information not only fits into the cell but fits into the cell nucleus? Eukaryotes solve this problem by a combination of supercoiling and packaging DNA around the histone family of proteins (described below). Prokaryotes do not contain histones (with a few exceptions). Prokaryotes tend to compress their DNA using **nucleoid-associated-proteins (NAPs)** and **supercoiling,** as shown in Figure 8.4.5.

DNA supercoiling refers to the over- or under-winding of a DNA strand and is an expression of the strain on that strand. Supercoiling is important in a number of biological processes, such as compacting DNA and regulating access to the genetic code. DNA supercoiling strongly affects DNA metabolism and possibly gene expression. Additionally, certain enzymes such as **topoisomerases** can change DNA topology to facilitate functions such as DNA replication or transcription.

In a "relaxed" double-helical segment of B-DNA, the two strands twist around the helical axis once every 10.4–10.5 base pairs of sequence. Adding or subtracting twists, as some enzymes can do, impose strain. If a DNA segment under twist strain were closed into a circle by joining its two ends and then allowed to move freely, the circular DNA would contort into a new shape, such as a simple figure-eight, as shown in Figure 8.4.5. Such a contortion is a *supercoil*. The noun form "supercoil" is often used in the context of DNA topology.

Figure 8.4.5: DNA Supercoiling. The supercoiled structure of linear DNA molecules with constrained ends. The helical nature of the DNA duplex is omitted for clarity. *mage by: Richard Wheeler*

Positively supercoiled (overwound) DNA is transiently generated during DNA replication and transcription, and, if not promptly relaxed, inhibits (regulates) these processes. The simple figure eight is the simplest supercoil and is the shape a circular DNA assumes to accommodate one too many or one too few helical twists. The two lobes of the figure eight will appear rotated either clockwise or counterclockwise with respect to one another, depending on whether the helix is over- or underwound. For each additional helical twist being accommodated, the lobes will show one more rotation about their axis. As a general rule, the DNA of most organisms is negatively supercoiled.

Lobal contortions of a circular DNA, such as the rotation of the figure-eight lobes above, are referred to as *writhe*. The above example illustrates that twisting and writhing are interconvertible. Supercoiling can be represented mathematically by the sum of *twist* and *writhe*, The *twist* is the number of helical turns in the DNA and the writhe is the number of times the double helix crosses over on itself (these are the supercoils). Extra helical twists are positive and lead to positive supercoiling, while subtractive twisting causes negative supercoiling. Many topoisomerase enzymes sense supercoiling and either generate or dissipate it as they change DNA topology.

In part, because chromosomes may be very large, segments in the middle may act as if their ends are anchored. As a result, they may be unable to distribute excess twist to the rest of the chromosome or to absorb twist to recover from underwinding—the

segments may become *supercoiled*, in other words. In response to supercoiling, they will assume an amount of writhe, just as if their ends were joined.

Supercoiled circular DNA forms two major structures; a *plectoneme* or a *toroid*, or a combination of both. A negatively supercoiled DNA molecule will produce either a one-start left-handed helix, *the toroid*, or a two-start right-handed helix with terminal loops, the *plectoneme*. *Plectonemes* are typically more common in nature, and this is the shape most bacterial plasmids will take. For larger molecules, it is common for hybrid structures to form – a loop on a toroid can extend into a plectoneme as shown in Figure 8.4.6. DNA supercoiling is important for DNA packaging within all cells and seems to also play a role in gene expression.

Figure 8.4.6: Bacterial DNA Supercoiling. Atomic force microscopy (AFM) visualization of torsionally relaxed (A), and negatively supercoiled (B) bacterial plasmids pBR322. (C) Electron microscopy image of the E. coli chromosomal DNA displaying a hybrid toroidal-plectoneme structure. Image A and B from Witz, G. and Stasiak, A. (2009) Nucleic Acids Research 38(7):2119-2133. Image C from Prokaryotic Chromosomes

In addition to forming supercoiled structures, circular chromosomes from bacteria have been shown to undergo the processes of *catenation* and *knotting* upon the inhibition of topoisomerase enzymes. *Catenation* is the process by which two circular DNA strands are linked together like chain links, whereas *DNA knotting* is the interlooping structures occurring within a single circular DNA structure. These are illustrated in Figure 8.4.7. *In vivo*, the action of topoisomerase enzymes is critical to keep knots and catenoids from tangling the DNA structure.

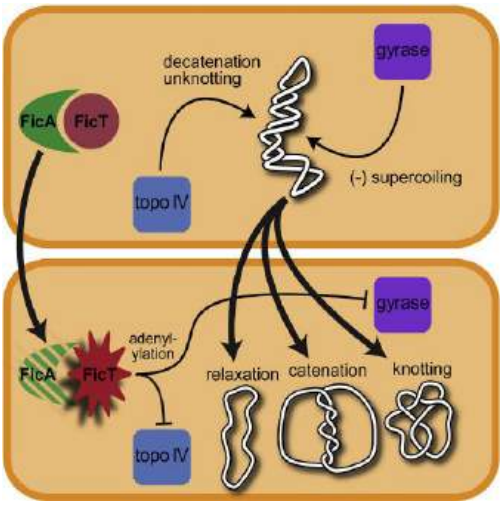

Figure 8.4.7: DNA Catenation and Knotting. The upper structure shows the negatively supercoiled form of bacterial DNA. The inhibition of topoisomerase enzyme activity leads to the relaxation, catenation, and knotting of the chromosomal structure. *Harms, A. et al. (2015) Cell Reports 12(9):1497-1507*.

Mitochondrial and Chloroplast DNA

Mitochondrial and Chloroplast DNA are circular suggesting a bacterial origin for both of these organelle structures. Sequence alignments further lend support for the *endosymbiotic theory*, which proposes that bacteria were engulfed by early eukaryotic organisms and subsequently became symbiotic to their eukaryotic counterpart, rather than being digested.

In the cells of eukaryotic organisms, the vast majority of the proteins present in the mitochondria (numbering approximately 1500 different types in mammals) are coded for by nuclear DNA. However, sequencing of the human mitochondrial genome has revealed 16,569 base pairs encoding 13 proteins, as shown in Figure 8.4.8. Many of the mitochondrially produced proteins are required for electron transport during the production of ATP.

Figure 8.4.8: Mitochondrial Genome. Mitochondria are organelle structures containing a double membrane, thought to have originated as an independent prokaryotic organism that was originally engulfed by a eukaryotic organism, where it became a symbiotic counterpart. Mitochondria contain circular chromosomal DNA that shares high sequence similarity with alphaprotobacteria. The human mitochondrial genome contains 16,569 base pairs encoding 13 proteins and ribosomal RNA (rRNA) components. *Images adapted from The National Human Genome Research Institute and Shanel, Knopfkind, and JHC*

8.4.4: Histones and Nucleosomes

Within eukaryotic chromosomes, chromatin proteins, known as **histones**, compact and organize DNA. These compacting structures guide the interactions between DNA and other proteins, helping control which parts of the DNA are transcribed.

Histones are highly basic proteins found in eukaryotic cell nuclei that package and order the DNA into structural units called **nucleosomes**. They are the chief protein components of chromatin, acting as spools around which DNA winds, and playing a role in gene regulation. Without histones, the unwound DNA in chromosomes would be very long (a length-to-width ratio of more than 10 million to 1 in human DNA). For example, each human diploid cell (containing 23 pairs of chromosomes) has about 1.8 meters of DNA wound on the histones, and the diploid cell has about 90 micrometers (0.09 mm) of chromatin.

There are five major families of histones, H1/H5, H2A, H2B, H3, and H4. Histones H2A, H2B, H3, and H4 are known as the core histones, while histones H1/H5 are known as the linker histones.

The core histones all exist as dimers, which are similar in that they all possess the histone fold domain: three alpha helices linked by two loops (Figure 4.13). It is this helical structure that allows for interaction between distinct dimers, particularly in a head-tail fashion (also called the handshake motif). The resulting four distinct dimers then come together to form one octameric nucleosome core, approximately 63 Angstroms in diameter. Around 146 base pairs (bp) of DNA wrap around this core particle 1.65 times in a left-handed super-helical turn to give a particle of around 100 Angstroms across, called a nucleosome as illustrated in Figure 8.4.9.

Figure 8.4.9: Nucleosome Core Structure. Histones H2A and H2B dimerize, and Histones H3 and H4 dimerize. Two dimers of each join to form a histone core octamer. The DNA double helix winds 1.65 times around the octamer core forming the nucleosome structure. *image adapted from Nucleosome Structure*

The linker histone H1 binds the *nucleosome* at the entry and exit sites of the DNA, thus locking the DNA into place and allowing the formation of higher order structure (Figure 4.14). The most basic such formation is the 10 nm fiber or beads on a string conformation. This involves the wrapping of DNA around nucleosomes with approximately 50 base pairs of DNA separating each pair of nucleosomes (also referred to as linker DNA).

The nucleosome contains over 120 direct protein-DNA interactions and several hundred water-mediated ones. Direct protein – DNA interactions are not spread evenly about the octamer surface but rather located at discrete sites. These are due to the formation of two types of DNA binding sites within the octamer; the α1α1 site, which uses the α1 helix from two adjacent histones, and the L1L2 site formed by the L1 and L2 loops. Salt links and hydrogen bonding between both side-chain basic and hydroxyl groups and main-chain amides with the DNA backbone phosphates form the bulk of interactions with the DNA. This is important, given that the ubiquitous distribution of nucleosomes along genomes requires it to be a non-sequence-specific DNA-binding factor. Although nucleosomes tend to prefer some DNA sequences over others, they are capable of binding practically to any sequence, which is thought to be due to the flexibility in the formation of these water-mediated interactions. In addition, non-polar interactions are made between protein side-chains and the deoxyribose groups, and an arginine side-chain intercalates into the DNA minor groove at all 14 sites where it faces the octamer surface. The spatial distribution and strength of DNA-binding sites about the octamer surface distort the DNA within the nucleosome core. The DNA is non-uniformly bent and also contains twist defects. The twist of free B-form DNA in solution is 10.5 bp per turn. However, the overall twist of nucleosomal DNA is only 10.2 bp per turn, varying from a value of 9.4 to 10.9 bp per turn.

The histone tail extensions constitute up to 30% by mass of histones, but are not visible in the crystal structures of nucleosomes due to their high intrinsic flexibility, and have been thought to be largely unstructured (Figure 4.14). The N-terminal tails of histones H3 and H2B pass through a channel formed by the minor grooves of the two DNA strands, protruding from the DNA every 20 bp. The N-terminal tail of histone H4, on the other hand, has a region of highly basic amino acids (16-25), which, in the crystal structure, forms an interaction with the highly acidic surface region of an H2A-H2B dimer of another nucleosome, being potentially relevant for the higher-order structure of nucleosomes. This interaction is thought to occur under physiological conditions also and suggests that acetylation of the H4 tail distorts the higher-order structure of chromatin.

Figure 8.4.10 shows an interactive iCn3D model of the human nucleosome (3afa). One member of each pair of histones is shown in cartoon rendering, while the other member of the pair is shown in the same color but in spacefill rendering. The structure of a human nucleosome (3afa) is shown below (H2A is shown in cyan, H2B in blue, H3 in magenta, and H4 in purple). Each strand of DNA is shown in a different shade of gray.

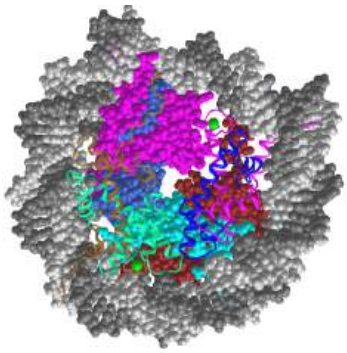

Figure 8.4.10: Human nucleosome (3afa). (Copyright; author via source).

The packing of DNA from dsDNA to the metaphase chromosomes is schematically shown in Figure 8.4.11. The formation of the DNA double helix represents the first-order packaging of the chromosome structure. The formation of nucleosomes represents the second level of packaging for eukaryotic chromosomes. *In vitro* data suggests that nucleosomes are then arranged into either a solenoid structure which consists of 6 nucleosomes linked together by the Histone H1 linker proteins or a zigzag structure that is similar to the solenoid construct. Both the solenoid and zigzag structures are approximately 30 nm in diameter. The solenoid and zigzag structures reported from *in vitro* data have not yet been confirmed to occur *in vivo.*

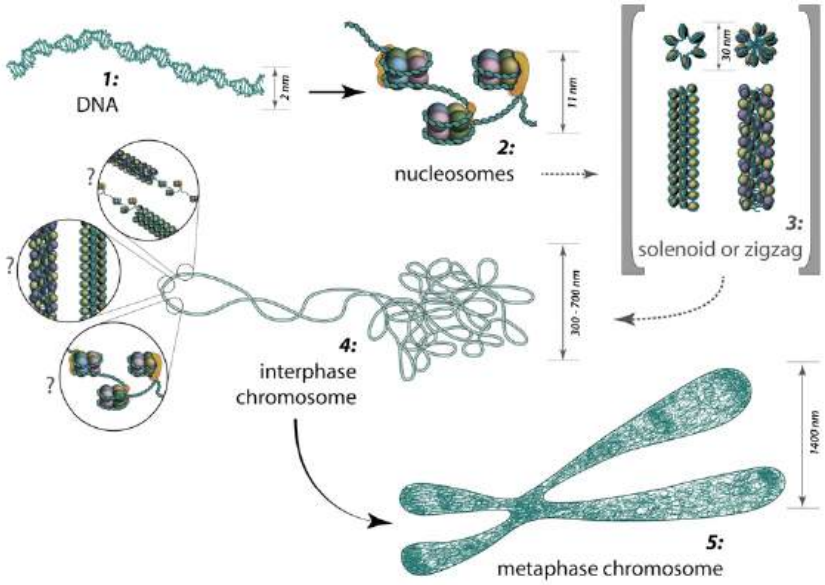

Figure 8.4.11: Chromosome Structure. (1) DNA double helix is approximately 2 nm in diameter. (2) The nucleosome core structure is approximately 11 nm in diameter. (3) The solenoid/zigzag structure is approximately 30 nm in diameter and is proposed to form chromosome loops (4) during cellular interphase and more condensed chromosome territories (5) during mitosis. *Image by MBInfo*

8.4.5: Telomeres

At the ends of the linear eukaryotic chromosomes are specialized regions of DNA called telomeres. The main function of these regions is to allow the cell to replicate chromosome ends using the enzyme telomerase, as the enzymes that normally replicate DNA cannot copy the extreme 3′ ends of chromosomes. A cartoon showing telomeres and their extension is shown in Figure 8.4.12

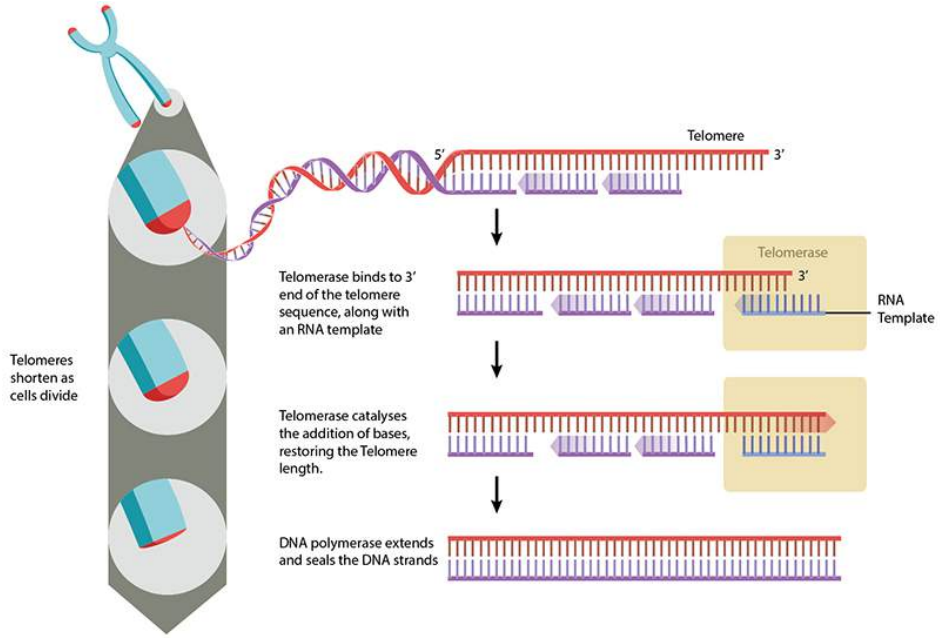

Figure 8.4.12: Telomer structure and extension. https://www.mechanobio.info/genome-r...are-telomeres/. Creative Commons Attribution-NonCommercial 4.0 International License.

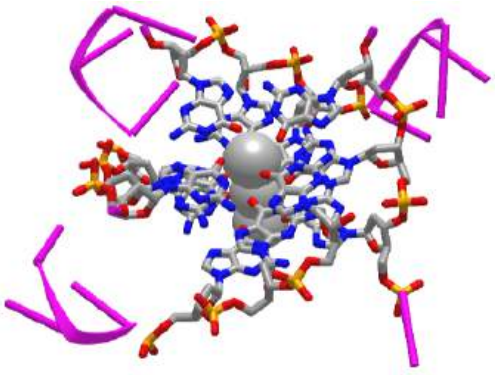
These specialized chromosome caps also help protect the DNA ends, and stop the DNA repair systems in the cell from treating them as damage to be corrected.

In human cells, telomeres contain 300-8000 repeats of a simple **TTAGGG** sequence. The repetitive **TTAGGG** sequences in telomeric DNA can form unique higher-order structures called **quadruplexes**. Figure 8.4.13 shows an interactive iCn3D model of parallel quadruplexes from human telomeric DNA (1KF1). The structure contains a single DNA strand **(**5'-AGGGTTAGGGTTAGGGTTAGGG-3') which contains four TTAGGG repeats.



NCBI iCn3D Figure 8.4.13: A buried phenylalanine in low molecular weight protein tyrosyl phosphatase (1xww) (Copyright; author via source).

Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...y5joFHDgWJQsQ6

Rotate the model to see 3 parallel layers of quadruplexes. In each layer, **4** noncontiguous guanine bases interact with a K^+ ion. Hover over the guanine bases in one layer and you will find that one layer consists of guanines 4, 10, 16, and 22, which derive from the last G in each of the repeats in the sequence of the oligomer used (5'-AGGGTTAGGGTTAGGGTTAGGG-3'). These quadruplexes certainly serve as recognition and binding sites for telomerase proteins. The guanine-rich telomere sequences which can form quadruplex may also function to stabilize chromosome ends

During DNA replication, the double-stranded DNA is unwound and DNA polymerase synthesizes new strands. However, as DNA polymerase moves in a unidirectional manner (from 5' to 3'), only the **leading strand** can be replicated continuously. For the complementary **lagging strand**, DNA replication is discontinuous. In humans, small RNA primers attach to the lagging strand

DNA, and the DNA is synthesized in small 5'-3' stretches of about 100-200 nucleotides, which are termed **Okazaki fragments.** The RNA primers are removed and replaced with DNA and the Okazaki DNA fragments are ligated together. At the end of the lagging strand, it is impossible to attach an RNA primer, meaning that there will be a small amount of DNA lost each time the cell divides. This ‘end replication problem’ has serious consequences for the cell as it means the DNA sequence cannot be replicated correctly, with the loss of genetic information. Hence most telomeres have 3´ overhangs. Bacteria DNA, which is circular, does not have the problem.

To prevent this, telomeres are repeated hundreds to thousands of times at the end of the chromosomes. Each time cell division occurs, a small section of telomeric sequences is lost to the end replication problem, thereby protecting the genetic information. At some point, the telomeres become critically short. This decreases leads to cell senescence, where the cell is unable to divide, or apoptotic cell death. Telomeres are the basis for the **Hayflick** limit, the number of times a cell can divide before reaching senescence.

Telomeres can be restored by the enzyme **telomerase**, which extends the telomere's length. Telomerase activity is found in cells that undergo regular division, such as stem cells and lymphocyte cells of the immune system. The enzyme has two major subunits. One is the catalytic enzyme named **telomerase reverse transcriptase (TERT)**, which is an RNA-dependent DNA polymerase. Almost all DNA polymerases use DNA as a template for replication. Some RNA viruses that use RNA as their genetic information like HIV encode their own **reverse transcriptase**, which directs the polymerization of a DNA copy of the viral RNA genome as part of its life cycle.)The virus that causes the Covid-19 pandemic is called severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). It is also an RNA virus but in contrast to HIV it uses and encodes an RNA-dependent RNA polymerase.)

The second subunit of telomerase is the **telomerase RNA (TR)**, which contains a template from which the new telomer is made. The enzyme makes many DNA copies from this to create a multitude of DNA repeat in the telomeres. Figure 8.4.14 shows the structure of the telomerase RNA used to build new telomers. Ovals show proteins that form part of the complex. 'For this discussion, the most important is TERT, telomerase reverse transcriptase, the RNA-dependent DNA polymerase which synthesizes new telomeric DNA from the template sequence of the RNA.

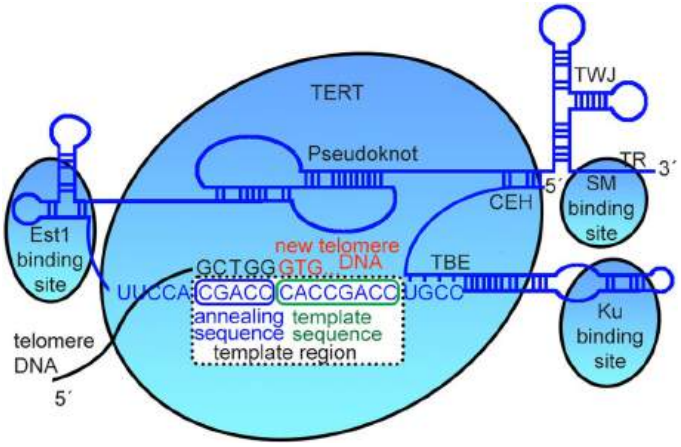


Figure 8.4.14: Telomerase RNA organization for the yeast Lachancea sp. The most relevant binding sites for protein-RNA interactions are indicated by blue ellipses (Est1, SM, and KU), and the bigger one is the contact region with the telomerase reverse transcriptase (TERT). TBE template boundary element, TWJ three-way junction, CEH core enclosed helix. Adapted from Waldl et al.36 Te template region is located between the EST1 binding site and Ku binding hairpins. Peska, V *et al. Sci Rep* **11,** 12784 (2021).Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

Trace the black single-stranded telomeric DNA strand from the 5' end (bottom left) to its 3' end containing the terminal sequence **5'GCTGG3'**. Now start tracing the telomerase RNA starting with its 5' end, which is between the CEH and SM binding site in Figure 8.4.14. It bends sharply near TBE, and continues to the right through the Ku binding site, where it forms stem-loops. It then continues into the template region containing a template sequence (3'CACCGACC5'), from which new telomeric DNA is made (5'GTGGCTGG3' - a slightly different repeat than the human repeat), and an annealing sequence (3'CGACC5'), which is complementary to the 3' end of the existing telomeric DNA (5'GCTGG3'). The RNA continues in the 3' direction through the Est1 bind site region, through the pseudoknot, and ends at the 3' end past the SM binding site.

Telomeres can also be extended through the Alternative Lengthening of Telomeres (ALT) pathway. In this case, rather than being extended, telomeres are switched between chromosomes by homologous recombination. As a result of the telomere swap, one set of daughter cells will have shorter telomeres, and the other set will have longer telomeres

A downside to telomere extension is the potential for uncontrolled cell division and cancer. Abnormally high telomerase activity has been found in the majority of cancer cells, and non-telomerase tumors often exhibit ALT pathway activation. As well as the potential for losing genetic information, cells with short telomeres are at a higher risk for improper chromosome recombination, which can lead to genetic instability and aneuploidy (an abnormal number of chromosomes).

8.4.6: Chromatin Structure

During interphase, distinct chromosomes as shown in Figure 8.4.4 are not observed. Rather each chromosome occupies a spatially limited, roughly elliptical domain which is known as a **chromosome territory (CT)**. Each chromosome territory is comprised of higher-order chromatin units of ~1 Mb each. These units are likely built up from smaller loop domains that contain the solenoid/zigzag structural motifs. On the other hand, 1Mb domains can themselves serve as smaller units in higher-order chromatin structures. With the development of high-throughput biochemical techniques, such as 3C (chromosome conformation capture) and 4C (chromosome conformation capture-on-chip and circular chromosome conformation capture), numerous spatial interactions between neighboring chromatin territories have been described as shown in Figure 8.4.15.

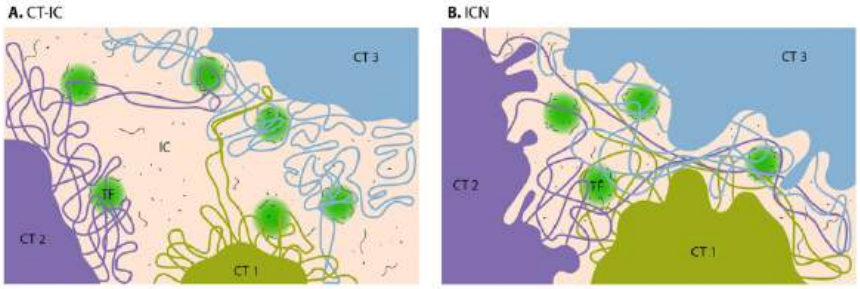

Figure 8.4.15: Computer Models of Chromosome Territory (CT) Structure. In the CT-IC model, the space between discrete CTs can be visualized in light and electron microscope and is called an interchromatin compartment (IC). Transcription factories (TF, green color) are localized predominantly in the perichromatin region. In the ICN model, the interchromatin compartment is not apparent. Instead, the space between CTs is occupied by intermingling decondensed chromatin loops, which often share the same transcription factories. *Image by MBInfo*

Chromosome territories are known to be arranged radially around the nucleus. This arrangement is both cell and tissue-type specific and is also evolutionarily conserved. The radial organization of chromosome territories was shown to correlate with their gene density and size. In this case, the gene-rich chromosomes occupy interior positions, whereas larger, gene-poor chromosomes, tend to be located around the periphery. Chromosome territories are also dynamic structures, with genes able to relocate from the periphery towards the interior once they have been 'switched on'. In other cases, genes may move in the opposite direction or simply maintain their position.

Figure 8.4.16 shows nano- to more micro-folding structures of chromosomes in the nucleus. The top left shows the most zoomed-in view where DNA is wound around histone complexes (nucleosomes), which condense to form 10 nm fibers. These condense further into **Topologically Associated Domains (TAD)** which further separate into **Compartments A and B**. These then pack into discrete **territories**. Individual chromosomes occupy their own chromosome territories in the nucleus.

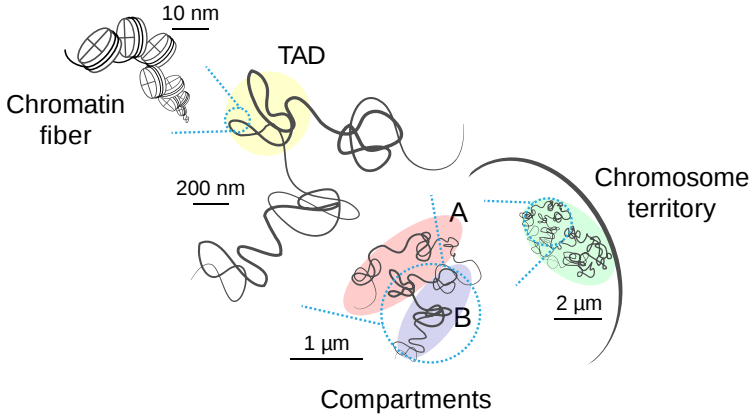

Figure 8.4.16: Schematic view of chromosome folding inside the nucleus Szabo Q et al. Sci Adv. 2019 Apr 10;5(4):eaaw1668. doi: 10.1126/sciadv.aaw1668. PMID: 30989119; PMCID: PMC6457944.Creative Commons Attribution NonCommercial License 4.0 (CC BY-NC)

This may seem very complex and it is, but it is somewhat analogous to protein folding, which starts with a linear primary sequence and moves into more complicated secondary structures, secondary structure motifs, domains, tertiary structures, and quaternary structures, which display varying degrees of symmetry.

Because these different types of folding and compaction of chromosomes are difficult to visualize, we will present several different representations of these nano- to microstructures to help your understanding. Figure 8.4.17 offers one that shows scaling factors and differential structures of chromosomes and chromatin.

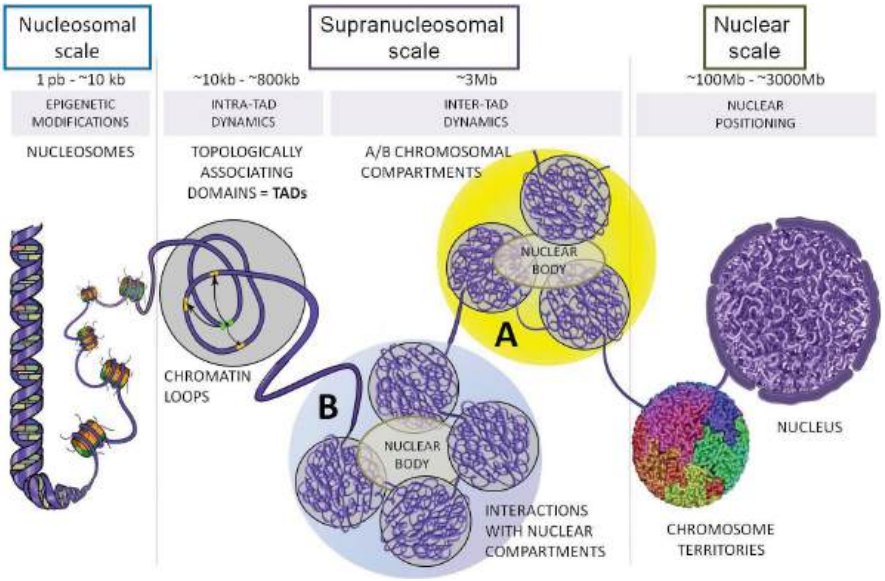

Figure 8.4.17: Schematic representation of genome organization in mammals. a, V.; Baudement, M.-O.; Lesne, A.; Forné, T. Contribution of Topological Domains and Loop Formation to 3D Chromatin Organization. *Genes* **2015**, *6*, 734-750. https://doi.org/10.3390/genes6030734. Creative Commons Attribution license (**http://creativecommons.org/licenses/by/4.0/**).

The large-scale A compartment is gene-rich and actively transcribed so it best represents euchromatin. In contrast, B compartments are gene-poor and best represent heterochromatin. At the subscale level, boundaries between TADs are transcriptionally rich and can be separated from other TADS by heterochromatin "islands".

Another representation of chromatin organization that emphasizes TADs is shown in Figure 8.4.18

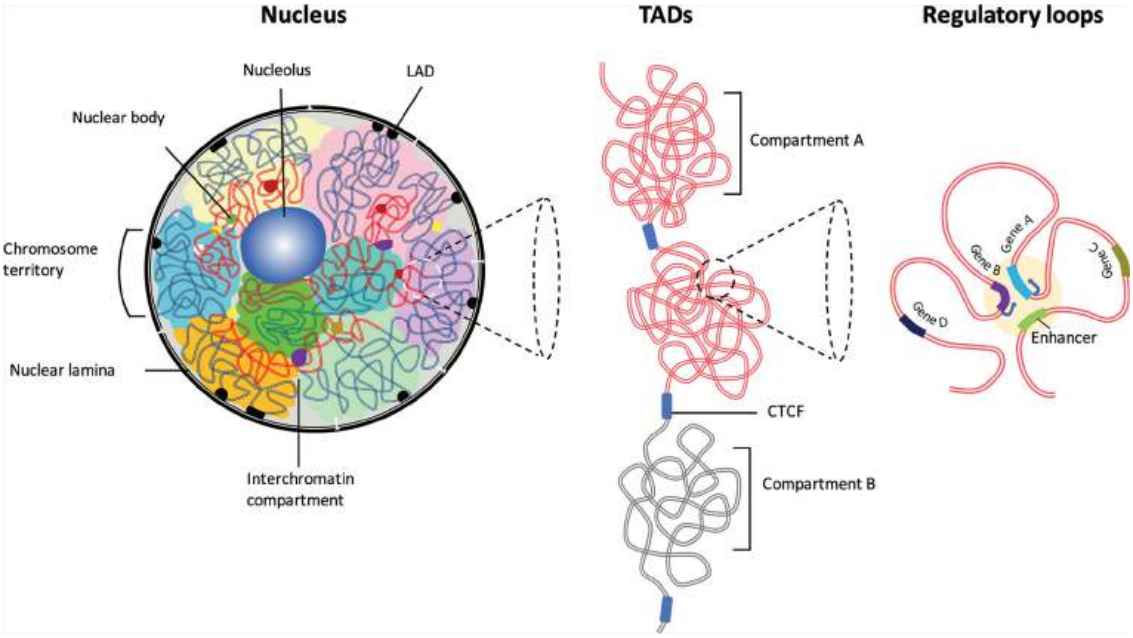

Figure 8.4.18: The hierarchical organization of the 3D chromatin inside the interphase nucleus. Chromatin interactions occur predominantly between compartments with similar biochemical or functional properties. The majority of the chromatin interactions are intra-chromosomal. Preferential self-interactions within the heterochromatin and euchromatin (A and B compartments) regions result in the formation of topologically associating domains (TADs), demarcated by boundary elements enriched with CTCF/Cohesin proteins. Jagan M. R. Pongubala and Cornelis Murre. Front. Immunol., 29 March 2021 | https://doi.org/10.3389/fimmu.2021.633825. Creative Commons Attribution License (CC BY).

The TAD boundaries in Figure 8.4.18 show a blue CTCF in-between compartments, with each TAD consisting of many interacting loops. A more detailed view is shown in Figure 8.4.19.

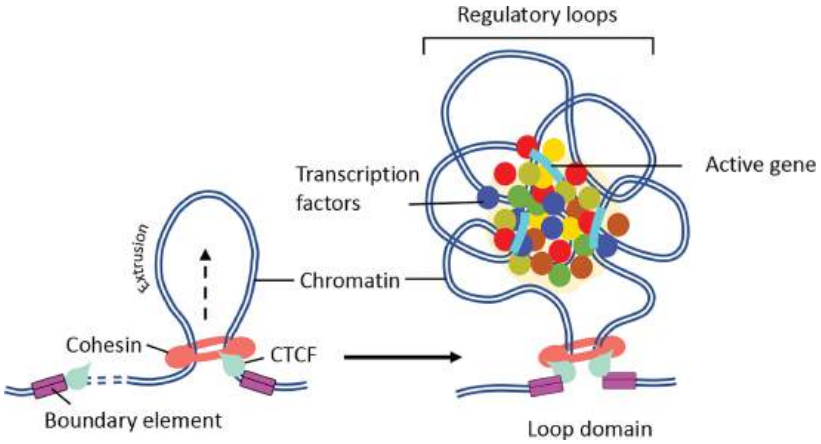

Figure 8.4.19: Jagan M. R. Pongubala and Cornelis Murre. Front. Immunol., 29 March 2021 | https://doi.org/10.3389/fimmu.2021.633825. Creative Commons Attribution License (CC BY).

A protein complex containing cohesin (which forms a ring) and CTCF is found at sites where loops of relationally transcribable DNA are extruded through the ring. The extruded loops interact with others to form a cluster of regulatory loops containing genes with similar potential for transcription (activated if they end up in Compartment A or repressed if in Compartment B). Cohesin is a functional complex that forms a ring that traps sister chromatids. During anaphase, the complex is cleaved and the sister chromatids separate. CTCF is a chromatin-binding factor with many associated activities.

"Mechanism of chromatin loop formation. TADs contain varying numbers of chromatin loops generated through loop extrusion by CTCF/cohesin
complexes. (Right panel) In the presence of NIPBL and MAU2, the cohesin complex loaded onto the DNA. Then, cohesin extrudes chromatin until a pair of convergent CTCF binding sites is reached. (Right panel) The N-terminus of CTCF and convergent

positioning of the CTCF-DNA complex stabilizes cohesin binding and stall chromatin extrusion leading to the establishment of higher-order chromatin organization. The intervening DNA between two convergent CTCF sites leads to the formation of a loop domain, which adopts a variety of complex shapes comprised of multiple regulatory loops. The internal structure of the loop domain is likely determined by polymer chromatin-chromatin self-interactions, which may be further stabilized by phase separation. The contacts within the loop domains facilitate the targeting of enhancers to specific genes (104). The black arrow depicts the direction of loop extrusion."

Special elements in the DNA called **enhancers** and **silencers** of gene transcription have long been known to influence gene transcription. These are sequences that are cis (i.e. on the same molecule of DNA, not trans factors like separate proteins that bind to promoters, for example) and can be quite distant from the proximal promoter sequence which controls the transcription of a target gene. How might they work from such a large distance from the promoter? One obvious answer is the DNA folds in 3D space so the enhancers and silencers are close to each in 3D space. Chromatin loop formation facilitates such promoter and enhancer/silencer interactions. Evidence suggests that specific enhancers and silencers are housed in loops in specific TADs so their effects are limited to a subset of genes. Enhancers and promoters seem to interact only within TADs, which suggests that TADS are a fundamental folding "domain" based on gene regulation. If boundaries between different TADS were removed, then promoters and enhancers in one TAD might affect transcription in other TADS, leading to aberrant gene expression. Chromatin loop formation facilitates interactions between promoter and enhancer/silencer elements. Figure 8.4.20 shows how enhancers and silencers can be brought close in space to promoters and their genes through TAD formation.

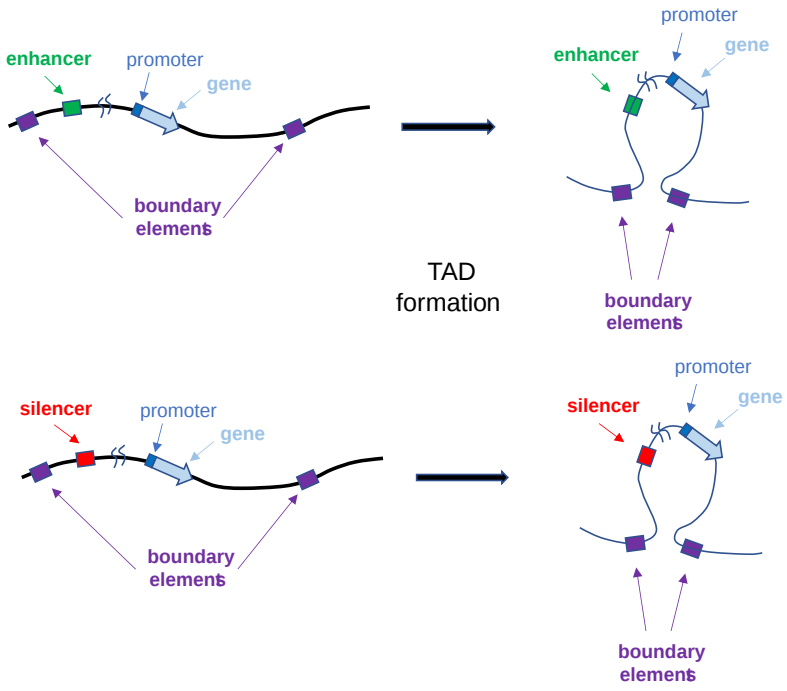

Figure 8.4.20: TADs bring enhancers and silencers close to promoters and their genes

TADs appear highly conserved in mammals and comprise most (90%) of the genome. The median size is about 880 Kb. The Boundaries between TADs have CCCTC-binding factor (CTCF) and the structural maintenance of chromosomes (SMC) cohesin complex. In Drosophila, TADs are organized by epigenetic state (methylation, condensation). For example, some TADS are transcriptionally active with epigenetic histone modifications (for example trimethylation of histone H3 lysines 4 and 36 or H3Kme3 and H3K36me3) that activate transcription). Others are transcriptionally repressed (enriched in H3K27me3 and containing Polycomb group (PcG) proteins) and some are more classically representative of heterochromatin.

8.4.7: Mechanisms of Separation of Euchromatin and Heterochromatin

From a chemistry focus, what are the interactions which stabilize TADs, compartments, and ultimately heterochromatin and euchromatin? It appears that the easiest way to conceptualize their separation in the nucleus is to use the idea of phase separations. Figure 8.4.21 shows a cartoon representation of the separation of heterochromatin and euchromatin in the zebrafish embryo. The

euchromatin is shown as more centrally located and dispersed with red dots indicating transcriptionally active sites. In the late blastula stage, gene expression is dramatically increased and the nucleolus and heterochromatin are not seen.

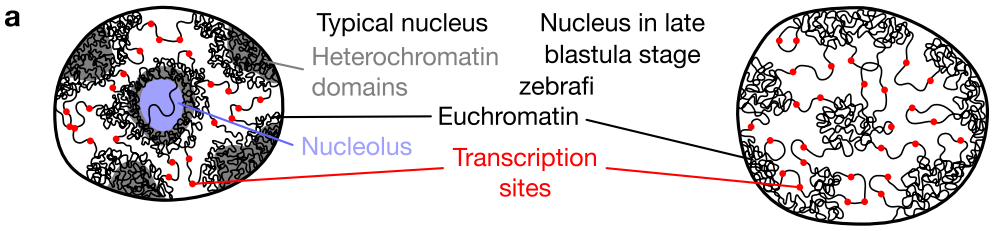

Figure 8.4.21: Sketch of nuclear compartmentalization in a typical nucleus and the nucleus of a late blastula (sphere) stage zebrafish embryo. Hilbert, L., Sato, Y., Kuznetsova, K. *et al.* Transcription organizes euchromatin via microphase separation. *Nat Commun* **12,** 1360 (2021). https://doi.org/10.1038/s41467-021-21589-3. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

Analyses show that transcription forms regions enriched in RNA, RNA binding proteins, and accordingly transcriptionally active chromatin that are separated from transcriptionally inactive, heterochromatin. Given the dispersion of the DNA required for transcription, the regions enriched in RNA are also depleted in "stainable" DNA. Micrographs showing the depletion of DNA in the actively transcribed regions are shown in Figure 8.4.22 Note the clear lack of DNA in the white rectangles, which contain high levels of RNA and RNA polymerase II (as a proxy for protein).

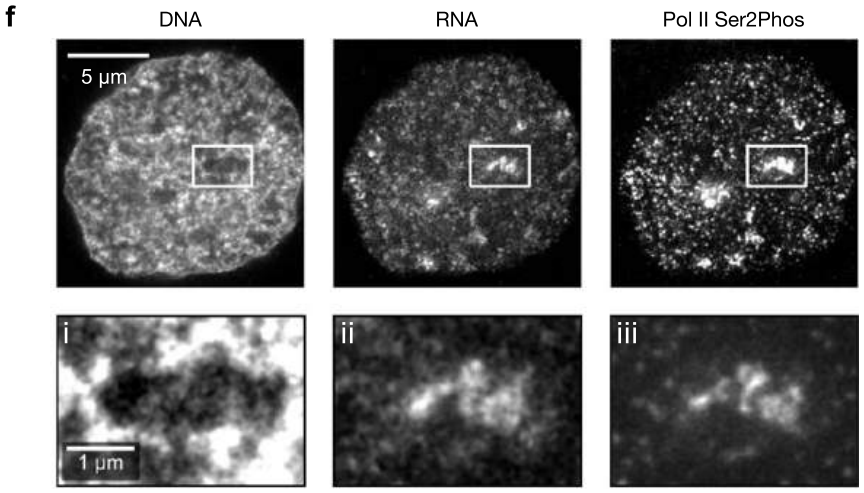

Figure 8.4.22: (F) Representative three-color micrographs showing DNA, RNA, and transcriptional activity (Pol II Ser2Phos) in a nuclear mid-section after transcription onset

It appears that the presence of a high concentration of RNA drives "phase" separation of heterochromatin and euchromatin. Hence euchromatin might act as an "oil in water" type microemulsion, with the euchromatin core stabilized by "tethered" RNA acting as an amphiphile. Ribonucleoproteins (RNPs) can be modeled as phase-separated droplets or condensates Figure 8.4.23 shows how increasing RNA leads to the formation of euchromatin "domains" which stay dispersed in the presence of continuing RNA formation.

Figure 8.4.23: (a) Cartoon representation of conventional phase separation and a microemulsion. The right panel focuses on the amphiphile in the microemulsion. Hilbert, L., Sato, Y., Kuznetsova, K. *et al.* Transcription organizes euchromatin via microphase separation. *Nat Commun* **12,** 1360 (2021). https://doi.org/10.1038/s41467-021-21589-3. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

A final summary cartoon that describes the formation and separation of chromosomal DNA into euchromatin and heterochromatin in Zebra fish is shown in Figure 8.4.24

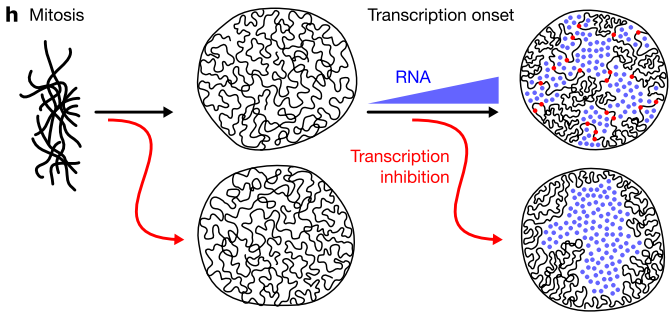

Figure 8.4.24: (h) Sketch summarizing the experimental observations to this point. 8.6: Enzymes for Genetic modifications

It is difficult to read newspapers and newsmagazines without encountering the CRISPR-Cas9 gene editing system that has the potential to make gene editing routine in disease diagnosis, treatment, and cure, as well as in genetic modification of organisms to improve their quality and quantity for food and natural product production. In this chapter section, we will explore the mechanism of restriction enzymes that made gene cloning possible as well as the CRISPR-Cas gene editing system.

8.6.1: Restriction Endonucleases

A ***restriction enzyme***, ***restriction endonuclease***, or ***restrictase*** is an enzyme that cleaves DNA into fragments at or near specific recognition sites within molecules known as restriction sites. Restriction enzymes are one class of the broader endonuclease group of enzymes. Restriction enzymes are commonly classified into five types, which differ in their structure and whether they cut their DNA substrate at their recognition site, or if the recognition and cleavage sites are separate from one another. To cut DNA, all restriction enzymes make two incisions, once through each sugar-phosphate backbone (i.e. each strand) of the DNA double helix. Here we will focus on the Type II restriction enzymes that are routinely used in molecular biology and biotechnology applications.

As with other classes of restriction enzymes, Type II Restriction Enzymes occur exclusively in unicellular microbial life forms—mainly bacteria and archaea (prokaryotes)—and are thought to function primarily to protect these cells from viruses and other infectious DNA molecules. Inside a prokaryote, the restriction enzymes selectively cut up *foreign* DNA in a process called ***restriction digestion*****;** meanwhile, host DNA is protected by a modification enzyme (a methyltransferase) that modifies the prokaryotic DNA and blocks cleavage. Together, these two processes form the ***restriction-modification system***.

The first Type II Restriction Enzyme discovered was HindII from the bacterium *Haemophilus influenzae* Rd. The event was described by Hamilton Smith (Figure 7.23) in his Nobel lecture, delivered on 8 December 1978:

‘"In one such experiment we happened to use labeled DNA from phage P22, a bacterial virus I had worked with for several years before coming to Hopkins. To our surprise, we could not recover the foreign DNA from the cells. With Meselson’s recent report in our minds, we immediately suspected that it might be undergoing restriction, and our experience with viscometry told us that this would be a good assay for such an activity. The following day, two viscometers were set up, one containing P22 DNA and the other Haemophilus *DNA. Cell extract was added to each and we began quickly taking measurements. As the experiment progressed, we became increasingly excited as the viscosity of the* Haemophilus *DNA held steady while the P22 DNA viscosity fell. We were confident that we had discovered a new and highly active restriction enzyme. Furthermore, it appeared to require only* Mg^{2+} *as a cofactor, suggesting that it would prove to be a simpler enzyme than that from* E. coli *K or B.*

After several false starts and many tedious hours with our laborious, but sensitive viscometer assay, Wilcox and I succeeded in obtaining a purified preparation of the restriction enzyme. We next used sucrose gradient centrifugation to show that the purified enzyme selectively degraded duplex, but not single-stranded, P22 DNA to fragments averaging around 100 bp in length, while Haemophilus *DNA present in the same reaction mixture was untouched. No free nucleotides were released during the reaction, nor could we detect any nicks in the DNA products. Thus, the enzyme was clearly an endonuclease that produced double-strand breaks and was specific for foreign DNA. Since the final (limit) digestion products of foreign DNA remained large, it seemed to us that cleavage must be site-specific. This proved to be case and we were able to demonstrate it directly by sequencing the termini of the cleavage fragments.’"*

Figure (\PageIndex{35}\): Hamilton Smith and Daniel Nathans at the Nobel Prize press conference, 12 October 1978 (reproduced with permission from Susie Fitzhugh). Restriction enzymes are named according to the taxonomy of the organism in which they were discovered. The first letter of the enzyme refers to the genus of the organism and the second and third to the species. This is followed by letters and/or numbers identifying the isolate. Roman numerals are used to specify different enzymes from the same organism. For example, the enzyme 'HindIII' was discovered in *Haemophilus influenzae*, serotype d, and is distinct from the HindI and HindII endonucleases also present within this bacterium. The DNA-methyltransferases (MTases) that accompany restriction enzymes are named in the same way, and given the prefix 'M.'. When there is more than one MTase, they are prefixed 'M1.', 'M2.', etc, if they are separate proteins or 'M1~M2.' when they are joined.

Restriction Enzymes that recognize the same DNA sequence, regardless of where they cut, are termed ***'isoschizomers'*** (iso = equal; skhizo = split). ***Isoschizomers*** that cut the same sequence at different positions are further termed ***'neoschizomers'*** (neo = new). ***Isoschizomers*** that cut at the same position are frequently, but not always, evolutionarily drifted versions of the same enzyme (e.g. BamHI and OkrAI). ***Neoschizomers,*** on the other hand, are often evolutionarily unrelated enzymes (e.g.EcoRII and MvaI).

Type II Restriction Enzymes are a conglomeration of many different proteins that, by definition, have the common ability to cleave duplex DNA at a fixed position within, or close to, their recognition sequence. This cleavage generates reproducible DNA fragments, and predictable gel electrophoresis patterns, properties that have made these enzymes invaluable reagents for laboratory DNA manipulation and investigation. Almost all Type II Restriction Enzymes require divalent cations, usually Mg^{2+}, as essential components of their catalytic sites. Ca^{2+}, on the other hand, often acts as an inhibitor of Type II Restriction Enzymes.

The recognition sequences of Type II Restriction Enzymes are ***palindromic***, with two possible types of palindromic sequences. The ***mirror-like palindrome*** is similar to those found in ordinary text, in which a sequence reads the same forward and backward on a single strand of DNA, as in GTAATG. The ***inverted repeat palindrome*** is also a sequence that reads the same forward and backward, but the forward and backward sequences are found in complementary DNA strands (i.e., of double-stranded DNA), as in GTATAC (GTATAC being complementary to CATATG). ***Inverted repeat palindromes*** are more common and have greater biological importance than ***mirror-like palindromes.*** The position of cleavage within the palindromic sequence can vary depending on the enzyme and can produce either single-stranded overhanging sequences (sticky ends) or blunt-ended DNA products. Examples of staggers and blunt end cuts by restriction enzymes are shown in Table 8.6.8 below.

EcoR1	G|AATTC CTTAA|G
Sma1	CCC|GGG GGG|CCC

Table 8.6.8: Staggered and blunt end cut sequences by EcoR1 and Sma1

Methylation can be used by the host to protect its own genome from cleavage. For example, the methylation of the EcoRI recognition sequence by the M.EcoRI methyltransferase (MTase), changes the sequence from GAATTC to GAm6ATTC (m6A = N6-methyladenine). This modification completely protects the sequence from cleavage by EcoRI.

Type II Restriction Enzymes initially bind non-specifically with the DNA and proceed to slide down the DNA scanning for recognition sequences as shown in Figure (\PageIndex{36}\):. Upon binding to the correct palindromic sequence the enzyme associates with the metal cofactor and mediates catalytic cleavage of the DNA using the mechanism of ***strain distortion*** and ***catalysis by approximation***.

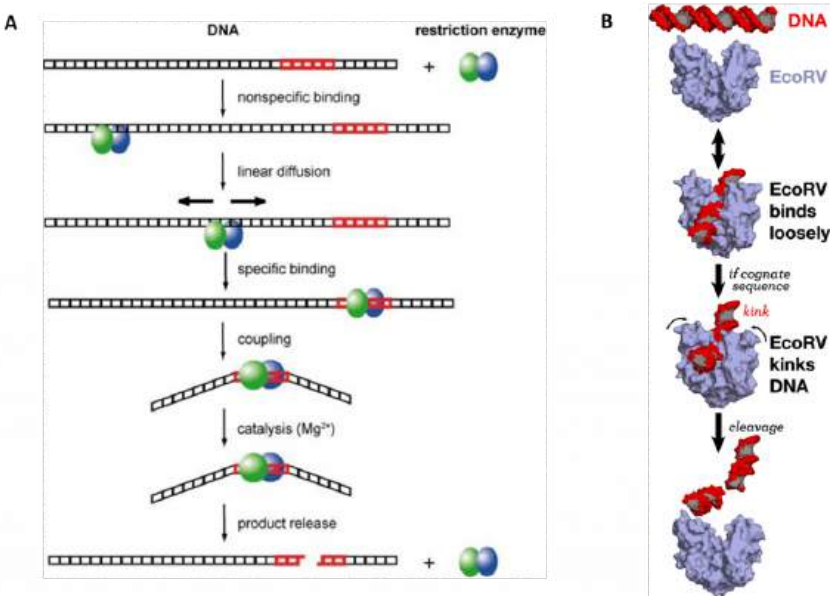

Figure (\PageIndex{36}\): DNA Recognition and Cleavage by Type II Restriction Endonucleases. (A) Pictorial view of an EcoRV dimer scanning nonspecifically along the DNA until a specific binding site is recognized. This causes coupling with the metal cofactor and strain distortion of the DNA. Hydrolysis of the phosphodiester bond is mediated and the DNA cleavage products are released from the enzyme. (B) shows a space-filling model of EcoRV DNA recognition and cleavage. Figure (A) from Pingoud, A., Wilson, G.G., and Wende, W. (2014) Nuc Acids Res 42(12):7489-7527. and Figure (B) from Thomas Splettstoesser

One of the most important questions regarding the catalytic mechanism of a hydrolase is whether hydrolysis involves a covalent intermediate, as is typical for the proteases described previously. This can be decided by analyzing the stereochemical course of the reaction. This was done first for EcoRI, and later for EcoRV. Both enzymes were found to cleave the phosphodiester bond with inversion of the chiral center at the phosphorus, which argues against the formation of a covalent enzyme–DNA intermediate. Thus, it is proposed that cleavage involves the direct nucleophilic attack of the substrate by a water molecule, as shown in Figure (\PageIndex{37}\) below.

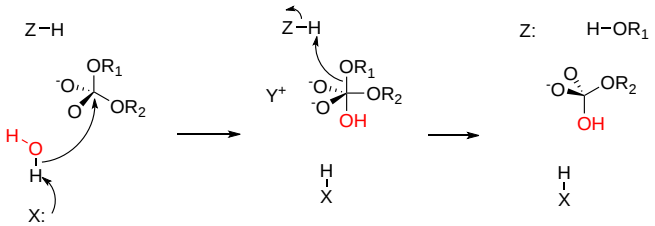

Figure (\PageIndex{37}\): A General Mechanism for DNA Cleavage by EcoRI and EcoRV. An activated water molecule attacks the phosphorous in-line with the phosphodiester bond to be cleaved, which proceeds with an inversion of configuration. X, Y, and Z are a general base, a Lewis acid, and a general acid, respectively. Figure adapted from:

Pingoud, A., Wilson, G.G., and Wende, W. (2014) Nuc Acids Res 42(12):7489-7527.

Type II restriction enzymes typically form a homodimer when binding with DNA, as shown in the crystal structure of ***Bgl*II** in Figure 7.26B. ***Bgl*II** catalyzes phosphodiester bond cleavage at the DNA backbone through a phosphoryl transfer to water. Studies on the mechanism of restriction enzymes have revealed several general features that seem to be true in almost all cases, although the actual mechanism for each enzyme is most likely some variation of this general mechanism (Figure 7.25). This mechanism requires a base to generate the hydroxide ion from water, which will act as the nucleophile and attack the phosphorus in the phosphodiester bond. Also required is a Lewis acid to stabilize the extra negative charge of the pentacoordinate transition state phosphorus, as well as a general acid or metal ion that stabilizes the leaving group (3'-O^-). In some Type II Restriction Enzymes, two divalent metal cofactors are required (such as in EcoRV and BamHI), whereas other enzymes only require one divalent metal cofactor (such as in EcoRI and BglII).

Structural studies of endonucleases have revealed a similar architecture for the active site with the residues following the weak consensus sequence Glu/Asp-$(X)_{9-20}$-Glu/Asp/Ser-X-Lys/Glu. ***Bgl*II's** active site is similar to other endonucleases', following the sequence Asp-$(X)_9$-Glu-X-Gln. In its active site, there sits a divalent metal cation, most likely Mg^{2+}, that interacts with Asp-84, Val-94, a phosphoryl oxygen, and three water molecules. One of these water molecules is able to act as a nucleophile because of its proximity to the scissile phosphoryl group (Figure 7.26A). The nucleophilic water molecule is positioned for attack onto the phosphoryl group by a hydrogen bond with the side chain amide oxygen of Gln-95 and its contact with the metal cation. Interaction with the metal cation effectively lowers its pK_a, promoting the water's nucleophilicity as shown in Panel A of Figure (\PageIndex{38}\) below (from Pingoud, A., Wilson, G.G., and Wende, W. (2014) Nuc Acids Res 42(12):7489-7527). During hydrolysis, the divalent cation can stabilize the 3'-O^- leaving group and coordinate proton abstraction from one of the coordinated water molecules

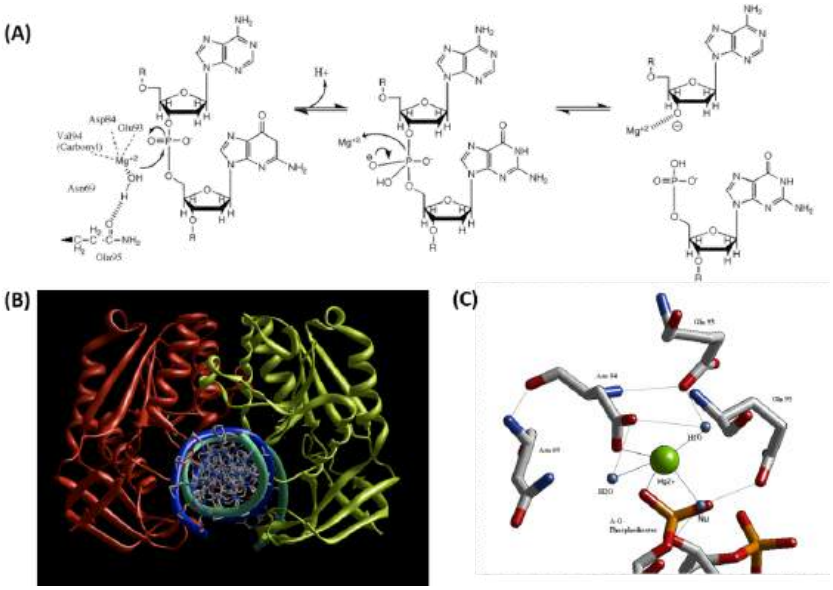

Figure (\PageIndex{38}\): Proposed Reaction Mechanism for the Type II Restriction Endonuclease, *Bgl*II. (A) Schematic diagram of the catalytic mechanism demonstrating the utility of Mg2+ ions and polar amino acid residues within the active site to activate and position a water molecule for nucleophilic attack on the phosphodiester bond of the DNA substrate. 8.6.2: CRISPR-Cas 9

The **CRISPR** (clustered regularly interspaced short palindromic repeats) operon was initially discovered as part of the adaptive immune system of bacteria and archaea, which must defend themselves against viruses (bacteriophages) and unwanted plasmids transferred from both bacteria. It would be ideal for bacteria to recognize previous exposure to viruses and their nucleic acids as the basis of their immunological memory system. Given the tendency of viral DNA to integrate into the host genome (which allows later transcription and translations of the viral genes in the process of new virus production), immunological memory could be based on that viral integrated DNA. Without going into detail, viral DNA can be integrated between two direct repeats in the bacterial genome. DNA from different viruses from previous exposures is also incorporated in the same fashion. One site of

integration is the CRISPR operon. The DNA of the CRISPR operon contains both protein-coding and noncoding regions which are transcribed and processed to form at least three RNA molecules, as shown in Figure (\PageIndex{24}\) below.

- a coding Cas 9 mRNA this is translated to produce the **Cas** 9 (**C**RISPR-**as**sociated protein);
- a noncoding cr-RNA (CRISPR RNA)
- a noncoding tracr-RNA (trans-activating CRISPR RNA)

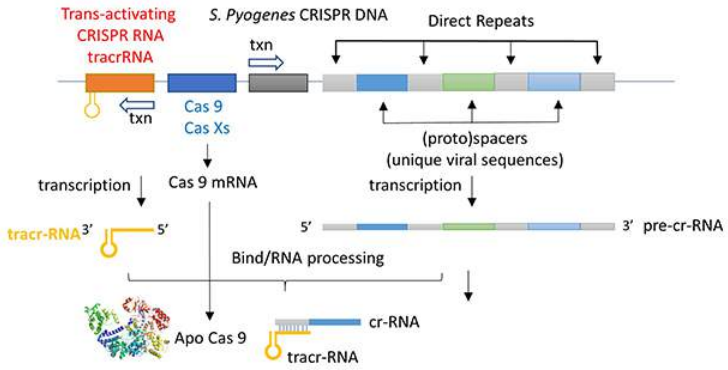

Figure (\PageIndex{24}\): DNA of the CRISPR operon

The two mature noncoding RNAs eventually associate to form a binary complex. When using CRISPR-Cas 9 in eukaryotic gene editing applications, the two noncoding RNAs are covalently combined into one large **s**ynthetic **g**uide RNA (**sg-RNA**), described later in this section. The Cas 9 protein is an endonuclease that cleaves both strands of bound target dsDNA in a blunt-end fashion at specific sequences. This occurs after the DNA binds to two arginines (1333 and 1335) in Cas9 through a short (3-5+ bases) recognition **protospacer adjacent motif** (**PAM**) located three base pairs from the cleavage site. The DNA must also bind in a complementary and specific fashion to the **protein-bound** noncoding cr+tracr-RNAs (or a single sg-RNA molecule for gene editing applications). Binding and cleavage of target DNA would render DNA from an invading bacteriophage inactive.

Basic research into the bacterial CRISPR system has led to revolutionary and explosive applications of this gene editing system in eukaryotes. The hope is that CRISPR technology will give us a precise and incredibly cheap way to do gene therapy in diseased cells and organisms. Given its role in transforming our ability to edit the genome and potentially cure genetically-based diseases, we will offer a detailed explanation of its mechanism.

We have discussed the structure and function of many proteins. Protein enzymes are key to life as they catalyze almost all biological reactions. Most key enzymes are regulated. The activity of Cas 9 must be carefully controlled. Think of the consequences if the enzyme were to cleave promiscuously at off-site targets! This section will help you understand several critical features of this enzyme:

1. How does the enzyme find its correct target site, a 20 nucleotide DNA sequence, and a proximal PAM site, among all the possible alternative sites? Think of how many PAM sequences there must be in the host DNA genome!
2. How can the enzyme be "turned" on when it finds its target site and remain off when free, but more importantly when it is bound off-site?

First, we will discuss the apo- form of the enzyme without bound substrate and RNA.

Apo- and Holo-Cas 9

This section will focus on the Type II-A Cas9 from *Streptococcus pyogenes* (SpyCas9 or SpCas9). Cas 9 is an endonuclease that cleaves both strands of DNA 3 base pairs from a DNA motif, NCC/NGG, called PAM. It has two distinct lobes. The nuclease lobe (NUC), amino acids 1-56 and 718-1368, has two different nuclease domains for the two cleavages. The recognition or receptor lobe (REC), amino acids 94-717, interacts with the RNA molecules. There is also an arginine-rich bridge helix (57-93).

The enzyme has two catalytic nuclease domains:

- HNH-like nuclease domain cleaves the "target" DNA strand, which is complementary to the RNA the confers specificity to the enzyme. The key catalytic residues are His 840 and Asn 854. It also contains a Mg ion;
- Ruv-like domain that cleaves the complementary "non-target" strand with key active site residues Asp 10, Glu 762, Asp 986, and His 983. It also contains a bound Mn ion. The two lobes are separated by two linkers, amino acids 712-717, and an arginine-rich bridge (basic helix - BH), amino acids 628-658.

The overall structure of the apoenyzme (without bound RNA and DNA,pdb id 4cmp) is shown in Figure (\PageIndex{25}\) below, which shows the NUC domain (light blue) with the two catalytic domains (HNH and Ruv), the REC domain (orange) and the BH helix (red).

Figure (\PageIndex{25}\): Apoenyzme Cas9 (without bound RNA and DNA (4cmp)

A close up view showing the two catalytic sites is shown in Figure (\PageIndex{26}\) below.

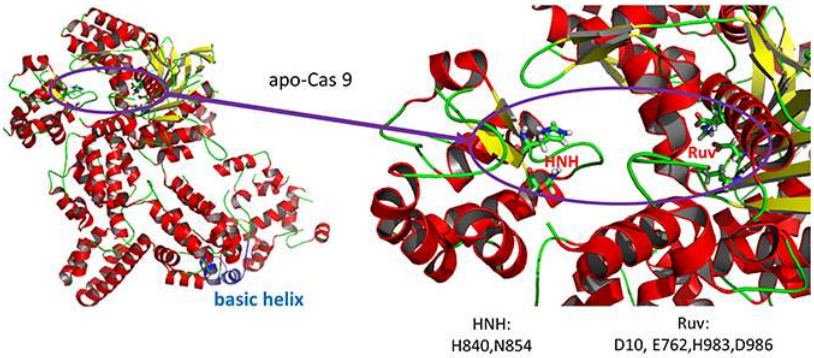

Figure (\PageIndex{26}\): Two catalytic sites in Cas9

Figure 8.6.27 shows an interactive iCn3D model of Streptococcus pyogenes Cas9 in complex with guide RNA and target DNA (4OO8) (long load time). The Cas9 enzyme is shown as a gray transparent surface with an underlying cartoon rendering. The DNA is shown as colored sticks. The RNA is shown as a cyan cartoon.

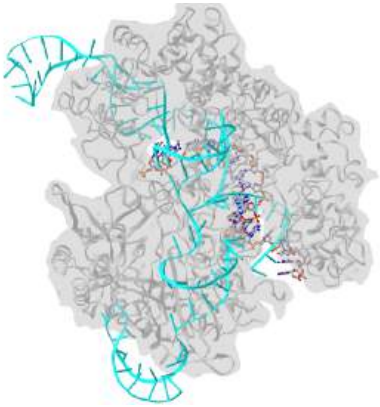

Figure 8.6.27: **Streptococcus pyogenes Cas9 in complex with guide RNA and target DNA (4OO8)**. (Copyright; author via source).

Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...RjzJBFVt5qRjS7 (long load time)

A comparison of the crystal structure of the apo-Cas 9 and the ternary Cas 9: sgRNA:DNA target strand complex shows a significant conformational change on binding nucleic acids. The structure of the holoenzyme (ternary complex) is shown in Figure (\PageIndex{28}\) below.

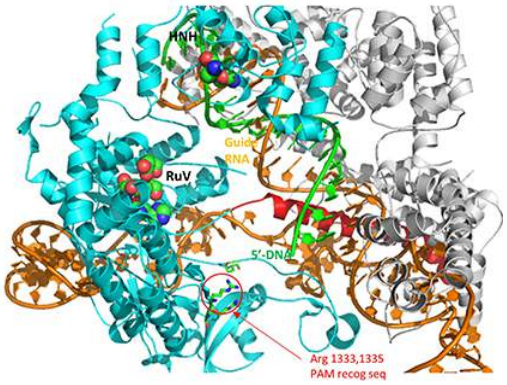

Figure (\PageIndex{28}\): Structure of the holoenzyme Cas9 (ternary complex)with bound guide RNA and DNA

The extent of the conformation change between apo- and holo-Cas 9 enzymes can be seen by examining the distance between D435 and E 944/945 in Figure (\PageIndex{29}\) below. The importance of this change will be described later.

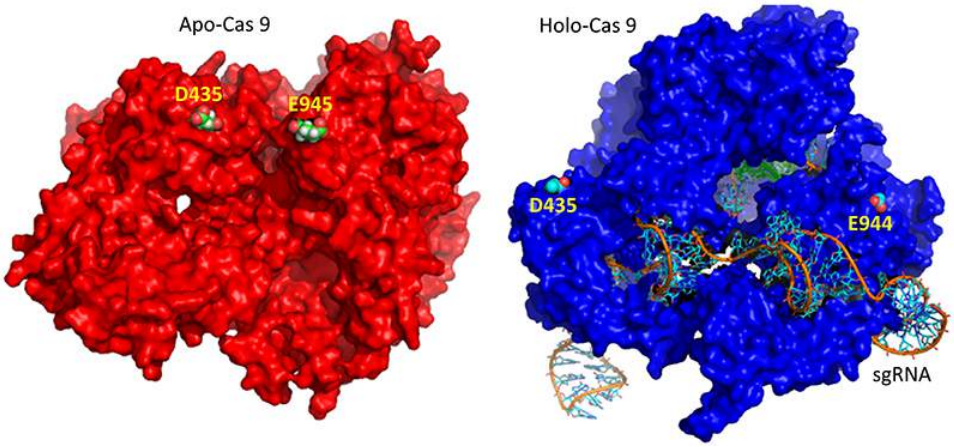

Figure (\PageIndex{29}\): Distance between D435 and E 944/945 going from the apo-Cas9 (left) to the holo-Cas 9 (right) enzyme

Figure (\PageIndex{30}\) below shows the pathway from the transcription of the relevant CRISPR genes (coding and noncoding) to the assembly of the ternary complex and the blunt end cut of the target DNA strand three nucleotides from the PAM sequence.

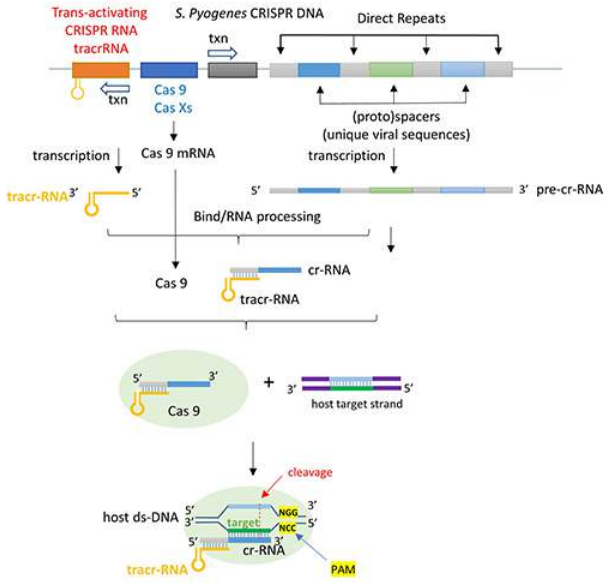

Figure (\PageIndex{30}\): Pathway from the transcription of the relevant CRISPR genes (coding and noncoding) to the assembly of the ternary complex and the blunt end cut of the target DNA strand three nucleotides from the PAM sequence

Figure (\PageIndex{31}\) below shows an expanded view of the ternary complex.

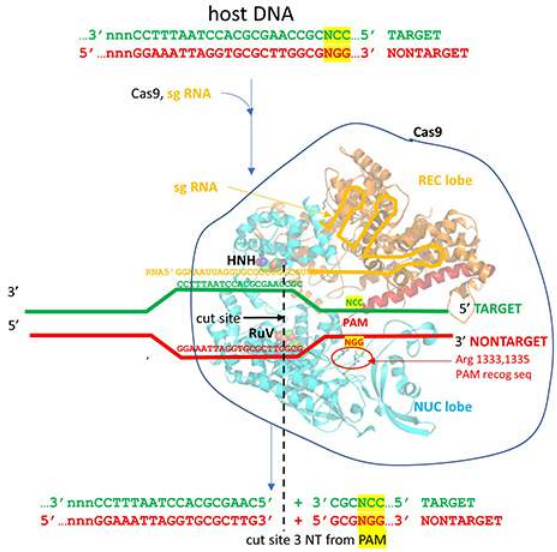

Figure (\PageIndex{31}\): Expanded view of the ternary complex of Cas9 with guide RNA and DNA

Mechanism of DNA binding and cleavage

The above figures do not speak to the mechanism of the binding processes that form the ternary complex. Kinetic and structural studies have been conducted to elucidate the mechanism of binding and cleavage and address the following questions:

- which binds first, the RNA or DNA?
- What are the consequences of the profound conformational changes on the formation of the ternary complex?

The **specificity** of target DNA binding depends both on enzyme:PAM DNA and enzyme:sgRNA (or tracr- and crRNA) interactions. It should seem improbable that the trinucleotide PAM DNA sequence (NGG in *S. pyogenes*), which interacts with a pair of arginines (R 1333, R 1335) through H-bonding, as shown in the images above, and other local sites in Cas 9 would provide the sole or even the majority of the binding interactions. Figure (\PageIndex{32}\) below shows the Args:PAM interaction (pdb code 4un3)

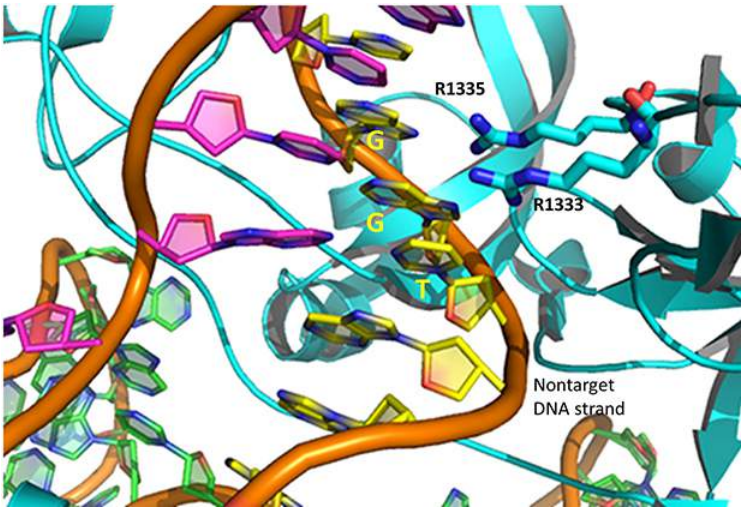

Figure (\PageIndex{32}\): Args:PAM interaction in holo-Cas9 (4un3)

Hence it is most likely that RNA binds first. Indeed, it does with the tracRNA implicated in the recruitment of Cas and the crRNA providing specificity for target DNA binding. The resulting Cas9:RNA binary complex could then search the relevant DNA genome. That would include the DNA of the bacteriophage in viral infection or eukaryotic DNA if the CRISPR DNA operon with the genes for Cas 9 and a sg-RNA was transfected into the eukaryotic cell. After RNA binding, the enzyme would change conformation and allow loose DNA binding through Cas 9: PAM interactions.

Studies have shown that the apo form can also bind DNA, but it does so loosely and indiscriminately. It dissociates quickly and binding is affected by generic polyanions such as the glycosaminoglycan heparin, which indicates its nonspecific nature. Once bound, both off-target and target DNAs would then be surveyed. If a target DNA contained a PAM sequence, the complex would undergo another conformational change to position the HNH and Ruv nuclease catalytic residues and locally unwind the duplex DNA to make the blunt-end cuts.

Cas 9 binding to the PAM site would promote better interaction of the unwound DNA and the bound RNA. If no PAM was present, no catalytically-effective Cas 9:target DNA would form. This prevents off-site cleavage. These allosteric changes and controls are vital to the function of the endonuclease. Here are some findings that support this proposed mechanism:

- the conformation of apo Cas 9 is catalytically inactive;
- on binding RNA to form a binary complex, Cas 9 undergoes a dramatic conformational change, mostly in the REC lobe. However, on binding DNA in a nonspecific fashion, the conformational changes are much smaller. This suggests that most changes in conformation occur before DNA binding. In a way, RNA acts as an allosteric activator of the enzyme (as well as the major source of binding specificity to target DNA). Conformational changes can be determined directly by comparison of crystal structures or spectral techniques such as fluorescence resonance energy transfer (FRET) between two different attached fluorophores.
- Cas 9: RNA interactions lead to ordering of the region of the RNA that interacts with the DNA PAM sequence and adjacent deoxynucleotides (a "seed sequence"), allowing the Cas 9:RNA complex to scan and interact with potential DNA targets with PAM sequences;
- Once a PAM site is found, conformational changes lead to unwinding of the dsDNA, which allows heteroduplex formation between the crRNA and the target DNA strand;
- since Cas 9 recognizes a variety of DNA target sequences (but of course only a specific PAM sequence), the binding of the target sequence depends on the geometry, not the sequence, of the target DNA;
- since binding of off-target DNA to the Cas 9:RNA complex occurs but with very infrequent cleavage, binding and cleavage are very distinct steps;
- on specific DNA binding, the HNH catalytic site moves near to the sessile DNA bond site. Crystal structures show that the active site His is not sufficiently close to facilitate cleavage, suggesting that binding of a second metal ion (see below) may be necessary. Molecular dynamics studies show that the HNH domain is "remarkably plastic".

Figure (\PageIndex{33}\) below show an animation that illustrates the relative conformational changes going from the apo Cas 9 to the binary Cas 9:sgRNA complex to the ternary Cas 9: sgRNA: target DNA complex. The NUC catalytic domain is shown in light blue, the REC (receptor or RNA binding domain) in orange, sgRNA in red, and the target DNA in green. Note again that on

binding RNA to form a binary complex, Cas 9 undergoes a dramatic conformational change, mostly in the REC lobe. The pdb protein sequences shown were aligned using pdbEfold.

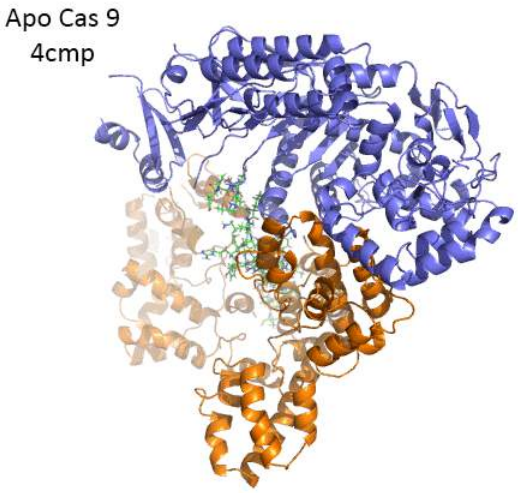

Figure (\PageIndex{33}\): Animation illustrating conformational changes going from the apo Cas 9 to the binary Cas 9:sgRNA complex to the ternary Cas 9: sgRNA: target DNA complex

A potential abbreviated catalytic mechanism for the Ruv nuclease domain is shown in Figure (\PageIndex{34}\) below. The red arrows indicate the second set of electron movements. His 983 acts as a general base to abstract a proton from the water making it a more potent nucleophile. An intermediate trigonal bipyramidal phospho-intermediate is formed, which, along with the preceding transition state, is stabilized by the proximal Mg^{2+} ion (an example of electrostatic or metal ion catalysis). The magnesium is positioned through its interaction with negatively charged carboxyl groups of Asp 10, Glu 762, and Asp 986.

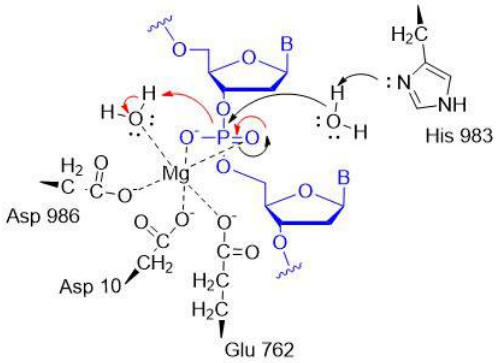

Figure (\PageIndex{33}\): Abbreviated catalytic mechanism for the Ruv nuclease domain of Cas9

A second metal ion might be recruited to the Ruv site to further facilitate the cleavage of the DNA. The HNH catalytic site has a structure (beta-beta-alpha) and conserved His in common with a class of nucleases that require one metal ion. In contrast, the Ruv catalytic site does not have this common secondary structural motif and has a critical histidine, both common features found in endonucleases that use two metal ions.

CRISPR and Eukaryotic Gene Editing

How could blunt-end cutting of both strands of DNA by Cas 9 lead to the holy grail of specific eukaryotic gene editing with no off-site effects? Cutting the DNA genome seems like a bad idea. It is potentially so bad that a myriad of DNA repair mechanisms has evolved to fix the cut. These include homologous recombination. If corrective DNA is supplied as well as the components of the CRISPR system, a cell could effectively add the corrective DNA after the double-stranded cut and repair a deleterious mutation. Consult a molecular biology textbook for more insight into homologous recombination.

Mutations in the PAM sequence prevent Cas9 nuclease activity. Hence the NGG PAM sequence is vital for the interactions and activities described above. This would seem to limit the utility of CRISPR-Cas 9 in eukaryotic gene editing until one realizes that

the GG dinucleotide has a 5.2% frequency of occurrence in the human genome, which corresponds to over 160 million occurrences. Even then it might not occur in a desired gene target. Cas 9 nuclease from other bacteria extends the range of activity of the CRISPR/Cas system as they interact with other PAM sequences (NNAGAA and NGGNG for *S. thermophilus* and NGGNG for *N. meningidtis*). Likewise, mutations in the *S. pyogenes* PAM (NGG) have been made as well. A D1135E mutation retains but increases the specificity for the normal NGG PAM site. D1135V, R1335Q, and T1337R mutations alter the optimal PAM recognition site to NGAN or NGNG.

CRISPR editing can be easily used to knock out specific genes. In addition, if cells are transfected with a plasmid with many target sequences, the system can be used to edit multiple genes in one experiment. This would be very useful in studies of diseases linked to multiple genes. Since the cost of CRISPR reagents (plasmids, RNAs) is so inexpensive, and the specificity of editing is so high, the great excitement about CRISPR use for gene editing in human disease and for modification of plant and fungal genomes is warranted.

Other systems have been developed to specifically bind to a target DNA sequence and then cleave it. They typically contain a protein that binds to a specific DNA target and an associated endonuclease that cleaves within the target DNA site. Typical prokaryotic restriction enzymes bind to and cut at a specific nucleotide sequence (for example Eco R1 cleaves at G/AATTC palindromic sequences) to form sticky ends. The protein itself binds to this DNA recognition site. Other examples are based on the structure of known transcription factors. Libraries of genetically engineered proteins with Zn finger DNA binding domains (designed for specific DNA target sequences) fused to endonucleases have been created for this purpose. Other examples are proteins called TALENs (transcription activator-like effector nucleases). These are fusion proteins containing a TAL effector DNA-binding domain and a nuclease. In each of these cases, a 3D-folded protein is the specific target DNA recognition molecule. Think how much easier it is to make in effect a 1D-DNA recognition element, a simple linear RNA sequence, which would adopt the correct 3D structure on the binding of its complementary target.

One major problem in the use of CRISPR for gene editing must be solved: how to get the CRISPR components in the correct cells in an organism. In effect, it's the same problem faced by small drug designers only the components are much larger. *Ex vivo* applications, when diseased cells are removed from the body, repaired by CRISPR, and then reinjected, are likely to have more success. In these cases, electroporation would allow the uptake of Cas 9 and the sg-RNA. I*n vivo* therapy has included the use of adeno-associated viruses in which genes for Cas 9 and sg RNA could be encapsulated. This technique, used for other gene delivery systems, has the advantage of being tolerated immunologically. However, this system allows for continual gene expression which is undesirable for gene editing. After an initial "fix" of a mutant gene, continued expression of the CRISPR-Cas 9 genes would increase the chances for off-target cutting. A more recent approach is to deliver the mRNA in artificial lipid nanoparticles that can be taken into cells. Once free and translated into protein and sg RNA inside the cell, gene editing has a chance to occur before the RNA and protein are degraded.

CHAPTER OVERVIEW

9: Investigating DNA

9.1: DNA Isolation, Sequencing, and Synthesis
9.2: Bioinformatics
9.3: Cloning and Recombinant Expression
9.4: DNA Microarrays
9.5: In Situ Hybridization
9.6: References

9.1: DNA Isolation, Sequencing, and Synthesis

9.1.1: Genomic and complementary DNA

The ability to sequence the DNA of an organism has revolutionized our understanding of biology and evolution. DNA can be isolated directly from living, dead, and even extinct species and the "primary" sequence of A, G, C, and T bases in the molecule determine. We can read (sequence), write (synthesize), and edit (mutate) DNA at will. Before we explore how to purify, sequence (read) and synthesize (write) DNA, it's important to differentiate two different types of DNAs, genomic and **complementary DNA** (cDNA), which is made by reverse transcribing messenger RNA into DNA. Since mRNA has no nucleotides encoded by introns, c-DNA provides just the coding sequences for protein.

Genomic deoxyribonucleic acid (gDNA) is chromosomal DNA, which does not include the extra-chromosomal DNA found in the mitochondria of eukaryotes or plasmids in bacteria (plasmids will be discussed in more detail in section 5.3 during the discussion of gene cloning and expression). Most organisms have the same genomic DNA in every cell (one exception is the genomic DNA for antibodies in B cells and T cells receptors in T-cells that have been altered as the cells become more terminally differentiated. It is also important to remember that only certain genes are active (expressed) in each cell. The subset of expressed genes is specific to a given differentiated cell and allows for the expression of specific cell functions. Liver cells, for example, don't express the gene for the protein opsin, which is expressed in retinal cells and is required for vision.

The genome of an organism (encoded by the genomic DNA) is the (biological) information of heredity that is passed from one generation of organism to the next. That genome is transcribed to produce various RNAs, which are necessary for the function of the organism. Precursor mRNA (pre-mRNA) is transcribed by RNA polymerase II in the nucleus. pre-mRNA is then processed by splicing to remove introns, leaving the exons in the mature messenger RNA (mRNA). Additional processing includes the addition of a 5' cap and a poly(A) tail to the pre-mRNA. The mature mRNA may then be transported to the cytosol and translated by the ribosome into a protein. Other types of RNA include ribosomal RNA (rRNA) and transfer RNA (tRNA). These types are transcribed by RNA polymerase II and RNA polymerase III, respectively, and are essential for protein synthesis. However, 5s rRNA is the only rRNA that is transcribed by RNA Polymerase III. ***cDNA is derived from mRNA, so it contains only exons but no introns.***

Figure 9.1.1 shows the flow of information stored in eukaryotic DNA and its eventual expression in mRNA.

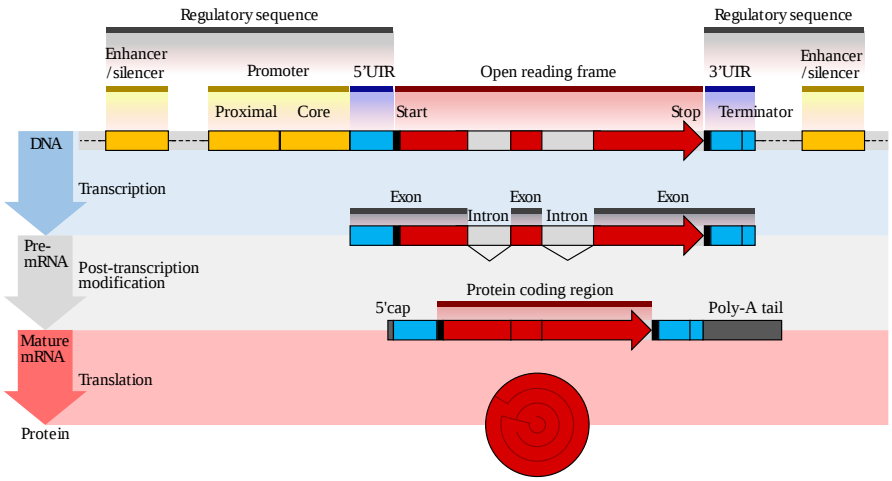

Figure 9.1.1: Eukaryotic gene structure. Shafee T, Lowe R (2017). *WikiJournal of Medicine* **4** (1). DOI:10.15347/wjm/2017.002. ISSN 20024436.Wikimedia Commons

Red indicates coding exons, which are separated by gray introns. At the beginning and end of a gene sequence (encoded by 3 exons in the figure below) are 5' and 3' **untranslated regions (UTRs)** which are also transcribed and are represented in the mature mRNA. Also, there are potential regulatory sequences, which are not transcribed (yellow) on both sides of the transcribable part of the gene. The 5'-end **promoter** is where transcription factors and RNA polymerase assemble before the start of transcriptions. In addition, there are regulatory **enhancers** and **silencers** more distal from the gene sequences. An open reading frame (ORF) is a region of the DNA that can be decoded into a mRNA and doesn't have a stop signal (codon) in it that would prematurely terminate transcription.

In contrast, **complementary DNA** (**cDNA**) is synthesized from a single-stranded RNA (e.g., messenger RNA (mRNA) or microRNA) template in a reaction catalyzed by the enzyme reverse transcriptase. Reverse transcriptase is an enzyme found in retroviruses such as HIV that have RNA as their core genetic material. Upon entering the host cell the RNA is reverse-transcribed to produce a copy of cDNA that can then integrate into the host's genomic DNA. In biotechnology, reverse transcriptase is often used to create cDNA from the mRNA expressed in specific cells or tissues. In this way, the eukaryotic genes can be cloned without any introns housed in the structure. This is especially useful if the goal is to express the protein in a prokaryotic (bacterial) host. Recall that bacterial DNA does not contain any intron sequences within its chromosomal DNA. Thus, if you are using a prokaryotic system to express eukaryotic proteins, you must use cDNA, as the prokaryotic system will not be able to remove intron sequences following gene transcription. The term *cDNA* is also used, typically in a bioinformatics context, to refer to an mRNA transcript's sequence expressed as DNA bases (GCAT) rather than RNA bases (GCAU).

The gene organization of prokaryotes is different in that they don't have introns. In addition, some genes for a common pathway for example are continuous in the DNA. These stretches of DNA are called operons. Transcription from an operon produces a polycistronic RNA transcript. The words cis and are used in chemistry to describe R groups on the same size (cis) or opposite sides (trans) of a double bond. In DNA, cis-elements are in a single DNA section while trans-elements usually refer to proteins (away from the gene) binding to the DNA. Hence the term polycistronic for bacterial operons (with multiple genes sequentially arranged in the DNA sequence). Figure 9.1.2 shows the organization of prokaryotic gene structure.

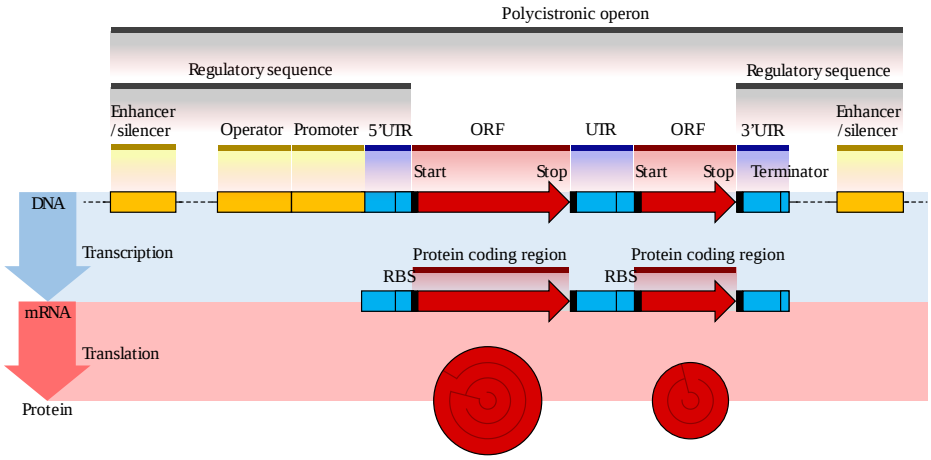

Figure 9.1.2: Prokaryotic gene structure. Shafee T, Lowe R (2017). "Eukaryotic and prokaryotic gene structure". *WikiJournal of Medicine* **4** (1). DOI:10.15347/wjm/2017.002. ISSN 20024436.Wikimedia Commons

9.1.2: DNA Extraction/Purification

The first isolation of DNA was done in 1869 by Friedrich Miescher. Now purification kits are available from multiple manufacturers.

DNA can be isolated from whole tissue or cell cultures. Let's consider just DNA extraction from cells grown in the lab. Cells are first collected by centrifugation and then treated with detergents like sodium dodecyl sulfate to lyse the cell membranes. Proteases and DNAase-free RNAase can be added to digest proteins and RNA, respectively.

Methods involving phenol/chloroform extractions:

In older methods, a mixture of phenol and chloroform or phenol/chloroform/isoamyl alcohol is used to extract DNA from the solution. Students who have performed liquid/liquid extractions in chemistry lab courses should recognize that this will form a biphasic mixture with water. Nonpolar substances like lipids and cellular debris will partition into the nonpolar phase (chloroform/phenol) or in the interface between them (as suspended insoluble material). Chloroform is very dense as it contains a chlorine atom). Phenol is somewhat soluble in water (8 g/100 g water) but very soluble in chloroform. In mixing during the extraction, the dissolved phenol alters the properties of water sufficiently enough to push the delicate equilibrium of proteins from the native to the denatured states, which aggregate and precipitate. On settling, DNA will remain in the aqueous phase. The use of chloroform/phenol in DNA extractions has a potential problem. Phenol (hydroxylated benzene) can lose one electron from the oxygen atom forming a free radical, which can be stabilized by resonance with pi electrons in the aromatic ring. Free radicals can damage DNA, so most new methods of purification do **not** use phenol/chloroform extractions.

Most methods involve precipitating the extracted DNA at some point in the purification process using cold ice-cold ethanol or isopropanol. DNA is to a first approximation a long polyanion so it would be very difficult to purify "naked" DNA from solution since the extensive negative charges on the DNA would prevent aggregate and precipitate formation. This is not a problem if the ionic strength of the medium is sufficiently high so bound positively charged counter-ions can shield the negative charges from each other, allowing precipitation.

Methods involving adsorption chromatography using silica gel: Nucleic acids bind or adsorb to a solid phase (silica or other) depending on the pH and the salt concentration of the buffer. If small amounts are needed (such as for isolating recombinant plasmid from bacteria), small spin columns are employed. This method relies on the fact that nucleic acid will bind to the solid phase of silica gel under certain conditions and then be released when those conditions are altered. These features are illustrated in Figure 9.1.3.

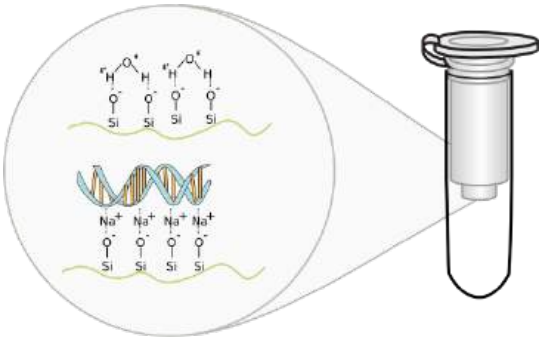

Figure 9.1.3: DNA-Silica gel interactions. *Image by Squidonius*

The solution containing DNA is applied to a small spin column containing silica gel and placed in a mini-centrifuge. On spinning, the nucleic acid will bind to the silica gel membrane as the solution passes through. After multiple "spin" washes to remove non-specific cellular components from the column, the DNA is eluted with a low salt elution buffer (or simply water). Unlike RNA which degrades very quickly, DNA is quite stable and can be stored for long periods at -20^{o}C.

Many student readers have used silica gel chromatography or silica gel thin-layer chromatography to separate and analyze organic mixtures. These techniques are usually performed in a mixture of organic solvents (like hexane/ethyl acetate for example). The use of silica gel to purify DNA from an aqueous solution might seem strange so we will briefly explore how DNA binds.

In silica gel, each silicon atom is tetrahedrally bonded (sp^3 hybridization) to four oxygen atoms, with each oxygen atom covalently linked to two silicon atoms. At the surface of the particle, the oxygen atoms are capped with H atoms, so the entire surface contains a "sea" of OHs, and therefore hydrogen bond donors and acceptors. At lower pHs, some could ionize to form O^- ions. If salt concentrations are high enough, the percentage of O^- ions increases, since they are stabilized by the cations in the salt (shifting the equilibrium to the ionized state).

DNA, a long negatively charged anion, can bind to the silica surface using two types of noncovalent interaction. It can form hydrogen bonds with the silica gel surface OHs. In addition, it can interact with the surface through ion-ion interactions mediated by bridging cations (like Na^+ from the high-concentration salt solution) as illustrated in the figure above. The binding solutions used in the spin column adsorption steps have high concentrations of chaotropic salts that disrupt water structure and hydrogen bonding. The salts also denature proteins and in effect dehydrate the DNA. Some chaotropic salts used include sodium iodide, sodium perchlorate, guanidinium thiocyanate, and guanidinium chloride. The sodium or guanidinium acts as bridging cations, allowing the adsorption of the negative DNA to negative charges on the silica gel surface. Sodium acetate and Tris-HCl are included to buffer pH from 6-7. Now it becomes easy to understand how pure water or low salt concentration solutions elute the bound DNA after extensive column washing since pure water or low salt solutions would strip the bound intermediary cations from the silica column.

After isolation, the DNA is dissolved in a slightly alkaline buffer, usually in a Tris-EDTA buffer, or in ultra-pure water. EDTA binds divalent cations like Ca^{2+}, which activate nucleases. Modifications made to these standard techniques are often done if the tissue being used is difficult to break down, if contaminants persist in the lysis solution that inhibit further reactions, or if the sample is extremely minimal, as is often the case in forensic investigations. In addition, different commercial kits will be tailored for the isolation of larger genomic DNA or smaller plasmid DNA.

The purity of a DNA preparation is usually determined by measuring the absorbance of the solution at 230, 260 (peak absorbance nucleic acids), and 280 nm (peak absorbance proteins), often using an instrument that requires a tiny droplet of solution. Figure (\PageIndex{4}\) below shows the relative absorbance spectra of proteins and nucleic acids.

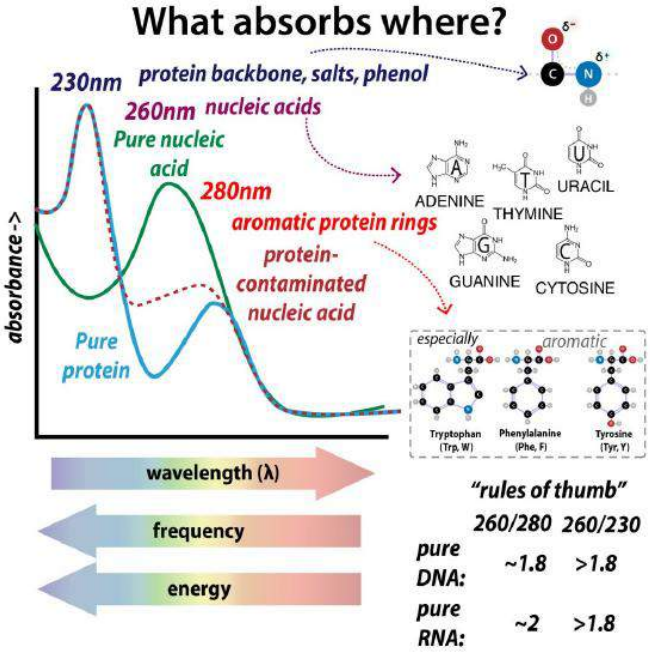

Figure (\PageIndex{4}\) relative absorbance spectra of proteins and nucleic acids. Brianna Bibel. The Bumbling Chemist https://thebumblingbiochemist.com/36...purity-ratios/

The A_{260}/A_{280} gives a measure of protein contamination, with a value around 1.8 indicating "pure" DNA. The A_{260}/A_{230} gives information on protein and other solution contamination. A pure solution of DNA that has an A_{260} = 1.0 has a concentration of 50 µg/mL = 50 ng/µL.

When the temperature of a dsDNA solution is increased, in some range of temperature the A_{260} increases by about 37%. This is called the hyperchromic effect which occurs when the bases in DNA unstack on denaturation of dsDNA to single-stranded DNA as the intrastrand hydrogen bonds break. Figure (\PageIndex{5}\) below shows a graph of A_{260} vs temperature. The midpoint of the cooperative change in the absorbance signifies that the population of DNA molecules is 50% denatured.

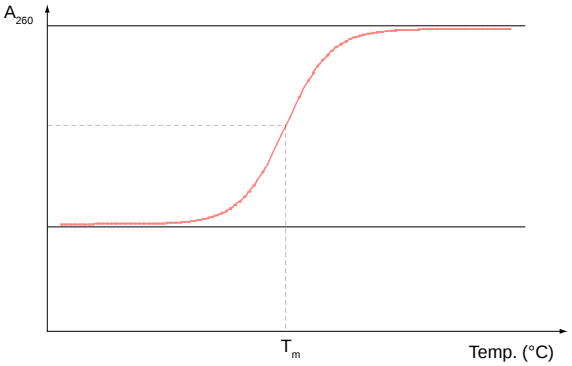

Figure (\PageIndex{5}\): Thermal denaturation curve of dsDNA. Fdardel - Own work, CC BY-SA 3.0, https://commons.wikimedia.org/w/inde...?curid=5949679

Given the cooperative of unfolding, it is less likely that the population consists of individual molecules that are 50% denatured (i.e. a single molecule being 50% double-stranded and 50% single-stranded). Accordingly, a lower concentration (33 µg/mL) of fully single-stranded DNA gives an A_{260} = 1.

9.1.2.1: DNA Sequencing Techniques

DNA sequencing is the process of determining the nucleic acid sequence – the order of nucleotides in DNA. It includes any method or technology that is used to determine the order of the four bases: adenine, guanine, cytosine, and thymine. The advent of rapid DNA sequencing methods has greatly accelerated biological and medical research and discovery.

Knowledge of DNA sequences has become indispensable for basic biological research and in numerous applied fields such as medical diagnosis, biotechnology, forensic biology, virology, and biological systematics. Comparing healthy and mutated DNA sequences can diagnose different diseases including various cancers, characterize antibody repertoire, and can be used to guide patient treatment. Having a quick way to sequence DNA allows for faster and more individualized medical care to be administered, and for more organisms to be identified and cataloged.

The rapid speed of sequencing attained with modern DNA sequencing technology has been instrumental in the sequencing of complete DNA sequences, or genomes, of numerous types and species of life, including the human genome and other complete DNA sequences of many animal, plant, and microbial species.

The first DNA sequences were obtained in the early 1970s by academic researchers using laborious methods based on two-dimensional chromatography. Following the development of fluorescence-based sequencing methods with a DNA sequencer, DNA sequencing has become easier and orders of magnitude faster.

