs in today's RCTs. An excellent discussion of the use of alpha-spending functions can be found in DeMets and Lan (6).

Monitoring for Lack of Effect

In addition to monitoring for definitive establishment of treatment effect, it is sometimes important to monitor for lack of effect, and to have the opportunity to terminate a trial early when the accumulating data are highly inconsistent with the existence of a clinically important treatment effect. Because such monitoring may increase the number of times that a treatment could be declared ineffective, but not the number of times it could be declared effective, the concern with these designs is not increase of the false positive rate but rather an increase in the rate of false negatives (type II errors). Monitoring procedures of this type (often referred to as *stochastically curtailed testing*) have been shown to reduce substantially the number of patients treated on clinical trials of ineffective treatments, while having minimal impact on type II error (7). These procedures are based on a re-calculation of the statistical power of the trial (the complement of the type II error, i.e., the probability that a true benefit will be statistically detected), given the data that have already been observed. Because the analyses take into account the already-observed data, they are often called *conditional power analyses*. Stochastically curtailed testing can be implemented in conjunction with a standard sequential design as described above.

Monitoring for Safety

Monitoring for safety is usually very different from efficacy monitoring. With the latter, the variable identified as the primary study endpoint — such as mortality, disease recurrence, occurrence of another undesirable clinical event — is prespecified, as is the analytical method that will be used to assess it. While it is often possible to prespecify certain safety outcomes of particular concern, interim safety monitoring must cover all types of adverse events, whether or not they are anticipated. Further, in many cases safety concerns arising in RCTs, even without the definitive probabilistic framework that would be demanded for an efficacy endpoint, will lead to modification or even early termination of the trial. A strong suggestion of harm, even without definitive proof, would likely be sufficient to warrant such actions when the intended benefit of the treatment is relatively modest.

ISSUES IN THE IMPLEMENTATION OF STOPPING RULES

Need for Judgment

Sequential designs have proved very useful in the conduct of RCTs fostering careful monitoring of interim data to ensure that patients are being treated appropriately and safely without sacrificing the validity of the statistical conclusions that will ultimately be drawn. This point notwithstanding, it is essential to recognize the impossibility of developing a design that will account for all contingencies that might occur in the trial. For example, suppose that the interim data at, say, the third look, show a positive effect of treatment that exceeds the threshold for early termination, but at the same time, unexpected safety concerns have emerged. A DSMB in that situation probably should not recommend stopping at that point on the basis that efficacy had been demonstrated; rather, it probably should recommend collection of additional data to help clarify the risk–benefit considerations. In some cases information about findings from other trials or related studies might affect the DSMB's perspective on the data from the trial being monitored. DSMBs must be prepared to consider all the available information pertaining to the safety and efficacy of the treatment being studied prior to making its recommendations, and cannot rely entirely on the statistical stopping thresholds as the basis for decision making. As stated by DeMets et al.:

> Although sophisticated statistical methods have been developed to assess the quantitative strength of trial results, it is important to note that statistical methods alone are not adequate to guide early termination decisions. The collective experience and judgment of the [data monitoring committee] is necessary. Making decisions about early termination requires consideration of many additional factors such as results on secondary outcomes, safety data, degree of compliance to the protocol, possible sources of bias in outcome evaluation, completeness and currency of data, and internal and external consistency of the data as well as emerging data from other trials (8).

Concerns About Designs That Permit Early Termination of Clinical Trials

While statisticians have paid much attention to the development of methods for interim analysis of clinical trials that preserve type I error at the desired level, it must be remembered that the only occasion for concern about type I error is when one might terminate a study and draw a final conclusion based on its interim results. Early termination options are most often important for trials of therapies that may, as compared with other available treatments, improve the likelihood of survival or reduce the probability or magnitude of disability. In many clinical trials, however, there may be good reasons to continue the trial to the planned conclusion even if an interim analysis demonstrates definitive benefit with respect to the primary efficacy variable. When the new treatment is aimed at relief of symptoms, or any endpoint that is neither serious nor irreversible, the need for a fuller safety database becomes more compelling; we must have adequate data on the possible risks before being able to conclude that the observed benefit outweighs these risks. (Adverse outcomes are caused by many factors, not just investigational treatments, so safety data collected in a randomized, controlled, blinded trial are much more reliable indicators of the potential adverse consequences of treatment than safety data collected using less rigorous methods such as uncontrolled case series or retrospective data base analyses.) Thus, in trials in which the outcome measures are neither death nor disability, there may be no need for sequential designs;

monitoring for safety, however, would of course remain important.