The canonical structure of DNA has four bases: thymine (T), adenine (A), cytosine (C), and guanine (G). DNA sequencing is the determination of the physical order of these bases in a molecule of DNA. However, DNA bases are often modified by epigenetic processes to control gene expression. Thus, many other modified bases may be present in a DNA molecule than the standard four bases. For example, in some viruses (specifically, bacteriophages), cytosine may be replaced by hydroxymethyl- or hydroxymethylglucose cytosine. In eukaryotic DNA, variant bases with methyl groups or phosphosulfate may be found as shown in Figure (\PageIndex{6}\) below. Depending on the sequencing technique, a particular modification, e.g., the 5mC (5 - methylcytosine) common in humans, may or may not be detected.

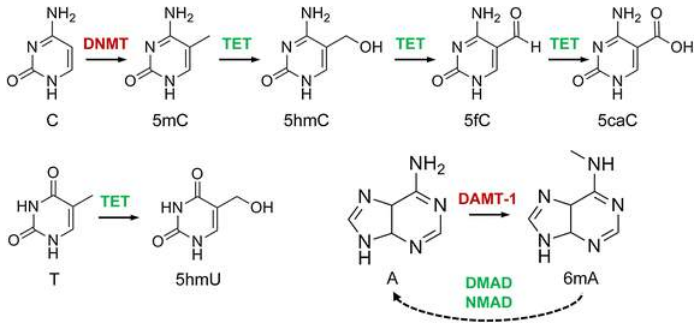

Figure (\PageIndex{6}\): **DNA modifications with epigenetic regulatory functions and their interdependencies.** Cytosine (C) is methylated to 5-methylcytosine (5mC) by DNA methyltransferases (DNMT) and then further oxidized to 5hmC, 5fC, and 5caC by Tet dioxygenases. 5-Hydroxyuracil (5hmU) is produced by Tet-catalysed oxidation of thymine (T). N6-methyladenine (6mA) is likely catalyzed by DNA N6 adenine methyltransferases (DAMT-1 in *C. elegans*), even though the biochemical activity of these enzymes remains to be characterized. The Tet-like ALKB enzymes NMAD (N6-methyl adenine demethylase 1) and DMAD (DNA 6mA demethylase) are involved in 6mA demethylation in *C. elegans* and *Drosophila*, respectively, possibly by using a conserved dioxygenase mechanism. *Image by Breiling and Lyko (2015) Epigenetics and Chromatin 8:24*

9.1.2.1.1: Early DNA sequencing methods

The first method for determining DNA sequences involved a location-specific primer extension strategy established by Ray Wu at Cornell University in 1970. DNA polymerase catalysis and specific nucleotide labeling, both of which figure prominently in current sequencing schemes, were used to sequence the cohesive ends of lambda phage DNA. Between 1970 and 1973, Wu, R Padmanabhan, and colleagues demonstrated that this method can be employed to determine any DNA sequence using synthetic location-specific primers. Frederick Sanger then adopted this primer-extension strategy to develop more rapid DNA sequencing methods at the MRC Centre, Cambridge, UK, and published a method for "DNA sequencing with chain-terminating inhibitors" in 1977. Walter Gilbert and Allan Maxam at Harvard also developed sequencing methods, including one for "DNA sequencing by chemical degradation". In 1973, Gilbert and Maxam reported the sequence of 24 base pairs using a method known as wandering-spot analysis. Advancements in sequencing were aided by the concurrent development of recombinant DNA technology, allowing DNA samples to be isolated from sources other than viruses.

Maxam-Gilbert sequencing requires radioactive labeling at one 5' end of the DNA and purification of the DNA fragment to be sequenced. Chemical treatment then generates breaks at a small proportion of one or two of the four nucleotide bases in each of the four reactions (G, A+G, C, C+T). The concentration of the modifying chemicals is controlled to introduce on average one modification per DNA molecule. Thus a series of labeled fragments is generated, from the radiolabeled end to the first "cut" site in each molecule. The fragments in the four reactions are electrophoresed side by side in denaturing acrylamide gels for size separation. To visualize the fragments, the gel is exposed to X-ray film for autoradiography, yielding a series of dark bands each corresponding to a radiolabeled DNA fragment, from which the sequence may be inferred.

The technical aspects of Maxam-Gilbert sequencing caused it to go out of favor once the Sanger sequencing method had been well established, as described below.

9.1.2.1.2: Sanger Sequencing Method

The chain-termination method developed by Frederick Sanger and coworkers in 1977 soon became the method of choice, owing to its relative ease and reliability. When invented, the chain-terminator method used fewer toxic chemicals and lower amounts of radioactivity than the Maxam-Gilbert method. Because of its comparative ease, the Sanger method was soon automated and was the method used in the first generation of DNA sequencers.

The classical chain-termination method requires a single-stranded DNA template, a DNA primer, a DNA polymerase, normal deoxynucleotide triphosphates (dNTPs), and modified di-deoxynucleotide triphosphates (ddNTPs), the latter of which terminate DNA strand elongation. These chain-terminating nucleotides lack a 3'-OH group required for the formation of a phosphodiester bond between two nucleotides, causing DNA polymerase to cease the extension of DNA when a modified ddNTP is incorporated. The ddNTPs may be radioactively or fluorescently labeled for detection in automated sequencing machines.

The DNA sample is divided into four separate sequencing reactions, containing all four of the standard deoxynucleotides (dATP, dGTP, dCTP, and dTTP) and the DNA polymerase. To each reaction is added only one of the four dideoxynucleotides (ddATP, ddGTP, ddCTP, or ddTTP), while the other added nucleotides are ordinary ones as shown in (\PageIndex{7}\) below.

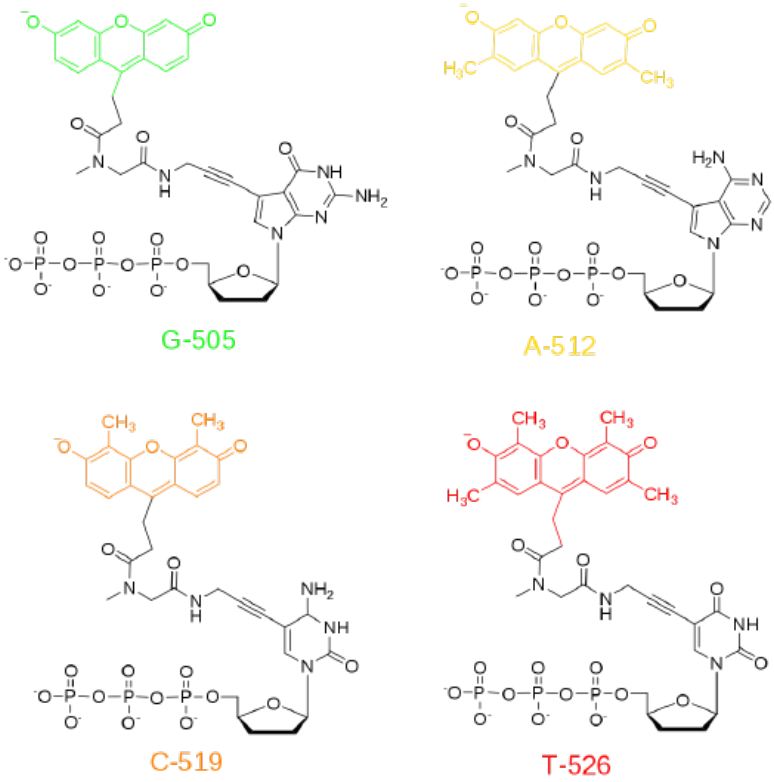

Figure (\PageIndex{7}\): **Fluorescent ddNTPs for Sanger Sequencing.** Dideoxynucleotides are utilized for sequencing as they cannot be extended further once they are incorporated into the nascent DNA. *Image by Fibonachi*

The dideoxynucleotide concentration should be approximately 100-fold lower than that of the corresponding deoxynucleotide (e.g. 0.005mM ddTTP : 0.5mM dTTP) to allow enough fragments to be produced while still transcribing the complete sequence. In total, four separate reactions are needed in this process to test all four ddNTPs. This is illustrated in Figure (\PageIndex{8}\) below.

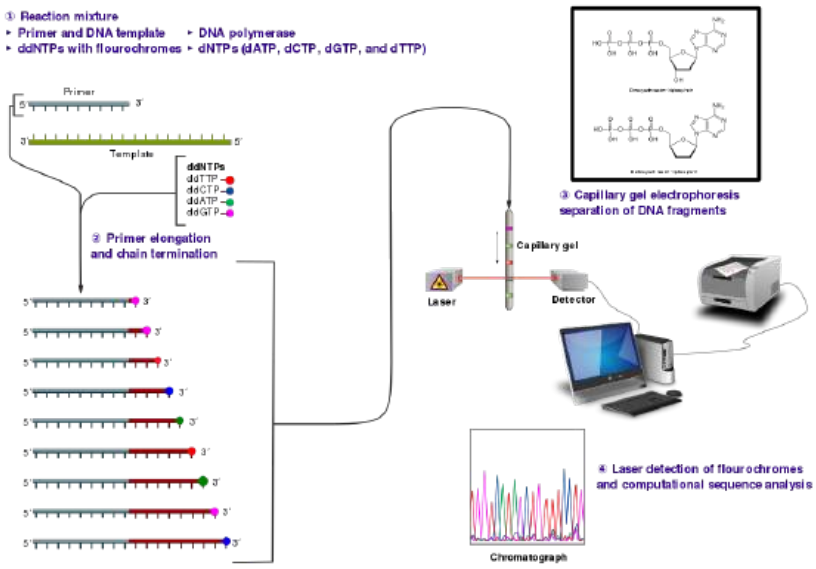

Figure (\PageIndex{8}\): **The Sanger (chain-termination) method for DNA sequencing.** (1) A primer is annealed to a sequence, (2) Reagents are added to the primer and template, including DNA polymerase, dNTPs, and a small amount of all four dideoxynucleotides (ddNTPs) labeled with fluorophores. During primer elongation, the random insertion of a ddNTP instead of a dNTP terminates the synthesis of the chain because DNA polymerase cannot react with the missing hydroxyl. This produces all possible lengths of chains. (3) The products are separated on a single-lane capillary gel, where the resulting bands are read by an imaging system. (4) This produces several hundred thousand nucleotides a day, data that require storage and subsequent computational analysis. *Image by Estevezj*

Following rounds of template DNA extension from the bound primer, the resulting DNA fragments are heat denatured and separated by size using gel electrophoresis. This technique was frequently performed using a denaturing polyacrylamide-urea gel with each of the four reactions run in one of four individual lanes (lanes A, T, G, C). The DNA bands may then be visualized by autoradiography or UV light and the DNA sequence can be directly read off the X-ray film or gel image, as shown in Figure (\PageIndex{9}\) below.

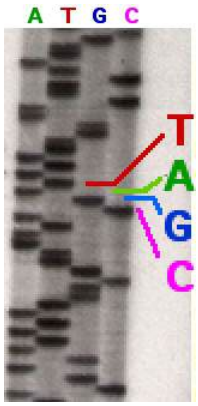

Figure (\PageIndex{9}\): **Traditional Sanger Sequencing Gel.** Sequence visualized by autoradiography. Each lane contains a single reaction that has all four regular nucleotides and a small amount of one of the dideoxynucleotides (ddNTPs). Over time, the ddNTPs will be incorporated at each position containing that specific nucleotide. The gel can then be read from the bottom to the top, as the smallest fragments (those fragments terminated the closest to the primer at the 5'-end) will run the farthest distance in the gel. The sequence of this fragment is 5'-TACGAGATATATGGCGTTAATACGATATATTGGAACTTCTATTGC-3'. *Image by John Schmidt*

Automation of the Sanger sequencing method was made possible when the shift from radioactively tagged nucleotides to fluorescently tagged nucleotides was made. Within the automated sequencers, capillary gel electrophoresis is performed rather than separating the samples using gel electrophoresis. The output from capillary electrophoresis are fluorescent peak trace chromatograms, as shown in **Figure** (\PageIndex{10}\) below. Automated DNA-sequencing instruments (DNA sequencers) can sequence up to 384 DNA samples in a single batch. Batch runs may occur up to 24 times a day greatly enhancing the speed with

which samples may be sequenced and analyzed. Common challenges of DNA sequencing with the Sanger method include poor quality in the first 15-40 bases of the sequence due to primer binding and deteriorating quality of sequencing traces after 400-500 bases.

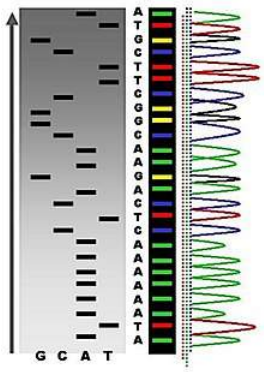

Figure (\PageIndex{10}\): **Side by Side Comparison of Gel Electrophoresis and Capillary Electrophoresis.** *Lefthand Diagram* shows the traditional autoradiogram of Sanger sequencing samples. The *Righthand Diagram* shows the same reactions using fluorescently tagged ddNTPs separated by capillary electrophoresis. The chromatogram output is shown on the far right. *Image by Abizar*

Sanger sequencing is the method that prevailed from the 1980s until ~2005. Over that period, great advances were made in the technique, such as fluorescent labeling, capillary electrophoresis, and general automation. These developments allowed much more efficient sequencing, leading to lower costs. The Sanger method, in mass production form, is the technology that produced the first human genome in 2001, ushering in the age of genomics.

9.1.2.1.3: Microfluidic Sanger Sequencing

Microfluidic Sanger sequencing is a ***lab-on-a-chip application*** for DNA sequencing, in which the Sanger sequencing steps (thermal cycling, sample purification, and capillary electrophoresis) are integrated on a wafer-scale chip using nanoliter-scale sample volumes (Figure (\PageIndex{11}\)). This technology generates long and accurate sequence reads while obviating many of the significant shortcomings of the conventional Sanger method (e.g. high consumption of expensive reagents, reliance on expensive equipment, personnel-intensive manipulations, etc.) by integrating and automating the Sanger sequencing steps.

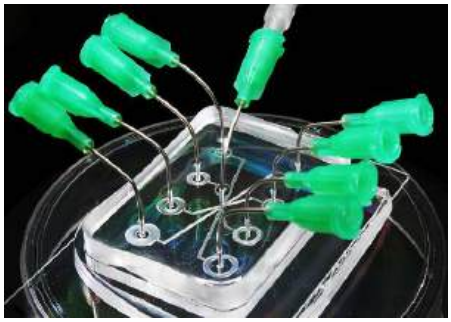

Figure (\PageIndex{11}\): **Lab-On-A-Chip Technologies.** Example of a microfluidic lab-on-a-chip device sitting on a polystyrene dish. Stainless steel needles inserted into the device serve as access points for fluids into small channels within the device, which are about the size of a human hair. *Image by National Institute of Standards and Technology (NIST)*

9.1.2.1.4: Next-generation sequencing (NGS)

Next-generation sequencing (NGS), also known as high-throughput sequencing, is the catch-all term used to describe several different modern sequencing technologies. These technologies allow for the sequencing of DNA and RNA much more quickly and cheaply than the previously used Sanger sequencing, and as such revolutionized the study of genomics and molecular biology. We present information from specific companies that have developed these new technologies without endorsements. Such technologies include:

Illumina Sequencing - In NGS, vast numbers of short reads are sequenced in a single stroke using the lab-on-a-chip technology described above. To do this, the input sample must be cleaved into short sections. In Illumina sequencing, 100-150bp reads are used. Somewhat longer fragments are ligated to generic adaptors and annealed to a slide using the adaptors. PCR is carried out to

amplify each read, creating a spot with many copies of the same read. They are then separated into single-stranded DNA to be sequenced as shown in Figure (\PageIndex{12}\) below.

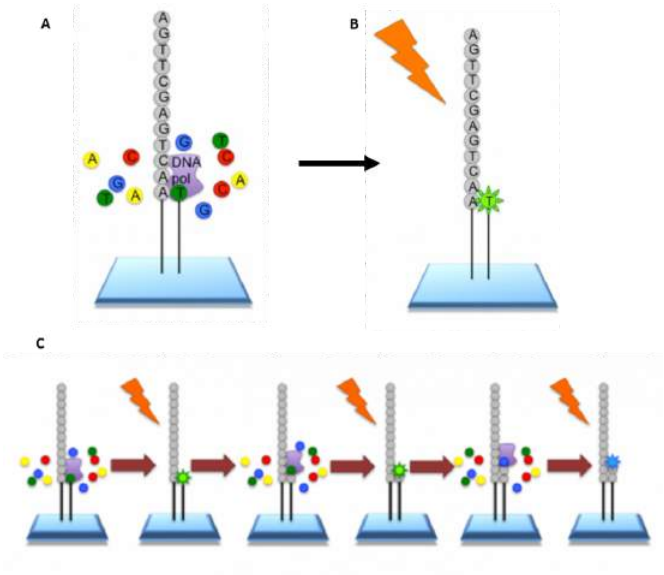

Figure (\PageIndex{12}\): **Procedure for Illumina Sequencing.** (A) The slide with PCR-amplified fragments of DNA is flooded with nucleotides and DNA polymerase. These nucleotides are fluorescently labeled with each color corresponding to a specific base. The reactions also have a terminator present, so that only one base is added at a time. (B) An image is taken of the slide. In each reaction location, there will be a fluorescent signal indicating that a specific base has been added. (C) The data is recorded and the slide is then prepared for the next cycle. In preparation, the terminators are removed, which will allow the next base to be added, and the fluorescent signal is cleaved, preventing the fluorescent signal from contaminating the next image. The process is repeated, adding one nucleotide at a time (G, A, T, or C) and imaging in between. All of the sequence reads will be the same length as single bases are added at each cycle. *Image modified from* EMBL-EBI

Roche 454-Sequencing is similar to the Illumina process but can sequence much longer reads. Like Illumina, it does this by sequencing multiple reads at once by reading optical signals as bases are added. As in Illumina, the DNA or RNA is fragmented into shorter reads, in this case, up to 1kb (1,000bp). Generic adaptors are added to the ends and these are annealed to beads, one DNA fragment per bead. The fragments are then amplified by PCR using adaptor-specific primers. Each bead is then placed in a single well of a slide with each well containing a single bead, covered in many PCR copies of a single sequence. The wells also contain DNA polymerase and sequencing buffers (Figure (\PageIndex{13}\).

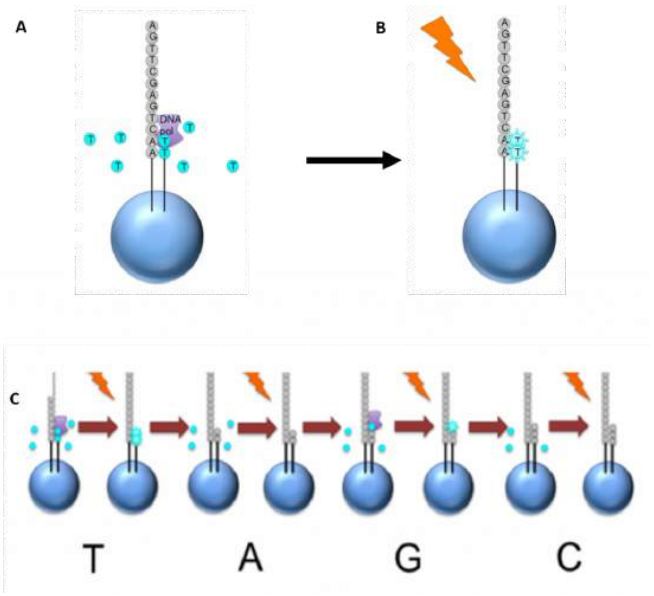

Figure (\PageIndex{13}\): **Procedure for Roche 454 Sequencing.** (A) Once the PCR product is attached to the bead, the slide is flooded with one of the four NTP species. Where this nucleotide is next in the sequence, it is added to the sequence read. If that single base repeats, then more will be added. So if we flood with Guanine bases, and the next in the sequence is G, one G will be added, however, if the next part of the sequence is GGGG, then four Gs will be added. (B) The addition of each nucleotide releases a light signal. These locations of signals are detected and used to determine which beads the nucleotides are added to. (C) The NTP mix is washed away. The next NTP mix is now added and the process is repeated, cycling through the four NTPs. All of the sequence reads from 454 sequencings will be different lengths, because different numbers of bases will be added with each cycle. *Image modified by EMBL-EBI*

Newer technologies such as the ***Ion Torrent Technology*** detect sequence data using electrical signals on a semiconductor chip, rather than optically reading dye-labeled nucleotides. This is possible as the addition of a dNTP to the DNA polymer causes the release of an H^+ ion (Figure (\PageIndex{14}\)). As in other kinds of NGS, the input DNA or RNA is fragmented, this time ~200bp. Adaptors are added and one molecule is placed onto a bead. The molecules are amplified on the bead by emulsion PCR. Each bead is placed into a single well of a slide. This is illustrated in Figure (\PageIndex{14}\) below.

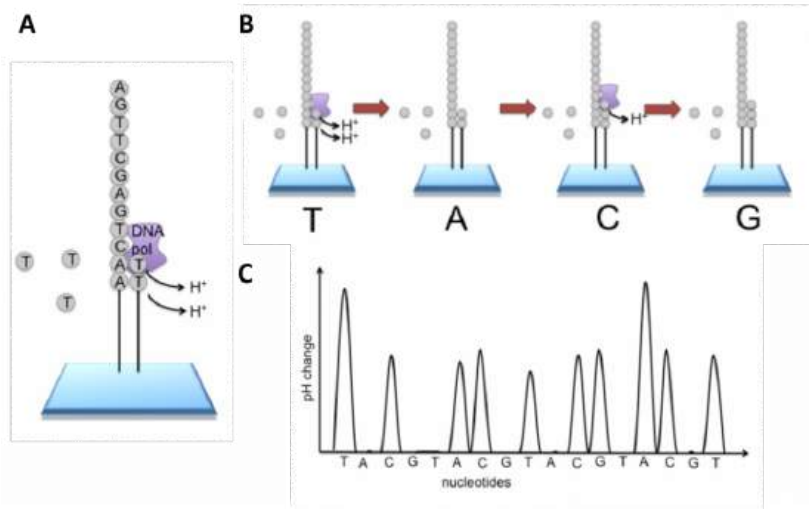

Figure (\PageIndex{14}\): **Ion Torrent Sequencing Technology.** (A) Similar to 454 sequencings, the slide is flooded with a single species of dNTP, along with buffers and polymerase. The pH is monitored in each of the wells after the addition of the specific dNTP. The pH will decrease when the dNTP is incorporated into the polymer causing the release of a proton (H^+). The changes in pH allow the determination of different dNTP species. (C) The pH change, if any, is used to determine how many bases (if any) were added with each cycle. *Image modified from EMBL-EBI*

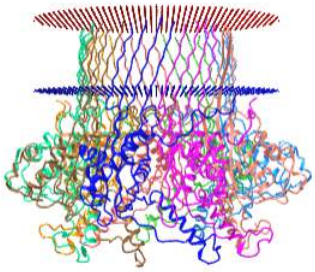
Nanopore Sequencing

In this technique, flow cells are constructed which contain nanopores in a nonlipid membrane that is resistant to current flow. When a voltage is applied across a membrane separating two salt solutions, the current through each nanopore channel can be detected by

a sensor chip. When a larger molecule moves through the pore, a disruption in basal current occurs. Computer algorithms have been developed that detect base-specific changes in the current as the base (even chemical-modified ones) moves through the membrane. The sequence is then decoded in real-time.

Single-stranded DNA or RNA can be driven through the pore by a transmembrane potential in a process similar to electrophoresis. The enzyme DNA helicase, a motor protein, can be attached to the outer part of the pore protein. This enzyme binds single-stranded DNA and moves along the DNA in a process that requires ATP. If the helicase is attached to the pore protein, the single DNA would then move, allowing control of its movement through the pore.

The nanopores are made of real membrane proteins (which we discuss in Chapter 11). One example is α-hemolysin, a heptamer that has an inner pore diameter of 1 nm. When embedded in real cells, it can allow the flow of K^+ (diameter around 250 pm = 0.25 nm) and other ions across the cell membrane, changing the osmotic balance and lysing the cell. The pore size of the proteins used in nanopore sequencing allows single-stranded DNA to flow through it. An interactive iCn3D model of protein used for nanopore sequencing, Curli transport lipoprotein CsgG (4uv3), is shown in the membrane bilayer in Figure 9.1.15.



NCBI iCn3D Figure 9.1.15: Curli transport lipoprotein CsgG (4uv3) for DNA nanopore sequencing. (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...LC5K3vSjYjtHN7

Nanopore technologies have enabled the production of small hand-held DNA sequencing devices that can be plugged into the USB drive on a laptop computer and utilized in the field under real-time collection conditions. Future modifications might replace protein pores with synthetic solid-state nanopores. For instance, the membrane might be made of graphene with pores of a specific size made in it.

Figure 9.1.16 shows an animation of a single-stranded DNA moving through a protein pore (blue) assisted by a motor protein (magenta)

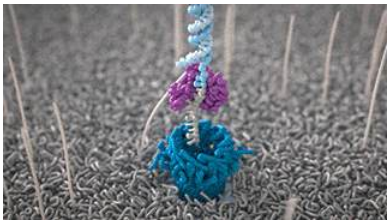


Figure 9.1.16: Single-stranded DNA moving through a protein pore (blue) assisted by a motor protein (magenta) Oxford Nanopore Tech. https://nanoporetech.com/how-it-works

Single Molecule, Real-Time (SMRT) sequencing

In this technique, either RNA or DNA is converted to dsDNA. Deoxynucleotide "adapters" are added to connect the 5'-end of strand 1 to the 3'-end of strand 2 and another adapter to connect the 3'-end of strand 1 to the 5'-end of strand 2 resulting in a "circular" ss-DNA molecule. This single molecule is then drawn into a nanophotonic nanowell made in a thin metal film deposited on glass. The dimensions of each well allow only a single circular ss-DNA molecule. Hundred of different circular ss-DNA molecules entering individual wells are shown in Figure 9.1.17. The blue stretches represent the adapters.

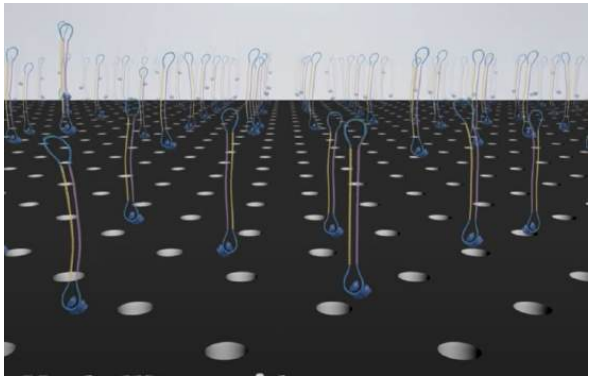

Figure 9.1.17. Nanowells for SMRT sequencing. https://www.youtube.com/embed/_lD8JyAbwEo

The wells are approximately 100 nm in diameter. DNA polymerase and dNTPs can be added to the nanowells, which contained a single molecule of immobilized circular ssDNA. The DNA is immobilized by its biotinylated or attachment to magnetic beads which interact with streptavidin-coated wells. When confined to the wells the apparent concentration of reactants for the polymerization can be quite high, allowing robust DNA polymerase activity.

DNA sequencing using real-time fluorescence monitoring can be done in a massively parallel fashion. The fluorophore is connected to the terminal phosphate of the dNTP. When a phosphodiester bond is made by the DNA polymerase, the fluorophore is released as a leaving group, and the result is a natural, unmodified DNA that continues to grow. The YouTube video below shows the entire process of a single molecule, real-time sequencing.

The four main advantages of Next Generation Sequencing (NGS) over classical sequencing are described below.

Sample size

NGS is significantly cheaper, quicker, needs significantly less DNA, and is more accurate and reliable than Sanger sequencing. Let us look at this more closely. For Sanger sequencing, a large amount of template DNA is needed for each read. Several strands of template DNA are needed for each base being sequenced (i.e. for a 100bp sequence you'd need many hundreds of copies, for a 1000 bp sequence you'd need many thousands of copies), as a strand that terminates on each base is needed to construct a full sequence. In NGS, a sequence can be obtained from a single strand. In both kinds of sequencing multiple staggered copies are taken for contig construction and sequence validation.

Speed

NGS is quicker than Sanger sequencing in two ways. Firstly, the chemical reaction may be combined with the signal detection in some versions of NGS, whereas in Sanger sequencing these are two separate processes. Secondly and more significantly, only one read (maximum ~1kb) can be taken at a time in Sanger sequencing, whereas NGS is massively parallel, allowing 300Gb of DNA to be read on a single run on a single chip.

Cost

The reduced time, people power, and reagents in NGS mean that the costs are much lower. The first human genome sequence cost in the region of $2.7 billion in 2003. Using modern Sanger sequencing methods, aided by data from the known sequence, a full human genome still cost $300,000 in 2006. Sequencing a human genome with NGS today costs roughly $1,000.

Accuracy

Repeats are intrinsic to NGS, as each read is amplified before sequencing, and because it relies on many short overlapping reads, each section of DNA or RNA is sequenced multiple times. Also, because it is so much quicker and cheaper, it is possible to do more repeats than with Sanger sequencing. More repeats mean greater coverage, which leads to a more accurate and reliable sequence, even if individual reads are less accurate for NGS.

The nanopore and single molecule, real-time (SMRT) sequencing were recently employed to complete the sequence for the full human genome (2022). Previous genomic sequences were missing regions with highly repetitive sequences at the centromeres and telomeres. The "Telomere-to-Telomere (T2T) Consortium performed the analysis which added 200 megabases of new sequence information that was missing from the previous best sequence.

9.1.2.2: DNA Synthesis Techniques

DNA synthesis is the natural or artificial creation of deoxyribonucleic acid (DNA) molecules. The term DNA synthesis can refer to ***DNA replication*** (which will be covered in more detail in Chapter XX), ***polymerase chain reaction (PCR),*** or ***gene synthesis*** (physically creating artificial gene sequences).

9.1.2.2.1: Polymerase Chain Reaction (PCR)

The Polymerase chain reaction (PCR) refers to a technique employed widely in the basic and biomedical sciences. PCR is a laboratory technique utilized to amplify specific segments of DNA for a wide range of laboratory and/or clinical applications. Building on the work of Panet and Khorana's successful amplification of DNA *in-vitro*, Kary Mullis and coworkers developed PCR in the early 1980s, having been met with a Nobel prize only a decade later. Allowing for more than the billion-fold amplification of specific target regions, it has become instrumental in many applications including the cloning of genes, the diagnosis of infectious diseases, and the screening of prenatal infants for deleterious genetic abnormalities.

Fundamentals

The main components of PCR are a template, primers, free nucleotide bases, and the DNA polymerase enzyme. The ***DNA template*** contains the specific region that you wish to amplify, such as the DNA extracted from a piece of hair for example. ***Primers***, or oligonucleotides, are short strands of single-stranded DNA complementary to the 3' end of each target region. Both a forward and a reverse primer are required, one for each complementary strand of DNA. ***DNA polymerase*** is the enzyme that carries out DNA replication. Thermostable analogs of DNA polymerase I, such as Taq polymerase, which was originally found in a bacterium that grows in hot springs, are a common choice due to their resistance to the heating and cooling cycles necessary for PCR.

PCR takes advantage of the complementary base pairing, double-stranded nature, and melting temperature of DNA molecules. This process involves cycling through 3 sequential rounds of temperature-dependent reactions: DNA melting (denaturation), annealing, and enzyme-driven DNA replication (elongation). ***Denaturation*** begins by heating the reaction to about 95^{o}C, disrupting the hydrogen bonds that hold the two strands of template DNA together. Next, the reaction is reduced to around 50 to 65^{o}C, depending on the physicochemical variables of the primers, enabling the ***annealing*** of complementary base pairs. The primers, which are added to the solution in excess, bind to the beginning of the 3' end of each template strand and prevent re-hybridization of the template strand with itself. Lastly, enzyme-driven DNA replication, or ***elongation***, begins by setting the reaction temperature to the amount which optimizes the activity of DNA polymerase, which is around 75 to 80^{o}C. At this point, DNA polymerase, which needs double-stranded DNA to begin replication, synthesizes a new DNA strand by assembling free nucleotides in solution in the 3' to 5' direction to produce 2 full sets of complementary strands. The newly synthesized DNA is now identical to the template strand and will be used as such in the progressive PCR cycles. The steps in PCR are animated in the video below.

Figure (\PageIndex{17}\) below illustrate the step involved in PCR amplification of target DNA.

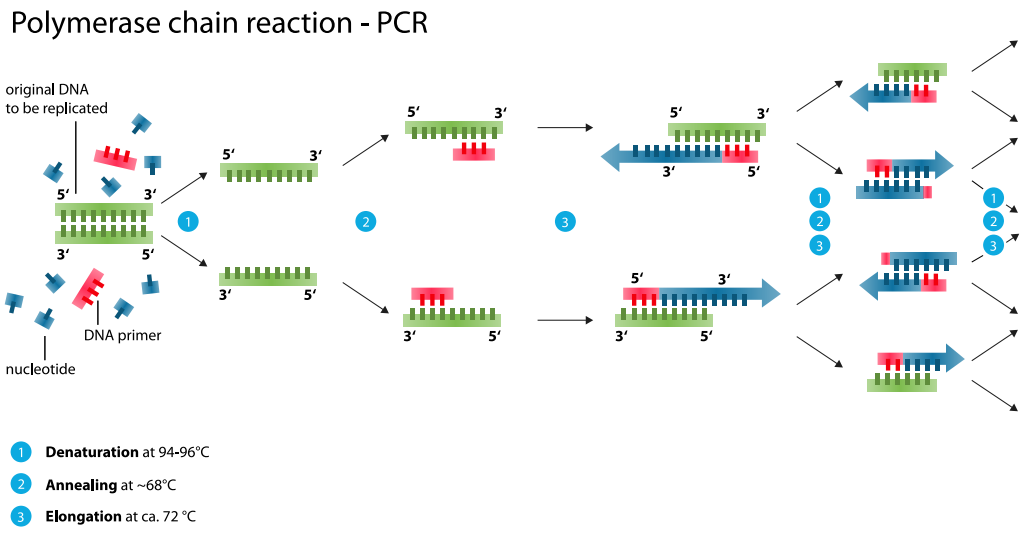

Figure (\PageIndex{17}\): Steps involved in PCR amplification of target DNA.

Figure (\PageIndex{18}\) shows a video animation of a PCR reaction.

Figure (\PageIndex{18}\): Video animation of a PCR reaction.

Given that previously synthesized DNA strands serve as templates, the amplification of DNA using PCR increases at an exponential rate, where the copies of DNA double at the end of each replication step. The exponential replication of the target DNA eventually plateaus around 30 to 40 cycles mainly due to reagent limitation, but can also be due to inhibitors of the polymerase reaction found in the sample, self-annealing of the accumulating product, and accumulation of pyrophosphate molecules.

9.1.2.2.2: Real-Time PCR

At its advent, PCR technology was limited to qualitative and or semi-quantitative analysis due to limitations on the ability to quantitate nucleic acids. At that time, to verify if the target gene was amplified successfully, the DNA product was separated by size via agarose gel electrophoresis. Ethidium bromide, a molecule that fluoresces when bound to dsDNA, could give a rough estimate of DNA amount by roughly comparing the brightness of separated bands, but was not sensitive enough for rigorous quantitative analysis.

Improvements in fluorophore development and instrumentation led to thermocyclers that no longer required measurement of only end-product DNA. This process, known as ***real-time PCR,*** or ***quantitative PCR (qPCR),*** has allowed for the detection of dsDNA during amplification. qPCR thermocyclers are equipped with the ability to excite fluorophores at specific wavelengths, detect their emission with a photodetector, and record the values. The sensitive collection of numerical values during amplification has strongly enhanced quantitative analytical power.

There are two main types of fluorophores used in qPCR: those that bind specifically to a given target sequence and those that do not. The sensitivity of fluorophores has been an important aspect of qPCR development. One of the most effective and widely used non-specific markers, SYBR Green, after binding to the minor groove of dsDNA, exhibits a 1000-fold increase in fluorescence compared to being free in solution (Video 5.1). However, if even more specificity is desired, a sequence-specific oligonucleotide, or hybridization probe, can be added, which binds to the target gene at some point in front of the primer (after the 3' end). These hybridization probes contain a reporter molecule at the 5' end and a quencher molecule at the 3' end. The quencher molecule effectively inhibits the reporter from fluorescing while the probe is intact. However, upon contact with DNA polymerase I, the hybridization probe is cleaved, allowing for the fluorescence of the dye (Video 5.1).

9.1.2.2.3: Reverse-Transcription PCR

Since its advent, PCR technology has been creatively expanded upon, and ***reverse-transcription PCR (RT-PCR)*** is one of the most important advances. Real-time PCR is frequently confused with reverse-transcription PCR, but they are separate techniques. In RT-PCR, the DNA amplified is derived from mRNA by using reverse-transcriptase enzymes, to produce a cDNA copy of the gene. Using primer sequences for genes of interest, traditional PCR methods can be used with the cDNA to study the expression of genes qualitatively. Currently, reverse-transcription PCR is commonly used with real-time PCR, which allows one to quantitatively measure the relative change in gene expression across different samples.

Figure (\PageIndex{19}\) shows a video animation video showing the use of reverse transcription Polymerase Chain Reaction (RT-PCR) in COVID-19 testing.

Figure (\PageIndex{19}\): Video animation of the Reverse Transcription Polymerase Chain Reaction (RT-PCR)

Issues of Concern

One disadvantage of PCR technology is that it is extremely sensitive. Trace amounts of RNA or DNA contamination in the sample can produce extremely misleading results. Another disadvantage is that the primers designed for PCR require sequence data, and therefore can only be used to identify the presence or absence of a known pathogen or gene. Another limitation is that sometimes the primers used for PCR can anneal non-specifically to similar sequences, but not identical, to the target gene.

Another potential issue of using PCR is the possibility of primer dimer (PD) formation. PD is a potential by-product and consists of primer molecules that have hybridized with each other due to the strings of complementary bases in the primers. The DNA polymerase amplifies the PD, leading to competition for PCR reagents that could be used to amplify the target sequences.

Clinical Significance

PCR amplification is an indispensable tool with various applications within medicine. Often, it is used to test for the presence of specific alleles, such as in the case of prospective parents screening for genetic carriers, but it can also be used to diagnose the presence of disease directly and for mutations in the developing embryo. For example, the first time PCR was used in this way was for the diagnosis of sickle cell anemia through the detection of a single gene mutation.

Additionally, PCR has greatly revolutionized the diagnostic potential for infectious diseases, as it can be used to rapidly determine the identity of microbes that were traditionally unable to be cultured, or that required weeks for growth. Pathogens routinely detected using PCR include Mycobacterium tuberculosis, human immunodeficiency virus, herpes simplex virus, syphilis, and

countless other pathogens. Moreover, qPCR is not only used for testing the qualitative presence of microbes but also to quantify bacterial, fungal, and viral loads.

The sensitivity of diagnostic tools for mutations to oncogenes and tumor suppression genes has been improved at least 10,000-fold due to PCR, allowing for earlier diagnosis of cancers like leukemia. PCR has also enabled more nuanced and individualized therapies for cancer patients. Additionally, PCR can be used for the tissue typing done that is vital to organ implantation and has even been proposed as a replacement for antibody-based tests for blood type. PCR also has clinical applications in the field of prenatal testing for various genetic diseases and/or clinical pathologies. Samples are obtained either via amniocentesis or chorionic villus sampling.

In forensic medicine, short pieces of repeating, highly polymorphic DNA, coined short tandem repeats (STRs), are amplified and used to compare specific variations within genes to differentiate individuals.[9] Primers specific for the loci of these STRs are used and amplified using PCR. Various loci contain STRs in the human genome, and the statistical power of this technique is enhanced by checking multiple sites.

9.1.2.3: Gene Synthesis

Artificial gene synthesis, sometimes known as **DNA printing** is a method in synthetic biology that is used to create artificial genes in the laboratory. Based on solid-phase DNA synthesis, it differs from molecular cloning and polymerase chain reaction (PCR) in that it does not have to begin with preexisting DNA sequences. Therefore, it is possible to make a completely synthetic double-stranded DNA molecule with no apparent limits on either nucleotide sequence or size.

The method has been used to generate functional bacterial or yeast chromosomes containing approximately one million base pairs. Creating novel nucleobase pairs in addition to the two base pairs in nature could greatly expand the genetic code.

Synthesis of the first complete gene, a yeast tRNA, was demonstrated by Har Gobind Khorana and coworkers in 1972. Synthesis of the first peptide- and protein-coding genes was performed in the laboratories of Herbert Boyer and Alexander Markham, respectively.

Commercial gene synthesis services are now available. Approaches are most often based on a combination of organic chemistry and molecular biology techniques and entire genes may be synthesized "de novo", without the need for template DNA. Gene synthesis is an important tool in many fields of recombinant DNA technology including heterologous gene expression, vaccine development, gene therapy, and molecular engineering. The synthesis of nucleic acid sequences can be more economical than classical cloning and mutagenesis procedures. It is also a powerful and flexible engineering tool for creating and designing new DNA sequences and protein functions.

Gene optimization

While the ability to make increasingly long stretches of DNA efficiently and at lower prices is a technological driver of this field, increasing attention is being focused on improving the design of genes for specific purposes. Early in the genome sequencing era, gene synthesis was used as an (expensive) source of cDNAs that were predicted by genomic or partial cDNA information but were difficult to clone. As higher-quality sources of sequence-verified cloned cDNA have become available, this practice has become less urgent.

Producing large amounts of protein from gene sequences can sometimes prove difficult. Many of the most interesting proteins are normally regulated to be expressed in very low amounts in wild-type cells. Redesigning these genes offers a means to improve gene expression in many cases. Rewriting the open reading frame is possible because of the degeneracy of the genetic code. Thus it is possible to change up to about a third of the nucleotides in an open reading frame and still produce the same protein. The available number of alternate designs possible for a given protein is astronomical. For a typical protein sequence of 300 amino acids, there are over 10^{150} codon combinations that will encode an identical protein. Codon optimization, or replacing rarely used codons with more common codons sometimes has dramatic effects. Further optimizations such as removing RNA secondary structures can also be included. At least in the case of *E. coli*, protein expression is maximized by predominantly using codons corresponding to tRNA that retain amino acid charging during starvation. Computer programs are used to optimize this task. A well-optimized gene can improve protein expression 2 to 10-fold, and in some cases, more than 100-fold improvements have been reported. Because of the large number of nucleotide changes made to the original DNA sequence, the only practical way to create the newly designed genes is to use gene synthesis.

Oligonucleotide synthesis

Oligonucleotides are chemically synthesized using building blocks called nucleoside phosphoramidites. These can be normal or modified nucleosides that have protecting groups to prevent their amines, hydroxyl groups, and phosphate groups from interacting incorrectly. One phosphoramidite is added at a time, the 5' hydroxyl group is deprotected and a new base is added, and the process is repeated. The chain grows in the 3' to 5' direction, which is backward relative to DNA biosynthesis *in vivo*. In the end, all the protecting groups are removed. The solid phase DNA synthesis reaction is shown in Figure (\PageIndex{20}\) below.

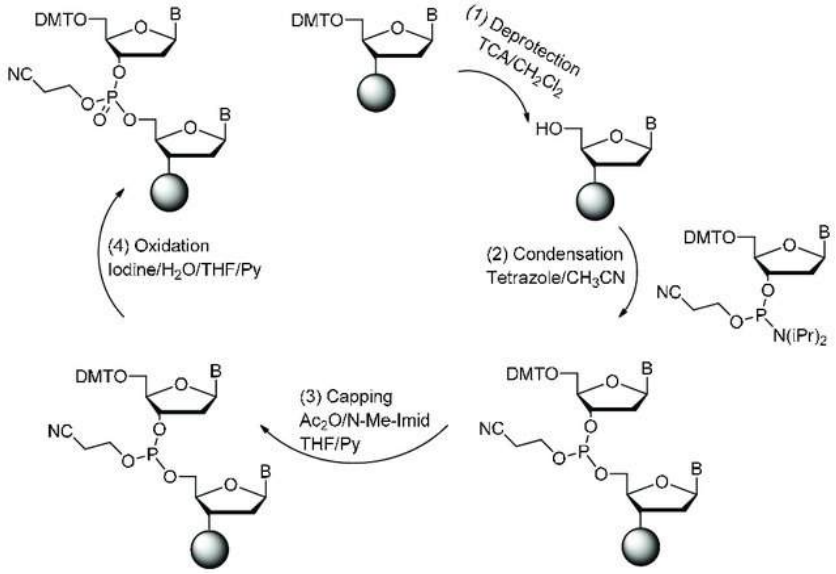

Figure (\PageIndex{20}\): **Four-step phosphoramidite oligodeoxynucleotide synthesis cycle.** The phosphoramidite method, pioneered by Marvin Caruthers in the early 1980s, and enhanced by the application of solid-phase technology and automation, is now firmly established as the method of choice. Phosphoramidite oligonucleotide synthesis proceeds in the 3 to 5 direction (opposite to the 5 to 3 direction of DNA biosynthesis in DNA replication). One nucleotide is added per synthesis cycle. The phosphoramidite DNA synthesis cycle consists of a series of steps outlined in the figure. *Image by Ni, S., et al (2017) International Journal of Molecular Sciences 18(8):1683*

Nevertheless, being a chemical process, several incorrect interactions occur leading to some defective products. The longer the oligonucleotide sequence that is being synthesized, the more defects there are, thus this process is only practical for producing short sequences of nucleotides. The current practical limit is about 200 bp (base pairs) for an oligonucleotide with sufficient quality to be used directly for a biological application. HPLC can be used to isolate products with the proper sequence. Meanwhile, a large number of oligos can be synthesized in parallel on gene chips. For optimal performance in subsequent gene synthesis procedures, they should be prepared individually and on larger scales.

9.1.2.3.1: DNA synthesis and synthetic biology

The significant drop in the cost of gene synthesis in recent years due to increasing competition of companies providing this service has led to the ability to produce entire bacterial plasmids that have never existed in nature. The field of synthetic biology utilizes the technology to produce synthetic biological circuits, which are stretches of DNA manipulated to change gene expression within cells and cause the cell to produce a desired product.

The ability to synthetically produce DNA will enable the development of environmental, medical, and commercially relevant products. For example, in 2015, Novartis, in collaboration with the Synthetic Genomics Vaccines inc. and the US Biomedical Advanced Research and Development Authority, announced that they had effectively created a synthetic DNA influenza vaccine. New synthetic DNA vaccines hold promise to provide an alternative to current egg-produced conventional vaccines that can be plagued by low efficacy.

DNA vaccines can avoid many issues associated with egg-based vaccine production by generating viral proteins within host cells. To create a DNA vaccine, an antigen-encoding gene is cloned into a non-replicative expression plasmid, which is delivered to the host by traditional vaccination routes. Host cells that take up the plasmid express the vaccine antigen which can be presented to immune cells via the major histocompatibility complex (MHC) pathways. CD4+ T helper cell activation following MHC class II presentation of secreted DNA vaccine protein is critical for the production of antigen-specific antibodies as shown in Figure (\PageIndex{21}\) below.

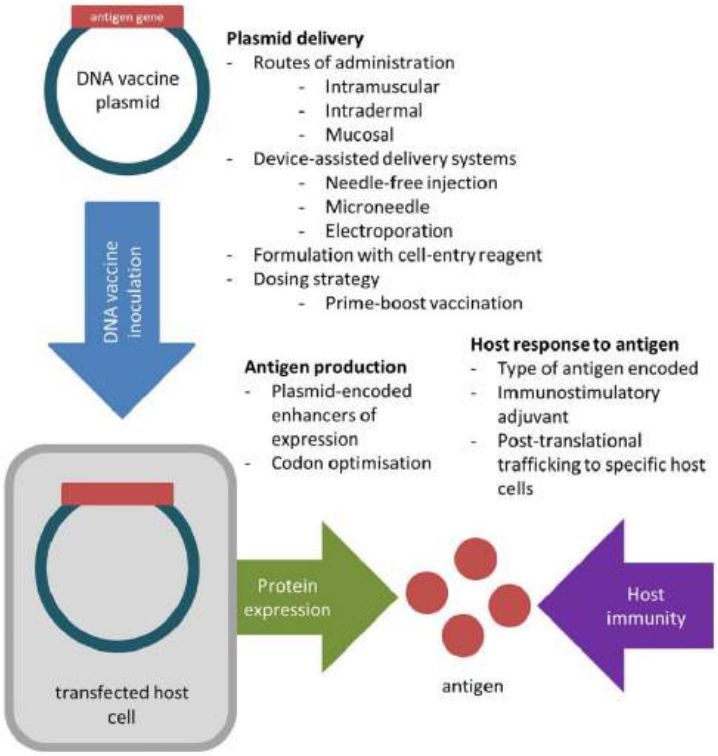

Figure by Lee, L.Y.Y., Izzard, L., and Hurt, A.C. (2018) Frontiers in Immunology, doi: 10.3389/fimmu.2018.01568

After two decades of research, DNA vaccine technology is gaining maturity—several veterinary DNA vaccines are currently licensed for West Nile virus and melanoma, and significantly, the first commercial DNA vaccine against H5N1 in chickens has recently been conditionally approved by the USDA. In addition, ongoing large animal trials of DNA vaccines against other diseases such as HIV, hepatitis, and Zika virus offer valuable insights that can be applied to influenza DNA vaccine design. Promising approaches have arisen from the numerous studies evaluating different DNA vaccine formulations and delivery systems, but a strategy that consistently elicits protection against influenza in large animal models has not yet emerged. Successful plasmid delivery and the use of appropriate adjuvants remain key challenges that need to be addressed before influenza DNA vaccines become effective for human use.

9.1.2.4: RNA Vaccines

Of course, amazing progress has been made in the creation of RNA vaccines as demonstrated by the Moderna and Pfizer RNA vaccines to the spike protein of the SARS-CoV2 virus. Models show that just in the US through 2022, Covid vaccines saved the US $1.15 trillion and 3 million lives. Just in the first year, the vaccines are estimated to have saved upwards of 20 million lives worldwide, an accomplishment worthy of every prize in the world! Many more could have been saved in the developing world if the vaccine was more widely available.

As we learned previously, RNA is much more labile to hydrolysis than DNA since RNA has a 2' OH group. Methods to stabilize RNA were required before an RNA vaccine could become a reality. More importantly, dsRNA is a danger signal that a viral infection may be present. dsRNA, a pathogen-associated molecular pattern (PAMP), binds to the Toll-like Receptor 3 (TLR3) and initiates an inflammatory response that would eliminate the RNA before it could be decoded to form a protein sequence that could elicit an antibody response, a requirement for a vaccine.

Katalin Karikó and Drew Weissman found that modifying the uracil bases to pseudouracil (Ψ) prevents the PAMP response and allows RNA to last long enough to create the protein sequence (i.e. it increases the stability of the RNA to hydrolysis). Pseudouracil (Ψ) is found in structural RNAs (transfer, ribosomal, small nuclear, and small nucleolar), and in fact is the most common modification found in RNA. It even is metabolized by a naturally occurring pathway back to uracil.

Figure (\PageIndex{22}\) below shows the structures of uracil and the N1-methyl derivative of pseudouracil attached to ribose in an RNA and their base pairing to adenine. The N1-methylpseudouracil base still bases pairs with an adenine base. Hence the RNA structure and its functional ability to be decoded into a protein sequence is **not** affected by the modification. In short, mRNAs

modified to contain pseudouracil have a much greater translational capacity as well as stability. In addition, methylation of uracil decreases the immunogenicity of RNAs that contain it.

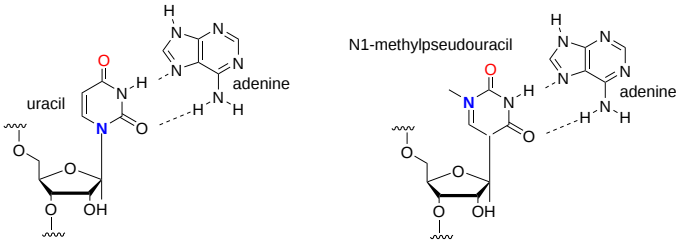

Figure (\PageIndex{22}\): Structural and base pairing features of uracil and N1-methylpseudouracil

Figure (\PageIndex{23}\) below shows a cartoon version of the modified mRNA (a) Covid-19 and its encapsulation into a lipid nanoparticle (b) for an mRNA vaccine.

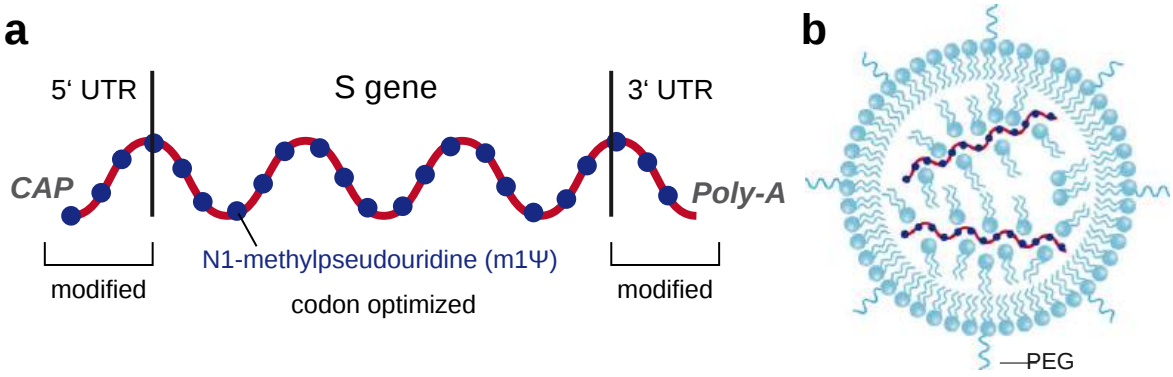

Figure (\PageIndex{23}\): Modified mRNA (a) Covid-19 and its encapsulation into a lipid nanoparticle (b) for an mRNA vaccine. Heinz, F.X., Stiasny, K. Distinguishing features of current COVID-19 vaccines: knowns and unknowns of antigen presentation and modes of action. *npj Vaccines* **6,** 104 (2021). https://doi.org/10.1038/s41541-021-00369-6. Creative Commons Attribution 4.0 International License

Panel (a) shows the generalized structure of the mRNA vaccine for the S gene which encodes the surface spike protein of the virus. Panel b shows the lipid nanoparticle that encapsulates and protects the mRNA vaccine. The lipids include proprietary mixtures of phospholipids, cholesterol, cationic (ionizable) lipids, and polyethylene glycol (PEGylated). Without the basic research of Karikó and Weissman (and many others), the world would not have had the Covid-19 vaccine in time to save so many lives. They were awarded the Nobel Prize in Medicine in 2023 for their work.

Biosynthesis of pseudouridine

The biosynthesis of pseudouridine, the most common modification of cellular RNA, is done after DNA transcription (i.e. post-transcriptionally) using the enzyme pseudouridine synthases (PUS), which is found in all kingdoms in life. The reaction involves

- cleavage of the C-N-glycosidic bond of uridine in RNA
- rotation of the cleaved uracil to align C5 of uracil and C1′ of the ribose
- formation of the C1′-C5 carbon–carbon bond.

These processes are illustrated in Figure (\PageIndex{24}\) below.

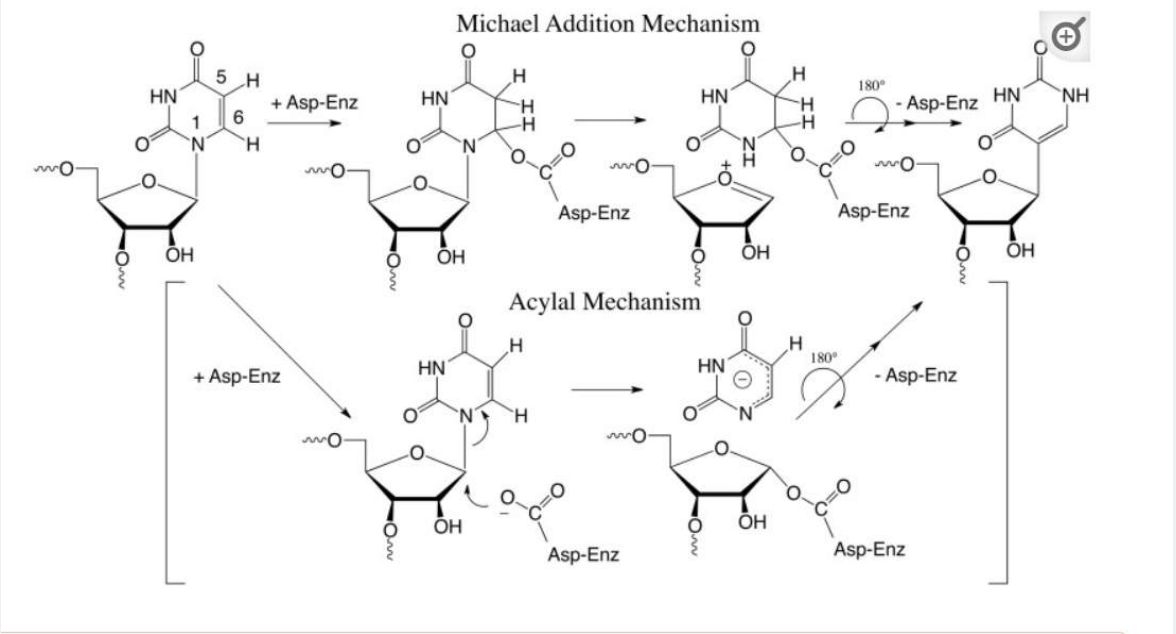

Figure (\PageIndex{24}\): Post-transcriptional modification of uridine to pseudouridine. Czudnochowski N. et al. The mechanism of pseudouridine synthases from a covalent complex with RNA, and alternate specificity for U2605 versus U2604 between close homologs. Nucleic Acids Res. 2014 Feb;42(3):2037-48. doi: 10.1093/nar/gkt1050. Epub 2013 Nov 7. PMID: 24214967; PMCID: PMC3919597. 9.2: Bioinformatics

9.2.1: Introduction

An unprecedented revolution has been observed in science with recent technological advances, which have provided a large amount of “omic” data. The crescent generation and availability of this information available in public databases were, and still are, a challenge for professionals from different areas. However, what is the challenge? In biology, the main challenge is to make sense of the enormous amount of structural data and sequences that have been generated at multiple levels of biological systems. Still, in bioinformatics, the development of tools is necessary (statistical and computational) capable of assisting in understanding the mechanisms underlying biological questions in the study. Besides, if we consider the complexity of science, this is a highly reductionist view. The era of a “new biology” emerges accompanied by the birth/development of other sciences, such as bioinformatics and computational biology, which have an integrated interface with molecular biology. Although considered recently, bioinformatics and genomics have evolved interdependently and promoted a historical impact on the available knowledge.

Bioinformatics is a hybrid science that links biological data with techniques for information storage, distribution, and analysis to support multiple areas of scientific research including biomedicine. It uses molecular biology and genetics, computer science, mathematics, and statistics to address data-intensive, large-scale biological problems are addressed from a computational point of view. Bioinformatics is fed by high-throughput data-generating experiments, including genomic sequence determinations and measurements of gene expression patterns. Database projects curate and annotate the data and then distribute it via the World Wide Web. Mining these data leads to scientific discoveries and in the end to the identification of new clinical applications.

A bioinformatics solution usually involves the following steps:

- Collect statistics from biological data
- Build a computational model
- Solve a computational modeling problem
- Test and evaluate a computational algorithm

It also addresses the following aspects:

- Types of biological information and databases
- Sequence analysis and molecular modeling
- Genomic analysis
- Systems biology

In the field of medicine in particular, many important applications for bioinformatics have been discovered. For example, it is used to identify correlations between gene sequences and diseases, to predict protein structures from amino acid sequences, to aid in the design of novel drugs, and to tailor treatments to individual patients based on their DNA sequences (pharmacogenomics). Using bioinformatics, we can now conduct global analyses of all the available data to uncover common principles that apply across many systems and highlight novel features.

Many bioinformatic tools are available online in the fields of genomics, comparative genomics, proteomics, drug discovery, cancer research, phylogenetics, forensic sciences, biodefense, nutrigenomics, gene expressions, protein structure/function, etc. Instead of endorsing any given tool, and constantly curating web addresses, which often change, we offer a series of links that readers can explore to find the tools appropriate to their needs.

9.3: Cloning and Recombinant Expression

To clone a gene from an organism and express it in either a prokaryotic or eukaryotic cells, DNA from a target source must be isolated, purified, amplified, analyzed and sequenced as described in previous sections.

9.3.1: Cloning

In general, cloning means the creation of a perfect replica. Typically, the word is used to describe the creation of a genetically identical copy. In biology, the re-creation of a whole organism is referred to as “reproductive cloning.” Long before attempts were made to clone an entire organism, researchers learned how to copy short stretches of DNA—a process that is referred to as ***molecular cloning***.

Molecular cloning allows for the creation of multiple copies of genes, the expression of genes, and study the of specific genes. To get the DNA fragment into a bacterial cell in a form that will be copied or expressed, the fragment is first inserted into a cloning vector.

Cloning vector

A Cloning vector small piece of DNA that can be stably maintained in an organism, and into which a foreign DNA fragment can be inserted for cloning purposes. The cloning vector may be DNA taken from a virus, the cell of a higher organism, or the plasmid of a bacterium. The vector contains features that allow for the convenient insertion or removal of a DNA fragment to or from the vector, for example by treating the vector and the foreign DNA with a restriction enzyme that cuts the DNA. DNA fragments thus generated contain either blunt ends or overhangs known as sticky ends, and vector DNA and foreign DNA with compatible ends can then be joined together by molecular ligation. After a DNA fragment has been cloned into a cloning vector, it may be further subcloned into another vector designed for more specific use.

There are many types of cloning vectors, but the most commonly used ones are genetically engineered plasmids. Cloning is generally first performed using *Escherichia coli*, and cloning vectors in *E. coli* include plasmids, bacteriophages (such as phage λ), cosmids, and bacterial artificial chromosomes (BACs). Some DNA, however, cannot be stably maintained in *E. coli*, for example very large DNA fragments. For these studies, other organisms such as yeast may be used. Cloning vectors in yeast include yeast artificial chromosomes (YACs). The common bacterial cloning plasmid, pRB322, is shown in Figure 9.3.1.

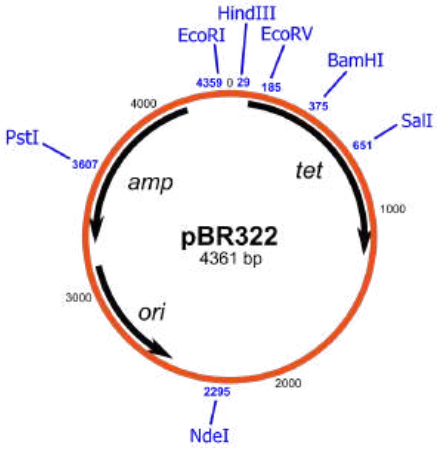

Figure 9.3.1: The cloning vector pRB322. *Image by Ayacop and Yikrazuul*

All commonly used cloning vectors in molecular biology have key features necessary for their function, such as a suitable cloning site with restriction enzymes and a selectable marker. Others may have additional features specific to their use. For reasons of ease and convenience, cloning is often performed using *E. coli*. Thus, the cloning vectors used often have elements necessary for their propagation and maintenance in *E. coli*, such as a functional ***origin of replication (ori).*** The ColE1 origin of replication is found in many plasmids. Some vectors also include elements that allow them to be maintained in another organism in addition to *E. coli*, and these vectors are called ***shuttle vectors***.

Cloning site

All cloning vectors have features that allow a gene to be conveniently inserted into the vector or removed from it. This may be a ***multiple cloning site (MCS) or polylinker***, which contains many unique restriction sites. The restriction sites in the MCS are first

cleaved by restriction enzymes, then a PCR-amplified target gene also digested with the same enzymes is ligated into the vectors using DNA ligase. The target DNA sequence can be inserted into the vector in a specific direction if so desired. The restriction sites may be further used for sub-cloning into another vector if necessary.

Other cloning vectors may use topoisomerase instead of ligase and cloning may be done more rapidly without the need for restriction digest of the vector or insert. In this TOPO cloning method, a linearized vector is activated by attaching topoisomerase I to its ends, and this "TOPO-activated" vector may then accept a PCR product by ligating both the 5' ends of the PCR product, releasing the topoisomerase and forming a circular vector in the process. Another method of cloning without the use of a DNA digest and ligase is by DNA recombination, for example as used in the Gateway cloning system. The gene, once cloned into the cloning vector (called entry clone in this method), may be conveniently introduced into a variety of expression vectors by recombination.

Restriction Enzymes

Restriction enzymes (also called restriction endonucleases) recognize specific DNA sequences and predictably cut them; they are naturally produced by bacteria as a defense mechanism against foreign DNA.

As the name implies, restriction endonucleases (or restriction enzymes) are "*restricted*" in their ability to cut or digest DNA. The restriction that is useful to biochemists is usually a ***palindromic DNA sequence***. Palindromic sequences are the same sequence forwards and backward. Some examples of palindromes: RACE CAR, CIVIC, A MAN A PLAN A CANAL PANAMA. DNA has two complementary strands. Therefore, the reverse complement of one strand is identical to the other.

Like with a palindromic word, the DNA palindromic sequence reads the same forward and backward. In most cases, the sequence reads the same forward on one strand and backward on the complementary strand. Restriction enzymes often cut DNA into a staggered pattern. When a staggered cut is made in a sequence, the overhangs are complementary as shown in Figure 9.3.2.

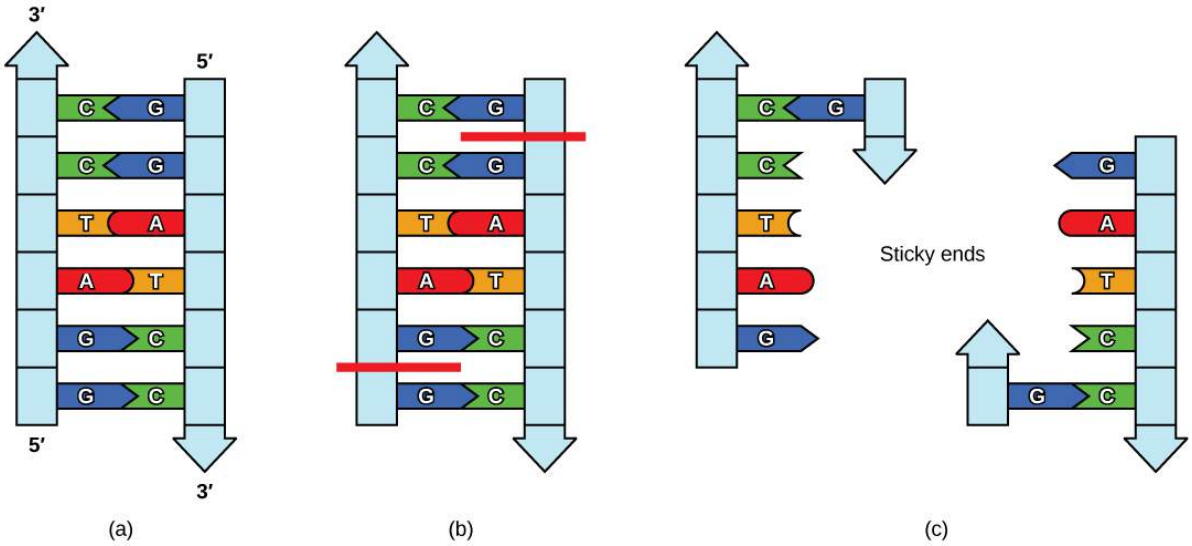

Figure_10_01_04.jpg">http://opentextbc.ca/biology/wp-cont...e_10_01_04.jpg

Figure 9.3.2: **Restriction Enzyme Recognition Sequences.** In this (a) six-nucleotide restriction enzyme recognition site, notice that the sequence of six nucleotides reads the same in the 5′ to 3′ direction on one strand as it does in the 5′ to 3′ direction on the complementary strand. This is known as a palindrome. (b) The restriction enzyme makes breaks in the DNA strands and (c) the cut in the DNA results in "sticky ends". Another piece of DNA cut on either end by the same restriction enzyme could attach to these sticky ends and be inserted into the gap made by this cut. http://opentextbc.ca/biology/wp-cont...e_10_01_04.jpg

Molecular biologists also tend to use these special molecular scissors that recognize palindromes of 6 or 8. By using 6-cutters or 8-cutters, the sequences occur rarely, but often enough, to be of utility. Figure 9.3.3 the sequence for HindII cuts.

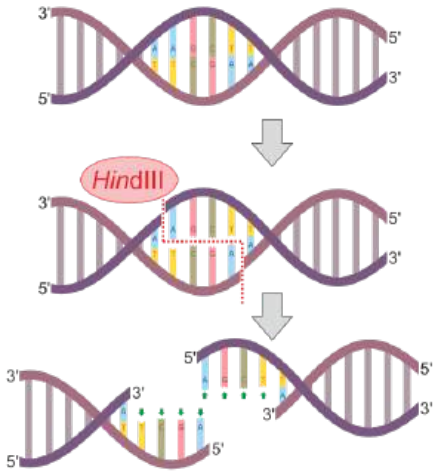

Figure 9.3.3: Sequence of HindIII stick end cuts.

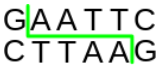
Figure 9.3.4 shows restriction enzyme cuts that leave sticky or blunt end.



SmaI restriction enzyme recognition site

Figure 9.3.4: **Restriction Enzymes.** Restriction enzymes recognize palindromic sequences in DNA and hydrolyze covalent phosphodiester bonds of the DNA to leave either “sticky/cohesive” ends or “blunt” ends. This distinction in cutting is important because an *EcoRI* sticky end can be used to match up a piece of DNA cut with the same enzyme to glue or ligate them back together. While endonucleases cut DNA, **ligases** join them back together. DNA digested with *EcoRI* can be ligated back together with another piece of DNA digested with *EcoRI*, but not to a piece digested with *SmaI*. Another blunt cutter is *EcoRV* with a recognition sequence of GAT | ATC.

Selectable marker

A selectable marker is carried by the vector to allow the selection of positively transformed cells. Antibiotic resistance is often used as a marker , an example being the beta-lactamase gene, which confers resistance to the penicillin group of beta-lactam antibiotics like ampicillin. Some vectors contain two selectable markers, for example, the plasmid pACYC177 has both ampicillin and kanamycin resistance genes. Shuttle vectors that are designed to be maintained in two different organisms may also require two selectable markers, although some selectable markers such as resistance to zeocin and hygromycin B are effective in different cell types. Auxotrophic selection markers that allow an auxotrophic organism to grow in a minimal growth medium may also be used; examples of these are *LEU2* and *URA3* which are used with their corresponding auxotrophic strains of yeast.

Another kind of selectable marker allows for the positive selection of plasmid with cloned genes. This may involve the use of a gene lethal to the host cells, such as barnase, Ccda, and the parD/parE toxins. This typically works by disrupting or removing the lethal gene during the cloning process, and unsuccessful clones where the lethalstill remains intact would kill the host cells, therefore only successful clones are selected.

Reporter genes

Reporter genes are used in some cloning vectors to facilitate the screening of successful clones by using features of these genes that allow successful clone clones easily identified. Such features present in cloning vectors may be the *lacZα* fragment for α complementation in the blue-white selection, and/or marker gene or reporter genes in frame with and flanking the MCS to facilitate the production of fusion proteins. Examples of fusion partners that may be used for screening are the green fluorescent protein (GFP) and luciferase. Figure 9.3.5 shows such a construct with GFP.

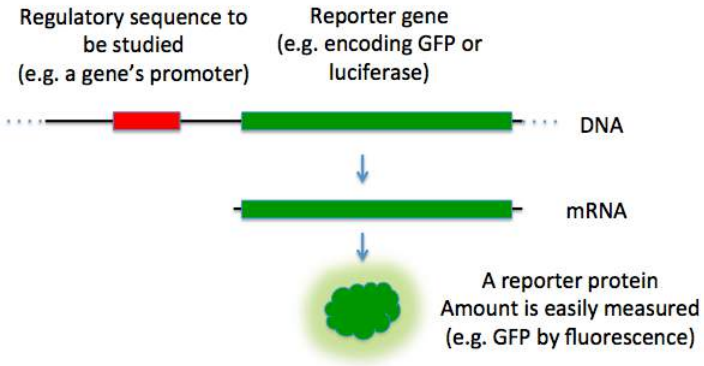


Figure 9.3.5: **Reporter Genes.** In this diagram, the green fluorescence protein is used as a reporter gene to study upstream regulatory sequences. *Image by TransControl*

Elements for expression

If the expression of the targeted gene is desired, then a cloning vector also needs to contain suitable elements for the expression of the cloned target gene, including a promoter and ribosomal binding site (RBS). The target DNA may be inserted into a site that is under the control of a particular promoter necessary for the expression of the target gene in the chosen host. Where the promoter is present, the expression of the gene is preferably tightly controlled and inducible so that proteins are only produced when required. Some commonly used promoters are the T7 and *lac* promoters. The presence of a promoter is necessary when screening techniques such as blue-white selection are used.

Cloning vectors without promoter and RBS for the cloned DNA sequence are sometimes used, for example when cloning genes whose products are toxic to *E. coli* cells. Promoter and RBS for the cloned DNA sequence are also unnecessary when first making a genomic or cDNA library of clones since the cloned genes are normally subcloned into a more appropriate expression vector if their expression is required.

9.3.2: Types of cloning vectors

A large number of cloning vectors are available, and choosing the right vector may depend on a number of factors, such as the size of the insert, copy number, and cloning method. Large DNA inserts may not be stably maintained in a general cloning vector, especially for those with a high copy number, therefore cloning large fragments may require a more specialized cloning vector.

Plasmids

Plasmids are autonomously replicating circular extra-chromosomal DNA. They are the standard cloning vectors and the ones most commonly used. Most general plasmids may be used to clone DNA inserts to 15 kb in size. Many plasmids have high copy numbers, for example, pUC19 has a copy number of 500-700 copies per cell, and a high copy number is useful as it produces a greater yield of recombinant plasmid for subsequent manipulation. However low-copy-number plasmids may be preferably used in certain circumstances, for example, when the protein from the cloned gene is toxic to the cells.

Bacteriophage

The bacteriophages most commonly used for cloning are the lambda (λ) phage and M13 phage. There is an upper limit on the amount of DNA that can be packed into a phage (a maximum of 53 kb). The average lambda phage genome is roughly 48.5 kb. Therefore to allow foreign DNA to be inserted into phage DNA, phage cloning vectors may need to have some of their non-essential genes deleted to make room for the foreign DNA. The phage sequence and cartoon structure are shown in Figure 9.3.6.

There is also a lower size limit for DNA that can be packed into a phage. This property can be used for selection - vectors without inserts may be too small, therefore only vectors with inserts may be selected for propagation.

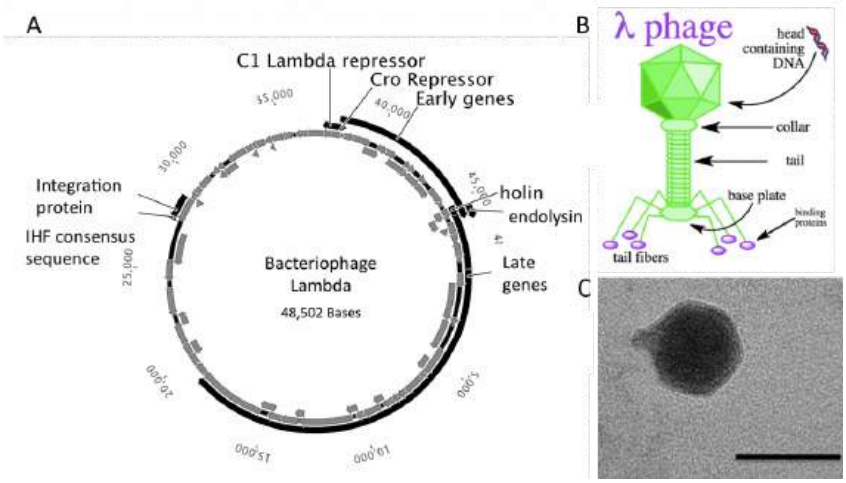

Figure 9.3.6: Lambda Phage. (A) Schematic representation of the circular genome of the lambda phage (B) Diagram of the Lambda Phage infectious particle and (C) Electron micrograph of the related bacteriophage, vibriophage VvAWI. The bar denotes 50 nm in length. *Images A and C are modified from Nigro, O, Culley, A., and Steward, G.F. (2012) Standards in Genomic Science 6(3):415-26, and image B is from Jack Potte*

Cosmids

Cosmids are plasmids that incorporate a segment of bacteriophage λ DNA that has the cohesive end sites (*cos*) which contain elements required for packaging DNA into λ particles. It is normally used to clone large DNA fragments between 28 and 45 Kb.

Bacterial artificial chromosome

Insert size of up to 350 kb can be cloned in a bacterial artificial chromosome (BAC). BACs are maintained in *E. coli* with a copy number of only 1 per cell. BACs have often been used to sequence the genome of organisms in genome projects, including the Human Genome Project. A short piece of the organism's DNA is amplified as an insert in BACs, and hen sequenced. Finally, the sequenced parts are rearranged *in silico*, resulting in the genomic sequence of the organism. BACs have largely been replaced in this capacity with faster and less laborious sequencing methods like whole genome shotgun sequencing and now more recently next-gen sequencing.

Yeast artificial chromosome

Yeast artificial chromosomes are used as vectors to clone DNA fragments of more than 1 megabase (1Mb = 1000kb = 1,000,000 bases) in size. They are useful in cloning larger DNA fragments as required in mapping genomes such as in the human genome project. It contains a telomeric sequence, an autonomously replicating sequence(features required to replicate linear chromosomes in yeast cells). These vectors also contain suitable restriction sites to clone foreign DNA as well as genes to be used as selectable markers.

Human artificial chromosome

Human artificial chromosomes may be potentially useful as gene transfer vectors for gene delivery into human cells, and a tool for expression studies and determining human chromosome function. It can carry very large DNA fragments (there is no upper limit on size for practical purposes), therefore it does not have the problem of limited cloning capacity of other vectors, and it also avoids possible insertional mutagenesis caused by integration into host chromosomes by a viral vector.

Animal and plant viral vectors that infect plant and animal cells have also been manipulated to introduce foreign genes into plant and animal cells. The natural ability of viruses to adsorb to cells, introduce their DNA and replicate has made them ideal vehicles to transfer foreign DNA into eukaryotic cells in culture. A vector based on Simian virus 40 (SV40) was used in first the cloning experiment involving mammalian Severall vectors based on viruses like Adenoviruses and Papilloma virus have been used to clone genes in mammals. At present, retroviral vectors are popular for cloning genes in mammalian cells. In the case of plant transformation, viruses including the Cauliflower Mosaic Virus, Tobcco Mosaic Virus, and Gemini Viruses have been used with limited success.

9.3.3: Summary of DNA Cloning

Figure 9.3.7 provides a summary of the basic cloning methods most widely used in biochemistry laboratories. Foreign DNA is isolated or amplified using PCR to obtain enough material for the cloning procedure. The DNA is purified and cut with restriction enzymes, and then mixed with a vector that has been cut with the same restriction enzymes. The DNA can then be stitched back together with DNA ligase. The DNA can then be transformed into a host system, often bacteria, to grow large quantities of the plasmid containing the cloned DNA.

Restriction fragment patterning and DNA sequencing can be used to validate the cloned material. For a Video Tutorial on DNA Cloning visit HHMI - BioInteractive.

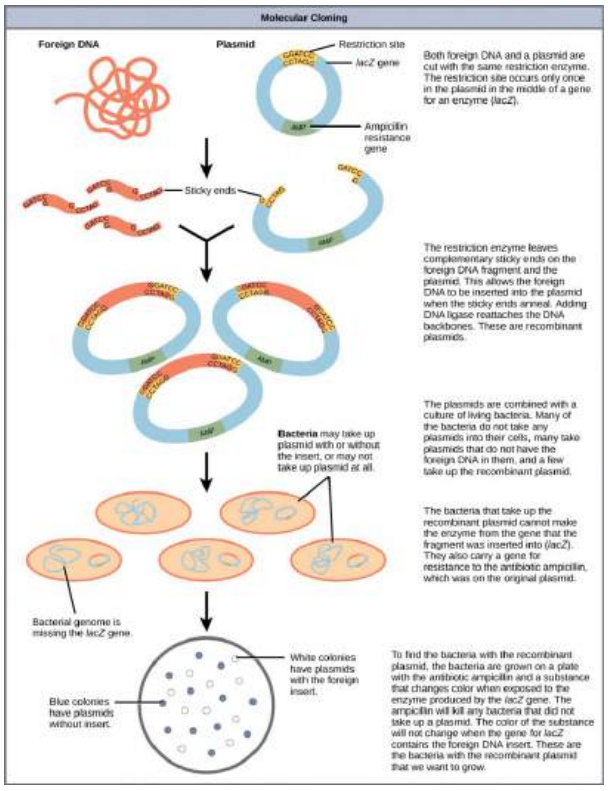

Figure 9.3.7: **Diagram Showing the Major Steps in Cloning.**

Plasmids with foreign DNA inserted into them are called recombinant DNA molecules because they contain new combinations of genetic material. Proteins that are produced from recombinant DNA molecules are called recombinant proteins. Not all recombinant plasmids are capable of expressing genes. Plasmids may also be engineered to express proteins only when stimulated by certain environmental factors, so that scientists can control the expression of the recombinant proteins.

9.3.4: Reproductive Cloning

Reproductive cloning is a method used to make a clone or an **identical copy of an entire multicellular organism**. Most multicellular organisms undergo reproduction by sexual means, which involves the contribution of DNA from two individuals (parents), making it impossible to generate an identical copy or a clone of either parent. Recent advances in biotechnology have made it possible to reproductively clone mammals in the laboratory.

Natural sexual reproduction involves the union, during fertilization, of a sperm and an egg. Each of these gametes is ***haploid,*** meaning they contain one set of chromosomes in their nuclei. The resulting cell, or zygote, is then ***diploid*** and contains two sets of chromosomes. This cell divides mitotically to produce a multicellular organism. However, the union of just any two cells cannot produce a viable zygote; there are components in the cytoplasm of the egg cell that are essential for the early development of the embryo during its first few cell divisions. Without these provisions, there would be no subsequent development. Therefore, to produce a new individual, both a diploid genetic complement and an egg cytoplasm are required. The approach to producing an artificially cloned individual is to take the egg cell of one individual and to remove the haploid nucleus. Then a diploid nucleus

from a body cell of a second individual, the donor, is put into the egg cell. The egg is then stimulated to divide so that development proceeds. This sounds simple, but it takes many attempts before each of the steps is completed successfully.

The first cloned agricultural animal was Dolly, a sheep who was born in 1996 (see **Figure 9.3.8** below). The success rate of reproductive cloning at the time was very low. Dolly lived for six years and died of a lung tumor. There was speculation that because the cell DNA that gave rise to Dolly came from an older individual, the age of the DNA may have affected her life expectancy. Since Dolly, several species of animals (such as horses, bulls, and goats) have been successfully cloned.

There have been attempts at producing cloned human embryos as sources of embryonic stem cells. In the procedure, the DNA from an adult human is introduced into a human egg cell, which is then stimulated to divide. The technology is similar to the technology that was used to produce Dolly, but the embryo is never implanted into a surrogate mother. The cells produced are called embryonic stem cells because they can develop into many different kinds of cells, such as muscle or nerve cells. The stem cells could be used to research and ultimately provide therapeutic applications, such as replacing damaged tissues. The benefit of cloning in this instance is that the cells used to regenerate new tissues would be a perfect match to the donor of the original DNA. For example, a leukemia patient would not require a sibling with a tissue match for a bone-marrow transplant.

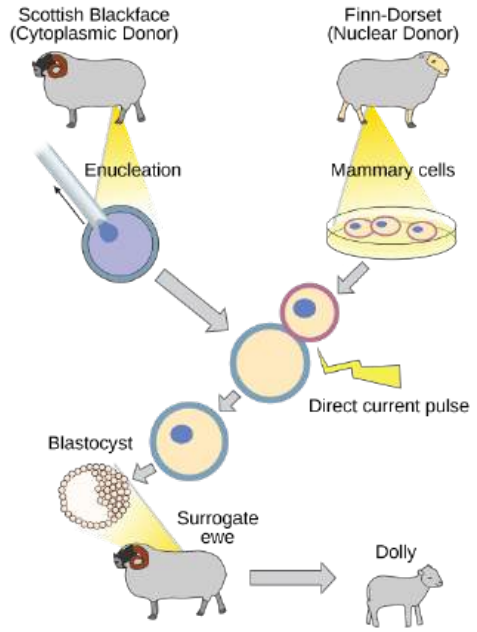

Figure 9.3.8: Cloning of Dolly, the first agricultural animal to be cloned.

To create Dolly, the nucleus was removed from a donor egg cell. The enucleated egg was placed next to the other cell, then they were shocked to fuse. They were shocked again to start division. The cells were allowed to divide for several days until an early embryonic stage was reached, before being implanted in a surrogate mother.

Why was Dolly a Finn-Dorset and not a Scottish Blackface sheep?

Because even though the original cell came from a Scottish Blackface sheep and the surrogate mother was a Scottish Blackface, the DNA came from a Finn-Dorset.

9.3.5: Genetic Engineering

Genetic engineering uses recombinant DNA technology to modify an organism's DNA to achieve desirable traits. The addition of foreign DNA in the form of recombinant DNA vectors that are generated by molecular cloning is the most common method of genetic engineering. An organism that receives the recombinant DNA is called a ***genetically modified organism (GMO)***. If the foreign DNA that is introduced comes from a different species, the host organism is called ***transgenic***. Bacteria, plants, and animals have been genetically modified since the early 1970s for academic, medical, agricultural, and industrial purposes.

Watch this short video explaining how scientists create a transgenic animal.

Although the classic methods of studying the function of genes began with a given phenotype and determined the genetic basis of that phenotype, modern techniques allow researchers to start at the DNA sequence level and ask: "What does this gene or DNA element do?" This technique, called ***reverse genetics***, has resulted in reversing the classical genetic methodology. One example of

this method is analogous to damaging a body part to determine its function. An insect that loses a wing cannot fly, which means that the wing's function is flight. The classic genetic method compares insects that cannot fly with insects that can fly, and observes that the non-flying insects have lost wings. Similarly in a reverse genetics approach, mutating or deleting genes provides researchers with clues about gene function. Alternately, reverse genetics can be used to cause a gene to overexpress itself to determine what phenotypic effects may occur.

9.3.6: CRISPR Technology

CRISPR stands for ***clustered regularly interspaced short palindromic repeats*** and represents a family of DNA sequences found within the genomes of prokaryotic organisms such as bacteria and archaea. These sequences are derived from DNA fragments of bacteriophages that have previously infected the prokaryote and are used to detect and destroy DNA from similar phages during subsequent infections. Hence these sequences play a key role in the antiviral defense system of prokaryotes. Figure 9.3.9 shows the c**rystal structure of a CRISPR RNA-guided surveillance complex, Cascade, bound to a ssDNA target,**

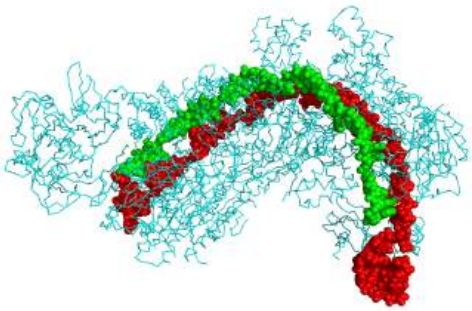

Figure 9.3.9: **Crystal structure of a CRISPR RNA-guided surveillance complex, Cascade, bound to a ssDNA target.** CRISPR system Cascade protein subunits CasA, CasB, CasC, CasD, and CasE (cyan) bound to CRISPR RNA (green) and viral DNA (red) based on PDB 4QYZ and rendered with PyMOL. *Image from Boghog*

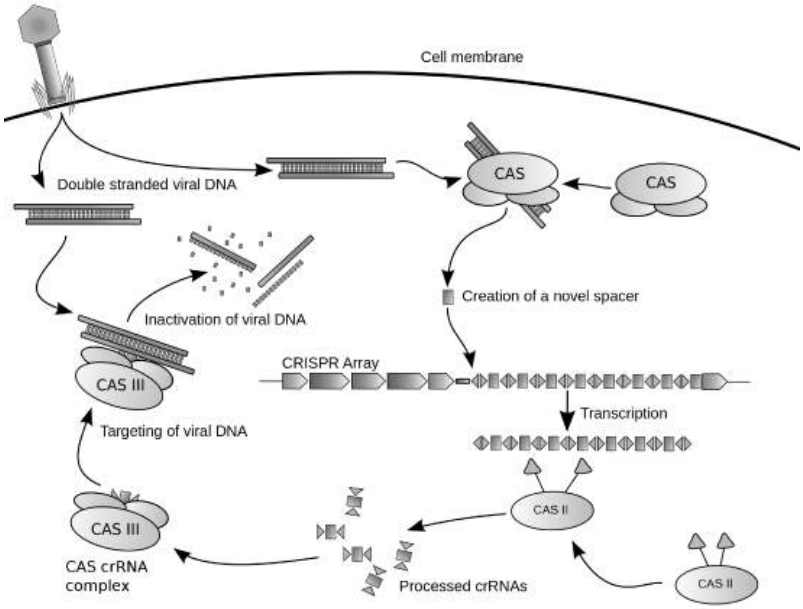
Cas9 (or "CRISPR-associated protein 9") is an enzyme that uses CRISPR sequences as a guide to recognize and cleave specific strands of DNA that are complementary to the CRISPR sequence. Cas9 enzymes together with CRISPR sequences form the basis of a technology known as CRISPR-Cas9 that can be used to edit genes within organisms. This editing process has a wide variety of applications including basic biological research, the development of biotechnology products, and the treatment of diseases. Figure 9.3.10s shows a d**iagram of the CRISPR prokaryotic antiviral defense mechanism**



(\PageIndex{10}\): **Diagram of the CRISPR prokaryotic antiviral defense mechanism.** *Image by James Atmos*

The CRISPR-Cas system is a prokaryotic immune system that confers resistance to foreign genetic elements such as those present within plasmids and phages that provide acquired immunity. RNA harboring the spacer sequence helps Cas (CRISPR-associated) proteins recognize and cut foreign pathogenic DNA. Other RNA-guided Cas proteins cut foreign RNA. CRISPR is found in approximately 50% of sequenced bacterial genomes and nearly 90% of sequenced archaea.

9.4: DNA Microarrays

A ***DNA microarray*** (also commonly known as a DNA chip or biochip) is a collection of microscopic DNA spots attached to a solid surface. Scientists use DNA microarrays to measure the expression levels of large numbers of genes simultaneously or to genotype multiple regions of a genome. Each DNA spot contains picomoles (10^{-12} moles) of a specific DNA sequence, known as *probes* (or *reporters* or *oligos*). These can be a short section of a gene or other DNA element that is used to hybridize a cDNA or cRNA (also called anti-sense RNA) sample (called *target*) under high-stringency conditions. Probe-target hybridization is usually detected and quantified by the detection of fluorophore-, silver-, or chemiluminescence-labeled targets to determine the relative abundance of nucleic acid sequences in the target. The original nucleic acid arrays were macroarrays approximately 9 cm × 12 cm and the first computerized image-based analysis was published in 1981. It was invented by Patrick O. Brown. Figure 9.4.1 shows a schematic of DNA Microarrays.

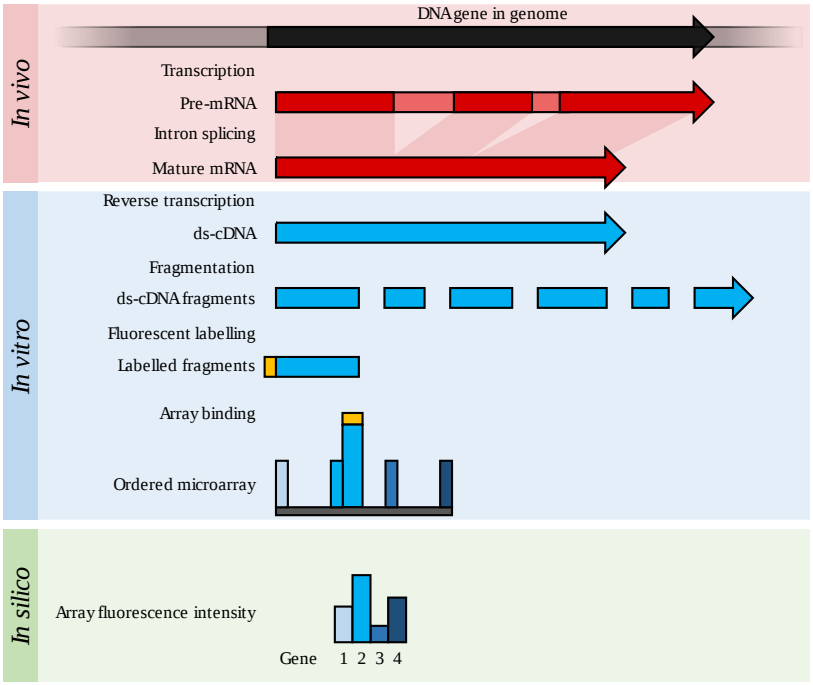


Figure 9.4.1: Schematic of DNA Microarrays. Image by Thomas Shafee

Within the organisms, genes are transcribed and spliced to produce mature mRNA transcripts (red). The mRNA is extracted from the organism and reverse transcriptase is used to copy the mRNA into stable ds-cDNA (blue). In microarrays, the ds-cDNA is fragmented and fluorescently labeled (orange). The labeled fragments bind to an ordered array of complementary oligonucleotides, and measurement of fluorescent intensity across the array indicates the abundance of a predetermined set of sequences. These sequences are typically specifically chosen to report on genes of interest within the organism's genome.

The core principle behind microarrays is a hybridization between two DNA strands, the property of complementary nucleic acid sequences to specifically pair with each other by forming hydrogen bonds between complementary nucleotide base pairs. A high number of complementary base pairs in a nucleotide sequence means tighter non-covalent bonding between the two strands. After washing off non-specific bonding sequences, only strongly paired strands will remain hybridized. Fluorescently labeled target sequences that bind to a probe sequence generate a signal that depends on the hybridization conditions (such as temperature),and washing after hybridization. The total strength of the signal, from a spot (feature), depends upon the amount of target sample binding to the probes present on that spot. Microarrays use relative quantitation in which the intensity of a feature is compared to the intensity of the same feature under a different condition, and the identity of the feature is known by its position. Figure 9.4.2s shows the hybridization of target and probe DNA on a microarray.

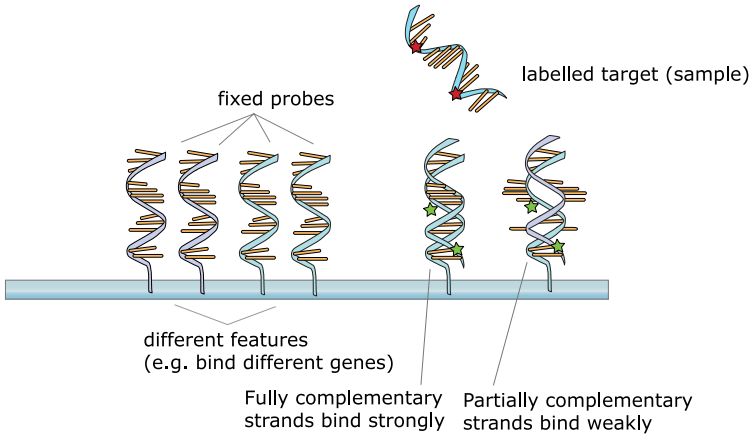

Figure 9.4.2: Hybridization of Target DNA with the Probe DNA During Microarray Analysis. Image by Squidonius

Many types of arrays exist and the broadest distinction is whether they are spatially arranged on a surface or coded beads:

- The traditional solid-phase array is a collection of orderly microscopic "spots", called features, each with thousands of identical and specific probes attached to a solid surface, such as glass, plastic, or silicon biochip (commonly known as a *genome chip*, *DNA chip* or *gene array*). Thousands of these features can be placed in known locations on a single DNA microarray.
- The alternative bead array is a collection of microscopic polystyrene beads, each with a specific probe and a ratio of two or more dyes, which do not interfere with the fluorescent dyes used on the target sequence.

DNA microarrays can be used to detect DNA (as in comparative genomic hybridization), or detect RNA (most commonly as cDNA after reverse transcription) that may or may not be translated into proteins. The process of measuring gene expression via cDNA is called expression analysis or expression profiling.

9.4.1: Fabrication

Microarrays can be manufactured in different ways, depending on the number of probes under examination, costs, customization requirements, and the type of scientific question being asked. Arrays from commercial vendors may have as few as 10 probes or as many as 5 million or more micrometer-scale probes.

9.4.2: Spotted vs. *in situ* synthesized arrays

Play media

Microarrays can be fabricated using a variety of technologies, including printing with fine-pointed pins onto glass slides, photolithography using pre-made masks, photolithography using dynamic micromirror devices, ink-jet printing, or electrochemistry on microelectrode arrays.

In *spotted microarrays*, the probes are oligonucleotides, cDNA, or small fragments of PCR products that correspond to mRNAs. The probes are synthesized before deposition on the array surface and are then "spotted" onto glass. A common approach utilizes an array of fine pins or needles controlled by a robotic arm that is dipped into wells containing DNA probes and then depositing each probe at designated locations on the array surface. The resulting "grid" of probes represents the nucleic acid profiles of the prepared probes and is ready to receive complementary cDNA or cRNA "targets" derived from experimental or clinical samples. This technique is used by research scientists around the world to produce "in-house" printed microarrays from their labs. These arrays may be easily customized for each experiment, because researchers can choose the probes and printing locations on the arrays, synthesize the probes in their labs (or collaborating facility), and spot the arrays. They can then generate their own labeled samples for hybridization, hybridize the samples to the array, and finally scan the arrays with their equipment. This provides a relatively low-cost microarray that may be customized for each study and avoids the costs of purchasing often more expensive commercial arrays that may represent vast numbers of genes that are not of interest to the investigator. Publications exist which indicate in-house spotted microarrays may not provide the same level of sensitivity compared to commercial oligonucleotide arrays, possibly owing to the small batch sizes and reduced printing efficiencies when compared to industrial manufacturers of oligo arrays.

In *oligonucleotide microarrays*, the probes are short sequences designed to match parts of the sequence of known or predicted open reading frames. Although oligonucleotide probes are often used in "spotted" microarrays, the term "oligonucleotide array" most often refers to a specific technique of manufacturing. Oligonucleotide arrays are produced by printing short oligonucleotide sequences designed to represent a single gene or family of gene splice-variants by synthesizing this sequence directly onto the array surface instead of depositing intact sequences. Sequences may be longer (60-mer probes such as the Agilent design) or shorter (25-mer probes produced by Affymetrix) depending on the desired purpose; longer probes are more specific to individual target genes, shorter probes may be spotted in higher density across the array and are cheaper to manufacture. One technique used to produce oligonucleotide arrays includes photolithographic synthesis (Affymetrix) on a silica substrate where light and light-sensitive masking agents are used to "build" a sequence one nucleotide at a time across the entire array. Each applicable probe is selectively "unmasked" before bathing the array in a solution of a single nucleotide, then a masking reaction takes place and the next set of probes are unmasked in preparation for a different nucleotide exposure. After many repetitions, the sequences of every probe become fully constructed. More recently, Maskless Array Synthesis from NimbleGen Systems has combined flexibility with large numbers of probes. Figure 9.4.3 shows a diagram of a typical dual-color microarray experiment.

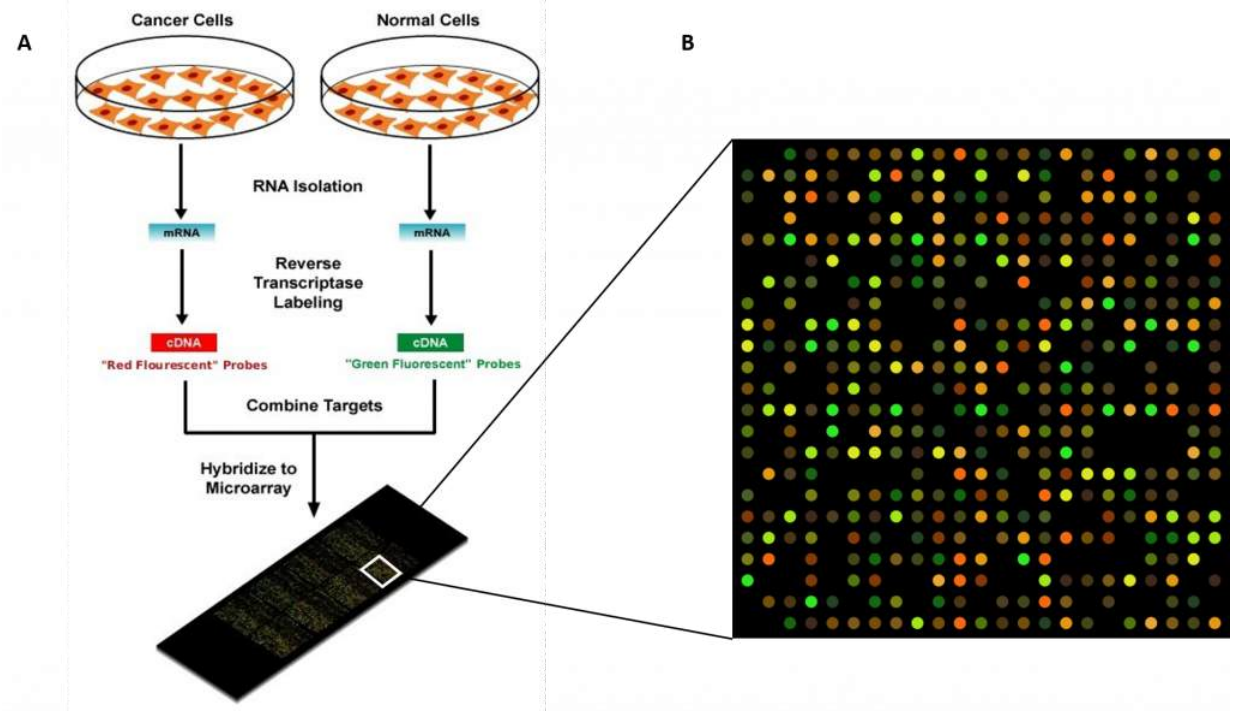

Figure 9.4.3: Diagram of a typical dual-color microarray experiment. Within a dual-color microarray, the probe DNA is typically hybridized with cDNA prepared from two different samples, each labeled with a different fluorescent probe. The analysis will yield green fluorescence for one sample that upregulates gene expression, whereas the other sample tagged with a red fluorescence marker will indicate that the other condition elicits gene expression at that location. Yellow indicates gene expression in both samples. Image A modified from Larssono and Image B from Guillaume Paumier

Two-color microarrays or ***two-channel microarrays*** are typically hybridized with cDNA prepared from two samples to be compared (e.g. diseased tissue versus healthy tissue) and that are labeled with two different fluorophores. Fluorescent dyes commonly used for cDNA labeling include Cy3, which has a fluorescence emission wavelength of 570 nm (corresponding to the green part of the light spectrum), and Cy5 with a fluorescence emission wavelength of 670 nm (corresponding to the red part of the light spectrum). The two Cy-labeled cDNA samples are mixed and hybridized to a single microarray that is then scanned in a microarray scanner to visualize the fluorescence of the two fluorophores after excitation with a laser beam of a defined wavelength. Relative intensities of each fluorophore may then be used in ratio-based analysis to identify up-regulated and down-regulated genes.

Oligonucleotide microarrays often carry control probes designed to hybridize with RNA spike-ins. The degree of hybridization between the spike-ins and the control probes is used to normalize the hybridization measurements for the target probes. Although absolute levels of gene expression may be determined in the two-color array in rare instances, the relative differences in expression among different spots within a sample and between samples are the preferred method of data analysis for the two-color system.

Examples of providers for such microarrays include Agilent with their Dual-Mode platform, Eppendorf with their DualChip platform for colorimetric Silverquant labeling, and TeleChem International with Arrayit.

In ***single-channel microarrays*** or ***one-color microarrays***, the arrays provide intensity data for each probe or probe set indicating a relative level of hybridization with the labeled target. However, they do not truly indicate abundance levels of a gene but rather a relative abundance when compared to other samples or conditions when processed in the same experiment. Each RNA molecule encounters protocol and batch-specific bias during the amplification, labeling, and hybridization phases of the experiment making comparisons between genes for the same microarray uninformative. The comparison of two conditions for the same gene requires two separate single-dye hybridizations. Several popular single-channel systems are the Affymetrix "Gene Chip", Illumina "Bead Chip", Agilent single-channel arrays, the Applied Microarrays "CodeLink" arrays, and the Eppendorf "DualChip & Silverquant". One strength of the single-dye system lies in the fact that an aberrant sample cannot affect the raw data derived from other samples, because each array chip is exposed to only one sample (as opposed to a two-color system in which a single low-quality sample may drastically impinge on overall data precision even if the other sample was of high quality). Another benefit is that data are more easily compared to arrays from different experiments as long as batch effects have been accounted for.

9.5: In Situ Hybridization

In situ hybridization (ISH) is a type of hybridization that uses a labeled complementary DNA, RNA, or modified nucleic acids strand (i.e., probe) to localize a specific DNA or RNA sequence in a portion or section of tissue (*in situ*) or if the tissue is small enough (e.g., plant seeds, *Drosophila* embryos), in the entire tissue (whole mount ISH), in cells, and in circulating tumor cells (CTCs). This is distinct from immunohistochemistry, which usually localizes proteins in tissue sections.

In situ hybridization is used to reveal the location of specific nucleic acid sequences on chromosomes or in tissues, a crucial step for understanding the organization, regulation, and function of genes. The key techniques currently in use include *in situ* hybridization to mRNA with oligonucleotide and RNA probes (both radio-labeled and hapten-labeled), analysis with light and electron microscopes, whole mount *in situ* hybridization, double detection of RNAs and RNA plus protein, and fluorescent *in situ* hybridization to detect chromosomal sequences. DNA ISH can be used to determine the structure of chromosomes. Fluorescent DNA ISH (FISH) can, for example, be used in medical diagnostics to assess chromosomal integrity. RNA ISH (RNA *in situ* hybridization) is used to measure and localize RNAs (mRNAs, lncRNAs, and miRNAs) within tissue sections, cells, whole mounts, and circulating tumor cells (CTCs). *In situ* hybridization was invented by Mary-Lou Pardue and Joseph G. Gall.

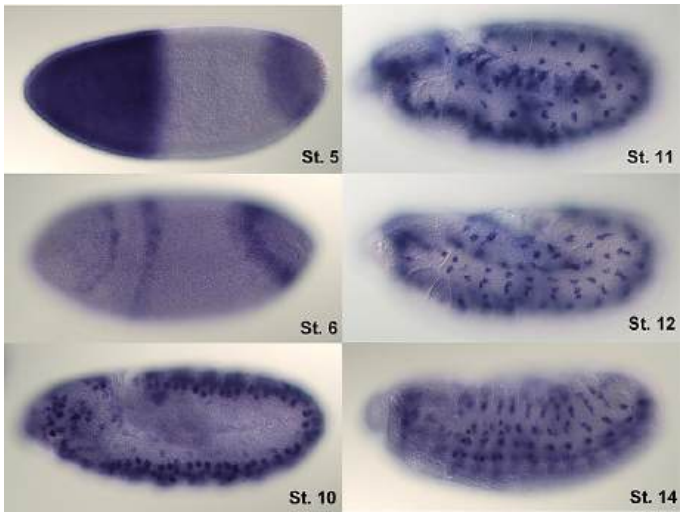

Figure 5.28 In Situ Hybridization of wild-type *Drosophila* embryos at different developmental stages for the RNA from a gene called hunchback. *Image by Nina*

For hybridization histochemistry, sample cells and tissues are usually treated to fix the target transcripts in place and to increase access to the probe. As noted above, the probe is either a labeled complementary DNA or, now most commonly, a complementary RNA (riboprobe). The probe hybridizes to the target sequence at elevated temperature, and then the excess probe is washed away (after prior hydrolysis using RNase in the case of unhybridized, excess RNA probe). Solution parameters such as temperature, salt, and/or detergent concentration can be manipulated to remove any non-identical interactions (i.e., only exact sequence matches will remain bound). Then, the probe that was labeled with either radio-, fluorescent- or antigen-labeled bases (e.g., digoxigenin) is localized and quantified in the tissue, using either autoradiography, fluorescence microscopy, or immunohistochemistry, respectively. ISH can also use two or more probes, labeled with radioactivity or other non-radioactive labels, to simultaneously detect two or more transcripts.

An alternative technology, branched DNA assay, can be used for RNA (mRNA, lncRNA, and miRNA) *in situ* hybridization assays with single molecule sensitivity without the use of radioactivity. This approach (e.g., ViewRNA assays) can be used to visualize up to four targets in one assay, and it uses patented probe design and bDNA signal amplification to generate sensitive and specific signals. Samples (cells, tissues, and CTCs) are fixed, then treated to allow RNA target accessibility (RNA un-masking). Target-specific probes hybridize to each target RNA. Subsequent signal amplification is predicated by specific hybridization of adjacent probes (individual oligonucleotides [oligos] that bind side by side on RNA targets). A typical target-specific probe will contain 40 oligonucleotides, resulting in 20 oligo pairs that bind side-by-side on the target for the detection of mRNA and lncRNA, and 2 oligos or a single pair for miRNA detection. Signal amplification is achieved via a series of sequential hybridization steps. A pre-amplifier molecule hybridizes to each oligo pair on the target-specific RNA, then multiple amplifier molecules hybridize to each pre-amplifier. Next, multiple-label probe oligonucleotides (conjugated to alkaline phosphatase or directly to fluorophores) hybridize to each amplifier molecule. A fully assembled signal amplification structure “Tree” has 400 binding sites for the label

probes. When all target-specific probes bind to the target mRNA transcript, an 8,000-fold signal amplification occurs for that one transcript. Separate but compatible signal amplification systems enable multiplex assays. The signal can be visualized using a fluorescence or brightfield microscope.

CHAPTER OVERVIEW

10: Lipids

10.1: Introduction to lipids
10.2: Lipids Aggregates in Water - Micelles and Liposomes
10.3: Membrane Bilayer and Monolayer Assemblies - Structures and Dynamics
10.4: Working with Lipids
10.5: Problems

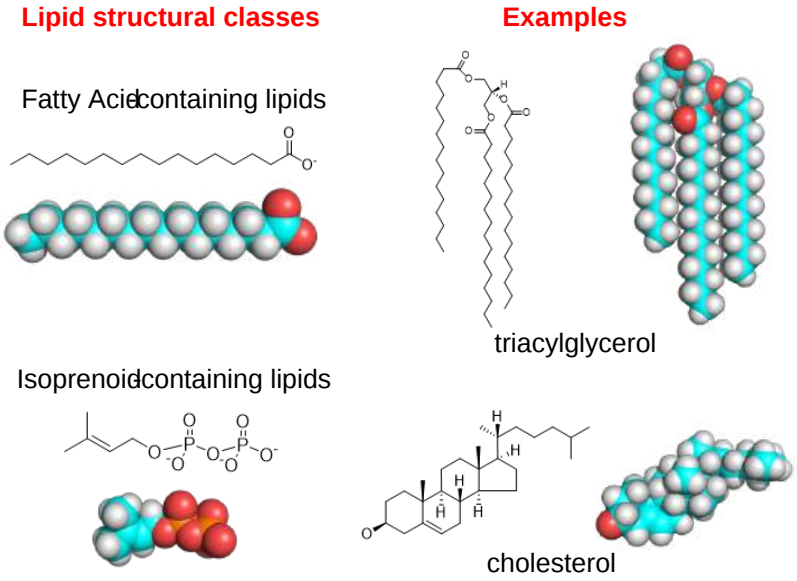
10.1: Introduction to lipids

10.1.1: Introduction to Lipids

(Thanks to Rebecca Roston for providing a cohesive organizational framework and image templates)

Lipids are organic molecule molecules that are soluble in organic solvents, such as chloroform/methanol, but sparingly soluble in aqueous solutions. These solubility properties arise since lipids are mostly hydrophobic. One type, triglycerides, is used for energy storage since they are highly reduced and get oxidized to release energy. Their hydrophobic nature allows them to pack efficiently through self-association in an aqueous environment. Triglycerides are also used for insulation since they conduct heat poorly, which is good if you live in a cold climate but bad if you wish to dissipate heat in a hot one. Triglycerides also offer padding and mechanical protection from shocks (think walruses). Another type of lipid forms membrane bilayers, which separate cellular contents from the outside environment, or separate intracellular compartments (organelles) from the cytoplasm. Some lipids are released from cells to signal other cells to change to specific stimuli in a process called cell signaling. From a more molecular perspective, lipids can act as cofactors for enzymes, pigments, antioxidants, and water repellents. As we saw with proteins, lipid structure mediates their function. So let's probe their structures.

Lipids can be split into structural classes in a variety of ways. An earlier classification divided them into those that release fatty acids on based-catalyzed hydrolysis to form soaps in a saponification reaction and those that don't. A much better and broader classification is based on if the lipids contain fatty acids or isoprenoids, as shown in Figure 10.1.1 below.



10.1.1.1:

Figure 10.1.1: Fatty acids and isoprenoid lipids

The nonpolar chains of the fatty acid are drawn in the figure above in the lowest energy zig-zag fashion as we saw when we discussed the main chain conformation of proteins (Chapter 4.1). In that chapter, we started with the exploration of a long 12 C chain carboxylic acid, dodecanoic acid. In the lowest energy conformation, the dihedral angles are all $\pm$ 180^0 to minimize torsional strain in the molecule. Rotation around one C-C bond can produce a gauche form, which introduces a kink into the chain as shown in Figure 10.1.2

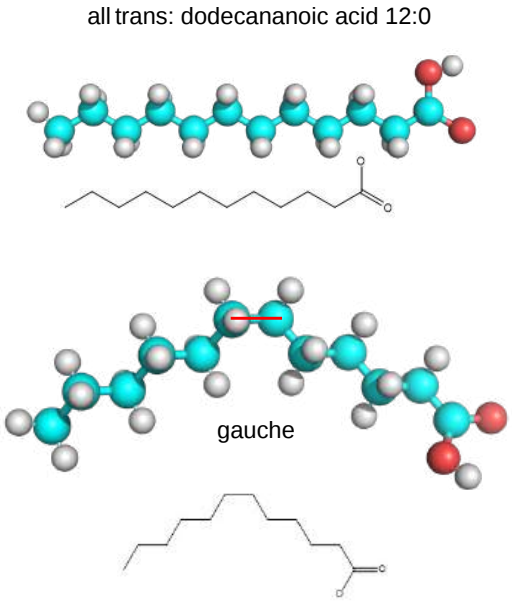


Figure 10.1.2: Trans and Gauche bonds in a fatty acids

10.1.2: Fatty Acids

Fatty acids can be free or covalently linked by ester or amide link to a base molecule like triglycerides or membrane lipids. The key principle that we learned with our study of proteins, that structure determines function, also applies to lipids. The figure below shows three different types of molecules, a free fatty acid, a wax with an esterified fatty acid, and a glycolipid with a fatty acid connected by an amide link in another type of lipid (glycosphingolipid). Each has different properties leading to different functions. Waxes for instance are very nonpolar and water-insoluble. They are amorphous solids at room temperature but, depending on their structure, can easily melt to form high-viscosity liquids. They are used as a coating on the surfaces of leaves to help prevent water loss. The glycolipids (glyco- as it contains a monosaccharide group) are constituents of membrane bilayers. Figure 10.1.3 shows the general structures of fatty acid-containing waxes and other lipids.

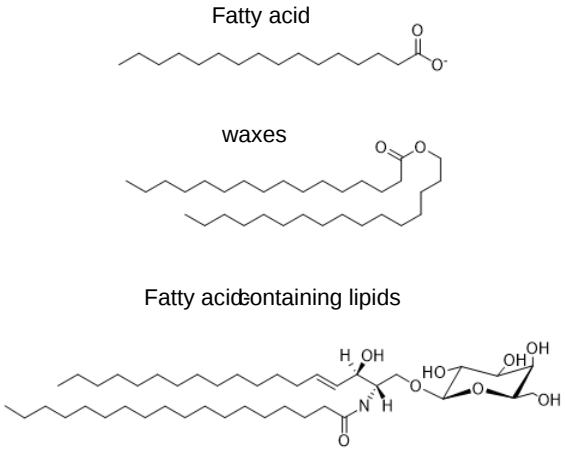

Figure 10.1.3: Fatty acids in waxes and glycolipids

Fatty acids vary in length, usually contain an even number of carbon atoms, and can be saturated (have no double bonds in the acyl chain), or unsaturated (with either one -monounsaturated - or multiple - polyunsaturated - cis double bond(s)). The double bonds are NOT conjugated as they are separated by a methylene (-CH_2-) spacer. Fatty acids can be named in many ways.

- symbolic name: given as x:y $^{\Delta\ a,b,c}$ where x is the number of carbon atoms in the chain, y is the number of double bonds, and a, b, and c are the positions of the start of the double bonds counting from C1 - the carboxyl carbon. Double bonds are usually cis (Z).
- systematic name using IUPAC nomenclature. The systematic name gives the number of carbon atoms in the chain (e.g. hexadecanoic acid for 16:0). If the fatty acid is unsaturated, the base name reflects the number of double bonds (e.g. octadecenoic acid for 18:1 $^{\Delta\ 9}$ and octadecatrienoic acid for 18:3$^{\Delta\ 9,12,15}$).
- common name: (e.g. oleic acid, 18:1$^{\Delta 9}$), which is found in high concentration in olive oil)

They can be named most easily with a symbolic name. Figure 10.1.4 shows examples of fatty acids and their symbolic names.

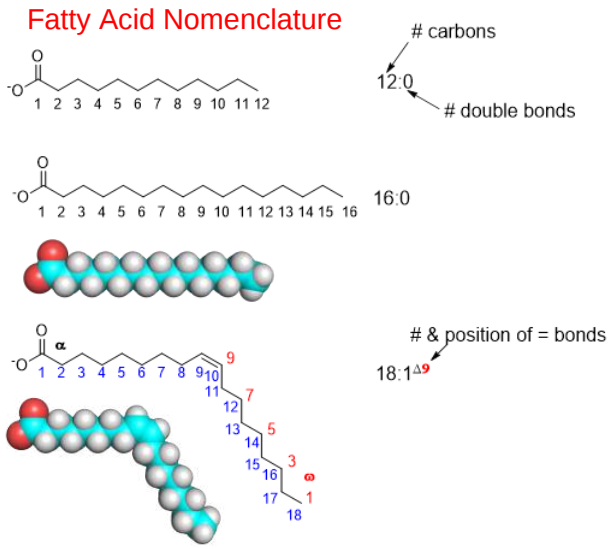

Figure 10.1.4: Some fatty acids and their symbolic names.

There is an alternative to the symbolic representation of fatty acids, in which the carbon atoms are numbered from the distal end (the n or ω end) of the acyl chain (the opposite end from the alpha carbon). Hence 18:3 $^{\Delta\ 9,12,15}$ could be written as 18:3 (ω -3) or 18:3 (n -3), where the terminal C is numbered one and the first double bond starts at C3.

The most common saturated fatty acids found in biochemistry textbooks are listed in the table below. Note how the melting point increases with the length of the hydrocarbon chain. This arises from increasing noncovalent induced dipole-induced dipole attractions between the long chains. Heat must be added to lessen these attractions to allow melting. Table 10.1.1 below shows examples of fatty acids and their symbolic names.

Symbolic	common name	systematic name	structure	mp(C)
12:0	Lauric acid	dodecanoic acid	$CH_3(CH_2)_{10}COOH$	44.2
14:0	Myristic acid	tetradecanoic acid	$CH_3(CH_2)_{12}COOH$	52
16:0	Palmitic acid	Hexadecanoic acid	$CH_3(CH_2)_{14}COOH$	63.1
18:0	Stearic acid	Octadecanoic acid	$CH_3(CH_2)_{16}COOH$	69.6
20:0	Arachidic aicd	Eicosanoic acid	$CH_3(CH_2)_{18}COOH$	75.4

Table 10.1.1: Examples of fatty acids and their symbolic names

Table 10.1.2 below shows common unsaturated fatty acids. Arachidonic acid is an (ω -6) fatty acid while docosahexaenoic acid is an (ω -3) fatty acid. Note the decreasing melting point for the 18:X series with an increasing number of double bonds.

Symbol	common name	systematic name	structure	mp(C)
16:1$^{\Delta 9}$	Palmitoleic acid	Hexadecenoic acid	$CH_3(CH_2)_5CH{=}CH{-}(CH_2)_7COOH$	-0.5
18:1$^{\Delta 9}$	Oleic acid	9-Octadecenoic acid	$CH_3(CH_2)_7CH{=}CH{-}(CH_2)_7COOH$	13.4

Symbol	common name	systematic name	structure	mp(C)
$18:2^{\Delta 9,12}$	Linoleic acid	9,12 -Octadecadienoic acid	$CH_3(CH_2)_4(CH{=}CHCH_2)_2(CH_2)_6COOH$	-9
$18:3^{\Delta 9,12,15}$	α-Linolenic acid	9,12,15 -Octadecatrienoic acid	$CH_3CH_2(CH{=}CHCH2)3(CH2)6COOH$	-17
$20:4^{\Delta 5,8,11,14}$	arachidonic acid	5,8,11,14- Eicosatetraenoic acid	$CH3(CH2)_4(CH{=}CHCH_2)_4(CH_2)_2COOH$	-49
$20:5^{\Delta 5,8,11,14,17}$	EPA	5,8,11,14,17-Eicosapentaenoic-acid	$CH_3CH_2(CH{=}CHCH_2)_5(CH_2)_2COOH$	-54
$22:6^{\Delta 4,7,10,13,16,19}$	DHA	Docosohexaenoic acid	22:6w3	

Table 10.1.2: Common unsaturated fatty acids

Let's consider how the presence of double bonds in fatty acids influences their melting points. Figure 10.1.5 shows common variants of fatty acids each with 18 carbon atoms. Compare the Lewis structure and spacefill models below. What a difference a cis double bond makes!

The double bonds in fatty acids are cis (Z), which introduces a "permanent" kink into the chain, similar to the"temporary" kink in the saturated dodecanoic acid carboxylic acid with a single gauche bond (Figure 2). The kink is permanent since there is no rotation around the double bond unless it is broken (which can happen through photoisomerization reactions). The more double bonds, the greater the kinking. The more kinks, the less chance for van der Waals contacts between the acyl chains, and reduces induced-dipole-induced dipole interactions between the chains, leading to lowered melting points.

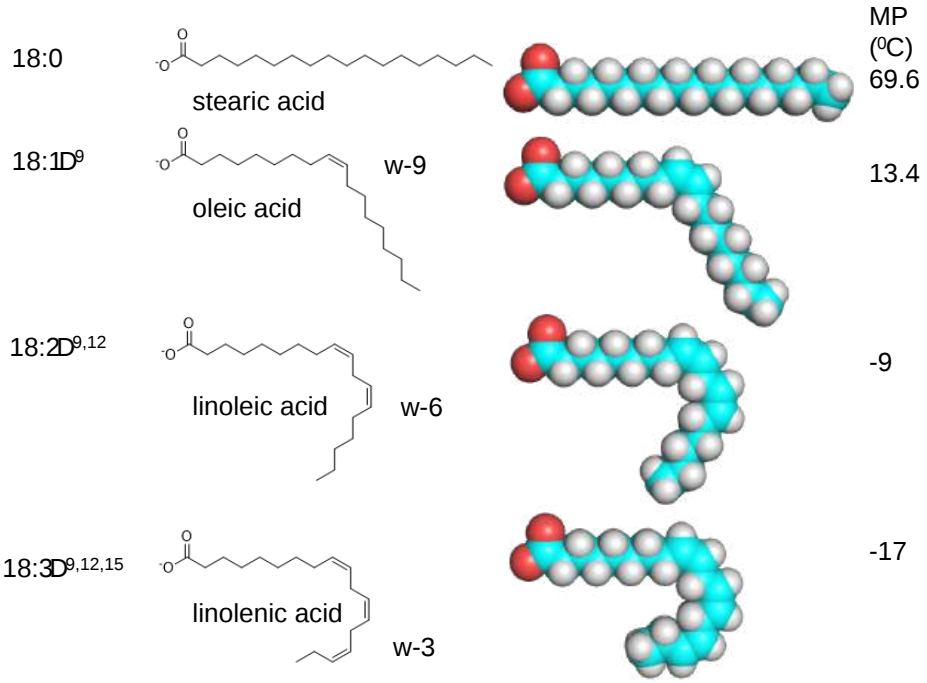

Figure 10.1.5: Fatty acids with 18 carbon atoms

Now in your mind, replace the cis double bond in oleic acid with a trans. You should now see a long "zig-zag" shaped molecule with no kinks. Trans fatty acids are rare in biology but are produced in the industrial partial hydrogenation of fats, which is done to decrease the number of double bonds and make the fats more solid-like and tastier while decreasing rancidity. These trans fatty acids would pack closer together and affect the structure and function of the lipid in a given environment (such as a membrane bilayer). Increased consumption of trans fatty acids is associated with an increased risk of cardiovascular disease.

Table 10.1.3 shows the percentages of fatty acids in different oils/fats

FAT	<16:0	16:1	18:0	18:1	18:2	18:3	20:0	22:1	22:2	.
Coconut	87	.	3	7	2	.	.	.	.	.

FAT	<16:0	16:1	18:0	18:1	18:2	18:3	20:0	22:1	22:2	.
Canola	3	.		11	13	10	.	7	50	2
Olive Oil	11	.	4	71	11	1	.	.	.	.
Butter-fat	50	4	12	26	4	1	2	.	.	.

Table 10.1.3: Percentages of fatty acids in different oils/fats

The fatty acid composition differs in different organisms:

- animals have 5-7% of fatty acids with 20-22 carbons, while fish have 25-30%
- animals have <1% of their fatty acids with 5-6 double bonds, while plants have 5-6% and fish 15-30%

As there are essential amino acids that cannot be synthesized by humans, there are also essential fatty acids that must be supplied by the diet. There are only two, one each in the n-6 and n-3 classes:

- n-6 class: α-linoleic acid (18:2 n-6, or $18:2^{\Delta 9,12}$) is a biosynthetic precursor of arachidonic acid (20:4 n-6 or $20:4^{\Delta 5,8,11,14)}$
- n-3 class: linolenic acid (18:3 n-3, or $18:3^{\Delta 9,12,15}$) is a biosynthetic precursor of eicosapentaenoic acid (EPA, 20:5 n-3 or $20:5^{\Delta 5,8,11,14,17}$) and to a much smaller extent, docosahexaenoic acid (DHA, 22:6 n-3 or $22:6^{\Delta 4,7,10,13,16,19}$).

These two fatty acids are essential since mammals cannot introduce double bonds in fatty acids beyond carbon 9. These essential precursor fatty acids are substrates for intracellular enzymes such as elongases and desaturases (to produce 20:4 n-6, 20:5 n-3, and 22:6 n-3 fatty acids), and beta-oxidation type enzymes in the endoplasmic reticulum and another organelle, the peroxisome. The peroxisome is involved in the oxidative metabolism of straight-chain and branched fatty acids, peroxide metabolism, and cholesterol/bile salt synthesis. Animals fed diets high in plant 18:2(n-6) fats accumulate 20:4(n-6) fatty acids in their tissues while those fed diets high in plant 18:3(n-3) accumulate 22:6(n-3). Animals fed diets high in fish oils accumulate 20:5 (EPA) and 22:6 (DHA) at the expense of 20:4(n-6).

Many studies support the claim that diets high in fish that contain abundant ω-3 fatty acids, in particular EPA and DHA, reduce inflammation and cardiovascular disease. ω-3 fatty acids are abundant in high-oil fish (salmon, tuna, sardines), and lower in cod, flounder, snapper, shark, and tilapia.

Some suggest that contrary to images of early hominids as hunters and scavengers of meat, human brain development might have required the consumption of fish which is highly enriched in arachidonic and docosahexaenoic acids. A large percentage of the brain consists of lipids, which are highly enriched in these two fatty acids. These fatty acids are necessary for the proper development of the human brain and in adults. Deficiencies in these might contribute to ADHD, dementia, and dyslexia. These fatty acids are essential in the diet and probably could not have been derived in high enough amounts from the eating of the brains of other animals. The mechanism for the protective effects of n-3 fatty acids in health will be explored later in the course when we discuss prostaglandins synthesis and signal transduction.

Aggregates of Fatty Acids in Aqueous Solution: Micelles

Structure determines both properties and function. It should be obvious that free, unesterified fatty acids are very (but not completely) insoluble in water. When added to water, they saturate the solution at a very low concentration and then phase separate out into aggregates called micelles. The structure of a micelle formed from dodecylsulfate, a common detergent with a sulfate instead of a carboxylate head group, is shown below. All of the nonpolar Cs and Hs of the long alkyl chains are "buried" and are not exposed to water, whereas the sulfate head groups are solvent exposed.

Figure 10.1.6 shows an interactive iCn3D model of image

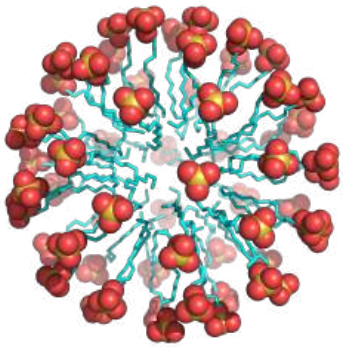

Figure 10.1.6: Sodium dodecylsulfate micelle (Copyright; author via source).
Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...KECTiGaPPScED7

Fatty acids (carboxylates and sulfates) are **amphiphilic**, with a larger polar/charged head group that tapers down to a hydrophobic tail, forming a cone-like structure. This cone structure allows the packing of many of these single chains amphiphiles into a micelle, as shown in Figure 10.1.7.

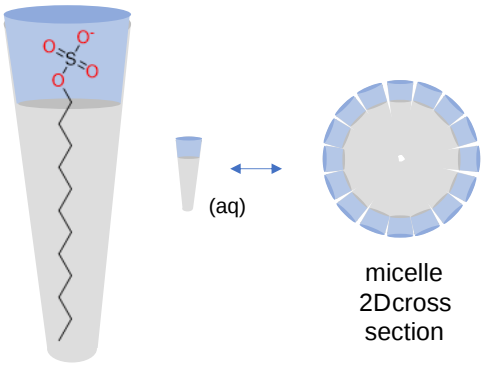

Figure 10.1.7: Cone-like representation of sodium dodecylsulfate free and in a micelle

Free fatty acids are transported in the cell and the blood not in micelles but by fatty acid-binding proteins. The most abundant protein in the blood, albumin, binds and transports fatty acids. Figure 10.1.8 shows an interactive iCn3D model of hexadecanoic acid bound to human albumin (1E7H). The fatty acids are shown in colored spacefill rendering.

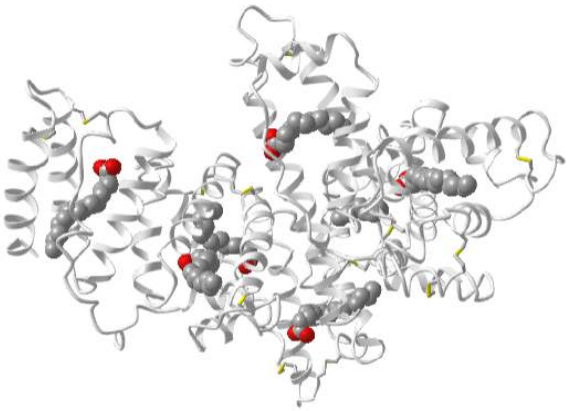

Figure 10.1.8: Hexadecanoic acid bound to human albumin (1E7H). (Copyright; author via source).

10.1.3: Waxes

You are familiar with ear wax and also the waxy surface of plants. Ear wax contains long-chain fatty acids (saturated and unsaturated) and alcohols derived from them. (They also contain isoprenoid derivatives like squalene and cholesterol). The waxy cuticle surface layers of plants contain very-long-chain fatty acids (C_{20}–C_{34}) and their derivatives including alkanes, aldehydes, primary and secondary alcohols, ketones, and esters, (They also contain isoprenoid derivatives as well). We will consider waxes as very long-chain fatty acids and their derivatives, as shown in Figure 10.1.9.

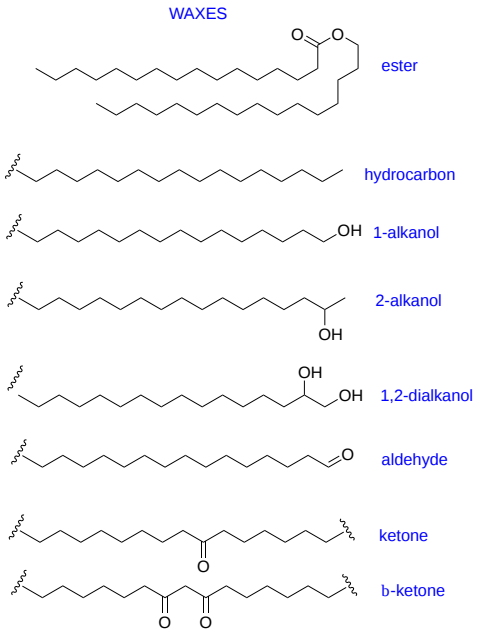

Figure 10.1.9: Waxes

These molecules are extremely nonpolar and as such makes great barriers preventing water loss through leaves and water penetration into the ear. This group of molecules clearly shows that the properties (insolubility, high melting point) and function (hydrophobic barrier/protection) arises from structure (very long chain carbon molecules, few electronegative atoms, and lack of C=C double bonds).

10.1.4: Fatty Acid-Containing Lipids

We can categorize these lipids based on function or structure (even though these are related).

Function

- storage lipids - triacylglycerols
- membrane lipids - many different lipids

Structure

- glycerolipids, which use glycerol as a backbone for fatty acid attachment
- sphingolipids, which use sphingosine as a backbone

The structures of glycerol and sphingosine are shown in Figure 10.1.10 Fatty acids are connected to these two "backbone" structures by either ester (mostly) or amide links.

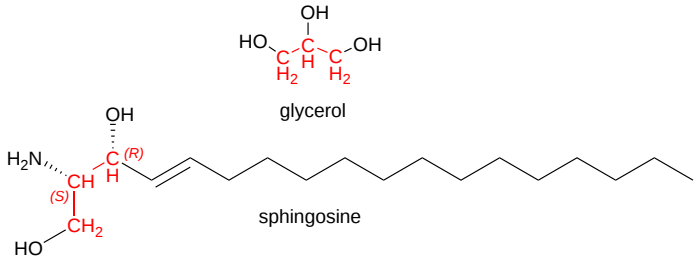

Figure 10.1.10 : Structures of glycerol and sphingosine

Let's explore the classes of fatty acid-containing lipids that use these two "backbone" structures.

10.1.5: Storage Lipids - Triacylglycerols (TAGs)

Triacylglycerols contain the majority of fatty acids in species that store fatty acids for energy. You will often see them named triglycerides or triacylglyceride, but this is a term used more in clinical chemistry and industry (and often in the media). Figure 10.1.11 shows a schematic diagram of the glycerol backbone with three fatty acids esterified to it. They are glycerolipids as they contain a glycerol base.

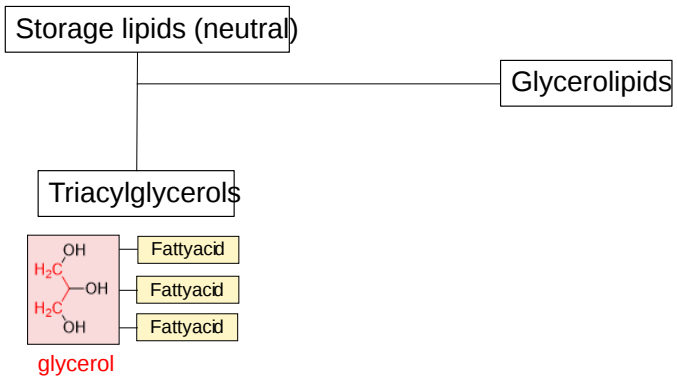

Figure 10.1.11: Structural features and nomenclature for triacylglycerols

Glycerol is not chiral but given the incredible diversity of fatty acids, glycerols likely have three different fatty acids esterified to them, making them chiral. If triacylglycerols contain predominately saturated fatty acids, they are solids at room temperature and are called **fats**. Those with multiple double bonds in the fatty acids are likely liquids at room temperature. These are called **oils**. Triacylglycerols are even more insoluble than fatty acids, which contain a polar and mostly charged carboxylate.

Figure 10.1.12 shows a triacylglycerol containing all 16:0 saturated fatty acids (left) and one containing all $16{:}2^{\Delta 9,12}$ polyunsaturated fatty acids. The figures were constructed with a specific set of dihedral angles to illustrate a point, that polyunsaturated fats in a triacylglycerol don't pack as tightly and have lower induced dipole-induced dipole attractions between the acyl chains than is possible with saturated fatty acyl chains. Hence the melting point of triacylglycerols containing polyunsaturated fatty acids is lower than for those with saturated ones.

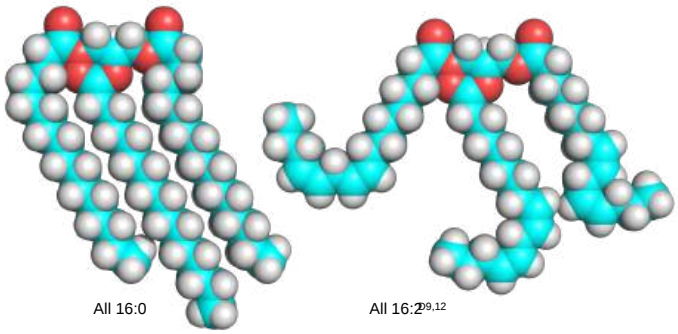

Figure 10.1.12: Triacylglycerol containing all 16:0 saturated fatty acids (left) and one containing all 16:$2^{\Delta 9,12}$ polyunsaturated fatty acids.

Let's repeat the key mantra: the structure of lipids determines their function. Consider the very insoluble triacylglycerols which are used as the predominant storage form of chemical energy in the body. In contrast to polysaccharides such as glycogen (a polymer of glucose), the carbon atoms in the acyl chains of the triacylglycerol are in a highly reduced state. The main source of energy to drive not only our bodies but also our society is obtained through oxidizing carbon-based molecules to carbon dioxide and water, in a reaction that is highly exergonic and exothermic. Sugars are already part way down the free energy "hill" since each carbon is partially oxidized. 9 kcal/mol (38 kJ/mol) can be derived from the complete oxidation of fats, in contrast to 4.5 kcal/mol (19 kJ/mol) from that of proteins or carbohydrates.

In addition, glycogen is highly hydrated. For every 1 g of glycogen, 2 grams of water is H-bonded to it. Hence it would take 3 times more weight to store the equivalent mass of carbohydrates compared to triacylglycerol, which is stored in anhydrous lipid "droplets" within cells. In addition, fats are more flexible, given the large number of conformations available to the acyl chain C-C bonds by simple rotation around the C-C bonds. Polysaccharides have monomeric cyclohexane-like chair structures and are much more rigid.

Another interesting point is that glucose and glycogen are found in cells, and they can be mobilized quickly for energy needs. Yes, fats are present in all cells as well (for example all cells have interior and exterior cell membranes). However, the major storage form of fat, triacylglycerols, is stored in special cells called adipocytes, which comprise adipose or fat tissue, and must be mobilized by signaling agents and transported in the form of fatty acids to cells for utilization. Again, triacylglycerols don't form membranes, which separate outside and inside aqueous environments. They are simply so insoluble that they phase-separate into lipid droplets. Their formation and structure are a bit more complex than that, though, and we will discuss lipid droplets more in the next section.

10.1.6: Membrane Lipids

Membranes are bilayers of amphiphilic lipids that separate the outside and inside (cytoplasm) aqueous environments in cells and the cytoplasm and interior contents of organelles within cells. In general, single-chain lipid amphiphiles form micelles. Amphiphilic membrane lipids typically have **two** nonpolar tails connected to a polar head, giving them a less conical and more cylindrical shape that disallows micelle formation while favoring bilayer formation. Figure 10.1.13 shows a short section of a bilayer membrane made from lipids with a polar (and charged) head group (phosphocholine) and two 16:0 chains. The red and blue spheres represent the O and N atoms of the head groups, which are sequestered to the exterior parts of the bilayer, where they would interact with water. The nonpolar 16:0 tails are shown in cyan, clearly illustrating the nonpolar nature of the interior of the bilayer.

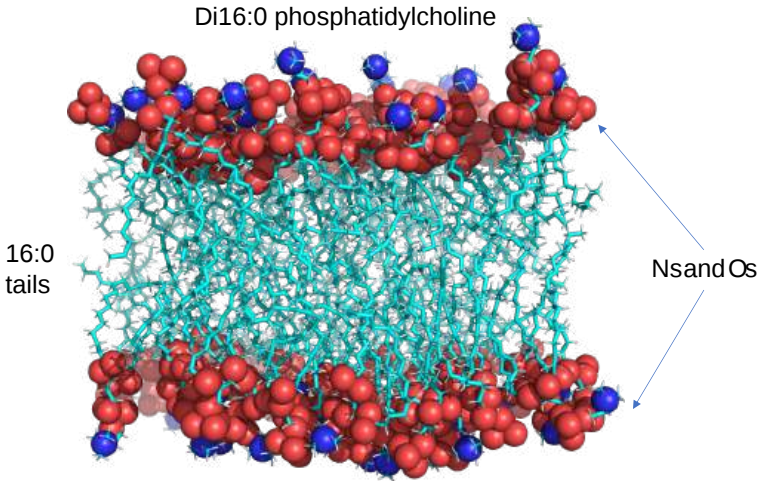

Figure 10.1.13: Bilayer membrane made from lipids with a polar (and charged) head group (phosphocholine) and two 16:0 chains.

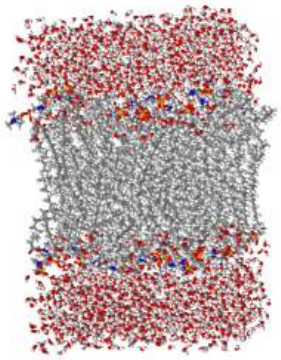
Figure 10.1.14shows an interactive iCn3D model of a hydrated bilayer of the di16:0 phosphatidycholine bilayer.



NCBI iCn3D Figure 10.1.14 Hydrated di16:0 phosphatidycholine bilayer (Copyright; author via source).
Click the image for a popup.

We will consider two general types of fatty acid-containing membrane lipids, **glycerolipids**, with two fatty acids esterified to a glycerol base, and **sphingolipids** with one fatty acid in amide link to a different base, sphingosine. Sphingosine comes with its own built-in long alkyl chain that provides the "second" nonpolar chain. There are many different polar/charged head groups for these membrane lipids.

Now let's look in more detail at the double-chain amphiphiles comprising these membrane bilayers.

10.1.7: Glycerolipids

There are two main types of glycerolipids, glycerophospholipids, and glyceroglycolipids, which are the most common lipids in membranes.

Glycerophospholipids

Figure 10.1.15shows the structural features and nomenclature for glycerophospholipids.

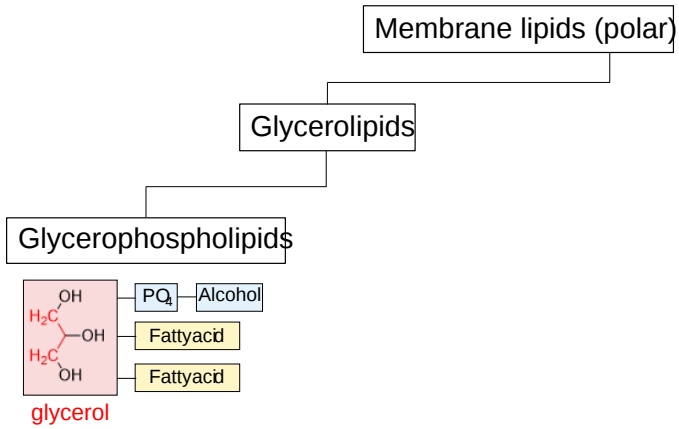


Figure 10.1.15: Structural features and nomenclature for glycerophospholipids

These lipids have enormous structural variability given the large number of different fatty acids (both saturated and unsaturated) and head groups that can be attached to a phosphate attached to the carbon 3 of glycerol. The structures of the most common glycerophospholipids are shown in Figure 10.1.16

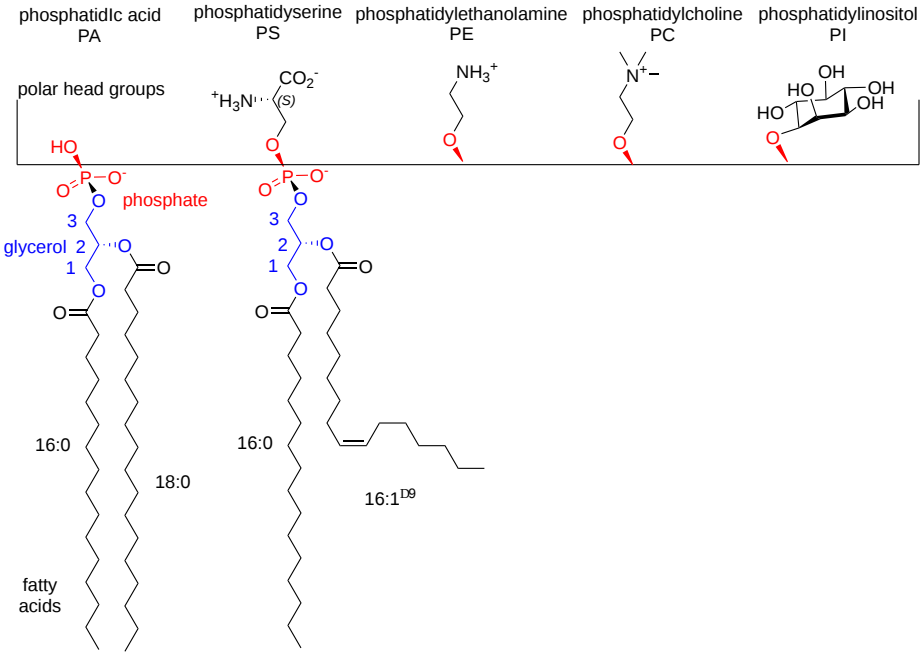

Figure 10.1.16: Common glycerophospholipids

Phosphatidylcholine (PC) has the common name lecithin while phosphatidylserine (PS) is called cephalin.

Note that the head groups all have charges since they all have a negatively charged phosphate. PS has two additional charged atoms which would effectively cancel out. PE has a charged amine but could become uncharged at pH values approaching its pKa. PC has a quaternary amine which is charged independent of pH, which would give PC a net 0 charge but with two discrete charges.

Glyceroglycolipids

These do not have a phosphate group attached to the oxygen on C3 of glycerol. Rather they have a mono- or oligosaccharide or, more loosely, a betaine group, each attached by an ether linkage to the glycerol C3 carbon. Figure 10.1.17Structural features and nomenclature for glyceroglycolipids.

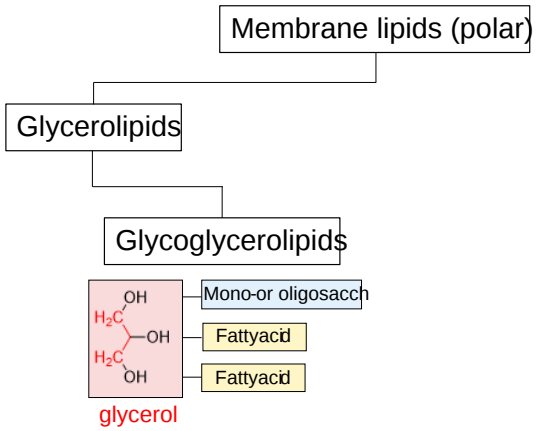

Figure 10.1.17: Structural features and nomenclature for glyceroglycolipids

Figure 10.1.18shows some examples of glyceroglycolipids.

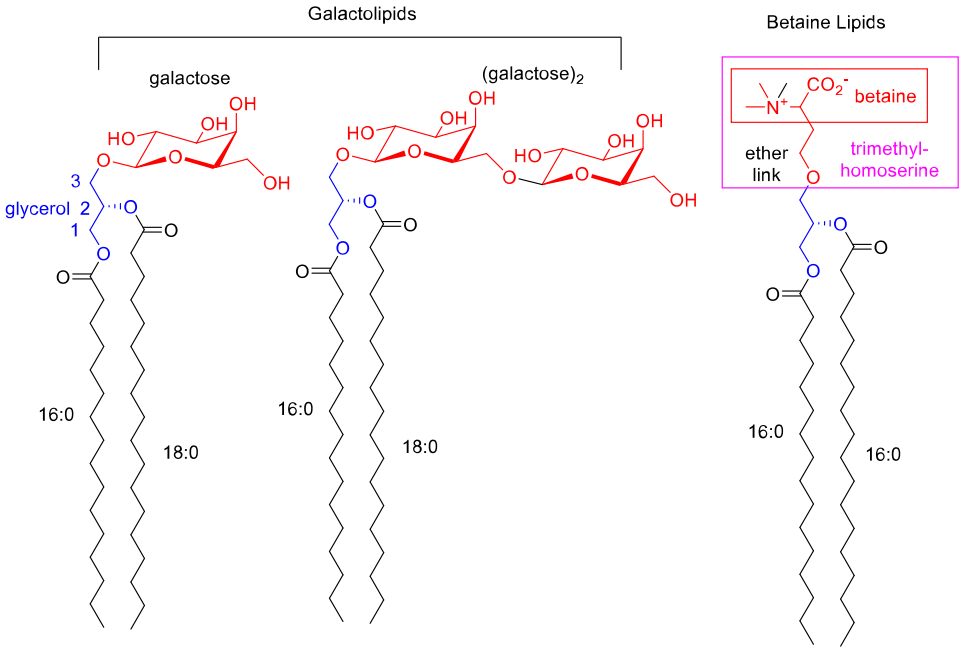

Figure 10.1.18: Examples of glycoglyerolipids.

Again there are an enormous number of different glycoglycerolipids, owing to the diversity of head groups and fatty acids esterified to glycerol at C1 and C2.

The above figure (right) shows an example that has no phosphate but also doesn't have a mono- or polysaccharide for a head group. Rather it has a betaine group. Betaine is the common name for trimethylglycine but is used for any N-trimethylated amino acids. Betaine glycerolipids are found in lower eukaryotic organisms (algae, fungi, and some protozoa), in photosynthetic bacteria, and in some spore-producing plants like ferns. Some would call these lipoamino acids.

10.1.8: Membrane Lipids - Sphingolipids

Sphingolipids contain a sphingosine backbone and a fatty acid linked through an amide bound. The simplest sphingolipids are the ceramides, which are double-chain amphiphiles but without further modification of the functional groups on the polar head of sphingosine. The structures of both sphingosine and ceramide are shown below in Figure 10.1.19

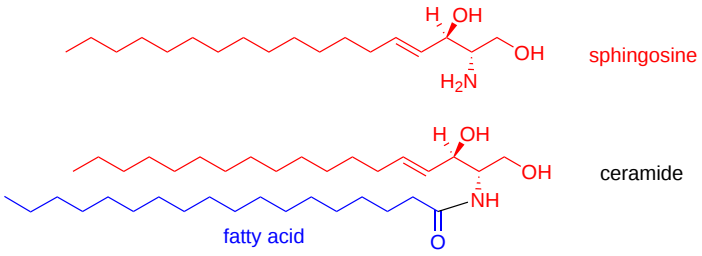

Figure 10.1.19 Structures of sphingosine and ceramide

Ceramides are abundant in the skin where they help provide a protective barrier. Skin creams also contain ceramides. These lipids make up only about 1% of body lipids and there are over 200 different ceramides in humans arising from the different fatty acids linked to sphingosine. They have a key role in cell signaling and can also affect cardiovascular health in ways that are just being appreciated. Since they are double-chain amphiphiles, they are found in membranes where they alter the properties of the bilayer (including membrane fluidity). Ceramides with long acyl tails (especially those with 16, 18, or 24 carbons) seem especially deleterious.

Phosphosphingolipids and glycosphingolipids

These membrane lipids have a ceramide base but also contain modifications at the polar functional groups of the sphingosine head. Let's consider the phosphosphingolipids and the glycosphingolipids together. These groups do not use glycerol as a base for the attachment of fatty acids and head groups. Rather they use molecule sphingosine. Figure 10.1.20 shows the structural features and nomenclature of sphingolipids.

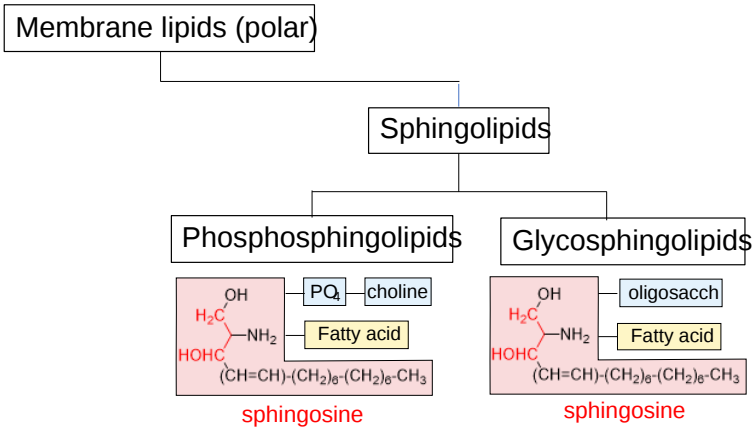

Figure 10.1.20: Structural features and nomenclature for sphingolipids

Examples of both classes are shown in Figure 10.1.21. Note the base sphingosine (in red) provides an amine to attach a fatty acid through an amide bond and an OH for attachment of the head group.

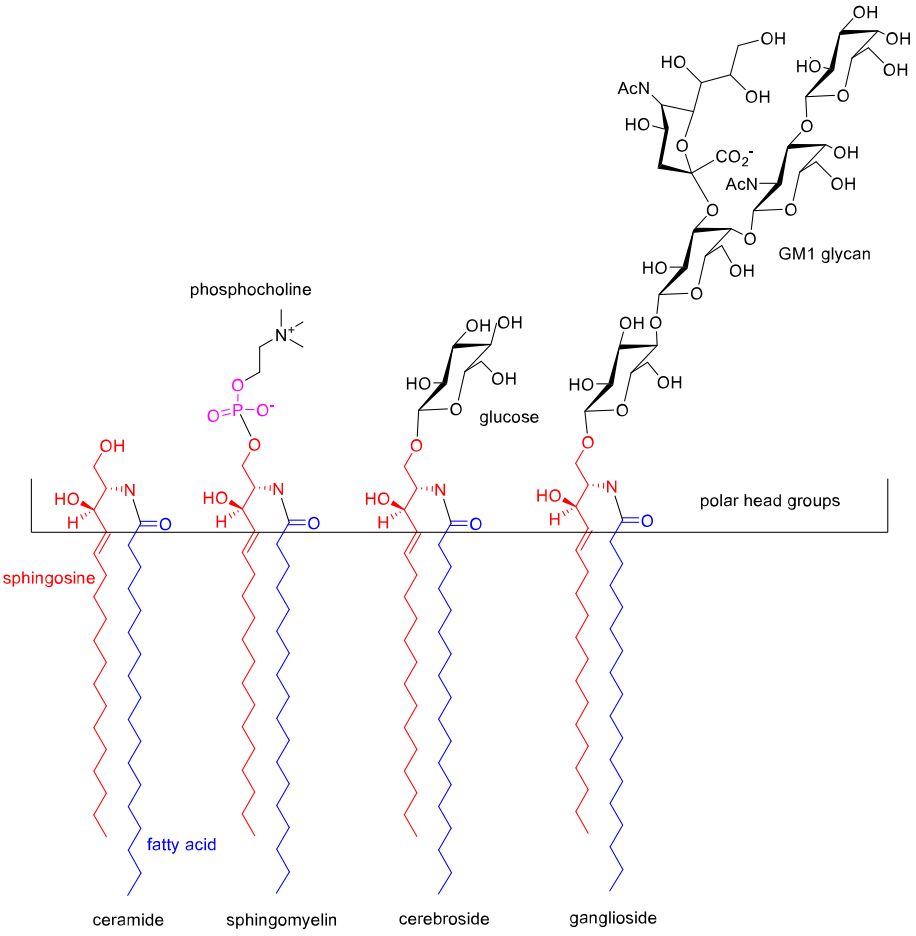

Figure 10.1.21: Examples of phosphosphingolipids and glycosphingolipids

Sugar-containing glycosphingolipids are **found largely in the outer face of plasma membranes.** The primary lipid of myelin, which coats neuronal axons and insulates them from loss of electrical signaling down the axon, is galactocerebroside

Figure 10.1.22shows a summary of all of the different types of fatty acid-containing lipids

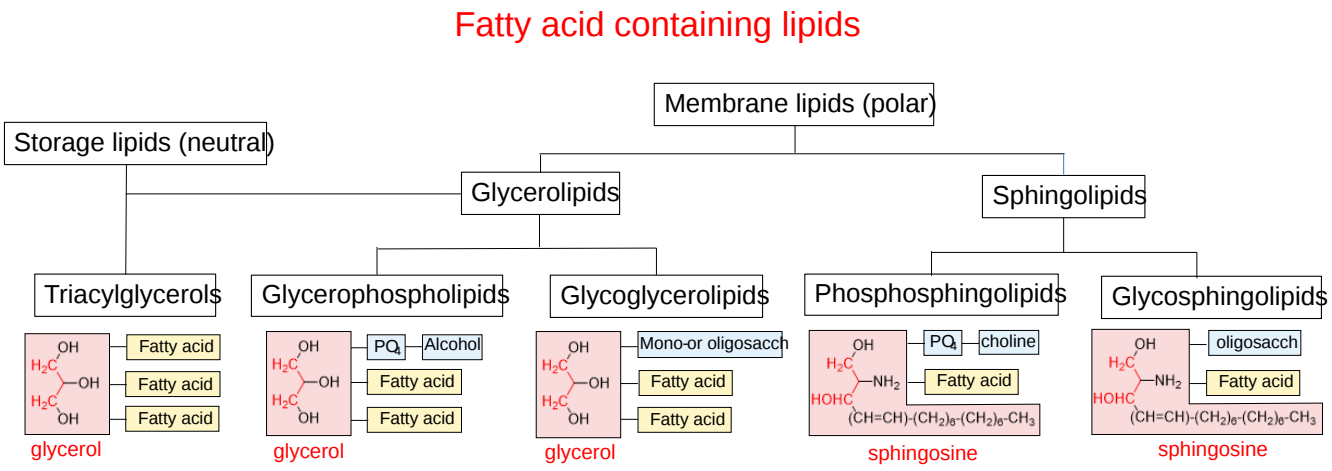

Figure 10.1.22: Summary of structural features and nomenclature for fatty acid-containing lipids

Over a 1000 different lipids are found in eukaryotic cells. This complexity has led to the development of an even more comprehensive classification system for lipids. In this system, lipids are given a very detailed as well as all-encompassing definition: "hydrophobic or amphipathic small molecules that may originate entirely or in part by carbanion-based condensations of

thioesters (fatty acyl, glycerolipids, glycerophospholipids, sphingolipids, saccharolipids, and polyketides) and/or by carbocation-based condensations of isoprene units (prenol lipids and sterol lipids)." Eight different categories of lipids are listed in the parentheses above. We will stick to the definition used throughout this chapter.

10.1.9: Shapes of membrane lipids

Let's look at the general shape of the double-chain amphiphiles that make bilayers. We saw the long-chain fatty or sulfate acids form conical structures which fit nicely together when they self-aggregate to form micelles. In contrast, membrane-forming double-chain amphiphiles have more cylindrical shapes that can't be fitted together in micelles but rather form a less curved bilayer structure, as shown in Figure 10.1.23 We will consider the variety of membrane structures in the next section.

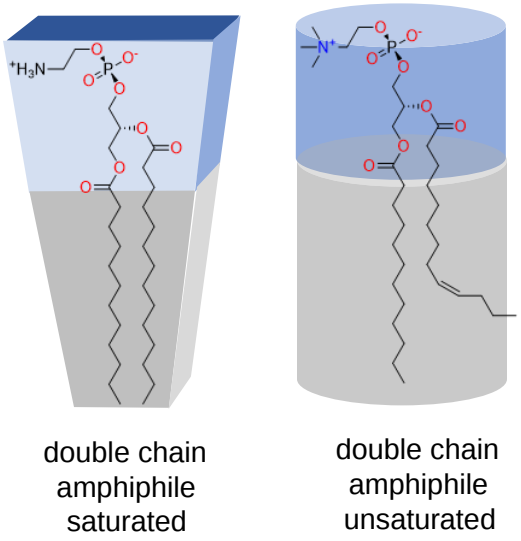

Figure 10.1.23: General shape of the double-chain amphiphiles that make bilayers

10.1.10: Triacylglyceride/Phospholipid Stereochemistry

Glycerol is an achiral molecule since C2 has two identical substituents, -CH_2OH. Glycerol in the body can be chemically converted to triglycerols and phospholipids (PL) which are chiral, and exist in one enantiomeric form. How can this be possible if the two CH_2OH groups on C2 of glycerol are identical? It turns out that even though these groups are stereochemically equivalent, we can differentiate them as described in the figure below. Let's replace the -CH_2OH in one of the end carbons with -CH_2OD. With this simple change, glycerol is now chiral. Look at the top half of Figure 10.1.24

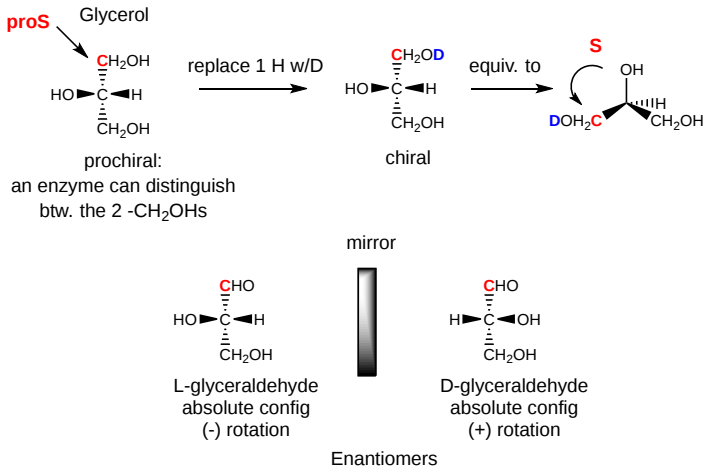

Figure 10.1.24: Potential chirality of Glycerol - ProS

Glycerol is oriented with the OH on C2 (the middle carbon) pointing to the left. The OH of the top carbon in this orientation, C1, is replaced with OD, where D is deuterium to make the molecule chiral (four different groups attached to C2). By rotating the

molecule such that the H on C2 points to the back, and assigning priorities to the other substituents on C2 (OH =1, $DOCH_2$ =2, and CH_2OH = 3), it can be seen that the resulting molecule is in the S configuration. We simply name the C1 carbon which we modified with deuterium as the **proS** carbon. Likewise, if we replaced the OH on C3 with OD, we will form the R enantiomer. Hence C3 is the proR carbon. This shows that in reality, we can differentiate between the two identical CH_2OH substituents. We say that glycerol is not chiral, but **prochiral**. (Think of this as glycerol has the potential to become chiral by modifying one of two identical substituents.)

In the bottom half of Figure 10.1.23 we can relate the configuration of glycerol above, (when OH on C2 is pointing to the left) to the absolute configuration of L-glyceraldehyde, a simple sugar (a polyhydroxyaldehyde or ketone), another 3C glycerol derivative. This molecule is chiral with the OH on C2 (the only chiral carbon) pointing to the left. It is easy to remember that any **L** sugar has the OH on the **L**ast chiral carbon pointing to the **L**eft. The enantiomer (mirror image isomer) of L-glyceraldehyde is D-glyceraldehyde, in which the OH on C2 points to the right. Biochemists use L and D for lipid, sugar, and amino acid stereochemistry, instead of the R, S nomenclature you used in organic chemistry. The stereochemical designation of all the sugars, amino acids, and glycerolipids can be determined from the absolute configuration of L- and D-glyceraldehyde.

Now let's see how an enzyme can take a prochiral molecule like glycerol and phosphorylate only one of the -CH_2OHs to make one specific isomer, glycerol-3-phosphate, a key intermediate in the biosynthesis of phosphatidic acid (PA), a glycerophospholipid, as well as chiral triacylglycerols, shown in Figure 10.1.25. The far left part of the pathway shows how the proR CH_2OH of glycerol is phosphorylated to produce one specific enantiomer, L-glycerol-3-phosphate. (The top part of the figure shows another way to make this molecule from glucose through the glycolytic pathway we will encounter in a future chapter.

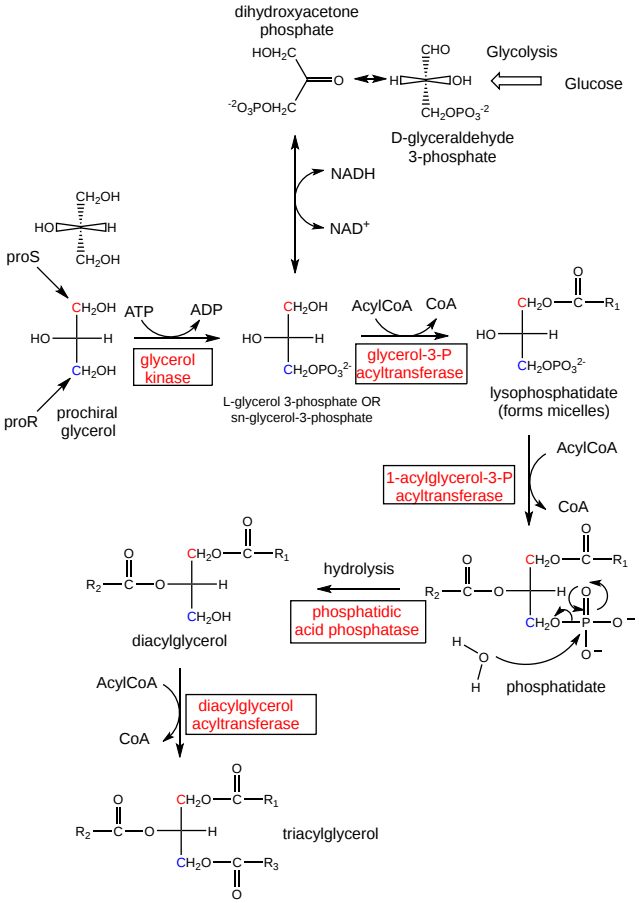

Figure 10.1.25: Synthesis of derivatives from prochiral glycerol

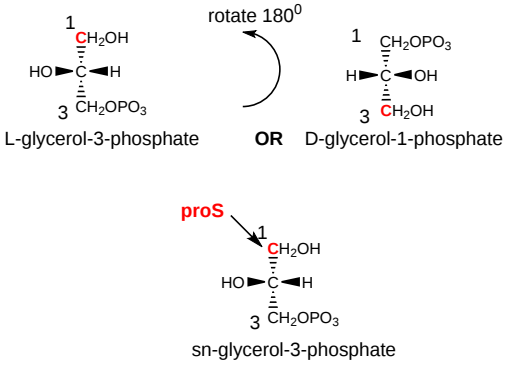
The first step (above figure) involves the phosphorylation of the OH on C3 by ATP (a phosphoanhydride similar in structure to acetic anhydride, an excellent acetylating agent) to produce the chiral molecule glycerol phosphate. Based on the absolute configuration of L-glyceraldehyde, and using this to draw glycerol (with the OH on C2 pointing to the left), we can see that the phosphorylated molecule can be named L-glycerol-3-phosphate. However, by rotating this molecule 180 degrees, without changing

the stereochemistry of the molecule, we don't change the molecule at all, but using the D/L nomenclature above, we would name the rotated molecule D-glycerol-1-phosphate. This is illustrated in Figure 10.1.26



Assign 1 position to group occupying the proS position of a prochiral center (glycerol). Orient molecule with C1 at top.

Figure 10.1.26: Stereospecific numbering system (sn) for glycerol

We can't give the same molecule two different names. Hence biochemists have developed the **stereospecific numbering system (sn)**, which assigns the 1-position of a prochiral molecule to the group occupying the proS position. The proS C1 is hence at the sn-1 position. With that designation, C2 is at the sn-2 position, and C3 is at the sn-3 position. Using this nomenclature, we can see that the chiral molecule described above, glycerol-phosphate, can be unambiguously named as sn-glycerol-3-phosphate. The hydroxyl substituent on the proR carbon was phosphorylated.

It is interesting to note that archaea use isoprenoid chains linked by ether bonds to *sn*-glycerol 1-phosphate in their synthetic pathways. As noted above, bacteria and eukaryotes use fatty acids attached by ester bonds to *sn*-glycerol 3-phosphate

The enzymatic phosphorylation of the proR CH_2OH of glycerol to form sn-glycerol-3-phosphate is illustrated in Figure 10.1.27. As we were able to differentiate the 2 identical CH_2OH substituents as containing either the proS or proR carbons, so can the enzyme. The enzyme can differentiate identical substituents on a prochiral molecule if the prochiral molecule interacts with the enzyme at three points. Another example of a prochiral reactants/enzyme system involves the oxidation of the prochiral molecule ethanol by the enzyme alcohol dehydrogenase, in which only the proR H of the 2 H's on C2 is removed. (We will discuss this later.)

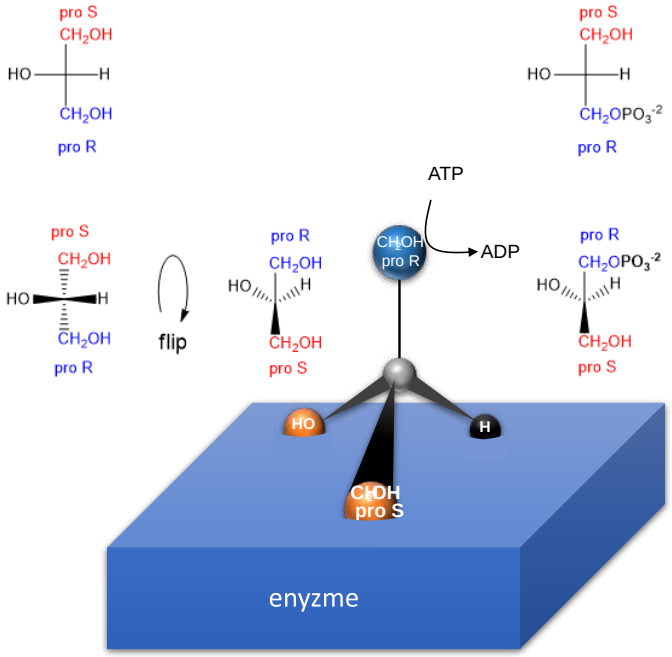


Figure 10.1.27: Enzymatic phosphorylation of the proR CH_2OH of glycerol to form sn-glycerol-3-phosphate

10.1.11: Isoprenoid-containing lipids

This is the last class of lipids we will consider. They do not contain fatty acids. Rather they contain isoprene, a small branched alkadiene, which can polymerize into larger molecules containing isoprene monomer to form isoprenoids, often called terpenes. Instead of using isoprene as the polymerization monomer, either dimethylallyl pyrophosphate (DMAPP) or isopentenylpyrophosphate (IPP) are used biologically.

Figure 10.1.28 shows how DMAPP and IPP (both containing 5Cs) are used in a polymerization reaction to form geranyl-pyrophosphate (C10), farnesyl pyrophosphate (C15) and geranyl-geranyl pyrophosphate (C20).

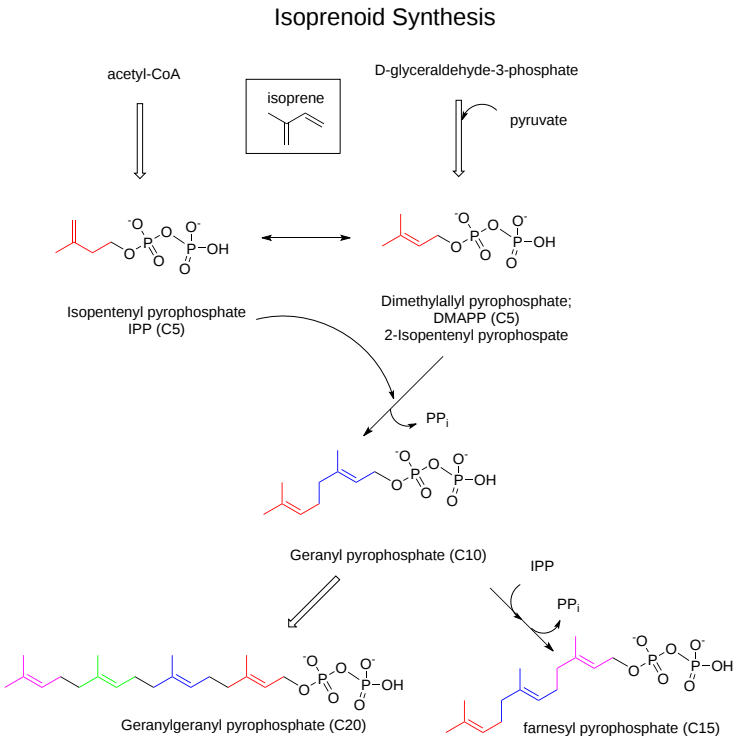

Figure 10.1.28: Synthesis of geranyl-pyrophosphate (C10), farnesyl pyrophosphate (C15) and geranyl-geranyl pyrophosphate (C20)

Many isoprenoid lipids are made from farnesyl pyrophosphate. For membrane purposes, the most important of these is cholesterol. Figure 10.1.29 shows an overview of the synthesis of cholesterol from two farnesyl pyrophosphates linking together in a "tail-to-tail" reaction to form squalene, a precursor of cholesterol. Each isoprene unit (5Cs) is shown in different colors to make it easier to see.

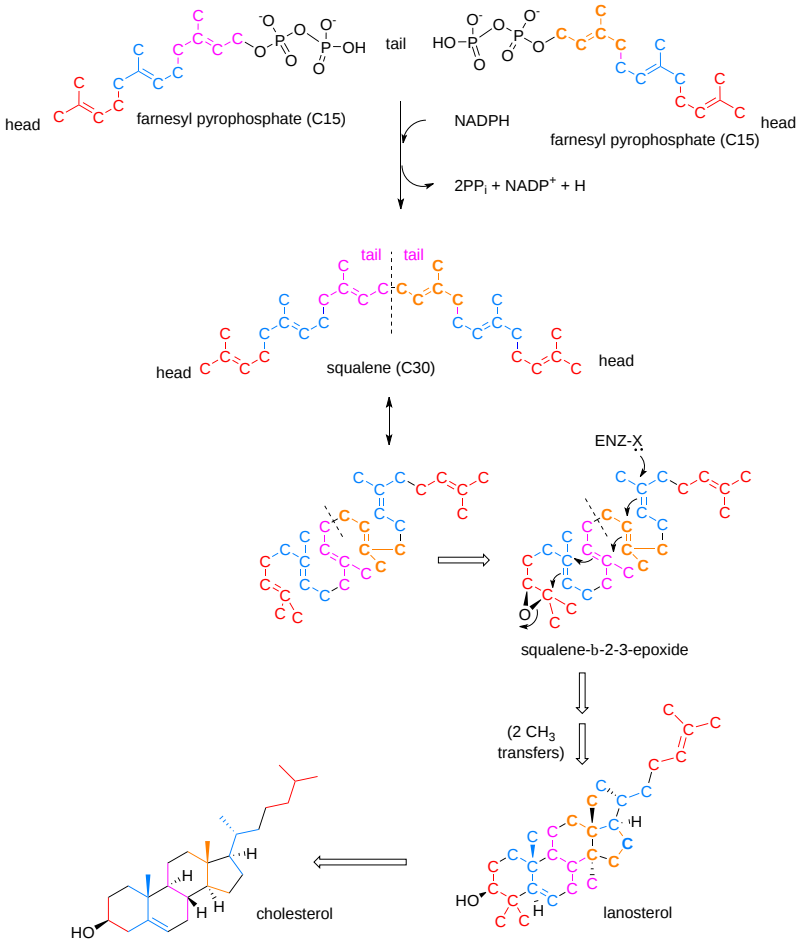

Figure 10.1.29: Synthesis of squalene from isoprene units

Other biologically important isoprenoid-containing vitamins are shown in Figure 10.1.30

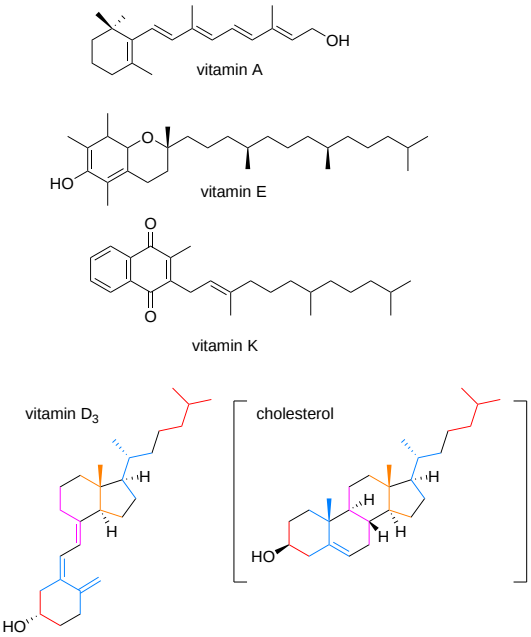

Figure 10.1.30: Isoprenoid vitamins

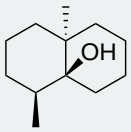
The smell of fresh rain

Everyone who has walked in the woods after a fresh rain knows the smell of a terpene called **geosmin**, "an Earthy-smelling substance" found in abundance in a group of substances collectively called petrichor, derived from the Greek petra (rock) and ichor (blood of gods). The structure of geosmin is shown below.



These substances are released when water falls or soils and rocks, and seeps into pores from which aerosols are released. Too hard of a rain will saturate pores in rocks and prevent the release. Some insects like the springtail are attracted to geosmin. The synthesis of geosmin by bacteria and blue-green algae is under the control of transcription factors which also affect bacterial spore formation. The attracted insects carry away the spores. Flies are repelled by geosmin, which is detected by a receptor at very low geosmin concentration. In contrast, the *Aedes aegypti* mosquito is attracted to geosmin which parallels the fact that the mosquito is not affected by bacterial toxins.

10.1.12: One last look at lipid structure and shapes

With the exclusion of waxes and triacylglycerols, the other lipids we have discussed, including the mostly planar molecule cholesterol, are amphiphilic. We have seen that single-chain fatty acids form micelles while lipids with two nonpolar chains and a polar/charged head group form bilayers. Given the relative size of the head group and the degree of unsaturation of the double bonds in fatty acids, the overall shapes of the membrane-forming lipids differ as illustrated below. They are arranged like dominos in the membrane based on their geometric volumes. Preferential clustering of identical types can cause local and extended changes in a prototypical bilayer structure.

Membranes and their components must be dynamic to enable all the functions and activities of a membrane. Ligands bind to membrane receptors (usually proteins), which can invaginate and pinch off to form an intracellular vesicle containing the receptor for processing. Likewise, vesicles can pinch off into the extracellular space. Cells must divide. Think of the membrane changes necessary for that! Also, consider that the length of cholesterol is half that of a typical double-chain amphiphile so it fits into just one of the bilayer lipid leaflets where it modulates lipid bilayer property. Figure 10.1.31 shows a series of lipids and their shape profiles.

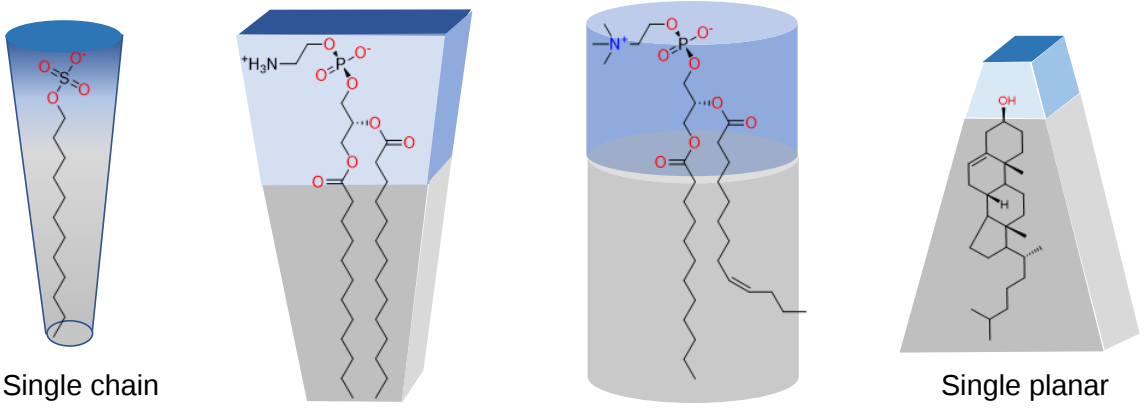


Figure 10.1.31: A series of lipids and their shape profiles

We will consider membranes in greater detail in section 10.3. Next, however, we will explore in more detail the properties of micelle and lipid droplet systems before addressing the more structurally complicated lipid bilayers.

10.1.12.1: End-of-Chapter Questions

? Exercise 10.1.1

x) A cell membrane has the ability to remodel in response to stress to promote membrane integrity. In the situations below, how could the membrane be remodeled to prevent damage? (I.e. what types of lipids could be added/removed to ensure homeostasis)

a) Increase in temperature

b)

x) What are the three classes of lipids? Explain their similarities and differences.

x) For each lipid below, name the type of lipid (membrane lipid, triacylglycerol, storage lipid, sphingolipid, wax, sterol, membrane glycerolipid, none of these), if it could be found in membrane, and if it is fatty acid or isoprene derived.

(Insert pics of lipids)

10.2: Lipids Aggregates in Water - Micelles and Liposomes

10.2.1: Single Chain Amphiphiles and Micelles

An understanding of lipids in simple solutions in the lab is incredibly helpful to understanding them *in vivo*. The same physical-chemical constraints would apply to the complex environment of the cell. What is different in the cell is that lipids are found in a cellular environment that is incredibly crowded with proteins that bind, synthesize, and breakdown lipids. Nevertheless, we can apply what we know from the test tube experiments to the cell.

To understand how molecules might react, it helps a bit to pretend you are a molecule and ask yourself what would you do! We want to know how lipid molecules, specifically single and double-chain amphiphiles, interact with each other and solvent when they are added to water. Before you read the answer, look at the image below and ask yourself the question: What would I do if I were a single chain amphiphile and jumped into water as shown in Figure 10.2.1?

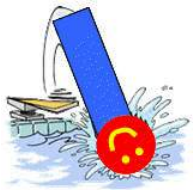

Figure 10.2.1: A cartoon single-chain amphiphile diving into a pool

Here is what they do. When added to water, some single-chain amphiphiles dissolve in water while others form a monolayer on the surface of the water. If enough enter the solution and exceed their net solubility, they self-aggregate to form micelles. These outcomes are shown in Figure 10.2.2

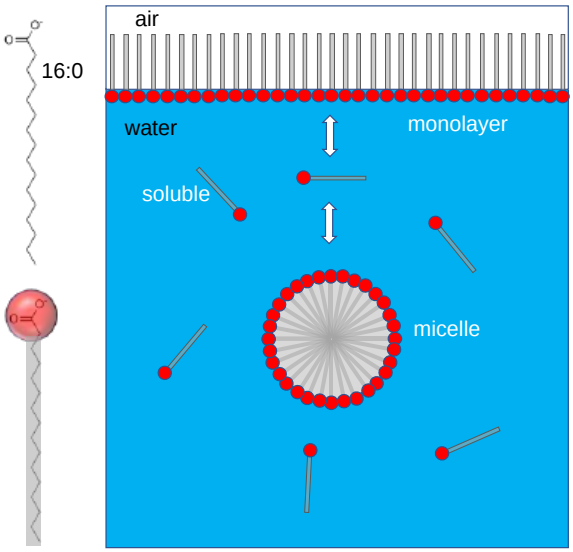

Figure 10.2.2: Distribution of single chains amphiphiles in an aqueous solution

Figure 10.2.3shows an interactive iCn3D model of an sodium dodecylsulfate (SDS) micelle

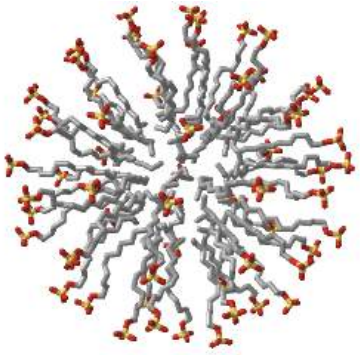

Figure 10.2.3: Sodium dodecylsulfate (SDS) micelle (Copyright; author via source).
Click the image for a popup or use this external link: not available

Double-chain amphiphiles, in contrast, form bilayers instead of micelles. (Note: single and double-chain amphiphiles can form other multimolecular aggregate structures as well, but micelles and bilayers are the most common and are the only ones we will consider.)

The micelle interior is completely nonpolar. Spherical bilayers that enclose an aqueous compartment are called vesicles or liposomes. Micelles and bilayers, formed from single and double-chain amphiphiles, respectively, represent noncovalent aggregates and hence are formed by an entirely physical process. No covalent steps are required.

Common single-chain amphiphiles that form micelles are detergents (like sodium dodecyl sulfate - SDS) as well as fatty acids, which themselves are detergents. Sodium hydroxide feels slippery on your skin since the base hydrolyses the fatty acids esterified to skin lipids. The free fatty acids then aggregate spontaneously to form micelles which act like detergents, and are also slippery.

Micelle/detergents in water are an example of an emulsion of two liquids that are generally immiscible in each other unless one is dispersed into small droplets into the other Fine oil drops can be dispersed in water and fine aqueous drops can be dispersed in a nonpolar liquid. Many vaccines are formulated as this later type of emulsion. Grease and oil in your clothes can be carried away by "diving" into the nonpolar part of the detergent micelle which is dispersed in water as an emulsion. Another example of an emulsion or more properly a colloid is a cloud, a dispersion of liquid water droplets in a solvent, the atmosphere.

The formation of these structures can be understood from the study of noncovalent interactions but also through thermodynamics. In a micelle, the buried acyl chains can interact and be stabilized by induced dipole-induced dipole forces as the nonpolar carbons and hydrogen are in van der Walls contact. They are sequestered from water. This view fits our simple axiom of "like-dissolves like". The polar head groups can be stabilized by ion-dipole bonds between charged head groups and water. Likewise, H-bonds between water and the head group stabilize the exposed head groups in water. Repulsive forces may also be involved. Head groups can repel each other through steric factors, or ion-ion repulsion from like-charged head groups. The attractive forces must be greater than the repulsive forces, which lead to these molecular aggregates.

From a thermodynamic approach, one problem arises with this simple explanation. For a micelle or bilayer to form, many monomers must aggregate to form a single micelle or vesicle, which is entropically disfavored! So let's delve into the thermodynamics of micelle formation.

ΔG, the free energy chance for a reaction, determines the spontaneity and extent of a chemical or physical reaction. The free energy of the system depends on 3 variables, temperature T, pressure P, and n, the number of moles of each substance. For the latter, think of solute X on two different sides of a permeable membrane. If the concentration of X is the same on each side, as shown in the system below, the system is in equilibrium as shown in Figure 10.2.4

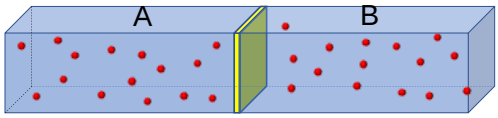

Figure 10.2.4: Equilibrium state of a species distribute in solutions separated by a semipermeable membrane.

If the system is composed of two different parts, A and B, the system is at equilibrium (ΔG=0) if $T_A = T_B$, $P_A = P_B$, and the change in the absolute free energy per mole of A is $\Delta G_A/\Delta n = \Delta G_B/\Delta n$. More precisely, using simple calculus, we would discuss incremental changes in absolute free energy/mol, dG_A/dn for A (often called the chemical potential of A, μ_A), and dG_B/dn or

μ_B)for B. At equilibrium $dG_A/dn = dG_B/dn$. (We will use the symbol G here instead of μ). G then is the absolute free energy/mol (again often called the chemical potential), where $G=G^o + RTln[A]$. The equations you used in introductory chemistry can be written.

$$\begin{aligned} \Delta G &= \Delta G^0 + RTInQr \\ \Delta G &= \Delta H - T\Delta S \\ \Delta G^0 &= \Delta H^0 - T\Delta S^0 \\ \Delta G^0 &= -RTInKeq \end{aligned} \tag{10.2.1}$$

Now let's apply this to the chemical equation for micelle formation:

n SCA <==> 1 micelle

where SCA represents a single chain amphiphile. At first glance, we might suspect that:

- $\Delta H^0 < 0$ since the induced dipole-induced dipole interactions among the buried acyl chains in the micelle would be much more favorable than the water-acyl interactions for the monomeric amphiphile in solution. This notion is supported by our aphorism, "like dissolves like". Of course, we couldn't ignore polar interactions (H bonding for example) among the head groups and water, but we might expect these to be equally favorable in both the monomeric and micellular states.
- $\Delta S^0 < 0$ since we are forming a very ordered state (a single micelle) with much less entropy from a state (single chains amphiphiles dispersed in solution) with much more entropy.

Hence it would appear that micelle formation is enthalpically favored but entropically disfavored. Let's examine this issue more closely. First, we need to obtain a greater understanding of ΔG^o which should give us a clue as to where a SCA would "want" to be in this mixture. Remember, ΔG^0 is a constant that at a given T, P, and solvent conditions and depends only on the relative stability of a molecule in a given environment and not its concentration.

Traube, in 1891, noticed that single chain amphiphiles tend to migrate to the surface of the water and decrease its surface tension (ST.) He observed that the decrease in ST is directly proportional to the amount of amphiphile, added up until a certain point, at which added amphiphile has no additional effect. In other words, the response of ST saturates at some point.

We are more interested in what happens to amphiphiles in bulk water, not at the surface. As we showed in Figure 2 above, monomeric single chain amphiphiles are in equilibrium with single chain amphiphiles in micelles. Assume you have a way to measure monomeric single chain amphiphile in solution. What happens to its concentration as you add more and more SCA to the mixture? Turns out you observe the same effect that Traube noted with changes in surface tension. This explanation goes like this: as more amphiphile is added, more goes into bulk solution as monomers. At some point, there are enough amphiphiles added to form micelles. After this point, added amphiphiles form more micelles and no further increases in monomeric single chain amphiphiles are noted. The concentration of amphiphile at which this occurs is the critical micelle concentration (CMC). Figure 10.2.5 shows a graph of monomeric single chain amphiphile in solution versus the concentration added to the solution.

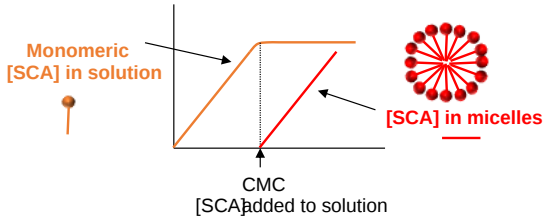

Figure 10.2.5: Monomeric single chain amphiphile in solution versus the concentration added to the solution

This saturation effect can be observed with other systems as well.

- Consider the amount of NaCl(aq) in the solution as more NaCl(s) is added to water. At some point, the water is saturated with dissolved NaCl, and no further increase in NaCl (aq) occurs.
- Consider the amount of a sparing soluble hydrocarbon (HC) in water. After saturation, phase separation occurs.

Now consider the addition of a drop of a slightly soluble hydrocarbon liquid (HC_L) into water, as pictured in the diagram below. At t=0, the system is not at equilibrium and some of the HC will transfer from the pure liquid to water, so at time t=0, $\Delta G_{TOT} < 0$.

This is illustrated in Figure 10.2.6

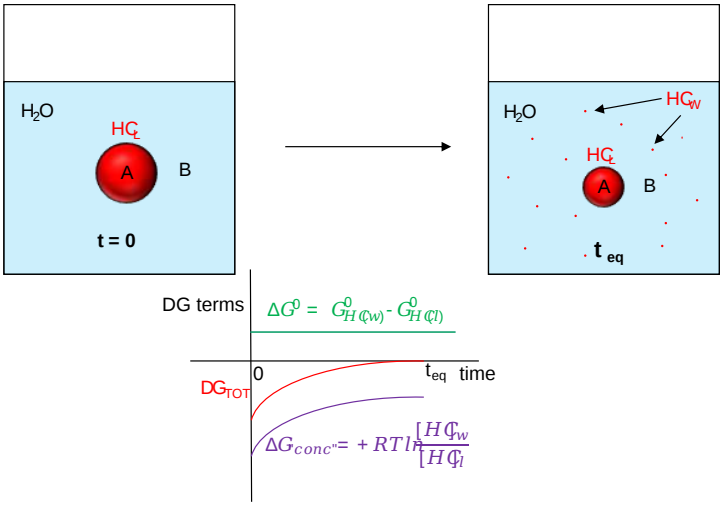

Figure 10.2.6: Addition of slightly soluble liquid hydrocarbon to water - ΔG vs time

The following equations can be derived.

$$\begin{aligned} \Delta \mathrm{G_{TOT}} = (G_{\mathrm{HC-W}}) - (G_{\mathrm{HC-L}}) = \mathrm{G^0_{HC-W}} + RT\ln[\mathrm{HC}]_{\mathrm{W}} - \left(\mathrm{G^0_{HC-L}} + RT\ln[\mathrm{HC}]_{\mathrm{L}}\right) = \\ \Delta \mathrm{G_{TOT}} = \left(\mathrm{G^0_{HC-W}} - \mathrm{G^0_{HC-L}}\right) + RT\ln([\mathrm{HC}]_{\mathrm{W}} - \ln[\mathrm{HC}]_{\mathrm{L}}) = \\ \Delta \mathrm{G_{TOT}} = \Delta \mathrm{G^0} + RT\ln\frac{[\mathrm{HC}]_{\mathrm{W}}}{[\mathrm{HC}]_{\mathrm{L}}} \end{aligned} \tag{10.2.2}$$

Now add a bit more complexity to the last example. Add a hydrocarbon x, to a biphasic system of water and octanol and shake it vigorously as shown in Figure 10.2.7. At equilibrium, x would have "partitioned" between the two mostly immiscible phases.

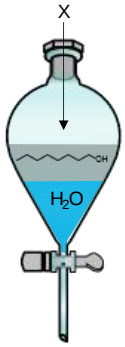

Figure 10.2.7: Addition of a hydrocarbon x to a biphasic system of water and octanol

A simple favorable reaction can be written for this system: x aq → x oct.

If X is a hydrocarbon, $\mathbf{\Delta G} < 0$. Also, $\mathbf{\Delta G^o} < 0$, since this term is independent of concentration and depends only on the intrinsic stability of x in water in comparison to that of octanol. This simple equation holds:

$$\Delta \mathrm{G_{TOT}} = \left(\mathrm{G^0_{X-oct}} - \mathrm{G^0_{X-w}}\right) + RT\ln\frac{[\mathrm{X}]_{\mathrm{oct}}}{[\mathrm{X}]_{\mathrm{w}}} = \Delta \mathrm{G^0} + RT\ln\frac{[\mathrm{X}]_{\mathrm{oct}}}{[\mathrm{X}]_{\mathrm{w}}} \tag{10.2.3}$$

At equilibrium, ΔG^0=0 and the equation can be rewritten as:

$$\Delta \mathrm{G^0} = -RT\ln\frac{[\mathrm{X}]_{\mathrm{oct}}}{[\mathrm{X}]_{\mathrm{w}}} = -\mathrm{RTlnK_{part}} \tag{10.2.4}$$

where K_{part} is the equilibrium partition coefficient for X in octanol and water. This can readily be determined in the lab. Just shake a separatory flask with a biphasic system of octanol and water after injecting a bit of X. Then separate the layers and determine the concentration of x in each phase. Plug these numbers into the last equation. You should be able to predict the sign and relative

magnitude of ΔG^o since it does not depend on concentration, but only on the intrinsic stability of the molecules in the different environments. K_{paft} values are often determined for drugs since they often must diffuse across cell membranes to move into the cytoplasm where they can act. Drugs hence must have a reasonable K_{part} to pass through the membrane but not so high that they are insoluble.

10.2.2: Double Chain Amphiphiles and Bilayers

In contrast to single chain amphiphiles, double-chain amphiphiles added to water form monolayers and vesicles called liposomes, as shown in Figure 10.2.8.

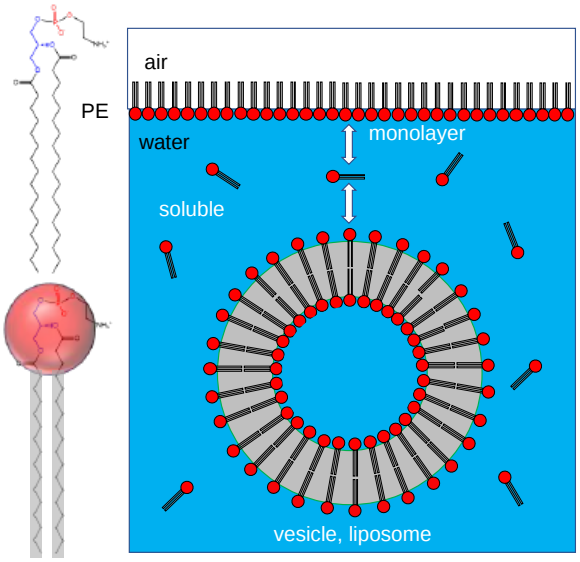

Figure 10.2.8: Distribution of double chains amphiphiles in an aqueous solution

They can be unilamellar, consisting of a single bilayer surrounding the internal aqueous compartment, or multilamellar, consisting of multiple bilayers surrounding the enclosed aqueous solution. You can image imagine that multilamellar vesicles resemble an onion with its multiple layers. Cartoons of unilamellar and multilamellar liposomes are shown in Figure 10.2.9, where each concentric circle represents a bilayer.

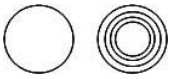

Figure 10.2.9: unilamellar and multilamellar liposomes (vesicles)

Liposomes vary in diameter. They can be generally categorized into small (S, diameter < 25 nm), intermediate (I, diameter around 100 nm), and large (L, diameter from 250-1000 nm). If these vesicles are unilamellar, they are abbreviated as SUV, IUV, and LUV

The chemical composition of liposomes made in the lab can be widely varied. Most contain neutral phospholipids like phosphatidylcholine phosphatidyl ethanolamine (PE), or sphingomyelin (SM), supplemented, if desired, with negatively charged phospholipids, like phosphatidyl serine (PS) and phosphatidyl glycerol (PG). In addition, single-chain amphiphiles like cholesterol (C) and detergents can be incorporated into the bilayer membrane, which modulates the fluidity and transition temperature (Tm) of the bilayer. If present in too great a concentration, single-chain amphiphiles like detergents, which form micelles, can disrupt the membrane so completely that the double-chain amphiphiles become incorporated into detergent micelles, now called mixed micelles, in a process that effectively destroys the membrane bilayer.

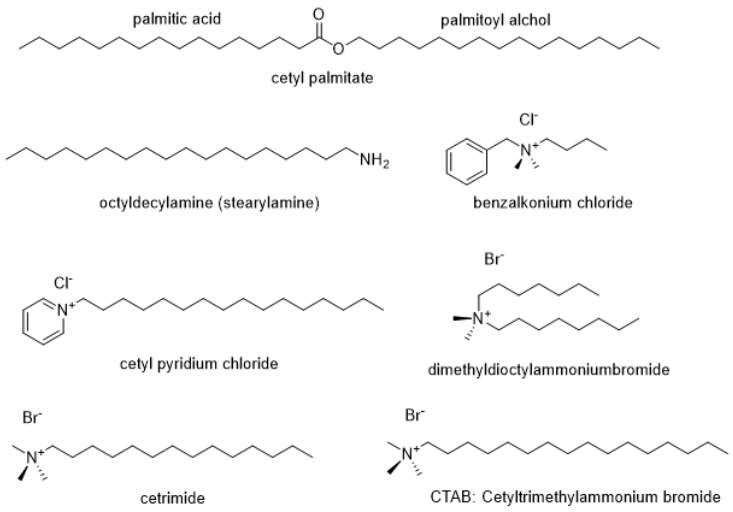
The properties of liposomes (charge density, membrane fluidity, and permeability) are determined by the lipid composition and size of the vesicle. The desired properties will be, in turn, determined by the use of the particular liposome. The vesicles offer wonderful, simple models to study the biochemistry and biophysics of natural membranes. Membrane proteins can be incorporated into the liposome bilayer using the exact method you will be using. But apart from these purposes, liposomes can be used to encapsulate water-soluble molecules such as nucleic acids, proteins, and toxic drugs. These liposomes can be targeted to specific cells if antibodies or other molecules which will bind specifically to the target cell can be incorporated into the bilayer of the

vesicle. Intraliposomal material may then be transferred into the cell either by fusion of the vesicle with the cell or by endocytosis of the vesicle.

Liposomes could also be called lipid nanoparticles as they have sizes ranging up to 1000 nm. Liposomes are vesicular - with small aqueous-filled compartments. They can be made with encapsulated drugs for delivery to target cells through blood transport. They act as an emulsion in water.

Lipid nanoparticles can also be particulate (insoluble), which slowly degrade and release their contents slowly in situ. Most recently, particulate lipid nanoparticles have helped save the world by being used to encapsulate messenger RNA (mRNA) for the spike protein from the SARS-CoV-2 virus which causes the COVID-19 pandemic. These lipid nanoparticles are used in the vaccine against the coronavirus mRNA molecules which encode the spike protein are "encapsulated" in the lipid nanoparticle. The mRNA contains specially modified nucleotides to increase their stability. The lipid nanoparticles also contain positively-charged lipids which help stabilize the negatively charged mRNA from degradation. The nanoparticles are endocytosed into cells, where the mRNA can be translated into SARS-CoV-2 spike protein, required for whole virus entry into the cell. The spike protein is then recognized by the immune system.

The lipids used in the formulation of these nanoparticles include fatty acids, mono-, di- and triglycerols, glycerophospholipids, waxes (like cetyl palmitate), and other positively charged lipids including stearyl amine, benzalkonium chloride, cetrimide, cetyl pyridinium chloride, and dimethyldioctadecylammonium bromide. These are shown in Figure 10.2.10



10.2.3:

Figure 10.2.10 Amphiphiles used to make lipid nanoparticles

10.2.4: Why Micelles and Bilayers?

Micelles and liposomes form spontaneously - i.e. $\Delta G < 0$. But why do single chain amphiphiles form micelles and double-chain amphiphiles form bilayers? Let's think about this from a thermodynamics and structural sense.

As the number of Cs in the nonpolar carbon (NC) chain increases, the ΔG for the transferring into a micelle, or by analogy, for a single chain amphiphile entering a micelle, becomes more and more negative (i.e more favored). The following equation seems to apply to the transfer of a single chain amphiphile into a micelle:

$\Delta G^o = G^o$ (mic) - G^o (aq) = + number - 709 NC

$$\Delta G^\circ = G^\circ \text{ (mic)} - G^\circ \text{(aq)} = + \text{number} - 709\text{NC} \tag{10.2.5}$$

where NC is the number of carbon atoms in the chain. The first positive term depends on the nature of the head group, while the second negative term is independent of the head group. These + and - terms bring us back to the principle of opposing forces we discussed when we looked at the noncovalent interactions involved in micelle and bilayer formation.

There are attractive interactions, including induced dipole-induced dipole interactions among the chains and dipole-ion, and H-bond interactions with water and the head groups. There are likewise repulsive interactions arising from steric hindrance with bulky

heady groups and ion-ion repulsions. Of course, there are also entropic considerations. Let us now consider these factors as we explore what might happen to a preformed micelle as we try to put more single chain amphiphiles (**sca**) into it.

As we increase the number of Cs in the SCA, the micelles would have a larger radius. For a given SCA with a fixed number of Cs, once a spherical micelle is formed, it can no longer retain its spherical shape if more SCAs are added. Imagine increasing the diameter of a spherical micelle 10x. A large part of the inside would have no atoms or be filled with water, which would not be favorable. Therefore, if the micelle is to grow, it can do so only by changing shape to something other than a sphere. By squeezing a tennis ball, one can imagine that the shape could distort to a circular cylinder with end caps. In this way, the acyl chains can still interact. The only problem is that head groups will now be closer than they were in the sphere. This is simplistically illustrated in Figure 10.2.11.

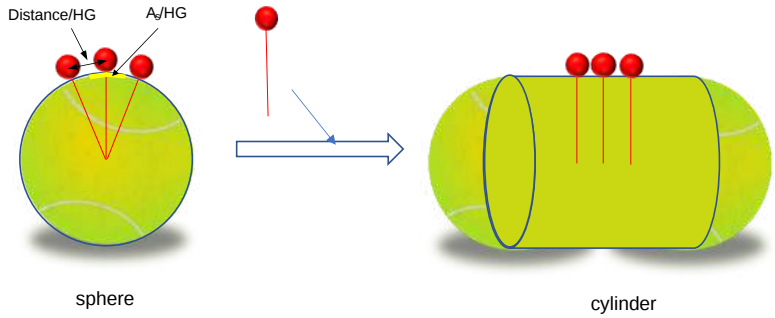


Figure 10.2.11: Hypothetical change in head group interactions on the conversion of spherical vesicle to a cylindrical vesicle

Imagine in a sphere the head groups radiating in a perpendicular direction from the sphere surface. As the sphere is distorted into a cylinder, the head groups would come closer together, and hence they will experience more steric interference. If a cylinder can be formed, however, it could continue to grow as long as needed with no further compression required. Imagine now that you further compressed the cylinder into a planar "bilayer" structure. The head groups would be even closer and experience even more repulsion. This bilayer will not form since growth can occur in the cylindrical phase without the added repulsion.

Now consider a double-chain amphiphile (DCA). In the case of a SCA, the number (N) of head groups (HG) = the number of acyl chains (CH). Hence the surface area per HG is equal to the area per HC. Or: As/N HG = As/ N CH. For a DCA, N HG = N CH/2, therefore As/N HG = 2As/NCH. There is twice the surface area available per head group compared to that of the SCA. Therefore the DCA can tolerate more compression. It can easily be compressed to a bilayer, which as we saw, has much less As/HG. The cylindrical form has too much space per head group since water can enter the structure. The extra closeness of head groups in the bilayer can be tolerated even more since the ΔG^{o} for transfer of a DCA into a micelle is 60% more negative than that of a SCA. The As/HG for closed vesicles differs only slightly from that of a truly planar bilayer since the vesicles are so large compared to a micelle.

Once again, we have discovered that structure mediates function. We can account for the fact that SCA and DCA form micelles and bilayers, respectively, by understanding the structure of the monomers!

In reality, things are more complicated.