Some investigators have argued that even in circumstances when mortality or serious morbidity is the trial endpoint, we ought not to be terminating trials early except in the rarest of situations. Their rationale is that the results of a trial with truncated enrollment may be less convincing to the medical community than results based on a larger patient population, and that a positive trial that does not lead physicians to change their practices has not accomplished any worthwhile purpose and might as well not have been performed. Concerns about the adequacy of estimates of treatment effect from trials stopped early and the consequent concern about the ability to derive reliable cost-benefit considerations for the treatment studied, may threaten the acceptance of results from such trials (9).

The counterargument is that it is unethical to continue enrolling patients in RCT when one of the treatments being compared has already been demonstrated to be superior. To do so entails a deliberate withholding of the therapy known to be superior from those subjects who are assigned to the other (inferior therapy) arm of the trial. It is hard to imagine that fully informed subjects would agree to cooperate with such a plan. Deliberate withholding of known effective therapy without the consent of the subjects is unethical. It at least appears to violate the standard set forth in Article 1.5 of the Declaration of Helsinki: "Concern for the interests of the subject must always prevail over the interests of science and society" (10).

The fundamental controversy here is perhaps more accurately focused on the level of evidence that should be required for a trial to be considered positive, rather than whether interim analysis, possibly leading to early termination, should be performed. If the threshold for statistical significance were to be set at $p < 0.01$ (or lower), the required sample size would be substantially larger (30 to 60 percent larger, for power in the typically acceptable range) than for a trial using the more conventional $p < 0.05$ threshold, and the O'Brien-Fleming stopping boundaries that would result would require much more extreme evidence of benefit for early stopping — possibly even enough to be persuasive to a highly skeptical medical community.

Boston University
Boston, Massachusetts

OUTLINE

INTRODUCTION

The Common Law

There is little common law on research with human subjects in the United States. Common law is distinct from statutes enacted by legislatures and from regulations issued by government agencies. Unlike statutes and regulations, common law rules have no single official text. They consist of principles defining general rights and obligations that are summarized from the reasoning of court decisions in lawsuits. This gives the common law flexibility to adapt itself to new circumstances without the need for rewriting a law in its entirety. It also means that the principles and their application are subject to interpretation, and often dispute, which permits a degree of uncertainty that can be discomfiting to those who seek absolute predictability in the law.

Common law in the United States developed from English common law applied in the colonies before Independence (1). It remains within the jurisdiction of the states, each of which is free to develop its own principles and rules, thereby eroding some of the commonality of the common law. Nonetheless, at the level of generality with which we are concerned here, there is enough consistency in principle and doctrine to permit useful generalizations. For detailed application of common law rules in any one state, it is essential to consult that state's specific laws.

For decades, the common law remained in the background of research policy. The fact that common law imposed duties of care on researchers and granted rights to human subjects of research did not prevent scandalous abuses of research subjects. Perhaps the most comprehensive statement of researcher's duties in what may be considered international common law is the Nuremberg Code, the 10 principles set forth in the 1947 judgment against Nazi physicians convicted of crimes against humanity (murder and torture) under the guise of medical experimentation (2). The judgment, by American judges in a military tribunal established by the United States Military Government for Germany after World War II, is also precedent for common law duties of researchers in the United States. Yet few American courts have even referred to the Nuremberg Code, much less applied it, in cases involving research subjects (3).

Revelations of unethical research and experimentation with human beings without their consent did not give rise to vigorous enforcement of common law principles, perhaps because common law rights must be enforced by lawsuits brought by those whose rights are violated. Instead, in the 1960s and the 1970s, such revelations inspired new federal guidelines and regulations (4–9). Federal laws requiring those who receive federal funding for research with human subjects to comply with specific regulations intended to protect subjects from such abuses have been harmonized into what is known as the Common Rule (10). The Common Rule applies to the Departments of Agriculture, Commerce, Defense, Education, Energy, Health and Human Services (including the Office of the Secretary, the Food and Drug Administration, the National Institutes of Health), Housing and Urban Development, Justice, Transportation, and Veterans Affairs, and the Consumer Product Safety Commission, Environmental Protection Agency, International Development Cooperation Agency (including the Agency for International Development), National Aeronautic and Space Administration, and National Science Foundation. Although the Common Rule incorporates basic elements of the common law into its regulatory provisions, the Common Rule has had more influence on the conduct of research than the common law (11).

Nevertheless, the common law remains the legal backstop to fill gaps left by regulations. More important, it provides research subjects with a legal remedy for injuries (which federal regulations do not). Thus the common law can be seen as describing the legal boundaries for lawful research and responding to the claims of injured research subjects, within which more specific statutes and regulations carve out particular additional duties.