The general rule holds that single chain amphiphiles form micelles and double-chain amphiphiles form bilayers. However, under the right condition, single-chain fatty acids can form bilayers if the pH is low enough that the head group is protonated and uncharged. Why would that make a difference? Fatty acids like oleic acid would be a prime candidates for components of the membranes of protocells in the evolution of life from abiotic conditions. Likewise, short double-chain amphiphiles can make micelles. In addition, other lipids phases can be observed. Which aggregates or phases ultimately form depends on the structure of the lipid, the solvent conditions, and the temperature. These include the following phases:

- lamellar gel (Lb) and lamellar liquid crystalline (La) phases
- hexagonal HI (cylinders packed in the shape of a hexagon with polar heads facing out into the water
- hexagonal HII (cylinders packed in the shape of a hexagon with acyl chains pointing out as in reverse micelles, and
- micellar (M).

We will discuss them in more detail in the next section.

10.3: Membrane Bilayer and Monolayer Assemblies - Structures and Dynamics

10.3.1: An overview of lipid bilayers

A membrane bilayer consists of more than just two leaflets of amphiphilic leaflets. It also contains membrane proteins (which we will discuss in the next chapter) which can also be attached to carbohydrates. Most assuredly you have seen various representations of a bilayer before. Before we proceed with a more detailed description of the lipids in the bilayer and its associated properties, we present Figure 10.3.1 to focus our discussion.

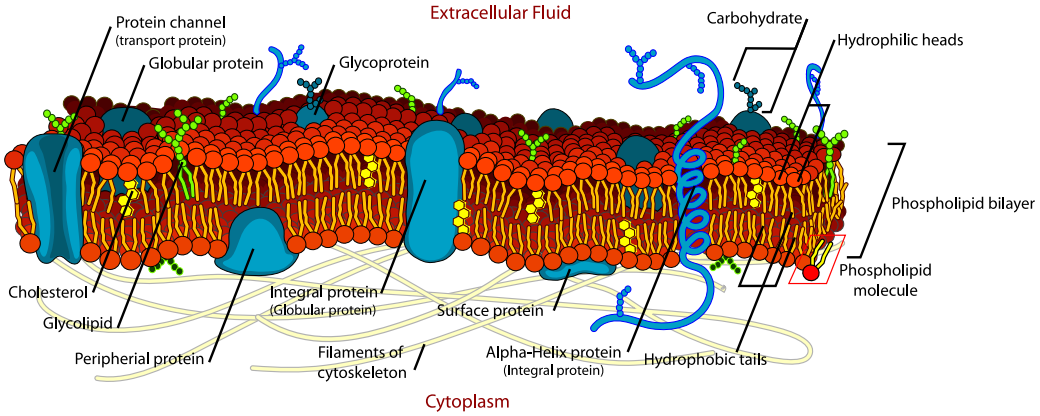

Figure 10.3.1: A representation of a membrane bilayer with peripheral and integral membrane proteins. https://cnx.org/contents/FPtK1zmh@8.108:q2X995E3@12/The-Cell-Membrane. Creative Commons Attribution 4.0 International license.

To understand the movement of lipids in an actual cell, a better understanding of lipid synthesis and trafficking in cells is important. Table 10.3.1 below shows the distribution of four classes of lipids in a macrophage, a type of immune cell (Andreyev, A.Y. et al) while the following figure shows how the lipids composition of membranes organelle membranes.

Table 10.3.1: Distribution of Lipids in Resting Macrophage

Lipid Categories	Nucleus	Mitochondria	ER	Plasma Memb	microsome	cytosol	Whole cell
Glycero-phospholipids	149	152	150	151	142	109	155
Prenol lipids	5	5	5	5	5	5	5
Sphingolipids	48	47	48	48	48	47	48
Sterol lipids	13	12	12	13	11	5	12
Total	215	216	215	217	206	166	220

Lipids in membranes are often distributed asymmetrically. The inner and outer leaflets of a biological membrane usually have different PL compositions. For example, in red blood cell membranes, the outer leaflet is composed mostly of sphingomyelin (SM) and PC, while the inner leaflet is composed mostly of PE and phosphatidyl serine (PS). This phospholipid contains the amino acid serine linked through its side chain (-CH2OH) to phosphate in position 3 of diacylglycerol. With a negative charge on the phosphate and carboxylate and a positive charge on the amine of PS, this phospholipid is acidic with a net negative charge. All the PS is located in the inner leaflet! This observation will become important later on when we discuss programmed cell death. A dying cell will expose PS in the outer leaflet. This is one of the markers of a dying cell. The membrane lipid composition in an average mammalian cell is shown in Table 10.3.2 below.

Table 10.3.2: Membrane lipid composition in an average mammalian cell.

Lipid	%
PC	45-55
PE	15-25

Lipid	%
PI	10-15
PS	5-10
PA	1-2
SM	5-10
cardiolipin (bis-PG)	2-5
cholesterol	10-20

Lipid membranes also surround the variety of intracellular organelles found in eukaryotic cells. As a refresher, Figure 10.3.2 shows the anatomy of a typical eukaryotic cell with its variety of intracellular organelles.

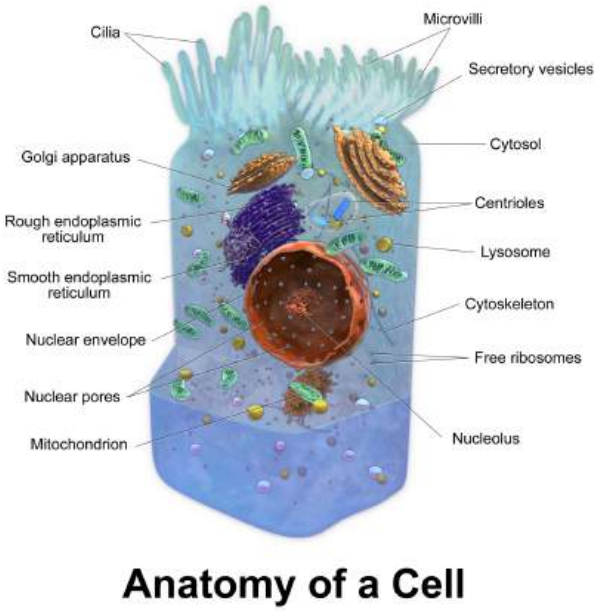

Figure 10.3.2: The Anatomy of a eukaryotic cell. https://opm.phar.umich.edu/biological_membranes https://creativecommons.org/licenses/by/3.0/

Figure 10.3.3 shows the average distribution of membrane lipids in different eukaryotic organelles.

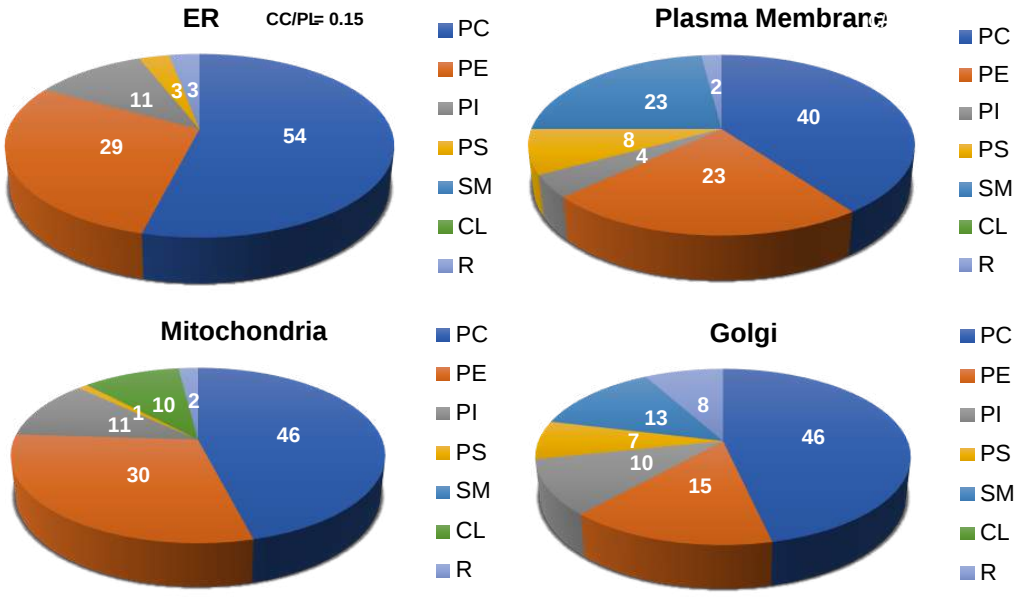

Figure 10.3.3: Average distribution of membrane lipids in different eukaryotic organelles

Figure 10.3.4, our last overview, shows the location of lipid synthesis and the resulting distribution of lipids in each leaflet. Note that most lipids are synthesized in the endoplasmic reticulum (ER).

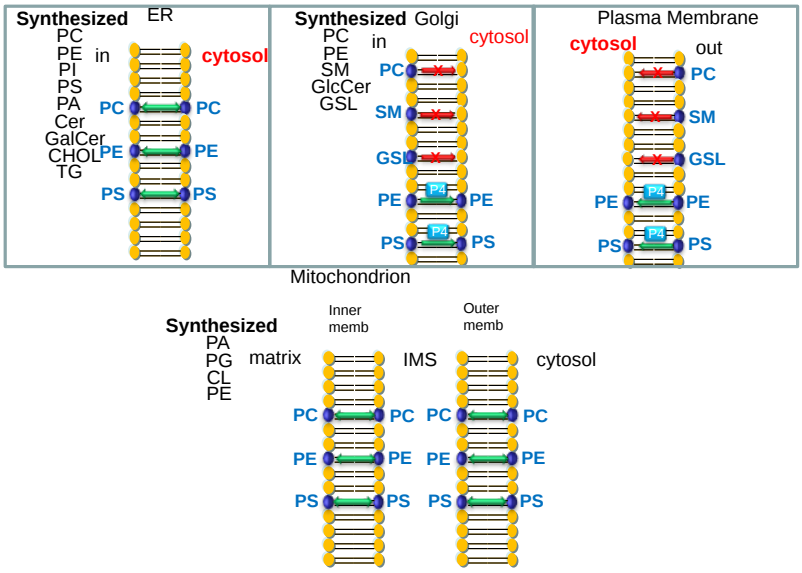

Figure 10.3.4: Location of lipid synthesis and the resulting distribution of lipids in each leaflet.

10.3.2: Dynamics of Membrane Bilayers

Molecules are not static, but rather are dynamic. This also applies to molecular aggregates. In the first part of the section, we will discuss the rigid movement of whole lipid molecules in a bilayer, within a leaflet, and between leaflets. In the second part and the following supplement, we will consider the movement of atoms within a molecule. The movements include motions like bond bending, bond stretching, and torsion angle changes as we saw in the previous chapter section on the conformations of n-butane. The position of all atoms within a molecule can be simulated as a function of time - a molecular dynamics simulation. Such motions affect the energy of the molecule, which can be calculated for given atom positions using classical molecular mechanics and electrostatics.

Liposomes and bilayers in general must be somewhat dynamic, otherwise, they would be impenetrable barriers across which nothing could pass. Cell membranes must separate the outside of a cell from the inside, but they must also allow the passage of

molecules and even ions across the membrane. What is the evidence that membranes are dynamic?

First, lipids can diffuse laterally in the membrane. This can be shown as follows. Make a liposome from phosphatidylethanolamine, PE, which has been labeled with TNBS (trinitrobenzensulfonate). The NH_2 on the head group of PE can attach the TNBS which undergoes nucleophilic aromatic substitution with the expulsion of the SO_3^{2-}. The TNB group attached to the PE head group absorbs UV light and emits light of a higher wavelength in a process called fluorescence. Next, using a fluorescent microscope, the fluorescence intensity of a region of the surface can be recorded. Then shine a laser on a small area of the surface, which can photobleach the fluorescence in the area. Over time, fluorescence can be detected from the region again. The rate at which it returns is a measure of the lateral diffusion of the labeled lipids into the region. Lipids can undergo lateral diffusion at a rate of about 2 mm/s. This implies that the lipids can transit the surface of a bacteria in 1 sec.

Transverse or flip-flop diffusion (movement of a phospholipid from one leaflet to the other, not within a given leaflet) should be more difficult. Experimentally, this is investigated as shown in the diagrams below.

Flip-Flop Diffusion in Liposomes: To test flip-flop diffusion in an artificial membrane, liposomes are made with a mixture of PC and a PC derivative with a nitroxide spin label (has a single unpaired electron) as shown in Figure 10.3.5.

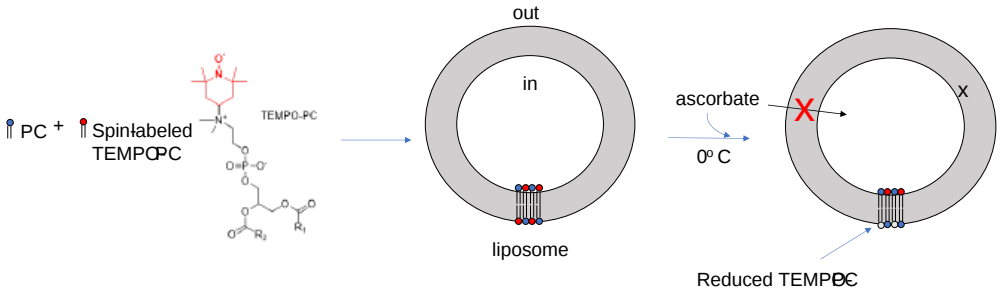

Figure 10.3.5: Flip-flop diffusion in vesicles

Both the inner and outer leaflets of the membrane have the labeled PC. Like a proton in NMR spectroscopy, a single electron has a spin that can give rise to an electron-spin resonance (ESR) signal (as a proton gives rise to a nuclear magnetic resonance signal) when irradiated with the appropriate frequency electromagnetic radiation (microwave frequency for ESR, radio frequency for NMR) in the presence of a magnetic field. The liposomes are kept at 0°C and the ESR signal is determined. Ascorbic acid, a water-soluble vitamin, and antioxidant/ reducing agent is added to the liposomes. This reduces the spin-labeled PC in the outer leaflet, but not the inner leaflet of the bilayer since ascorbic acid can not enter the liposome or otherwise interact with it. This reduces the ESR signal to a lower, constant value.

The sample is divided into two. One sample is left at 0°C, the other is raised to 30°C. The ESR signal is recorded as a function of time. The 0°C prep shows no change in ESR with time, while the 30°C prep ESR signal decreases with time. This decrease results from flip-flop diffusion of labeled PC from the inner leaflet to the outer, and subsequent reduction by ascorbic acid. These experiments in experimental bilayer systems like liposomes show that flip-flop diffusion is orders of magnitude slower than lateral diffusion.

Flip-Flop Diffusion in Bacterial Cells

An analogous experiment can be done with bacteria. Radiolabeled $^{32}PO_4^-$ is added to cells for one minute, which leads to the labeling of newly synthesized phospholipid (PL) which locates in the inner leaflet. The cells are then split into two samples. One sample is reacted immediately with TNBS, which will label only PE in the outer leaflet. The other sample is incubated for 3 minutes (to allow PL synthesis) and then reacted with TNBS. This is shown in Figure 10.3.6.

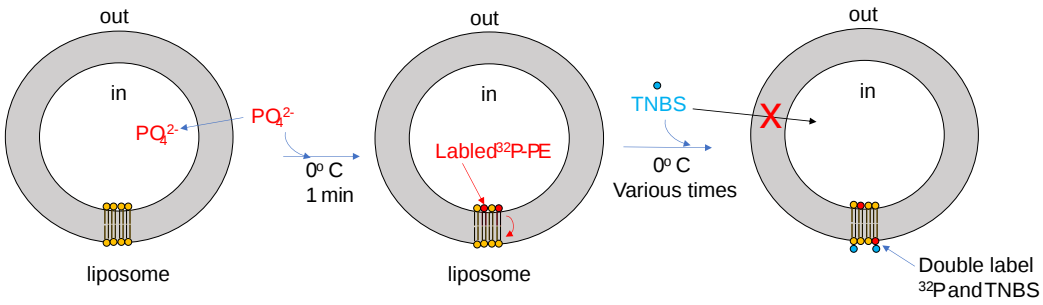

Figure 10.3.6: Flip-Flop Diffusion in Bacterial Cells

After a short labeling period, the cells are destroyed by adding organic solvents which prevent new lipids biosynthesis. The lipids are extracted into the solvent and then subjected to TLC.

The lipids can be labeled in three ways. Some will be labeled with ^{32}P alone, some with TNBS alone, and some with both ^{32}P and TNBS. TLC (or other techniques such as HPLC or GC) can easily separate PC and TNBS-labeled PC since they have different structures and hence will migrate to different places on a TLC plate. No chromatographic technique could, however, separate PC and ^{32}P-PC, since their molecular structure is the same, the only difference being in the nuclei of the P (different number of neutrons).

Those lipids with double labels (TNB and ^{32}P) must have flipped from the inner leaflet to the outer leaflet where they could be labeled with TNBS. The cells incubated for 3 minutes before the addition of TNBS have a much higher level of doubly labeled PLs. Quantitating these data as a function of differing time of incubation at elevated temperatures show that the rate of flip-flop diffusion is much higher in cells than in liposomes, which suggests that the process is catalyzed, presumably by a protein transporter (flippase or Transbilayer amphipath transporter - TAT) in cells.

The actual movement of lipids in bilayers is catalyzed by different enzymes, including flippases, floppases, and scramblases, as illustrated in Figure 10.3.7. Most required ATP hydrolysis for the physical movement of the lipid across leaflets.

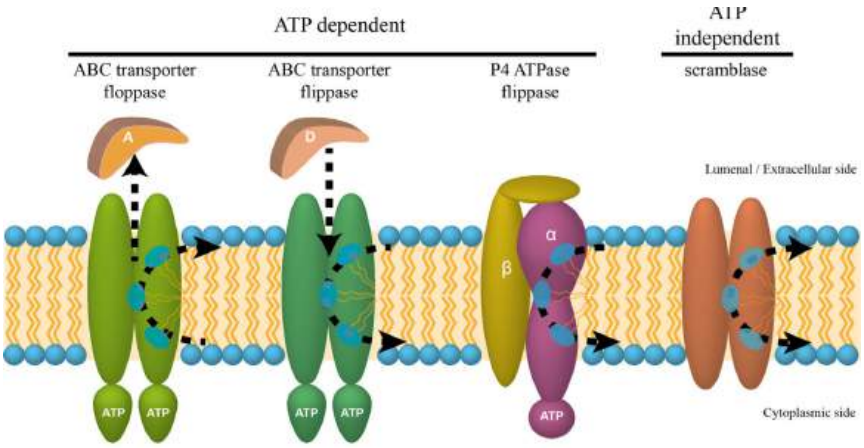

Figure 10.3.7: Enzymes that move lipids between leaflets. Juliana Rizzo et al. https://doi.org/10.1016/j.csbj.2019.09.001. Creative Commons: https://creativecommons.org/licenses/by/4.0/

Figure 10.3.8 shows an interactive iCn3D model of a human plasma membrane phospholipid flippase with bound phosphatidylserine (PS) shown in spacefill.

The iCn3D model below shows the structure of a human plasma membrane phospholipid flippase with bound phosphatidylserine (PS) shown in spacefill. This protein moves PS from the outer to the inner plasma membrane leaflet, maintaining its asymmetric distribution. The other common aminophospholipid, PE, is also found predominantly in the inner leaflet. In contrast, PC and SM are found predominately in the outer leaflet. The movement of PS is from low to a high concentration and requires ATP. A build-up of PS in the outer leaflet is one signal that initiates programmed cell death (apoptosis) in the cell. Clotting is also initiated when cellular damage leads to exposed PS.

Flippases are proteins that move lipids from the outer to the inner leaflet, while floppases move them from the inner to the outer leaflet. Most are also ATPases. Both promote lipid asymmetry in the membrane and floppases also help move lipids out of the cell. Scramblases moved lipids in either direction and break the asymmetry of the lipid distribution. They are important in signaling. For example, they are used to expose phosphatidylserine to the outer leaflet which promotes programmed cell death.

10.3.3: Conformational Transitions in Bilayers

If a vesicle preparation is placed in a sensitive calorimeter and the temperature slowly increased, it is observed that the vesicle preparation absorbs a significant amount of heat at a temperature characteristic of the PLs which compose the vesicle. This is analogous to what would happen if solid water was heated. At the melting point of water, an increment of heat is required, the heat of fusion, to break H-bonds and cause melting. Likewise, the heat of vaporization is measured when H-bonds are broken on the liquid-gas transition. These transitions are associated with non-covalent processes, namely, breaking H-bonds. Graphs of heat absorbed (Q) as a function of temperature, or heat absorbed/T (i.e. the heat capacity) vs temperature for the melting and evaporation of water is shown in Figure 10.3.9. These transitions occur at the melting point (T_M) and the boiling point.

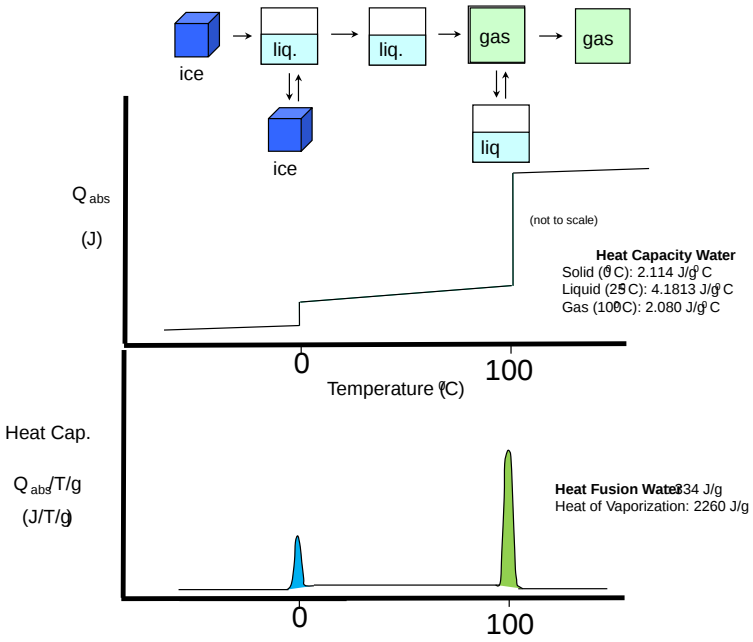

Figure 10.3.9: heat absorbed (Q) vs temperature (top) and heat absorbed/T (heat capacity) vs temperature for the melting and evaporation of water

The bottom heat capacity graph is nothing more than the derivative curve (or slope at each point) of the Q_{abs} curve!

Likewise, lipid vesicles undergo phase transitions comparable to the melting of water. One large phase transition at a "melting point" (T_M) = 42^0 C can be seen in the graph of heat capacity vs temperature for vesicles made of DPPC shown in Figure 10.3.10

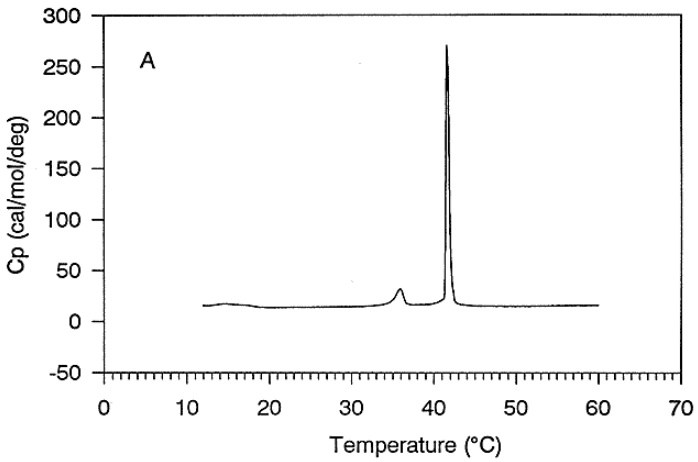

Figure 10.3.10: Heat capacity vs temperature for vesicles made of DPPC

This transition is caused by conformational chains in the packing of the acyl chains of the phospholipids as the acyl chains change from trans to gauche conformations. These changes involve not the simple translation of lipid molecules within and between bilayers but rather the movement of atoms within the molecules. These kinds of motions can be modeled using molecular dynamics simulations. Before the transition, the acyl chains are more tightly packed in the **gel phase**, and after they are less tightly packed in the **liquid crystalline phase** since many chains are in the gauche conformation. A minor transition is also noted at around 36^0 C. This is associated with changes in the orientation of head groups.

As with water going from ice to liquid, the vesicles after the phase transition are still intact. It's not like the transition of liquid to gas phase water. Vesicles in the liquid crystalline phase are more fluid, dynamic, and hence more permeable. Note that the liposomes have not been destroyed but simply have undergone a phase change, much like ice turning to liquid water.

The phases of lipid vesicles are given the names gel and liquid crystalline to reflect the rigidity of the bilayer.

- **Gel phase** (L_β): In the gel phase, which is found at temperature < T_M, the lipids are ordered with maximal packing. The acyl chains in both leaflets can be tilted so that they align in a parallel fashion (as shown in the figure below) or in a cross-tilted fashion in which they tilt toward each other. In the gel phase, the lipids diffuse slowly. This phase is sometimes called the solid phase. The gel phase is favored by low temperature and high saturation of esterified fatty acids. Saturated PC bilayers give a gel phase in the lab,
- **Liquid crystalline phase** (L_α): In this liquid crystalline phase, which is found at temperature > T_M, some saturated acyl chains have undergone all trans to gauche conformational changes. These introduce kinks into the chains which reduce packing. The notation L_α is used for bilayers of pure lipids
- **Liquid crystalline ordered** (L_0) and **Liquid crystalline disordered** (L_d): These phases typically occur with the addition of relatively high amounts of cholesterol. Cholesterol modulates the fluidity of membranes as we will see in a bit and affects bilayer properties at temperature both < and > T_M. The L_0 phase is often enriched in saturated (sphingo)lipids and cholesterol while the L_d phase is often enriched in unsaturated glycerophospholipids. The **liquid crystalline disordered** (L_d) has fast translational diffusion and lower order while the **Liquid crystalline ordered** (L_0) has fast diffusion with higher order.

Most membrane lipids *in vivo* contain unsaturated fatty acids and use specific lipids for given environments to avoid the gel phase. Figure 10.3.11shows some of these phases

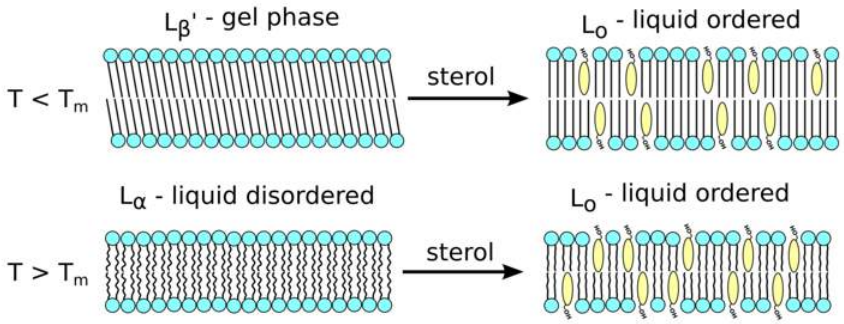

Figure 10.3.11: Common phases in membrane bilayers https://phys.libretexts.org/Courses/...se_Transitions

Figure 10.3.12shows a snapshot of a molecular dynamics simulation of a bilayer in a gel (A) and liquid crystalline (B) phase. Note that the width of the liquid crystalline phase is smaller.

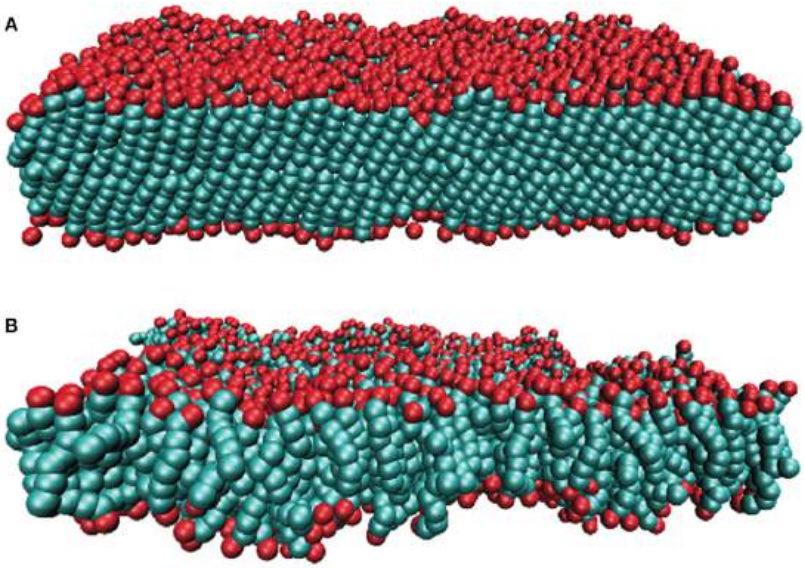

Figure 10.3.12: Snapshot of a molecular dynamics simulation of a bilayer in a gel (A) and liquid crystalline (B) phase. Tayebeh Jadidi et al. Bioeng. Biotechnol., 22 April 2014 | https://doi.org/10.3389/fbioe.2014.00008. **Creative Commons Attribution License (CC BY)**.

Vesicles made of different PL have different T_M as shown in Table 10.3.3below.

Table 10.3.3: Melting point (TM) of vesicles made with different phospholipids

Lipid	T_M	Lipid	T_M

Lipid	T_M	Lipid	T_M
12:0 PC	-1	12:0 PA	31
14:0 PC	23	14:0 PA	50
16:0 PC	41	16:0 PA	67
18:0 PC	55	18:0 PA	76
18:1 PC	-20	18:1 PA	-8
18:2 PC	-53	-	-
18:3 PC	-60	-	-

Vesicles make from phospholipids with bigger head groups have a lower T_M, since they are less "stable". For example, the Tm for vesicles of di-16:0 versions of PA, PE, and PC have T_Ms of 67, 63, and 41 degrees C, respectively, as shown in Figure 10.3.13

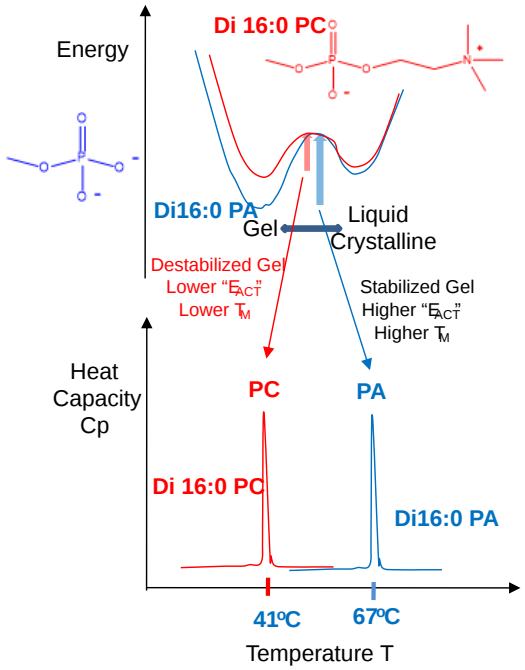

Figure 10.3.13: Melting point (T_M) of 16:0 vesicles with different head groups

10.3.4: Cholesterol and Membrane Fluidity

Cholesterol is also a ubiquitous component of animal cell membranes. Its size will allow it to fit into either leaflet with its polar OH pointed to the outside. One function of cholesterol in membranes is to keep the membrane fluid at any reasonable temperature. When a membrane is at a temperature less than the T_M, it is ordinarily in a gel, not a liquid crystalline phase. The cholesterol helps prevent the ordered packing of the acyl chains of the PLs, which increases their freedom of motion. Hence the fluidity and permeability of the membrane are increased. At temperatures greater than the T_M, the rigid ring of cholesterol reduces the freedom of the acyl chains to rotation and hence decreases the number of chains in the gauche conformation. This decreases fluidity and permeability. Cholesterol affects membrane structure at temperatures both below and above the T_M as

Figure 10.3.14shows the results of a molecular dynamics simulation depicting the relative order in a DMPC membrane with and without cholesterol

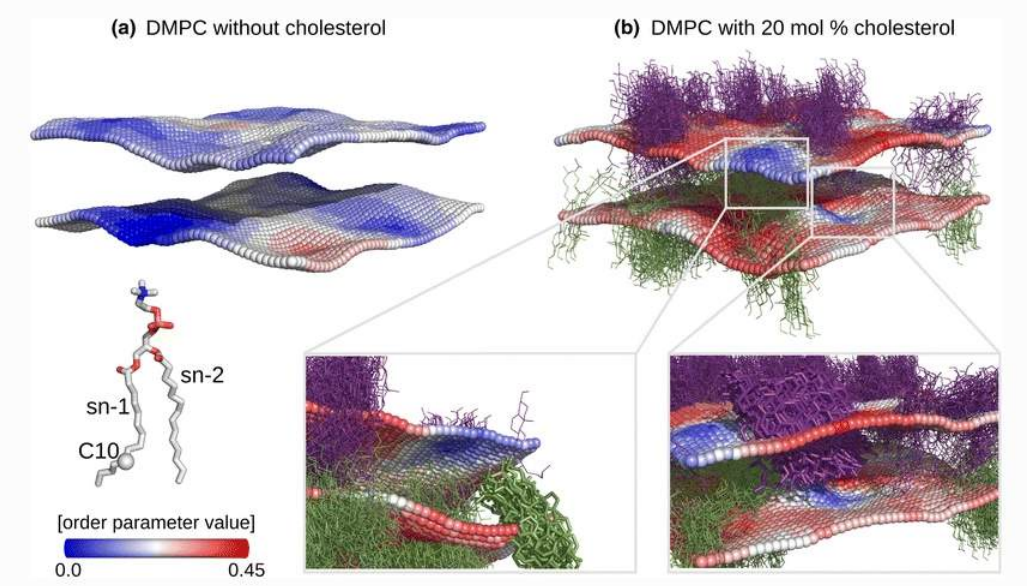

Figure 10.3.14: "S_{CD} order parameter analysis of cholesterol-enriched DMPC bilayer. Order parameter values for the C10 carbon of the acyl chain sn-1 are shown. The box area was 5.6 × 5.6 nm^2 and 50 bins were used along the *x* and *y* axes. **a** Local deuterium order parameters of a pure DMPC membrane averaged over a 100 ns MD trajectory. **b** Local S_{CD} order parameters for a 20 mol% DMPC bilayer averaged over a 10 ns MD trajectory excerpt. The cholesterol molecules represented as *lines* are overlayed for all the frames. The enlarged view figures emphasize the areas where cholesterol (visualized as sticks) decreases ordering of the lipid chains on the opposite leaflet" (from below ref)

10.3.5: Lipid Rafts and Nanodomains

Not only are lipids asymmetrically distributed between leaflets of a bilayer, but they are also distributed asymmetrically within a single leaflet. Certain lipids often cluster within a leaflet to form lipid "rafts" which can be considered to result from lateral phase separation of the lipids within one leaflet of the bilayer. Divalent cations like calcium, which can bind to negatively charged PLs like PS, can cause "rafts" of PS to form, giving rise to lateral asymmetry within a leaflet of a bilayer. Rafts also appear to be enriched in cholesterol and lipids with saturated fatty acids, especially sphingolipids, which would lead to regions of enhanced packing and reduced fluidity. Cholesterol would stabilize packing in spaces created with lipids with large head groups. You can think of these rafts as nanodomains, analogous to the domains we observed in protein structure.

Cholesterol appears to be a key player in the formation of lipid rafts. It is planar and inflexible and would pack better with saturated fatty acid chains and could also induce them to elongate to form lower energy zig-zag structures in which all the methylene groups are anti. Lipid rafts would represent a more ordered lipid phase (Lo) compared to the more disordered surrounding phase (Ld). Also compared to the structure of glycerophospholipids, the atoms in the region linking the head group and the nonpolar fatty acid chains in sphingolipids have greater potential for H bond interactions with cholesterol and other sphingolipids, as shown in Figure 10.3.15

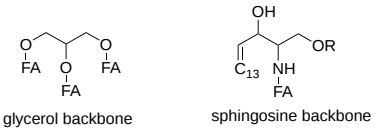

Figure 10.3.15: Comparison of glycerol and sphingosine headgroup structure. FAs are fatty acids esterified (glycerol) or amide link (sphingosine)

Rafts probably bind or exclude the binding of other biological molecules like proteins. Some proteins are chemically modified with a glycosylphosphoinositol (GPI) group at the carboxy terminus. The PI group can insert into the membrane, anchoring the protein to the bilayer. Protein also appear to induce raft formation. Lipids rafts appear to be enriched in glycosylphosphoinositol (GPI)-anchored proteins as we will see in Chapter 11.1. Recent studies have shown that the Ebola virus interacts with lipid rafts in the process of entering and exiting the infected cell. Rafts are also involved in how cells sense and respond to their environment. Signaling molecules on the outside of the cell can bind receptor proteins in the membrane. As we will see later, conformational changes in the receptor protein signal the inside of the cells that the receptor is bound with a ligand. Once bound, the receptor can move in the membrane and often cluster in outer leaflet rafts that contain cholesterol and sphingolipids. Inner leaflet rafts have also

been observed. Figure 10.3.16 shows two versions of an animated version of a lipid raft. The large shapes represent membrane proteins selectively found in the rafts. The most modern definition of a lipid raft is a nanoscale assembly of sphingolipids, cholesterol, and proteins that can be stabilized into platforms.

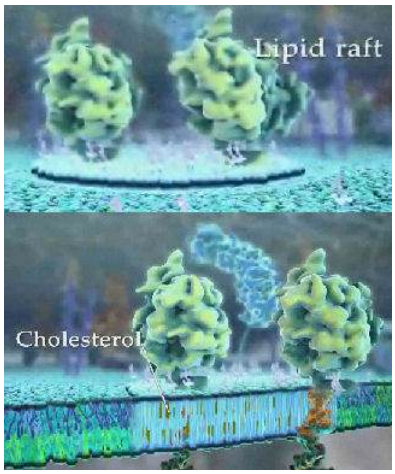

Figure 10.3.16: Lipid Rafts enriched in SM and Cholesterol. (screen capture from: http://multimedia.mcb.harvard.edu/anim_innerlife.html)

Figure 10.3.17 shows a simplified model of a lipid raft.

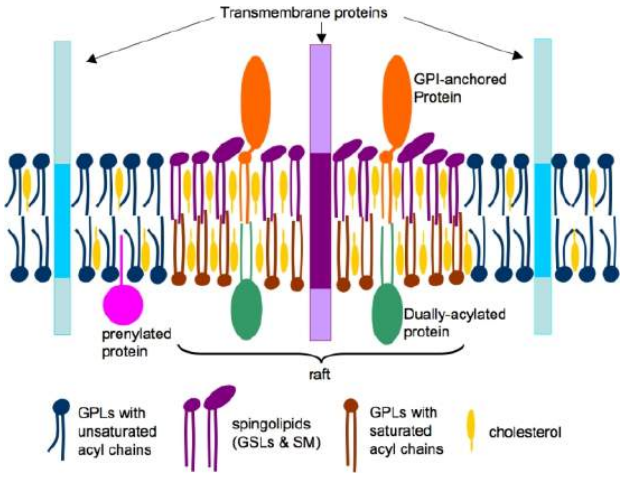

Figure 10.3.17: A simplified model of lipid rafts in cell membranes. https://www.researchgate.net/figure/..._fig4_45952334. license: https://creativecommons.org/licenses/by/3.0/

"The phospholipids (blue and brown) and cholesterol (yellow) are distributed in both the leaflets, whereas sphingolipids (violet) are enriched in the outer leaflet of the bilayer. The acyl chains of raft lipids are generally long and saturated (violet and brown), whereas those in non-raft domains are shorter and contain singly or multiply unsaturated acyl chains (blue). Raft domains contain concentrations of dually-acylated (green) and GPI-anchored (brown) proteins, whereas transmembrane (blue) and prenylated (green) proteins are usually non-raft associated."

Lipid bilayers, in contrast to single proteins, for example, are physical mixtures. In a thermodynamic sense, entropy would disfavor raft formation as random mixing is favored. Enhance enthalpic must drive the interaction between neighboring molecules to produce nanodomains and rafts.

10.3.6: Lipid Phase Diagrams

You are familiar with the phase diagrams of water from introductory chemistry classes. Phase diagrams show the different phases that are accessible under different sets of conditions such as temperature and pressure. A traditional phase diagram for water is shown in Figure 10.3.18

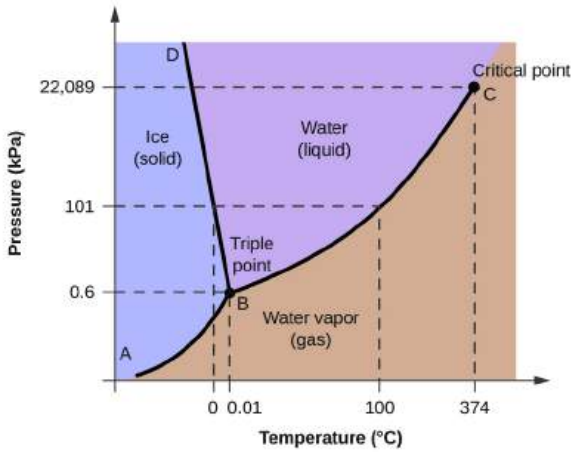

Figure 10.3.18: A traditional phase diagram for water. https://opentextbc.ca/chemistry/chap...hase-diagrams/. Chemistry by Rice University is licensed under a Creative Commons Attribution 4.0 International License.

The horizontal dotted line at 101 kPa shows the states of water as a function of temperature at 101 kPa = 1 atm pressure. The phase transition of solid to liquid water occurs at 0^0 C (freezing/melting point of water) while the liquid to gas transition occurs a 100^0 C (boiling point of water). At a reduced pressure (0.6 atm), all three phases of water can exist at 0.01 ^{0} C, the triple point of water.

In an analogous fashion, lipid bilayers have phase transition diagrams as well. Instead of showing phases as a function of temperature and pressure, they are usually shown as a function of temperature and concentration of a specific lipid component such as cholesterol, which as described above affects T_M, fluidity, and raft formation. An example of a **theoretical** phase diagram for membranes composed of saturated dipalmitoylphosphatidylcholine (16:0), the most common saturated fatty acid in animals, plants, and microorganisms vs cholesterol content is shown in Figure 10.3.19

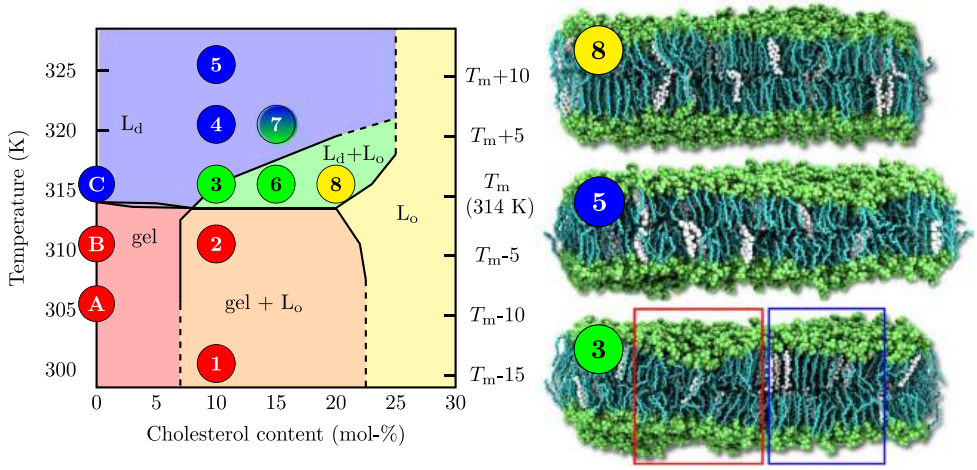

Figure 10.3.19: Javanainen, M., Martinez-Seara, H. & Vattulainen, I. Nanoscale Membrane Domain Formation Driven by Cholesterol. *Sci Rep* **7,** 1143 (2017). https://doi.org/10.1038/s41598-017-01247-9. **https://rdcu.be/chbtH.** http://creativecommons.org/licenses/by/4.0/.

DPPC vesicles have a T_M = 41 ^{0}C or 314 K. The phase diagrams show that when cholesterol is added to DPPC bilayers at temperatures above T_M, the bilayers change from the liquid-disordered (Ld) phase to the uniform liquid-ordered (Lo) phase at around 20 mol% cholesterol. At cholesterol concentrations between around 10-20 mol% and temperatures just above the T_M, both the L_0 and L_d phases coexist. The coexistence of two phases mimics a raft. At low cholesterol levels, the bilayer changes from the gel (or L_β) to the L_d phase. At really high cholesterol, only the L_0 phase exists. This makes sense as the fatty acids are all saturated and cholesterol's rigid rings reduce the freedom of the acyl chains to rotation and hence decrease the number of chains in the gauche conformation. Yet as an "impurity" (cholesterol) has been added to the system, the system is less rigid, and more fluid-like. From 0-7 mol% cholesterol, two phases exist, the gel (or L_β) and the L_d phase. Between 7-23 mol% cholesterol, a combination of phases is seen.

As mentioned above, the outer leaflet of mammalian plasma membranes is composed mostly of sphingomyelin (SM) and PC, while the inner leaflet is composed mostly of phosphatidyl ethanolamine (PE) and phosphatidyl serine (PS), along with cholesterol. These

don't appear to separate into L_d and L_0 phases and appear not to form nanodomains or rafts. In the lab, outer membrane lipids easily form vesicles but the inner leaflet polyunsaturated PEs form other phases (hexagonal or cubic). It appears that asymmetric lipid distribution is critical for biological bilayer formation.

Since nanodomains are difficult to observe and study experimentally, molecular dynamics simulations are used to provide insight into their structure and properties. The right-hand images to the right show snapshots of the membrane from molecular dynamic simulations. Cholesterol is shown in white in Figure 10.3.19 **8** shows the membrane in the Lo phase, **5** shows it in the Ld phase (note the reduced membrane width), and **3** in an ordered (blue box) and disordered (red box) phase. The simulations support the theoretical phase diagram showing the coexistence of the L_d and L_0 phases as well as finding a hexagonal-closest packed cholesterol poor with L_d domains in the region of the phase diagram showing the coexistence of both L_d and L_0 phases. In addition, cholesterol is excluded from most ordered regions. This is shown in Figure 10.3.20 showing a top-down view of the membrane. The dark green lipid headgroups are those that are hexagonally closest packed, an ideal you will remember from introductory chemistry courses.

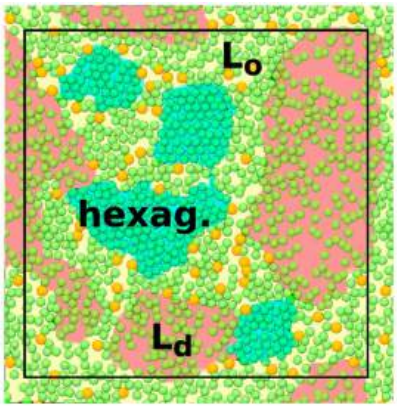

Figure 10.3.20: Top-down view showing membrane phase observed in a molecular dynamics simulation. Javanainen, M. et al. ibid.

Now imagine what a phase diagram would look like for a three (DOPC, sphingomyelin, and cholesterol) or more component system! We won't show any but from the "simple" two-component system described above, it should be evident that we have a long way to go before understanding the complexity of membrane bilayers. Ternary bilayers system often from more macroscopic (vs nanoscopic) domains (or rafts) which can be studied using fluorescence microscopy.

The actual biological membrane must be able to adopt very nonplanar shapes with positive and negative curvature. Membranes must also be able to fuse (for example the egg and sperm). Another lipid phase, which we have not yet discussed, may be involved. New lipid phases of a single membrane lipid can form based on the relative percentages of lipid and water. These include hexagonal phases. Figure 10.3.21 shows an image of a hexagonal phase of phosphatidylethanolamine with 16:0 fatty acids. Note the water inside of the middle ring of PE molecules.

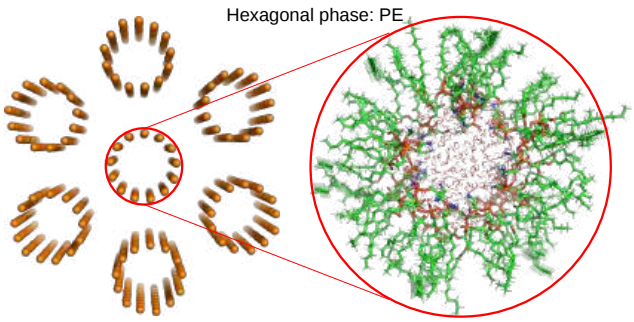

Figure 10.3.21: Hexagonal phase of phosphatidylethanolamine with 16:0 fatty acids

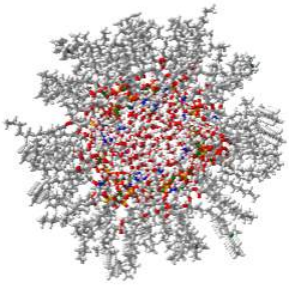
Figure 10.3.22 shows an interactive iCn3D model shows the inner ring outlined in the red circle. Note that water surrounds each of the closest packed lipid tubules which extend back into the figure in 3D. This phase creates an aqueous channel through the interior of each tubule.



NCBI iCn3D Figure 10.3.22 Hexagonal phase of phosphatidylethanolamine with 16:0 fatty acids (Copyright; author via source). Click the image for a popup or use this external link: not available

Figure 10.3.23shows variants of the hexagonal phase as well as a cubic phase of lipids.

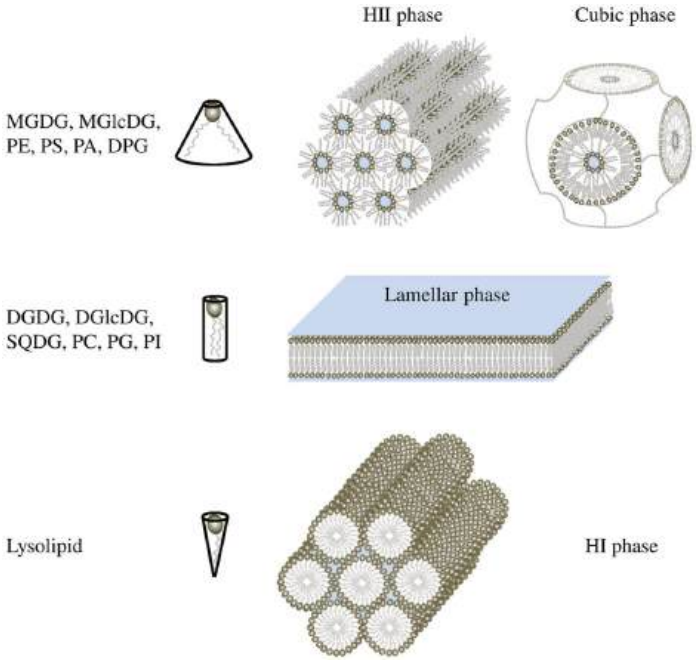


Figure 10.3.23: Hexagonal and cubic phases of lipids. Juliette Jouhet. Importance of the hexagonal lipid phase in biological membrane organization.. Frontiers in Plant Science, Frontiers, 2013, 4, pp.494. ff10.3389/fpls.2013.00494ff. ffhal-00942927f. Creative Commons.

Double-chain amphiphiles with a small polar head (like PE and PA) are more likely to form a hexagonal II phase with elongated tubules than are more cylindrical lipids like PC. Note that if a single fatty acid is removed from a double-chain amphiphile like PE, a narrow conical shape single-chain amphiphile arises, which can either form a micelle (not shown) or a hexagonal I phase. *In vitro*, equimolar amounts of PC (which forms the laminar phase) and PE (which can form an HII phase) can either form the HII phase(at low aqueous pressure) or a lamellar phase (at high aqueous pressure).

Are hexagonal lipid phases found in biological membranes? The answer is likely yes in the formation of unusual cellular structures. The plant plasmodesmata, shown in Figure 10.3.24 is one such structure. Just focus on the two bilayers connected by the membrane-lined membranes of the channel.

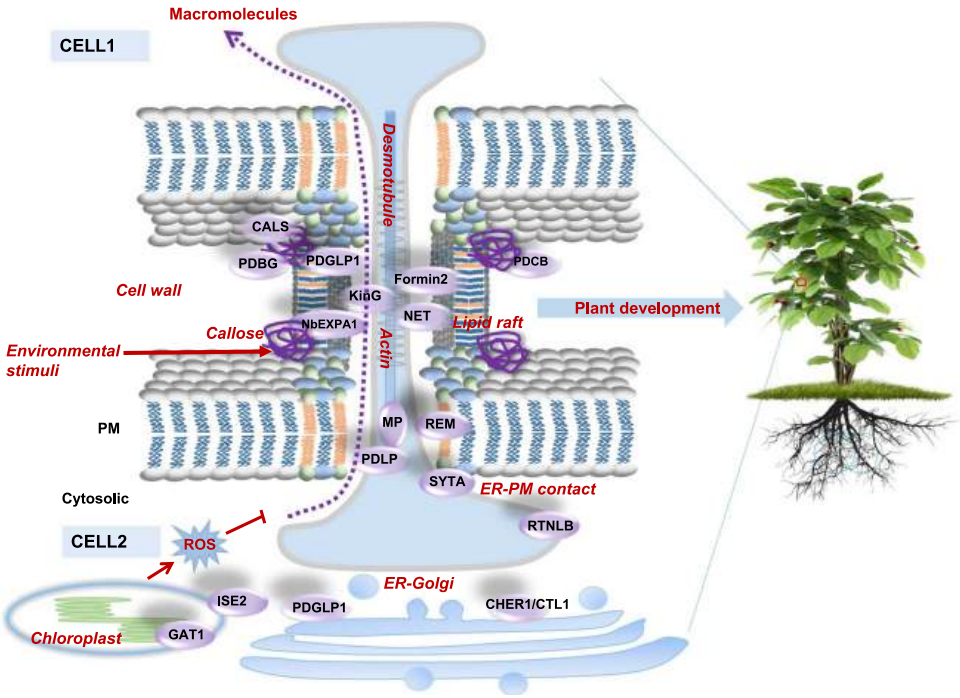

Figure 10.3.24 Plant plasmademata. Yanbiao Sun et al. https://www.nature.com/articles/s41438-019-0129-3. Creative Commons license. http://creativecommons.org/licenses/by/4.0/.

Plasmodesmata are membrane-lined channels that cut across the plant cell wall and directly connect cells, allowing the flow of water and nutrients between the cells. HII phases have been seen in the endoplasmic reticulum membrane. These membranes, along with the mitochondrial inner membrane and the inner membrane of chloroplasts are highly curved and contain higher concentrations of lipids that allow that curvature as well as the formation of H II phases. The function of some membrane enzymes as well as processes such as membrane fusion and fission are enhanced by HII-forming lipids.

10.3.7: Piecing it all together

Our emerging understanding of lipid structure has taken us from micelles and vesicles to the complexity of actual biological membranes with different phases and nanodomain structures. This complexity is needed as membranes must be dynamic in ways the proteins, for example, aren't. They must be able to pinch off either as extracellular or intracellular vesicles, for example, in the process of exocytosis and endocytosis. Both positive and negative curvatures of the membrane must be enabled. The incredible complexity of the "Lego-like" lipid monomers that assemble and rearrange into every fluctuating membrane is yet another exquisite illustration of our repeat mantra, that structure and shape mediate all function. The "Lego-like" membrane monomers in various phases and regions of membrane curvature are illustrated in Figure 10.3.25

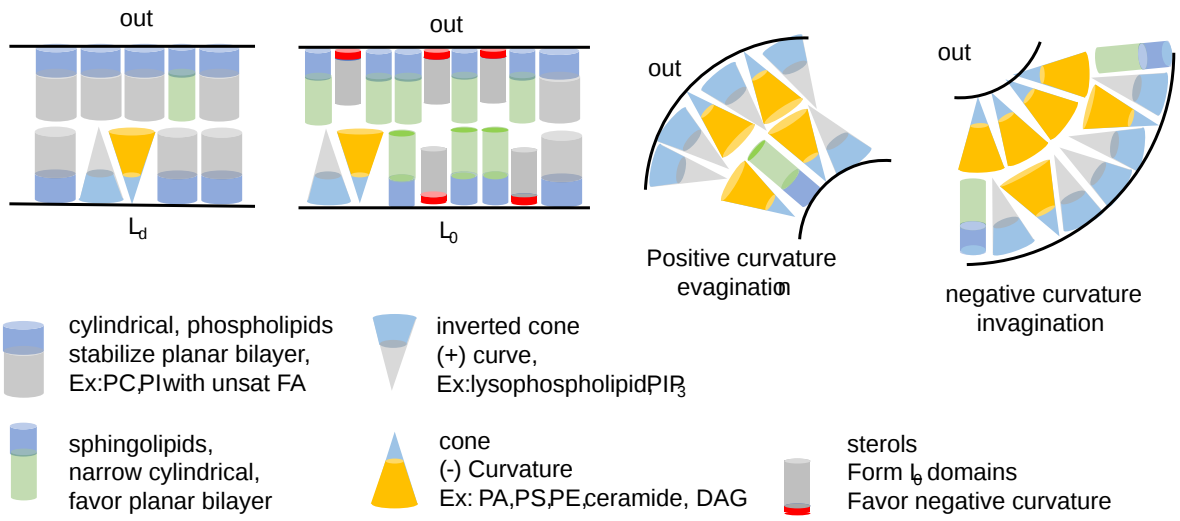

Figure 10.3.25: "Lego-like" membrane monomers in various phases and regions of membrane curvature

Given their shape, some glycerolipids don't even appear to spontaneously form bilayers by themselves. The shape and type of fatty acids found in the membrane lipids will determine the local properties of the membrane, its phases, and the presence of nanodomains. The activity of membrane enzymes, and membrane fission and fusion events, will also depend on the local properties of membranes. The figure above. doesn't even account for the presence of peripheral and integral membrane proteins, which we will discuss in the next section.

As we learned with proteins, we can be misled by looking at beautiful but static images of protein. Their dynamic motion is critical to their function. In addition to the dynamic membrane events discussed above, there is a myriad of other events that take place at and in membranes. Here are a few.

10.3.8: Other dynamic events in bilayers

Membranes are not static. They are synthesized, their contents shuffled, they fuse with other membranes, and large proteins are inserted into them. Let's explore some of these.

10.3.8.1: **Membrane Trafficking**

Movement of key "cargo" molecules into (endocytosis) and out of (exocytosis) the cells occurs mostly through membrane-encapsulated vesicles. Vesicles contain all types of biological molecules including lipids, both synthetic and absorbed. Part of the differences in lipid composition between membrane layers and between different organelles derived from this highly orchestrated and controlled movement of vesicles. Details are shown in Figure 10.3.26 below.

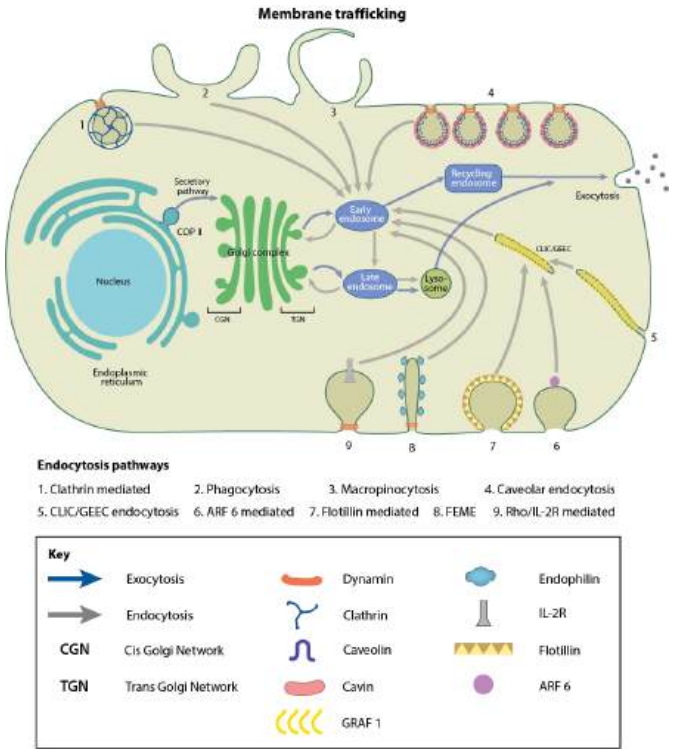

Figure 10.3.26: Players in membrane trafficking. https://www.mechanobio.info/what-is-...e-trafficking/. Creative Commons Attribution-NonCommercial 4.0 International License

In eukaryotes, the biosynthetic secretory pathways move molecules from the endoplasmic reticulum to the cis Golgi (CGN) to the trans-Golgi (TGN) and to the plasma membrane (for integral membrane proteins) or for secretion. Since most lipids are synthesized in the endoplasmic reticulum (ER), their distribution to different locations in cells is critical in maintaining the asymmetric distribution of lipids found in cells.

10.3.8.2: Fusion of membranes: Fusion Peptides

Another dynamic event in membranes is the fusion of two bilayers from two different cells vesicles or of a vesicle and cell membrane. These events are facilitated by fusion peptides. Figure (\PageIndex{27}\) below shows a molecular dynamics simulation snapshot showing how a fusion peptide in a single DMPC bilayer causes a constriction of the bilayer with the two leaflets approaching each other.

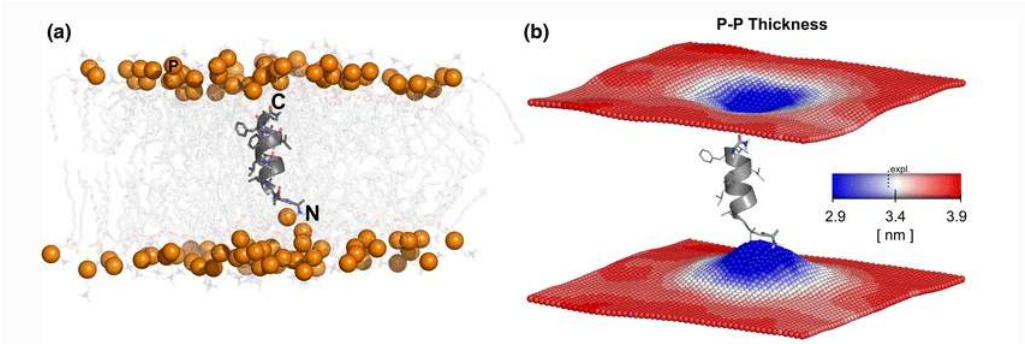

Figure (\PageIndex{27}\): A molecular dynamics simulation snapshot showing how a fusion peptide resides in a single bilayer. The first 12 amino acids of a GP41 peptide are inserted in a DMPC membrane patch.

Figure (\PageIndex{28}\) below shows the area per lipid (APL).

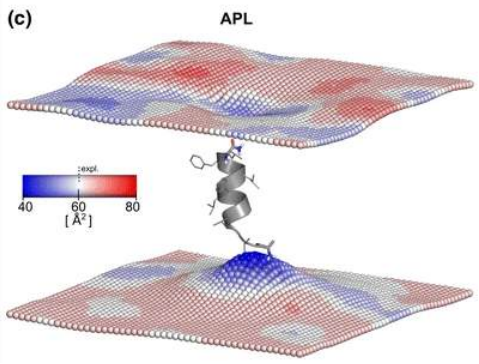

Figure (\PageIndex{28}\): Area per lipid (APL) of a DMPC membrane with an inserted fusion peptide.

10.3.8.3: Insertion of Membrane Proteins

Another dynamic event is the insertion of a membrane protein. Now let's look at changes in the bilayer on insertion of the voltage-dependent anion channel (VDAC) membrane protein, as shown in Figure (\PageIndex{29}\) below.

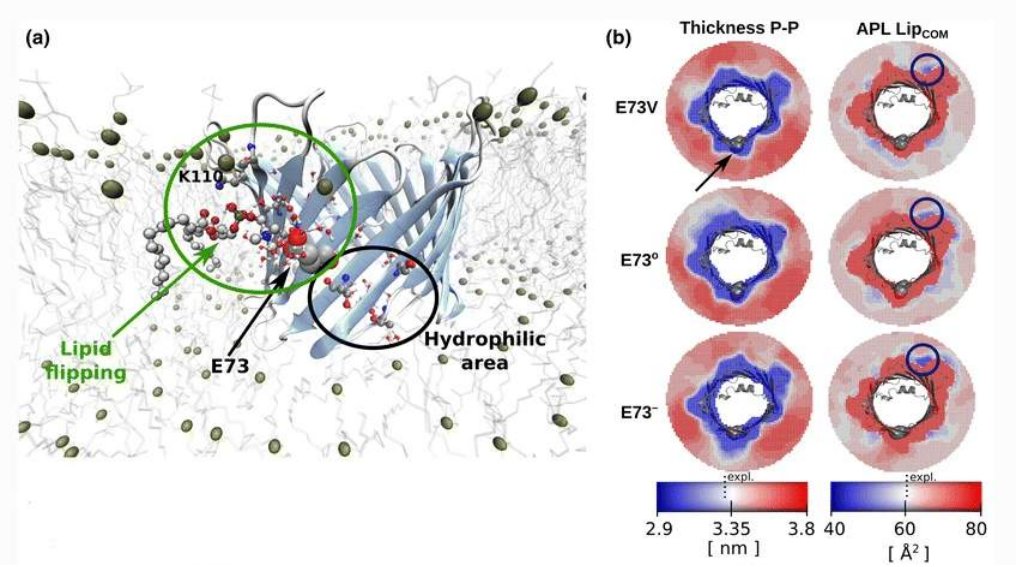

Figure (\PageIndex{29}\): Local membrane properties of a bilayer with an embedded membrane protein VDAC. CVytautas Gapsys et al, https://link.springer.com/article/10...822-013-9684-0. Creative Commons CC BY license.

Panel a shows the voltage-dependent anion channel (VDAC) is shown in a cartoon β-barrel representation. Residue E73 and the water molecules nearby are represented as spheres. Serine and threonine residues constituting hydrophilic areas close to E73 are shown in ball and stick representation. In the snapshot, a DMPC lipid is shown flipping close to the E73 and K110 residues.

Panel b shows top view perspectives of the circular representation of the local thickness, calculated considering phosphorus atoms, and area per lipid.

10.3.9: Introduction to Lipid Signaling - Chemical Cleavage of Membrane Lipids

Everything in this chapter so far describes the structure and dynamics of the components of the lipid components of a bilayer. The dynamic changes described involve the physical movement of lipids molecules in the membrane. Let's briefly introduce another type of movement that involves not only physical but chemical changes in the cell. What happens when specific lipids in membranes are chemically cleaved by **lipases**, enzymes which are analogous to protease? It turns out these changes lead to signaling within the cell. We will only briefly introduce lipid signaling in this chapter, but explore it in more detail in Chapter 12.

Lipids are not just used as a passive component of membranes, or as a source of stored energy. They are involved in the process of signal transduction at the cell membrane, a process by which the interior components of the cell respond to a signal external to the cell, allowing the cell to respond to its local environment. Usually, a chemical signal on the outside of the cell is the "primary messenger" that causes the cell to respond. Usually, the chemical transmitter of information does not get into the cell. Rather it binds to surface receptors on the cell membrane surface. Somehow, the cells sense that a ligand is bound to the outside. Enzymes,

usually in the membrane or at the intracellular surface of the lipid bilayer are activated. Many of these enzymes cleave lipids in the membrane. The cleaved fragments of the lipid molecules serve as intracellular signals or "secondary messengers", which can bind to intracellular enzymes to activate intracellular processes. Figure (\PageIndex{30}\) below shows some of the lipid mediators which are generated by the process and signal the cell to respond.

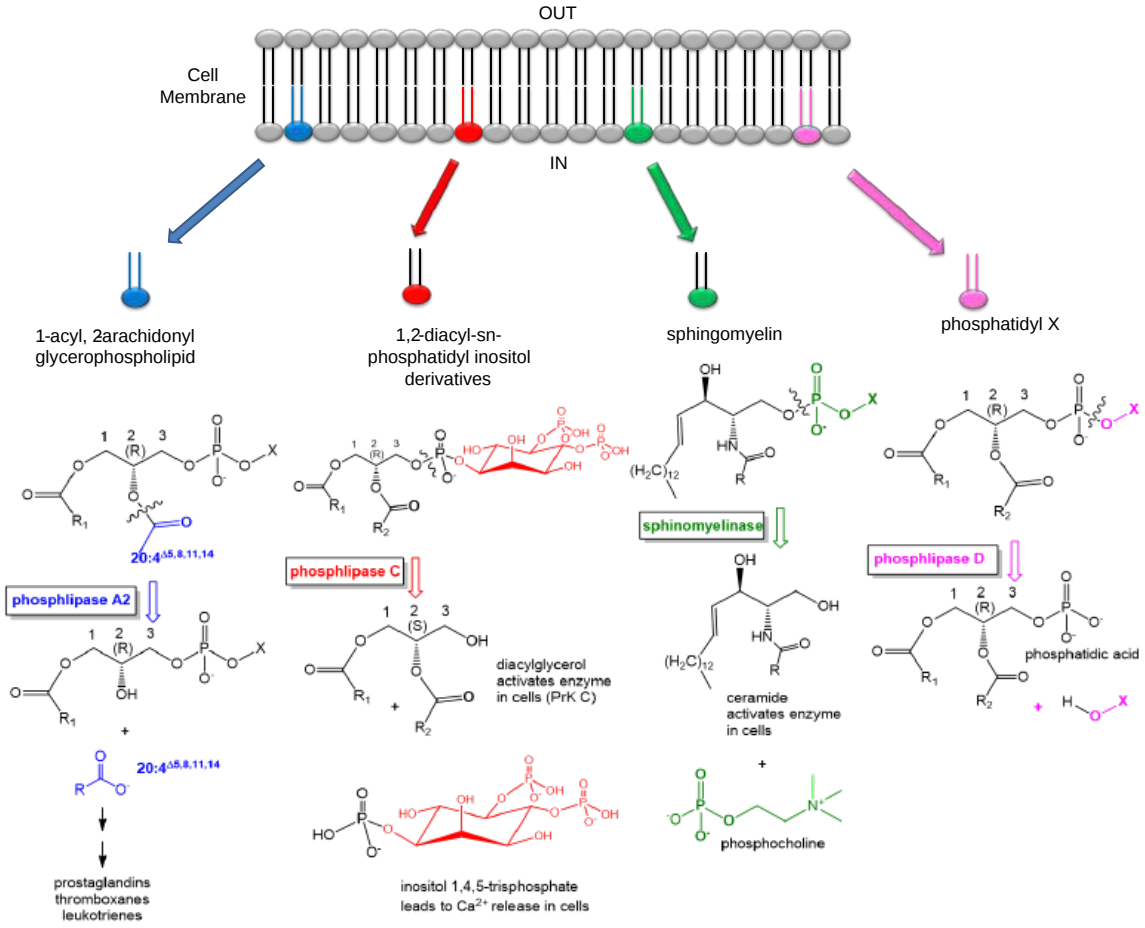

Figure (\PageIndex{30}\): Membrane lipids involved in signaling

Fatty acid amides are potent mediators of neurological processes. In one interesting experiment, sheep were sleep deprived. Reasoning that the brain might release a biochemical signal into cerebrospinal fluid to induce sleep, scientists at Scripps removed some of this fluid and isolated a substance that was not found in rested sheep. On analysis, the structure was shown to be an amide of oleic acid. Oleylethanolamide has been shown to bind to the peroxisome-proliferator-activated receptor-a (PPAR-a) which resides in the nucleus. This ligand, by affecting gene transcription, appears to regulate body weight and the feeling of fullness after eating (satiety) as it leads to reduced eating.

People have sought the natural neurotransmitter which binds to the same receptor in the brain as THC, the active ingredient of marijuana. The endogenous cannabinoid is an amide of arachidonic acid, anandamide. Figure (\PageIndex{31}\) below shows the structures of key fatty acid amides and THC.

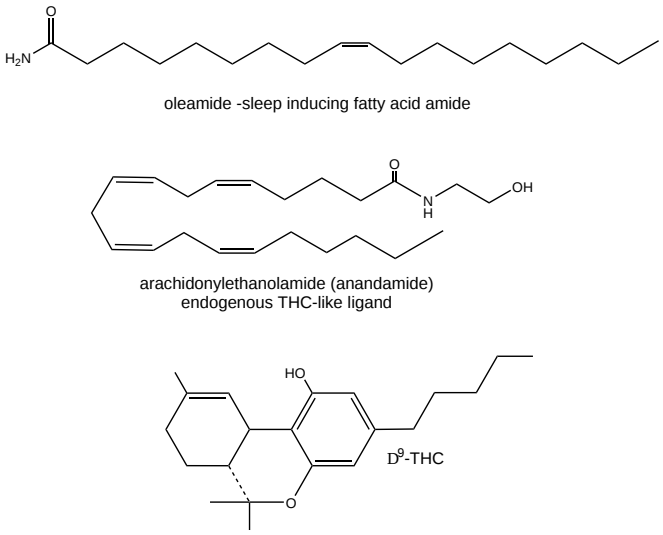

Figure (\PageIndex{31}\): Fatty Acid Amides: Neurochemical Mediators

This fatty acid amide is an example of a class of lipid derivatives called N-acylethanolamines (NAEs). These molecules, with acyl groups that vary in the number of carbons and double bonds, are found widely in organisms in nature. Naturally occurring anandamide leads to increased food intake after a short period of reduced food intake. One of the known physiological effects of THC is increased food consumption (the munchies).

Lucanic et al (2011) have shown that decreases in NAEs extend the life span of the small roundworm C. elegans, which has become a model organism to study genes in eukaryotes. Caloric restriction has been shown to increase the life span in a variety of organisms. In invertebrates, anandamide seems to inhibit food intake, even in organisms that lack a receptor similar to which cannabinoids bind. This might seem paradoxical in that anandamide (and THC) in humans seems to induce eating. However, under long periods of caloric restriction (low-level starvation) in rats, anandamide levels are suppressed, leading to a low energy-consuming state.

In general, it appears that reductions in NAEs occur during periods of caloric restriction. Mutant worms which have reduced levels of NAEs through targeted enzyme disruptions that affected either NAE synthesis or degradation have longer life spans. If normal (wild-type) worms were placed under caloric restriction but given EPA-ethanolamine (the most abundant NAE in these worms), they did not have an extended lifespan.

10.3.10: Membrane Monolayers - Lipid droplets and lipoproteins

We explored membrane bilayers that contain two leaflets above. These bilayers separate the outside and inside of cells as well as the outside and inside of internal organelles. It turns out that there are two main types of lipid-encapsulated structures in which only one phospholipid leaflet separates the interior contents from the outside. These are lipid droplets and lipoproteins. In both cases, the monolayers encapsulate TAGs and cholesterol esters - hydrophobic molecules, so there is no need for another inner leaflet to stabilize an encapsulated aqueous environment.

10.3.10.1: Lipid Droplet formation

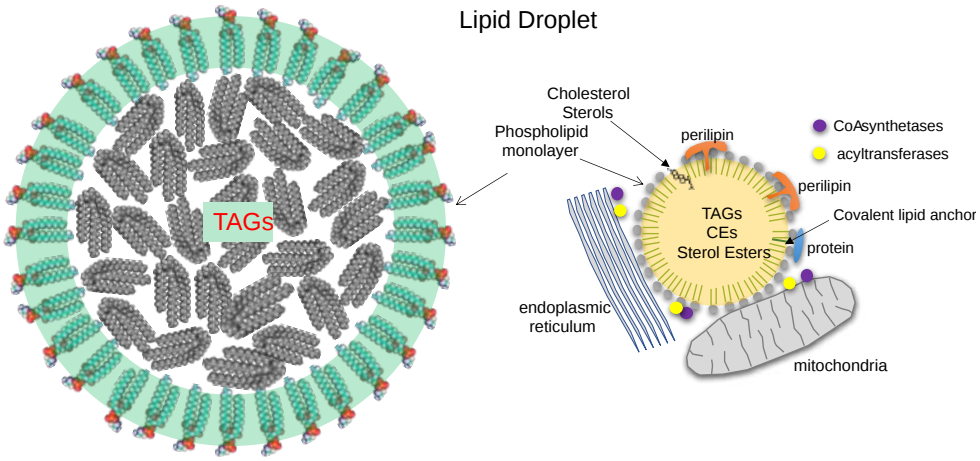
So how are triacylglycerols stored in cells? In lipid droplets! In contrast to the common single and double-chain amphiphiles, which have charged atoms in their head groups and which form micelles and bilayers, respectively, triacylglycerols (TAGs) and cholesterol esters (CEs), which are almost completely nonpolar, coalesce into lipid droplets in cells. These droplets can range from very big, which are found in adipocytes (fat cells) where they take up almost all of the available space and where they are used for energy storage, to small, which are found in all cells, where they are used mostly for membrane biogenesis and energy mobilization. When esterified into esters, fatty acids, and steroids also pose less potential toxicity to cells. Lipid droplets are often found in close approximation or attachment to mitochondria, endoplasmic reticulum (ER), and peroxisomes (where plasmalogens with ether-linked fatty acid instead of ester-linked are synthesized), all organelles intimately involved in membrane and energy biochemistry. Many of the enzymes (acyltransferases for example) required for TAG metabolism are found in the mitochondria and the ER.

Since lipids droplets are specialized to cells and don't form if TAGs are just added to water, we'll discuss their structures and their dynamic assembly in this section.

The droplets are now considered actual cellular organelles. In contrast to other organelles which are bounded by a bilayer member, lipid droplets are surrounded by a monolayer of phospholipids which prevents exposure of the nonpolar contents to the aqueous cytoplasm. PC and PE appear to be the major phospholipids in the monolayer and both are synthesized mostly in the ER. There are many different proteins involved in the formation and interaction with lipid drops, including

- perilipins: There are multiple types of perilipins. Perilipin 1 is found in adipocytes and cells that synthesize steroids (adrenals, ovaries, and testes). Perilipin 2 and 3 are found in most cells
- Acyl CoA synthetases and acyltransferase: These enzymes activate free fatty acids for metabolic processes.
- seipins: These are involved in lipid droplet shape number, and size. It appears to be involved in the formation of lipid drops and moving them from the ER to the cytoplasm.
  Facilitates initiation of LD formation, and ensures that vectorial budding of LDs from the ER is directed toward the cytoplasm

It appears that lipid droplets arise from the ER which are involved in membrane biogenesis and "trafficking" of membranes to different locations in the cell. A general structure of a **lipid droplet** is shown in Figure 10.3.32 The left figure shows just internal triacylglycerols (TAGs), but the inside would also contain cholesterol ester (fatty acid esterified to the cholesterol OH) and the monolayer would also contain unesterified cholesterol.



(\PageIndex{32}\): Cartoon view of a lipid droplet.

How might these complex lipid droplets form in a cell if not by phase separation? With the help of proteins. of course. Figure 10.3.31shows how newly synthesized TAGs (made in the ER membrane, could self-aggregate in the bilayer to form a "lens" which on further growth and addition of lipid binding proteins could bud off into the cytoplasm to form the droplets.

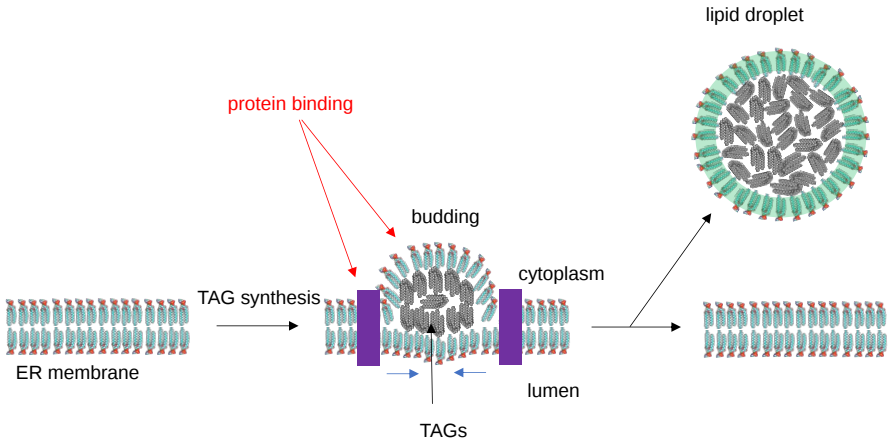


Figure 10.3.33: Formation of a lipid droplet

Figure 10.3.33 shows an incredible image of diacylglycerols (DAG) accumulating in a bilayer to form a clear lens in the membrane. This was produced by a molecular dynamics simulation.

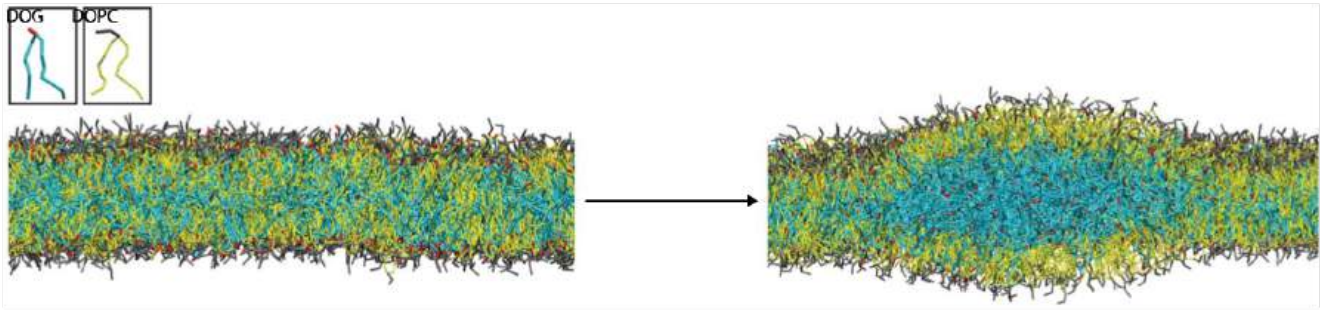

Figure 10.3.33: Molecular dynamic simulation of diacylglycerols (DAG) accumulating in a bilayer to form a clear lens in the membrane. Pablo Campomanes, Valeria Zoni & Stefano Vanni. Nature. https://www.nature.com/articles/s42004-019-0175-7.pdf. Creative Common License: http://creativecommons.org/ licenses/by/4.0/.

Figure (\PageIndex{34}\) below shows a cartoon illustrating the synthesis of a lipid droplet from the ER membrane.

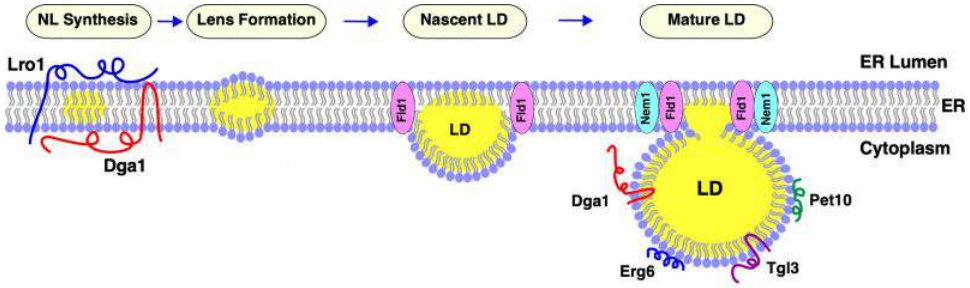

Figure (\PageIndex{34}\): **LD biogenesis in the ER.** ER-localized triacylglycerol-producing enzymes, Lro1, and Dga1 catalyze neutral lipid (NL, indicated in yellow) synthesis from opposite sides of the ER membrane. The NL then accumulates between the two leaflets of the ER membrane leading to the formation of lipid lenses. These NL lenses grow in size to become nascent LDs, which then emerge towards the cytoplasm where they further mature. Fld1 and Nem1 proteins show punctate localization at ER-LD contact sites. The acyltransferase Dga1 and the TAG lipase Tgl3 translocate onto the periphery of mature LDs. Finally, LD-marker proteins such as the perilipin ortholog Pet10 and the sterol biosynthetic enzyme Erg6 decorate the surface of the mature LD. http://microbialcell.com/researchart...icrobial-cell/ . Creative Commons Attribution 4.0 International License.

A membrane protein not displayed in the above figure, seipin, denotes the location for lipid droplet formation in the ER membrane. Mutants of the protein are associated with lipodystrophy. In yeast, seipin and another membrane protein Ldb16, associate to allow lipid droplet formation. Seipin aggregates to form a homo 10-mer in the membrane but in contrast to human cells, it alone can not concentrate triacylglycerol in the membrane. It requires the binding of another protein, Ldb16, for that to happen.

Figure (\PageIndex{35}\) below shows yeast, human and fly seipin and their properties.

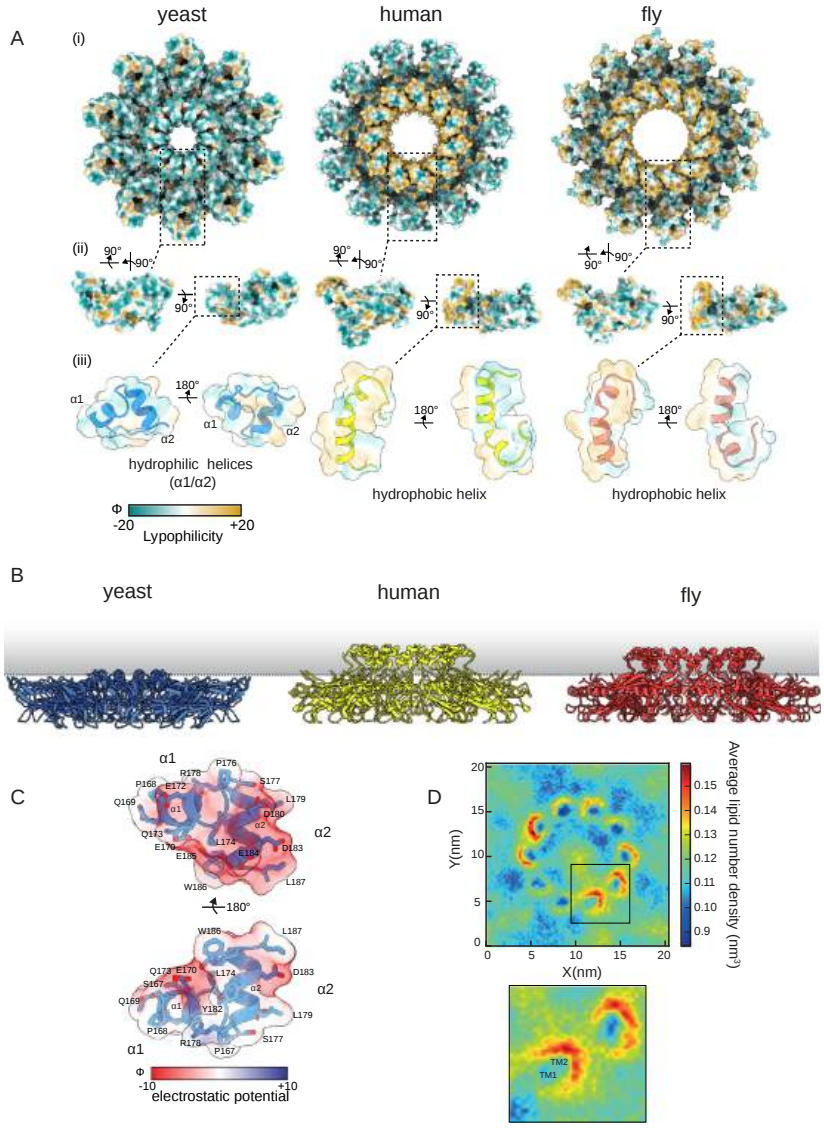

Figure (\PageIndex{35}\): Yeast, human and fly seipin and their properties. *Nat Commun* **12**, 5892 (2021). https://doi.org/10.1038/s41467-021-26162-6. Klug, Y.A., Deme, J.C., Corey, R.A. *et al.* Mechanism of lipid droplet formation by the yeast Sei1/Ldb16 Seipin complex. Panel **A** shows a lipophilicity potential on the surface of yeast (left), human (middle), and fly (right) as viewed as (i) homodecamer assembly from the cytosol, (ii) individual protomers, or (iii) transparent overlay over zoomed in cartoon representation of the central α1-α2 helices. Surfaces are colored from hydrophilic (dark cyan) to hydrophobic (gold).

Panel B shows a side view of the luminal domains of yeast, human (PDB 6DS5) and fly (PDB 6MLU) Seipin in relation to the plane of the ER membrane (indicated by a dotted line).

Panel C shows the charge distribution of the yeast Sei1 central helices (α1, α2), depicted as a transparent Coulombic electrostatic potential surface representation (Red, negative charge; blue, positive charge; white, no charge) overlayed over a cartoon representation (light blue) to show acidic side chains.

Panel D shows a top view of molecular dynamic simulations of Sei1 in a POPC membrane with 3% trioleylglycerol. Images depict the average lipid number density of trioleylglycerol. Inset – zoom of the corresponding box showing positions of TM1 and TM2.

The lumenal domains form the ring with a floor as shown in Panel A above. In addition, the transmembrane segments for the cage top and sides. A switch area between the lumenal and transmembrane segments which can occupy two different conformations

appears important for function. The closed cage allows accumulation and hence phase-separation of triacylglycerols, while the open form allows the nascent droplet to grow and then bud.

The Ldb16 has helical regions enriched in serine and threonine, as is required for TAG loading. These -OH-containing amino acids are present in seipins in humans and flies. Site-specific mutations of the serine and threonines in the region of Ldb16 lead to problems with lipid droplet formation.

Figure (\PageIndex{36}\) below shows a cartoon of the serine- and threonine-enriched helix in Ldb16.

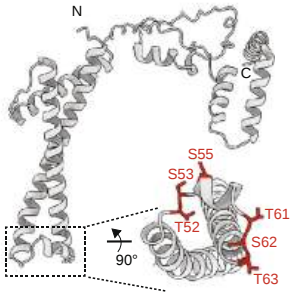

Figure (\PageIndex{36}\): Cartoon of Ldb16 predicted helix enriched in serine and threonine. Klug et al, ibid.

Another model for the assembly of lipid droplets by the Sei1-Ldb16 yeast complex is shown in Figure (\PageIndex{37}\) below.

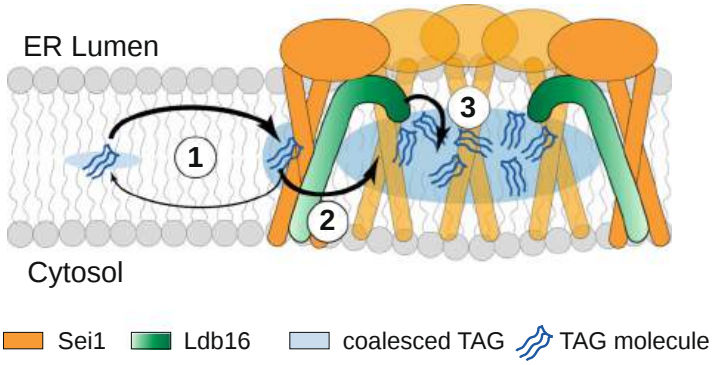

Figure (\PageIndex{37}\): Sequential TAG interactions mediate LD assembly by the Sei1-Ldb16 complex. In the ER bilayer, TAG molecules (blue) concentrate in the proximity of Seipin oligomers (orange) via weak interaction with Sei1 TMs. TAG molecules within the ring interact strongly with Ldb16 (green) hydroxyl-containing residues, facilitating TAG coalescence and lens formation. Klug et al, ibid.

Figure 10.3.38shows an interactive iCn3D model of the homo 10-mer yeast seipin membrane complex **(7OXP).**

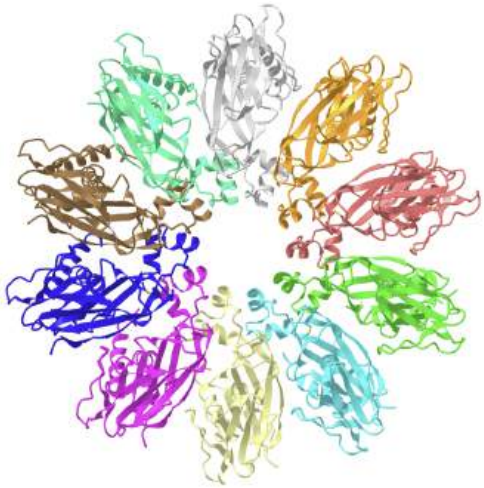

Figure 10.3.38 Yeast seipinhomo 10-mer yeast seipin membrane complex (7OXP). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...wMLHBncjFZMbFA

The two transmembrane segments (helices) from each of the monomers are evident by rotating the structure so the homo 10-mer ring is viewed from the side.

10.3.10.2: Lipoproteins

We eat, digest, and transport dietary fat. We also make fat and transport it through the blood as well. We saw that free fatty acids are carried in the blood by the most abundant protein in the blood, albumin. What about the very insoluble triacylglycerols and cholesterol esters? Turns out they are also transported in the blood by nanoparticles similar to lipid droplets. They are called lipoproteins since, like lipid droplets, they have proteins associated with them.

Lipoproteins vary in density and size. The densest is called high-density lipoproteins (HDL). As they get larger and more filled with, they form less dense lipoproteins (low density - LDL, intermediate density - IDL, and very low density - VLDL). These contain nondietary lipids made by organs like the liver. Dietary fats are processed in the intestine into very large particles called chylomicrons. Their relative size and density are shown in Figure 10.3.39

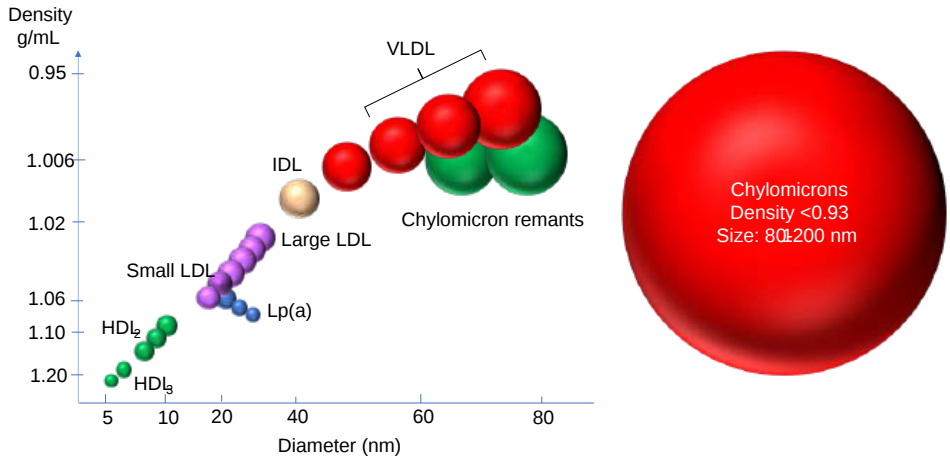

Figure 10.3.39: Size distribution of lipoproteins

Introduction to Lipids and Lipoproteins. Kenneth R. Feingold, MD. Creative Commons (CC-BY-NC-ND) license. A copy of the license can be viewed at http://creativecommons.org/licenses/by-nc-nd/2.0/. With permission.

As with lipid droplets, lipoproteins have a single outer monolayer leaflet containing double chain membrane lipids like phosphatidylcholine and free cholesterol Inside are the triacylglycerols and cholesterol esters. Proteins are bound to the outer monolayer. Figure 10.3.40 shows two renderings of discoidal HDL particles containing a single type of protein, Apo-A1. The TAGs are shown in cyan line rendering on the inside, along with cholesterol esters (in spacefill). The bottom part of the figure shows the polar Ns and Os decorating the outer part of the monolayer of phosphatidylcholine surrounding the TAGs and cholesterol esters.

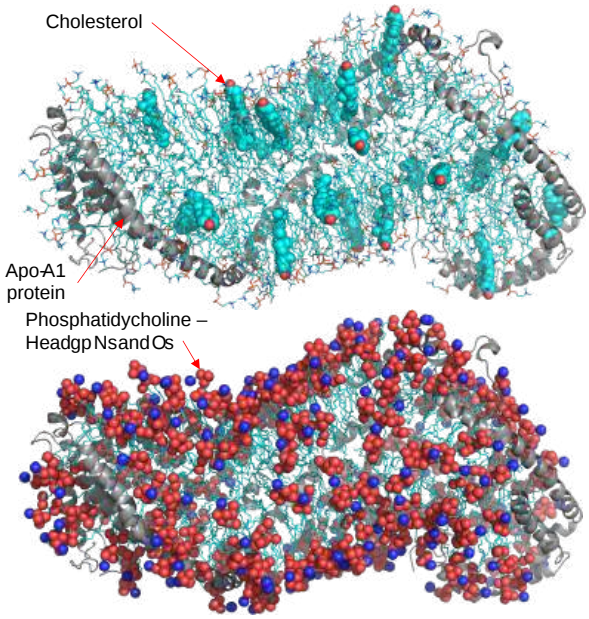

Figure 10.3.40: Two renderings of discoidal HDL particle containing a single type of protein, Apo-A1

10.4: Working with Lipids

10.4.1: Introduction

Lipids, although small compared to large biopolymers like proteins, nucleic acid, and large glycans, are very heterogenous in structure, given the large array of fatty acid and isoprenoid chain lengths, numbers of double bonds, etc that appear in different lipid classes. In addition to analyzing lipid structure, lipids are used in the laboratory to create liposomes (vesicles), which serve as models for membrane bilayers and encapsulation of chemical species (drugs, vaccines) for medical use and solubilization of membrane proteins. In this section, we will concentrate on the creation of lipid vesicles (critical for the encapsulation of RNA vaccines against the SARS CoV-2 spike protein) and the chemical analysis of biological lipids, whose composition affects health and disease states.

10.4.2: Liposomes

Liposomes produced in the lab can be unilamellar, consisting of a single bilayer surrounding the internal aqueous compartment, or multilamellar, consisting of multiple bilayers surrounding the enclosed aqueous solution. You can imagine the multilamellar vesicles resemble an onion with its multiple layers. Cartoons of unilamellar and multilamellar liposomes are shown in Figure 10.4.1, where each concentric circle represents a bilayer.

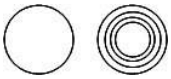

Figure 10.4.1: Cartoons of unilamellar and multilamellar liposomes (each concentric circle represents a bilayer)

Liposomes vary in diameter. They can be generally categorized into small (S, diameter < 25 nm), intermediate (I, diameter around 100 nm), and large (L, diameter from 250-1000 nm). If these vesicles are unilamellar, they are abbreviated as SUV, IUV, and LUV, respectively. Their various sizes are shown in Table 10.4.1 below, in comparison to other large biological structures.

50 nm	200 nm	2000 nm	others
SUV nuclear pore Cell membrane: 7 Ribosome: 20	LUV lysosome HIV: 100	E. Coli Mitochondria: 3000	Red blood cell: 7,000 animal cell: 10,000 – 30,000 Human egg: 120,000

Table 10.4.1: Sizes of liposomes/vesicles compared to other biological structures

The chemical composition of liposomes can be widely varied. Most contain neutral phospholipids like phosphatidylcholine (PC), phosphatidyl ethanolamine (PE), or sphingomyelin (SM), supplemented, if desired, with negatively charged phospholipids, like phosphatidyl serine (PS) and phosphatidyl glycerol (PG). In addition, single-chain amphiphiles like cholesterol (C) and detergents can be incorporated into the bilayer membrane, which modulates the fluidity and transition temperature (Tm) of the bilayer. If present in too great a concentration, single-chain amphiphiles like detergents, which form micelles, can disrupt the membrane so completely that the double-chain amphiphiles become incorporated into detergent micelles, now called mixed micelles, in a process that effectively destroys the membrane bilayer.

Given the large degree of unsaturation at C2, what do you expect the transition temperature of a liposome composed only of egg yolk PC to be? (Vesicles made using more saturated PC from mammalian sources have Tm of around 40^{o}C.) This high degree of unsaturation makes egg yolk PC very susceptible to oxidation, which could alter the properties of the liposome dramatically. Synthetic PC made with saturated fatty acids could alleviate that problem.

The properties of liposomes (charge density, membrane fluidity, and permeability) are determined by the lipid composition and size of the vesicle. The desired properties will be, in turn, determined by the use of the particular liposome. The vesicles offer wonderful, simple models to study the biochemistry and biophysics of natural membranes. Membrane proteins can be incorporated into the liposome bilayer using the exact method you will be using. But apart from these purposes, liposomes can be used to encapsulate water-soluble molecules such as nucleic acids, proteins, and toxic drugs. These liposomes can be targeted to specific cells if antibodies or other molecules which will bind specifically to the target cell can be incorporated into the bilayer of the

vesicle. Intraliposomal material may then be transferred into the cell either by fusion of the vesicle with the cell or by endocytosis of the vesicle.

Since phospholipids will spontaneously form some type of bilayer structure when placed in water, most efforts in liposome production involve producing vesicles with the desired size, lamellar structure, and physical characteristics, which as previously stated are controlled both by liposome size and chemical composition. Also, ways must be developed to entrap the desired molecule inside the vesicle in the most cost-effective manner, and with minimal leaking of contents. All methods of production involve drying of organic solvent-solubilized lipids, dispersion of the lipids in the appropriate aqueous solution, and formation of monolamellar (one bilayer) liposomes or vesicles. Finally, the vesicles are characterized (chemical composition, T_m, permeability, size, etc.)

Drying of lipids

Purified lipids of the desired composition (often egg PC:cholesterol:PS in molar ratios of 0.9:1.0:0.1) are dissolved in a purified, water-free organic solvent mixture (often chloroform/methanol, 2:1 v/v) and dried down in a round bottom flask on a rotary evaporator under reduced pressure (using a water aspirator) and slightly elevated temperature (20-40^{o}C). The rapid rotation of the flask will ensure that the lipid is dispersed over a large surface area, and will increase the rate of evaporation. To remove the last traces of solvent, the dried flask is usually placed under a high vacuum overnight. If a small volume (< 1 ml) of lipid solution is used, the solvent can be evaporated under a stream of nitrogen. To avoid entrapment of residual chloroform in the lipid film, the film is dissolved in t-butyl-methyl ether or diethylether, and dried several times. Alternatively, the residual solvent can be removed under a high vacuum.

Dispersion of the lipids

There are three main methods of dispersing lipids into an aqueous solution to form liposomes.

a. mechanical dispersion - in this method, lipid dried onto the inside glass surface of a container is hydrated with an aqueous solution, which peals off the lipid to form multilamellar - MLV - (multiple bilayers separated by water) vesicles. Only a small part of the aqueous solution is encapsulated inside the liposome, so this is not the method of choice for the encapsulation of expensive or rather insoluble solutes. Depending on the degree of agitation and the nature of the lipid used, different-sized liposomes can be prepared.

b. organic solvent dispersion - In these methods, the lipids, which are dissolved in organic solvents, are injected through a fine needle, at a slow rate, into an aqueous solution in which the organic solvent may be miscible (such as ethanol) or immiscible (such as ether). In each case, the lipids orient at the interface between the organic solvent and aqueous solution, to form bilayer structures. Injection of ethanol-dissolved lipids provides a simple way to produce SUV, but because liposome formation can not occur at an ethanol concentration greater than 7.5%, only a fraction of the total aqueous phase can be entrapped in the vesicle; hence this technique is not cost-effective for entrapment of an expensive solute. Alternatively, the lipid can be dissolved in ether and slowly injected into an aqueous solution which is warmed so that the ether evaporates at the rate at which it is injected. Since the ether is volatilized, large amounts of lipid can be introduced and the encapsulation efficiency of the aqueous solution is high.

c. detergent dispersion and solubilization - In this method, lipids are solubilized in an aqueous solution through the addition of detergents. The detergents are removed slowly from the solution, resulting in the spontaneous formation of liposomes. Detergents are single-chain amphiphiles that spontaneously form micelles in an aqueous solution when the concentration of free lipid rises to a minimum critical value, the critical micelle concentration (CMC); at this concentration, self-association of detergent results in the formation of a stable aggregate, the micelle. This is illustrated in Figure 10.4.2

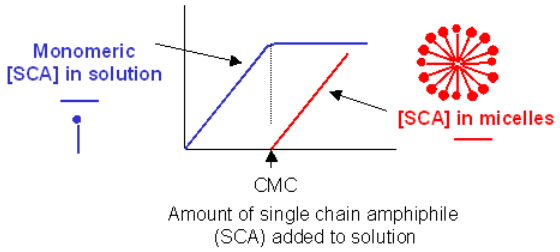

Figure 10.4.2: [Single chain amphiphile] in solution vs [Single chain amphiphile] added - the CMC

Table 10.4.2below shows the properties and CMC of various detergents.

Table 10.4.2: Properties and CMC of various detergents (data from Avanti Polar Lipids)

Name	mM	mg/ml	MW
n-hepty glucopyranoside	70	19.5	278
n-octyl glucopyranoside	23.2	6.8	292
n-nonyl glucopyranoside	6.5	2.0	306
n-decyl maltoside	2.19	1.1	499
n-dodecyl maltotrioside	0.2	0.16	825
Triton X-100 (a)	0.24	0.15	625
Nonidet P-40 (b)	0.29	0.02	603
Tween 20 (c)	0.033	0.04	1364
Brij 98 (d)	0.025	0.04	1527
sodium deoxycholate	2-6	1.7	415
sodium taurocholate	10-15	6.7	538
sodium cholate	14	6.0	431
sodium dodecyl sulfate	8.3	2.4	289

10.4.3: Making liposomes by dialysis

Lipids are deposited in a small container. An aqueous solution is then added, containing water-soluble molecules for encapsulation. Detergent is then added at a concentration in excess of the lipid concentration and greater than its CMC. The lipid molecules are then "emulsified" in the detergent micelle. The solubilized mixture is then placed in a semi-permeable dialysis bag, which is placed in a large volume of an aqueous solution. The free detergent in solution is in equilibrium with the detergent in the micelle. The bag contains microscopic holes large enough for the monomeric detergent molecule to pass through, but small enough so that the large micelle can not. The lipid, during this process, is embedded in the micelle forming a detergent-lipid mixed micelle. As dialysis continues, the monomeric detergent partitions throughout both the volume in the bag and the volume surrounding the bag, while the mixed micelle remains in the bag. If the aqueous solution surrounding the bag is changed several times with fresh solution, the equilibrium in the bag is shifted to the monomeric form. Alternatively, detergent-adsorbing beads (such as Bio Bead SM-2 by Bio-Rad) can be placed in the aqueous solution surrounding the bag to speed up the process of detergent re-equilibration. Eventually, all the detergent is in this form, and during the process, which occurs slowly, the lipid in the mixed micelle self-associates to form a liposome. A detergent of low monomer molecular weight and a high CMC is most desirable for this method of liposome production. Another method of removing the free detergent is through gel filtration chromatography. In this technique, molecules of disparate molecular weights can be separated from each other. An explanation follows this discussion. This method of formation of unilamellar liposomes is the method of choice if membrane proteins are to be inserted into the liposome bilayer to target the liposome. It is not the best method, however, for quantitative encapsulation of expensive soluble molecules.

10.4.4: Making Liposomes by Extrusion

These multilamellar liposomes can be further processed to form unilamellar liposomes by several techniques. These include probe or bath sonication of the MLVs, extrusion at high pressure of the MLVs through membrane filters of defined pore size, or pH-induced vesiculation in which a transient change in pH destabilizes the MLVs in favor of unilamellar liposomes. Another technique involves the fusion of SUVs by repeated freezing and thawing or by fusion of SUVs containing acidic phospholipids (such as PS) through Ca^{2+}-mediated aggregation.

Figure 10.4.3 below shows the structure of vesicles as they undergo multiple freeze/thaw cycles.

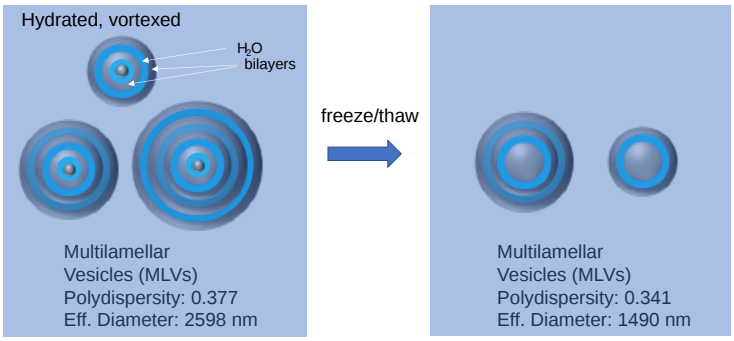

Figure 10.4.3: Structure of multilamellar vesicles as they undergo multiple freeze/thaw cycles

Figure 10.4.4shows the final step in making large unilamellar vesicles by extrusion of freeze/thaw intermediates.

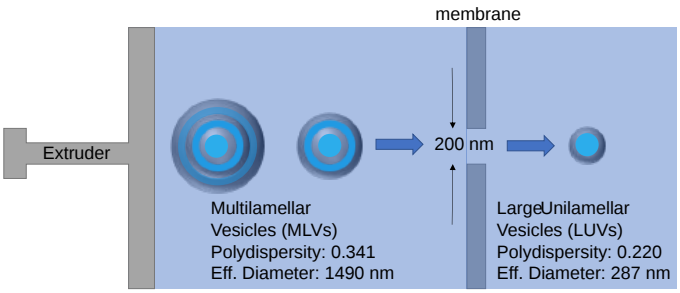

Figure 10.4.4: Conversion of multilamellar vesicles to unilamellar vesicles by extrusion

Once the liposomes are formed, they must be separated from free monomeric lipids, detergents, and unencapsulated solutes. This can be done again by dialysis, or more readily by size exclusion chromatography. Macromolecules of different sizes can be separated on a column in which the stationary phase is a polymerized agarose or acrylamide bead, which contains pores of various sizes. A small molecule (such as monomer detergent, free lipid, or small aqueous solute) in the mobile phase (aqueous buffered solution) may enter the pores in the bead, while a larger macromolecule or aggregate (such as a large protein, a micelle, or a liposome) may not, due to size restriction. The result is that a larger fraction of the overall volume of the column is available to the smaller molecules, which thus spend a longer time on the column and are eluted by the mobile solvent after the larger species. Liposomes can be characterized both chemically, to determine the average lipid and protein (if they were incorporated) composition of the bilayer, and physically, to determine the size, permeability, lamellarity, and amount of encapsulated material. Size is usually determined by electron microscopy or indirectly by light scattering from these large species.

10.4.5: Chemical Analysis of Lipids

There are so many lipids and their derivatives that are so subtlety different that the most sensitive ones are needed for separation and analysis. The field of lipidomics focuses on the analysis of the structure and function of all lipids in the cell. The most useful techniques are analysis (and separation) by gas chromatography (GC) followed by mass spectrometry (MS). NMR spectroscopy is also important. For GC analysis, the lipid must be made volatile, which limits its use in some circumstances. MS analysis is the most sensitive. MS requires ion formation, and techniques like electrospray ionization and matrix-assisted laser desorption/ionization (MALDI) are used.

10.4.5.1: Gas chromatography

(This section is adapted from https://www.intechopen.com/chapters/64008. Creative Commons Attribution 3.0 License). In GC, gas is the mobile phase that carries lipids through the stationary phase of the column. Gas chromatography (GC) is used to separate organic compounds from a mixture in the gas form. For this purpose, the GC uses interactions among the sample components and the stationary/mobile phases. After lipid extraction with chloroform and/or methanol, the samples (lipid mixture) are usually liquids and must be exposed to a high temperature at the gas chromatograph entrance (injector). Vaporized, the samples are carried by a gas, which is usually a nonheavy and inert gas (i.e., hydrogen, helium), through a long capillary column containing a high or low polarity material (stationary phase)

The gaseous compounds generated from the vaporized sample interact with the stationary phase which allows each compound to elute/separate at a different time (retention time). Because GC considers both the chemical and physical properties of the vaporized compounds, those with more chemical affinity to the stationary phase will take a longer time to be removed from the column and the temperature will influence the overall process. This explains why the column stays in an oven, which is programmed to work at different temperature ranges (i.e., temperature programming) in which the compounds are carried out by the gas according to their boiling point until they get to an electronic detector.

At the end of GC analysis, the electronic detector generates a chromatogram based on retention time by intensity. This allows a qualitative identification of the lipid compounds by comparing their retention times with certified standards using the flame ionization detector (FID) or by deduction of spectra information using a mass spectrometer as a detector. Lipid quantification can also be performed using analytical procedures of external or internal certified standards in GC analysis.

The main points to be considered when assessing FAs by GC analysis are the carrier gas flow rate, column length, and temperature because these can influence the order or retention time of the lipid compounds and then must be precisely standardized. The column length of the stationary phase influences the resolution of the analytes, once the number of theoretical plates (hypothetical zone in which two phases establish an equilibrium with each other) is respectively high in the longer column. As fat and oils have high boiling points not supported by the stationary phase, a previous derivatization reaction step is required after lipid extraction from the biological sample, in which triacylglycerol and free fatty acids are transformed into their respective free fatty esters with lower boiling points (transesterification/esterification reaction). Several methods are available for FAs derivatization.

Particularly for cholesterol analysis, the sample preparation must consider a derivatization reaction. This allows to block protic sites of steroids obtained after an unsaponifiable lipid extraction had been performed, and also, diminishes dipole-dipole interactions, increases the volatility of the compounds, and to generate products with reduced polarity. Cholesterol derivatization is usually achieved by using trimethylsilyl compounds as reagents (silylation reaction). A common method for this purpose uses *N*,*O*-bis(trimethylsilyl-trifluoroacetamide/trimethylchlorosilane).

10.4.5.2: Mass spectrometry

Mass spectrometry (MS) has become the method of choice for lipid analysis, offering label-free detection at high sensitivity and structural characterization capability. However, large-scale lipid analysis with a comprehensive capability of revealing all levels of structure information still represents a significant analytical challenge for lipidomics. General protocols, for instance, have five levels in terms of structure information, including lipid class, fatty acyl identities, fatty acyl *sn*-positions, and C=C location/geometry (viz cis/trans) in the fatty acyl. Successful attempts for determining C=C locations in fatty acyls or their *sn*-positions have already been reported for MS analysis, enabling the characterization of detailed structure moieties and identification of lipid structure isomers. An extremely useful feature offered by lipid isomer analysis is the relative quantitation achieved at high precisions without requiring the use of lipid standards, which are not readily available. Remarkably, our recent study demonstrated a close correlation between the lipid C=C location isomer compositions and Type II diabetes, which owes to tighter regulation on lipid desaturation, allowing efficient elimination of interferences due to variations among samples"

Various methods have been explored for differentiating the lipid C=C location and *sn*-position isomers. Ozone-induced dissociation (OzID) and ultraviolet photodissociation (UVPD) have been used to determine both *sn*-positions and C=C locations in GPs. By coupling the Paternò-Bŭchi (PB) photochemical reaction with tandem MS (MS/MS), qualitative and quantitative analysis of lipids with C=C specificity from complex biological samples can be accomplished. PB reaction converts the C=C to an oxetane which can be preferentially fragmented by low-energy collision-induced dissociation (CID).

An ideal analytical tool for lipidomics to survey a wide range of lipids in discovery work should not only provide detailed information at multiple lipid structure isomer levels (e.g., C=C location/geometry and *sn*-position), but also be feasible for large-scale quantitative analysis. UVPD is capable of assigning C=C locations and *sn*-positions of fatty acyls, while OzID may be the only one that has been well demonstrated for assigning C=C locations in *sn*-specific fatty acyls. One problem of OzID is the long reaction time required for the ion trap implementation, however recent work has demonstrated the ability to perform OzID on LC-compatible time scales in the high-pressure regions of the MS system. For the PB reaction method, both shotgun analysis and HPLC-PB-MS/MS workflow have been developed for identifying a large number of C=C location isomers. Figure 10.4.5 describes methods for the determination of C=C location and sn-isomers in lipids.

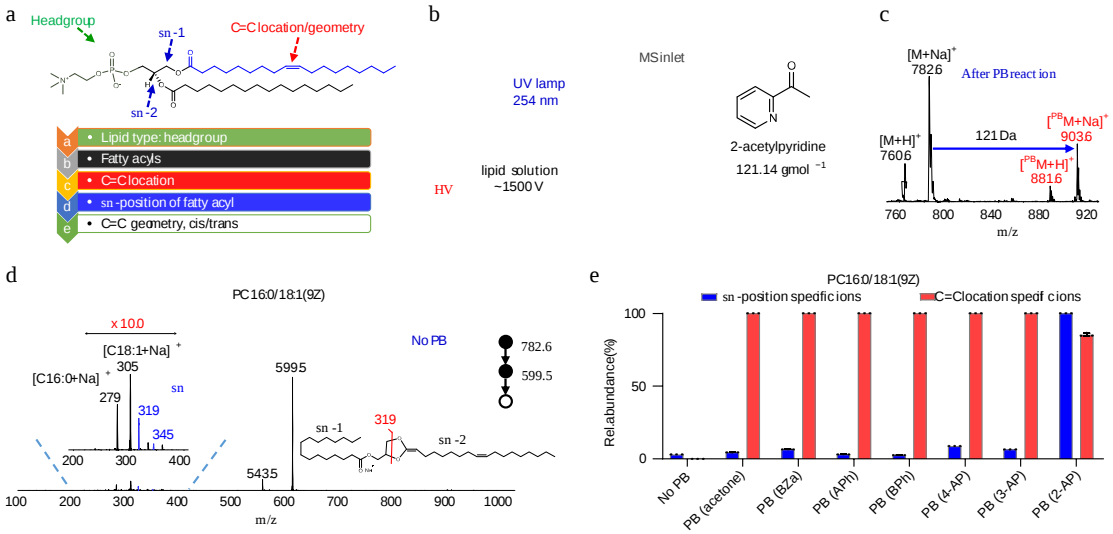

Figure 10.4.5: Methods for the determination of C=C location and sn-isomers in lipids. **a** The chemical structure of PC 18:1(9Z)/16:0. **b** Schematic of the experimental setup for online derivatization of unsaturated GPs by coupling 254 nm irradiation with nanoESI-MS. **c** MS spectrum of PC 16:0/18:1(9Z) after 30 s reaction. **d** MS^3 spectrum of PC 16:0/18:1(9Z) without PB derivatization. Sodiated lipid precursors were first fragmented to generate product ions after headgroup loss (−183 Da). Product ion at *m/z* 599.5 was further fragmented to release *sn*-1-specific diagnostic ions at *m/z* 319 (C16:0) and 345 (C18:1). **e** Comparison the relative abundance of *sn*-position and C=C location specific ions of PC 16:0/18:1(9Z) without and with PB derivatization using different PB reagents (Bza: benzaldehyde, APh: acetophenone, BPh: benzophenone, AP: acetylpyridine). The error bar represents the standard deviation, $n = 3$. 10.5: Problems

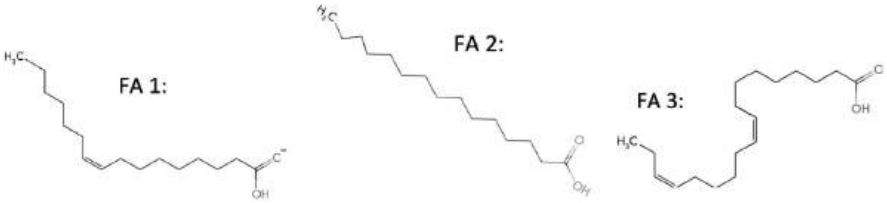
10.1 Questions

1) Explain why some lipid classes are membrane-forming and some are not. Give examples that support your logic.

2) a. Using the images of fatty acids below, write the symbolic name (N:N) for each.



For the following use FA 1, 2, 3, or 4, some may have more than one answer.

b. Which fatty acid melts at the highest temperature?

c. Which fatty acid is a w-3 fatty acid and is essential for human growth and development?

d. Which fatty acid, if found in a membrane bilayer, would increase membrane fluidity?

e. Which fatty acid is the most unlikely to be found in nature, and why?

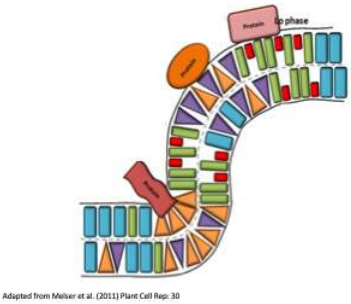
3) For the following questions, use the interactive micelle from Section 10.1:

a. When looking at the micelle in “Ball and Stick” form, do you think the core (center of the micelle) could be accessible to water molecules? Explain.

b. Examine the micelle under Style -> Surface Type -> Molecular Surface. Did your answer from part a change? Do there appear to be any solvent-accessible regions that water could use to enter the core?

c. Finally, examine the micelle under Style -> Surface Type -> Solvent Accessible. Does this view change your answer to a.? Can you think of any medical or research applications in which a micelle could be useful given what you have found about its solvent accessibility?

4)Using the figure below, hypothesize what type of lipid could be represented by the geometrical shapes in the membrane. Why are the different shapes necessary for membrane formation? Could a membrane be formed with only one shaped lipid? If so, what, and explain why.



5) A cell membrane has the ability to remodel in response to stress in order to maintain membrane integrity. In the situations below, how could the membrane be remodeled to promote an intact structure? (I.e. what types of lipids could be added or removed to maintain a functional membrane?

a. Increase in temperature

b. Decrease in temperature

6)

For each lipid below, name the type of lipid (membrane lipid, triacylglycerol, storage lipid, sphingolipid, wax, sterol, membrane glycerolipid, none of these), if it could be found in a membrane, and if it is a fatty acid or isoprenoid derived.

CHAPTER OVERVIEW

11: Biological Membranes and Transport

11.4: Diffusion Across a Membrane - Pores
11.5: Active Transport
11.4: Diffusion Across a Membrane - Pores

11.1: Membrane and Membrane Proteins

11.1.1: Introduction

One easily understandable function of membrane bilayers is to separate the inside and outside of the cell or intracellular organelles. Yet as we mentioned before, such barriers can not be so rigid and impenetrable that they prevent the movement of materials across the membrane. Also, all cells must sense and respond to their environment through a process called signal transduction. We have already discussed lipid molecules involved in signaling. Now let's turn our attention to proteins that associate with the membrane and confer added functionalities to it. Figure 11.1.1 reviews some of the features of membranes we've discussed before and shows a simple bilayer (top) to the complicated membrane/cell wall of bacteria.

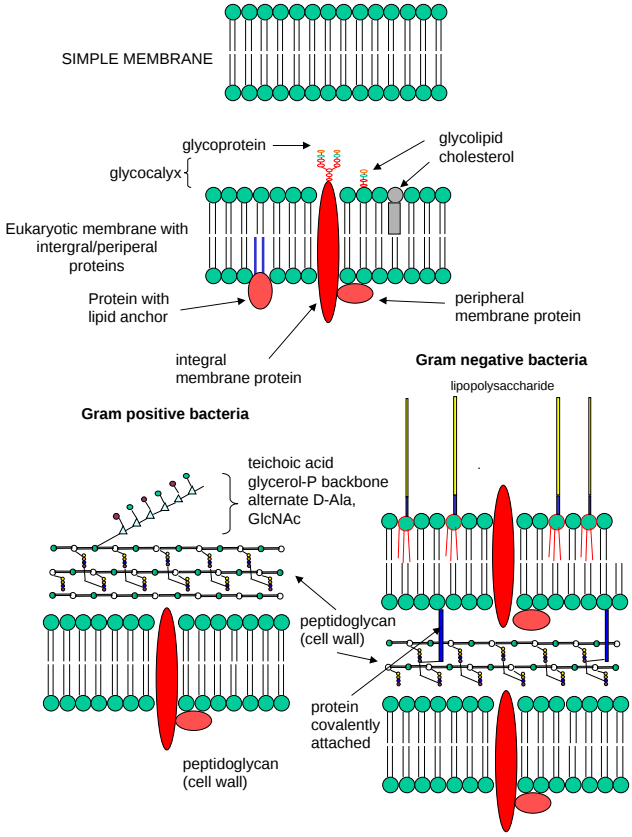

Figure 11.1.1: Membrane from simple to complex

11.1.2: Types of Membrane Proteins

Although we presented this image earlier, Figure 11.1.2 reviews the details that should now be clearer to you. In this section, we will explore membrane proteins in more detail.

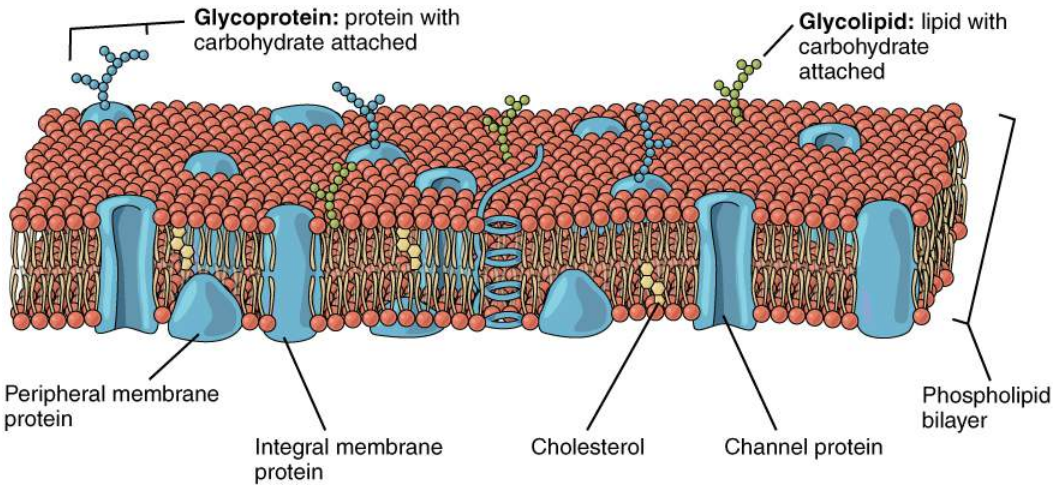

Figure 11.1.2: A cell membrane with peripheral and integral membrane proteins. https://commons.wikimedia.org/wiki/F...Components.jpg. This file is licensed under the Creative Commons Attribution 4.0 International license.

Proteins can be loosely associated with the membrane (**peripheral or extrinsic**) or can embed deeply and most typically pass through the membrane and become a transmembrane (also called i**ntegral or intrinsic)** protein. Sometimes they pass through using a single alpha helix, while other times they pass through multiple times (for example seven times in G-protein coupled receptors). They can also be classified based on the number of leaflets of the membrane they cross, as shown in Figure 11.1.3.

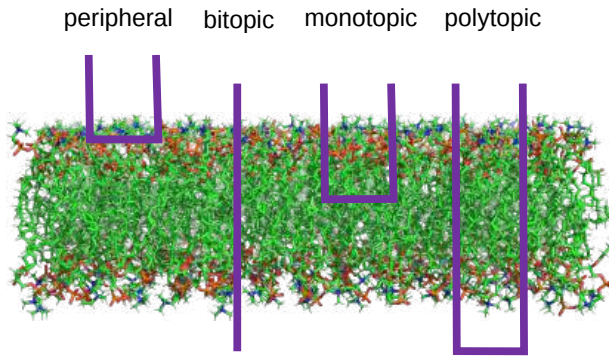

Figure 11.1.3: Peripheral and biotopic, monotopic, and polytopic integral membrane proteins

11.1.3: Peripheral Proteins

The proteins interact with a membrane through protein-lipid head group interactions, but might slightly penetrate the membrane. Those that do would be classified as monotopic peripheral. Peripheral proteins are generally easy to remove from a membrane in vitro by changing solution ions concentration as the interactions are often ion-ion nature. The first model below shows the binding of a matrix Metalloproteinase (MPP) 12 to a lipid bilayer. This protein is involved in inflammation, wound healing, arthritis, cardiovascular disease, and remodeling of neural synapses, suggesting a broad role in recovery from cell and tissue aberrations. MMP-12 is secreted by macrophages so it is considered a water-soluble (aqueous) protein. It travels to viral cells and appears to display activity not in aqueous solution but near membranes, implying activation of the enzyme through binding to the bilayer.

Studies show the catalytic domain of MMP 12 can bind bilayers through both α- and β- secondary structure regions of the protein. Figure 11.1.4 shows an interactive iCn3D model of the protein and its interaction with the membrane through the alpha-helical region. Once bound to the membranes, catalytic activity increases.

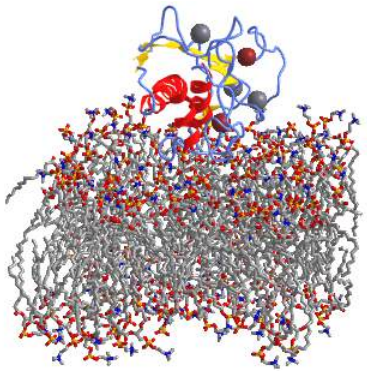

Figure 11.1.4: Catalytic domain of peripheral membrane Protein MMP 12 Interacting with a bilayer. (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...wyF6WvRMx9JP6A

Other MMPs localize to membranes in other ways. MMP-7 interacts with heparan sulfate proteoglycans (CD44) and lipid rafts. Others bind transmembrane proteins like integrins.

Other examples of peripheral protein include many precursor forms of protein clotting factors. Clotting is initiated when the serine protease thrombin cleaves fibrinogen to form fibrin, which self-associates to form a fibrin clot, or when thrombin activates receptors in platelets. The soluble precursor of thrombin, prothrombin, a zymogen, is activated on membrane binding through interactions with several proteins assembled on a negatively charged phospholipid (like phosphatidylserine) bilayer in the prothrombinase complex. How does the precursor zymogen interact with the membrane? It requires calcium ions, which bind to a series of **gamma-carboxylated glutamic acid (GLA)** residues on the zymogen. The enzyme that carboxylates the zymogen depends on Vitamin K.

Figure 11.1.5 shows an interactive iCn3D model of bovine prothrombin Fragment 1 (N terminal) bound to a bilayer through its GLA domain (1NL2).

Figure 11.1.5: Bovine prothrombin Fragment 1 (N terminal) bound to a bilayer through its GLA domain (1NL2). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...SG6qByvpAsvwe6

The Gla sidechains are shown in CPK-colored sticks and interact with Ca^{2+} ions (gray spheres). Click on this link to see a zoomed view of just the calcium ions and Gla sidechains: https://structure.ncbi.nlm.nih.gov/i...xydtj8a4WHgdb7

The Gla domain in the absence of calcium ions is disordered. On binding, an ordered linear alignment of bound calcium ions is formed, stabilizing the ordered structure of the Gla domain and allowing interaction with the membrane. Three nonpolar amino acid side chains, Phe 5, Leu 6, and Val 9, are now clustered and exposed, allowing penetration of this hydrophobic patch part-way into the membrane. They are represented in cyan spacefill just underneath the surface of the red dots in the model above (the red

dots are dummy atoms that represent the outer bilayer leaflet). Given this penetration, this protein domain would then be considered monotopic.

What is not shown in the model is the role of negatively charged phosphatidyl serine. Studies have shown that the head group of serine in lysophosphatidylserine (which has only one acyl group) provides additional ion-ion interactions with the Ca^{2+} ions that also bind Gla residues 17 and 21. Arg 10 and Arg 16 also interact with the phosphatidyl serine head group. Phosphatidylcholine could also spatially fit into the active site but electrostatic interactions would prevent it. Why?

11.1.4: Lipid-Anchored Proteins

We have studied lipids, proteins, and carbohydrates. Although phospholipids can spontaneously form bilayers, the actual structure of biological membranes is made much more complicated through the addition of protein and carbohydrate substituents to the membrane. Soluble proteins can be made to insert into bilayers by the addition of nonpolar attachments. Localization to a membrane changes the functional expression of the protein. Several examples of such attachments are described below.

11.1.4.1: Fatty acid linkers

Two common covalent modifications of proteins are N-myristoylation (attached myristic acid - 14:0 - through an amide link) and S-palmitoylation (attached palmitic acid - 16:0 - through a thioester link with a Cys).

Myristoylation is usually a cotranslational modification in eukaryotic and viral proteins that occurs after cleavage of the N-terminal methionine. Figure 11.1.6 shows an image of the serine/threonine phosphatase 2C (1A6Q) with its N-terminal glycine myristoylated. It should be obvious how this post-translationally modified protein interacts with a membrane.

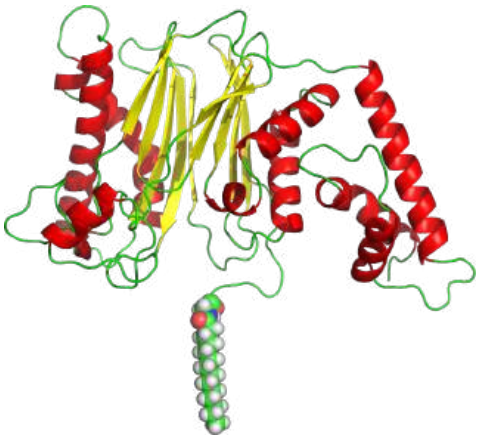

Figure 11.1.6: The serine/threonine phosphatase 2C (1A6Q) with its N-terminal glycine myrisoylated

This modification is a key part of initiating immune system signal transduction pathways. The modification is catalyzed by N-myristoyltransferase (NMT) using myristoyl-coenzyme as the fatty acid acyl donor. This activates the function of the protein in part by reducing the dimensionality of substrate diffusion to the protein to the 2D surface of the membrane instead of a 3D search in the cytoplasm. NMT acylates protein at this consensus sequence: $G^1X^2X^3X^4S/T^5X^6R^7R^8$.

Likewise, many signaling proteins are palmitoylated, leading to protein recruitment to membranes. Small G proteins like Ras, Rho, and the alpha subunit of heterotrimeric G proteins are often palmitoylated. This modification is also be found in transmembrane proteins in which localization is not an issue (see example xx below). In such circumstances, the modification might however help in targeting the proteins to rafts within the membrane. Palmitic acid is saturated and the addition of it to a protein might target it to more ordered regions of the membrane with cholesterol and sphingolipids within rafts.

11.1.4.2: Isoprenoids linkers:

The isoprenoids farnesyl (15C) or geranylgeranyl (20C)are added to a CAAX carboxy-terminal sequence in a target protein like RAS, where C is Cys, A is aliphatic, and X is any amino acid, which helps target proteins to the membrane. The enzymes used for these modifications are farnesyltransferase (FTase) and protein geranlygeranyltransferase
I (GGTase I), respectively. For this and the other modifications, it has the potential to do more than target proteins to the membrane. The modification can also modulate protein-ligand interactions and protein stability. Ras, a key signaling protein, is a target of prenylation.

Ras and other small G proteins are involved in a large percentage of human cancers. As the G protein Ras has somewhat of a billiard ball surface with obvious sites to target drugs that would affect its aberrant function in cancers, efforts have been made to target the prenyltransferases necessary to target it to the membrane.

In humans, there are 3 different genes in the Ras family, H-Ras and N-Ras, whose gene products localize to both plasma and Golgi membranes, and K-Ras, which localizes predominantly to the plasma membrane. These and other G proteins bind GTP and possess GTPase activity. The GTP-bound form is active, while the GDP form is inactive. Point mutations that attenuate or prevent GTP cleavage leave the protein continually activated which contributes to oncogenesis.

KRas has two predominant isoforms, 4A, the canonical form (also called 2A), and 4B (also called 2B) that arise from alternative splicing of the primary RNA transcript. The C-terminal protein sequences of isoform 4A and 4B differ significantly.

Isoform 4A: QYRLKKISKEEKTPGCVKIKKCIIM

Isoform 4B: KHKEKMSKDGKKKKKKSKTKCVIM

The farnesylation motif site containing the modified Cys are highlighted in yellow above. The same cysteine is also often carboxymethylated. The Cys six residues from the farnesylated Cys in isoform 4A are also often palmitoylated

Figure 11.1.7 shows isoform KRas 4B bound to a membrane bilayer through its farnesylated tail. (PDB file provided by Alemayehu (Alex) Gorfe. Viney Nair and Andrew McCammon). The tail is essential for its function at the plasma membrane where KRAS-mediated signaling events occur. Phosphodiesterase-δ (PDEδ) binds to KRAS4b and plays an important role in targeting it to cellular membranes. Note that the farnesyl attachments only penetrate part of the upper leaflet.

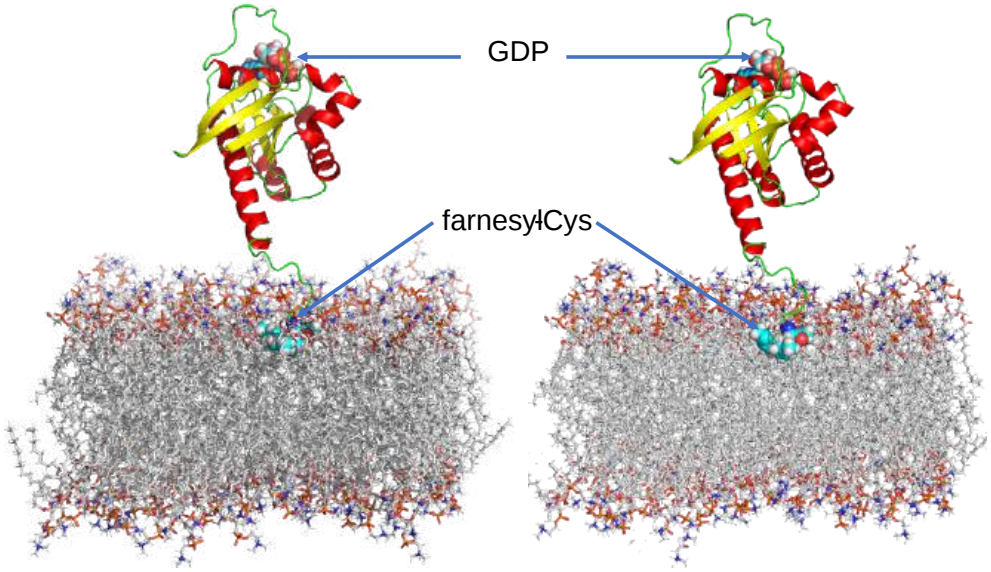

Figure 11.1.7: Isoform KRas 4B bound to a membrane bilayer through its farnesylated tail

11.1.4.3: Glycosyl-phosphatidylinositol linkers

Normally soluble cytosolic proteins can become attached to membranes through the addition of a glycosyl phophatidylinositol (GPI). The attachment usually contains a conserved tetrasaccharide core of three mannoses (Man) and one unacetylated glucosamine (GlcN) linked to the carboxy terminus of the protein. The GPI can be further modified with extra galactoses and mannoses, as well as additions to the PI group, which secures the protein in the membrane. Figure 11.1.8 shows the common backbone for GPI anchors. Note the additions of the phosphoethanolamines to the core polysaccharide.

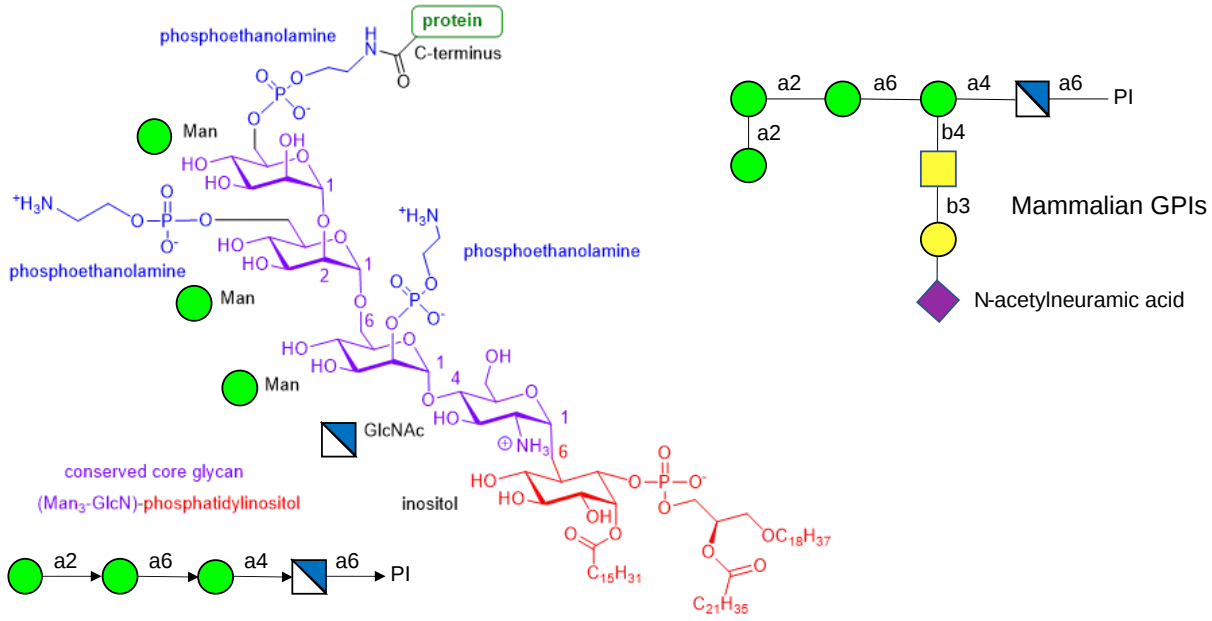

Figure 11.1.8: Common backbone of GPI anchors

GPIs are found in eukaryotic cells and link many surface antigens, adhesion molecules, and hydrolases to the membrane. GPIs from Plasmodium falciparum, the malarial parasite which kills about two million people each year, appear to act as a toxin and are the most common CHO modification of the parasite protein. Mice immunized against the GPI sequence, NH_2-CH_2-CH_2-PO_4-Man (α1-2) 6Man (α1-2) Man (α1-6) Man (α1-4) GlcNH2 (α1-6) myo-inositol-1,2-cyclic-phosphate, were substantially protected from malarial symptoms and death after they were exposed to the actual parasite.

Figure 11.1.9 shows a cross-section of a membrane (with cholesterol, PE, SM) containing the glycosylated form of the human complement regulatory protein CD59 protein (1cdr) with a GPI anchor attached at its C-terminus. Note that the middle part of the anchor (glycan) holds the actual protein well above the top of the lipid bilayer. The soluble protein is also glycosylated. The protein binds to complement proteins C8 and/or C9, which are effector immune proteins that assemble on the surface of a cell undergoing lysis.

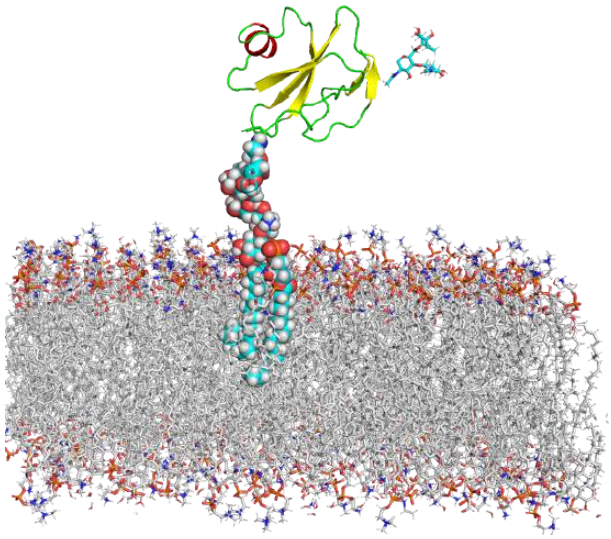

Figure 11.1.9: Cross section of a membrane containing the glycosylated form of the human complement regulatory protein CD59 protein (1cdr) with a GPI anchor attached at its C-terminus

The GPI anchor is shown in spacefill. Note that it only extends halfway into the bilayer, as you would expect from the size of the fatty acids attached to the phosphatidyl inositol. The glycan part of the GPI is shown in spacefill between the lipid and its protein attachment site. The protein is also glycosylated in the extracellular domain.

Something new!

A new (5/21) and totally unexpected type of glycosylated molecule has been found at the outer leaflet of mammalian cells - a glycosylated RNA, as shown in Figure 11.1.10 This adds RNA to the lipids and proteins as a target for glycosylation. These surface glycoRNAs interact with antibodies again ds-RNA and the Siglec lectin family. They are found in cells in vivo and cultured cells in vitro.

11.1.5: Transmembrane (Integral) Proteins

These proteins pass through the membrane either one in one pass, usually with a single alpha-helix or many membrane-spanning helices. For example, G protein-coupled receptors, often called serpentine receptors, cross the membrane seven times. There are three different types based on the number of types the protein crosses the membrane and the type of secondary structure used in crossing: biotopic (single pass), alpha-helical polytopic, and beta-barrel. These proteins are found in all types of membranes and have many types of functions, from receptors, receptor ligands, structural, adhesion, transport, gene regulation, and transport.

11.1.5.1: Transmembrane Biotopic - Single Pass Proteins

The are 4 types of single-pass transmembrane proteins:

- Type I: N-terminal outside of the cell (extracellular) and the precursor signal sequence on the N-terminus which is a localization sequence is removed
- Type II: N-terminal intracellular and with the transmembrane domain close to the N-terminus
- Type III: N-terminus extracellular and no signal sequence in precursor protein
- Type IV: N-terminus intracellular and the transmembrane domain close to the C-terminus

The transmembrane domain of single-pass integral membrane proteins consists of a single alpha-helices with nonpolar side chains extending outward from the helical axis where they interact with the nonpolar lipid parts of the membrane. These nonpolar sides are more stable in nonpolar environments.

To study such proteins in a less complex environment, membranes are often "dissolved" in nonpolar, single-chain amphiphilic detergents. These single-chain amphiphiles form micelles in the absence of membrane proteins but can form **mixed micelles** in which the nonpolar part of the protein is surrounded in the detergent micelle by the nonpolar acyl chains of the detergent.

Figure 11.1.11(top) below shows just the transmembrane and juxtamembrane (next to the membrane) domains of the single pass Notch protein, which is critical in many signal transduction pathways.

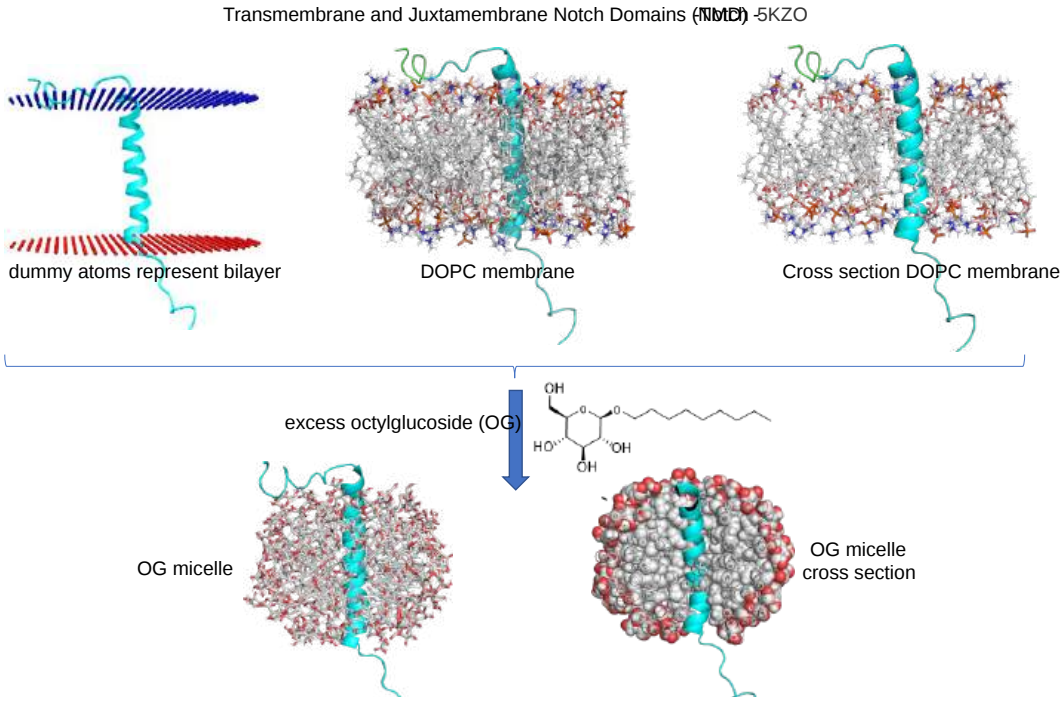

Figure 11.1.11: Transmembrane and juxtamembrane domains of the single pass Notch protein in a bilayer and an octylglucoside micelle

The top images in the figure above show different ways to represent the protein in the bilayer, with the right-hand image showing a cross-section through the membrane to better show how the protein passes through the bilayer.

The bottom images in the figure above show the protein after excess detergent, in this case, octylglucoside, is added to the protein-containing bilayer.

Here are some examples of bitopic single-pass transmembrane proteins

Cadherins

All structures need support and connections. At the macro level, the skeleton supports the mass and organization of organs and tissues in whole organisms. Within an organ, how can cells hold together? How do they adhere to each other? Certainly not through outer leaflet lipid contacts as the outer surface of the leaflet is typically charged. The extracellular matrix does provide some of the glue that holds cells together. At a more detailed level, transmembrane proteins are involved. One class of adhesive proteins is cadherins, a calcium-dependent cell adhesion molecule. There are over 100 human cadherins. They are mostly ditopic, single transmembrane pass proteins. Their cytoplasmic domains interact with proteins like catenin, which then bind to the interior cytoskeletal network composed of actin and other proteins. This provides a way for the intracellular region to regulate the extracellular interactions of the cell.

The extracellular domain is composed of five repeating "cadherin" domains, each around 110 amino acids, that can fold independently. Calcium ions bind at the domain interfaces. A cadherin can interact with other cadherin domains on other cadherins on other cells, leading to cell adhesion. Essentially, the receptor cadherin on one cell binds the ligand cadherin on the other. As metastatic tumor cells lose their adhering feature and leave the site of the primary tumor, you would expect that mutations in cadherins are often involved. They may also be involved in cell sorting during morphogenesis, "regulation of tight and gap junctions, and in the control of intercellular spacing".

Figure 11.1.12 shows a "constructed" image of cadherin-1 (1L3W) interacting with cytoplasmic β-catenin (1I7X) through a modeled transmembrane helix (amino acids QIPAILGILGGILALLILILLLLLFLRR, amino acids 706-731). No full-length structure of cadherin in a membrane is available.

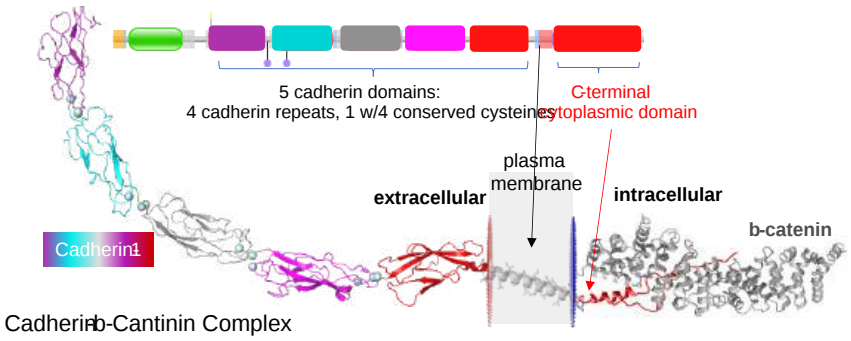

Figure 11.1.12: A constructed" image of cadherin-1 (1L3W) interacting with cytoplasmic β-catenin (1I7X) through a modeled transmembrane helix

Membrane Protein Kinases

Kinases are enzymes that phosphorylate substrates. Hexokinase is a protein enzyme that catalyzes the phosphorylation of a hexose substrate such as glucose. A **protein kinase** is a protein enzyme that phosphorylates a protein substrate. That protein could be another copy of itself or another protein. We will see in Chapter 12 that many protein kinases are involved in cell signaling. Many tyrosine protein kinases are bitopic single-pass integral membrane proteins that become active on binding a ligand. Typically, on binding an extracellular ligand, two monomeric copies of the kinase form a dimer in the membrane, activating a tyrosine kinase cytoplasmic domain, which typically phosphorylates (using ATP as a substrate) the other member of the dimer in an "autophosphorylation" reaction. Sometimes the dimers are held together by disulfide bonds.

Figure 11.1.13shows a "constructed" image of the human dimeric insulin receptor.

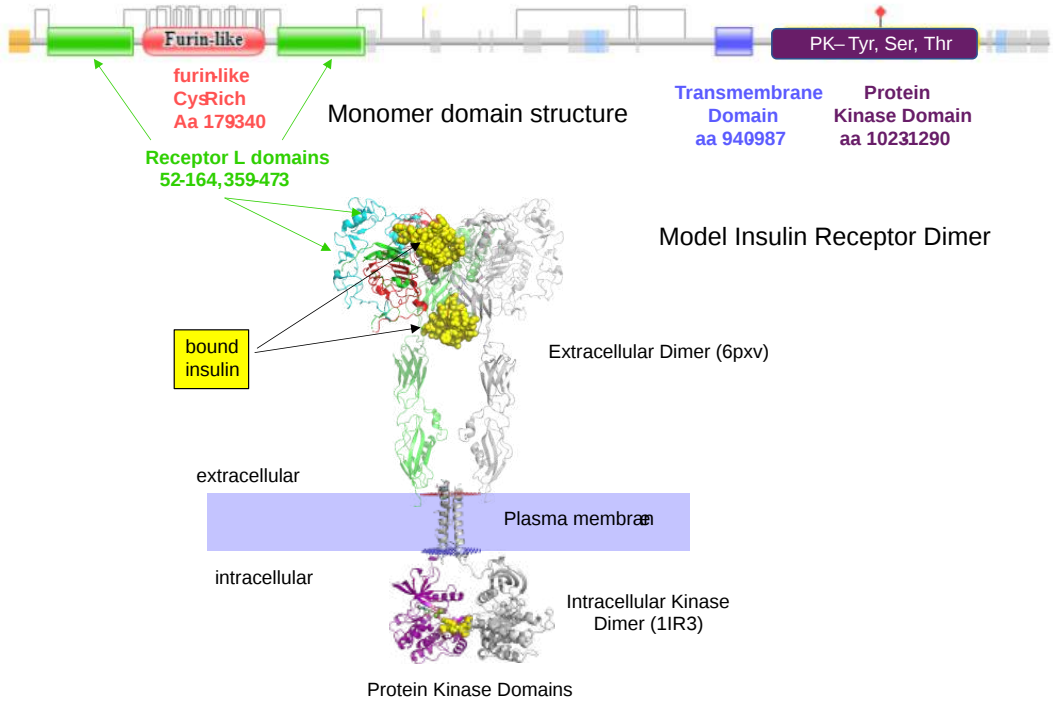

Figure 11.1.13: aA "constructed" image of the human dimeric insulin receptor

One of the monomers is shown in gray. The other monomer is shown in colors corresponding to the domain organization of the protein. Each extracellular dimer (6PXV) has two insulins bound (yellow spacefill). The intracellular domains (1IR3) are activated on insulin binding. No full-length structure of full insulin receptor in a membrane is available.

Almost half of all helical membrane proteins in humans are bitopic, compared to between 20-25% in prokaryotes. Humans have 10-20 fold more bitopic proteins than E.Coli. There appear to be about 196 bitopic proteins in E. coli (located in the inner membrane) and 70 in M. jannaschii (Archea in plasma membrane). In humans, 57% are in the plasma membrane, with the rest distributed between the Golgi, ER, nuclear, mitochondrial and chloroplast membranes. In single-celled yeast, only 8% are in the plasma membrane.

Beta-Dystroglycan

This protein is another example of a bitopic protein with a single alpha-helix membrane domain. Dystroglycan is a dimer of alpha and beta subunits. Alpha-dystroglycan is a peripheral protein that binds beta-dystroglycan, a transmembrane protein. Alpha dystroglycan also binds lassa virus and lymphocytic choriomeningitis virus glycoprotein, as it serves as viral receptors. It also binds the protein dystrophin, a protein missing in Duchenne muscular dystrophy, which affects 1 out of 5000 live male births. As an integral transmembrane protein, beta-dystroglycan connect the extracellular matrix to the cytoskeleton through dystrophin. Alpha- and beta-dystroglycan share the same gene, which codes one long protein which is proteolyzed post-translationally to form the alpha (N-terminal end) and beta subunits (C-terminal end).

Figure 11.1.14shows a schematic outline of dystrophin and the dystrophin-associated glycoprotein complex (DAGC).

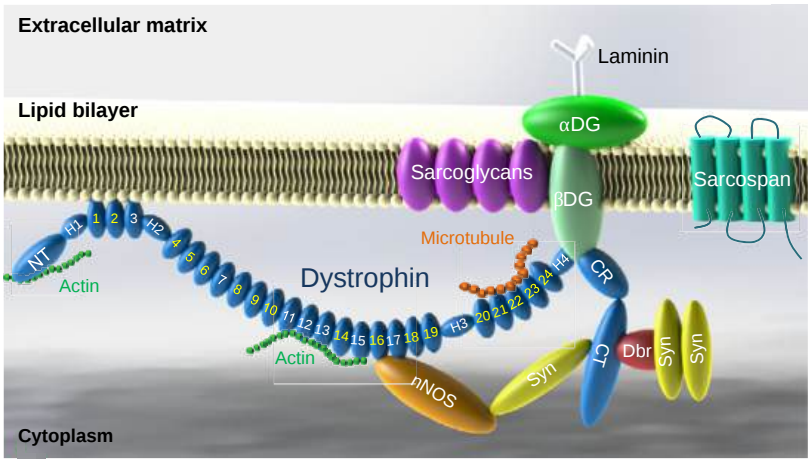

Figure 11.1.14 Schematic outline of dystrophin and the dystrophin-associated glycoprotein complex (DAGC). Dystrophin contains N-terminal (NT), middle rod,
cysteine-rich (CR), and C-terminal (CT) domains. The middle rod domain is composed of 24 spectrin-like repeats (numerical numbers in the cartoon, positively
charged repeats are marked in white color) and four hinges (H1, H2, H3, and H4). Dystrophin has two actin-binding domains located at NT and repeats 11-15,
respectively. Repeats 1-3 interact with the negatively charged lipid bilayer. Repeats 16 and 17 form the neuronal nitric oxide synthase (nNOS)-binding domain.
Dystrophin interacts with microtubules through repeats 20-23. Part of H4 and the CR domain binds to the β-subunit of dystroglycan (βDG). The CT domain of
dystrophin interacts with syntrophin (Syn) and dystrobrevin (Dbr). Dystrophin links components of the cytoskeleton (actin and microtubule) to laminin in the
extracellular matrix. Sarcoglycans and sarcospan do not interact with dystrophin directly but they strengthen the entire DAGC, which consists of dystrophin,
DG, sarcoglycans, sarcospan, Syn, Dbr, and nNOS. .Disease Models & Mechanisms (2015) doi:10.1242/dmm.018424vailable via license: CC BY 3.0

11.1.6: Transmembrane - Alpha-helical polytopic

There are so many intriguing examples of these proteins. We'll illustrate just two.

Rhodopsin-like receptors and pumps

These proteins are involved in cell signaling and are the target of most pharmaceutic drugs. **G protein-coupled receptors (GPCRs)** are incredibly important and we will discuss them extensively in Chapter 12.

GPCRs are cell receptors that span the membrane seven times in a serpentine fashion. They bind ligands (neurotransmitters, hormones, etc) in the extracellular or internal membrane domains (the latter for hydrophobic ligands), and through propagated conformations changes alter the cytoplasmic domain where they functionally interact with a heterotrimeric G protein.

Figure 11.1.15 shows an interactive iCn3D model of the human cannabinoid receptor with bound cholesterol and Δ^9-tetrahydrocannabinol (Δ^9-THC) in spacefill (5xra). The red dummy atoms represent the outer leaflet and the blue the inner.

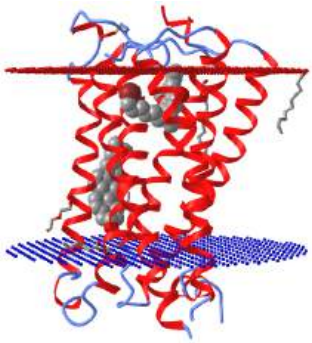

Figure 11.1.15: Human cannabinoid receptor with bound cholesterol and Δ^9-tetrahydrocannabinol (Δ^9-THC). (5xra). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...PaTFrkGFgKeP2A

Δ^9-THC is a partial agonist and tunes the response of the receptor. The active site is conformationally somewhat flexible or plastic. Other ligands bound to it act as antagonists instead of agonists and must do so by eliciting nonactive conformations.

ABC Transporter

Figure 11.1.16shows an interactive iCn3D model of the P-glycoprotein multidrug resistance transporter protein (6nf1).

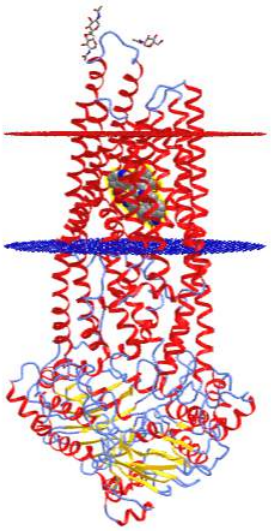

Figure 11.1.16: P-glycoprotein multidrug resistance transporter protein (6nf1). (Copyright; author via source). Click the image for a popup or use this external link:https://structure.ncbi.nlm.nih.gov/i...zzXduCZjhCMaw9

The spacefill ligands represent Zosuquidar, which binds with high affinity to P-glycoprotein and inhibits its activity, making it a cancer agent as it prevents chemotherapeutic drugs that have entered the cell from being pumped out. The protein chain interacting with it on the cytoplasmic face is an antibody fragment used to stabilize the P-glycoprotein so crystals could form.

11.1.7: Transmembrane Beta-barrel transmembrane

We will focus on two of these proteins.

Outer Membrane Factor (OMF) - Gram-negative bacteria

Figure 11.1.17shows an interactive iCn3D model of a beta-barrel transmembrane protein OPRM - Outer Membrane Factor (4y1k) from Pseudomonas aeruginosa that acts as a pore. It also has a palmitoyl fatty acid in thioester linkage to Cys 1 of the protein for extra but unneeded anchorage.

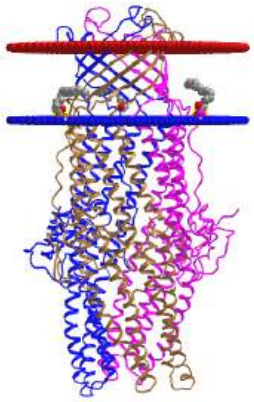

Figure 11.1.17: Beta-barrel transmembrane protein OPRM - Outer Membrane Factor (4y1k) from Pseudomonas aeruginosa (4y1k). (Copyright; author via source). Click the image for a popup or use this external link:https://structure.ncbi.nlm.nih.gov/i...xrAuW1oFtY5FL7

Use this link for another view: https://structure.ncbi.nlm.nih.gov/i...FtY5FL7&t=4Y1K (OPM) in iCn3D

This protein is part of a large complex of proteins that spans both the inner and outer membranes of Gram-negative (examples E. Coli and Pseudomonas aeruginosa) bacterial cell walls. Unfortunately for humans, this protein complex pumps out toxins (to the bacteria) like antibiotics, which makes bacteria resistant to these drugs. The OPRM acts as the outer passageway or duct for the pumped molecules. The Bacterial Outer Membrane Factor (OMF) protein differs in sequence but all form the beta-barrel duct. The E. Coli version of OMF has a triacylated lipid modification of the N-terminus. The N terminal lipid modification might be necessary for the initial attachment of the protein to a membrane before the insertion of the beta-barrel. As such, the enzymes involved in the attachment of the tail could be targets for new antibiotics.

Voltage-dependent anion channel (VDAC) - mouse

This protein regulates the movement of molecules between the cytoplasm and the interior of the mitochondria across the outer mitochondrial membrane. VDAC also serves as a docking site or scaffold for the assembly of molecules into a complex that regulates mitochondrial function. The protein's conformation and hence function are regulated by changes in the transmembrane potential, which we will explore in the next sections. Hence the protein and its function are voltage-dependent. Figure 11.1.18 shows an interactive iCn3D model of mouse VDAC with a beta-barrel formed by 19 beta-strands (3emn).

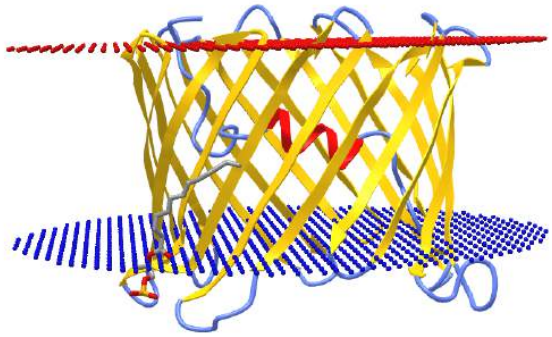

Figure 11.1.18: Mouse voltage-dependent anion channel (VDAC) (3emn). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...WxUqWaGPxgHH79

Note the N-terminal alpha-helix resident inside the channel opening. This helical section moves on changes in membrane potential, gating open and hence regulating the flow of metabolites and ions across the membrane through the pore. At a low transmembrane potential (10 mV), the conductance is high as the channel is in the open state. When the potential increases to 30 mV (either + or -) conductance drops as the protein forms the closed state.

Now that you understand the structure of membrane proteins, let's explore a key type of function of a subset of integral membrane proteins: the movement of molecules/ions across the membrane.

11.2: Diffusion Across a Membrane - Passive and Facilitated Diffusion

Learning Objectives

- Understand the structure and function of biological membranes.
- Describe the different types of diffusion and how they operate across a membrane.
- Explain the concept of concentration gradient and how it drives diffusion.
- Describe the mechanisms of passive and facilitated diffusion, including their differences and similarities.
- Understand the role of carrier proteins and channels in facilitated diffusion.
- Describe the factors that can affect the rate of diffusion across a membrane.
- Understand the importance of membrane transport in maintaining homeostasis in cells and organisms.

11.2.1: Diffusion Across a Membrane

We have studied molecular aggregates (micelles and bilayers) and macromolecular structures (mostly proteins). We also studied binding interactions which are the first steps in the expression of the biological activity of a macromolecule. For some proteins, reversible binding is their sole function (consider the binding of dioxygen to myoglobin and hemoglobin). For many others, it is not. For those, what can happen next?

You already have one possible answer. A bound reactant, which we will call a substrate, can be converted to a product in a chemical step involving the breaking and making of covalent bonds catalyzed by a protein enzyme. However, there is an even simpler process that does not involve covalent bond changes. If a small molecule is bound to a membrane protein, it could be transported in a purely physical step across a membrane. Just as reactions can proceed with and without an enzyme, a solute can move down a concentration gradient across a semi-permeable membrane, driven by diffusion alone in a thermodynamically favorable process, either by itself, in a process called **passive diffusion**, or with the assistance of a membrane protein, in a process called **facilitated diffusion**. Large **pores** made of assemblies of proteins can also be formed that allow the passage of many solutes across the membrane.

There are many occasions when it would be optimal to move a molecule across a membrane from a region of low to high concentration. This process is called **active transport**. It is not thermodynamically favored so it requires an external energy source. This is often the thermodynamically favored cleavage of ATP to ADP and Pi. The uphill transport can also be powered by the downhill diffusion of a "co-transport" molecule from high to low concentration. We will explore all of these processes in this and the remaining chapter sections. First, we should understand the simplest process, "passive diffusion", that requires no protein "help".

Let's step back and think about how difficult it is for a chemical species to cross a lipid bilayer. Chemical intuition would tell us that both size and polarity are important. The bigger the size and the greater the charge, the more difficult it would be to cross the membrane. The permeability coefficient is related to the ease with which solutes traverse the membrane. Figure 11.2.1 shows the permeability coefficients for relevant biological molecules.

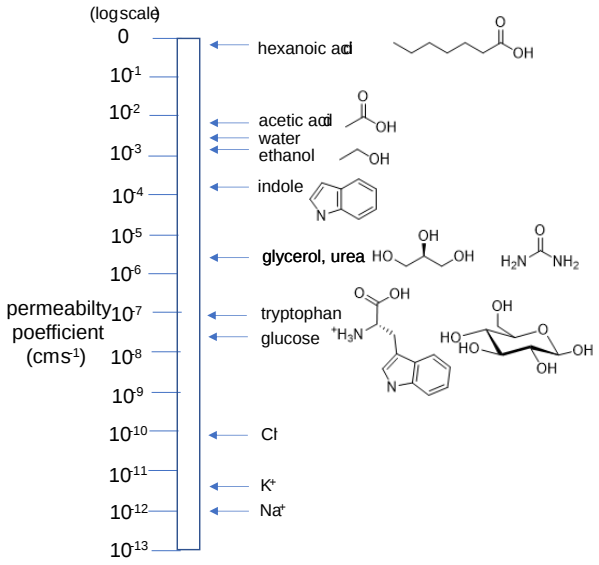

Figure 11.2.1: Permeability coefficients for relevant biological molecules

Smaller, higher charge density ions (like Na^+) have a lower permeability coefficient than do larger, lower charge density ions (like K^+) as seen in (Table 11.2.1). What about natural membranes?

Table 11.2.1: Permeability coefficient (cm/s) of natural and synthetic membranes to D-Glucose and D-mannitol at 25 °C

Membrane Preparation	D-Glucose	D-Mannitol
Synthetic Lipid Bilayer	2.4×10^{-10}	4.4×10^{-11}
Calculated Passive Diffusion	4×10^{-9}	3×10^{-9}
Intact Human Erythrocyte (red blood cell)	2.0×10^{-4}	5×10^{-9}

Looks like D-glucose gets a little help in getting across. We'll see the mechanism below.

11.2.2: Passive Diffusion

Let's start with the passive diffusion of uncharged solute A across a membrane, which can be represented by the chemical equation $A_{out} \leftrightarrow A_{in}$. Intuitively, you probably believe that the rate of **net** diffusion or the **flux** of A across the membrane is directly proportional to the concentration gradient across the membrane. If concentrations of A are identical across the membrane, the net flux J should be 0. If you double the concentration gradient, the net rate should double. We will see that the net rate is a linear function of [ΔA] across the membrane. Figure 11.2.2 shows the flux of A_{out} across a semipermeable membrane of thickness Δx (we will use dx instead when Δx is very small).

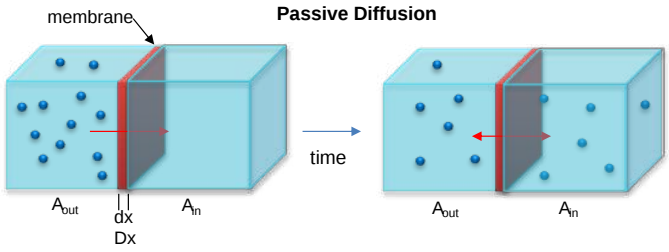

Figure 11.2.2: Flux of A_{out} across a semipermeable membrane of thickness Δx

Let's animate diffusion using a PHET simulation, as shown in Figure 11.2.3

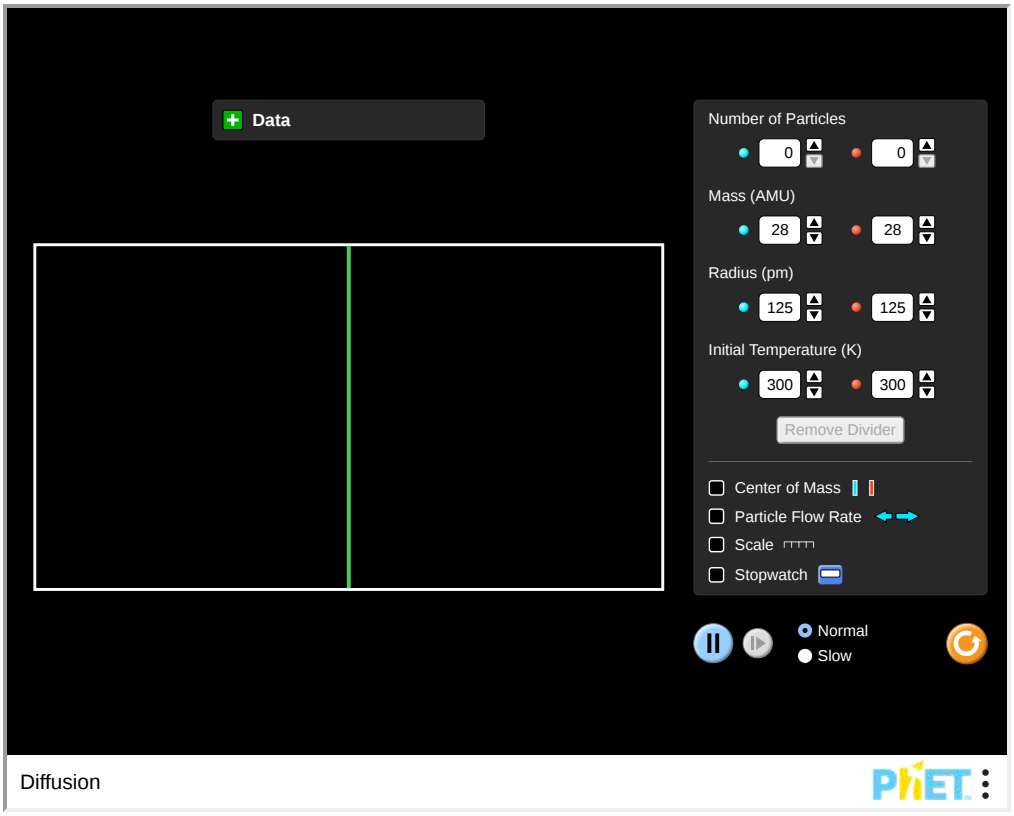

Figure 11.2.3: PHET animation of passive diffusion. PHET: https://phet.colorado.edu/

The flux of molecules A (\(J_A\)) is proportional to the concentration gradient across the membrane, $\Delta A/\Delta x$ (which we will refer to as dA/dx which is the derivative of A with respect to x). The equation below is Fick's First Law of Diffusion:

$$\mathrm{J_A} \propto \frac{d\,\mathrm{A}}{dx} = -\mathrm{D}\frac{d\,\mathrm{A}}{dx} \tag{11.2.1}$$

where D is the diffusion coefficient. The negative sign is necessary since concentration increases to the left in the figure above in the opposite direction of net flux which is to the right. For these derivations, we will assume the $\mathrm{J_A}$ is the initial flux. That is, the flux is measured for a short enough time that the relative concentrations of A on both sides of the membrane do not change significantly. It should be clear that eventually the net flux levels off to zero when the concentrations of A on both sides of the membrane are equal. Under these conditions, the free energy $G_{A\,out} = G_{A\,in}$, so $\Delta G = 0$. This thermodynamic relation can also be expressed as

$$J_A = -L\frac{dG_A}{dx} \tag{11.2.2}$$

This equation bridges the kinetic and thermodynamic aspects of diffusion.

Dimensional analysis of Fick's 1st Law (Equation 11.2.1) shows that the units of D are $\mathrm{cm^2/s}$ which gives the number (dimensionless) of molecules crossing a 1 $\mathrm{cm^2}$ surface area of membrane each second.

J = moles/area/sec = $\mathrm{mol/cm^2{\cdot}s}$ = - $(\mathrm{cm^2/s})$ $\mathrm{mol/cm^3/cm}$. Hence the units of D are $\mathrm{cm^2/s}$.

Let's rearrange Fick's 1st Law and use a bit of calculus to get Equation 4.

$$\begin{aligned} \mathrm{J_A}\int_0^{\mathrm{x}} \mathrm{dx} &= -D\int_{\mathrm{A_{out}}}^{A_{\mathrm{in}}} \mathrm{dA} \\ \mathrm{J_A x} &= -\mathrm{D}\,(\mathrm{A_{in}} - \mathrm{A_{out}}) \\ \mathrm{J_A} &= \frac{\mathrm{D}}{\mathrm{x}}(\mathrm{A_{out}} - \mathrm{A_{in}}) \end{aligned} \tag{11.2.3}$$

or

$$J_A = P\,(A_{\text{out}} - A_{\text{in}}) = P\Delta A \tag{11.2.4}$$

where P is the permeability coefficient, which has units of $cm^2/s/cm$ or cm/s. (We discussed permeability coefficients for different solutes traversing model bilayers when we discussed lipids.) That unit is less intuitive to understand but the final unit is very intuitive.

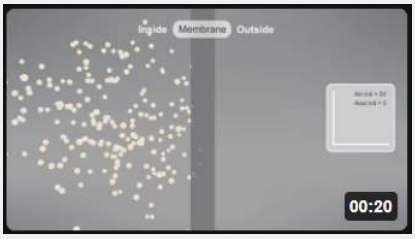
A plot of J_A vs (A_{out} - A_{in}) is linear, with a slope of P = D/x

It's important to remember that there is still diffusion of A across the membrane at equilibrium since the equilibrium is dynamic. There is no net diffusion, however. This is where animations come in handy.

The table below shows the reaction diagram (left), graphical results of the progress curve(middle), and animations for the reversible diffusion $A_{out} \leftrightarrow A_{in}$ across a membrane with the conditions shown below. The reactant A and product are called species and are shown as green spheres. The yellow square is a reaction node indicating a reaction connects A to P. The lines connect the species that participate in the reaction. The velocities (slope of the concentration vs time curve at any given time) are called **fluxes, J**, in Vcell and many other similar programs. When we get to metabolism, we will talk about fluxes of metabolites through pathways. Also, fluxes are used to describe the rate of movement of solute through membranes.

Animations

Now let's look at animations of the same passive diffusion reaction of a neutral species across a semi-permeable membrane. Animations are by Shraddha Nakak and Hui Liu.

$A_{out} \leftrightarrow A_{in}$ $[A_{in}]_{t=0} = 100$; $[A_{out}]_{t=0} = 0$; P = 2	$A_{out} \leftrightarrow A_{in}$ $[A_{in}]_{t=0} = 50$; $[A_{out}]_{t=0} = 0$; P = 2
	


Note the dynamic nature of the diffusion. An equilibrium is reached when the number of particles inside equals those outside. Diffusion occurs in both directions from compartments of equal volume so that the particles moving to the outside don't escape into a comparatively huge volume. (Animations by Shraddha Nayak and Hui Lui)

11.2.3: Passive Diffusion of ions across a membrane - Transmembrane Potentials

Before we move on to facilitated diffusion, let's alter the scenario a bit and use a charged solute. In the example of passive diffusion above, the only thermodynamic driving force for the movement of A across the membrane was the ΔG_A, the change in free energy/mol of A across the membrane (or more strictly $\Delta\mu$ = change in chemical potential). Solute A moves spontaneously across the membrane from high to low concentration. But what if A was charged?

We could add a bunch of positively or negatively charged species to Figure 11.2.2 and ask what would happen. You can't go to a chemical stockroom and find a bottle of K^+ ions but you could find a bottle of neutral KCl. Let's make our experiment system a vesicle that has 0.1 M KCl in the aqueous inner compartment with 0.1 M NaCl on the outside. We could easily prepare such vesicles by making large unilamellar vesicles (LUVs) with entrapped 0.1M KCl in a solution of 0.1 M KCl and then separate the vesicles from the 0.1 M KCl not encapsulated on liposome formation using a size exclusion gel chromatography column equilibrated and eluted in 0.1 M NaCl. These vesicles are illustrated on the left of Figure 11.2.4

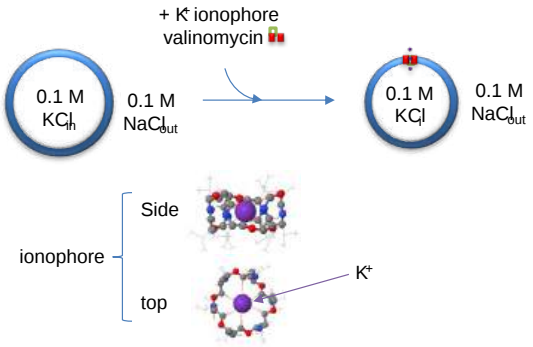


Figure 11.2.4: Making vesicles with a transmembrane potential

In these prepared vesicles is there a net thermodynamic driving for K^+ and Cl^- to move from inside to outside the vesicle? Not for Cl^- since its concentration is the same on both sides of the membrane (see Fick's 1st Law above). However, there is a clear thermodynamic driving force to take $K^+_{in} \rightarrow K^+_{out}$. If the membrane was impermeable, net outward flux would not occur even though it is favored thermodynamically. Think of this as an example of a reaction under complete kinetic control! Note that in this example there is also a net driving force to move Na^+ ion from outside to inside as well.

In our next step, let's make the membrane permeable to only K^+ ions. We can do this by adding a small antibiotic, valinomycin, which binds in the membrane and once there binds and carries K^+ ions across the membrane. It is called an **ionophore.** Figure 11.2.5 shows an interactive iCn3D model of K^+ bound to Valinomycin.

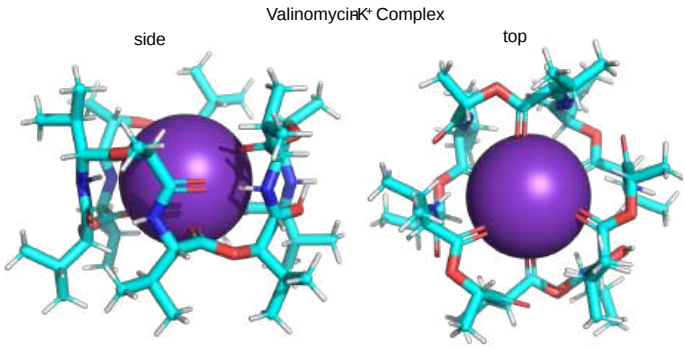

Figure 11.2.5: K^+ bound to Valinomycin (xxxx). (Copyright; author via source). Click the image for a popup or use this external link: Not available

Valinomycin, from *Streptomyces fulvissimus*, is a cyclic peptide consisting of L and D-Val along with L-lactate and D-hydroxyisovalerate, connected through both ester and amide bonds. The K^+ ion is in the center. The six valine carbonyl oxygens bind the K^+ ion. The hydrophilic groups are pointed toward the center, while the hydrophobic groups point to the outside of the structure, allowing the K^+ ion to be sequestered in a polar environment as the nonpolar exterior of the complex passes through the membrane. This ionophore is specific for K^+ and binds the smaller Na+ ion weakly. This can be accounted for by two factors. The smaller sodium ion doesn't bind as tightly to the chelating carbonyl oxygens. Also, the sodium ion has a higher charge density, so the Na^+/water interactions must be more stable and more difficult to break than those to K^+. The ion must be desolvated before it binds to the complex. Other ionophores are specific for other ions.

Once the ionophore is bound, the kinetic barriers to K^+ efflux are removed and it starts moving K^+ from inside to outside. However, as soon as it does, the charge balance across the membrane is lost, with the outside becoming net positive and the inside becoming net negative. A transmembrane electric potential develops across the membrane. This disfavors stops K^+ efflux to the outside and eventually stops it even as the concentration difference of K^+ across the membrane still favors efflux.

If you were a positive ion stuck in the middle of a membrane, as illustrated in Figure 11.2.6, which way would you move?

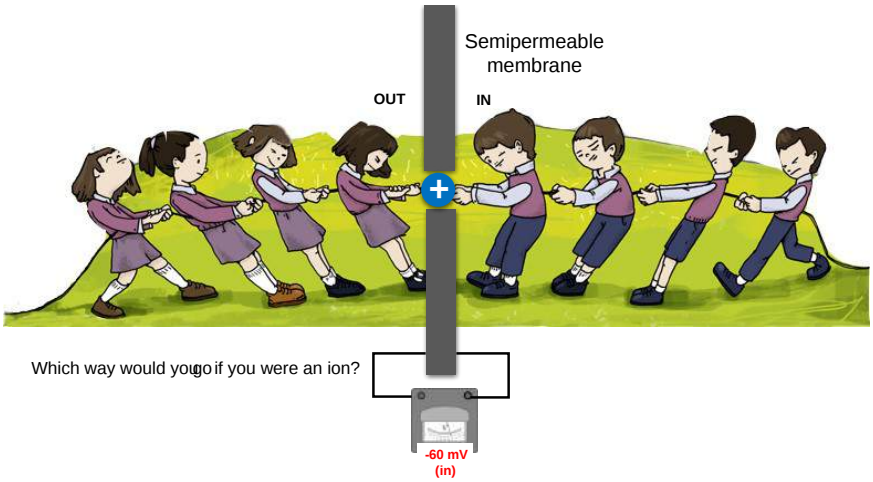

Figure 11.2.6: Which way does a positive ion move across a membrane with a transmembrane potential? (adapted from https://commons.m.wikimedia.org/wiki/File:Dib_1.jpg

There are now two thermodynamic driving forces for K^+ movement from inside to outside:

- a $\Delta G_{concentration}$ which favors K^+ efflux. At time t=0, $\Delta G_{concentration} << 0$ and it becomes a bit less negative (less favored) with efflux.
- a $\Delta G_{membrane\ pot}$ which is zero to start and slowly becomes positive, increasingly disfavoring K^+ efflux.

When these driving forces are equal and opposite, **net** K^+ movement across the membrane stops and the system is in dynamic equilbrium.

Since we use electric potential to describe electrical phenomena (electron, ion movement), we often use the word **chemical potential** in this case to describe the movement of ions across a concentration gradient. Add them together and we call it the **electrochemical potential**.

$$\begin{aligned} \Delta G_{electrochemical} &= \Delta G_{chemical} + \Delta G_{electrical} \text{ or} \\ \Delta \mu_{electrochemical} &= \Delta \mu_{chemical} + \Delta \mu_{electrical} \end{aligned} \tag{11.2.5}$$

We can use this understanding to derive an equation for flux J of a charged solute across a membrane of a given potential. The equation is called the Goldman Equation and is shown below.

$$J = \frac{P\frac{ZF}{RT}(E_1 - E_2)\, C_1 \left(1 - \frac{C_2}{C_1} e^{\frac{ZF}{RT}(E_2 - E_1)}\right)}{1 - e^{\frac{ZF}{RT}(E_2 - E_1)}} \tag{11.2.6}$$

where

- P is the permeability coefficient
- Z is the charge or valence on the ion
- F is the Faraday constant
- R is the ideal gas constant
- T is temperature
- E2-E1 and the reverse is the transmembrane potential
- C2-C1 are the concentrations of the ions across the membrane

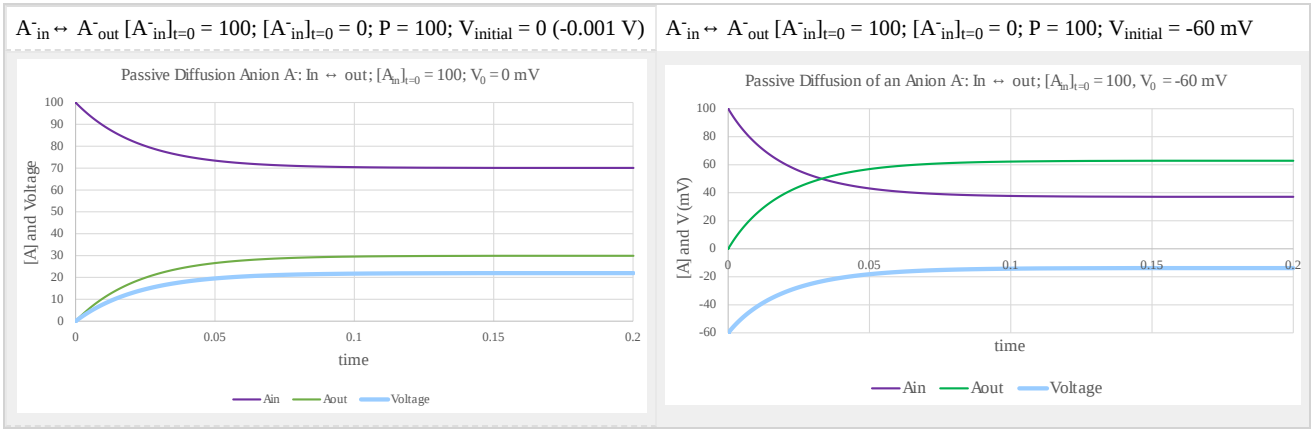
Compare this to the Nernst equation which you learned in introductory chemistry courses.

$$E = E^o - \frac{RT}{nF} \ln Q \tag{11.2.7}$$

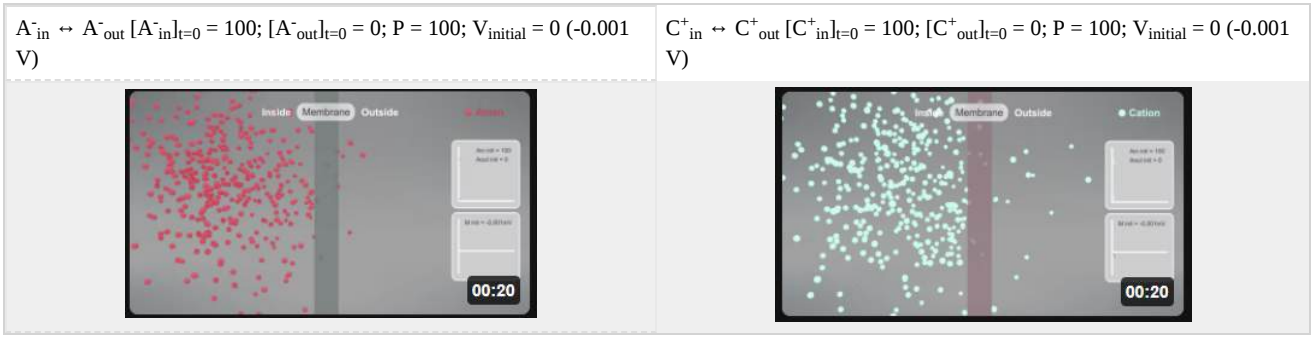
that relates the reduction potential of an electrochemical reaction to the standard electrode potential, temperature, and concentration where E is the potential difference.

Now let's run a Vcell simulation for the diffusion of an anion across a semipermeable membrane. To do so we must first set the initial transmembrane potential to solve the Goldman equation numerically. At present, this type of simulation **can not** be

embedded into this book. So instead, the concentration vs time graphs for two different simulations, one at an **initial** transmembrane potential (E_2-E_1) = - 0.001 (i.e. 0) and one at -60 mV (a typical cell resting potential), are presented in the Figure below. In each, the reaction is $A^-_{in} \leftrightarrow A^-_{out}$ $[A^-_{in}]_{t=0}$ = 100.



Here are animations that show the selective reversible movent of anions (A^-, left panel, red) and cations (C^+, right panel, cyan) as they move across a membrane from the inside to the outside. This is a very simplified simulation as it shows no counter ions on either side. Assume they exist as it would be impossible to have a "container" with just anions or cations. The initial transmembrane potential (t=0) is 0 (actually -0.001 to allow the calculations using Vcell).



As anions move to the outside (left animation), the inside becomes less negative with respect to the outside, so the membrane potential V becomes more positive. This is indicated by the membrane changing to a blue color. Conversely, as cations move to the outside (right animation), the inside would become more negative with respect to the outside, so the membrane potential V becomes more negative. This is indicated by the membrane changing to a red color. (Animations by Shraddha Nayak and Hui Lui)

11.2.4: Facilitated Diffusion

Now let's return to the diffusion of a noncharged solute down a concentration gradient (i.e. favored) after binding to a membrane receptor. The answer to that question depends on the biological function of the macromolecule. We can simplify this process by adding one additional step as reflected in the equilibrium binding expression shown below:

$$M + L \rightleftharpoons ML \rightleftharpoons M + X$$

This expression indicates that the free ligand has changed in some fashion to x. In the next two chapters, we will consider two kinds of transformations:

- L is a ligand on the outside of a biological membrane (Lout) that binds to a membrane protein receptor, R. This undergoes a conformational change (as we studied in the binding of dioxygen to hemoglobin) which leads to the expulsion of the bound ligand to the inside of the membrane (Lin). This can be modeled with the simple equation:

  $$R + L_{out} \rightleftharpoons RL \rightleftharpoons R + L_{in}.$$

  This process is called facilitated diffusion and represents a physical as opposed to chemical process since no covalent bonds are made or broken. This process proceeds down a concentration or chemical potential gradient ($\Delta\mu < 0$) and hence is spontaneous

(thermodynamically favored). If the ligand concentration is higher inside the cell, net diffusion moves it to the outside of the cell. Passive (non-facilitated) diffusion is kinetically slow in the absence of a receptor since membranes present formidable barriers to the passage of polar molecules.

- L is a ligand (or substrate S) that binds to a protein enzyme, E. The bound substrate is chemically altered to produce a new product, P, which dissociates from the enzyme. This can be expressed most simply as:
  E + S <==> ES <==> E + P .

Consider the mechanism illustrated in Figure 11.2.7.

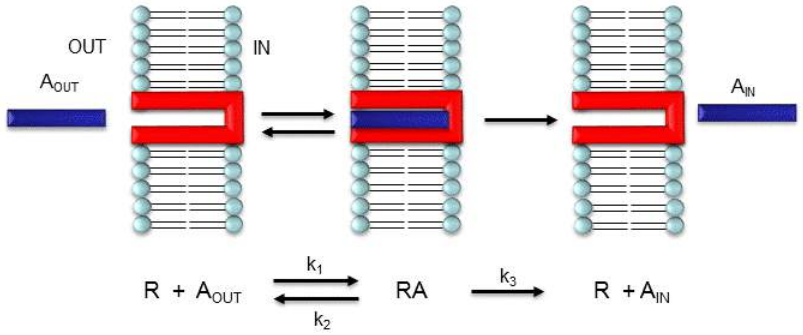


Figure 11.2.7: Mechanism for faciliatated diffusion

Let's assume that for this system the initial flux will be measured. We would like to derive equations that show J as a function of Aout (assuming that Ain is negligible over the time course of measuring the initial flux. Also, assume that the J facilitated is much greater than J passive. In contrast to passive diffusion, JA is not proportional to Aout but rather to [Abound].

Consider this example to help you understand that proportionality. Pretend that the receptor is a truck that can carry one particle across the membrane at a time (i.e. 1/1 stoichiometry). Also, assume that the particle can't get across without being carried by the truck. If there are no trucks in the membrane, no load can be delivered. If there are trucks in the membrane but no particles in them, no load will be delivered. As the number of particles available to be loaded into the truck increase, the truck will have an increased chance to be loaded (depending of course on the affinity of the particle for the truck). If the number of loaded trucks is doubled, the number of particles dumped to the other side will double. Therefore, by analogy,

JA is proportional to [RA], or

$$J_A = \text{const}[\text{RA}] = \text{k}_3[\text{RA}] \tag{11.2.8}$$

How can we calculate RA when we know A and R? Let us assume that Atotal (A0) is much greater than R0, as is the likely biological case, and Ain = 0. We can calculate RA using the following equations, and the same procedure we used for the derivation of the binding equation

$$[\text{ML}] = \frac{[\text{M}_0]\,[\text{L}]}{\text{K}_\text{D} + [\text{L}]} \tag{11.2.9}$$

The equation for the dissociation constant K_D

$$\text{K}_\text{D} = \frac{[\text{A}]_{\text{eq}}[\text{R}]_{\text{eq}}}{[\text{RA}]_{\text{eq}}} = \frac{(\text{A})(\text{R})}{\text{RA}} \tag{11.2.10}$$

The equation of mass balance of R

$$\text{R}_0 = \text{R} + \text{RA} \text{ so } \text{R} = \text{R}_0 - \text{RA} \tag{11.2.11}$$

Since we will assume that A_0 is much greater than R_0, we will not need the mass balance for A (which is Ao = A + RA).

Substitute x into x and rearrange to get:

$$\begin{aligned} \text{K}_\text{D}(RA) = (A)(\text{R}) = (A)\,((\text{R}_0) - (A)(RA) \\ \text{K}_\text{D}(RA) + (A)(RA) = (A)\,(\text{R}_0) \\ (\text{K}_\text{D} + \text{A})\,(RA) = (A)\,((\text{R}_0) \\ (RA) = \frac{(\text{R}_0)\,A}{\text{K}_\text{D} + \text{A}} \end{aligned} \tag{11.2.12}$$

Substitute x into z gives the final equation,

$$J_A = k_3[RA] = \frac{k_3 (R_0) A}{K_D + A} = \frac{J_{max} A}{K_D + A} \tag{11.2.13}$$

It should be clear to you from this equation that:

- a plot of J_A vs A is hyperbolic
- $J_A = 0$ when $A = 0$.
- $J_A = J_{max}$ when A is much greater than K_D
- $A = K_D$ when $J_A = J_{max}/2$.

These are the same conditions we detailed for our understanding of the binding equation.

This derivation is based on the assumption that the relative concentrations of A, R, and AR can be determined by the K_D for the interactions and the concentrations of each species during the early part of diffusion (i.e. under initial rate conditions). Remember under these conditions, A_{out} does not change much with time. Is this a valid assumption? Examine the mechanism shown in the above figure. A_{out} binds to R with a second order rate constant k_1. RA has two fates. It can dissociate with a first-order rate constant k_2 to A_{out} + R (to give the original species), or dissociate with a first-order rate constant of k_3 to give A_{in} + R (as A moves across the membrane). If we assume that $k_2 >> k_3$ (i.e. that the complex falls apart much more quickly than A is carried in), then the relative ratios of A, R, and RA can be described by K_D. Alternatively, you can think about it this way. If A binds to R, most of A will dissociate, and a small amount will be carried across the membrane. If this happened, then R is now free, and will quickly bind A_{out} and reequilibrate. This occurs since the most likely fate of bound A is to dissociate, not to be carried across the membrane, since $k_3 << k_2$.

11.2.5: "Receptors" in Facilitated Diffusion

Two types of proteins are involved in facilitated diffusion, **carriers and channels**. **Carrier** proteins (also called permeases or transporters) such as the glucose transporter (GLUT1) move solute molecules across a membrane while **channels/pores** facilitate the diffusion of ions down a concentration gradient by providing a pore in the membrane. We won't describe in this section the more complicated processes of phagocytosis and endocytosis. These processes are illustrated in Figure 11.2.8

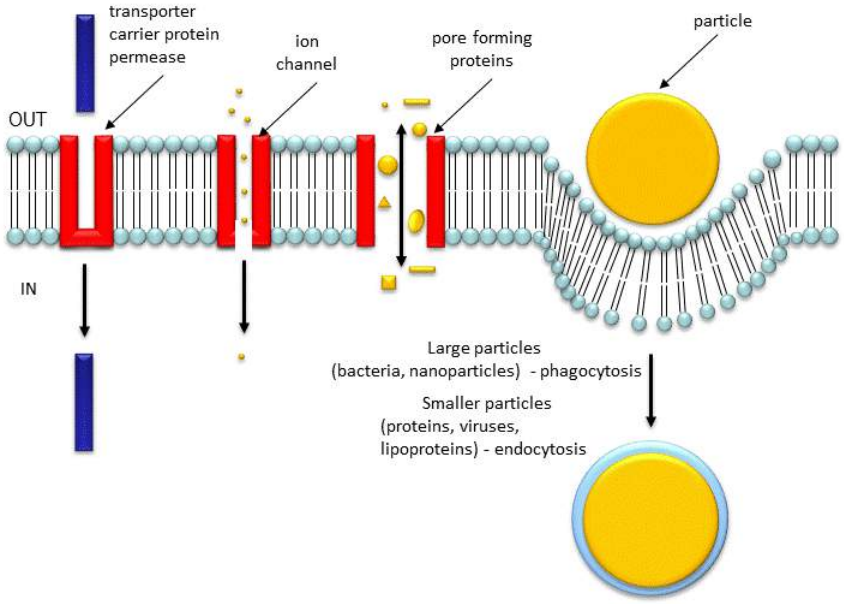

Figure 11.2.8: Movement of particles across a membrane

In the case of permeases and transport proteins, ligands bind and induce a conformational change in the receptor as illustrated in the case of the glucose transport protein shown in Figure 11.2.9

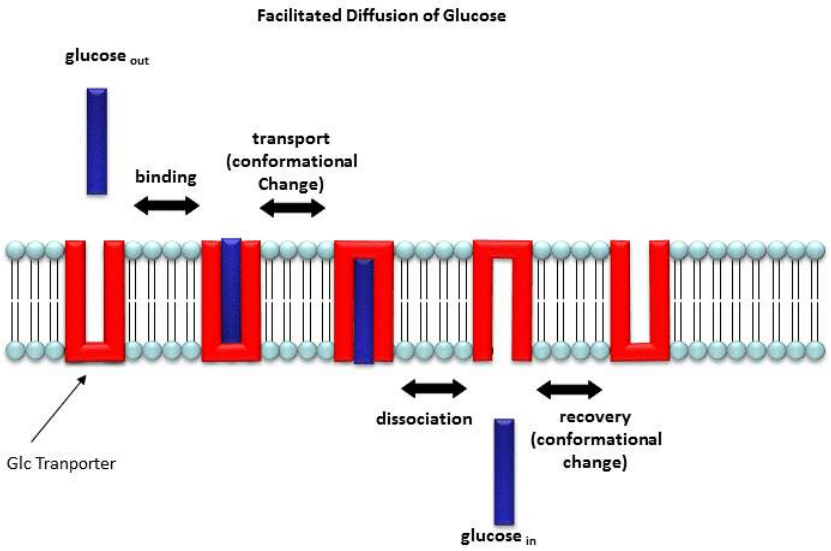

Figure 11.2.9: Model for facilitated diffusion of glucose across a membrane

In channels and pores, a ligand can bind to the receptor (channel protein), which induces a conformational change in the receptor, a "ligand-gated" channel through the membrane. This process would lead to the diffusion of many ions across the membrane (down a concentration gradient) until the channel closes (which can be induced by ligand dissociation or other events).

The mathematics we derived for the carrier proteins does not apply to the channel proteins. In addition, there are other ways to "gate" open a channel protein, which we will discuss later. Also, some transporters can move solute molecules across a membrane against a concentration gradient. These proteins require an external energy source (like ATP or coupling to the favorable collapse of a second transmembrane gradient) to drive this thermodynamically unfavored process. This is called active transport and will be discussed in the next chapter section.

Both links above are from the Theoretical and Computational Biophysics group at the Beckman Institute, University of Illinois at Urbana-Champaign. These molecular dynamic simulations were made with VMD/NAMD/BioCoRE/JMV/other software support developed by the Group with NIH support.

11.2.6: Carrier proteins (permeases or transporters)

Now let's look at some examples of carrier proteins:

Glucose Transport Proteins

Glucose is a key metabolic fuel so its movement into cells is critical and hence highly regulated. There are multiple types of glucose transporters. **GLUT 1**, a plasma membrane protein, found in most cells, is responsible for constitutive or basal glucose uptake while **GLUT 4** is involved in insulin-regulated uptake in skeletal and heart muscles and adipose cells, of glucose after meals. Its official name is **solute carrier family 2** or, **facilitated glucose transporter member 4.** No structure is yet available for GLUT 4 but there is for GLUT1, which is highly expressed in cancer cells that have high energy demands.

Figure 11.2.10 shows an interactive iCn3D model of a glucose transporter, GLUT1 (5eqg), bound to an inhibitor, cytochalasin B (spacefill). The inhibitor binds in the inward-open state where glucose binds.

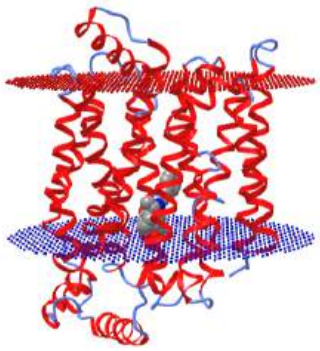

Figure 11.2.10: Glucose transporter, GLUT1 bound to the inhibitor, cytochalasin B (5eqg). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...zUTZEcTWQrQAX6

Mitochondrial ADP-ATP Carrier Protein

We will see in a few chapters that most of the ATP made in cells takes place in the mitochondrial matrix. It won't do cells much good if it stays in there since it is needed in the cytoplasm and elsewhere to drive unfavored processes. Likewise, when ATP is depleted in a cell, ADP is concomitantly high. What is needed is an inner mitochondrial membrane protein that can shuttle ATP out of the mitochondria and ADP in down concentration gradients. It would not make sense to need to power an uphill movement of ATP into the mitochondria from low to high concentration driven by ATP cleavage. Let's look at the structure of the bovine ADP-ATP carrier protein which resides in the inner membrane. Figure 11.2.11 shows an interactive iCn3D model of the bovine mitochondrial ADP-ATP carrier protein (1okc).

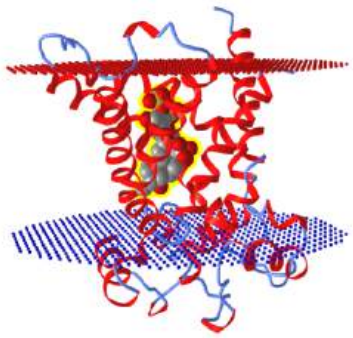

Figure 11.2.11: Bovine mitochondrial ADP-ATP carrier protein (1okc). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?Zc9iLpCncYYD7gBc6

The transmembrane domain contains six alpha-helices which form a depression leading to the inner leaflet. The cyan spacefill amino acids on the bottom of the depression are RRRMM, which is a motif found in nucleotide carrier protein. A conformational transition must transiently open the depression into a channel. The spacefill molecule in CPK colors represents carboxyatractyloside, a diterpene glycoside that inhibits the carrier protein.

A Special Case: Fatty acid carrier proteins

You might guess that free fatty acids, derived for example from lipids after the actions of lipases on triacylglycerol, would **not** need a carrier protein to move across the cell membrane since they are almost completely nonpolar. Hexanoic acid can indeed pass readily, but for solute diffusion across the membrane, size matters as well. A whole family of proteins, **Fatty Acid**

Transport Proteins (FATPs) have evolved to help long-chain fatty acids across membranes. Human fatty acid transport proteins are transmembrane proteins. Its mechanism of action is unclear. No crystal structures of these are readily available. Many proteins in this class catalyze the formation of fatty acid-CoASH derivatives, which is an endergonic reaction powered by ATP. The mechanism of fatty acid movement across the membrane probably may involve simple diffusion coupled to processes driven by ATP. However, there is still controversy on the role of passive vs facilitated diffusion for fatty acids.

First, let's consider the problems facing a cell in moving fatty acids across two aqueous environments. Figure 11.2.12 shows a mass balance depiction of the reservoirs of fatty acid in the extracellular and intracellular environment.

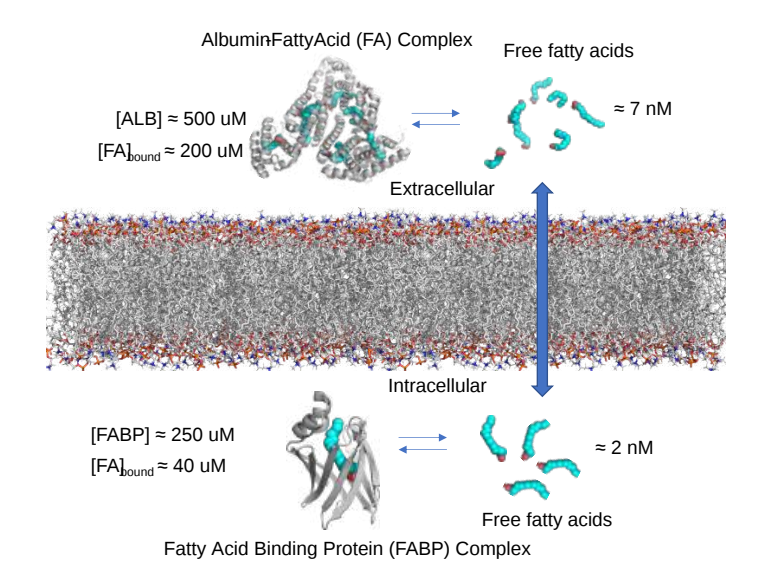

Figure 11.2.12: Mass balance depiction of the reservoirs of fatty acid in the extracellular and intracellular environment

Free fatty acids are very insoluble in aqueous solution so their concentrations on either side of the membrane are very low, in the low nanomolar range. Hence there is no great thermodynamic drive to move free fatty acids across the membrane. If you assume that fatty acids can reasonably transverse the membrane without a carrier protein, there would be no huge kinetic barriers to movement except their low concentrations.

On each side of the membrane, the free fatty acids are in an "equilibrium" with protein-bound amino acids. In the blood and interstitial fluids, albumin, which can bind multiple fatty acids, is in high concentration, so it can act as a buffer to keep free fatty acids in a useful concentration range. Likewise, in the cytoplasm, **fatty acid binding proteins (FABPs)**, which typically bind just one fatty acid, are also relatively high in concentration and buffer the free fatty acids in the cytoplasm. One other note. Free fatty acids are single-chain amphiphiles which makes them detergents, which could easily lyse cell membranes, so their free concentrations must be kept very low compared to the critical micelle concentration.

Figure 11.2.13 shows an interactive iCn3D model of the human brain fatty acid-binding protein bound to docosahexaenoic acid (1fdq).

Figure 11.2.13: Human brain fatty acid-binding protein bound to docosahexaenoic acid (1fdq). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...M2sTpEuU6hj5RA

How do long-chain fatty acids cross the membrane? We will first examine the role of proteins. Let's look at a couple of players.

Fatty acid transport proteins (FATPs): There are six members of the human FATP family, which is also known as the Solute carrier family 27. **FATP 1 (SLC27A-1)** is found in plasma and endoplasmic reticulum membranes and based on sequence analysis it is a single-pass membrane protein. Its highest expression is in muscle and adipose cells. It possesses a C-terminal AMP binding domain and acyl-CoA synthase activity. The mouse protein has an N terminal transmembrane domain and predictions from the human sequence show there is likely just one transmembrane helix at the N terminus (amino acid 13-35). Given that, and the absence of a 3D structure, it would appear that this protein would not bind and transfer the bound lipid across the membrane through a conformational change in the transmembrane domain. FATP 4, located in the ER membrane, is predicted to have 2 transmembrane helices, which still would probably be inadequate to serve as a class translocase. It is expressed in the endoplasmic reticulum cell membrane.

Platelet Glycoprotein 4 (CD36): Another candidate is platelet glycoprotein 4, which is also called CD36, Glycoprotein IIIb, fatty acid translocase, or the thrombospondin receptor. The protein has many functions and binds many types of proteins (thrombospondin, fibronectin, collagen or amyloid-beta) and lipids (oxidized low-density lipoprotein (ox-LDL), anionic phospholipids, long-chain fatty acids, and bacterial diacylated lipopeptides). It is present in plasma and Golgi membranes. Sequence analysis shows that it passes through the membrane twice (amino acids 7-29 and 441-463) and it also is palmitoylated at both N- and C-terminal ends. A PDB structure (5LGD) for most of the protein except the putative N- and C-terminal helices are known. In the structure, it is bound to a malarial protein (shown in grey) and two palmitic acids (spacefill) bound in the nonmembrane domains. Again, from this description, it doesn't appear that the bound fatty acids are translocated via a conformational change in the receptor as described above for glucose and ADP/ATP.

Fatty Acid Binding Proteins (FABPs): These proteins might also take part in the process. In addition to the cytoplasmic form, there is also a plasma membrane-associated fatty acid-binding protein ($FABP_{pm}$), also known as FABP-1. It's the same protein as mitochondrial aspartate aminotransferase (UniProtKB - P00505 (AATM_HUMAN). It has many possible functions.

Figure 11.2.14 shows a possible model for how fatty acids may transfer or be handed off from albumin to membrane-bound GP36 or FATP-1, possibly through an intermediary protein like FABPpm (for GP36).

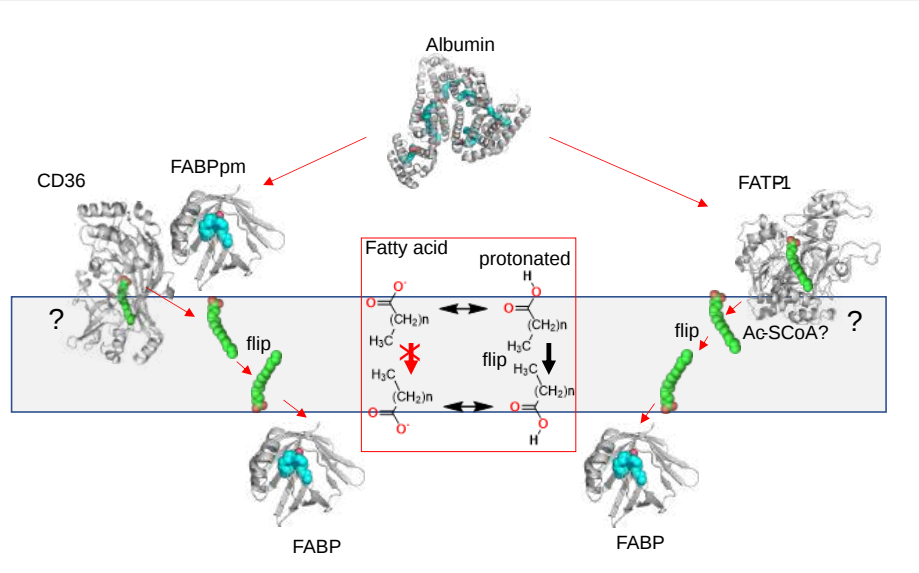

Figure 11.2.14: Possible model for how fatty acids may move from albumin to membrane-bound GP36 or FATP-1

Some proteins (albumin, FABP) deliver fatty acids to the membrane proteins (CD36, FATP-1), which deliver free fatty acids into the outer leaflet, where they flip to the inner leaflet, where they are picked up by membrane-associated cytoplasmic fatty acid binding proteins (FABP). Until structures are known for the transmembrane-bound proteins GP36 and FATP-1, whose full amino acid sequences don't suggest a classic carrier protein, this mechanism is a reasonable one. FATP-1 has acyl-CoA synthase activity so it is likely that the transferred fatty acid is converted to the acyl-CoASH before movement to the cytoplasm. Fatty acid transporters are also implicated in insulin resistance and type 2 diabetes.

The alternative model proposes that long-chain fatty acids, the preferential energy source for cardiac muscle, can cross the membrane by passive diffusion (red boxed area above) even if the activity of CD36 is inhibited. Diffusion depends on an alteration of the pKa of outer membrane adsorbed free fatty acids (around 7.5) compared to free fatty acids in solution (around

4.5). The protonated fatty acid adsorbed to the membrane would move into the outer leaflet where it would flip to the inner leaflet and be picked up by cytoplasmic and/or peripheral membrane proteins. This process would be associated with movement of H^+ across the leaflet as well. This type of diffusion has been observed in protein-free lipid vesicles and cells. Likewise, long chain fatty amines (instead of carboxylic acids) can diffuse into vesicles and cells which would support this passive diffusion if fatty acid-binding proteins don't bind the amine forms.

11.3: Diffusion Across a Membrane - Channels

11.3.1: Introduction

If you punched a hole or pore in the membrane, depending on its size, multiple types of chemical species could flow through it simultaneously. We'll talk about pores in the next section. Let's focus on channels, which have much smaller openings, which are gated open to allow ion flow through them. They are often called **ionotropic** receptors. Channels can be "gated" open by many mechanisms including ligand binding, change in membrane potential, lipid interactions, and mechanical stress. Opening a channel to ion flow allows quick passage of information (in this case an electrical signal) into the cell, leading to quick cellular responses. This is an ideal signaling mechanism for neural cells which demand quick responses.

We'll show examples of each type of gating mechanism. Before we do, it is helpful to know typical extracellular and intracellular ion concentrations in a mammalian neuron, for example (Table 11.3.1).

Table 11.3.1: Extracellular and intracellular ion concentration in a mammalian neuron

ion	extracellular = $[ion]_{out}$ (mM)	intracellular = $[ion]_{in}$ (mM)
Na^+	145 mM	5-10 mM
K^+	5 mM	140 mM
Cl^-	110 mM	10 mM
Ca^{2+} (free)	1.2 mM	100 nM

When ion channels are opened in neural cell membranes, the direction of favorable thermodynamic flow is down a concentration (chemical potential) gradient but the direction is also affected by the transmembrane potential. Typical resting potentials of neural cells are about -60 to -70 mV (negative inside). If a nonspecific **cation** channel is gated open, the kinetic barriers to diffusion are relieved and at that moment Na^+ ions would flow in due to both the chemical and electrical potential, while K^+ ions would flow out but with less driving forces since its efflux is hindered by the negative transmembrane potential. How are such large gradients of these ions formed? We'll answer that in the next section on active transport.

11.3.2: Pentameric ligand-gated ion channels (pLGICs)

These channels play a key role in neuronal signaling. They are ligand-gated channels. In neural systems, the ligands are neurotransmitters. All are comprised of five monomers, which together form the functional channel with the pore formed in the center of the pentameric structure. The subunits can be identical (homopentamer) or different (heteropentamer). All have "Cys-loop" motifs so they have been called Cys-loop receptors as well. Examples include the mammalian nicotinic acetylcholine, serotonin (5-HT), γ-aminobutyric (GABA), glycine, and glutamate receptors.

Figure 11.3.1 shows the generic structure of the pLGICs

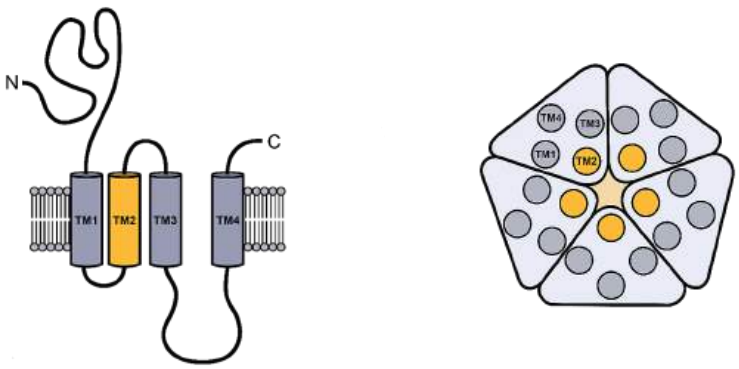

Figure 11.3.1: Generic structures of pentameric ligand-gated ion channels. Smelt, Charles L.C.; (2019) Allosteric modulation of pentameric ligand-gated ion channels. Doctoral thesis (Ph.D.), UCL (University College London). https://discovery.ucl.ac.uk/id/eprint/10075893/. Original content in this thesis is licensed under the terms of the Creative Commons Attribution 4.0 International (CC BY 4.0) Licence (https://creativecommons.org/licenses/by/ 4.0/)

The monomeric structure is shown on the left. Each contains four transmembrane helices (TM1-4). A top-down view of the pentameric structure is shown to the right. The pore surface forms at the interface of the central TM2 helices. The ligand (neurotransmitter) binds to the extracellular domain with contributions from all the subunits. On ligand binding, TM2 and TM3 rearrange to allow the formation of a transient pore and passive diffusion of specific ions.

pLGICs are incredibly interesting and pharmacologically relevant. In general, they have two different types of binding sites.

Orthosteric sites bind ligands in the extracellular domains. When bound, a conformational change leads to the rearrangement of helices opening the pore. The natural ligand is also called the agonist as it promotes the function (either neuron excitation or inhibition) of the ion channel. The binding of the natural ligand/agonist opens up the channel to ion flow. This can lead to activation or excitation of the neural cell if positive cations flow into the cell, which depolarizes the cell as the transmembrane potential becomes more positive. Neurotransmitters that lead to this response are excitatory. Alternatively, the binding of inhibitor neurotransmitters in the orthosteric site can lead to inhibition of the neural cell activation if the channel is a ligand-gated anion channel. This hyperpolarizes (makes the transmembrane potential more negative), leading to inhibition of neural cell activation. Inhibitors or antagonists of channel function, whose structure typically resembles at least somewhat the structure of the endogenous ligand or agonist, also bind to the orthosteric site.

Allosteric sites are distal to the orthosteric site. Ligands that bind to allosteric sites also lead to conformational changes that either augment or diminish the effect of normal ligand/agonist binding by modulating ion flow through the pore.

pLGICs interact with analgesics and anesthetics which makes them even more interesting.

Figure 11.3.2 shows two excitatory pLGICs, the 5-hydroxytryptamine (5HT) (left) and nicotinic acetylcholine (right) receptors. The ligand binds in an orthosteric site in the extracellular domain (ECD), which is composed mostly of beta secondary structure. Allosteric sites are often found in the transmembrane domain.

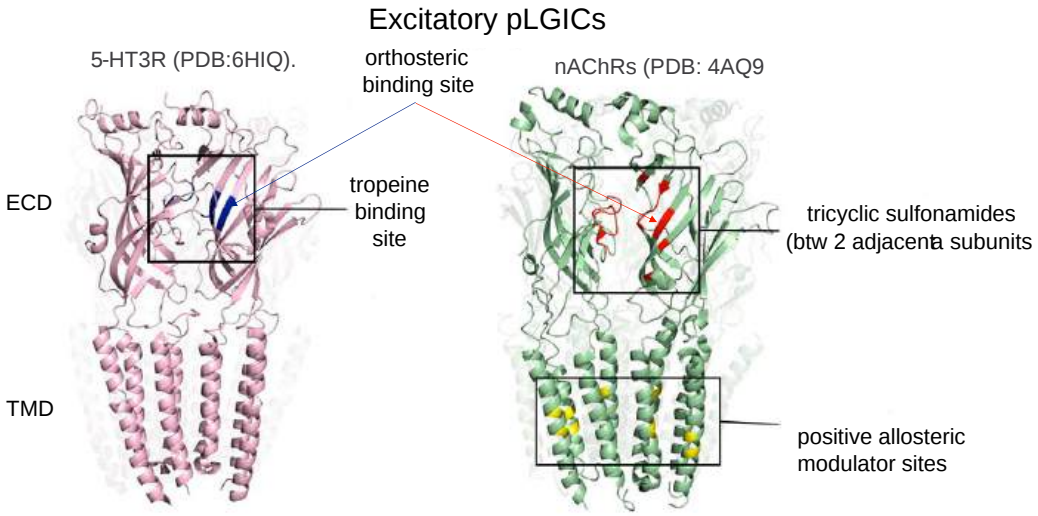

Figure 11.3.2: Two excitatory pLGICs, the 5-hydroxytryptamine (5HT) (left) and nicotinic acetylcholine (right) receptors. Adapted from Lara César O., Burgos Carlos F., Moraga-Cid Gustavo, Carrasco Mónica A., Yévenes Gonzalo E. Pentameric Ligand-Gated Ion Channels as Pharmacological Targets Against Chronic Pain, Frontiers in Pharmacology, 11 (2020), 167. https://www.frontiersin.org/article/...har.2020.00167, **Creative Commons Attribution License (CC BY)**.

Likewise, Figure 11.3.3 shows orthosteric binding sites for GABA and glycine, as well as the binding of modulators that can bind in the TMD or, in the case of benzodiazepines in the ECD as well.

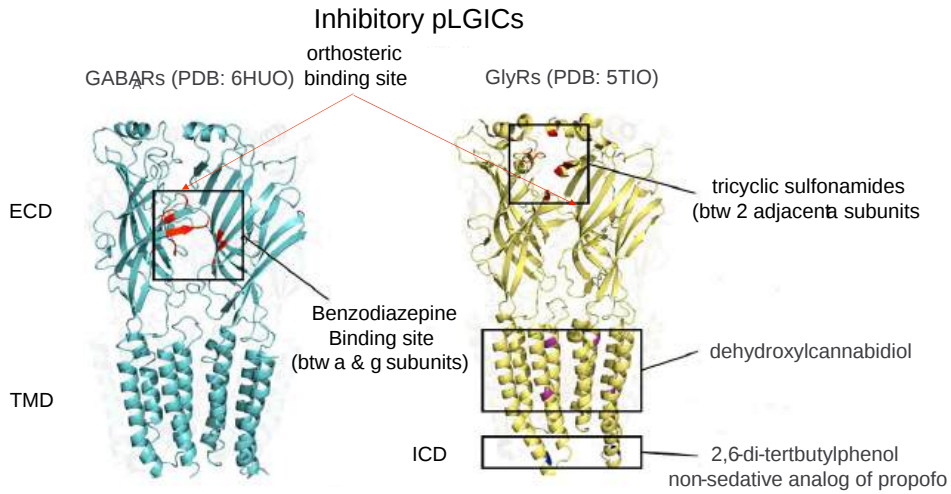

Figure 11.3.3: Orthosteric binding sites for GABA and glycine, adapted from Lara César O., Burgos Carlos F., Moraga-Cid Gustavo, Carrasco Mónica A., Yévenes Gonzalo E. Pentameric Ligand-Gated Ion Channels as Pharmacological Targets Against Chronic Pain, Frontiers in Pharmacology, 11 (2020), 167. https://www.frontiersin.org/article/...har.2020.00167, **Creative Commons Attribution License (CC BY)**.

How do inhalational aesthetics work?

The actual mechanisms of how anesthetics work are still unclear. These fascinating molecules can alter function in a variety of organisms including bacteria, yeast, worms, flies, and plants, as well as animals. Of course, their effect on consciousness appears to be found only in animals. Their selective "turning off" of a function (consciousness) of an entire organ (the brain) is stunning! One theory suggests that they exert their effects through bulk changes in the lipid bilayer, as the potency of anesthetics is generally related to their hydrophobicity. Most are nonpolar and have long been known to work on membranes, presumably altering ion flow through neural membrane ion channels. Typical inhalational and intravenous anesthetics are shown in Figure 11.3.3, along with their date of first use.

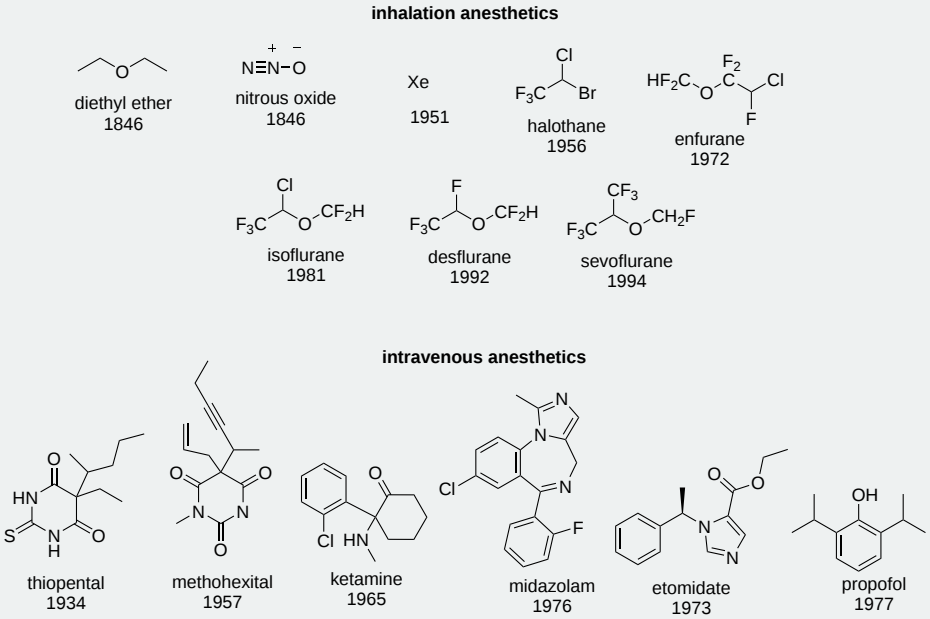

Figure 11.3.3: Structure of common inhalational and intravenous anesthetics. Adapted from Eur J Anaesthesiol. 2009 Oct; 26(10): 807–820. doi: 10.1097/EJA.0b013e32832d6b0f

A very robust correlation is found between the minimum alveolar concentration (MAC, in atmospheres) of inhalational anesthetics and their partition coefficient into olive oil (a measure of their hydrophobicity). This is illustrated in the Meyer-

Overton plot shown in Figure 11.3.3

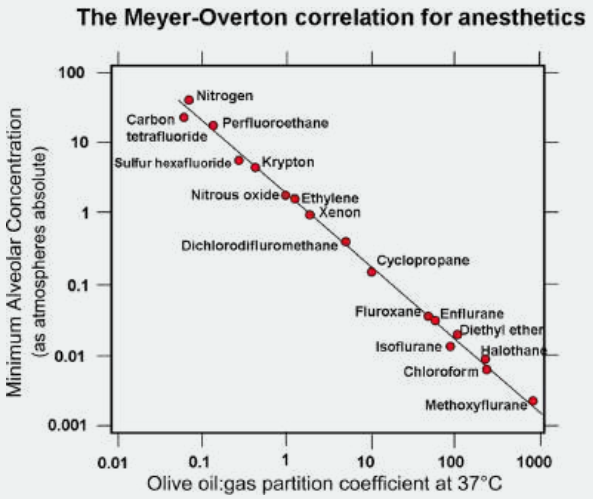

Figure 11.3.3 The Meyer-Overton plot of minimum alveolar concentrations (in atmospheres) vs partition coefficient into olive oil for inhalation anesthetics. https://commons.wikimedia.org/wiki/F...orrelation.png

The MAC is the concentration of inhaled anesthetic within the alveoli at which 50% of people do not move in response to a surgical stimulus (i.e. it is much like an IC_{50} for receptor inhibition). What's so fascinating is the range of molecular species, including N_2 and most Noble gases, that can act as anesthetics. Consider N_2, a nonpolar and nonreactive molecule, which comprises 80% of the atmosphere. From the graph, it is evident that it takes high pressure for it to exert its anesthetic properties. That can occur when scuba diving using regular air in tanks. Divers can experience nitrogen narcosis (also called depth intoxication or rapture of the deep) when using just compressed air. Hence a mixture of 21% oxygen, 35% helium, and 44% nitrogen is often used. Nitric oxide is used by dentists to alter consciousness and pain perception but does not cause general anesthesia except in some who can be hypersensitive to its use.

Additional studies suggest protein:anesthetic interactions are important. For example, the activity of the water-soluble protein luciferase is affected by them. Some molecules (like dichlorohexafluorocyclobutane), expected to have anesthetic properties based on their hydrophobicity, don't. The (S) enantiomer of isoflurane is 50% more potent than the (R) enantiomer in rats, which is hard to explain based on nonspecific partitioning into a bilayer.

Most modern theories suggest that they more directly affect specific target proteins and their proximal interacting lipids in neuromembrane bilayers. The main targets of anesthetics appear to be pLGICs. Anesthetics reduce neuron excitability and firing. Hence you could hypothesize that they inhibit excitatory pLGICs (such as the 5HT and acetylcholine receptors) and/or activate inhibitory ones such as the GABA and glycine receptors. pLGICs are pharmacological targets of many general anesthetics. However, anesthetic inhibition of certain GABA channels and potentiation of nicotinic acetylcholine channels have also been observed.

Recent elegant studies have shown that the inhaled anesthetic chloroform and isoflurane affect K^+ ion flow through the potassium channel subfamily K member 2, known also as the outward rectifying potassium channel protein TREK-1. The channel converts between a voltage-insensitive potassium leak channel and a phosphorylated voltage-dependent outward rectifying potassium channel. It doesn't affect the channel protein directly but indirectly through alteration in the local membrane which affects the location of phospholipase D2 (PLD2), a protein anchored to the membrane by covalent attachment of palmitic acid. PLD2 hydrolyzes phosphatidylcholine, with a positively charged choline head group, to choline and phosphatidic acid, with a negatively charged phosphate head group

The effect of these general anesthetics appears to be on lipid rafts in neural membranes. Lipid rafts are enriched in cholesterol and saturated lipids, especially sphingomyelins such as monosialotetrahexosylganglioside1 [GM1]. Rafts are especially important in the brain where cholesterol can reach up to 45% of plasma membrane lipids. Typical rafts are about 100 nm in diameter. In the presence of hydrophobic anesthetics, the rafts become larger and more dispersed, as the anesthetic partitions into them.

Membrane proteins also partition into rafts. One such protein is phospholipase D2 (PLD2), which is targeted to the inner leaflet rafts by post-translation palmitoylation. In the presence of general anesthetics, the PLD1 laterally translates away from the disrupted and enlarged lipid raft and binds to a disordered C-terminal region of the TREK-1 protein. This localizes the PLD2 and helps activate it to produce high local concentrations of phosphatidic acid with its negatively charged head group. That group interacts with a positive region of the TREK-1 protein, inducing a conformational change in the channel which opens it to K^+ efflux. In effect, PLD2 activates TREK-1 through the local formation of phosphatidic acids.

The opening of the channel hyperpolarizes the cell membrane (making the inside more negative, and inhibiting neural activity (a hallmark of anesthesia). These concerted actions are shown in Figure 11.3.a below.

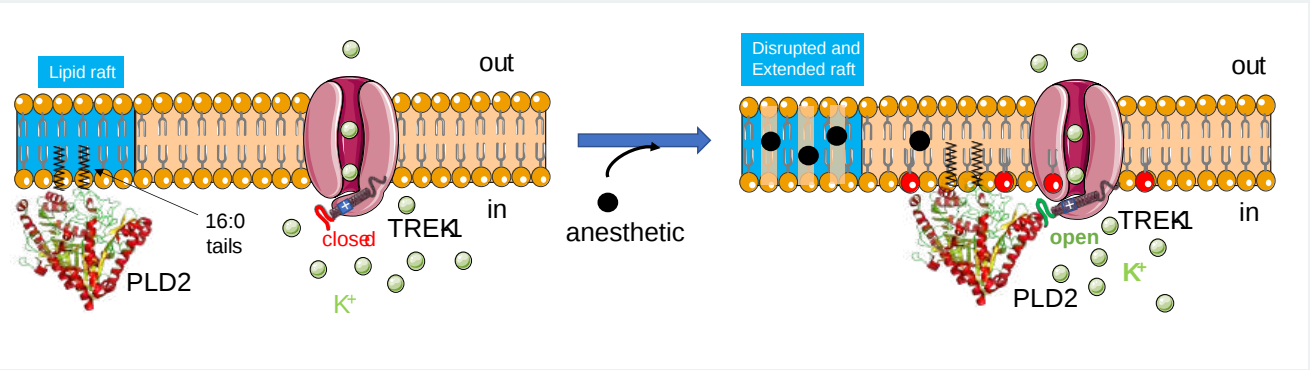

Figure 11.3.a: Effects of general anesthetics in the TREK-1 in the channel. After https://www.pnas.org/content/117/24/13757. r Creative Commons Attribution-NonCommercialNoDerivatives License 4.0 (CC BY-NC-ND)

Deletion of the TREK-1 gene decreases the effect of the anesthetics. If a catalytically inactive mutant of PLD2 (K758R) is overexpressed, all effects of chloroform were eliminated.

We will now explore two pLGIC, the eukaryotic nicotinic acetylcholine channel, and a prokaryotic analog, GLIC.

11.3.2.1: Nicotinic acetylcholine channel (6cnj)

One very interesting channel is the one involved in nicotine addiction. It binds nicotine (an exogenous alkaloid) and the normal endogenous neurotransmitter, acetylcholine. Both compete for the same orthosteric binding site. Since the binding of nicotine gates open the channel, nicotine acts as an agonist. The similarities in their structures are illustrated in Figure 11.3.4

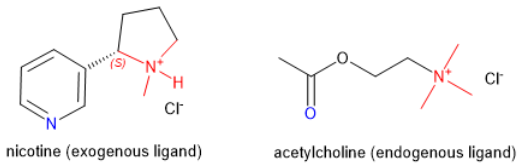

Figure 11.3.4: Structures of nicotine and acetylcholine

The membrane protein is a ligand (acetylcholine)-gated (open-close) positive ion (Na^+ or K^+) channel, involved in fast neural communication (such as at the neuromuscular junction). The quaternary structure of the pentameric receptor consists of two α4 and three β2 subunits - $(\alpha4)_2(\beta2)_3$. This isoform is the most abundant in the human brain and the one involved in nicotine addiction.

The iCn3D model (6CNJ) below has two bound nicotines (spacefill) in the extracellular domain and one Na^+ ion (spacefill) in the transmembrane domain containing the pore. The Na^+ or K^+ ions flow across the membrane down a concentration gradient in a thermodynamically favored process.

Figure 11.3.5 shows an interactive iCn3D model of the nicotinic acetylcholine channel with two bound nicotines (spacefill) in the extracellular domain and one Na^+ ion (spacefill) in the transmembrane domain containing the pore (6CNJ). (long load time)

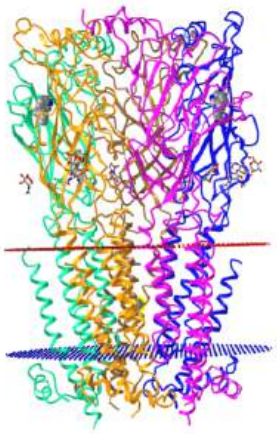

Figure 11.3.5: Nicotinic acetylcholine channel with two bound nicotines (spacefill) in the extracellular domain and one Na^+ ion (spacefill) in the transmembrane domain containing the pore (6CNJ). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...rbXmpaha6FYNB8

The Na^+ or K^+ ions flow across the membrane down a concentration gradient in a thermodynamically favored process.

The gold, blue, and brown β2 subunits are glycosylated on Asn 143 and are shown with a Man (β4) GlcNAc (β4) GlcNAc N-linked oligosaccharide. Nicotine is bound between two alpha-beta interfaces. One is shown between the green (alpha) and gold (beta) subunits and the other is between the magenta (alpha) and blue (beta) subunits.

11.3.2.2: GLIC: A prokaryotic pLGIC

This protein is a **proton**-gated cation channel with specificity for both Na^+ and K^+, which diffuse down their electrochemical gradients. In a sense, H^+s in the extracellular side act as "ligands" as the channel is opened with increasing H^+ concentration (decreasing pH) on the outside of prokaryotic cells. The protein is homologous to eukaryotic pLGICs. Structures of the protein from Gloeobacter violaceus bound to **propofol**, an anesthetic, are known. GLICs also interact with ethanol and barbiturates as well. Hence they serve as models to elucidate the binding and effects of anesthetics.

In contrast to eukaryotic pLGICs, the "ligand - H^+" does not bind in the orthosteric site in the extracellular domain occupied by traditional ligands. Rather changes in protonation states of key proton acceptors and donors in the protein lead to conformational changes analogous to those found on binding ligands to orthosteric sites on classical pLGICs. The external pH associated with half-maximal inward current, pH_{50} is approximately 5.1 ± 0.2.

Evidence suggests that when pH is lowered from 7 to 4, Glu 35 (distant from the orthosteric site), with a pKa - 5.8, becomes protonated. It connects through other H^+ acceptors and donors in the open form through a hydrogen bond network. These include two triads of amino acids found at the interface between the extracellular (ECD) and transmembrane (TMD) domains. R192-D122-D32 comprise a conserved "electrostatic triad". The second is Y197-Y119-K248. The network allows bridging of the effects starting with Glu 35 in the ECD into the transmembrane region where allosteric effectors usually interact with the protein.

Figure 11.3.6 shows an interactive iCn3D model of the open form of GLIC (3P50) with bound propofol (long load time)

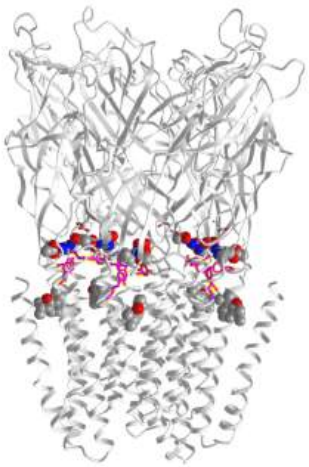

Figure 11.3.6: The open form of the prokaryotic pentameric GLIC ion channel with bound propofol (3P50). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...v92cdeunVY65R8 (long load time)

Orient the iCn3D model below with the extracellular domain (mostly beta structure) at the top and the transmembrane domain (alpha-helical) at the bottom. Key molecular players involved in the interactions described above, from the top down:

- Glu 35 (stick, color CPK)
- R192-D122-D32 electrostatic triad (sphere, CPK color)
- Y197-Y119-K248 triad (stick, color magenta)
- propofol (sphere, color CPK)

Propofol and another anesthetic, desflurane, bind at the same site localized in the upper part of the transmembrane domain of each of the five subunits.

The model below shows the mostly nonpolar (induced dipole-induced dipole) interactions between one bound propofol and side chains in the TMD. Also shown is an interaction between phosphatidylcholine and propofol.

Figure 11.3.7 shows an interactive iCn3D model showing the mostly nonpolar (induced dipole-induced dipole) interactions between one bound propofol and side chains in the TMD. Also shown is an interaction between phosphatidylcholine and propofol. (long load time)

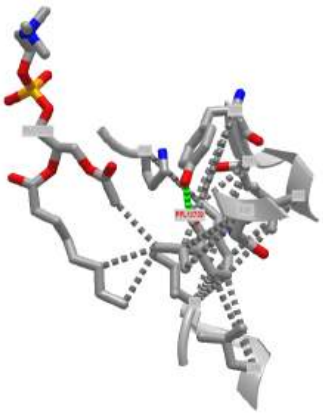

Figure 11.3.7: Propofol interactions in the transmembrane domain of the pentameric GLIC ion channel (3P50). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...s8dJnmX7SFKjLA

11.3.3: Voltage-Gated Ion Channels

In contrast to pentameric ligand-gated ion channels, which require 5 monomeric subunits to aggregate into a quaternary structure to form a pentameric pore, **voltage-gated ion channels** can form a channel from an aggregate of monomeric proteins, each containing a single 6 transmembrane helical unit, or from a longer polypeptide containing multiple repeating 6 transmembrane helical units.

Figure 11.3.8 shows a cartoon of a common voltage-gated K^+ channel. The monomer (top), denoted as the α subunit, contains a transmembrane domain containing 6 helix segments. Four of these monomers aggregate to form the actual homo- or heterotetrameric channel (bottom).

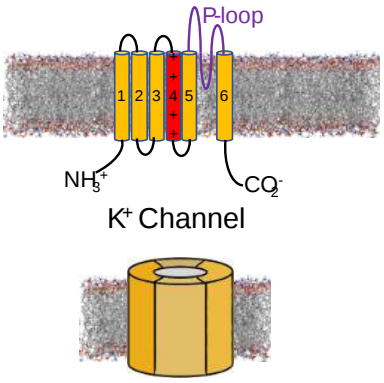

Figure 11.3.8: Cartoon of a common voltage-gated K^+ channel

The genes for the K_v channel family, which facilitate K^+ diffusion across the membrane, encode α subunits of approximately 500 amino acids and a molecular weight of about 57,000. **Four of** these α subunits come together in the membrane to form the

functional channel, a tetramer of α subunits, which together make one central pore. The α subunit can form homo- or heterotetramers since there are different α subunit encoding genes. In addition, the functional channel has smaller, regulatory β subunits as well.

A cartoon structure of a typical voltage-gated Na^+ channel is shown in Figure 11.3.9. It is a **single** polypeptide (α) chain that contains 4 sequential repeats of the 6 transmembrane helical segments (I-IV). The functional channel (bottom) has just one polypeptide chain.

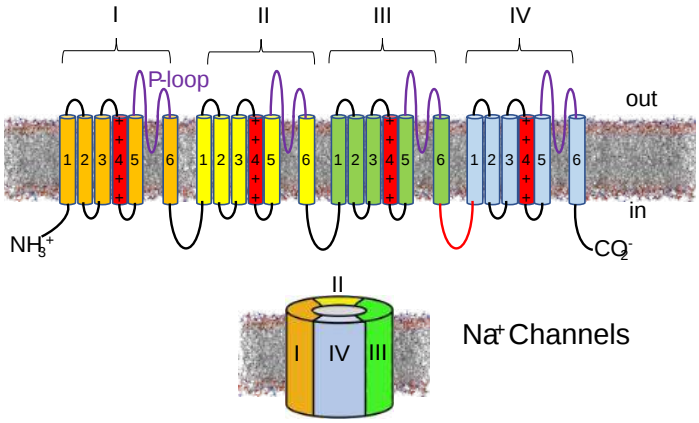

Figure 11.3.9: Cartoon structure of a typical voltage-gated Na^+ channel adapted from https://www.anaesthesiajournal.co.uk...264-4/fulltext

The Na^+ channel has a molecular weight of around 229K and about 2000 amino acids (each 4x that of the K^+ channel α subunit). It is glycosylated and subjected to multiple post-translational modifications. Usually, the protein in the central nervous system is a complex of the α subunit, and small additional regulatory β subunits, which modify the kinetics and voltage-dependency of the α subunit channel.

Segment (helix) 4 of each of the four repeat units illustrated above is the conserved "voltage" sensor. It contains multiple, charged amino acids whose disposition changes with changes in the transmembrane potential, allowing conformational changes in the protein and gating of ion flow. Each of the 4 repeating units above also contains an extracellular P-loop (colored purple in segment I in purple) connecting helix 5 and helix 6.

We will focus on K^+ channels with some additional information on the Na^+ channel below.

K^+ Permeation through Kv1.2 Channel

Voltage-dependent potassium channels (Kv) have 4 subunits and can be homo- or heterotetramers. They allow the voltage-gated flow of potassium ions through the membrane. Several obvious questions should arise. How can they be selective for K^+ ions? That is, how can they allow the larger K^+ ion to passively flow through and not the smaller Na^+ ions? Secondly, how can a change in the transmembrane potential cause the channel to open or close? That question boils down to how a change in transmembrane potential can change the conformation of proteins. We'll show several iCn3D models of this protein.

Figure 11.3.10 shows a simplified view of the rat Kv1.2 channel (3lut) from top and side views (without parts of the cytoplasmic domain), showing each of the 4 identical monomeric subunits in a different color. Each monomer has S1-S6 transmembrane segments.

Shaker Potassium Channel Kv1.2

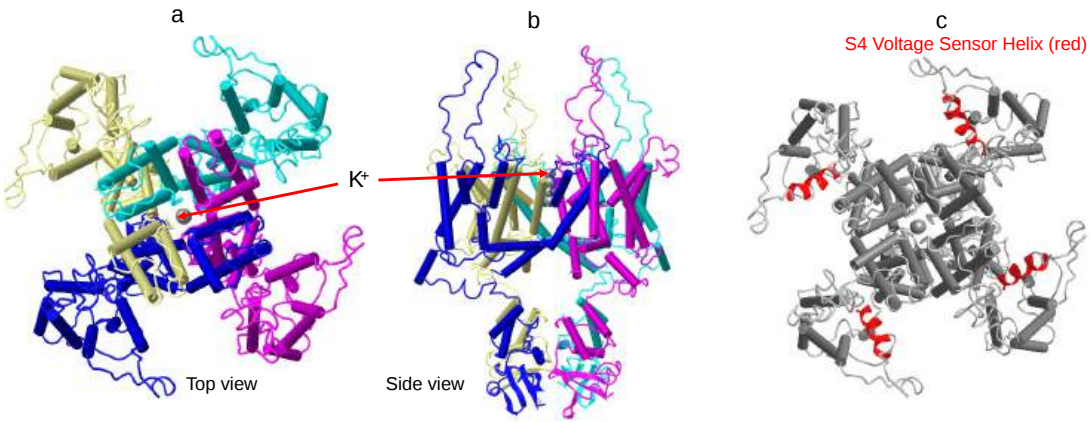

Figure 11.3.10: Rat Kv1.2 channel (3lut) from top and side views (without parts of the cytoplasmic domain), showing each of the 4 identical monomeric subunits in a different color.

The protein is found in the brain and central neuron plasma membranes and also in the cardiovascular system. K^+ ions diffuse through the center from the extracellular to intracellular side down a concentration gradient but potentially against the transmembrane potential. The four monomers in the homotetramer form one central pore.

Figure 11.3.11shows an interactive iCn3D model showing the rat Kv1.2 channel (3lut) described in Figure 11.3.10

K^+ selectivity - All potassium ion channels, even if not voltage-gated, solve the selectivity dilemma in a similar way. All have in the narrowest part of the pore in the center of the channel this consensus sequence - Thr-Thr-Val-Gly-Try-Gly (TTVGYG) - which is found in the P-loop. These are shown in gold and brown colors in the figure above. The -OHs in the selectivity filter can interact with a dehydrated K ion but not with a dehydrated Na ion, which can not approach close enough to form significant interactions. Surrounding the filter are twelve aromatic amino acids which constrain the size of the pore opening. The interactions of the filter O's with the K ion make up for the energetically disfavored dehydration of the ion. The filter contains K^+ ions which repel each other, assisting in the vectorial discharge of the ions through the membrane. These ions must form weak interactions with the selectivity filter. The actual pore is mostly hydrophobic, which facilitates ion flow through the membrane.

Figure 11.3.15 below shows a closeup of the selectivity filter. Four Thr 374s (second Thr in the selectivity filter sequence of TTVGYG) from the four different monomers in the channel are clearly shown interacting with the top K^+ ion (gray sphere).

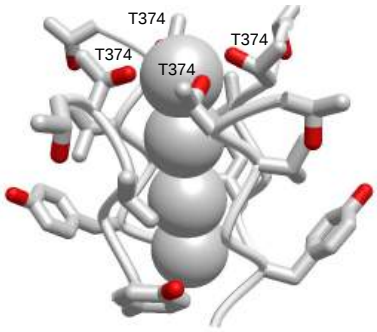

Figure 11.3.15: K^+ Selectivity filter of the Kv1.2 potassium channel (3lut)

Figure 11.3.16shows an interactive iCn3D model detailing key residues in the K^+ selectivity filter of the Kv1.2 potassium channel (3lut). Hover over the residues to identify them.

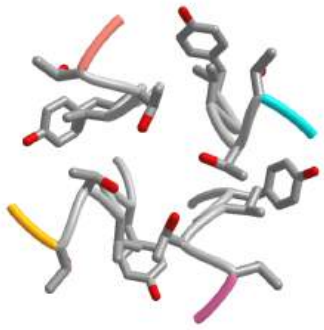

Figure 11.3.16: Key residues in residues in the K^+ selectivity filter of the Kv1.2 potassium channel (3lut) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...FFKJVVHtbpuYj6

Different voltage-gated ion channels alter ion selectivity through changes in these amino acids in the P-loop, as illustrated in Table 11.3.2below. As channels lose specificity of K^+, they gain specificity for Na^+ and Ca^{2+}. Red highlights denote conserved residues and yellow residues that are chemically similar.

sequence	specificity
TVGYG	strong K^+ channels
CIGYG	weak K^+, HCN channels
TVGDG	TRP channels
STFEG	ionotropic glutamate receptors
LCGEW	strong Ca^{2+} voltage-gated channels

Table 11.3.2 P-loop specificity side chains in voltage-gated ion channels

Voltage gating -

Helix S4 in each monomer in the transmembrane domain of the complex is the voltage sensor. The sequence of this helix is LAILRVIRLVRVFRIFKLSRH. Note the arginines and lysine highlighted in blue. They repeat every 3 amino acids. The voltage-sensor domain must be shielded from the nonpolar acyl of the bilayer. Four conserved Arg residues on S4, part of the voltage-

sensor domains, are shielded from the lipids and coupled to an amphiphilic helix running parallel to the plane of the membrane. The arginines move under the influences of forces arising from changes in the membrane's electric field initiated by ion movement through other ion channels in the membrane. Mechanical work is done by the electric field on the voltage sensor as the charged Arg residues are moved through the electric field. The movement is coupled through the amphiphilic helix to the pore which changes conformation. In turn, the S4 and coupled S5 helices of the voltage sensor do mechanical work on the pore by altering its conformation to open/close the pore, specifically at the activation gate of the pore. This seems quite similar to how iron movement into the heme plane in hemoglobin on oxygenation pulls the proximal His on the F8 helix which then transmits a conformation change to other helices in the subunit, leading to cooperative conformational changes in the tightly packed protein. About 12 charges move across the transmembrane potential field.

Channels, once open, must be inactivated. In the case of the voltage-gated potassium channel, inactivation occurs when the amino-terminal cytoplasmic domain binds to the potassium pore on the cytoplasmic side, in interaction likened to the binding of a "ball on a chain" (the cytoplasmic domain) to the pore opening. The chain acts to tether the ball domain so it may swing to bind to the pore opening. The ball domain contains both positively charged and hydrophobic regions. Where is the ball domain in the absence of inhibition? Recent studies (Oliver et al.) have shown that a positive domain can bind to proximal phosphatidyinositol 4,5-bisphosphate (PIP2) lipids on the inner leaflet of the membrane bilayer. When so bound, inactivation of the channel is prevented. As you will see in the next section, PIP2 can also be cleaved to form diacylglycerol and inositol 1,4,5-trisphosphate when cells are activated by external factors (hormones, growth factors, etc) in the process of signal transduction.

Figure 11.3.17 shows a molecular dynamics simulation showing K^+ interaction with the channel lining and the "knock-on" mechanism showing how an incoming K^+ ion can repel a K^+ ion in the pore through the channel.

Figure 11.3.17: Molecular dynamics simulation of K^+ movement through a channel

---

Recent Updates: June 2023 - Sodium Channels

Voltage-gated sodium channels (Na_V)

The eukaryotic voltage-gated sodium channels (NaV) allow inward movement of Na^+ ions which depolarizes a neuron and sets off an action potential in nerve and muscle cells. (For more information on neuron signaling, see Chapter 28.9). The NaV has an alpha subunit that forms the pore plus beta subunits that associate with it and modulate its activity. Nine eukaryotic isoforms exist. NaV has 4 domains, I-IV, each containing segments 1-6. Each of the S1-S4 segments forms a voltage-sensitive domain and each of the S5 and S6s form the pore. In contrast to eukaryotic NaVs which have a single chain, bacterial NaVs contain 4 identical subunits. Post-translation modification of the alpha subunit can regulate its activity.

As important as it is to initiate Na^+ influx to trigger neuron firing, it is equally important to turn it off to control neural signaling. The inward Na^+ current is stopped by a fast inactivation that occurs within a few milliseconds.

Many neurotoxins bind to the NaV and regulate its activity. Key examples are the α-scorpion and sea anemone toxins which both inhibit the fast inactivation of the NaV leading to prolonged or sequential action potentials. These toxins binds to the voltage sensor in domain IV which is key for the fast inactivation in the absence of the toxin.

The S4 helical segments in each domain are the key voltage sensors. Each of the S4 segments has 4-6 positively charged Arg and Lys side chains. On depolarization of the cell (when the inside becomes less negative and more positive), this helix move "up" from the cytoplasmic side (which is increasingly more positive) which opens voltage-gated channel. Specificity for the small Na^+ ion (over the K^+ and Ca^{2+} ions) is determined mainly by 4 amino acids, DEKA (Asp-400, Glu-755, Lys-1237, and Ala-1529) found in P loops of domain I-IV, respectively. This selectivity filter is conserved.

Figure 11.3.18below shows a cartoon of the NaV with two associated, regulatory beta chains.

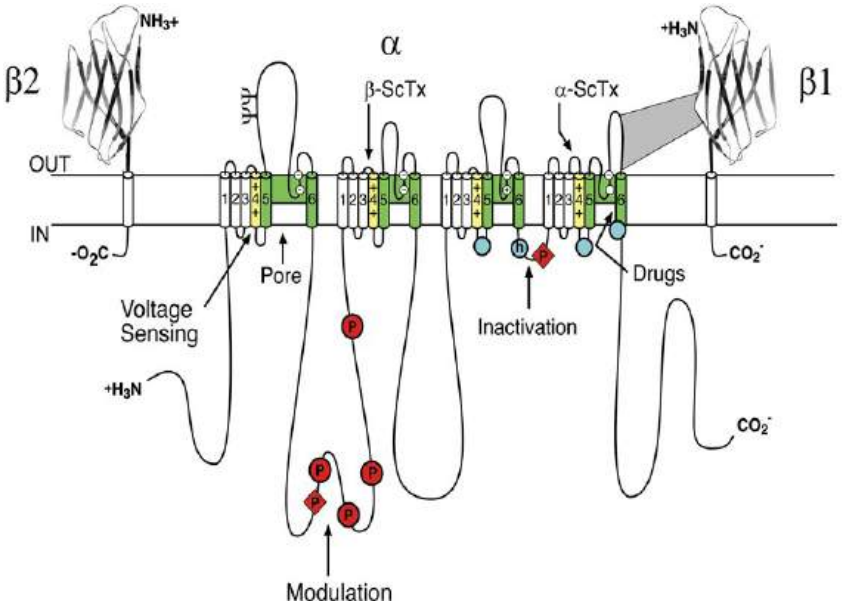

Figure 11.3.18 Cartoon of eukaryotic voltage-gated sodium channel (Nav) with two associated, regulatory beta chains. https://www.guidetopharmacology.org/...rd?familyId=82. **CC BY-SA 4.0**

Note the sites for posttranslational modification by phosphorylation and drug interactions. Cylinders represent probable α-helical segments S1-S6. Bold lines represent the polypeptide chains of the selectivity filter and tetrodotoxin binding site; The yellow S4 segments are the voltage sensors. The "h" in the blue circle is in the inactivation gate loop. Blue circles are sites implicated in forming the inactivation gate receptor. Sites of binding of α- and β-scorpion toxins (ScTX) and a site of interaction between α and β1 subunits are also shown. Tetrodotoxin is a specific blocker of the pore of sodium channels, whereas the α- and β-scorpion toxins block fast inactivation and enhance activation, respectively, and thereby generate persistent sodium current that causes depolarization block of nerve conduction.

Table 11.3.3shows the different types of neurotoxin receptors sites found in NaVs

Neurotoxin Receptor Site #	Toxin or Drug	Domains
1	Tetrodotoxin	IS2–S6, IIS2–S6
	Saxitoxin	IIIS2–S6, IVS2–S6
	μ-Conotoxin	
2	Veratridine	IS6, IVS6
	Batrachotoxin	
	Grayanotoxin	
3	α-Scorpion toxins	IS5–IS6, IVS3–S4
	Sea anemone toxins	IVS5–S6

4	β-Scorpion toxins	IIS1–S2, IIS3–S4
5	Brevetoxins	IS6, IVS5
	Ciguatoxins	
6	δ-Conotoxins	IVS3–S4
local anesthetic drug sites	Local anesthetic drugs	IS6, IIIS6, IVS6
	Antiarrhythmic drugs	
	Antiepileptic drugs	

Table 11.3.3 Neurotoxin receptor sites in NaVs. https://www.guidetopharmacology.org/...rd?familyId=82. **CC BY-SA 4.0**

A view of the effective pore in the bacterial Nav is shown below in Figure 11.3.19

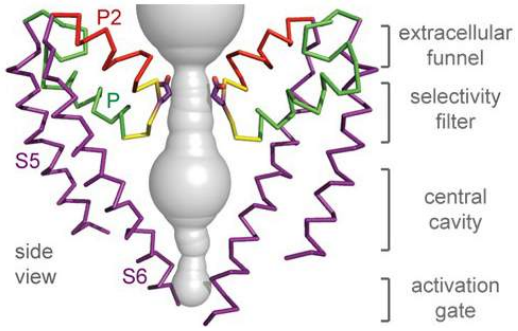

Figure 11.3.19 **Structure of the bacterial sodium channel NavAb pore B.** Architecture of the NavAb pore. Glu177 side-chains in the P loop are shown in purple. The pore volume is shown in grey. The P and P2 alpha helices that form the scaffold for the selectivity filter and outer vestibule are shown in green and red, respectively. https://www.guidetopharmacology.org/...rd?familyId=82. **CC BY-SA 4.0**

As mentioned above, the bacteria NaVs have 4 monomeric subunits. In contrast to the K^+ channel, which requires the K^+ ions to be dehydrated to make sufficient interactions with the pore and to pass through, the Na^+ ions need to be hydrated. Figure 11.3.20 shows an interactive iCn3D model of the A and B chains of the bacterial NaV voltage-gated sodium channel pore and C-terminal domain (5BZB)

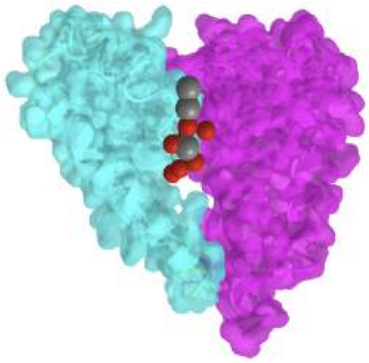

Figure 11.3.20 A and B chains of bacterial NavMs voltage-gated sodium channel pore and C-terminal domain (5BZB) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...vRmDqmDHGsYLh8

One subunit is shown in a transparent cyan surface and the second one is shown in magenta. Three Na^+ ions are shown (gray spheres). Eight water molecules are shown interacting with them in the pore. The other two subunits are not shown for clarity.

The voltage-gated sodium channel has three major conformational states:

- a basal **closed** state found at resting cell potentials in which the pore of Na^+ is occluded by an activation gate
- an **open** state found when a depolarizing potential is reached in the cell

- an **inactivated** state formed within 10 ms of opening of the channel when the inactivation gate with a a Ile-Phe-Met (IFM) sequence motif, found in the intracellular linker between domain III and IV (near the cytoplasmic face of the receptor) closes off the pore to further Na^+ entry.

The protein converts back to the closed state when the transmembrane potential is restored to its initial value (around -70 mV) and the positively charged S4 segments move back towards the cytoplasmic face.

A cartoon of the three-state model for the Na^+ channels (as other voltgage-gates ion channels in general) is shown in Figure 11.3.21below.

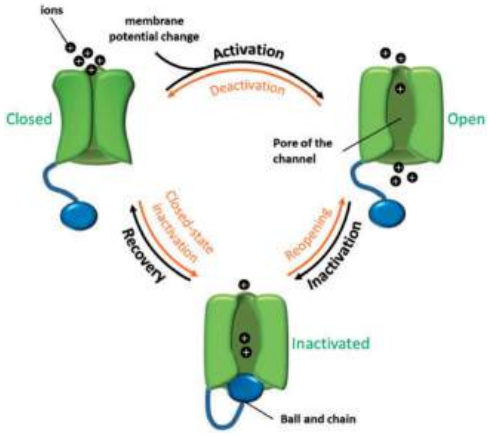

Figure 11.3.21: Three-state model for the voltage-gated ion channels. Hinard, Valerie & Britan, A & Rougier, Jean-Sébastien & Bairoch, Amos & Abriel, Hugues & Gaudet, Pascale. (2016). ICEPO: The ion channel electrophysiology ontology. Database : the journal of biological databases and curation. 2016. 10.1093/database/baw017. Creative Commons Attribution License (http://creativecommons.org/licenses/by/4.0/)

The YouTube video by Pete Meighan below shows an incredibly clear description of the three conformational states of the channel and the conversion from closed to open to inactivated states.

To understand these conformations states, we need to look a the structure of the protein in greater detail. Figure 11.3.22below shows multiple representations of the voltage-gated sodium channel. The pore domain PD is formed from helix segments 4 and 5 on each of the IV domains of the protein. The voltage sensor domain is formed from the S1-S4 segments, of which segment S4, containing multiple positively-charged Arg and Lys, is key.

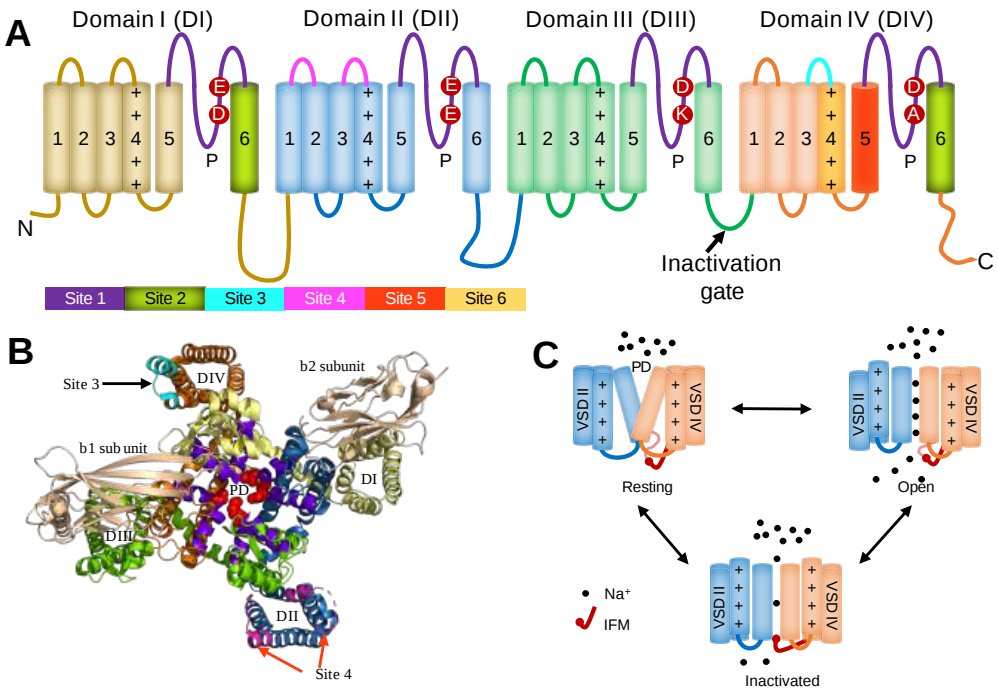

Figure 11.3.22 Structure features of the voltage-gated sodium channel. Dongol, Y.; C. Cardoso, F.; Lewis, R.J. Spider Knottin Pharmacology at Voltage-Gated Sodium Channels and Their Potential to Modulate Pain Pathways. *Toxins* **2019**, *11*, 626. https://doi.org/10.3390/toxins11110626. Creative Commons Attribution (CC BY) license (**http://creativecommons.org/licenses/by/4.0/**)

Panel (**A**) shows a schematic representation of the α-subunit of voltage-gated sodium (Na_V) channel. Four non-identical domains (DI–DIV) feature six neurotoxin receptor sites (Sites 1–6) and key residues contributing to the outer Na^+ ion selectivity filter (EEDD) and inner selectivity filter (DEKA). The connecting S5–S6 linker is called P-loop (P) which together with S5 and S6 segments from each domain contributes to the formation of the Na^+ ion selective channel pore. Sites 1-6 (colored purple, green, cyan, magenta, etc) are sites where inhibitors such as toxins bind.

Panel (**B**) shows the structure of the $Na_V1.7$ channel (PDB 6J8G). Four voltage sensing domains (VSDs), DI (yellow), DII (blue), DIII (green), and DIV (orange), are shown with their corresponding pore-forming segments (S5 and S6) arranged to form the pore domain (PD) selective to Na^+ ions. The P-loop that contributes to forming the inner selectivity filter is colored in red spheres (DEKA) and outer selectivity filter (EEDD) is colored in purple. The S6 segments of all the four domains contribute to form the intracellular region of the pore. Site 3 (cyan) and Site 4 (pink) are the major binding sites for spider knottins (neurotoxins). The β1 and β2 subunits which interact with DIII and DI, respectively, are highlighted in beige color.

Panel (**C**) shows a schematic of the three main conformational states of the protein which control gating of Na_V channels. At polarized potentials, the DI–DIV S4 segments are drawn towards the intracellular side due to the positive gating charges to render the closed conformation (down state). Upon depolarization, the forces holding the down state are relieved and DI–DIII S4 segments are rapidly released extracellularly to open the S6 channel gate in the open conformation (up state). Note the movement of the S4 helix with its positive charged toward the extracellular side of the membrane. The DIV S4 moves up slowly compared to DI–DIII S4 and drives the fast inactivation, where the channel is occluded intracellularly by the Ile, Phe, and Met (IFM) motif. After cell repolarization, the channel returns to a closed (resting) state.

Figure 11.3.23 shows an interactive iCn3D model of a ternary complex of human Nav1.2 with the beta2 regulatory subunit and conotoxin IIIA (6J8E)

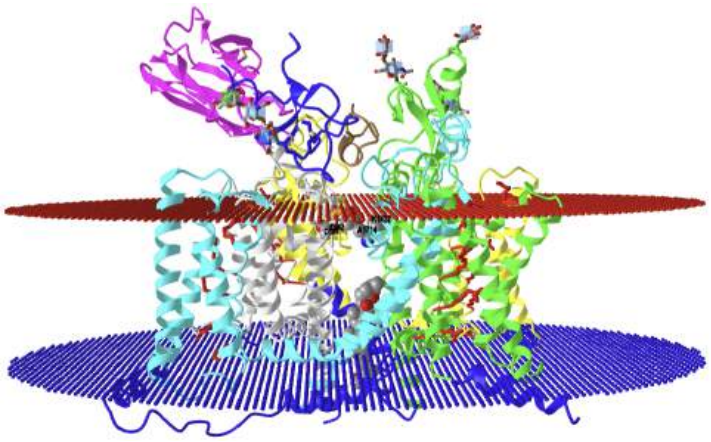

Figure 11.3.23 Human sodium channel Nav1.2-beta2-KIIIA ternary complex (6J8E) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?aYxomdUqZHqbMmE5A

Domains I-IV are shown in gray, yellow, green and cyan, respectively. The separate beta-2 regulatory subunit is shown in magenta. The positive side chains in each of the S4 segments of the four domains are shown as red sticks. The side chains of the inner 4 amino acids (DEKA) comprising the selectivity filter are shown in spacefill, CPK colors, and labeled. The brown peptide cartoon on the extracellular side (red sphere layer for outer leaflet) is the μ-conotoxin KIIIA. The spacefill molecule in the pore near the blue sphere layer representing the inner leaflet is the neurotoxin **veratridine** (VTD), which inhibits channel inactivation and lengthens the action potential with possibly fatal consequences. A single Na^+ ion is shown at the top of the pore as an orange sphere labeled Na. The μ-conotoxin blocks the pore. The Ile1488-Phe1489-Met1490 (IFM) motif, found in the intracellular linker between domain III and IV (near the cytoplasmic face of the receptor, responsible for the fast inactivation, are shown in gray spheres and labeled with single-letter codes.

The selectivity filter DEKA is different from the selectivity filter in another sodium channel (NavAb) which has 4 glutamate. Asp and Ala line the wall of the filter region and Glu and Lys can attract and release, respectively, the Na^+ ion. For fast inactivation, the IFM motif must interact with an"inactivation gate receptor" within the protein itself. Likely candidates for this are short intracelllar loops connecting all the S4 and S5 segments. This receptor appears to contain 3 amino acids, F1651, L1660 and N1662.

Figure 11.3.24 shows another interactive iCn3D model of a ternary complex of human Nav1.2 with the beta2 regulatory subunit and conotoxin IIIA (6J8E) highlighting just the DEKA selectivity filter, the IFM motif, and its receptor inactivation gate F1651, L1660 and N1662.

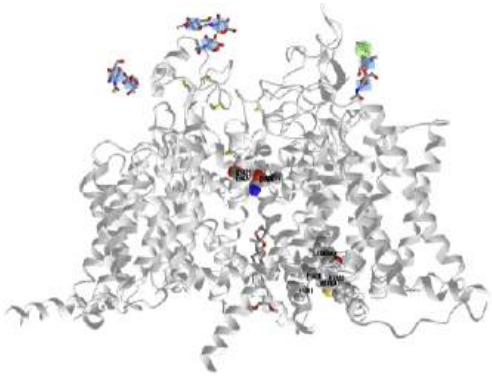

Figure 11.3.24 Human sodium channel Nav1.2-beta2-KIIIA ternary complex highlighting just the DEKA selectivity filter and the IFM and its receptor inactivation gate F1651, L1660 and N1662 (6J8E). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?tq3kXbT44GeCCUcY7

They are all shown in spacefill and labeled. Orient the molecule with the cytoplasmic domain at the top. The leaflets of the bilayer are omitted for clarity but the cytoplasmic pore inhibitor is still shown in sticks.

Figure 11.3.25below shows a closeup of the bound Na^+ ion.

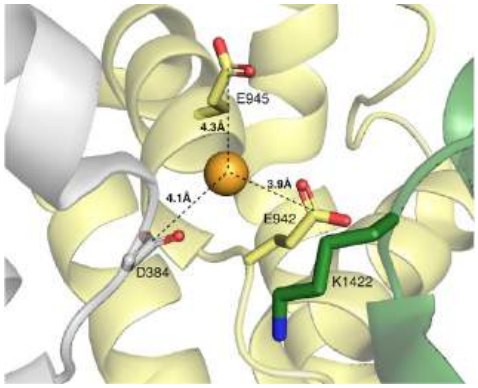

Figure 11.3.25 Sodium ion in the SF of the PDB ID 6J8E $Na_v1.2$ cryo-EM structure. The pore blocker μ-conotoxin KIIIA is not shown. Alberini et al. *J. Chem. Theory Comput.* 2023, 19, 10, 2953–2972. April 28, 2023. https://doi.org/10.1021/acs.jctc.2c00990. Creative Commons.

Structures of the closed state, the open state, and the inactivated state of NaV1.5 are now known. Key regions are shown in Figure 11.3.26below. The open state was the hardest to solve since it closes in milliseconds to form the inactive state as described above. Mutations in the Ile-Phe-Met (IFM) motif to QQQ prevented inactivation. This would ordinarily be deleterious to an organism but in the presence of a small molecule inhibitor, propafenone, it was possible to isolate this state.

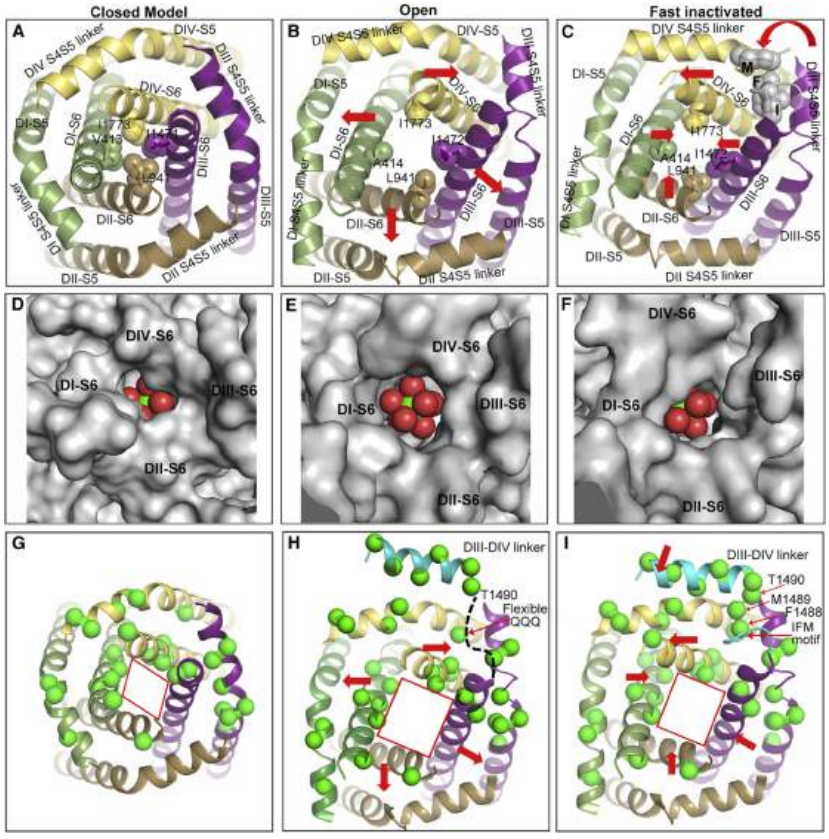

Figure 11.3.26 Closed, open, and inactivated conformations of the activation gate and the locations of arrhythmia mutations. Daohua Jiang, Richard Banh, Tamer M. Gamal El-Din, Lige Tonggu, Michael J. Lenaeus, Régis Pomès, Ning Zheng, William A. Catterall. Open-state structure and pore gating mechanism of the cardiac sodium channel. Cell, Volume 184, Issue 20, 2021, 5151-5162.e11, ISSN 0092-8674,. https://doi.org/10.1016/j.cell.2021.08.021. Reprinted with permission from Elsevier. May not be sublicensed, assigned, or transferred to any other person without publisher's written permission.

Panel (A) shows the closed activation gate of $Na_V1.5$ generated by MODELER based on the resting-state structure of Na_VAb (PDB: 6P6W), sealed by a square of hydrophobic side chains of hydrophobic residues V413, L941, I1471, and I1773 (spacefill, black) that in the closed state completely seal off the cytoplasmic opening in the pore. These ring of amino acid side chains come together on conformational changes resulting from the engagement of the IFM motif with its internal receptor.

Panel (B) shows the open activation gate of $Na_V1.5$/QQQ triple mutation. Red arrows indicate the directions of movement of S6 segments compared to the resting state.

Panel (C) shows the partially open but nonconductive activation gate of $rNa_V1.5_C$ in the inactivated state. Red arrows indicate the directions of movement of the S6 segments compared to the open state.

Panels (D–F) show structures from (A) to (C) are shown in space-filling surface representation with hydrated Na^+ placed in the central cavity behind the activation gate. Red and green spheres represent water and Na^+, respectively. van der Waals distances measured across the orifice of the activation gate are 4.3 Å (*D*I-*D*III) × 2.8 Å (*D*II-*D*IV) for the resting/closed state, 6.9 Å (*D*I-*D*III) × 5.0 Å (*D*II-*D*IV) for the inactivated state, and 7.3 Å (*D*I-*D*III) × 8.2 Å (*D*II-*D*IV) for the $Na_V1.5$/QQQ open-state structure.

Panels (G–I) show structures from (A) to (C) with the locations of arrhythmia mutations causing LQT-3 overlaid as green spheres

The spacefill models in D-E clearly show that the cytoplasmic opening is "open" in the open state E (obviously), and occluded to increasing degrees in the inactive state (F) and closed state D.

Finally, figure 11.3.27shows an interactive iCn3D model of the electrostatic surface potential of the rat $Na_v1.5$ channel (6UZ3)

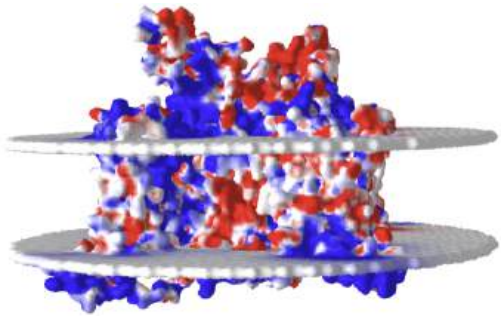

Figure 11.3.27: Electrostatic surface potential of the rat $Na_v1.5$ channel (6UZ3) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...UZdQeUUPtYGgR6

The red indicates negative potential and the blue positive potential. The white is neutral. Note that the bilayer representations are essentially neutral with respect to their effect on the overall surface potential. Tilt the model to view the top and bottom entrance to the pore and the overall negative charge density expected in the net attraction of the positive Na^+ ions.

11.3.4: Lipid-Gated Ion Channels

Membrane receptors are in the lipid bilayer, so it should not be too surprising that specific lipids might bind and trigger conformational changes in the receptor, mediating a specific biological activity. The specific lipid might form during an upstream event, then bind to the receptor, triggering function in a process of signal transduction, which we will explore in the next chapter. Let's look at receptors gated by binding of the lipid phosphatidylinositol bisphosphate (PIP_2). It is found in small concentrations in membranes and can be cleaved in by phospholipase C to form a small polar intracellular signaling molecule, IP_3 (discussed in Chapter 12). PIP_2 can also recruit proteins to the membrane and participate in signaling events that way. For this section, we will discuss how it binds to a K^+ ion channel protein and open so K^+ can flow into cells (the opposite direction of the normal efflux), which helps control transmembrane potential.

Kir2.2 -Inward rectifier potassium channel Kir2.2

The names of this channel can best be understood if you understand the meaning of the word rectify. The verb has several meanings but for us, the best definition is to **correct**. What does this channel correct? When is it functional? We'll explore the details more in the next chapter we first a better understanding of what happens to the actual Na^+ and K^+ ion concentrations outside and inside the cell during neural activation. How much do they change? We need this to understand the driving force for the Kir2.2 channels that move K^+ into the cell, which is opposite the usual direction. From that sense, it is "rectifying" the K^+ concentrations.

How much do the actual concentrations of Na^+ and K^+ ions change when a neuron is excited?

When a neural cell is activated or fires, the cell membrane potential goes from a resting potential of around -60 to -70 mV (inside negative) to a more positive potential as Na^+ ions enter the cell through voltage-gated Na^+ channels (after an early neurotransmitter-gated ion channel is open after ligand binding) with the ions flowing down a **chemical and electric potential** gradient. At a certain membrane potential (about +30 mV), K^+ channels open allowing an efflux of K^+, also down both a **chemical and electric potential** gradient, returning the cell potential close to its equilibrium value potential of around -60 to -70 mV (inside negative). But how much do the actual K^+ and Na^+ ion concentrations change in this process? The somewhat counterintuitive answer is hardly any at all!

We need to understand how the membrane acts as a capacitor first. The charge Q on a surface of a plate or side of a membrane is proportional to the voltage across the plate or membrane. Figure 11.3.28 shows how a membrane with a transmembrane potential acts as a capacitor. The dielectric medium in the capacitor will determine how quickly the charges on the plate will dissipate. When the medium is an insulator, resistant to charge flow, the plates remained charged longer. The same is true for the membrane. The hydrophobic bilayers act as an insulator and resist the discharge of the membrane potential. The bilayer offers high resistance (low conductance) to charge flow. Only when channels are open and the ions become reasonably permeable to flow does the membrane potential change over short periods. The following derivation is adapted.

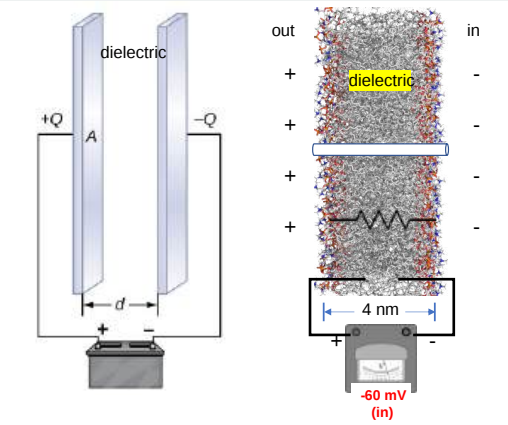

Figure 11.3.28: A membrane as a capacitor. After https://openpress.usask.ca/physics15...d-capacitance/. **License**: CC BY: Attribution

It makes sense that the stored charge (Q) on either side of the membrane is proportional to the membrane voltage. We can write the following simple equations:

$$\begin{aligned} Q &\propto V \\ Q &= \mathrm{C}V \end{aligned} \tag{11.3.1}$$

where C, the proportionality constant, is the capacitance with units of the Faraday (which you remember from introductory chemistry). Let's normalize this equation for an area of 1 cm^2. The measured capacitance of lipid bilayers is about 10^{-6}F/cm^2. Let's assume a voltage change from -70 mV to + 30 mV for a total of 0.1 V. Hence

$$Q = \frac{10^{-6}\ \mathrm{F}}{\mathrm{cm}^2}(0.1\ \mathrm{V}) = \frac{10^{-7}\mathrm{Coul}}{\mathrm{cm}^2} \tag{11.3.2}$$

Let's change that into the number of elementary charges on the surface of the membrane per μm^2 surface area.

$$\left(\frac{10^{-7}\mathrm{Coul}}{1\ \mathrm{cm}^2}\right) x \left(\frac{1\ \mathrm{ion}}{1.6\times10^{-19}\mathrm{Coul}}\right) = \frac{6.25\times10^{11}\ \mathrm{ions}}{\mathrm{cm}^2} \times \frac{1\ \mathrm{cm}^2}{10^8\,\mu\mathrm{m}^2} = \frac{6,250\ \mathrm{ions}}{\mu\mathrm{m}^2} \tag{11.3.3}$$

What does this mean for an ordinary eukaryotic cell? Let's model the cell as a sphere with a diameter of 10 µm.

Knowing the equations for the volume (V = (4/3)πr^3) and surface area ($4\pi r^2$), the volume of 10 µm cell is about 524 μm^3 and the surface area is 314 μm^2. The table below shows the resting ion concentrations in a cell and the actual number of ions in the 524 μm^3 volume of the cell (column 3).

Using the calculated value of 6250 ions moved/μm^2, the total number of K^+ and accordingly Na^+ ions that move across 314 μm^2 of total cell membrane surface area is about 2 million. The results are shown in Table 11.3.3 below.

1. ion	2. $[ion]_{intracellular}$ (mM)	3. # $ions_{intracellular}$	4. total ions moved during neuron response	5. change in $[ion]_{intracellular}$
sodium	10 mM	3.2×10^9 Na^+	~ 2,000,000 in on depolarization	~6.3 x 10^{-2} mM (~0.6% change)
potassium	150 mM	4.7×10^{10} K^+	~ 2,000,000 out on repolarization	~6.3 x 10^{-2} mM (~0.6% change)

Table 11.3.3 How many ions move across a membrane

$$\frac{2 \times 10^6 \mathrm{Na}^+ x \left(\frac{1\ \mathrm{mol Na}^+}{6.022 \times 10^{23} \mathrm{Na}^+}\right)}{524 \mu M^3 \times \left(\frac{1\ \mathrm{L}}{10^{15} \mu M^3}\right)} = 6.3 \times 10^{-6} \mathrm{M} = 6.3 \times 10^{-3} \mathrm{mM} \tag{11.3.4}$$

The actual change in intracellular Na^+ ion concentration on excitation is only about 0.6% of the initial $[Na^+]_{intracellular}$ on excitation and depolarization of the cell. We can also assume that the K^+ ion changes to the same degree in repolarization. So when the Na^+ and K^+ channels open, the "flood gates" are **not** opened. Permeability does increases, but this leads to a tiny influx of Na^+ ions, which is **not** sufficient to change the intracellular Na^+ concentration. It is, however, enough to change the transmembrane potential! It's a misconception that there are significant changes in ion concentration across the membrane on depolarization and repolarization of the cell. The Goldman-Hodgkins-Katz equation (previous section), shows that the membrane potential is a function of both concentrations and permeability coefficients.

Now we can present the inward rectifying potassium channels, which facilitate the movement of K^+ **into** the cell from the outside. This is in the opposite direction of the usual flow of the ions. Since the ions are moving towards higher levels of K^+ inside the cell, it would appear this would be an example of either passive diffusion favored only by the electrical potential or a case of active transport. None of these is true. K^+ ions diffuse from outside to inside the cell since outward diffusion is substantially blocked by molecules such as polyamines and Mg^{2+}! We don't have to invoke active transport or a violation of the basic rules of thermodynamics. The channels thus display strong inward currents and weak outwards ones.

The channels allow large conduction of K^+ ions if the membrane potential is more negative compared to the resting K^+ ion equilibrium potential but less if more positive, so the net effect is to maintain the resting K^+ potential.

There are several subfamilies of Kir channel. They are always potentially active (open) except those gated by G-proteins (see next chapter) or by ATP binding. (these are involved in metabolism). Kir activity is regulated by phospholipids and proteins. Now we will explore the Kir 2.2 channel, which is gated-open by PIP_2, a membrane lipid, not by changes in the transmembrane potential. Yet by opening this channel and allowing the inward flow of K^+ ions, PIP_2 is regulating the transmembrane potential. It is the agonist for the Kir 2.2 channel.

Instead of having monomeric units with S1-S6 transmembrane helical segments with a voltage sensor (S4) and P loop and S5-S6 selectivity filter, it has just 2 transmembrane helices. Both the N- and C-termini are in the cytoplasm, connected by an extracellular loop (H5) which helps form the prototypical K^+ selectivity filter with the consensus sequence T-X-G-Y(F)-G. Similar to the voltage-gated K^+ channel, four of these aggregate to form homo- or heterotetramers in the membrane. Figure 11.3.29 illustrates these points.

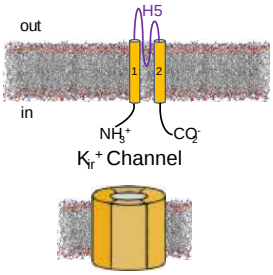

Figure 11.3.29: The Kir potassium channel

The proteins have large intracellular domains (ICD). On binding of PIP_2 to the region between the transmembrane and ICD, which produces a large conformational change, allowing K^+influx. The model below shows the R186A mutant tetrameric Kir 2.2 channel (3SPG) with four bound PIP_2 analogs containing two short fatty acids (octanol) esterified to the glycerol backbone. There appear to be two binding sites for lipids, a nonspecific site in the TMD and a specific one for PIP_2 in the ICD.

Figure 11.3.30shows an interactive iCn3D model of the inward rectifying R186A mutant tetrameric Kir 2.2 channel (3SPG) with four bound PIP_2 analogs containing two short fatty acids (octanol) esterified to the glycerol backbone. Hover over the residues to identify them.

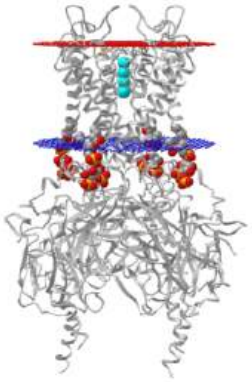

Figure 11.3.30: Inward rectifying R186A mutant tetrameric Kir 2.2 channel (3SPG). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3...S5vuBsdbSSqwV8 (long load time)

Figure 11.3.31shows an animation that shows the monomeric Kir protein morphing from the apo state (without PIP_2, 3JYC) to the PIP_2 bound state (3SPI).

Figure 11.3.31: Monomeric Kir protein morphing from the apo state (without PIP_2, 3JYC) to the PIP_2 bound state (3SPI)

Another PIP_2-gated ion channel is the transient receptor protein (TRP) channel. These channels play a role in vascular tone. Smooth muscle cells have TRPC3 and TRPC6 channels, Na^+ or Ca^{2+} channels that cause depolarization, leading to smooth muscle contraction and vasoconstriction.

11.3.5: Mechanosensitive channels

We saw in the previous chapter that some pores (not channels) are gated open not by voltage, or specific agonists such as neurotransmitters or even specific lipids like PIP_2 but by more general changes in membrane bilayers properties (membrane tension, curvature, pressure). Likewise, specific channel proteins can be gated by changes in the physical properties of the bilayer. We will consider one mechanically-active channel, TRAAK.

TRAAK - Potassium channel subfamily K member 4

The protein is a K^+ ion channel that is not sensitive to voltage changes but is open on the mechanical deformation of the bilayer. The channel can be opened by making the cytoplasm basic, raising the temperature. It is involved in pain sensation and pressure transduction. The TRAAK 4 opening is blocked by the presence of lipid from the inner leaflet which occludes the pore. If the lipid is removed by physical changes, transmembrane helix 4 rotates, which prevents the lipid from blocking the channel, which opens. Further changes in the coupled transmembrane helices 2 and 3 stabilize the opening.

Figure 11.3.32 shows an interactive iCn3D model of the TRAAK channel protein (4wff) in the **closed** state. Hover over the residues to identify them.

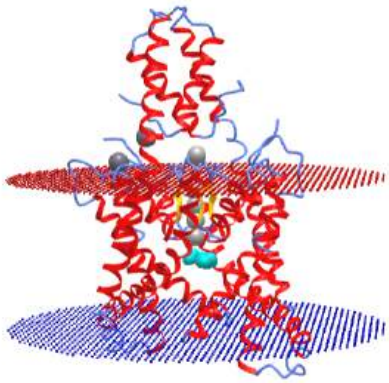

Figure 11.3.32: **Potassium channel subfamily K member 4** TRAAK channel protein in the **closed** (4wff) state. Hover over the residues to identify them. (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...UzX6p5d36VicdA

The K^+ ions are aligned in the channel. Decane, a nonpolar molecule, is shown in spacefill and colored cyan. The decane is probably decanoic acid in which the carboxyl group was not defined in the structure due to high flexibility. This suggests that the "decanoic acid" is not tightly bound. It binds through the cytoplasmic side through an opening in the membrane protein. In the open state, transmembrane helix 4 rotates, blocking access to the cavity. Hence lipid binding gates the channel closed.

11.4: Diffusion Across a Membrane - Pores

11.4.1: Pores and Pore-Forming Proteins (PFPs)

If you form a pore in a cell bilayer, molecules of all sizes could move either way based on their electrochemical potential. They will move from regions of a higher to lower electrochemical potential in a thermodynamically favorable process. Hence movement through pores represents a special case of facilitated diffusion when part of the driving force is not just a concentration gradient but also an electrical potential. Several questions might come to mind.

- What proteins are involved in pore formation?
- How is the specificity of solute movement through the pore regulated?
- What is the mechanism of pore formation?

Pore formation can lead to cell death, which is the function of some pore-forming proteins (PFPs) including the toxin Hemolysin E (also known as HlyE, ClyA, SheA) secreted from E. Coli and S. Aureus. Human proteins also form a membrane attack complex (examples include the membrane attack complex-perforin/cholesterol-dependent cytolysin (MACPF/CDC) superfamily and the membrane attack complex (MAC). The MAC consists of an assembly of proteins involved in the complement system (part of the effector branch in the innate immune system), which leads to cell death of Gram-negative bacteria like E. Coli. Figure 11.4.1 illustrates the assembly process of the membrane attack complex and the complexity of interactions required to form a lethal pore in a cell.

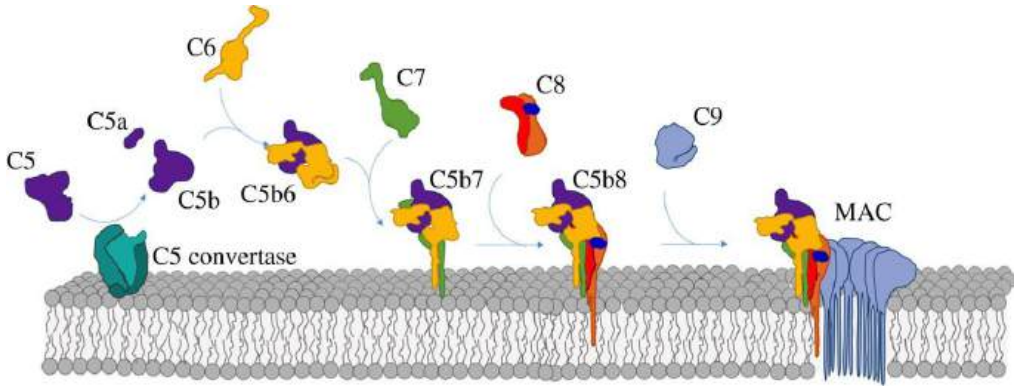

Figure 11.4.1: Human membrane attack complex. Charles Bayly-Jones et al. Philosophical Transactions of the Royal Society B: Biological Sciences, Volume 372, Issue 1726. June 2017 https://doi.org/10.1098/rstb.2016.0221. The Royal Society under the terms of the Creative Commons Attribution License http://creativecommons.org/licenses/by/4.0/

Complement protein C9 can adopt a soluble form or membrane form which in aggregates form the pore leading to cell death. This is a common feature of PFPs.

PFPs could create a pore by altering membrane lipid packing to form a toroid-like hole (Figure 11.4.2) and/or by inserting in a membrane and forming a pore within the protein complex itself. In either mechanism, lipid packing is altered.

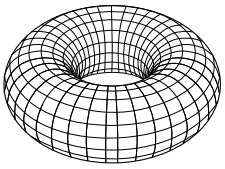

Figure 11.4.2: By GYassineMrabetTalk - Own work, CC BY-SA 3.0, https://commons.wikimedia.org/w/inde...?curid=3134923

Biophysical evidence shows some support for the formation of "toroidal pores".

Lipid rearrangements in the membrane could lead to a hydrophilic or hydrophobic pore lining as shown in Figure 11.4.3

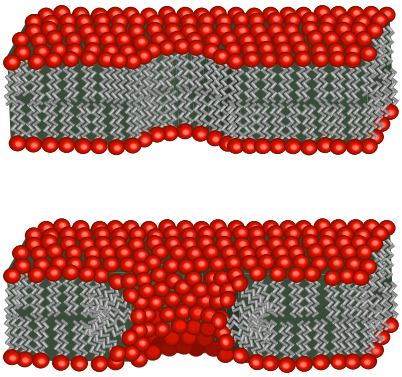

Figure 11.4.3: Diagram of possible lipid arrangements at the edge of a pore through a lipid bilayer. (above) In the absence of any rearrangement, the pore walls will be hydrophobic since the alkane tails are exposed. (below) Some researchers believe that the lipids at the edge re-orient to line the pore wall with hydrophilic head groups. Lipid bilayer. (2023, January 15). In *Wikipedia*. https://en.Wikipedia.org/wiki/Lipid_bilayer

We started our study of lipid bilayers with pure lipid systems and then added membrane proteins. Let's do the same with pore formation. A common technique to form a pore in pure lipid bilayers and also in cells is **electroporation**. This is a technique used to move a DNA with a target gene into either a prokaryotic cell (transformation) or eukaryotic cell (transfection) for exogenous gene expression. In the absence of PFPs, this requires the alteration of surface tension by applying an electrical potential. This forms depressions in the membrane, altering the nonpolar acyl chain packing. In the process, small wire-like columns of water appear, which like hydrophobic pores ultimately rearrange into hydrophilic toroidal pores. Figure 11.4.4 shows snapshots of molecular dynamics simulations as a function of the time of pore formation in electroporation.

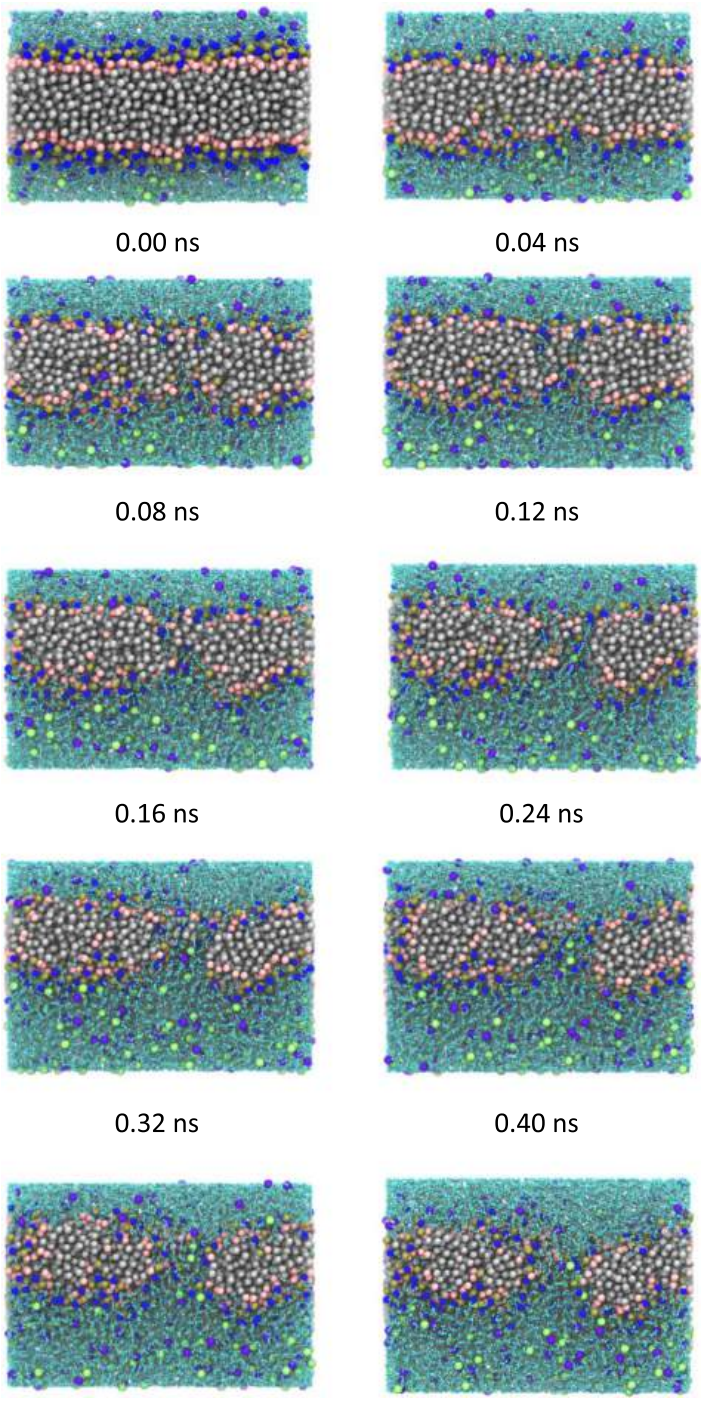

Figure 11.4.4: Zhou, C., Liu, K. Molecular dynamics simulation of reversible electroporation with Martini force field. BioMed Eng OnLine 18, 123 (2019). https://doi.org/10.1186/s12938-019-0743-1. Creative Commons Attribution 4.0 International License, http://creativecommons.org/licenses/by/4.0/

How does DNA pass through the pores in the bilayer? In pure lipid vesicles, it appears to pass through by electrophoresis. Most students are familiar with the electrophoresis of DNA fragments through pores in agarose gels. In actual living cells, small nucleic acids like small interfering RNA (siRNA) and antisense DNA molecules appear to pass through the bilayer by electrophoresis. Large DNAs like plasmids containing a gene for expression bind to the cell and form cell surface aggregates, which appear to be endocytosed into the cell. Electroosmosis, the movement of liquids under the influence of an electric field, also plays a role.

11.4.2: Pores - Outer Membrane Factor (OMF) and Voltage-Dependent Anion Channel (VDAC)

Now let's consider pores made of PFPs. We have already discussed two types of beta-barrel transmembrane proteins, the outer membrane factor (OMF) of Gram-negative bacteria and the voltage-dependent anion channel (VDAC). Both are examples of proteins called **porins** with typical beta-barrel topology.

VDAC: At low membrane potentials, VDAC (also known as mitochondrial porin), the most abundant protein in the mitochondrial outer membrane, moves metabolites and Ca^{2+} ions across the outer membrane of mitochondria. VDAC exist in an open state at 0 or very low transmembrane potentials that allows for the transfer of key metabolic anions (pyruvate, oxaloacetate, malate, succinate, ATP, ADP, and P_i, which are involved in metabolism) and Ca^{2+}, and in a closed state (above or below $\pm$ 30 mV), which is not completely closed as it allows for the transfer of ions with a preference for cations. The closed state does not allow for the transfer of ATP. The transition to the closed state is promoted by tubulin and actin (cytoskeletal proteins), negatively charged lipids such as phosphatidyl ethanolamine and cardiolipin, and also covalent phosphorylation by protein kinases. Bcl2, proteins involved in the regulation of programmed cell death (apoptosis) also interact with VDAC. In contrast to ligand-gated channels which require ligand binding to open the channel, pore complexes are unusually open. Millions of ATPs/second move across the membrane through the open pore but none through the closed pore.

Figure 11.4.5 shows an interactive iCn3D model of mouse VDAC1 (4c69) with bound ATP loosely held in the site. An alpha helix partly occludes the central pore of this β-barrel protein.

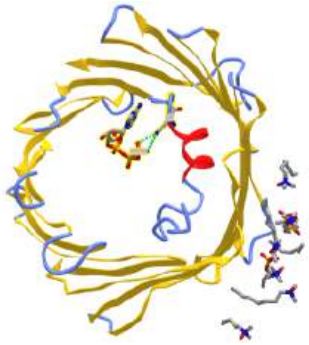

Figure 11.4.5: Mouse voltage-dependent anion channel - VDAC1 (4c69) with bound ATP loosely held in the site. (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?Ueb4wg26f5oEVL4Y9

One ATP is bound in the barrel and interacts with Lys 12 and Lys 20 at each end of the cavity-bound helix. The alpha-helix narrows the pore opening and presumably changes orientation in a voltage-sensitive fashion to gate the pore open and closed, hence regulating the conductance of ions through the pore. That the orientation of the charged arginine side chains would be dependent on the transmembrane potential should be somewhat obvious.

Aquaporins

Aquaporins can move a billion water molecules per second across membranes and exclude ions including protons. Waters proceed in a single file through the pore. Instead of moving waters through, it might simply move "H^+ ions" through by the alignment of subsequent H bond donors and acceptors in a "wire" of water molecules. This is prevented by two conserved asparagine residues in the center of the channel, which disrupt water to water hydrogen bond network in the channel waters that could facilitate proton transfer. Instead, the central waters form hydrogen bonds to the central asparagines. This, along with local membrane potentials, causes opposite orientations of the water in different leaflet sides of the membrane, precluding H^+ transfer.

Here is a movie of a molecular dynamics simulation of water moving through a porin called aquaporin, GlpF, from E. Coli.

Science magazine (Tajkhorshid et al., Science Apr 2002, 296:525). Used with permission from the Theoretical and Computational Biophysics Group, the National Institutes of Health (NIH) Resource for Macromolecular Modeling and Bioinformatics, at the Beckman Institute, University of Illinois at Urbana-Champaign.

OMF: The outer membrane factor (see previous section) is one member of a class of bacterial porins, which are the most abundant proteins in the outer membrane of Gram-negative bacteria. They are classified as non-specific or specific (with respect to the solute that passes through), or monomeric, dimeric, or trimeric based on their structure. In Gram-negative bacteria, which have two lipid bilayers, the movement of solute from inside to outside includes at least three sets of proteins. Active transport (discussed in the next section) needs an energy source and is used by inner membrane transport proteins, including ATP-binding cassette (ABC)-type, resistance nodulation division (RND)-type and major facilitator superfamily (MFS)-type transporters. These are connected to membrane fusion proteins (MFP) that span the periplasm, which then interacts with at least 21 different types of porins. Molecules with molecular weights greater than 600 generally can not get through the nuclear envelope of Gram-negative bacteria, limiting the size of potential antibiotics, which must enter by passive diffusion.

11.4.3: Mechanosensitive ion channels - Mscs (which are pores!)

As the name applies, these ion channels (with openings large enough to be called pores) are gated open/closed by mechanical (physical) changes in the properties of the membrane, not extracellular/intracellular ligands or voltage changes. Certain bilayer lipids also activate the Mscs. There are two types, small (MscS) and large (MscL) mechanosensitive ion channels. Changes in local (boundary layer) and nonlocal lipids are involved in the gating of the channel (in the next section we will discuss lipid-gated ion channels). They are found in prokaryotes, archaea ,and eukaryotes. They are also called stretch-gated ion channels.

Mcss transduces a physical force (stretching and change in turgor pressure) into an electric signal - a flow of ions across the membrane. Turgor pressure is the internal pressure that "presses" the cytoplasm and cell membrane towards the cell wall in bacteria and plant cells. It arises mostly from the osmotic flow of water into the cell. If bacterial cells are placed in a high salt concentration solution (hypertonic), water flows out of the cell and the cell membrane shrinks to the inside of the volume confined by the cell wall. When placed in a hypotonic solution, water flows into the cell and the cell membrane presses out to the cell wall. The response of these channels is fast, in the millisecond range, which is about as quick as a cellular response can be. Some variants of these channels are called **piezochannels**, based on the piezoelectric effect that describes how a voltage is produced when some materials are deformed by mechanical stress which causes a redistribution of charges.

Bacteria normally have high concentrations of both K^+ and negatively charged anions, especially glutamate, which leads to a high turgor pressure from the inward osmotic flow of water. At low external osmolarity, turgor pressure in the cell could be as high as 4 atm. If placed in external solutions of high osmolarity, bacterial cells respond by the increased movement of solutes into the cell.

Mscs are particularly important when bacteria are subjected to sudden osmotic shock. If they are placed in pure water, for example, water would flow down a concentration gradient into the cell and cause the cell to swell and lyse, killing the cell. This is done in the lab to prepare almost pure hemoglobin from ruptured red blood cells. The Mscs are opened under these conditions and small species from the cytoplasm flow out, helping to keep the cell viable. Their openings must be regulated to prevent too much outward flow, which would kill the cell.

In other organisms they are also involved in touch (stretch), hearing (vibration, sound waves), and responses to gravity. Stimuli to activate them include fluid shear stress (relevant to endothelial cells that line blood vessels), membrane stretch (relevant to skeletal and cardiac muscle cells), or even indentation of a bilayer with a pipette. Changes in transmembrane turgor or other mechanical pressures cause membrane tension. Yet even in the absence of these changes, Mscs can be activated by anesthetics, phospholipids missing one fatty acid (called lysophospholipids), and certain polyunsaturated lipids. These stimuli also perturb the membrane bilayers.

Given the pore size, these proteins are less selective to ion flow compared to voltage-gate channels (see next section). Depending on the amino acids that line the pore, some Mscs would allow the preferential flow of anions while some allow cation flow.

Some somatosensory channels (i.e. not pore) proteins also respond to pressure. When open, these can be selective to specific ions like Na^+ or K^+. Examples include some variants of the Transient Receptor Potential (TRP) ion channels. Other membrane proteins can also be activated by physical force. but true Mscs have some key characteristics. If mutated or deleted, the mechanosensory response is removed. If added to a cell, a mechanosensory response results.

a. Small-conductance mechanosensitive channel

This protein is a homoheptamer with three helices from each monomer involved in the overall structure. Two (helices 1 and 2) interact more with the lipid components of the bilayer. Interactions of specific lipids with the helices seem to promote closing but changes under high pressure lead to the opening of the pore. Half of each helix 3 forms the pore, while the other half is more parallel to the membrane and interacts with a large cytoplasmic domain.

Figure 11.4.6 shows the differences between the closed form of E. Coli MscS (2oau) and the open form (2vv5) viewing down the pore axis. The heptameric protein is shown in gray. Two key valines (105 and 109) on each chain are shown in spacefill and colored cyan. These hydrophobic amino acids act like gate-keepers, helping to keep water out, acting like a "vapor seal". In the closed state, the pore is sealed by the closing of the leucine "rings" as one half of helix 3 pack more closely. Many members of the MscS family vary significantly in size and can have between 3-11 transmembrane regions. The closed pore has a diameter of about 4.8 Å, while the open pore is 13 Å across.

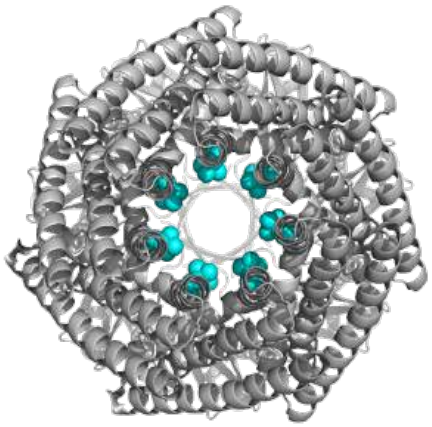

Figure 11.4.6: Differences between the closed form of E. Coli MscS (2oau) and the open form (2vv5) viewing down the pore axis.

Most of you would have studied Ohm's law, given by

$$\mathrm{V} = \mathrm{IR} \text{ or } \mathrm{I} = \frac{\mathrm{V}}{\mathrm{R}} \tag{11.4.1}$$

where I (amps) is the current, R (ohms) is the resistance and V (volts) is the voltage. A more general variant of this law used in physics is

$$\mathrm{J} = \sigma \mathrm{E} \tag{11.4.2}$$

where J is the current density, E is the electric field, and σ is the conductivity (inverse of resistance) which depends on the material. The unit of sigma σ is $ohms^{-1}$ or mhos (ohm written backward). That unit has been renamed the Siemen (S). Mscs channels have a small conductance of approximately 1 nS in 400 mM salt solution.

b. Large conductance mechanosensitive ion channel (MscL):

The channels have large conductances (3 nS) and concomitantly larger pore sizes, allowing the flow of water, ions, and even small proteins. Again they are involved in diffusion down an electrochemical gradient through pores so not active transport just gated diffusion.

Figure 11.4.7 shows an interactive iCn3D model of the pentameric MscL from Mycobacterium tuberculosis (2oar), a Gram-positive bacteria that causes tuberculosis. About 23% of the world's population is affected by this pathogen. It causes about 1.5 million deaths each year. Compare this to the total number of deaths during the COVID pandemic (2020-21) of over 3 million (as of May 2021). It has killed over 1 billion people throughout human history (but not as many as malaria). The pore diameter is about 30 Å across.

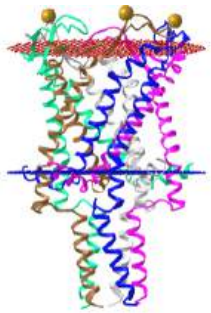

Figure 11.4.7: Closed state of the pentameric MscL from Mycobacterium tuberculosis (2oar). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...LsRZZbmFy5NRF6

11.4.4: Pore-forming alpha-helical toxins

We started this chapter section with a discussion of the major attack complex (MAC) of the innate immune system. Pathogens also employ pore formation to kill host cells. Many secrete soluble proteins which aggregate in the membrane to form either alpha-helical or beta-barrel pores. The proteins are called pore-forming toxins (PFTs). Killing occurs when either cytoplasmic components leak out or bacterial toxins, such as diphtheria and anthrax toxin, move into the cell.

Figure 11.4.8 shows an interactive iCn3D model of the pore formed by cytolysin A (ClyA, also known as HlyE), an alpha-PFT used by some E. Coi and Salmonella enterica strains. The pore is a large dodecamer that forms from soluble monomeric ClyA (2wcd). It has a pore diameter of about 40 Å,

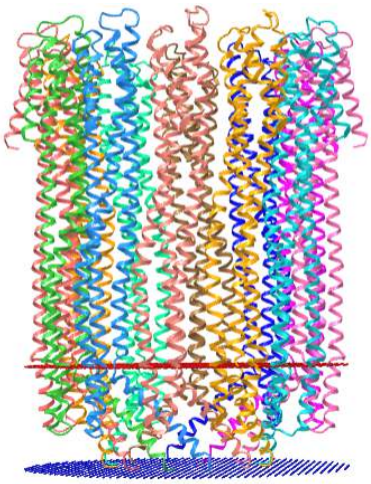

Figure 11.4.8: Pore formed by cytolysin A (ClyA, also known as HlyE). (2wcd) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...RXUsE24d9d8NT6

Figure 11.4.9 shows the soluble monomeric form of cytolysin A (ClyA, HlyE) (1QOY). Nonpolar side chains are shown in cyan. The transparent surface is mostly polar, making the monomer soluble.

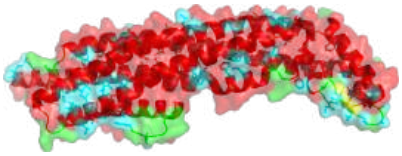

Figure 11.4.9: Soluble monomeric form of cytolysin A (ClyA, HlyE) (1QOY)

Figure 11.4.10 shows the changes in conformation between the single chain soluble form (shown in the figure above) and a single chain of the membrane oligomeric channel.

Figure 11.4.10: Changes in conformation between the single chain soluble form and the same chain in the channel

We started this chapter section by exploring electroporation and the formation of a toroidal-like hole in the lipid bilayer. In the case of ClyA, the protein aggregate itself forms the pore, not the lipids themselves, although lipid rearrangements are necessary to form the protein complex.

11.4.5: Gap Junctions

Connexins are voltage-gated channels that allow for the flow of ions, metabolites, nucleotides, and small peptides. A connexin has four transmembrane helices and two extracellular loops, Six protomers of these come together in a single cell to form a channel complex called a **connexon** or hemichannel. Beta structures in the connexin hemichannel of one cell docks with a similar channel on an adjoining cell to form a full channel passing through the membranes of both cells forming a gap junction between the cells. This is shown in Figure 11.4.11. There are 20 different connexins encoded in the human genome.

The left figure below shows the six protomers, each in a different color and a gray rectangle representing the bilayer of a single connexon or hemichannel. The right side of the figure shows a full gap junction channel between two cells, with the membranes represented by gray rectangles. The connexin 26 monomer was used to create the diagram. Mutations in this protein are associated with hearing loss.

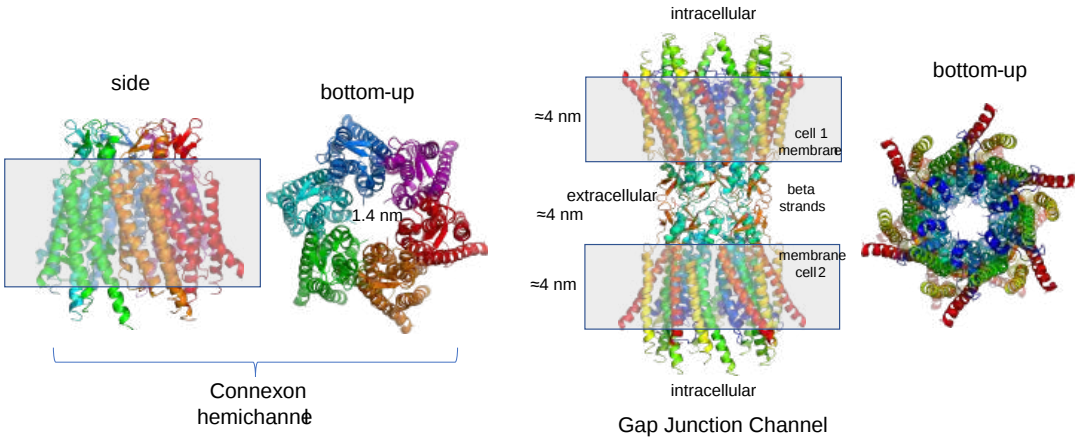

Figure 11.4.11: Connexon channel and the gap junction

The left figure above shows the six protomers, each in a different color and a gray rectangle representing the bilayer of a single connexon or hemichannel. The right side of the figure shows a full gap junction channel between two cells, with the membranes represented by gray rectangles. The connexin 26 monomer was used to create the diagram. Mutations in this protein are associated with hearing loss.

The cytoplasmic entrance of the channel is positively charged. It forms a funnel, composed of 6 amino-terminal helices, which leads into a negatively charged transmembrane lining. The entrance diameter is 14 Å.

Here is a model of a full gap junction channel connecting two membranes using the human connexin 26 monomer (2zw3). Only the bottom membrane bilayer is represented by red and blue dummy atoms.

Figure 11.4.12 shows an interactive iCn3D model of a full gap junction channel connecting two membranes using the human connexin 26 monomer (2zw3). Only the bottom membrane bilayer is represented by red and blue dummy atoms.

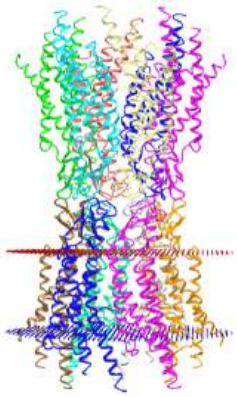

Figure 11.4.12: Gap junction channel connecting two membranes using the human connexin 26 monomer (2zw3). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?TpuQ6Agk8XWuApsWA

11.4.6: The Nuclear Pore Complex (NPC)

Channels have pores that can be gated open and allow the selective flow of ions. Pore-forming proteins have larger entrances that allow both small and large molecules to pass through the bilayer. The pore opening in even large mechanical sensitive channels (about pale in size compared to the nuclear pore complex, which has a combined molecular mass of around 125,000,000! Its outer diameter of ~1,200 Å and its inner one of about 425-Å. Figure 11.4.13 shows the relative size of nuclear pore compared to other molecular structures including the eukaryotic ribosome, nucleosome, a soluble tetrameric protein (rubisco, 270K), and MscL (shown as a circle which represents the pore diameter).

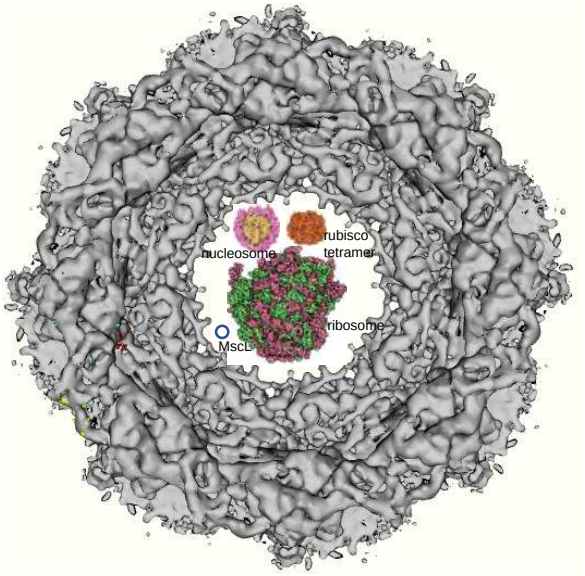

Figure 11.4.13: Relative size of nuclear pore compared to other molecular structures including the eukaryotic ribosome, nucleosome, a soluble tetrameric protein (rubisco, 70K) , and MscL (shown as a circle which rrepresentsthe pore diameter)

Its job is to shuttle small molecules by passive diffusion down a concentration gradient through the pore. In addition, it moves large molecules and molecular structures (proteins, RNA, and perhaps ribosomes) across the nuclear membrane in a process that requires energy. The proteins that comprise this complex are called **nucleoporins (nups)**, of which there appear to be around 34 in humans. Each NPC complex contains around 1000 **nucleoporins**. The complex fuses the inner and outer nuclear membranes.

We have focused so much on single bilayer membranes that comprise the plasma membrane and membranes of organelles like the Golgi complex and lysosomes, it might come as a surprise (perhaps not to biology students) that the nuclear membrane or envelope appears to consist of two bilayers. Most know that the mitochondria have two bilayers, an inner and outer membrane, similar to Gram-negative bacteria. Mitochondrial are believed to have arisen from bacteria so the double bilayer there makes sense. Figure 11.4.14shows the nuclear membrane or envelope of two bilayers (1) with an outer ring (2), spokes (3), a basket (4), and filaments (5). The NPC spans both bilayers.

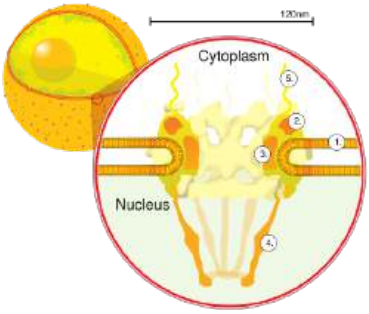

Figure \(\PageIndex{14\): Nuclear membrane or envelope of two bilayers (1) with an outer ring (2), spokes (3), a basket (4) ,and filaments (5) https://en.Wikipedia.org/wiki/File:N...e_crop.svg.png; Creative Commons Attribution-Share Alike 2.5 Generic

The outer bilayer of the nuclear envelope is continuous with the endoplasmic reticulum as shown in Figure \(\PageIndex{15\) below. The dots on the ER membrane are ribosomes, making this the rough ER (as opposed to smooth ER, which has no attached ribosomes).

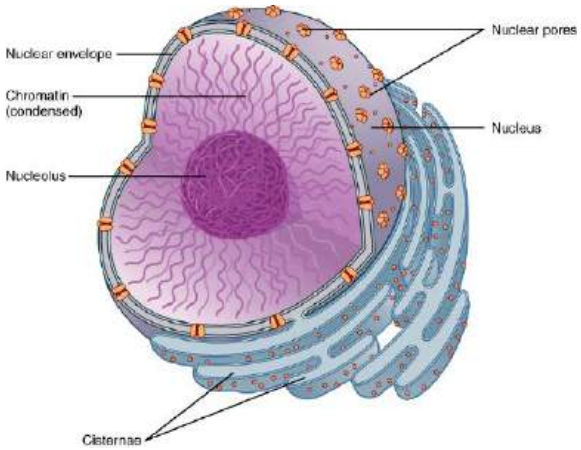

Figure \(\PageIndex{15\): The outer bilayer of the nuclear envelope is continuous with the endoplasmic reticulum https://commons.wikimedia.org/wiki/F...18_Nucleus.jpg; OpenStax, CC BY 4.0 <https://creativecommons.org/licenses/by/4.0>, via Wikimedia Commons

Figure \(\PageIndex{16\) below shows a model of the basket-like structure of the nuclear pore complex (NPC). It, as well as Figure XX, shows that instead of two separate bilayers, in actuality, there is just one bilayer with each leaflet bending around at the NPC and reversing directions! Think of the interesting lipids and protein components that enable the bend! Alternatively, you could say that 2 different membranes fuse at the NPC.

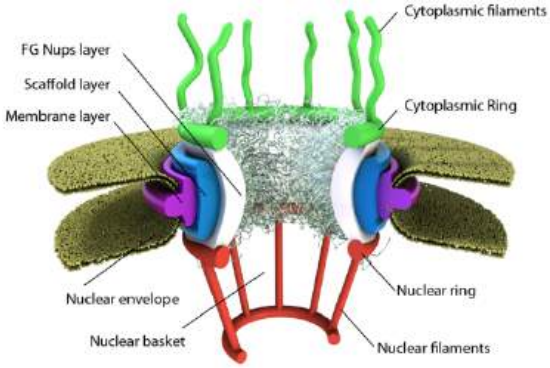

Figure \(\PageIndex{16\): A model of the basket-like structure of the nuclear pore complex **Citation:** Azimi M, Mofrad MRK (2013) Higher Nucleoporin-Importinβ Affinity at the Nuclear Basket Increases Nucleocytoplasmic Import. PLoS ONE 8(11): e81741. https://doi.org/10.1371/journal.pone.0081741. Creative Commons Attribution License,

The NPC consists of 32 copies of each specific nucleoporin (Nup) except two. One of those has 48 copies and the other 16 (even these sum to 2x32 Nups). Three rings form and surround the pore. There is a 16-membered ring of Nups facing the cytoplasm (**cytoplasmic ring**) and another 16-membered ring of Nups facing the nucleoplasm (**nuclear ring**). There is 8-fold rotational symmetry in each ring, suggesting a dimeric repeat of Nups in the rings. Eight Nups in the cytoplasmic ring have a disordered end that sticks out into the cytoplasm as filaments. In contrast, the disordered ends of eight Nups in the nuclear ring form filaments which bind together to form a ring at the bottom of the nuclear basket.

The **inner ring** (called the **FG Nups layer** in the figure above), between the cytoplasmic and nucleoplasmic rings, also consists of Nups with ordered domains and disordered parts. The disordered parts of the inner ring Nups have repetitive sequences enriched in phenylalanine and glycine (hence the name FG Nups) and stick out into the central pore. These disordered region act as a filter allowing certain molecules to pass and excluding those greater with molecular weights greater than 40K. Large molecules need transport proteins called karyopherin transport factors to move through the pore.

The core structure of the NPC, obtained through cryoelectron microscopy, is shown in Figure \(\PageIndex{17\) below.

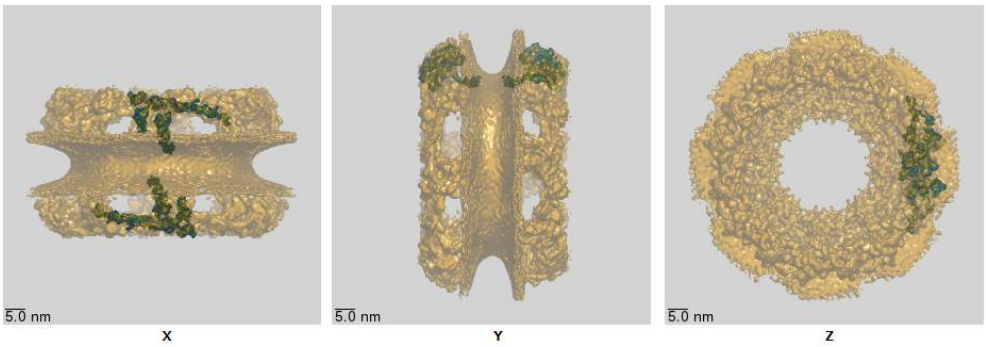

Figure \(\PageIndex{17\): The core structure of the Nuclear Pore Complex https://www.ebi.ac.uk/pdbe/entry/emd...-3103/analysis

The double bilayers are very evident. The nuclear and cytoplasmic filaments, as well as the disordered FG repetitive sequences that stick into the pore from the inner ring, are not seen since they are very flexible and don't' adopt single conformations using standard structure determination methods.

Figure 11.4.18 shows an interactive iCn3D model of the nuclear pore complex (NPC) core (5a9q), whose structure was obtained using cryoelectron microscopy. (load slowly)

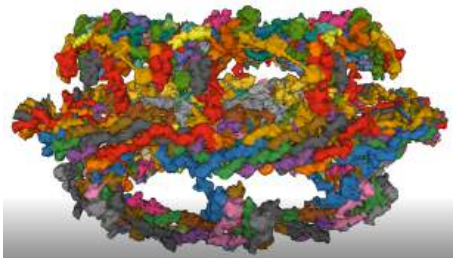
A cartoon figure showing the variety of Nups in the NPC is shown in Figure 11.4.19

Figure 11.4.19: A cartoon version of the various NUPS in the nuclear pore complex. Donnaloja F., Jacchetti E., Soncini M., Raimondi M. T.Front. Physiol., 12 July 2019 | https://doi.org/10.3389/fphys.2019.00896**Creative Commons Attribution License (CC BY)**.

In this figure, the cytoplasmic and nucleoplasmic rings are both shown in green, each mostly formed by 16 copies of the Y-complex, arranged in two eight-membered rings. The inner ring, predominantly formed by 32 copies of the Nup93 complex is shown in red. Transmembrane nucleoporins are depicted in violet, and the cytoplasmic filaments and nuclear basket structure are in orange. Attached to the inner ring are Nup62 complexes (depicted in blue), which form a cohesive meshwork within the central channel through their FG-repeat domains. Not indicated is the position of Nup98, a FG-repeat-containing nucleoporin important for the transport and exclusion function of NPCs; its position in the NPC is less defined, but it might be part of the inner ring. Similarly, Aladin (also known as AAAS), Gle1, Rae1, and Npl1 (also known as hCG1 and NUPL2) have been omitted.

Large proteins and RNA that pass through the pore must first be bound to a cargo receptor, which can move the "cargo" across the pore with concomitant GTP hydrolysis. This is a process that is closer to active transport so we will discuss that in Chapter 11.3.

The entire nuclear pore complex was solved in 2022 using cryoEM. Here are two videos showing the dilated complex (7R5J). Click on the images to download mp4 animations of the complex.



11.5: Active Transport

In the previous sections, we explored facilitated diffusion, diffusion through channels, and diffusion through larger pores. In each case, once a carrier/permease protein was available, or a channel (gated by ligand binding, change in membrane potential, lipid binding, or mechanical forces) or a pore formed, solute flows down a chemical gradient (facilitated diffusion) or electrochemical gradient in a thermodynamically favored process. But what about moving solutes from low to high concentration, against a concentration gradient, which would be necessary to capture the last bit of a vital nutrient or energy source? Active transport does just that, but it requires an energy source to do so. Many different types of chemical species are actively transported across the cell and organelle membranes, including sugars, amino acids, (deoxy)nucleotides, metabolites (like carboxylic acids),

11.5.1: Type of Active Transport

For active transport to occur, a membrane receptor is required which recognizes the ligand to be transported. Of major interest to us, however, is the energy source used to drive transport against a concentration gradient. The biological world has adapted to use almost any source of energy available.

ATP hydrolysis: One would expect that this ubiquitous carrier of free energy would be used to drive active transport. This is one of the predominant roles of ATP in the biological world. 70% of all ATP turnover in the brain is used for the creation and maintenance of a Na and K ion gradient across nerve cell membranes using the membrane protein Na^+/K^+ ATPase.

Energy released by oxidation: You may have encountered this in previous biology courses. Active transport of protons driven by oxidative processes is exergonic. In electron transport in respiring mitochondria, NADH is oxidized as it passes electrons to a series of mobile electron carriers (ubiquinone, cytochrome C, and eventually dioxygen) using protein complexes in the inner membrane of the mitochondria. The energy lost in this thermodynamically favored process is coupled to conformational changes in the complex which caused protons to be ejected from the matrix into the inner membrane space. One can imagine a series of conformation-sensitive pKa changes in various side chains in the complexes which lead in concert to the vectorial discharge of protons.

Light: Photosynthetic bacteria have a membrane protein called **bacteriorhodopsin** which contains **retinal**, a conjugated polyene derived from beta-carotene. It is analogous to the visual pigment protein rhodopsin in retinal cells. Absorption of light by retinal induces conformation changes in the retinal and bacteriorhodopsin, which leads to the vectorial discharge of protons.

The collapse of an ion gradient: The favorable collapse of an ion gradient can be used to drive the transport of a different species against a concentration gradient. We have already observed that the collapse of a proton gradient across the inner mitochondria membrane (through F_0F_1ATPase) can drive the thermodynamically unfavored synthesis of ATP. The collapse of a proton gradient provides a proton-motive force that can drive the active transport of sugars. Likewise, a sodium-motive force can drive the active transport of metal ions. Since the energy to make the initial ion gradients usually comes from ATP hydrolysis, ATP indirectly powers the transport of the other species against a gradient.

Active transport can be divided into two classes:

- primary - driven by "primary" energy sources, which for us means ATP or photons
- secondary - driven by coupled transport (also called cotransport) of solutes down a concentration gradient, which provides the thermodynamic force to move a solute "uphill".

Active transporters can also be divided into classes based on the direction of movement of the solute and any cotransported solute into uniport (no cotransported solute), symport (solute and cosolute transported in the same direction) and antiport (solute and cosolute transported in the opposite direction) as shown in Figure 11.5.1.

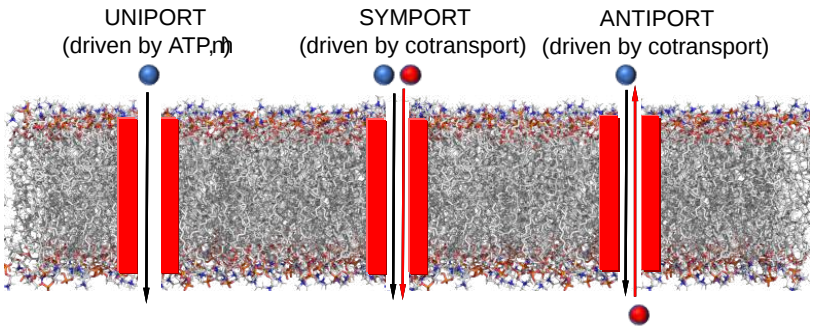


Figure 11.5.1: Uniport (no cotransported solute), symport (solute and cosolute transported in the same direction), and antiport (solute and cosolute transported in the opposite direction) transporters

Examples of these different mechanisms can be found in facilitated diffusion as well as active transport. Examples of these types include:

- uniport: An often-used example is GLUT 1, which catalyzes the FACILITATED DIFFUSION (not active transport) of glucose down a concentration gradient. A somewhat complicated example of a uniport active transporter is the Na^+/K^+ ATPase, which moves Na^+ ions out of a cell and K^+ into a cell, both against concentration gradients. The movement of one ion does not provide the chemical potential thermodynamic driving force to move the other. Rather the hydrolysis of ATP is required. So this protein can be called a uniport active transporter for two different ions.
- symport: Another glucose transporter, the glucose symporter (SGLT1), found in the small intestines, heart, and brain, cotransports one glucose or galactose for every two Na^+ ions that move into the cells down a concentration gradient.
- antiport: The sodium-calcium exchanger pumps out one Ca^{2+} ion (low to high concentration) driven by the influx of three Na^+ into the cell. This keeps Ca^{2+} low in the cytoplasm.

If the species moved is charged, two other terms are used:

- electrogenic - a net electrical imbalance is generated across the membrane by symport or antiport of charged species
- electroneutral - no net electrical imbalance is generated across the membrane by symport or antiport of charged species

In this chapter section, we will explore examples of several types of active transporters. All are polytopic with alpha-helical transmembrane domains, which through a series of conformational transitions can move chemical species that are bound to the receptor or channel protein to move through the membrane through the creation of transient openings in the protein. We will end with another look at the nuclear pore complex and see how it allows the movement of large proteins and RNA molecules through its pore through a very different type of mechanism. In that case, it is not active transport since the relative concentration of the transported species on either side of the pore is less important than the mechanism by which certain species are targeted to move into and out of the nucleus.

11.5.2: Major Facilitator Superfamily (MFS) Transporters

There are about 74 different families of active transporter in the Major Facilitator Superfamily (MFS), which is the largest of secondary transporters using symport or antiport mechanisms. There are also uniporters within this family. Different members of the MFS move a diverse array of solutes, including sugars, nucleotides, peptides, and drugs across membranes against a concentration gradient. All have two membrane domains consisting of six transmembrane helix bundles that pack to give an apparent two two-fold rotational axis of symmetry (also called pseudo C_2 axis). The ligand to be transported binds between the two domains in a central cavity potentially open to either side of the membrane. Figure 11.5.2 panel A (top) below shows a cartoon of the 12 helices and 6-helix bundles. Helix 1 and 4 in domain one and the analogous ones in domains 7 and 10 are involved in ligand movement through the membrane. Correspondingly, helices 2, 5, 8, and 11 are involved in domain-domain interactions. The bottom figure (B) shows two views of the protein with the ligand in spacefill rendering.

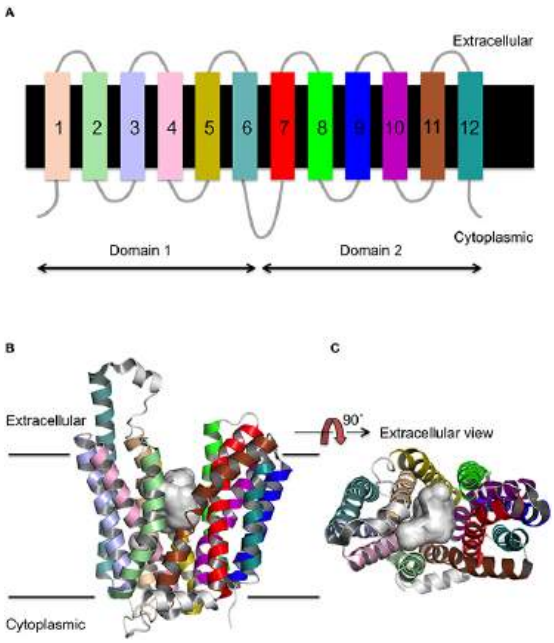

Figure 11.5.2: Structure of the Major Facilitator Superfamily (MFS). images from Lee J, Sands ZA and Biggin PC (2016) A Numbering System for MFS Transporter Proteins. *Front. Mol. Biosci*. 3:21. doi: 10.3389/fmol.2016.00021 **Creative Commons Attribution License (CC BY)**

As structure mediates function, they all display a similar "clamp and switch" mechanism, in which solute binds to the protein in an open (to binding) conformation, leading to conformation changes forming a closed form, followed by further conformational changes which cause the complex to open to the other side of the membrane. Figure 11.5.3 shows hands opening, closing, and reopening in the other direction as an analogy for this "clamp-switch" mechanism.

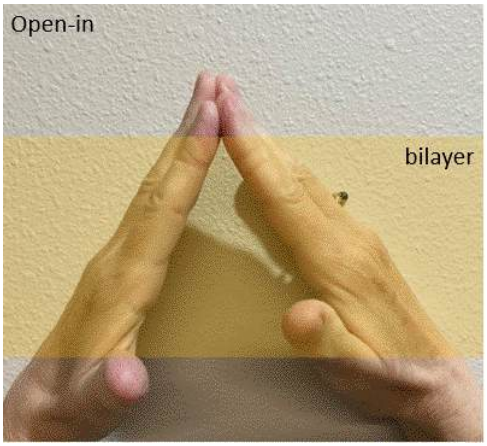

Figure 11.5.3: Hands opening, closing, and reopening in the other direction as an analogy for this "clamp-switch" mechanism of the Major Facilitator Superfamily (MFS)

We will describe two different transporters in this family.

Human monocarboxylate transporter (7BP3)

These proton-linked monocarboxylate transporters (MCTs) move many monocarboxylates (including lactate, pyruvate, and the ketone bodies acetoacetate, beta-hydroxybutyrate and acetate) out of the cell, driven by the flow of protons across the membrane in the same directions (symport). In cells engaging in glycolysis, a fundamental energy utilization pathway, it catalyzes the high-affinity transport of pyruvate, the end product of glycolysis, and lactate, a reduced derivative of pyruvate, out of the cell. In cells that are not engaged in glycolysis, their activity is effectively turned off. The flux of pyruvate/lactate has steep dependence on their concentrations, allowing the protein to act as an on-offf switch for transport. A step dependency of activity on concentration is a hallmark of cooperative interactions. Structural analyzes show conformational changes in the interface of the dimeric form of the transporter.

We will see when we study glycolysis, the conversion of the oxidized pyruvate to its reduced form lactate requires a reducing agent, in this case, NADH, which is oxidized back to NAD^+, an oxidizing agent required for glycolysis to continue. When pyruvate is high, NADH is also high, allowing for the conversion of pyruvate to lactate, which can be exported out of the cell. The interconversion is described by this reaction:

$$\text{Pyruvate} + \text{NADH} \leftrightarrow \text{Lactate} + NAD^+$$

Using MCT 2 to remove lactate from the cell pulls the above reaction to the right, regenerating NAD^+, and allowing glycolysis to continue.

Figure 11.5.4shows an interactive iCn3D model of the inward open human monocarboxylate transporter 2 (7BP3).

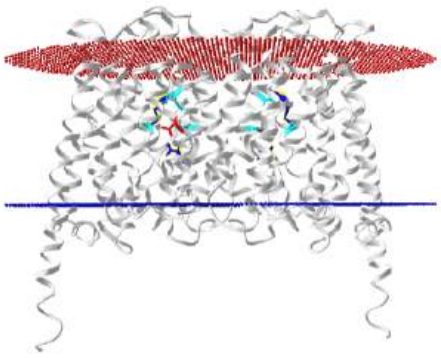

Figure \(\PageIndex{4\): Inward open human monocarboxylate transporter 2 (7BP3). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...yq5U8v4BvdDA57

Several key residues are shown. Aspartic acid 293 (side chains in red sticks) is conserved in all MCTs studied and is likely involved in H^+ transport. It is surrounded by Val 156, Met 289, Ala 290, and Phe 351 (side chains in cyan sticks), all nonpolar amino acids which would elevate the pKa of Asp 293, allowing it to stay protonated until a conformational change would alter its environment, leading to proton release. Two positive charged residues, Lys 38 and Arg 297 (side chains in blue sticks) are involved in substrate interactions. Lys 38 faces to the outside of the cell in the inward open conformation. Figure \(\PageIndex{5\) below shows the same amino acids in a zoomed view. The amino acids are labeled.

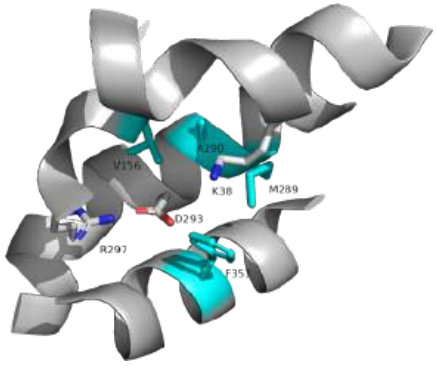

Figure \(\PageIndex{5\): Key amino acid side chains in inward open human monocarboxylate transporter 2 (7BP3)

Lactose Permease (Lactose-proton symport)

This E. Coli protein is also a symporter, which uses the movement of H^+ down a concentration gradient to drive lactose into E. Coli to capture as much lactose - an energy source - as possible. Deprotonation of a protonated Glu 269 leads to ligand binding as the protein has no binding site in the protonated site. Lactose induces the formation of its binding site. Figure \(\PageIndex{6\) below shows the change in conformation going from a more acidic pH (5.6, PDB 2CFP) to a more neutral pH (6.5, PDB 2CFQ). One lactose is transported from one H^+, which moves down a concentration gradient. Lactose moves from the outside periplasm to the cytoplasm.

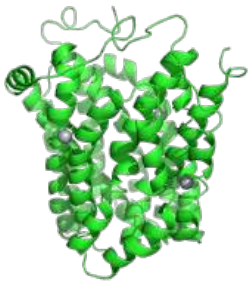

Figure \(\PageIndex{6\): Conformation changes in lactose permease from a more acidic pH (5.6, PDB 2CFP) to a more neutral pH (6.5, PDB 2CFQ)

Figure 11.5.7 shows an interactive iCn3D model of lac permease (1pv7), which highlights three residues essential for lactose binding (Glu 126, Arg 144, and Glu 269 in stick) and three involved in proton transfer (Arg 302, His 322 and Glu 325 in spacefill).

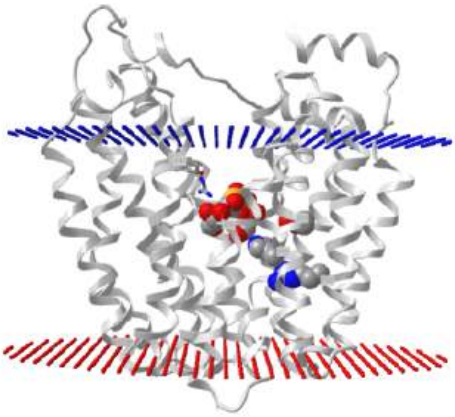

Figure 11.5.7: Lac permease (1pv7). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...9mt2juToECQPg6

It has a bound nonhydrolyzable lactose analog (beta-D-galactopyranose-(1-1)-1-thio-beta-D-galactopyranose), shown in spacefill, in the center hydrophilic cavity. The two 6-helix bundles, which give pseudo 2-fold symmetry are evident. The protein is in the open-to-inward conformation. (The blue dummy atoms represent the inner leaflet.)

Figure 11.5.8is a video of a molecular dynamics simulation showing lactose moving through lactose permease.

Figure 11.5.8 Molecular dynamics simulation showing lactose moving through lactose permease. https://www.ks.uiuc.edu/Gallery/Movi...annelProteins/

As with other members of the MFS transporters, lactose permease has 12 transmembrane helices that form two bundles. The lactose binding site is between the two bundles. When the protein is in the open-to-out conformation, it can bind protons, most likely at an exposed His. This enables lactose binding, which is followed by a conformational change to the open-to-in form. The protonated His loses a proton and lactose dissociates into the cytoplasm. Movement of both H^+ and lactose together must occur for transport.

Structural work by Singh et al on the Leu Transporter (LeuT), a member of the solute carrier 6 or sodium-coupled transporters, which is an active transporter requiring movement of Na ion into the cells to power the uptake of Leu, shows an "open-to-out" and occluded binding state for ligand (Leu). Tryptophan, a competitive nontransportable inhibitor binds to the open-to-out state but is too large for the obligate occluded state so it is not transported. Figure 11.5.9 shows inward open, closed, and outward conformations of different major facilitator superfamily transporters.

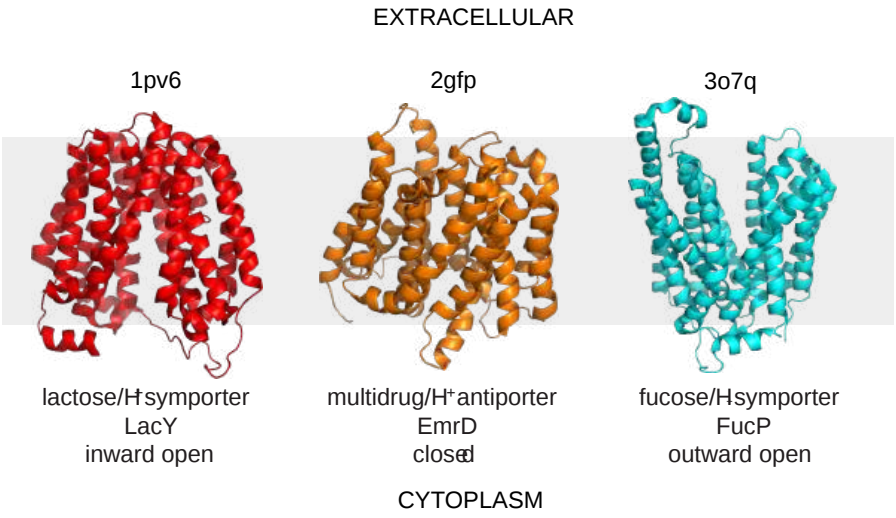

Figure 11.5.9: Inward open, closed, and outward conformations of different major facilitator superfamily transporters

Another member of the MFS Transporter family is LeuT, the leucine transport, which is similar to the neurotransmitter sodium symporter. Figure 11.5.10shows the transition between two conformational states. The first is the outward open leucine transporter (LeuT). This initial state has bound tryptophan, a competitive inhibitor, which is too big to transport, which traps the bound state in the open conformation. The second state has bound Leu and is closed. The conformational changes are subtle but sufficient to allow transient binding, occlusion, and expulsion to the other side of the membrane (not shown). Note also the two bound Na^+ ions (purple) clearly show that active transport through this transporter is driven by Na^+ ions. The ions are farther apart in the open state allowing access to the amino acid for transport.

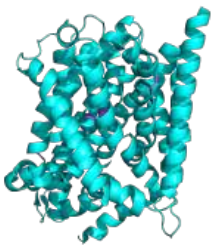

Figure 11.5.10: Transition between two conformational states of the Leu transporter

11.5.3: Membrane ATPases

Many active transporters power the uphill transport of solute through coupled exergonic cleavage of ATP. The largest family of is the **P-type ATPase**, which is used to transport a host of different solutes, including ions (Cu, Zn, Mn, Mg, Ca, Na, K, Cd, Co, Pb, Ni ,and H) and phospholipids (from one leaflet to another by translocases like flippases). They convert chemical energy (from

cleavage of phosphoanhydride bonds) to electrochemical potential energy. Over 160,000 P-type ATPases from prokaryotes and eukaryotes are known so they are highly prevalent and evolved early in time. They should be understood at both a structural and thermodynamic level.

How is energetic coupling achieved? An early model proposed by Albers and Post suggested that energetic coupling occurred by the covalent transfer of a terminal phosphate (P_i) from ATP to an Asp in the protein channel to form a covalent Asp-Pi intermediate, which is an example of a mixed anhydride. This is illustrated in Figure 11.5.11.

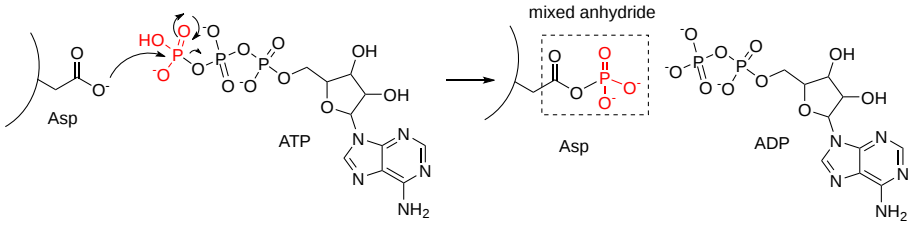

Figure 11.5.11: Formation of a high energy (compared to its hydrolysis products) mixed anhydride of Asp in membrane ATPase. (**Remember, there is no such thing as a "high energy" bond.**)

This reaction is disfavored thermodynamically since hydrolysis of ATP to form ADP proceeds with a **less negative** ΔG^0 than the same reaction with a mixed anhydride. However, ultimately hydrolysis of the mixed anhydride in the next step would make the overall coupled reactions favorable.

Another feature of the Post-Albers model is that the phosphorylated channel, P-ATPase, has two conformations:

- a high-affinity cation inward (cytoplasm) facing cation binding site called E_1
- a low-affinity cation outward (extracellular or luminal) facing cation binding site called E_2

Figure 11.5.12 is a more detailed (A) and simpler (B) set of chemical equations to represent the different states of E_1 and E_2 in the Post-Albers model.

The next three figures are from the following reference: Zhang, X.C., Zhang, H. P-type ATPases use a domain-association mechanism to couple ATP hydrolysis to conformational change. *Biophys Rep* **5,** 167–175 (2019). https://doi.org/10.1007/s41048-019-0087-1. Creative Commons Attribution 4.0 International License (http://creativecommons.org/licenses/by/4.0/

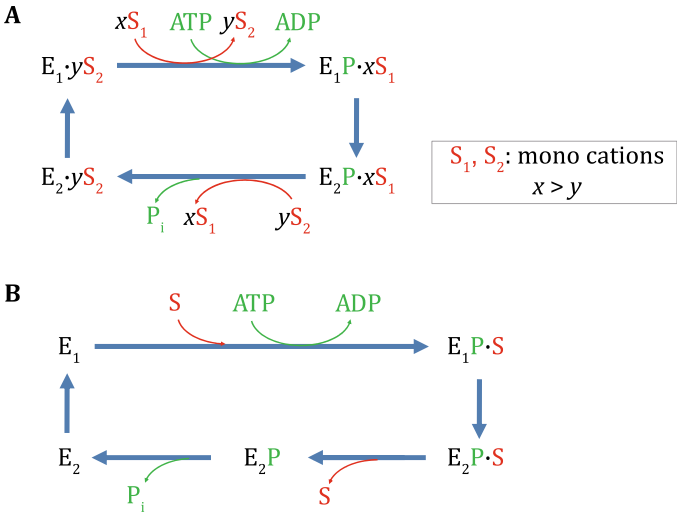

Figure 11.5.12: Chemical equations for conversion of states E_1 and E_2 for membrane ATPases in the Post-Albers mode

- The top line in both shows the reactions of E_1 (high affinity) with the substrate (ions) and ATP. Since E_1 is phosphorylated by ATP, it is considered a **kinase.**
- The bottom line in both shows the reactions of E_2 (low affinity) with the substrate (ions). Since E_2 is dephosphorylated, it is considered a **phosphatase**.

S_1 and S_2 differ for specific P-type ATPase.

Detailed Structures

Now let's look at the structures of a specific P-type ATPase, the sarcoplasmic/endoplasmic reticulum calcium ATPase 1 (or more simply a Ca^{2+} pump), which catalyzes the active uphill transport of Ca^{2+} from the cytoplasm back into the lumen of the sarcoplasmic reticulum (SR) in muscle cells and acts in the regulation of striated muscle contraction. The actual free concentration of Ca^{2+} in the SR is about 390 μM compared to 0.1-0.2 μM in the cytoplasm. On muscle excitation, Ca^{2+} floods out into the cytoplasm but must be actively transported back into the SR by the Ca^{2+} pump.

Here is the simplified chemical reaction: ATP + Ca^{2+}(cyto) + H_2O → ADP + Ca^{2+}(s. rect) + H^+ + P_i.

We'll stick with a cartoon representation of each of the various structure states of this calcium pump, as illustrated in Figure 11.5.13 (also from Zhang et al).

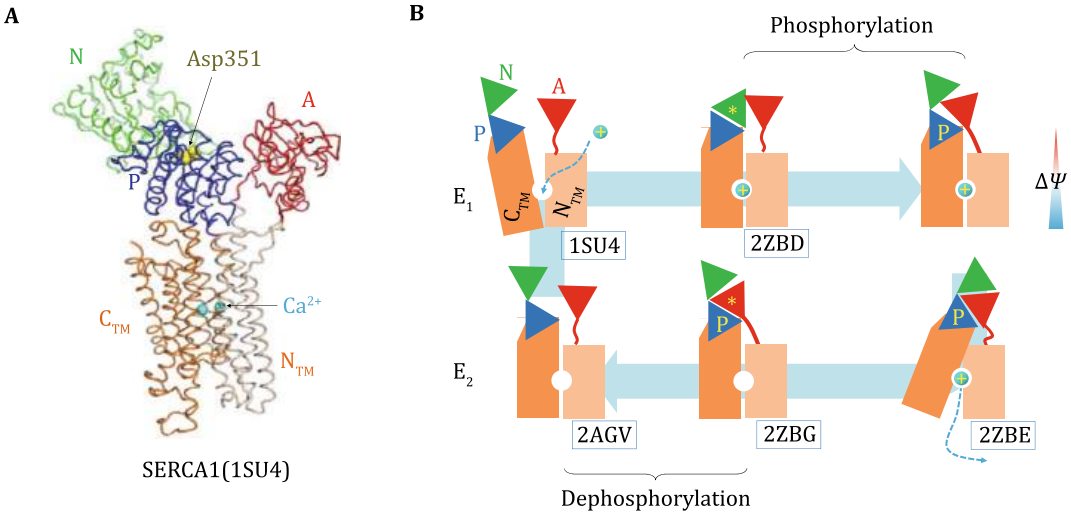

Figure 11.5.13: States of this calcium pump

Again, different states of E_1, the kinase state, are shown in the top line, while E_2, the phosphatase state, is shown in the bottom line. PDB IDs are shown for each state. Ca^{2+} is shown as a cyan sphere. Note how the cytoplasmic N (nucleotide-binding), P (phosphorylation), and A (actuator) domains and the single transmembrane domain, colored to show the C-terminal (C_{TM}) and N-terminal (N_{TM}). are represented in the cartoon version to the right. P represents the phosphorylated Asp 351 mixed anhydride. The asterisk * denotes a transition state for the phosphorylation of Asp 351 (top line) and its dephosphorylation (bottom line).

Ca^{2+} moves from the cytoplasm to the lumen of the SR. Note that the first E_1 state is open inward (to the cytoplasm) while the first E_2 state is open outward (to the lumen of the Sr, where the bulk of the Ca^{2+} ions are stored. This mimics the open-in and open-out states of the Major Facilitator Superfamily (MFS) channels discussed above.

Detailed Thermodynamics

Zhang et al provide two different views of the thermodynamics of Ca^{2+} ion pumping into the SR as shown in A (domain dissociation) and B (classic) in Figure 11.5.14 A quick view of the two "energy landscapes" show:

- Both go from higher to lower free energy as expected since ATP hydrolysis powers the process.
- They differ mostly in the energetic coupling steps

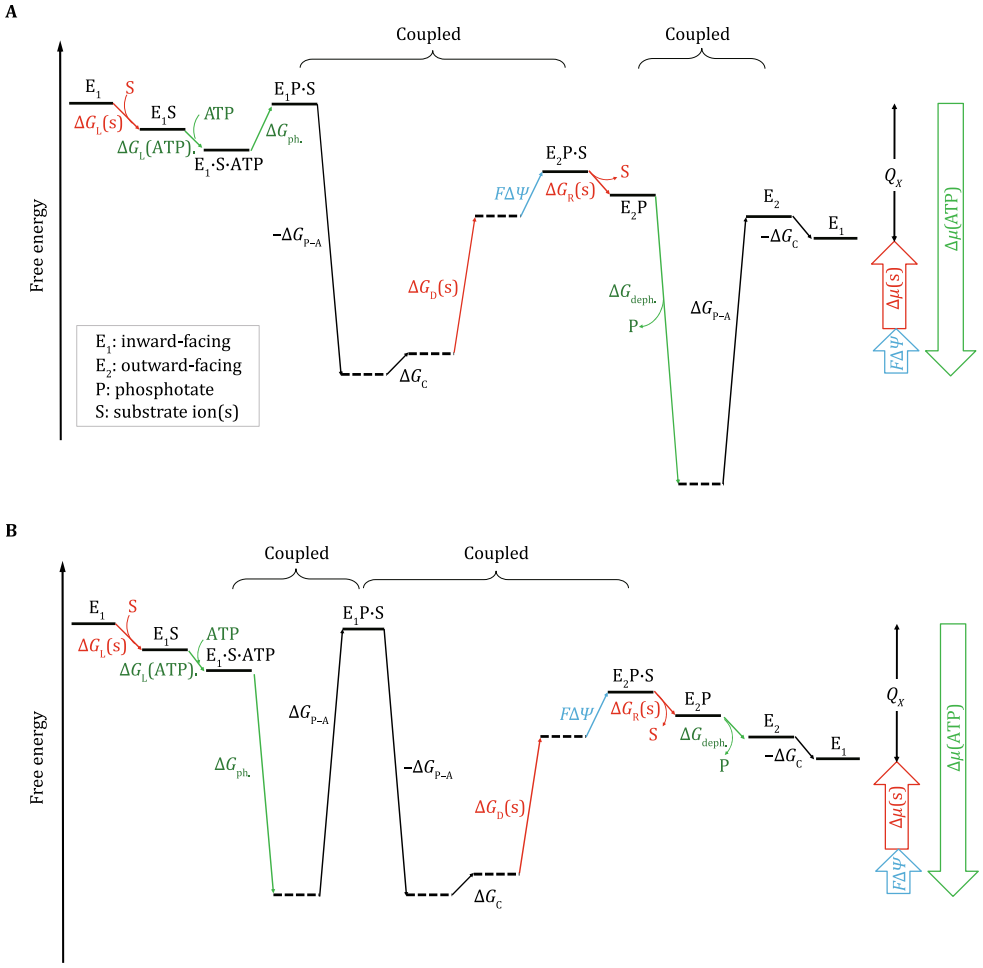

Figure 11.5.14: Thermodynamics of Ca^{2+} ion pumping into the SR as shown in A (domain dissociation) and B (classic)

In A, the actual energy released in ATP hydrolysis occurs when the Asp 351-P_i mixed anhydride is dephosphorylated (ΔG_{deph}), which is coupled to the dissociation of the P and A (** actuator) domains. This is shown in the structural cartoon near the last step in the complete cycle.

In the cartoon diagram, 6 states are represented. Any mechanism can be broken down into more and more states on a more complete description of the actual mechanism. For example, ATP cleavage to ATP can be represented by three states, ATP, ADP, and P_i, or many more if intermediates and transition states are included, the complete Ca^{2+} transport cycle in the thermodynamics diagram is broken down into 12 states, represented by 8 horizontal solid lines —— and 4 dashed ------ lines. Vertical lines with arrows show transitions between states.

- Green arrows → show changes in free energy due to the relative stability (chemical potential) of ATP.
- Red arrows → show changes in free energy due to the relative stability (chemical potential) of the substrate ions
- Cyan arrows → show changes in free energy due to the electrical potential of the substrate ions

ΔG_L are for steps involving loading of reactants, while ΔG_R are for release. In both diagrams, the conversion of state E_1·S·ATP to E_1P·S is uphill as we predicted for the formation of the

On the far right of each graph are identical sets of large unfilled arrows (since ΔG is a state function) as the beginning and ending free energies of free E_1 must be pathway (i.e. mechanism) independent. The two sets of upward unfilled arrows (red for the change in the chemical potential of the substrate ions and cyan for the change in the electric potential of the substrates are both positive as the ions move uphill from a lower to high electrochemical potential. The unfilled downward green arrow shows the change in free energy (or chemical potential) for ATP hydrolysis. Since energy cannot be created or destroyed, the narrow black arrow (Q_x) represents energy that is dissipated in the reaction cycle. The starting and ending states are identical (*i.e.*, E_1), only being differed by the energy dissipation (denoted as Q_X) of the P-ATPase transporter during one functional cycle.

The are other types of membrane ATPase whose structure and function differ from the P-type described above. Some run in reverse to synthesize ATP. They also vary in substrate ions. Here are several different types.

- F-ATPases (ATP synthases, F_1F_0-ATPases): These are used to synthesize ATP and are powered by the collapse of a H^+ gradient. They are found n mitochondria, chloroplasts, and bacterial cell membranes. We will discuss these more in chapters on mitochondrial oxidative phosphorylation and photosynthesis in chloroplasts.
- V-ATPases (V_1V_0-ATPases): These are used to pump protons into organelles to acidify them (ex. lysosome) and are also found in bacteria.
- A-ATPases (A_1A_0-ATPases): These are used to synthesize ATP in Archaea.
- E-ATPases: These are found on the cell surface and hydrolyze extracellular nucleotide triphosphate.

Let's now look at some special features of one P-type ATPase that transports both Na^+ and K^+ ions and is important in establishing their intracellular and extracellular concentration in neurons, so they are critical for neuron function.

Na^+/K^+ ATPase

This protein keeps the K^+_{in} and Na^+_{out} high compared to their respective concentrations on the other side of the neural cell membranes. ATP and **3** Na^+ ions bind to the cytoplasmic domain of the enzyme in the E_1 conformation. As described more generally above, in the presence of Na ions, the bound ATP is cleaved in a nucleophilic attack by an Asp side chain of the protein. Hence, the protein is a Na^+-activated ATPase or kinase. The phosphorylated enzyme changes conformation to the E_2 form in which Na^+ ions are now on the outside of the cell membrane, from which they dissociate. The phosphorylated protein in conformation E_2 now binds 2 $\mathbf{K}^+$ ions on the outside, which activates hydrolysis of the Asp-PO_3 mixed anhydride link. The dephosphorylated protein is more stable in the E1 conformation, to which it changes as it brings K^+ ions into the cell. Hence this protein is an electrogenic antiporter. P-Type transporters are inhibited by vanadate (VO_4^{3-}), a transition state analog of phosphate. Transport mediated by P-type membrane proteins can, in the lab, be used to drive ATP synthesis.

Detailed kinetic analysis of ATP and VO_4^{3-} interactions show there are low-affinity and high-affinity sites for each on Na/K ATPase. The high-affinity vanadate site appears to be the same as the low-affinity ATP site, which suggests that vanadate binds tightly to the E2 form of the enzyme. The low-affinity vanadate site appears to be the same (based on competition assays) as the ATP site, which is probably the E_1 form. Hence vanadate binds preferentially to the E2 form which would inhibit the transition to the E_1 form. Vanadate also inhibits phosphatases, enzymes that cleave phosphorylated Ser, Thr, and Tyr phosphoesters in proteins. This supports the notion that vanadate binds preferentially to the E2 form, which has a phosphoanhydride link (Asp-O-phosphate) that is hydrolyzed, promoting the conversion of E_2 back to E_1. Vanadate is probably a transition state analog inhibitor in that it can readily adopt a trigonal bipyramidal structure, mimicking the transition state for cleavage of the tetrahedral anhydride bonds of ATP and Asp-O-PO_3.

Figure 11.5.15is a YouTube animation of the Na^+/K^+ ATPase from xx. Permission Question?

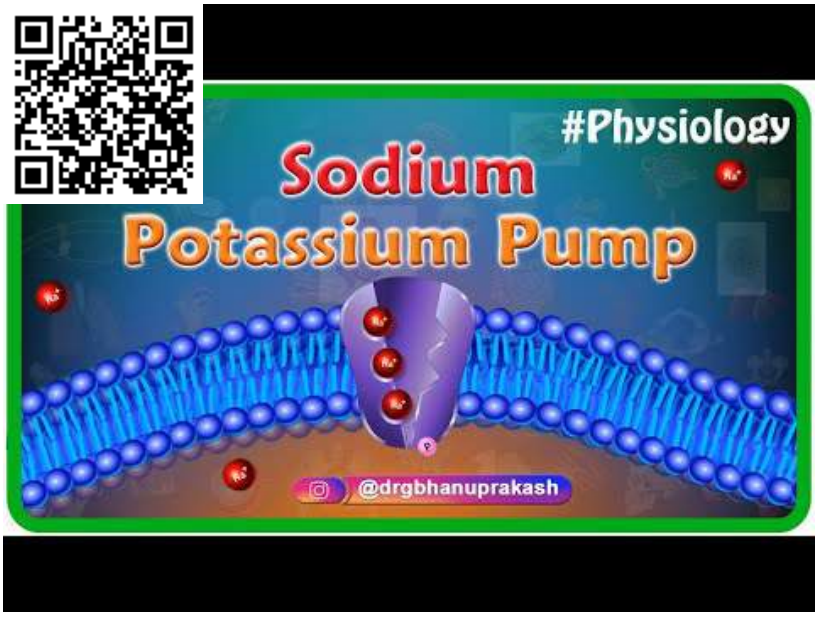

Figure 11.5.15: Animation of the Na^+/K^+ ATPase pump

These interactions are depicted in Figure 11.5.16 below (after Stryer 4th ed)

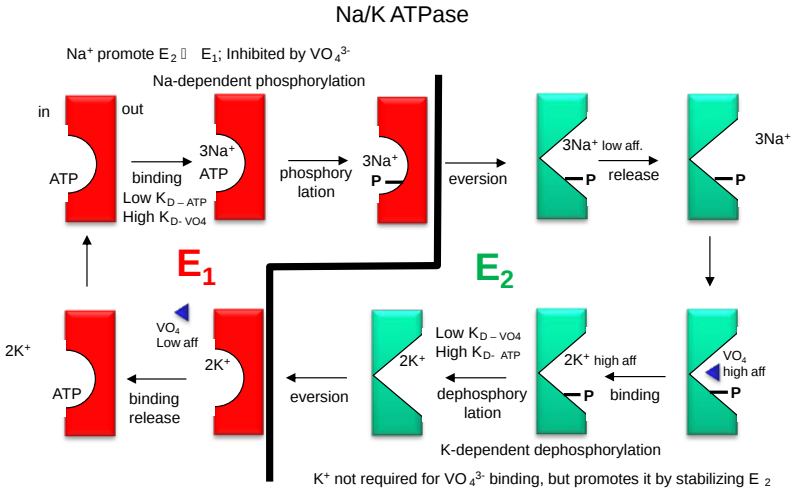

Figure 11.5.16: Steps of the Na^+/K^+ ATPase pump

ABC Transporters

The proteins comprise one of the largest families of membrane proteins with seven main families (ABCA to ABCG). Up to 3% of all bacterial proteins encode proteins associated with the ABC transporters. Different ABC transporters move a variety of required chemical species, from small (ions, sugars, amino acids, nucleosides, vitamins) to large (peptides, lipids, oligonucleotides, and polysaccharides) into the cell. They also remove toxic (to the cell) molecules such as xenobiotics (molecules foreign to the cell like drugs, toxins, etc) and potentially toxic metabolites. All of these require ATP hydrolysis. Moving toxic molecules out of the cell is beneficial to the health of the cell, but in the case of a tumor cell, not to the benefit of the organism. TAs in other active transporters using ATP, its hydrolysis leads to two different conformations, open-outward and open-inward. All ABC transporters have a LSGGQ amino acid sequence in the NBD. They also have a phosphate-binding loop (P-loop or Walker A motif). Most eukaryotic ABC transporters move solutes from the inside to the outside of the cell.

The various structures within the ABC transporter superfamily are shown in Figure 11.5.17. The transmembrane domain (TMD, in green) and the nucleotide-binding domain (NBD, blue) are present in most versions of the gene. PK represents prokaryotic and EK eukaryotic organisms (shown at the very right for each).

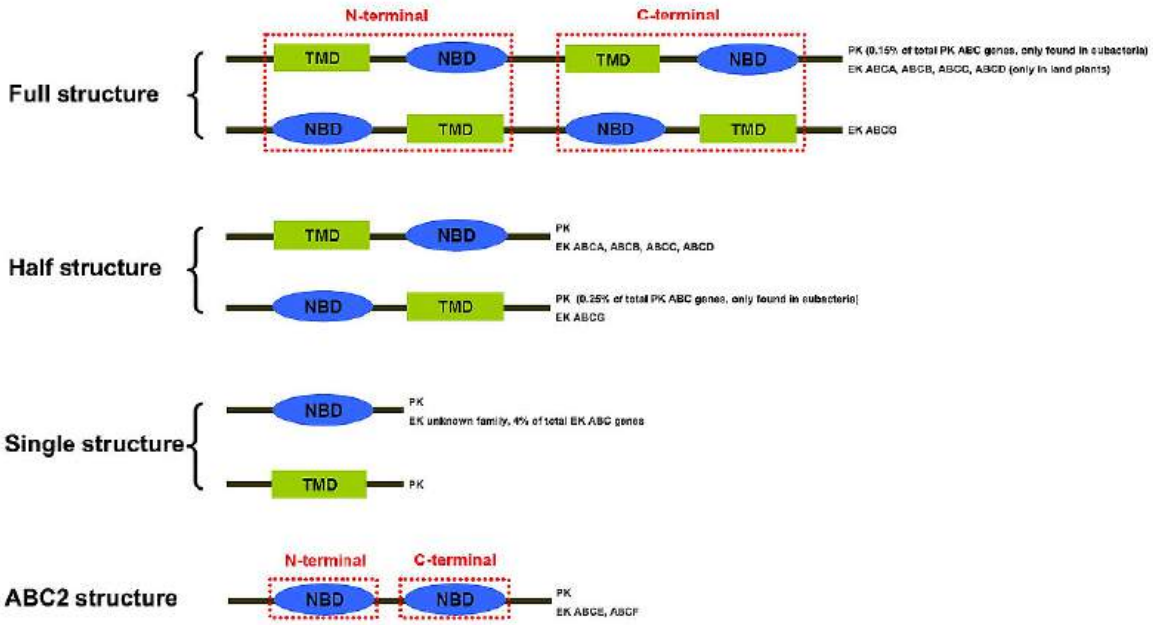

Figure 11.5.17: Variations in the structures within the ABC transporter superfamily ng, J., Feng, J., Yuan, D., *et al.* Tracing the structural evolution of eukaryotic ATP binding cassette transporter superfamily. *Sci Rep* **5,** 16724 (2015). https://doi.org/10.1038/srep16724. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/

The ABC transporter genes denoted as full structures have 2 TMDs and 2 NMDs while half structures have one of each. Some of the genes encode either a single NBD or a single TMD (prevalent in prokaryotes, along with half structures). The ABC2 structure has only two NBDs. The single structure represents the ABC transporter gene with a single TMD or NBD; ABC2 structure represents the ABC transporter gene with only two NBDs. The families possessing certain structures are listed on the right. TMDs typically have 6-10 transmembrane α-helices. Those that are involved in the export of chemical species have six.

Structural cartoons representing domain and ligand binding for a variety of ABC transporters are shown in Figure 11.5.18below.

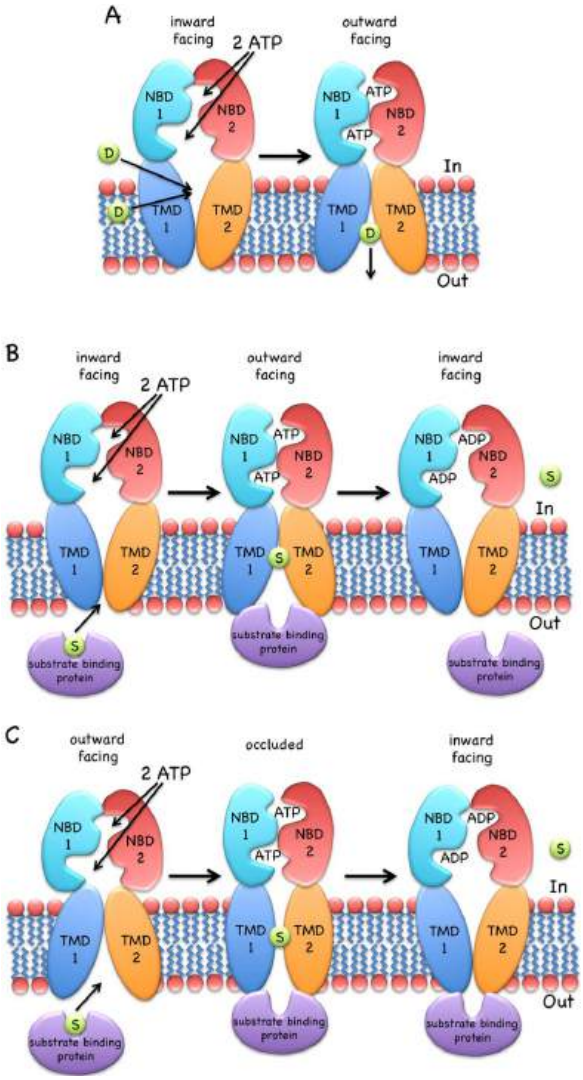

Figure 11.5.18: Domain and ligand binding for a variety of ABC transporters Structure and mechanism of ABC transporters. Stephan Wilkens. F1000Prime Reports 2015, 7:14 (doi:10.12703/P7-14). Creative Commons Attribution-Non Commercial License (http://creativecommons.org/licenses/.../3.0/legalcode).

(A) shows an inward-open drug (D) exporter. Binding of 2 ATPs cause dimer formation between the two NBD domains, resulting in a conformation change to outward facing which allows dissociation of the drug. Hydrolysis of ATP enables the release of ADP/P_i and dissociation of the 2 NBD domain, which results in conformational change to the inward-open form.

(B) shows the delivery of a substrate (S) from its binding protein (ex. part of the ABC transporter complex MalEFGK involved in maltose/maltodextrin import) in the periplasm of E. Coli for delivery into the cell.

(C) shows an outward-open variant of (B) (ex. part of the Vitamin B12 import system permease protein BtuC)

The mammalian protein multi-drug resistance (MDR), also known as P-glycoprotein, Phospholipid transporter ABCB1 or ATP-dependent translocase ABCB1**,** is an example of an ABC Transporter. It moves both drugs across the membrane as well as phospholipids, including phosphatidylcholine, phosphatidylethanolamine, ceramides, and sphingomyelins, from the inner to the outer leaflet of the membrane. The gene for this protein is often mutated in tumor cells which moves chemotherapeutic drugs from the cell.

Figure 11.5.19 shows an interactive iCn3D model of the structure of the mouse P-glycoprotein (4M2T) bound to a cyclic peptide inhibitor in the inward open conformation is shown below. Most proteins bind substrates specifically but P-glycoprotein binds them quite indiscriminately which makes this protein so useful in pumping drugs out of the cell.

11.5.4: Another look at the Nuclear Pore Complex

We examined the incredibly complicated structure of the nuclear pore in the previous section. Both small molecules and large proteins (synthesized in the cytoplasm) and RNAs (synthesized in the nucleus) move through its large pore. The movement of solutes through its gaping pore does not require either ATP cleavage in a primary active transport or the collapse of a chemical gradient in a secondary active transport process. Then why study it in this chapter section? It turns out that the regulation of the process requires **GTP** cleavage and a gradient of a particular protein called **Ran**.

What's fascinating about the nuclear pore is its selectivity for protein transfer across the pore. What proteins are allowed in and out? What is the origin of the specificity? The specificity is determined in part by a protein family called the karyopherin-βs (22) of receptors, which bind and transport nuclear proteins. There are two types of these nuclear **transport receptors or transport factors:**

- **Importins** facilitate the movement of proteins into the nucleus (ex. nuclear proteins like histones, DNA and RNA polymerases, etc).
- **Exportins** facilitate the movement of RNA (except mRNA) out of the nucleus.

Large proteins destined to be moved through the nuclear pore are called **cargo** proteins. They have a molecular signal that differentiates them from molecules that should stay in the cytoplasm or move into organelles or be secreted from the cell. The signals are called:

- **NLS** or nuclear localization sequences
- **NES** or nuclear export sequences

There is no obvious NLS consequence and different motifs are used by different cargos. A classical NLS is enriched in Lys and Arg residue. Others appear enriched in Pro-Tyr or Ile-Lys. Large domain structures might also participate in the NLSs. Prediction programs are used to identify clusters of lysines and arginines with gaps between the clusters. Classical NESs appear to be rich in leucines in an 8-15 amino acid sequence with regularly spaced conserved hydrophobic amino acids.

A third player, **RAN** (Ras-related nuclear protein), is involved that determines which way the transport receptor:cargo complex moves. Ran is a small protein that binds and can hydrolyze GTP to GDP. It is a member of the small G proteins that are GTPase.

Ran itself can run (a pun) or move across the nuclear membrane and is found in both the cytoplasm and nucleus. What determines which way a Cargo:receptor complex goes? It depends on whether GTP or GDP is bound to RAN! There are higher concentrations of RanGTP in the nucleus and lower concentrations in the cytoplasm.

- Importins bind cargo proteins with a NLS in the cytoplasm where RanGTP is low, move into the nucleus, and release the cargo protein when the abundant RanGTP displaces the bound cargo protein
- Exportins bind both a cargo protein with a NES and Ran:GTP to form a ternary Exportin:Cargo:RanGTP complex in the nucleus. This moves into the cytoplasm, where the Ran bound GTP is hydrolyzed to GDP, causing the complex to dissociate, freeing the exported cargo protein from the complex.

Importins are dimeric structures consisting of an alpha and beta subunit. The alpha subunit binds to the cargo protein through the NLS sequence on the cargo protein. The beta subunit interacts with the nucleoporin proteins (Nups) in the

These interactions are shown in Figure 11.5.21

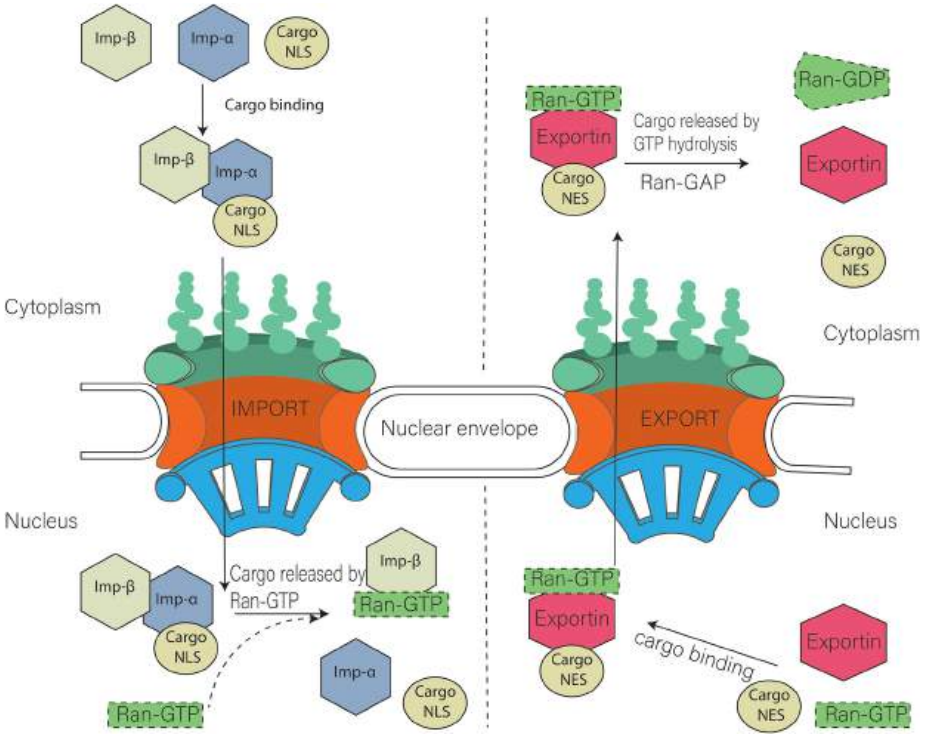

Figure 11.5.21: Model of nuclear import and export. Cargo containing NLS (Nuclear localization signal) is imported with the help of Importin α and importin β heterodimer. Nuclear export of cargo having NES (nuclear export signal) is carried out with the help of exportins. Ran GTP is also required during that process. Khan Asmat Ullah, Qu Rongmei, Ouyang Jun, Dai Jingxing. Front. Physiol., 03 April 2020 | https://doi.org/10.3389/fphys.2020.00239. **Creative Commons Attribution License (CC BY)**.

Figure 11.5.22 shows an interactive iCn3D model of the Delpi electrostatic surface potential map of the putative NLS from the carboxy-terminal of a cargo protein, the W protein of the Hendra virus (4M2T)which is imported into the nucleus.

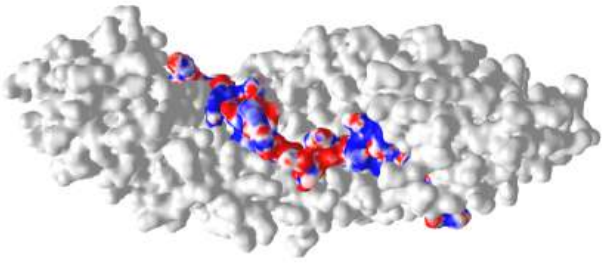

Figure 11.5.22: Delphi electrostatic surface potential map of the putative NLS from the carboxy-terminal of a cargo protein, the W protein of the Hendra virus (6BW9) which is imported into the nucleus (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...mUkDXG1KoiieTA

The virus derives from bats and has recently emerged. The peptide sequence containing the NLS has the following sequence: 419 CLGRRVVQPGMFADYPPTKKARVLLR 444. The red surface indicates the negative potential and the blue positive potential, which is associated with the Lys and Arg side chains in the consensus sequence. It is shown bound to the human importin-α3 subunit (molecular surface shown in white), which binds the NLS sequence with high affinity.

An astute reader might ask why GTP stays bound and is not cleaved into GDP in the nucleus by the intrinsic GTPase activity of Ran. It turns out there is yet another protein found only in the cytoplasm (i.e. it doesn't have a nuclear import signal), which binds to Ran:GTP and promotes GTP → GDP exchange. So oddly, hydrolysis of a nucleotide triphosphate (GTP, not ATP as in the case of most transporters discussed above) is required for nuclear import. A different but very fascinating mechanism!

The cargo complexes described above must still pass through the nuclear pore. In section 11.3 we discussed the structure of the nuclear pore which consists of many nucleoporin proteins (NUPs). The **inner ring** is called the **FG Nups layer.** The disordered parts of the inner ring Nups have repetitive sequences enriched in phenylalanine and glycine (hence the name FG Nups) and stick out into the central pore. The FG repeats can take multiple forms including Phe-Gly (FG), Gly-Leu-Phe-Gly (GLFG), or Phe-any-Phe-Gly (FXFG). These are intrinsically disordered proteins and the disordered regions in the pore act as a filter allowing certain molecules to pass and excluding those greater with molecular weights greater than 40K. Large molecules complexed to importins/exportins move through the pore. This disordered mesh prevents passive diffusion of molecules through it but allows protein complexes with cargo:exportin/importin complex through. It's a bit like electrophoresis of small protein complexes through the pores of an acrylamide or agarose gel polymerized matrix, only without the "push" of an electric field. Presumably, the FG-Nups make transient hydrophobic (induced-dipole:induced dipole) interactions between the FGs on the Nups and the nuclear transport receptors.

Figure 11.5.23 shows an **export** complex (5XOJ) from yeast of Ran (cyan with bound GTP in spacefill) bound to an **exportin** (Xpo1p, white surface) and 3 Nup42p peptides containing SxFG/PxFG repeats (spacefill, side chains, which are mostly nonpolar). To bind 3 Nup peptides, the exportin Xpo1 also contains repeating binding sites on domains called HEAT repeats 14–20 of Xpo1p, The exportin Xpo1p is shaped like a toroid with 21 HEAT repeat domains that have two antiparallel sheets with connecting loops of different sizes.

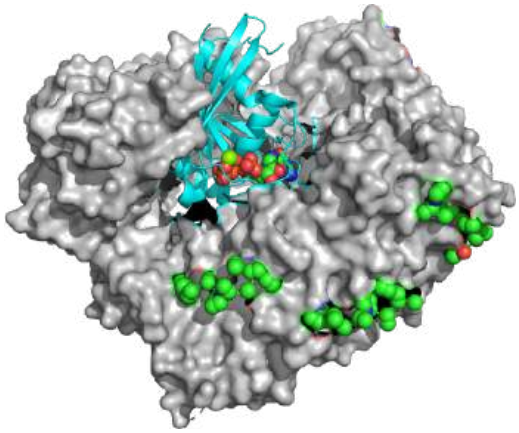

Figure 11.5.23: Yeast export complex (5XOJ) with Ran (cyan with bound GTP in spacefill) bound to an **exportin** (Xpo1p, gray surface) and three Nup42p peptides containing SxFG/PxFG repeats (spacefill, side chains))

Some believe the unfolded mesh of FGs in the core might condense on the binding of motifs on importins/exportins or through FG:FG domain associations. But what is the basis for importins/exportins interactions with the FG structures? To study it in more detail Fragasso et al designed and made an artificial FG-Nup that binds to an importin transport receptor **Kap95** that interacts with a cargo protein with a nuclear localization sequence (NLS) in cargo proteins. They attached them to the inside of solid-state nanopores and demonstrated the fast movement of Kap95 through the derivatized nanopore while a control "non cargo" without a NLS, BSA) was blocked. Underivatized nanometer-sized pores are made in a silicon nitride synthetic membrane (SiN) by using an ion or electron beam to tune the size of the hole.

Figure 11.5.24(top image) shows colored code structures of the inner ring (top of figure) snapshots of different yeast GLFG NUPs. These are named after their Gly-Leu-Phe-Gly repeating motifs and are especially cohesive. The GLFG-Nups, shown in red, are mostly found in the inner ring compared to FxFG/FG-Nups shown in green.

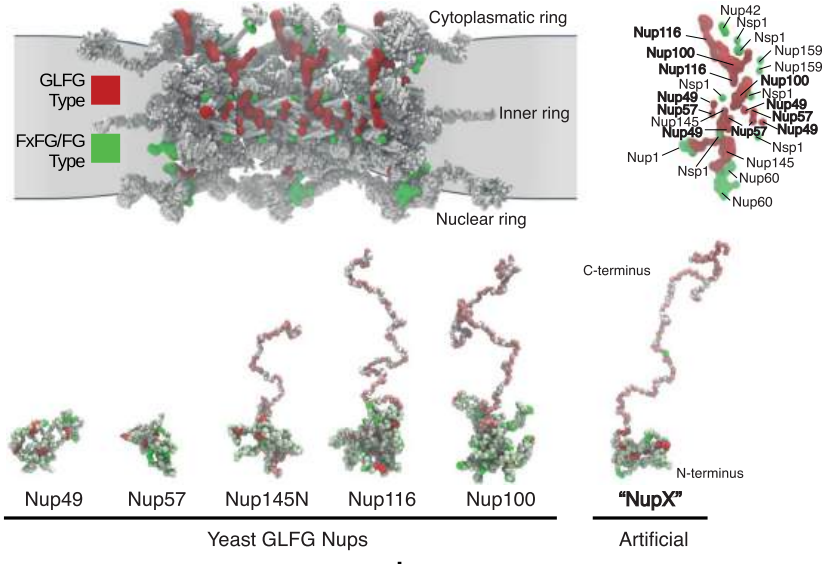

Figure 11.5.24: Inner ring (top of figure) snapshots of different yeast GLFG nups. Fragasso, A., de Vries, H.W., Andersson, J., *et al.* A designer FG-Nup that reconstitutes the selective transport barrier of the nuclear pore complex. *Nat Commun* **12,** 2010 (2021). https://doi.org/10.1038/s41467-021-22293-y. The bottom part of Figure 11.5.24shows snapshots of molecular dynamics simulations of various yeast GLFG-Nups compared to the NupX synthetic one. Three of the yeast GLFG Nups and the synthetic NupX show a compact and extended domain Each has a collapsed cohesive domain at one end (characterized by a low charge to hydrophobic amino acid residue ratio (C/H), lots of alternating FG and GLFG repeats, with light green showing non-FG/GLFG/charged residues) and an extended domain at the other end (high ratio of charged/hydrophobic amino acids, no FG repeats, pink-red showing non-FG/GLFG/charged residues). Bright green shows the FG repeats, red the GLFG repeats, and white the charged groups.

Figure 11.5.25shows the pore in the silicon nitride synthetic membrane (SiN) membrane before (left) and after derivitization with NupX.

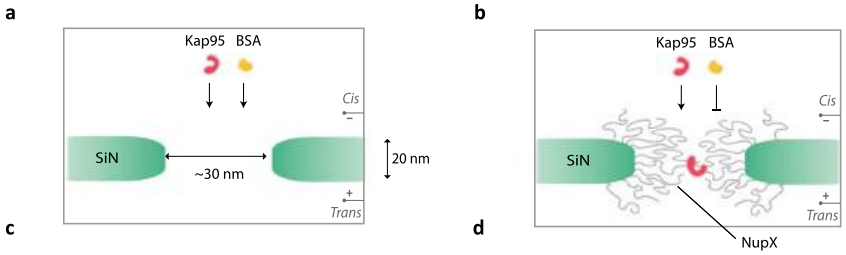

Figure 11.5.25: Pore in the SiN silicon nitride synthetic membrane before (left) and after derivatization with NupX

Figure 11.5.26shows derivatized pores in the SiN membrane of increasing size. In the smallest particle, the NupXs don't fit and are expelled from the pore. In the 30 nm particle, the NupX cohesive domains plug the hole. In the 45 nm pore, a hole appears.

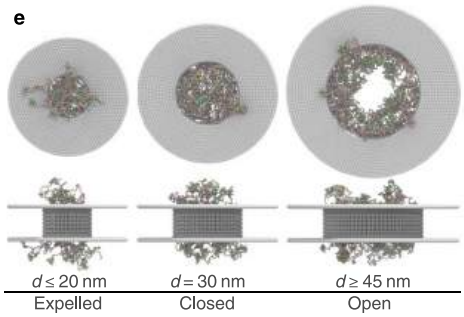

Figure 11.5.26 Derivatized pores in the silicon nitride (SiN) membrane of increasing size

Lastly, Figure 11.5.27 shows snapshots of 30 nm pores lines with NupXs. In panel c, an importin, Kap95 (spheres with orange binding spots) is shown forming transient interaction with and translocating through the NupX-lined hole. BSA (sphere without binding sites) may interact weakly but does not translocate through the pore.

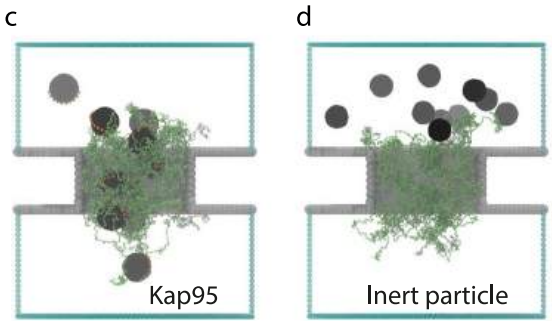

Figure 11.5.27: Snapshots of 30 nm pores lines with NupXs. and interacting with an importin, Kap95 (spheres with orange binding spots, panel C) and BSA (sphere, panel D)

11.4: Diffusion Across a Membrane - Pores

11.4.1: Pores and Pore-Forming Proteins (PFPs)

If you form a pore in a cell bilayer, molecules of all sizes could move either way based on their electrochemical potential. They will move from regions of a higher to lower electrochemical potential in a thermodynamically favorable process. Hence movement through pores represents a special case of facilitated diffusion when part of the driving force is not just a concentration gradient but also an electrical potential. Several questions might come to mind.

- What proteins are involved in pore formation?
- How is the specificity of solute movement through the pore regulated?
- What is the mechanism of pore formation?

Pore formation can lead to cell death, which is the function of some pore-forming proteins (PFPs) including the toxin Hemolysin E (also known as HlyE, ClyA, SheA) secreted from E. Coli and S. Aureus. Human proteins also form a membrane attack complex (examples include the membrane attack complex-perforin/cholesterol-dependent cytolysin (MACPF/CDC) superfamily and the membrane attack complex (MAC). The MAC consists of an assembly of proteins involved in the complement system (part of the effector branch in the innate immune system), which leads to cell death of Gram-negative bacteria like E. Coli. Figure 11.4.1 illustrates the assembly process of the membrane attack complex and the complexity of interactions required to form a lethal pore in a cell.

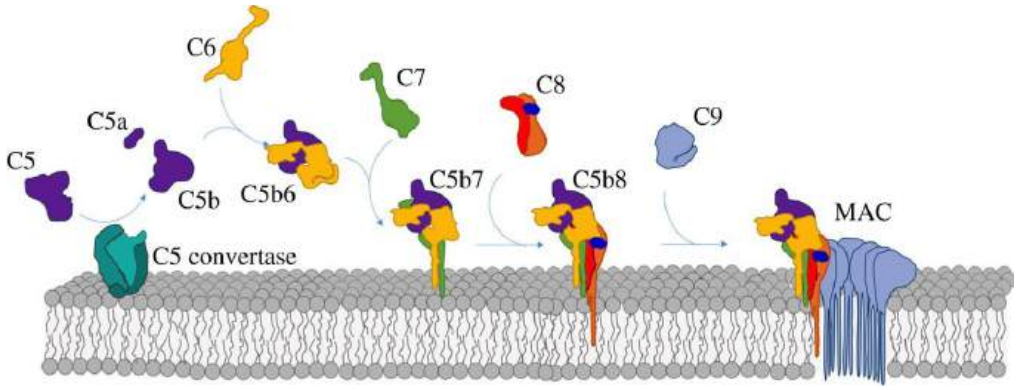

Figure 11.4.1: Human membrane attack complex. Charles Bayly-Jones et al. Philosophical Transactions of the Royal Society B: Biological Sciences, Volume 372, Issue 1726. June 2017 https://doi.org/10.1098/rstb.2016.0221. The Royal Society under the terms of the Creative Commons Attribution License http://creativecommons.org/licenses/by/4.0/

Complement protein C9 can adopt a soluble form or membrane form which in aggregates form the pore leading to cell death. This is a common feature of PFPs.

PFPs could create a pore by altering membrane lipid packing to form a toroid-like hole (Figure 11.4.2) and/or by inserting in a membrane and forming a pore within the protein complex itself. In either mechanism, lipid packing is altered.

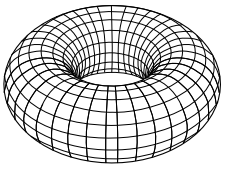

Figure 11.4.2: By GYassineMrabetTalk - Own work, CC BY-SA 3.0, https://commons.wikimedia.org/w/inde...?curid=3134923

Biophysical evidence shows some support for the formation of "toroidal pores".

Lipid rearrangements in the membrane could lead to a hydrophilic or hydrophobic pore lining as shown in Figure 11.4.3

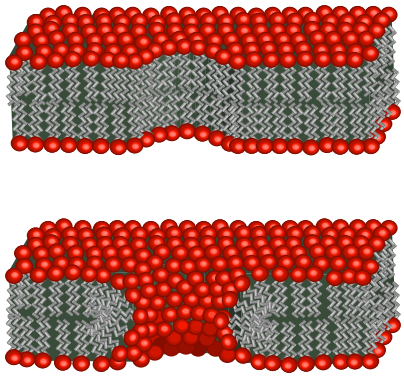

Figure 11.4.3: Diagram of possible lipid arrangements at the edge of a pore through a lipid bilayer. (above) In the absence of any rearrangement, the pore walls will be hydrophobic since the alkane tails are exposed. (below) Some researchers believe that the lipids at the edge re-orient to line the pore wall with hydrophilic head groups. Lipid bilayer. (2023, January 15). In *Wikipedia*. https://en.Wikipedia.org/wiki/Lipid_bilayer

We started our study of lipid bilayers with pure lipid systems and then added membrane proteins. Let's do the same with pore formation. A common technique to form a pore in pure lipid bilayers and also in cells is **electroporation**. This is a technique used to move a DNA with a target gene into either a prokaryotic cell (transformation) or eukaryotic cell (transfection) for exogenous gene expression. In the absence of PFPs, this requires the alteration of surface tension by applying an electrical potential. This forms depressions in the membrane, altering the nonpolar acyl chain packing. In the process, small wire-like columns of water appear, which like hydrophobic pores ultimately rearrange into hydrophilic toroidal pores. Figure 11.4.4 shows snapshots of molecular dynamics simulations as a function of the time of pore formation in electroporation.

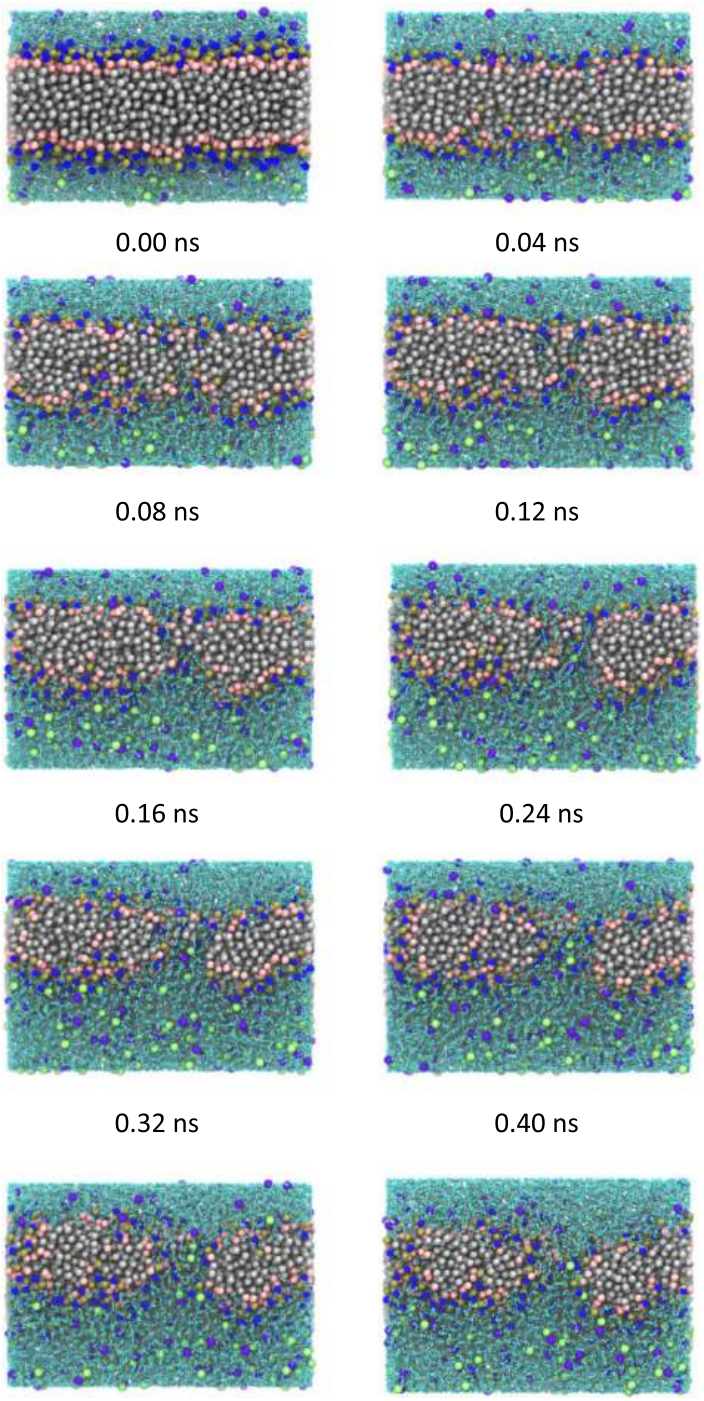

Figure 11.4.4: Zhou, C., Liu, K. Molecular dynamics simulation of reversible electroporation with Martini force field. BioMed Eng OnLine 18, 123 (2019). https://doi.org/10.1186/s12938-019-0743-1. Creative Commons Attribution 4.0 International License, http://creativecommons.org/licenses/by/4.0/

How does DNA pass through the pores in the bilayer? In pure lipid vesicles, it appears to pass through by electrophoresis. Most students are familiar with the electrophoresis of DNA fragments through pores in agarose gels. In actual living cells, small nucleic acids like small interfering RNA (siRNA) and antisense DNA molecules appear to pass through the bilayer by electrophoresis. Large DNAs like plasmids containing a gene for expression bind to the cell and form cell surface aggregates, which appear to be endocytosed into the cell. Electroosmosis, the movement of liquids under the influence of an electric field, also plays a role.

11.4.2: Pores - Outer Membrane Factor (OMF) and Voltage-Dependent Anion Channel (VDAC)

Now let's consider pores made of PFPs. We have already discussed two types of beta-barrel transmembrane proteins, the outer membrane factor (OMF) of Gram-negative bacteria and the voltage-dependent anion channel (VDAC). Both are examples of proteins called **porins** with typical beta-barrel topology.

VDAC: At low membrane potentials, VDAC (also known as mitochondrial porin), the most abundant protein in the mitochondrial outer membrane, moves metabolites and Ca^{2+} ions across the outer membrane of mitochondria. VDAC exist in an open state at 0 or very low transmembrane potentials that allows for the transfer of key metabolic anions (pyruvate, oxaloacetate, malate, succinate, ATP, ADP, and P_i, which are involved in metabolism) and Ca^{2+}, and in a closed state (above or below $\pm$ 30 mV), which is not completely closed as it allows for the transfer of ions with a preference for cations. The closed state does not allow for the transfer of ATP. The transition to the closed state is promoted by tubulin and actin (cytoskeletal proteins), negatively charged lipids such as phosphatidyl ethanolamine and cardiolipin, and also covalent phosphorylation by protein kinases. Bcl2, proteins involved in the regulation of programmed cell death (apoptosis) also interact with VDAC. In contrast to ligand-gated channels which require ligand binding to open the channel, pore complexes are unusually open. Millions of ATPs/second move across the membrane through the open pore but none through the closed pore.

Figure 11.4.5 shows an interactive iCn3D model of mouse VDAC1 (4c69) with bound ATP loosely held in the site. An alpha helix partly occludes the central pore of this β-barrel protein.

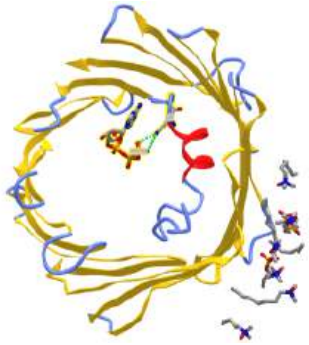

Figure 11.4.5: Mouse voltage-dependent anion channel - VDAC1 (4c69) with bound ATP loosely held in the site. (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?Ueb4wg26f5oEVL4Y9

One ATP is bound in the barrel and interacts with Lys 12 and Lys 20 at each end of the cavity-bound helix. The alpha-helix narrows the pore opening and presumably changes orientation in a voltage-sensitive fashion to gate the pore open and closed, hence regulating the conductance of ions through the pore. That the orientation of the charged arginine side chains would be dependent on the transmembrane potential should be somewhat obvious.

Aquaporins

Aquaporins can move a billion water molecules per second across membranes and exclude ions including protons. Waters proceed in a single file through the pore. Instead of moving waters through, it might simply move "H^+ ions" through by the alignment of subsequent H bond donors and acceptors in a "wire" of water molecules. This is prevented by two conserved asparagine residues in the center of the channel, which disrupt water to water hydrogen bond network in the channel waters that could facilitate proton transfer. Instead, the central waters form hydrogen bonds to the central asparagines. This, along with local membrane potentials, causes opposite orientations of the water in different leaflet sides of the membrane, precluding H^+ transfer.

Here is a movie of a molecular dynamics simulation of water moving through a porin called aquaporin, GlpF, from E. Coli.

Science magazine (Tajkhorshid et al., Science Apr 2002, 296:525). Used with permission from the Theoretical and Computational Biophysics Group, the National Institutes of Health (NIH) Resource for Macromolecular Modeling and Bioinformatics, at the Beckman Institute, University of Illinois at Urbana-Champaign.

OMF: The outer membrane factor (see previous section) is one member of a class of bacterial porins, which are the most abundant proteins in the outer membrane of Gram-negative bacteria. They are classified as non-specific or specific (with respect to the solute that passes through), or monomeric, dimeric, or trimeric based on their structure. In Gram-negative bacteria, which have two lipid bilayers, the movement of solute from inside to outside includes at least three sets of proteins. Active transport (discussed in the next section) needs an energy source and is used by inner membrane transport proteins, including ATP-binding cassette (ABC)-type, resistance nodulation division (RND)-type and major facilitator superfamily (MFS)-type transporters. These are connected to membrane fusion proteins (MFP) that span the periplasm, which then interacts with at least 21 different types of porins. Molecules with molecular weights greater than 600 generally can not get through the nuclear envelope of Gram-negative bacteria, limiting the size of potential antibiotics, which must enter by passive diffusion.

11.4.3: Mechanosensitive ion channels - Mscs (which are pores!)

As the name applies, these ion channels (with openings large enough to be called pores) are gated open/closed by mechanical (physical) changes in the properties of the membrane, not extracellular/intracellular ligands or voltage changes. Certain bilayer lipids also activate the Mscs. There are two types, small (MscS) and large (MscL) mechanosensitive ion channels. Changes in local (boundary layer) and nonlocal lipids are involved in the gating of the channel (in the next section we will discuss lipid-gated ion channels). They are found in prokaryotes, archaea ,and eukaryotes. They are also called stretch-gated ion channels.

Mcss transduces a physical force (stretching and change in turgor pressure) into an electric signal - a flow of ions across the membrane. Turgor pressure is the internal pressure that "presses" the cytoplasm and cell membrane towards the cell wall in bacteria and plant cells. It arises mostly from the osmotic flow of water into the cell. If bacterial cells are placed in a high salt concentration solution (hypertonic), water flows out of the cell and the cell membrane shrinks to the inside of the volume confined by the cell wall. When placed in a hypotonic solution, water flows into the cell and the cell membrane presses out to the cell wall. The response of these channels is fast, in the millisecond range, which is about as quick as a cellular response can be. Some variants of these channels are called **piezochannels**, based on the piezoelectric effect that describes how a voltage is produced when some materials are deformed by mechanical stress which causes a redistribution of charges.

Bacteria normally have high concentrations of both K^+ and negatively charged anions, especially glutamate, which leads to a high turgor pressure from the inward osmotic flow of water. At low external osmolarity, turgor pressure in the cell could be as high as 4 atm. If placed in external solutions of high osmolarity, bacterial cells respond by the increased movement of solutes into the cell.

Mscs are particularly important when bacteria are subjected to sudden osmotic shock. If they are placed in pure water, for example, water would flow down a concentration gradient into the cell and cause the cell to swell and lyse, killing the cell. This is done in the lab to prepare almost pure hemoglobin from ruptured red blood cells. The Mscs are opened under these conditions and small species from the cytoplasm flow out, helping to keep the cell viable. Their openings must be regulated to prevent too much outward flow, which would kill the cell.

In other organisms they are also involved in touch (stretch), hearing (vibration, sound waves), and responses to gravity. Stimuli to activate them include fluid shear stress (relevant to endothelial cells that line blood vessels), membrane stretch (relevant to skeletal and cardiac muscle cells), or even indentation of a bilayer with a pipette. Changes in transmembrane turgor or other mechanical pressures cause membrane tension. Yet even in the absence of these changes, Mscs can be activated by anesthetics, phospholipids missing one fatty acid (called lysophospholipids), and certain polyunsaturated lipids. These stimuli also perturb the membrane bilayers.

Given the pore size, these proteins are less selective to ion flow compared to voltage-gate channels (see next section). Depending on the amino acids that line the pore, some Mscs would allow the preferential flow of anions while some allow cation flow.

Some somatosensory channels (i.e. not pore) proteins also respond to pressure. When open, these can be selective to specific ions like Na^+ or K^+. Examples include some variants of the Transient Receptor Potential (TRP) ion channels. Other membrane proteins can also be activated by physical force. but true Mscs have some key characteristics. If mutated or deleted, the mechanosensory response is removed. If added to a cell, a mechanosensory response results.

a. Small-conductance mechanosensitive channel

This protein is a homoheptamer with three helices from each monomer involved in the overall structure. Two (helices 1 and 2) interact more with the lipid components of the bilayer. Interactions of specific lipids with the helices seem to promote closing but changes under high pressure lead to the opening of the pore. Half of each helix 3 forms the pore, while the other half is more parallel to the membrane and interacts with a large cytoplasmic domain.

Figure 11.4.6 shows the differences between the closed form of E. Coli MscS (2oau) and the open form (2vv5) viewing down the pore axis. The heptameric protein is shown in gray. Two key valines (105 and 109) on each chain are shown in spacefill and colored cyan. These hydrophobic amino acids act like gate-keepers, helping to keep water out, acting like a "vapor seal". In the closed state, the pore is sealed by the closing of the leucine "rings" as one half of helix 3 pack more closely. Many members of the MscS family vary significantly in size and can have between 3-11 transmembrane regions. The closed pore has a diameter of about 4.8 Å, while the open pore is 13 Å across.

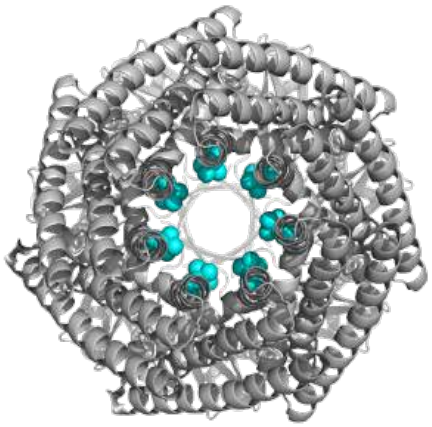

Figure 11.4.6: Differences between the closed form of E. Coli MscS (2oau) and the open form (2vv5) viewing down the pore axis.

Most of you would have studied Ohm's law, given by

$$\mathrm{V} = \mathrm{IR} \text{ or } \mathrm{I} = \frac{\mathrm{V}}{\mathrm{R}} \tag{11.4.1}$$

where I (amps) is the current, R (ohms) is the resistance and V (volts) is the voltage. A more general variant of this law used in physics is

$$\mathrm{J} = \sigma \mathrm{E} \tag{11.4.2}$$

where J is the current density, E is the electric field, and σ is the conductivity (inverse of resistance) which depends on the material. The unit of sigma σ is $ohms^{-1}$ or mhos (ohm written backward). That unit has been renamed the Siemen (S). Mscs channels have a small conductance of approximately 1 nS in 400 mM salt solution.

b. Large conductance mechanosensitive ion channel (MscL):

The channels have large conductances (3 nS) and concomitantly larger pore sizes, allowing the flow of water, ions, and even small proteins. Again they are involved in diffusion down an electrochemical gradient through pores so not active transport just gated diffusion.

Figure 11.4.7 shows an interactive iCn3D model of the pentameric MscL from Mycobacterium tuberculosis (2oar), a Gram-positive bacteria that causes tuberculosis. About 23% of the world's population is affected by this pathogen. It causes about 1.5 million deaths each year. Compare this to the total number of deaths during the COVID pandemic (2020-21) of over 3 million (as of May 2021). It has killed over 1 billion people throughout human history (but not as many as malaria). The pore diameter is about 30 Å across.

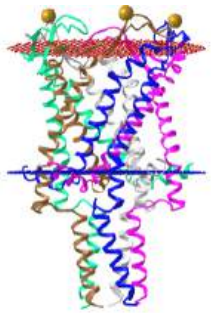

Figure 11.4.7: Closed state of the pentameric MscL from Mycobacterium tuberculosis (2oar). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...LsRZZbmFy5NRF6

11.4.4: Pore-forming alpha-helical toxins

We started this chapter section with a discussion of the major attack complex (MAC) of the innate immune system. Pathogens also employ pore formation to kill host cells. Many secrete soluble proteins which aggregate in the membrane to form either alpha-helical or beta-barrel pores. The proteins are called pore-forming toxins (PFTs). Killing occurs when either cytoplasmic components leak out or bacterial toxins, such as diphtheria and anthrax toxin, move into the cell.

Figure 11.4.8 shows an interactive iCn3D model of the pore formed by cytolysin A (ClyA, also known as HlyE), an alpha-PFT used by some E. Coi and Salmonella enterica strains. The pore is a large dodecamer that forms from soluble monomeric ClyA (2wcd). It has a pore diameter of about 40 Å,

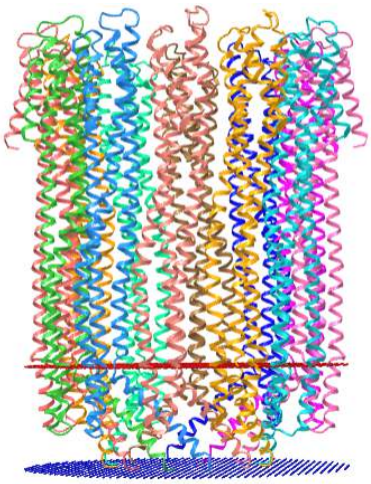

Figure 11.4.8: Pore formed by cytolysin A (ClyA, also known as HlyE). (2wcd) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...RXUsE24d9d8NT6

Figure 11.4.9 shows the soluble monomeric form of cytolysin A (ClyA, HlyE) (1QOY). Nonpolar side chains are shown in cyan. The transparent surface is mostly polar, making the monomer soluble.

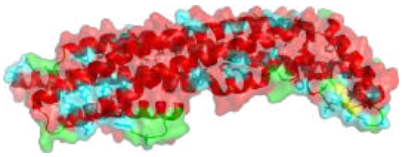

Figure 11.4.9: Soluble monomeric form of cytolysin A (ClyA, HlyE) (1QOY)

Figure 11.4.10 shows the changes in conformation between the single chain soluble form (shown in the figure above) and a single chain of the membrane oligomeric channel.

Figure 11.4.10: Changes in conformation between the single chain soluble form and the same chain in the channel

We started this chapter section by exploring electroporation and the formation of a toroidal-like hole in the lipid bilayer. In the case of ClyA, the protein aggregate itself forms the pore, not the lipids themselves, although lipid rearrangements are necessary to form the protein complex.

11.4.5: Gap Junctions

Connexins are voltage-gated channels that allow for the flow of ions, metabolites, nucleotides, and small peptides. A connexin has four transmembrane helices and two extracellular loops, Six protomers of these come together in a single cell to form a channel complex called a **connexon** or hemichannel. Beta structures in the connexin hemichannel of one cell docks with a similar channel on an adjoining cell to form a full channel passing through the membranes of both cells forming a gap junction between the cells. This is shown in Figure 11.4.11. There are 20 different connexins encoded in the human genome.

The left figure below shows the six protomers, each in a different color and a gray rectangle representing the bilayer of a single connexon or hemichannel. The right side of the figure shows a full gap junction channel between two cells, with the membranes represented by gray rectangles. The connexin 26 monomer was used to create the diagram. Mutations in this protein are associated with hearing loss.

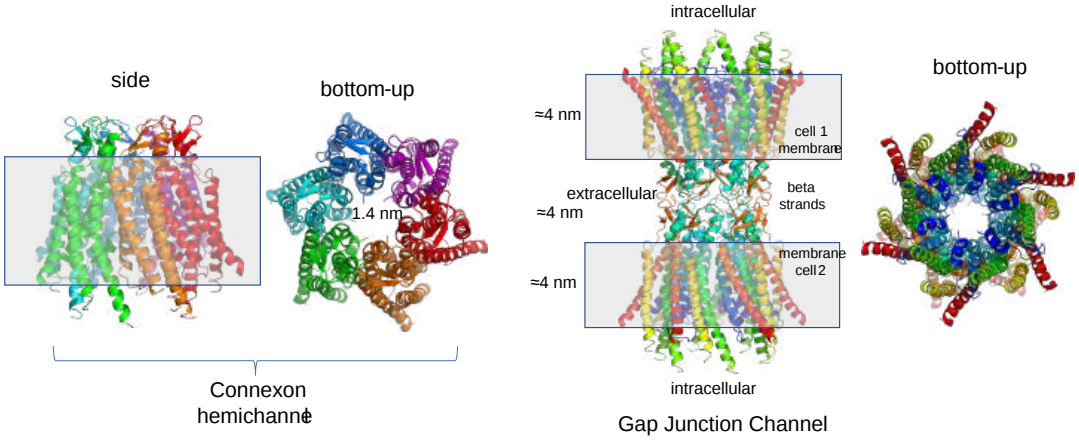

Figure 11.4.11: Connexon channel and the gap junction

The left figure above shows the six protomers, each in a different color and a gray rectangle representing the bilayer of a single connexon or hemichannel. The right side of the figure shows a full gap junction channel between two cells, with the membranes represented by gray rectangles. The connexin 26 monomer was used to create the diagram. Mutations in this protein are associated with hearing loss.

The cytoplasmic entrance of the channel is positively charged. It forms a funnel, composed of 6 amino-terminal helices, which leads into a negatively charged transmembrane lining. The entrance diameter is 14 Å.

Here is a model of a full gap junction channel connecting two membranes using the human connexin 26 monomer (2zw3). Only the bottom membrane bilayer is represented by red and blue dummy atoms.

Figure 11.4.12 shows an interactive iCn3D model of a full gap junction channel connecting two membranes using the human connexin 26 monomer (2zw3). Only the bottom membrane bilayer is represented by red and blue dummy atoms.

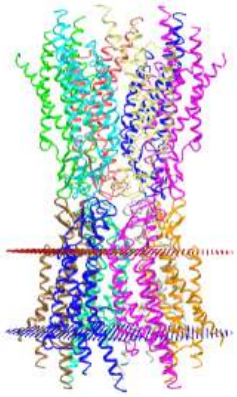

Figure 11.4.12: Gap junction channel connecting two membranes using the human connexin 26 monomer (2zw3). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?TpuQ6Agk8XWuApsWA

11.4.6: The Nuclear Pore Complex (NPC)

Channels have pores that can be gated open and allow the selective flow of ions. Pore-forming proteins have larger entrances that allow both small and large molecules to pass through the bilayer. The pore opening in even large mechanical sensitive channels (about pale in size compared to the nuclear pore complex, which has a combined molecular mass of around 125,000,000! Its outer diameter of ~1,200 Å and its inner one of about 425-Å. Figure 11.4.13 shows the relative size of nuclear pore compared to other molecular structures including the eukaryotic ribosome, nucleosome, a soluble tetrameric protein (rubisco, 270K), and MscL (shown as a circle which represents the pore diameter).

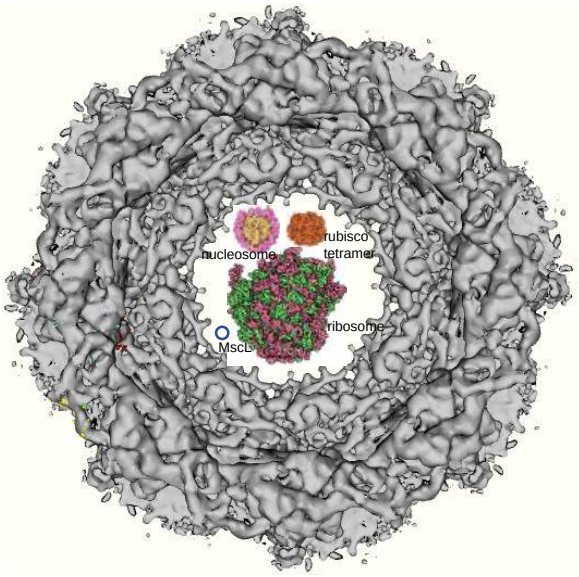

Figure 11.4.13: Relative size of nuclear pore compared to other molecular structures including the eukaryotic ribosome, nucleosome, a soluble tetrameric protein (rubisco, 70K) , and MscL (shown as a circle which rrepresentsthe pore diameter)

Its job is to shuttle small molecules by passive diffusion down a concentration gradient through the pore. In addition, it moves large molecules and molecular structures (proteins, RNA, and perhaps ribosomes) across the nuclear membrane in a process that requires energy. The proteins that comprise this complex are called **nucleoporins (nups)**, of which there appear to be around 34 in humans. Each NPC complex contains around 1000 **nucleoporins**. The complex fuses the inner and outer nuclear membranes.

We have focused so much on single bilayer membranes that comprise the plasma membrane and membranes of organelles like the Golgi complex and lysosomes, it might come as a surprise (perhaps not to biology students) that the nuclear membrane or envelope appears to consist of two bilayers. Most know that the mitochondria have two bilayers, an inner and outer membrane, similar to Gram-negative bacteria. Mitochondrial are believed to have arisen from bacteria so the double bilayer there makes sense. Figure

11.4.14shows the nuclear membrane or envelope of two bilayers (1) with an outer ring (2), spokes (3), a basket (4), and filaments (5). The NPC spans both bilayers.

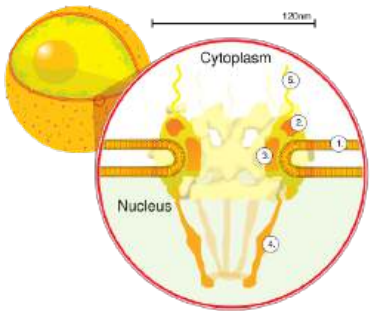

Figure \(\PageIndex{14\): Nuclear membrane or envelope of two bilayers (1) with an outer ring (2), spokes (3), a basket (4) ,and filaments (5) https://en.Wikipedia.org/wiki/File:N...e_crop.svg.png; Creative Commons Attribution-Share Alike 2.5 Generic

The outer bilayer of the nuclear envelope is continuous with the endoplasmic reticulum as shown in Figure \(\PageIndex{15\) below. The dots on the ER membrane are ribosomes, making this the rough ER (as opposed to smooth ER, which has no attached ribosomes).

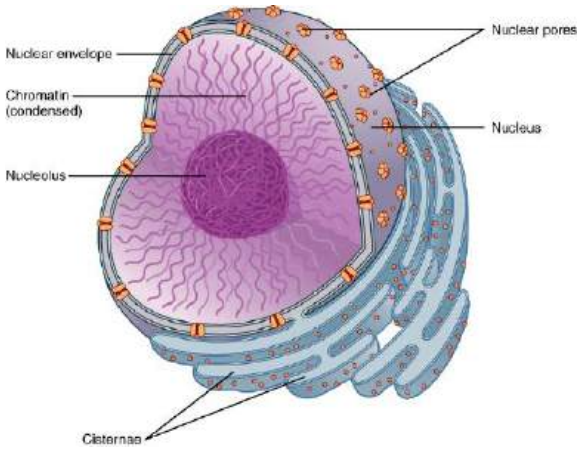

Figure \(\PageIndex{15\): The outer bilayer of the nuclear envelope is continuous with the endoplasmic reticulum https://commons.wikimedia.org/wiki/F...18_Nucleus.jpg; OpenStax, CC BY 4.0 <https://creativecommons.org/licenses/by/4.0>, via Wikimedia Commons

Figure \(\PageIndex{16\) below shows a model of the basket-like structure of the nuclear pore complex (NPC). It, as well as Figure XX, shows that instead of two separate bilayers, in actuality, there is just one bilayer with each leaflet bending around at the NPC and reversing directions! Think of the interesting lipids and protein components that enable the bend! Alternatively, you could say that 2 different membranes fuse at the NPC.

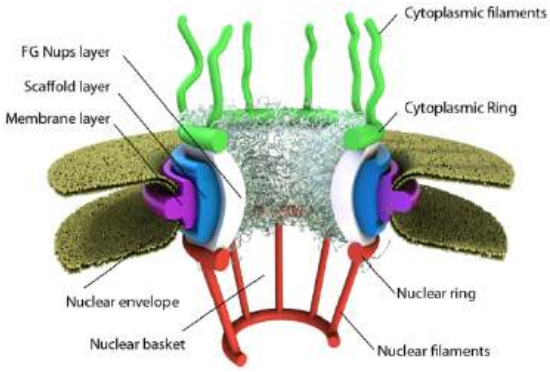

Figure \(\PageIndex{16\): A model of the basket-like structure of the nuclear pore complex **Citation:** Azimi M, Mofrad MRK (2013) Higher Nucleoporin-Importinβ Affinity at the Nuclear Basket Increases Nucleocytoplasmic Import. PLoS ONE 8(11): e81741. https://doi.org/10.1371/journal.pone.0081741. Creative Commons Attribution License,

The NPC consists of 32 copies of each specific nucleoporin (Nup) except two. One of those has 48 copies and the other 16 (even these sum to 2x32 Nups). Three rings form and surround the pore. There is a 16-membered ring of Nups facing the cytoplasm

(**cytoplasmic ring**) and another 16-membered ring of Nups facing the nucleoplasm (**nuclear ring**). There is 8-fold rotational symmetry in each ring, suggesting a dimeric repeat of Nups in the rings. Eight Nups in the cytoplasmic ring have a disordered end that sticks out into the cytoplasm as filaments. In contrast, the disordered ends of eight Nups in the nuclear ring form filaments which bind together to form a ring at the bottom of the nuclear basket.

The **inner ring** (called the **FG Nups layer** in the figure above), between the cytoplasmic and nucleoplasmic rings, also consists of Nups with ordered domains and disordered parts. The disordered parts of the inner ring Nups have repetitive sequences enriched in phenylalanine and glycine (hence the name FG Nups) and stick out into the central pore. These disordered region act as a filter allowing certain molecules to pass and excluding those greater with molecular weights greater than 40K. Large molecules need transport proteins called karyopherin transport factors to move through the pore.

The core structure of the NPC, obtained through cryoelectron microscopy, is shown in Figure \(\PageIndex{17}\) below.

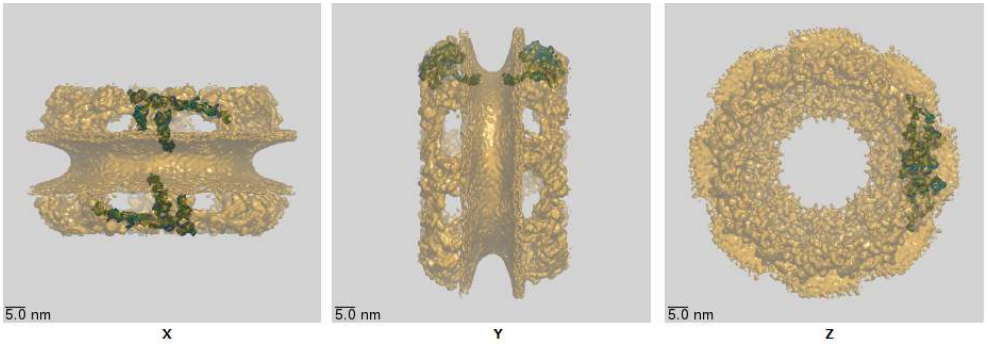

Figure \(\PageIndex{17}\): The core structure of the Nuclear Pore Complex https://www.ebi.ac.uk/pdbe/entry/emd...-3103/analysis

The double bilayers are very evident. The nuclear and cytoplasmic filaments, as well as the disordered FG repetitive sequences that stick into the pore from the inner ring, are not seen since they are very flexible and don't' adopt single conformations using standard structure determination methods.

Figure 11.4.18 shows an interactive iCn3D model of the nuclear pore complex (NPC) core (5a9q), whose structure was obtained using cryoelectron microscopy. (load slowly)

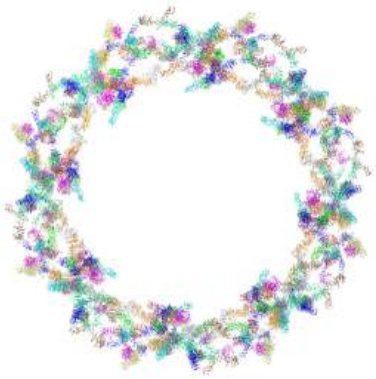

Figure 11.4.18: Nuclear pore complex (NPC) core (5a9q). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?NP7oQb235BCgPARA8

A cartoon figure showing the variety of Nups in the NPC is shown in Figure 11.4.19

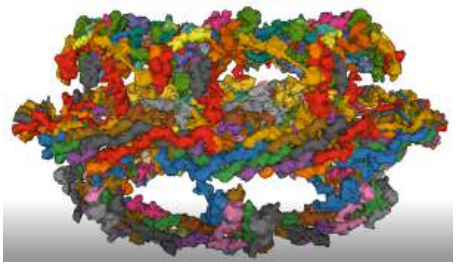
Figure 11.4.19: A cartoon version of the various NUPS in the nuclear pore complex. Donnaloja F., Jacchetti E., Soncini M., Raimondi M. T.Front. Physiol., 12 July 2019 | https://doi.org/10.3389/fphys.2019.00896**Creative Commons Attribution License (CC BY)**.

In this figure, the cytoplasmic and nucleoplasmic rings are both shown in green, each mostly formed by 16 copies of the Y-complex, arranged in two eight-membered rings. The inner ring, predominantly formed by 32 copies of the Nup93 complex is shown in red. Transmembrane nucleoporins are depicted in violet, and the cytoplasmic filaments and nuclear basket structure are in orange. Attached to the inner ring are Nup62 complexes (depicted in blue), which form a cohesive meshwork within the central channel through their FG-repeat domains. Not indicated is the position of Nup98, a FG-repeat-containing nucleoporin important for

the transport and exclusion function of NPCs; its position in the NPC is less defined, but it might be part of the inner ring. Similarly, Aladin (also known as AAAS), Gle1, Rae1, and Npl1 (also known as hCG1 and NUPL2) have been omitted.

Large proteins and RNA that pass through the pore must first be bound to a cargo receptor, which can move the "cargo" across the pore with concomitant GTP hydrolysis. This is a process that is closer to active transport so we will discuss that in Chapter 11.3.

The entire nuclear pore complex was solved in 2022 using cryoEM. Here are two videos showing the dilated complex (7R5J). Click on the images to download mp4 animations of the complex.



CHAPTER OVERVIEW

12: BIOENERGETICS AND BIOCHEMICAL REACTION TYPES

12.1: Biochemical Reactions and Energy Changes
12.2: Phosphoryl Group Transfers and ATP
12.3: The Chemistry and Biochemistry of Dioxygen
12.4: Biological Oxidation-Reduction Reactions

12.1: BIOCHEMICAL REACTIONS AND ENERGY CHANGES

12.1.1: INTRODUCTION

We have already discussed How Enzymes Work and Enzymatic Reaction Mechanisms in great detail in Chapter 6. Here we will focus on a lighter, less granular review of some key reaction mechanisms and the changes in Gibb's free energy associated with them, both in an uncatalyzed and enzyme-catalyzed reaction. Consider it a simple review of very basic organic reactions and thermodynamics in preparation for the comprehensive focus on reaction mechanisms in Unit 2: Bioenergetics and Metabolism.

12.1.2: BREAKING C-X BONDS

Many of the organic reactions involved in metabolism involve making and breaking bonds to carbon. There are three ways to break a bond to a C-X bond, producing either a carbocation, carbanion, or free radical intermediate, all of which are unstable and reactive, as illustrated in Figure 12.1.1. Both the carbocation and free radical are electron deficient, and the carbanion, although not electron deficient, has a negative on C, an atom that has a relatively low electronegativity.

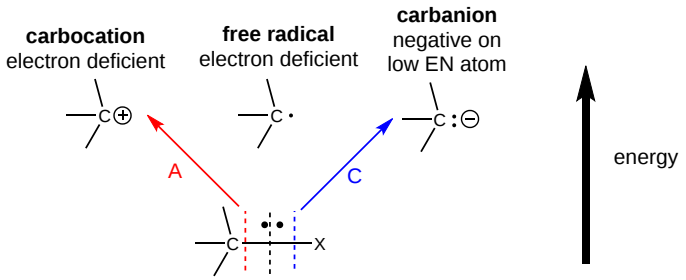


Figure 12.1.1: Ways to break a C-X bond

These unstable intermediates are higher in energy than the reactants, and hence the transition state, which is even higher in energy than the intermediates, must have a structure that resembles the intermediates more than the reactants, as shown in Figure 12.1.2. For the charged carbanion and carbocation intermediates, there is a developing charge in the transition state.

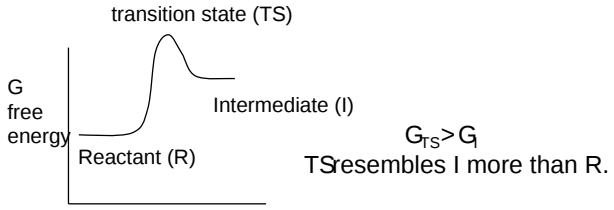

Figure 12.1.2: Gibb's free energy of reactants, transition state, and intermediate in breaking a bond.

The thermodynamics of the reactions is determined by the change in free energy between the intermediates and the reactants, while the kinetics of the reaction is determined by the difference in free energy between the transition states and the reactants, as shown in Figure 12.1.3. A catalyst lowers the energy of the transition state without affecting the energies of the reactants or intermediates (assuming that these are free and not bound to the catalyst.

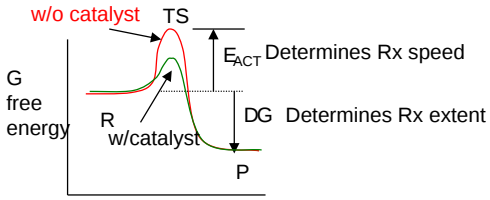

Figure 12.1.3: Activation energy and ΔG for a simple uncatalyzed and catalyzed reaction

The free energy diagram shown in Figure 3 is very simplistic. We need a diagram that better fits an enzyme-catalyzed reaction, using the simple reaction equation below.

$$E + S \leftrightarrow ES \rightarrow EP \leftrightarrow E + P$$

A free energy diagram taking into account the binding of E and S followed by the conversion of bound S to bound and then the free product is shown in Figure 12.1.4.

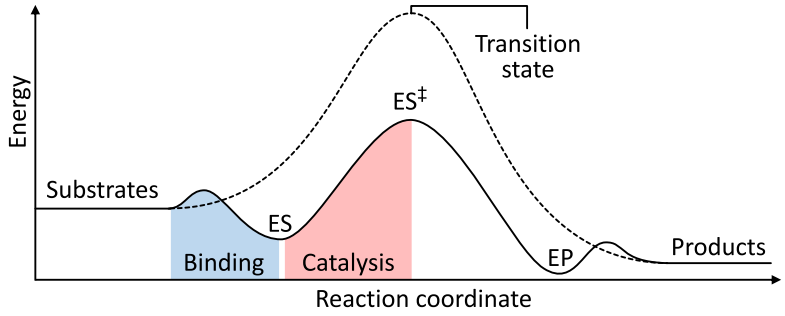

Figure 12.1.4: Simple free energy curve for the conversion for the enzyme-catalyzed conversion of substrate to product. https://commons.wikimedia.org/wiki/F...y_levels_2.svg

Even this diagram is overly simplified since it suggest that the bound substrate in the ES complex is converted to the bound product in one step with no intermediates.

The free energy diagram should include intermediates along the reaction pathway. An example of this is shown in Figure 12.1.5 for the reversible conversion of a 3-carbon sugar, dihydroxyacetone phosphate (DHAP) to another 3-carbon sugar, glyceraldehyde-3-phosphate, in a reaction catalyzed by the enzyme triose phosphate isomerase (we will study enzyme in the next chapter).

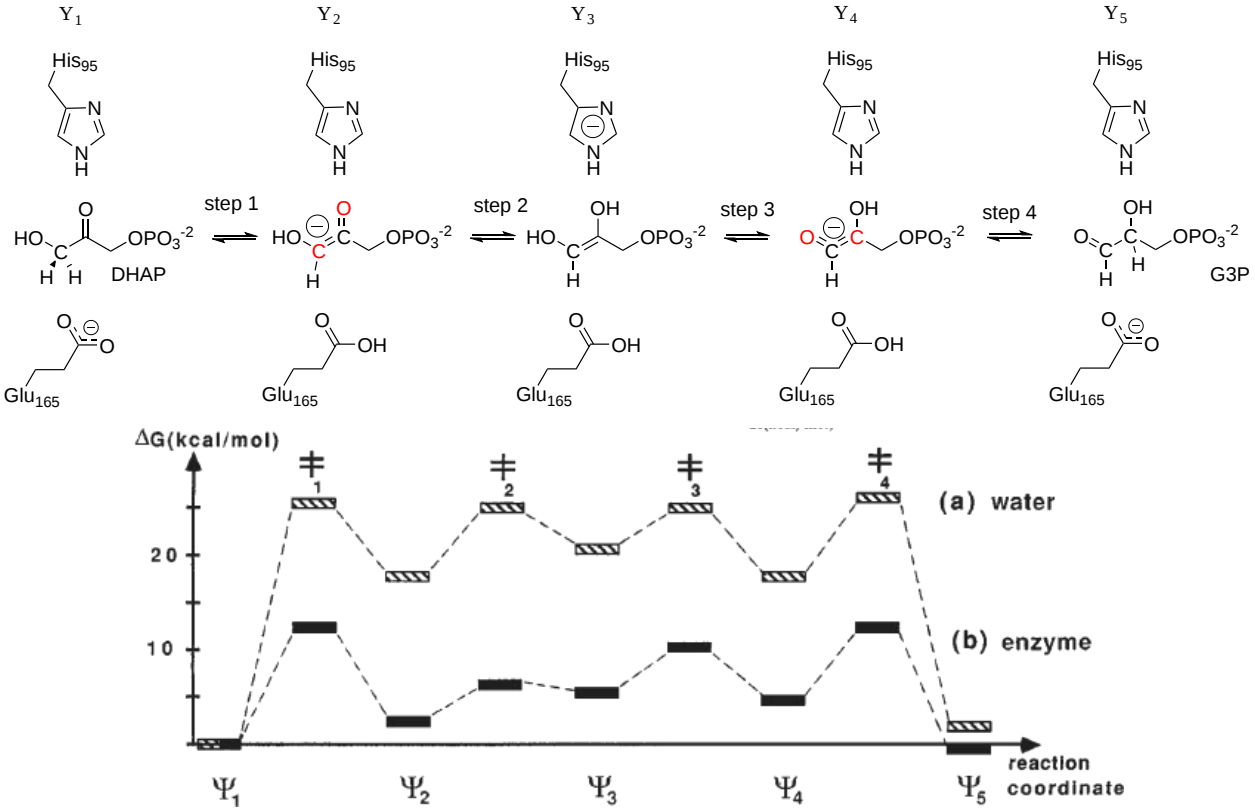

Figure 12.1.5: Complete free energy profile for all the elementary steps of the triosephosphate isomerase catalyzed reaction. Aqvist J, Fothergill M. Computer simulation of the triosephosphate isomerase catalyzed reaction. J Biol Chem. 1996 Apr 26;271(17):10010-6. doi: 10.1074/jbc.271.17.10010. PMID: 8626554. Creative Commons Attribution (CC BY 4.0)

Note that the enzyme lowers the activation energy of each of the steps in the overall reaction. Enzymes can also catalyze reactions by altering the reaction pathway although in this case, all the intermediates in the conversion are the same in both the uncatalyzed and catalyzed pathways.

A comparison of the thermodynamic reactivity of molecules of similar structures can be made by determining the relative stability of the reactants and products from structural considerations. Consider two reactants, R_1 and R_2, which produce products P_1 and P_2, respectively. Any structural features that preferentially stabilize R_2 compared to R_1, or P_2 compared to P_1, but don't stabilize R_2 and P_2 to the same extent, will lead to a greater driving force for $R_2 \rightarrow P_2$ compared to R_1. This is shown graphically in Figure 12.1.6:

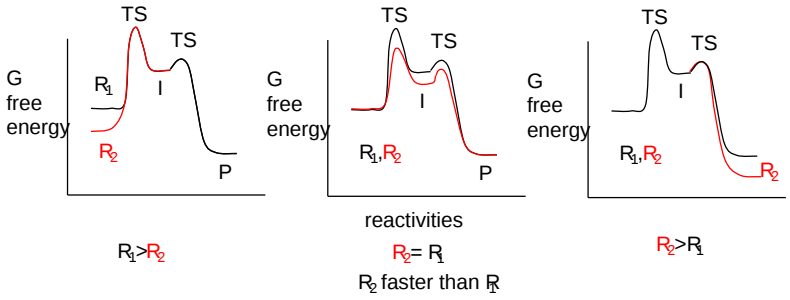

Figure 12.1.6: Free energy reaction digrams for two similar molecules

Mechanisms that lead to the stabilization of a reactant, intermediate, or product include resonance and inductive effects (electron release or withdrawal).

An example of how the comparative acidity of two similar molecules can be determined through a comparison of their structures is shown below for acetic acid and ethanol is shown in Figure 12.1.7.

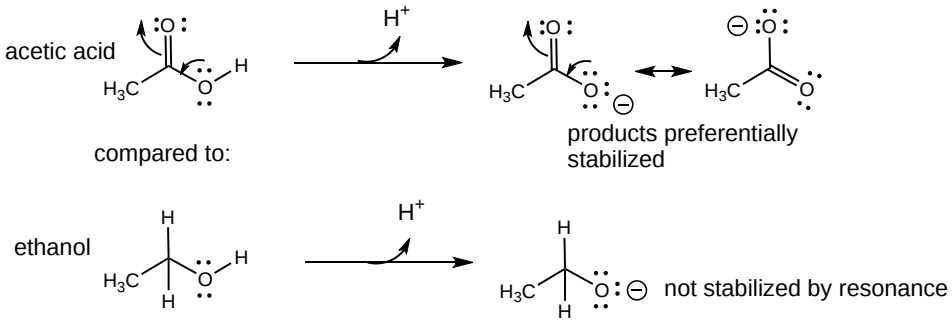

Figure 12.1.7: Comparative acidity of two similar molecules

The stronger acid, acetic acid, has the more stable (and hence less basic) charged product (the conjugate base)

An example of how an intermediate can be stabilized through resonance is shown in Figure 12.1.8 for the keto-enol tautomerization reaction, which is favored in the direction of the keto form, a weaker acid than the enol.

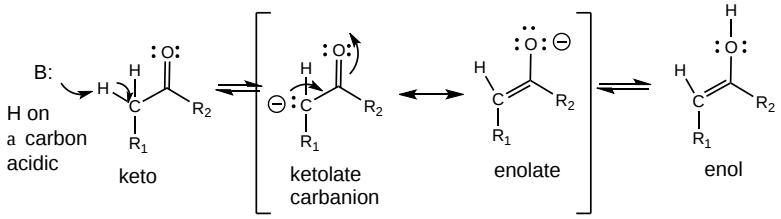

Figure 12.1.8: Comparative stability of keto and enol intermediates

An example of how the inductive effect (electron release and withdrawal) stabilizes/destabilizes carbocations and cations is shown in Figure 12.1.8.

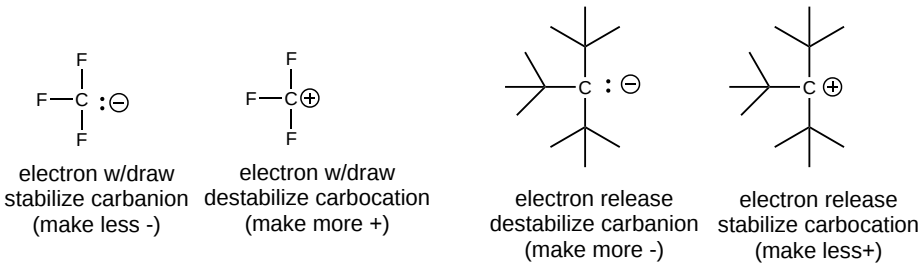

Figure 12.1.8: Factors contributing to stabilization of carbocations and carbanions

Also, remember that electron-withdrawing by the F's in the negatively charged conjugate base of trifluoracetic acid helps explains its lower pKa compared to acetic acid.

Lastly consider how the stabilization of a tertiary carbocation below helps explain the preferential formation of the tertiary alcohol over the secondary alcohol, as shown in Figure 12.1.9.

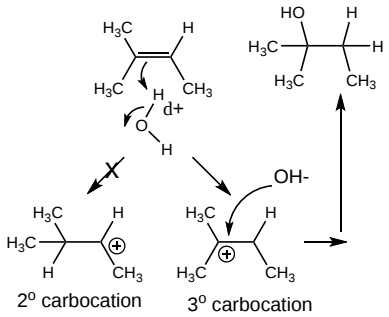

Figure 12.1.9: Preferential formation of tertiary alcohol

12.1.3: OXIDATION OF ORGANIC MOLECULES

Organic molecules are usually oxidized in two-electron steps. Two methods can be used to determine if a C atom in an organic molecule has been oxidized.

- If the number of bonds from C to oxygen increase, or the number of bonds to H decrease, the C is oxidized, More generally, if the number of bonds from C to a more electronegative atom increases, or the number of binds from C to a less electronegative atom decrease, the carbon is oxidized
- A more powerful method involves determining the oxidation number of the carbon atoms in the reactant and product. If the oxidation number becomes more positive, the C is oxidized.

The general rules for determining the oxidation numbers of the atoms in a molecule are:

1. O is generally 2-
2. H is usually 1+
3. in molecules consisting of one type of atom, (like O2) - i.e. a polyatomic element, the atoms have an oxidation number of 0.
4. the sum of the oxidation numbers of the atoms in a molecule equals the net charge on the molecule or ion.

In general, the oxidation number can be calculated as follows:

1. assign all nonbonded electrons of an atom to that atom
2. assign all bonded electrons to the more electronegative atom of the two atoms bonded
3. assign one electron of a bond to each atom if the two atoms are identical.
4. sum up the assigned electrons from 1-3. Subtract this number from the total number of electrons usually present in the outer shell of the atom (the group number). The result is the oxidation number.

An illustration of the sequential two-step oxidation of ethane to acetic acid and assigned oxidation numbers are shown in Figure 12.1.10.

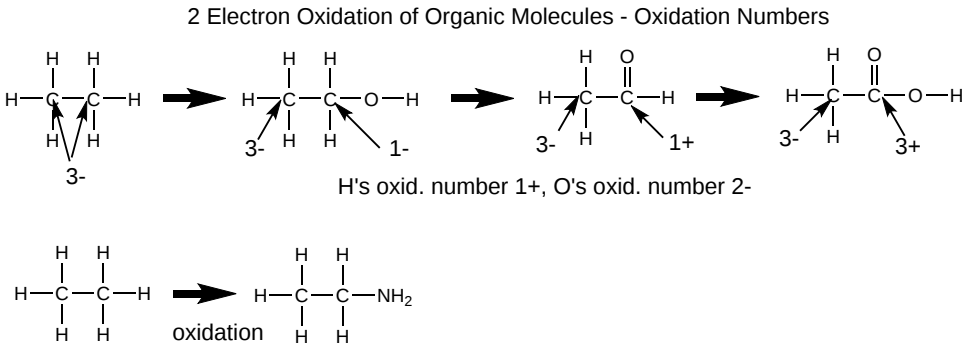

Figure 12.1.10: Change in oxidation number on the stepwise conversion of ethane to acetic acid

Reactions of Carbonyls: Aldehydes and Ketones

When water reacts with an aldehyde in a nucleophilic addition reaction, a 1,1 diol, or a geminal diol results. This reaction can be catalyzed by a base, which acts as the nucleophile (it's a stronger nucleophile than water) and adds to the carbonyl C. OH- is regenerated when the alkoxide produced abstracts a proton from water, regenerating OH-.

When an alcohol adds to an aldehyde or ketone, a hemiacetal or hemiketal, respectively, is formed. In the presence of an acid catalyst, the acid protonates the carbonyl oxygen, making the carbonyl more electrophilic. After the alcohol adds and forms the hemiacetal or hemiketal, the acid can protonate the OH group, leading to its expulsion as water in an acid-catalyzed elimination. The carbocation or resonant-form oxonium ion can react with another ROH to form an acetal or ketal. These steps are summarized in Figure 12.1.11.

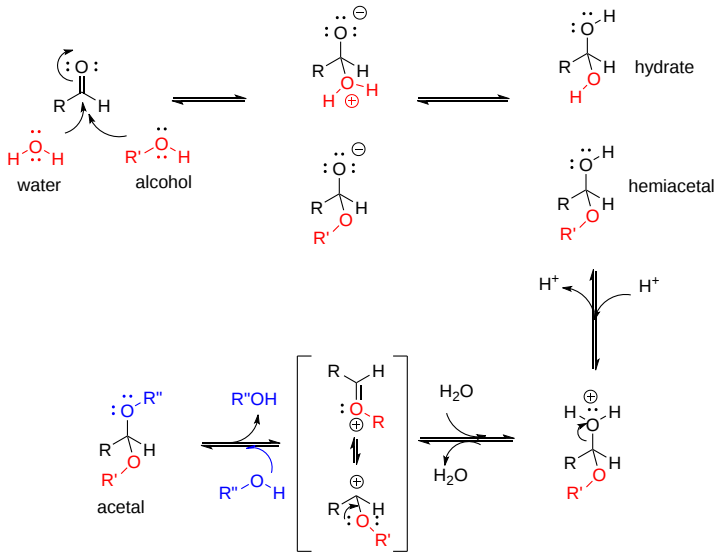

Figure 12.1.11: Nucleophilic addition to an aldehyde

If the nucleophile is an amine, an addition can occur, followed by an elimination to form an imine or Schiff base, as shown in Figure 12.1.12.

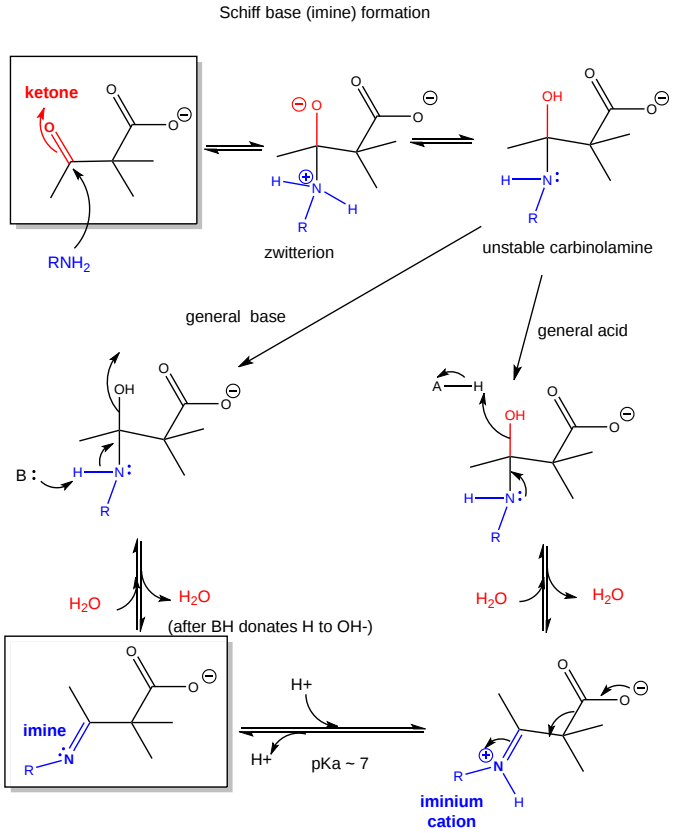

Figure 12.1.12: Schiff base formation

An acetal or ketal are geminal ethers (as water addition to aldehydes or ketones produced geminal diols). As with other ethers, these geminal ethers are stable to base and are hence often used as protecting groups to keep aldehydes and ketones from undesired reactions in

basic solution. Acetal formation is favored by excess anhydrous alcohol in acetic conditions, while acetal breakdown is accelerated by high concentrations of water and the presence of an acid catalyst.

Why are ethers and hence acetals/ketals resistant to bases? They are resistant to nucleophilic attack, such as by base, since the expelled group (alkoxide) is unstable. (Epoxides, in contrast, will react with OH- nucleophiles since the epoxide ring is strained and of high energy.). Ethers can react with acids, however, which protonate the ether O to form an oxonium ion. Nucleophilic attack (such as by Br-) on an adjacent C can occur (S_N2), with electrons flowing to the protonated oxonium ion (a great electron sink) as it departs.

12.1.4: REACTIONS OF CARBOXYLIC ACID DERIVATIVES

Carboxylic acids undergo nucleophilic substitution reactions, assisted by the fact that compared to aldehydes and ketones, they have good leaving groups. With the substitution reaction, the stability of the double bond in the carbonyl is retained. Two things control the reactivity of these derivatives: the stability of the reactants and the stability of the products. The relative reactivity of carboxylic acid derivatives is shown in Figure 12.1.13.

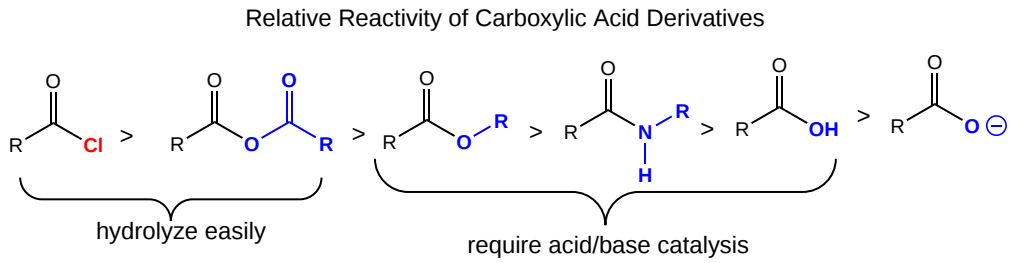

Figure 12.1.13: Relative reactivity of carboxylic acid derivatives

A reactant is less reactive if stabilized by resonance. Hence the relative reactivity is as follows: amide < ester < anhydride < acid chloride

The nonbonded electron pair on N of the amide, a less electronegative atom than O, can delocalize and form a resonant structure with a double bond with the carbonyl C more readily than the O in the ester. An electron pair on the bridging O in the anhydride, since its ability to form a double bond in a resonance structure, is split between the two carbonyls C is less effective in stabilizing either side than in the. (This is called competing resonances.) The reactant less stabilized by resonance is the acid chloride since a nonbonded pair of electrons on the larger chlorine molecule can't delocalize as readily given the C-Cl bond distance.

Notice this order of decreased stability based on resonance stabilization is also the order of increased electrophilicity of the carbonyl C (which is most electrophilic in the absence of electron delocalization from the adjacent N, O, or Cl.

The stability of the products also is important. If the deprotonated leaving group is considered as one of the products (which differentiates the different reactions), then the order of decreased stability of products is Cl^- > $RCOO^-$ > RO^- > RHN^-. This is shown in Figure 12.1.14. (Note: the pKa of ROH = 16 and R_2NH = 40)

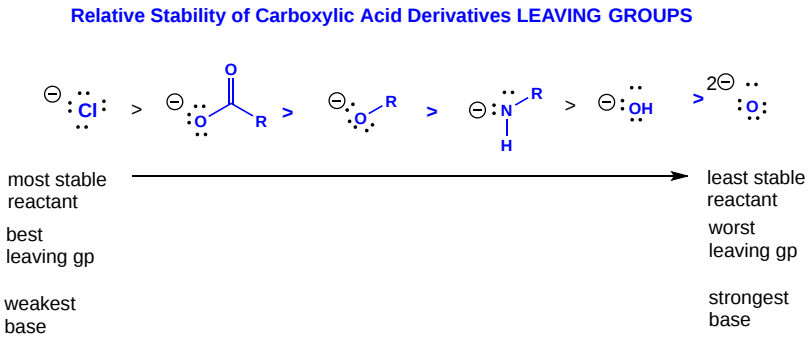

Figure 12.1.14: Relative stability of carboxylic acid derivative leaving groups

What determines the stability of products compared to reactants is the strength of bonds made and broken during the reaction.

In nucleophilic addition to aldehydes and ketones, the strength of the bond to the nucleophile must be greater than the strength of the pi bond broken in the carbonyl. A C-Cl bond strength is 81 kcal/mol (340 kJ/mol) compared to a pi C-O bond strength of 93 kcal/mol (389 kJ/mol). Hence a Cl- is not likely to add to a carbonyl C. Consider the hydration of formaldehyde (carbonyl with 2 H's), acetaldehyde (with 1 H and 1 methyl group, and acetone (with 2 methyl groups). The ΔGo for hydration of these is -19, -1, and +15 kcal/mol (63 kJ/mol), respectively, showing that increased electron release toward the carbonyl C, which makes it less electrophilic and more stable, decreases the reactivity of the carbonyl.

In nucleophilic substitution, the leaving group (anion) must be more stable than the nucleophile.

12.1.5:
KINETICS OF REACTIVITY OF CARBONYLS

The relative kinetic reactivity of various carbonyls toward nucleophiles follows the order of electrophilicity of the C. (i.e the extent of the positive charge on the carbonyl C.) The slow step in a nucleophilic attack is breaking the pi-carbonyl bond. If the reactant is stabilized by resonance in ways that reduce the electrophilicity of the carbonyl C, the reaction is slowed.

Nucleophilicity is a measure of the "affinity" of an atom or ion on an electrophilic C for the nucleophilic lone pair. This is similar to basicity which is a measure of the "affinity" of an atom or ion for a proton. Halides are not good nucleophiles for reactions with acid derivatives since the halide (like Cl-) is a better leaving group than the actual leaving group.

Making C-C Bonds

Metabolism can be divided into catabolic (breaking down) and anabolic (synthetic) reactions. To obtain energy, sugars, and fatty acids are converted to carbon dioxide. Hence C-C bonds must be broken. In contrast, C-C bonds must be synthesized in photosynthesis. In all reactions, electrons from bond broken flow to atoms where bonds will be made. Flow is from a source (a pair of electrons possibly with a negative charge) to a sink (a slightly or fully positive atom). Figure 12.1.15 shows a couple of ways to make a C-C bond using either the reaction of two carbon-centered radicals (free radical mechanisms are uncommon biologically) or a carbocation with a carbanion.

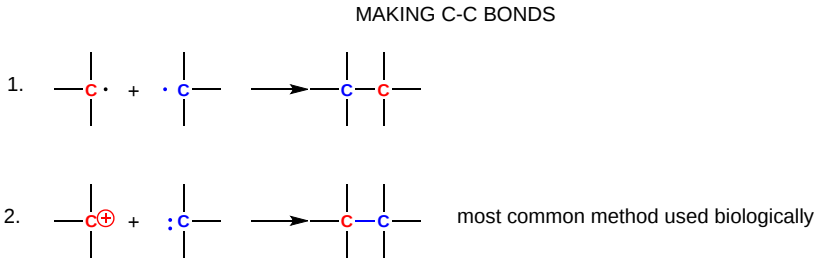

Figure 12.1.15: Making C-C bonds

A carbocation is unstable unless incorporated into a molecule in which it is stable, so instead of using them, the carbonyl C is used as the electrophilic carbon. (Instability of carbocations is reflected in their propensity to rearrangement.) Taking into account the resonance form of the C=O carbonyl bond with a positive on C and a negative on O, the net charge on the carbonyl is about +0.5. A carbanion, often stabilized as an enolate resonant form, is used as the negatively charged carbon. These features are illustrated in Figure 12.1.16.

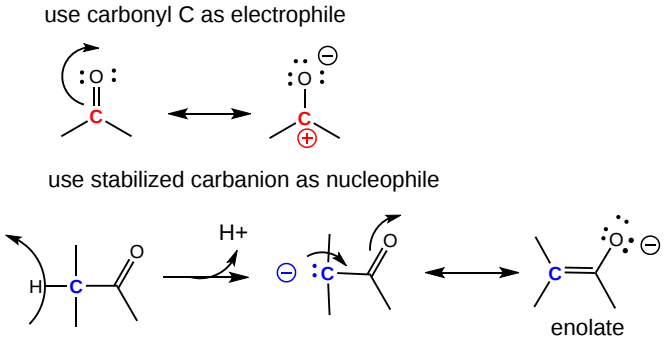

Figure 12.1.16: Carbonyl carbons as electrophiles and carbanions as nucleophiles

One method of making a C-C bond is an aldol condensation, in which a carbanion formed by the deprotonation of a C-H alpha to a carbonyl (which is stabilized by the enolate resonance form) acts as a nucleophile which adds to a carbonyl C in an aldehyde or ketone. The reaction is illustrated in Figure 12.1.17.

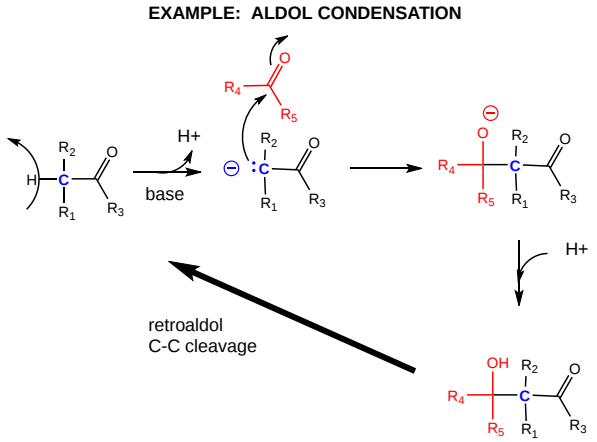

Figure 12.1.17: Aldol condensation

In another C-C bond synthesis reaction, a Claisen Condensation, a carbanion formed by the deprotonation of a C-H alpha to a carbonyl (which is stabilized by the enolate resonance form) acts as a nucleophile that substitutes at a carbonyl C in a carboxylic ester or thioester. This is illustrated in Figure 12.1.18.

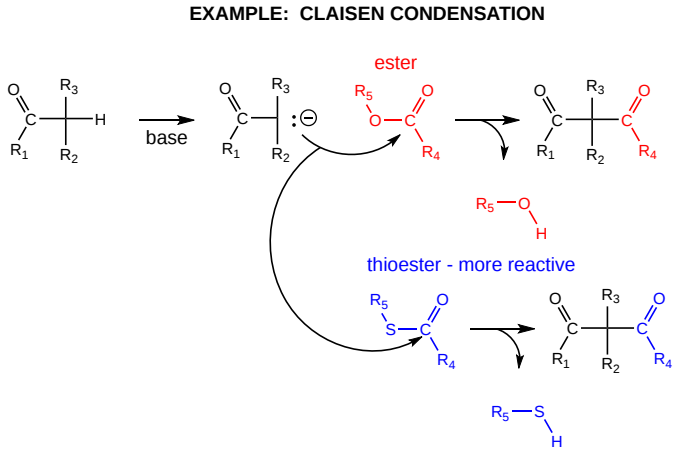

Figure 12.1.18: Claisen condensation

12.1.6: BREAKING C-C BONDS

In addition to a retroaldol condensation, a common method to break a C-C is through a decarboxylation reaction at a beta-keto acid. Notice in Figure 12.1.19 that the analogous reaction at an alpha-keto acid is unlikely since the electrons from the C-C bond that is cleaved have no "sink" to which to flow.

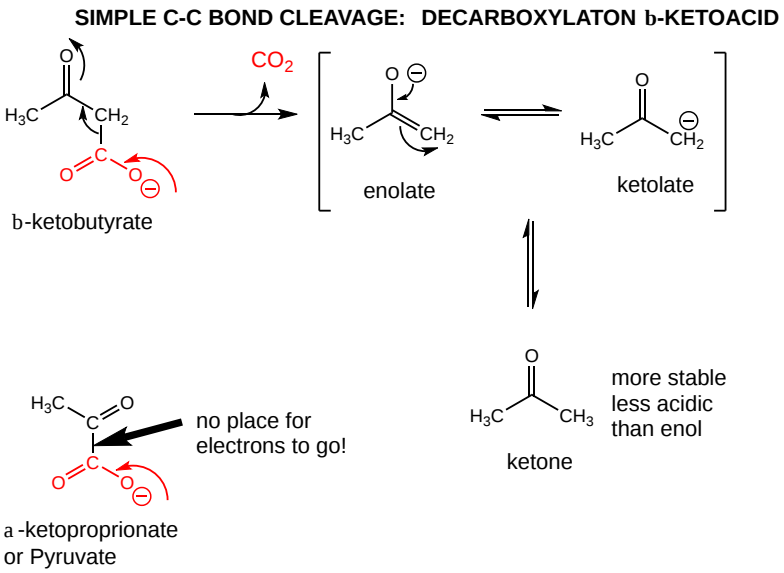

Figure 12.1.19 C-C bond cleavage by decarboxylation of beta-keto acids.

Alpha-keto acids can be decarboxylate using thiamine cofactors as discussed in Chapter 6.

12.2: PHOSPHORYL GROUP TRANSFERS AND ATP

12.2.1: ATP AND PHOSPHORYL TRANSFER REACTIONS

Biological oxidation reactions serve two functions, as described in the previous chapter. Oxidation of organic molecules can produce new molecules with different properties. For example, increases in solubility are observed on the hydroxylation of aromatic substrates by cytochrome P450 (which we will explore in another chapter section). Likewise, amino acids can be oxidized to produce neurotransmitters. Many biological oxidation reactions occur, however, to produce energy to drive thermodynamically unfavored biological processes such as protein and nucleic acid synthesis, or motility. Chemical potential energy is not just released in biological oxidation reactions. Rather, it is transduced into a more useful form of chemical energy in the molecule ATP (adenosine triphosphate). We will discuss the properties that make ATP so useful biologically, and how exergonic biological oxidation reactions are coupled to the synthesis of ATP.

ATP is used universally as a "carrier" of free energy, which effectively means that it has a high free energy compared to its hydrolysis reaction products. Using alternative language, ATP has a high-energy transfer potential. The structure of ATP and a simplified reaction mechanism for the cleavage of the terminal (γ) phosphoanhydride bond by water (hydrolysis) or an alcohol (alcoholysis) is shown in Figure 12.2.1 below.

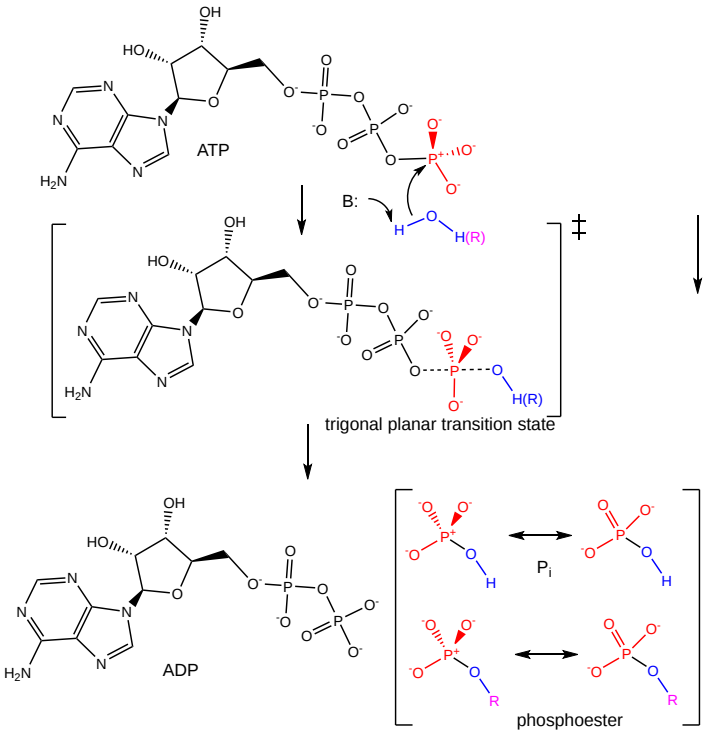

Figure 12.2.1: Mechanism for the hydrolysis and alcoholysis of the terminal phosphoanhydride bond in ATP

The reaction is also a nucleophilic substitution. Changing perspectives, the water or alcohol is phosphorylated by ATP. Hence the reaction can also be called a **phosphoryl transfer**. In Chapter 6.5, we can see that two different Enzyme Commission numbers might apply to reactions involving ATP. These are

- EC2 - transferases: transfer/exchange of group from one molecule to another. More specifically they are in category EC2.7 - transferring phosphorus-containing groups
- EC3- hydrolases: hydrolysis reactions. More specifically they are in category EC3.6 - acting on acid anhydrides

Most of the examples in this book would best be classified as **phosphoryl transfer** reactions.

The terminal phosphate is shown in an alternative resonance form with the P atom sp^3 hybridized with tetrahedral geometry and a +1 formal charge. The attack on the electrophilic P atom by the incoming nucleophile leads to the formation of a trigonal planar transition state with the dashed lines representing bond formation and breaking in an SN2-like reaction. The final products are ADP and either inorganic phosphate (Pi) or a phosphoester.

The hydrolysis reaction can be represented by a chemical equation or by a more typically written "biochemical" equation. Here is the chemical equation as recommended by the IUBMB/IUPAC:

$$\mathrm{ATP^{4-}(aq) + 2\,H_2O(l) \rightleftharpoons ATP^{3-}(aq) + HPO_4^{2-}(aq) + H_3O^+(aq)}$$

This equation is written to have both charge and mass balance. For example, the sum of charges on the left-hand side (-4) is the same as on the right-hand side (-4).

Of course, this is even a simplified equation since the reaction depends on the pH and the presence of divalent cations such as Mg^{2+}. Other species that could be included just for ATP^{4-} include $HATP^{3-}$, H_2ATP^{2-}, $MgHATP^{-}$, and Mg_2ATP, for example. The actual equilibrium constant would depend on the pH, the concentration of Mg^{2+}, and the total ionic strength of the solution. If these were all fixed, the reaction could be written as a simplified biochemical equation as shown below:

$$ATP + H_2O \rightleftharpoons ADP + Pi$$

We will most often use simplified biochemical equations when discussing metabolism.

Just as there are standard state conditions for chemical reactions (1 bar pressure for a gas, 1 M for a solute in solution), there are biochemical standard states for biochemical reactions. They are pressure = 1 bar, pH = 7 (i.e. $H_3O^+=10^{-7}$ M), Mg^{2+} = 1 mM, and ionic strength of either 0 or 0.25 M.

ATP contains two phosphoanhydride bonds (connecting the 3 phosphates) and one phosphoester bond (connecting a phosphate to the ribose ring). The pK_as for the reactions $HATP^{3-} \rightarrow ATP^{4-} + H^+$ and $HADP^{2-} \rightarrow ADP^{3-} + H^+$ are about 7.0, so the overall charges of ATP and ADP at physiological pH are -3.5 and -2.5, respectively. Each of the phosphorous atoms is highly electrophilic and can react with nucleophiles like the OH of water or an alcohol.

As we discussed earlier, anhydrides are thermodynamically more reactive than esters which are more reactive than amides. The large negative ΔG^o (-7.5 kcal/mol, -31kJ/mol) for the hydrolysis of one of the phosphoanhydride bonds can be attributed to relative destabilization of the reactants (ATP and water) and relative stabilization of the products (ADP = Pi). Specifically

- The reactants can not be stabilized to the same extent as products by resonance due to competing resonance of the bridging anhydride O's.
- The charge density on the reactants is greater than that of the products
- Theoretical studies show that the products are more hydrated than the reactants.

The ΔG^o for hydrolysis of ATP is dependent on the divalent ion concentration and pH, which affect the stabilization and the magnitude of the charge states of the reactants and products.

Carboxylic acid anhydrides are even more unstable to hydrolysis than ATP (-20 kcal/mol, -84 kJ/mol), followed by mixed anhydrides (-12 kcal/mol, -50 kJ/mol), and phosphoric acid anhydrides (-7.5 kcal/mol. -31 kK/mol). The terminal anhydride bond is often called a "high energy bond". **This is absolutely wrong and has created deep misconceptions about molecules like anhydrides**. What is true is that the anhydride reactants are high energy but *only compared to the energy of their cleavage products*, such that the reaction proceeds with a large negative ΔG^o.

There is no such thing as a high-energy bond. All covalent bonds lower the energy of a system of two separated atoms. Figure 12.2.2 shows molecules that are high energy compared to their hydrolysis products. Think of a graph of free energy. Carboxylic acid anhydrides and water (the reactants) have high energy compared to their collective products, two acetic acids, for example.

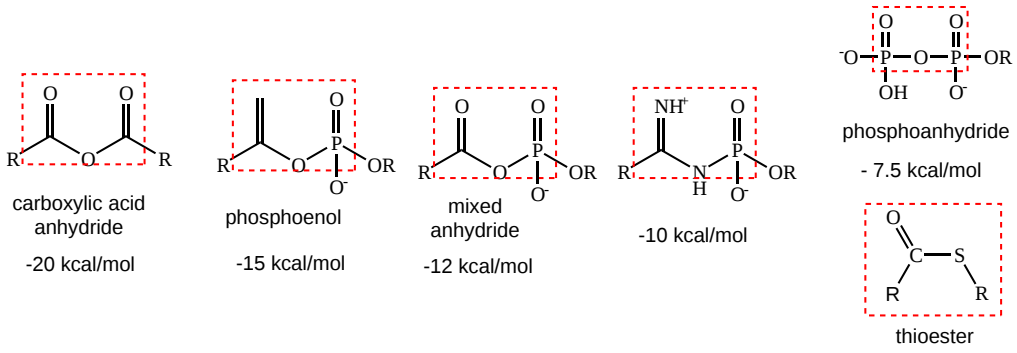

Figure 12.2.2: Molecules that are high energy *compared to their hydrolysis products*.

Some older books state that the terminal anhydride bond is "high energy". There is no such thing as a "high energy" bond. When a bond forms between two molecules, the energy is lowered. Energy input is required to break any bond.

Each of the molecules above except the thioester has a similar motif outlined with the red dotted rectangle. The thioester also is considered high energy compared to its hydrolysis product since the reactant is effectively destabilized compared to a carboxylic acid ester. This arises because the sulfur atom is larger in the thioester than the oxygen atom in the carboxylic acid ester. Hence the bond length of C-S (1.82 Å)is larger than for C-O (1.43 Å), so the C-S bond is weaker. In addition, the lone pairs on the S, which is more polarizable than O, are less likely to be shared with the C as part of the resonance stabilization of the ester. Both effects raise the energy of the thioester compared to the

carboxylic acid ester. The hydrolysis products of both esters are of similar energy. Hence the ΔG^o for the hydrolysis of the thioester is more negative and about the same for the hydrolysis of ATP.

How can ATP be used to drive thermodynamically unfavored reactions? First consider how the hydrolysis of a carboxylic acid anhydride, which has a ΔG^o = -12.5 kcal/mol (-52 kJ/mol) can drive the synthesis of a carboxylic acid amide, with a ΔG^o = + 2-3 kcal/mol (+ 4-12 kJ/mol). The reaction is:

anhydride + amine --> amide + carboxylic acid

This can be broken into two reactions, the hydrolysis of the anhydride, and the synthesis of the amide as shown in Figure 12.2.3.

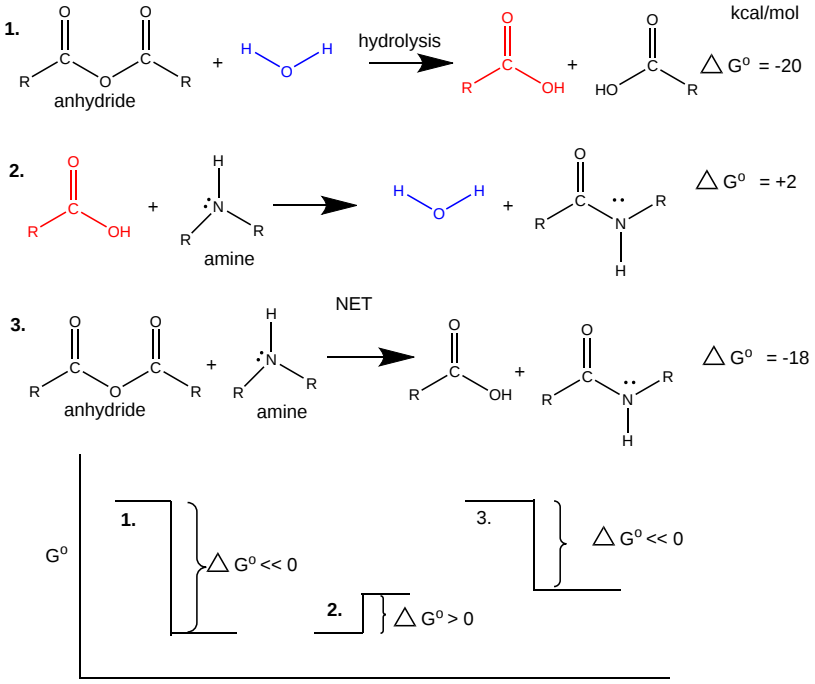

Figure 12.2.3: Individual and net reactions for the conversion for the formation of an amide from an anhydride and an amine

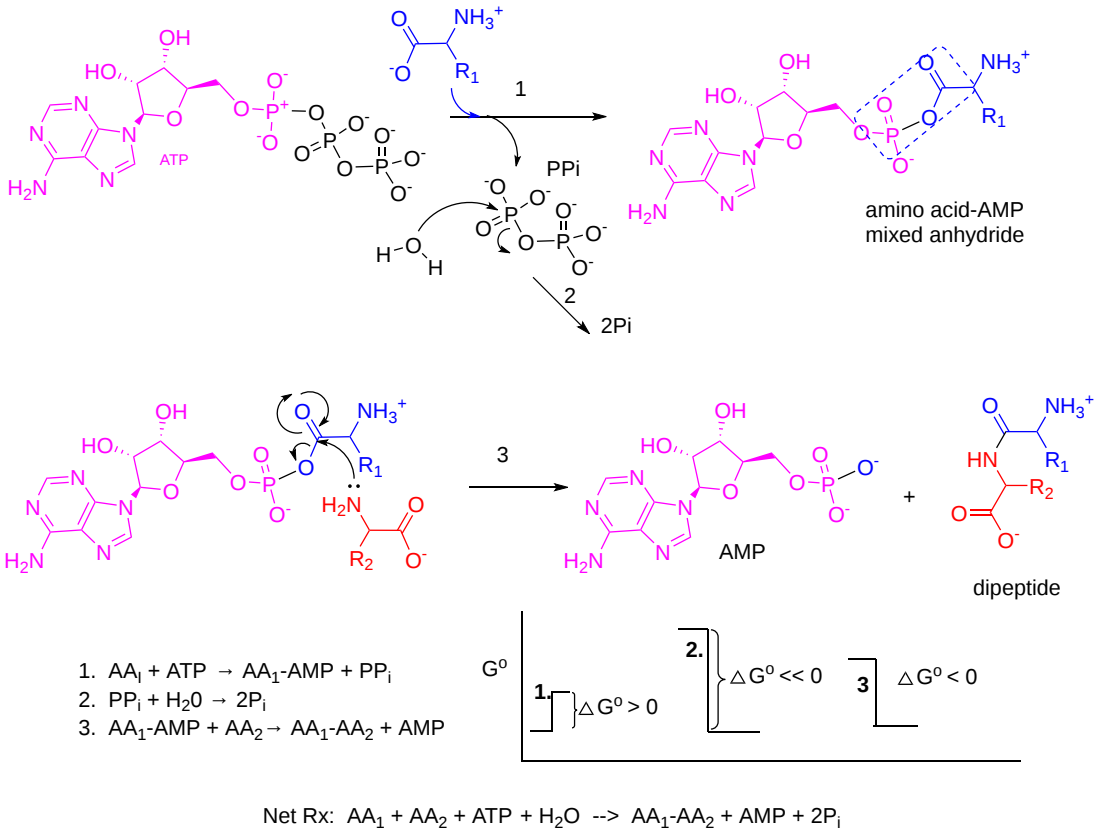
Now consider the reaction of glucose + Pi to form glucose-6-P. In this reaction, a phosphoester is formed, so the reaction would proceed with a positive ΔG^o = 3.3. Now if ATP was used to transfer the terminal (gamma) phosphate to glucose to form Glc-6-P, the reaction proceeds with a ΔG^o = -4.2 kcal/mol (-17.6 kJ/mol). This can be calculated since ΔG and ΔG^o are state functions and path independent. Adding the reactions and the ΔG^os give:

- glucose + Pi → glucose-6-P, ΔG^0 = 3.3
- ATP + H_2O → ADP + Pi , ΔG^0 = -7.5
- NET: glucose + ATP -→ Glucose-6-P + ADP, ΔG^o = -4.2

In most biological reactions using ATP, the terminal phosphate of ATP is transferred to a substrate using an enzyme called a kinase. Hence, hexokinase transfers the gamma phosphate from ATP to a hexose sugar. Protein kinase is an enzyme that transfers the gamma phosphate to a protein substrate.

ATP is also used to drive peptide bond (amide) synthesis during protein synthesis. From an energetic point of view, anhydride cleavage can provide the energy for amide bond formation. Peptide bond synthesis in cells is accompanied by cleavage of both phosphoanhydride bonds in ATP in a complicated set of reactions that are catalyzed by ribosomes in the cells. (This topic is considered in depth in Unit III). Figure 12.2.4 is a grossly simplified mechanism of how peptide bond formation can be coupled to ATP cleavage.



Net Rx: $AA_1 + AA_2 + ATP + H_2O$ --> AA_1-$AA_2 + AMP + 2P_i$

Figure 12.2.4: Individual and net reactions for the formation of a dipeptide from separate amino acids coupled with the cleavage of ATP. f

In the first reaction, the carboxylic acid end of amino acid 1 is activated to form a mixed carboxylic ester. The leaving group, Pi, is hydrolyzed in reaction 2 to help drive the reaction. An amide bond is formed in reaction 3, with the expulsion of an excellent leaving group, AMP. Phosphorylation reactions using ATP are nucleophilic substitution reactions that proceed through a pentavalent transition state. These reactions are also called phosphoryl transfer reactions.

One last note. ATP exists in cells as just one member of a pool of adenine nucleotides which consists of not only ATP but also ADP and AMP (along with Pi). These constituents are readily interconvertible. We break down an amount of ATP each day equal to our body weight. Likewise, we make about the same amount from the turnover products. When energy is needed, carbohydrates and lipids are oxidized and ATP is produced, which can then be immediately used for motility, biosynthesis, etc. It is very important to realize that although ATP is converted to ADP in a thermodynamically spontaneous process, the process is kinetically slow without an enzyme. Hence ATP is stable in solution. However, its biological half-life is not long since it is used very quickly as described above. This recapitulates a theme we have seen before. Many reactions (like oxidation with dioxygen, denaturation of proteins in nonpolar solvent, and now ATP hydrolysis) are thermodynamically favored but kinetically slow. This kinetic slowness is a necessary but of course insufficient condition, for life.

12.2.2: INTRODUCTION TO ACTIVE TRANSPORT

We have previously discussed how chemical potential energy in the form of reduced organic molecules can be transduced into the chemical potential energy of ATP. This ATP can be used to drive reductive biosynthesis and movement (from individual cells to whole organisms). ATP has two other significant uses in the cell.

Active Transport: Molecules must often move across membranes against a concentration gradient - from low to high chemical potential - in a process characterized by a positive ΔG. As protons could be "pumped" across the inner mitochondrial membrane against a concentration gradient, powered by the ΔG associated with electron transport (passing electrons from NADH to dioxygen), other species can cross membranes against a concentration gradient - a process called active transport - if coupled to ATP hydrolysis or the collapse of another gradient. Remember that active transport is different from facilitated diffusion we studied earlier, which occurs down a concentration gradient across the membrane. Many such species must be transported into the cell or intracellular organelles against a concentration gradient as illustrated in Figure 12.2.5:

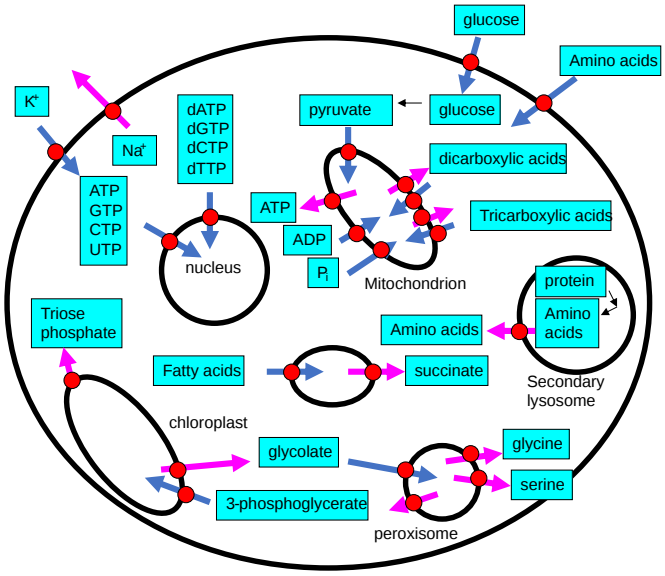


Figure 12.2.5: Examples of active transport reactions (source unfortunately lost)

Signal Transduction: All cells must know how to respond to their environment. They must be able to divide, grow, secrete, synthesize, degrade, differentiate, cease growth, and even die when the appropriate signal is given. This signal invariably is a molecule that binds to a receptor, typically on the cell surface. (Exceptions include light transduction in retinal cells when the signal is a photon and lipophilic hormones which pass through the membrane.) Binding is followed by shape changes in transmembrane protein receptors which effectively transmits the signal into the cytoplasm. We will discuss two main types of signal transduction pathways:

- nerve conduction, in which a presynaptic neuron releases a neurotransmitter causing a postsynaptic neuron to "fire";
- signaling at the cell surface which leads to the activation of kinases within the cytoplasm;

We will discuss signal transduction in the final two chapters.

For active transport to occur, a membrane receptor is required which recognizes the ligand to be transported. Of major interest to us, however, is the energy source used to drive transport against a concentration gradient. The biological world has adapted to use almost any source of energy available.

Energy released by oxidation: We have already encountered the active transport of protons driven by oxidative processes. In electron transport in respiring mitochondria, NADH is oxidized as it passes electrons to a series of mobile electron carriers (ubiquinone, cytochrome C, and eventually dioxygen) using Complex 1, 3, and 4 in the inner membrane of the mitochondria. Somehow the energy lost in this thermodynamically favored process was coupled to conformational changes in the complex which caused protons to be ejected from the matrix into the inner membrane space. One can imagine a series of conformation-sensitive pKa changes in various side chains in the complexes which lead in concert to the vectorial discharge of protons.

ATP hydrolysis: One would expect that this ubiquitous carrier of free energy would be used to drive active transport. This is one of the predominant roles of ATP in the biological world. 70% of all ATP turnover in the brain is used for the creation and maintenance of a Na and K ion gradient across nerve cell membranes using the membrane protein Na+/K+ ATPase.

Light: Photosynthetic bacteria have a membrane protein called bacteriorhodopsin which contains retinal, a conjugated polyene derived from beta-carotene. It is analogous to the visual pigment protein rhodopsin in retinal cells. Absorption of light by the retinal induces a conformation change in the retinal and protein, which leads to the vectorial discharge of protons ;

Collapse of an ion gradient: The favorable collapse of an ion gradient can be used to drive the transport of a different species against a concentration gradient. We have already observed that the collapse of a proton gradient across the inner mitochondria membrane (through FoF1ATP synthase) can drive the thermodynamically unfavored synthesis of ATP. The collapse of a proton gradient provides a proton-motive force that can drive the active transport of sugars. Likewise, a sodium-motive force can drive the active transport of metal ions. Since the energy to make the initial ion gradients usually comes from ATP hydrolysis, ATP indirectly powers the transport of the other species against a gradient.

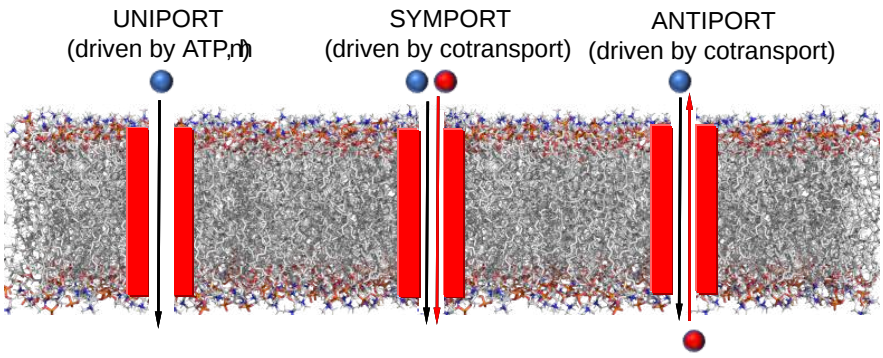

Figure 12.2.6: Types of coupled active transport

Often, the transport of one species is coupled to transport of another. If the species are charged, a net change in charge across the membrane may occur. Several terms are used to describe various types of transport, as we saw previously in Chapter 12, and which are illustrated in Figure 12.2.6.

- symport - two species are cotransported in the same direction by the same transport protein
- antiport - two species are cotransported in opposite directions by the same transport protein
- electrogenic - a net electrical imbalance is generated across the membrane by symport or antiport of charged species
- electroneutral - no net electrical imbalance is generated across the membrane by symport or antiport of charged species

---

12.3: THE CHEMISTRY AND BIOCHEMISTRY OF DIOXYGEN

12.3.1: THE HISTORY OF OXYGEN

Oxygen may be considered one of the most important elements in chemistry. Not counting hydrocarbons, there is a greater diversity of molecules with oxygen than with carbon. Given its role in the molecular world, very little time is spent on the chemistry of oxygen in undergraduate chemistry classes. Why is oxygen so special?

Oxygen reacts with atoms of all elements except the Noble gases to form molecules. One of the most important molecules of course, from a biological sense, is water. It :

- provides a perfect solvent for biomolecules
- moderates the earth's climate
- is the source of almost all the dioxygen in the air

From a chemical point of view, water is a(n):

- nucleophile and electrophile
- acid and base
- oxidizing agent and reducing agent
- a protic solvent that can form H-bonds

The formation of the earth and the development of life:

The gaseous and dusty environment from which the earth was formed contained metals and water, which as you remember from introductory chemistry, can react to form hydrogen gas. H_2 reacts with nonmetals (under various conditions of temperature and pressure) to form H_2S, HCl, CH_4, and NH_3 which contributed to the reducing nature of the early atmosphere. This kept the transition metals in their lowest oxidation states. Many metals, including the coinage metals (Cu, Ag, and Au) and the platinum group (Ru, Rh, Pd, Pt) were stable in elemental form.

Then, around 2.7-2.8 billion years ago, photosynthetic organisms (blue/green algae- also called cyanobacteria) developed which could oxidize water to form dioxygen. Oxygen was generally unavailable for redox chemistry before then as photosynthesis, the process that would evolve to oxidize water to produce dioxygen, was unavailable. Remember that to oxidize water to dioxygen, itself a strong oxidizing agent, requires a stronger oxidizing agent than dioxygen and lots of energy. Fossilized remains of cyanobacteria are found in stromatolites. Using knowledge of how atmospheric oxygen can alter the chemistry of different sulfur isotopes of SO_2, it has been shown that O_2 did not exist in the atmosphere as a whole above 1 ppm earlier than 2.4 billion years ago, although there might have been isolated pockets with higher concentrations. After that, it rose, presumably as a result of cyanobacteria. Before this time, bacteria oxidized a similar molecule, H_2S to form elemental sulfur. It could do this through the photosynthetic reduction of CO_2 by H_2S. Volcanic gases like H_2 might have kept oxygen levels from rising between 2.7 billion years ago and 2.4 billion years ago when its build-up started. Hydrogen in the form of H_2 and methane probably decreased around 2.4 billion years ago as methane with its hydrogen atoms escaped to the upper atmosphere and space. Methane levels would also be decreased by its easy reaction with dioxygen in the presence of UV light to form CO2. This would paradoxically lead to a cooling of the earth and pronounced glaciation as a more potent greenhouse gas, methane, was replaced with a less potent one, carbon dioxide.

Over the next billion years, dioxygen rose to perhaps 0.2 - 2% (compared to the present levels of 20%) Why? Because the early atmosphere was reducing, the added oxygen combined with a large "sink" of reduced metals (like elemental Cu and Fe) or nonmetals (like C and ammonia), preventing a large buildup. Only after these reduced substances were "titrated" did dioxygen build up to present levels. In addition, the oxygen might have increased weathering (by oxidation) of sulfur deposits which can lead to sulfides entering the ocean, where they could precipitate ocean iron ions that are necessary for cyanobacterial chemistry. This would place constraints on cyanobacterial growth until dioxygen levels in the atmosphere increased enough so sulfides were converted to sulfates. This first increase in atmospheric oxygen is often called the Great Oxidation Event as it correlated and presumably caused one of the greatest mass extinctions (of anaerobic organisms) of all time.

Around 2.3 billion years ago, as trace dioxygen had accumulated in the atmosphere, redox chemistry changed, although isotope evidence suggests that little dioxygen was found in water. Around 1.8 - 1.5 billion years ago, the earth's atmosphere became somewhat oxygenated, which was also coincident with the development of eukaryotic organisms. Until then, life was restricted to the oceans since there was no ozone to absorb dangerous UV radiation. The buildup of dioxygen in the air must have led to another extinction of anaerobic organisms since as we shall see, products of oxygen metabolism are very toxic. Some evolved to use dioxygen. Ozone developed, and life could then migrate from the sea to the land. It wasn't until around 600 million years ago that animals arose, however. Was this event associated with the development of a fully oxygenated (20%) atmosphere? Recent evidence, which shows that substantial oxygen wasn't available in the deep sea until about 600 million years, seems to suggest that. Based on an analysis of iron compounds in waters in Newfoundland, it appears that oxygen was very low in the sea 580 million years ago, during the Gaskier's glaciation period. Immediately after that it rose to levels

consistent with atmospheric dioxygen levels of 15%, levels necessary for large animals. Similar trends in carbon and sulfur isotopes in marine rocks in Oman also suggest large increases in oxygen at the end of the Gaskiers glaciation period. What caused this second great oxygenation event? One possibility is that organic matter was sequestered from a reaction with atmospheric dioxygen, as clays bound organic molecules in the ocean and lichens and zooplankton facilitated weather and production of insoluble organic material in the oceans.

Dioxygen is critically important for higher organisms, so an understanding of its chemistry becomes important. This chapter will show that dioxygen is a ground state diradical that has low solubility in an aqueous solution, reacts in a kinetically sluggish fashion in the oxidation reaction, and forms toxic byproducts as it gets reduced. Life forms hence evolved ways to deal with these problems, including ways to increase its solubility (with dioxygen binding and transport proteins), and enzymes (that could activate it kinetically and also detoxify oxygen by-products). Dioxygen is toxic to many cells. Obligate aerobes die in an oxygen environment as many of their cellular components get oxidized by this excellent oxidizing agent. Several strains of bacteria swim away from high levels of dioxygen. A graph showing the log of survival vs log pO2 is linear with a negative slope for a variety of organisms, including mice, fish, rats, rabbits, and insects. Pure oxygen can induce chest soreness, coughs, and sore throats in people. Premature infants put in pure dioxygen environments often developed blindness due to retrolental fibroplasia (a build-up of fibrous tissue behind the lens). The trade-off for this toxicity is clear. Energy is derived from organic molecules through oxidation. Before dioxygen became available to power aerobic catabolism of reduced molecules like fatty acids and less reduced sugars, such molecules were only partially oxidized. The glycolytic pathway, found in most organisms, oxidizes glucose (6 Cs) to two molecules of pyruvate (3 Cs). It was only with the availability of dioxygen did pathways evolve (Kreb Cycle, mitochondrial electron transport/oxidative phosphorylation) that allowed pyruvate to be fully oxidized to carbon dioxide, with the release of much more energy.

12.3.2: THE PROPERTIES OF DIOXYGEN

It is important to understand the properties of dioxygen since oxidation reactions using its power not only our bodies but our entire civilization. We will concentrate on biological reactions, but even these show the same characteristics as non-biological ones.

- oxidation of organic molecules by oxygen is thermodynamically favored but kinetically slow.
- pure oxygen environments are toxic to cells and organisms.

First, we will try to understand these properties of oxygen, and then we will see how organisms overcome these problems to use dioxygen.

We can understand both of these properties by looking at the molecular orbitals of oxygen and its reduction products as shown in the diagrams below. Ground state oxygen is a diradical, which explains the paramagnetic behavior of oxygen. The two unpaired oxygen each have a spin state of 1/2 for a total resultant spin S of 1, making ground state oxygen a triplet (2S+1) = 3. Organic molecules typically undergo 2 electron oxidation steps. Consider the stepwise oxidation of methane below. The oxidation number of C in methane is -4, -2 in methanol, 0 in formaldehyde, +2 in formic acid, and finally +4 in carbon dioxide, indicating two electron losses in each step. These states are shown in Figure 12.3.1.

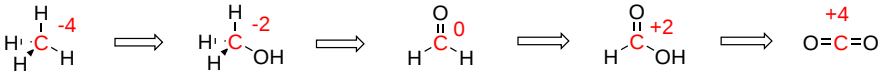

Figure 12.3.1:

The two electrons lost by the organic substrate are added to oxygen, but since the two lost electrons are spin paired, a spin flip must occur to allow the electrons to enter the unfilled oxygen orbitals. Alternatively, energy can be put into ground state dioxygen to produce excited state singlet oxygen (S=0, 2S+1 = 1). The source of the large activation energy required (about 25 kcal or 105 kJ/mol) to flip the electron spin accounts for the kinetic sluggishness of reactions of dioxygen with organic reactants.

A traditional Lewis structure for ground state dioxygen can not be easily written since the electrons are added in pairs, and dioxygen is a diradical. There are 6 electrons in the sigma molecular orbitals from second shell electrons (two each in σ2s, σ2s*, and σ2p,) and 6 electrons in the pi molecular orbitals from second shell electrons (two each in two different π2p orbitals, and one electron each in two different π2p*), so the net number of electrons in bonding orbitals is 4, giving a bond order (or number of 2). In contrast, it is easy to write the Lewis structure of singlet, excited state oxygen, since all electrons can be viewed as paired, with two net bonds (1 sigma, 1 pi) connecting the atoms of oxygen. Figure 12.3.2 shows the molecular orbital diagram for ground and excited state dioxygen.

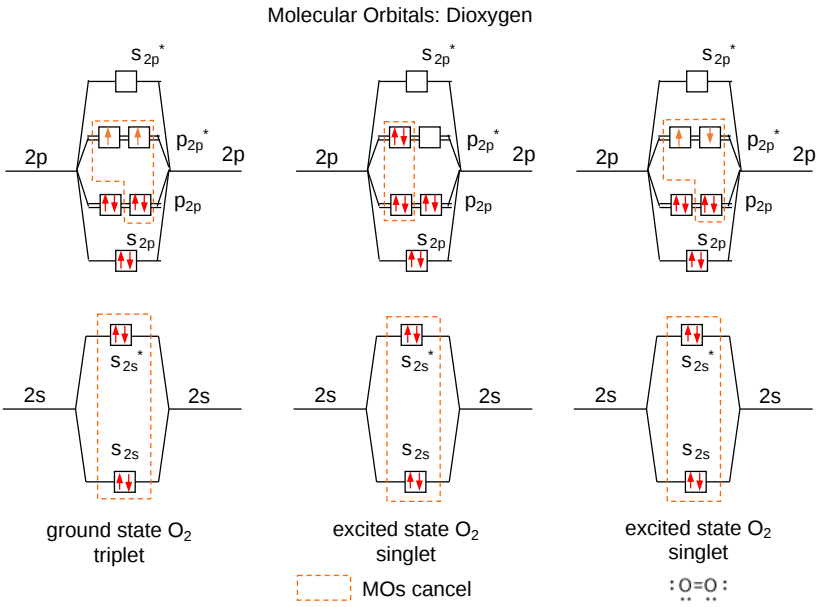

Figure 12.3.2: Molecular orbital diagram for ground and excited state dioxygen

This Lewis structure will be used to represent singlet, excited oxygen, which should react more quickly with organic molecules. The excited state singlet on the right is unstable and decays to the middle singlet state. The middle state is approximately 94.3 kJ/mol higher in energy than the ground state triplet (on the left). In quantum mechanical parlance, the transition from the ground state triplet to the singlet state is forbidden for several reasons, making it unlikely that absorption of a photon will induce the transition.

12.3.3: THE REDUCTION OF DIOXYGEN

When oxygen oxidizes organic molecules, it is reduced. By adding electrons one at a time to the molecular orbitals of ground-state dioxygen we produce the step-wise reduction products of oxygen. On the addition of one electron, superoxide is formed. A second electron produces peroxide. Two more produce 2 separated oxides since no bonds connect the atoms (the number of electrons in antibonding and bonding orbitals is identical). Each of these species can react with protons to produce species such as HO_2, H_2O_2 (hydrogen peroxide), and H_2O. It is the first two reactive reduction products of dioxygen that make it potentially toxic. Figure 12.3.3 shows the MO diagrams for the reduction products of dioxygen.

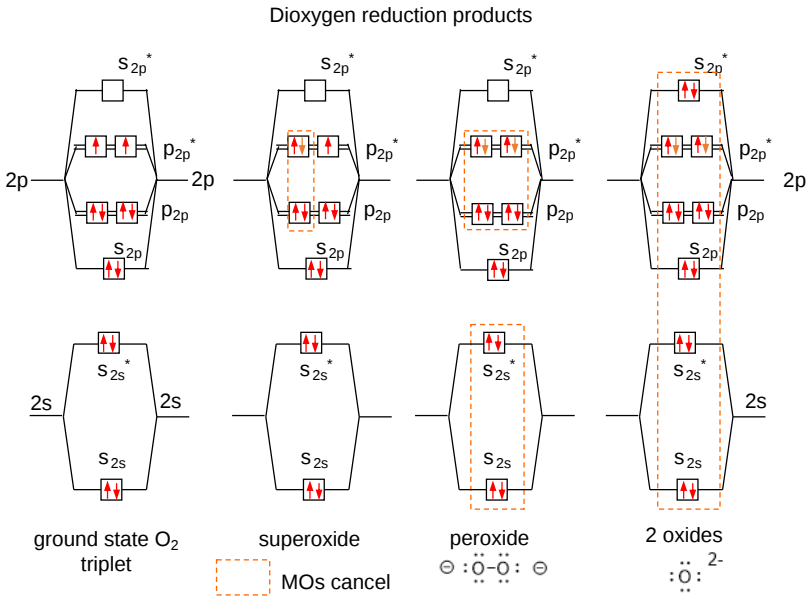

Figure 12.3.3: MO diagrams for the reduction products of dioxygen

How are the potential problems in oxygen chemistry dealt with biologically?

Kinetic sluggishness: Enzymes that utilize dioxygen must activate it in some way, which decreases the activation energy. Enzymes that use dioxygen typically are metalloenzymes, and often heme-containing proteins. Since metals such as Fe^{2+} and Cu^{2+} are themselves free radicals (i.e. they have unpaired electrons), they react readily with ground-state oxygen which itself is a radical. The molecular orbitals of the metal and oxygen combine to produce new orbitals which for oxygen are more singlet-like. Likewise, dioxygen reacts more readily with organic molecules which can form reasonably stable free radicals, such as flavin adenine dinucleotide (FAD), as we shall see later.

Dioxygen toxicity: Since toxicity arises from the reduction products of oxygen, enzymes that use oxygen have evolved to bind oxygen and its reduction products tightly (through metal-oxygen bonds) so they are not released into the cells where they can cause damage. In addition, enzymes that detoxify free dioxygen reduction products are widely found in nature. For example:

- superoxide dismutase catalyzes the dismutation (self-redox) of 2 superoxides into dioxygen and hydrogen peroxide;
- catalase converts hydrogen peroxide into water and oxygen;
- peroxidase catalyzes the reaction of hydrogen peroxide with an alcohol to form water and an aldehyde
- peroxiredoxins react with peroxides and thioredoxin (a small electron donor) to form water and oxidized thioredoxin.

Finally, free radical scavengers such as vitamins A, C, E, and selenium can react with reactive free radicals to produce more stable free radical derivatives of the vitamins and Se. More on this later.

12.3.4: THE REACTIONS OF DIOXYGEN AND ITS REDUCTION PRODUCTS

12.3.4.1: TRIPLET O_2 - GROUND STATE

Here are some reactions for the ground state (triplet O_2):

a. Metals ions - Metal ions are radicals themselves, so can easily react with dioxygen (think about rust). Here is one example

$$Fe^{2+} + O_2 \rightleftharpoons [Fe^{2+} - O_2 \rightleftharpoons Fe^{3+} - O_2^{-\cdot}] \rightleftharpoons Fe^{3+} + \underbrace{O_2^{-\cdot}}_{\text{superoxide}}$$

b. Autoxidation of organic molecules to produce peroxides - These are multistep reactions that have initiation, propagation, and termination steps.

$$RH \rightarrow R^{\cdot} \text{ (Initiation)}$$
$$R^{\cdot} + O_2 \rightarrow ROO^{\cdot} \text{ (Propagation)}$$
$$ROO^{\cdot} + RH \rightarrow R^{\cdot} + ROOH \text{ (Propagation)}$$
$$R^{\cdot} + R^{\cdot} \rightarrow R\text{-}R \text{ (Termination)}$$
$$ROO^{\cdot} + ROO^{\cdot} \rightarrow ROOR + O_2 \text{ (Termination)}$$
$$ROO^{\cdot} + R^{\cdot} \rightarrow ROOR \text{ (Termination}$$

Figure 12.3.4 summarizes the reactions of triplet ground state dioxygen.

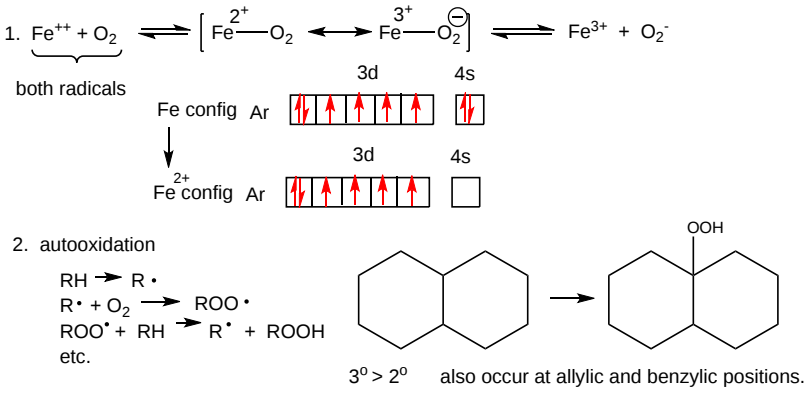

Figure 12.3.4: Reactions of triplet ground state dioxygen

The initiation step above occurs mostly at C atoms which can produce the most stable free radicals (allylic, benzylic position, and $3^o > 2^o >> 1^0$ carbons).

12.3.4.2: SINGLE O_2 - EXCITED STATE

Figure 12.3.5 shows some reactions for singlet dioxygen in which dioxygen is shown as with a double bond and two lone pairs on each oxygen.

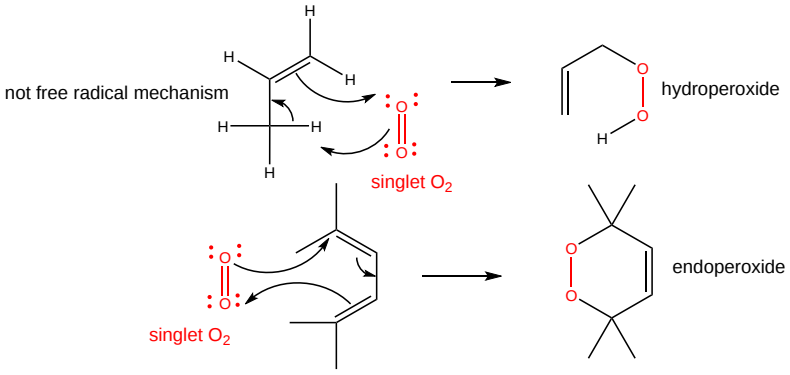

Figure 12.3.5: Some reactions for singlet dioxygen

Alkenes react with oxygen to form hydroperoxides, potentially through an epoxide intermediate. Dienes reacts with oxygen in a Diels-Alder pericyclic reaction to form endoperoxides. A molecular orbital perspective (that you may remember from chemistry classes) on this cycloaddition reaction is shown in Figure 12.3.6.

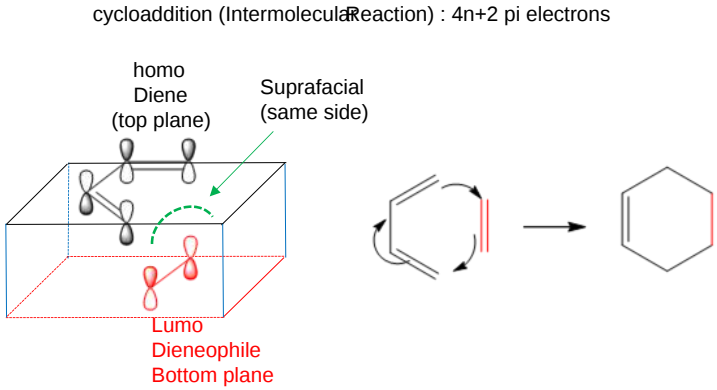

Figure 12.3.6: Pericyclic cycloaddition reactions using molecular orbitals

Singlet oxygen can be made from triplet oxygen by photoexcitation. Alternatively, it can be made from triplet oxygen through collision with an excited molecule which relaxes to the ground state after a radiationless transfer of energy to triplet oxygen to form reactive singlet oxygen. This later process accounts for the photobleaching of colored clothes when the conjugated dye molecules absorb UV and Vis light and relax to the ground state by transferring energy to triplet oxygen to form singlet oxygen. That can more readily react with the conjugated double bonds in the dye. These processes are summarized in Figure 12.3.7.

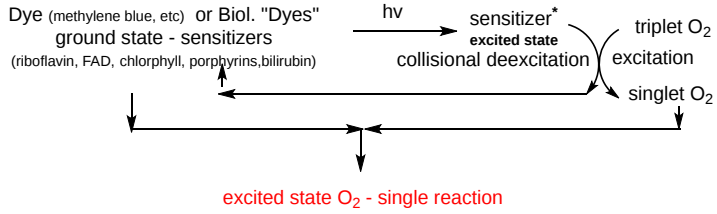

Figure 12.3.7: Photosensitization and the reaction of dyes with singlet state dioxygen

12.3.4.3: SUPEROXIDE

Common reactions of superoxide are shown below.

a. **Dismutation:** This reaction involves a specified reactant undergoing an oxidation reaction, followed by another molecule of the same reactant undergoing a reduction.

$$O_2^{-\cdot} + O_2^{-\cdot} + 2\,H^+ \rightleftharpoons H_2O_2 + O_2 \qquad \text{(slow)}$$

$$HO_2^{\cdot} + O_2^{-\cdot} + H^+ \rightleftharpoons H_2O_2 + O_2 \qquad \text{(fast)}$$

b. Acid/Base:

$$HO_2^{\cdot} \rightleftharpoons O_2^{-\cdot} + H^+ \qquad (pKa = 4.8)$$

c. With metal ions:

$$\underbrace{Fe^{3+}}_{\text{as in heme}} + O_2^{-\cdot} \rightarrow O_2 + Fe^{2+}$$

The enzyme superoxide dismutase catalyzes the dismutation reaction. The common eukaryotic cytosolic form contains Cu^{2+} and Zn^{2+} ions, which are coordinated by histidine side chains. The reaction proceeds in two steps or half-reactions. The first is the removal (oxidation) of an electron from superoxide ($O_2^{-\cdot}$) through its reduction by Cu^{2+}. This reaction forms Cu^{1+} and nontoxic O_2.

$$Cu^{2+} - SOD + O_2^{-\cdot} \rightarrow Cu^{+} - SOD + O_2$$

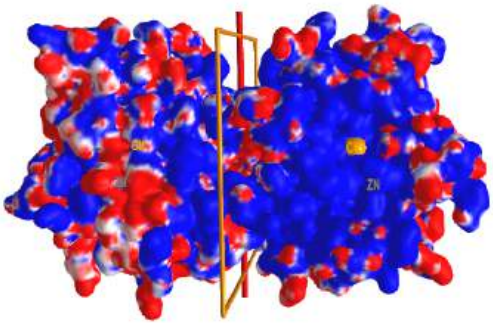
(reduction of Cu; oxidation of superoxide)

The second is the addition (reduction) of an electron from a second superoxide to Cu^{1+} to reform the catalytic Cu^{2+} and in the process form the reactive peroxide O_2^{2-} (unfortunately), which when protonated forms H_2O_2.

$$Cu^{+} - SOD + O_2^{-\cdot} + 2\,H^{+} \rightarrow Cu^{2+} - SOD + H_2O_2$$

(oxidation of copper; reduction of superoxide)

Figure 12.3.8 shows an interactive iCn3D model of the electrostatic potential surface of the superoxidase dismutase dimer showing Cu and Zn ions (2SOD).



NCBI iCn3D Figure 12.3.8: Electrostatic potential surface of the superoxidase dismutase dimer showing Cu and Zn ions (2SOD) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...zozKPVKr4MzES9

Two dimers are shown with a rotation C2 axis separating them. Red indicates the negative surface potential and blue the positive. Catalytic Cu^{2+} and Zn^{2+} ions are in each subunit and are shown in orange (Cu) and gray (Zn) spheres and labeled (disregard the label not centered on the orange and gray spheres). Note that the Cu^{2+} and Zn^{2+} ions are in the center of a large blue surface (positive potential), which helps "sweep up" any negatively charged superoxide O_2^{-} nearby. Rotate the complex around the C2 axis and you will see another large positive blue patch on the backside. These two positive electrostatic surfaces facilitate the electrostatic attractions and binding of the dangerous superoxide anion from the larger 3D region around the enzyme.

The Zn^{2+} in SOD is not redox active. What is its role? Both metals appear to increase the thermostability of the individual monomer and the dimer. In the presence of metal ions (a holo form of the enzyme), the dimer dissociates into monomers at a higher urea concentration than does the apo-dimer. Ion binding reduces the flexibilities of groups found in the dimer interface. The protein has a disulfide bond between Cys 57 and Cys 146. This bond stabilizes a metal ion binding loop that contributes to the binding interface in the dimer. The enzyme operates at diffusion-controlled rates (k_{cat}/K_M is between 10^8 and 10^9 $M^{-1}s^{-1}$), in part due to the attraction of any negatively charged superoxide by the electrostatic field around the dimer.

There are two other types of superoxidedismutates, one that uses either Mn^{2+} or Fe^{2+} (bacterial, mitochondrial, chloroplasts, protists) and another that uses Ni^{2+}(some prokaryotes).

12.3.4.4: PEROXIDE

In contrast to dioxygen which contains multiple bonds between the O atoms, peroxide has only one bond. It is quite weak and requires only 38 kcal/mol (160 kJ/mol) to break it. Remember, bonds can be broken in a heterolytic way (both electrons in a bond go to one of the atoms, or in a homolytic fashion, in which one electron goes to each atom.

Figure 12.3.9 shows typical reactions of peroxides.

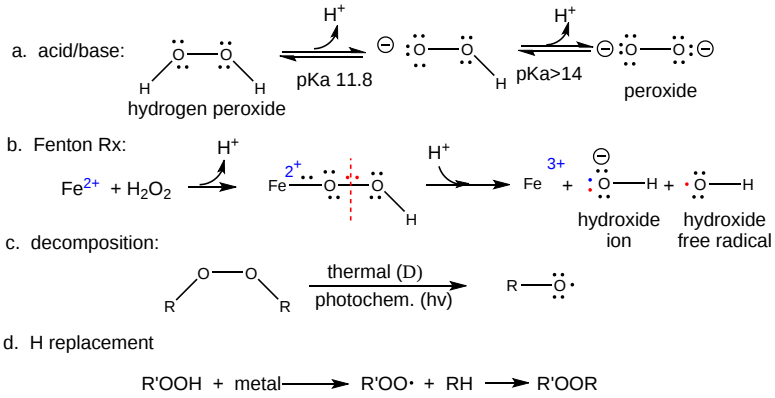


Figure 12.3.9: Reactions of peroxides

The reaction with Fe^{2+}, the **Fenton Reaction**, is similar to the reaction of triplet O_2 with Fe^{2+}. In this reaction, homolytic cleavage of the O-O bond occurs generating OH^- and the hydroxy free radical, $OH\cdot$, which will react with any molecule it encounters. Thermal or photochemical homolytic cleavage of peroxide also forms free radicals which react like the hydroxy free radical.

The enzyme **catalase** facilitates the decomposition of the reactive H_2O_2 to water and dioxygen. As such offers protection similar to that against superoxide offered by superoxide dismutase. This is the next reaction catalyzed by the enzyme catalase:

The human enzyme is a homotetramer with each monomer having a heme at the active site. The tetramer also binds $NADP^+$ (2/tetramer) but its function is unclear. A potential mechanism for catalase is shown in Figure 12.3.10.

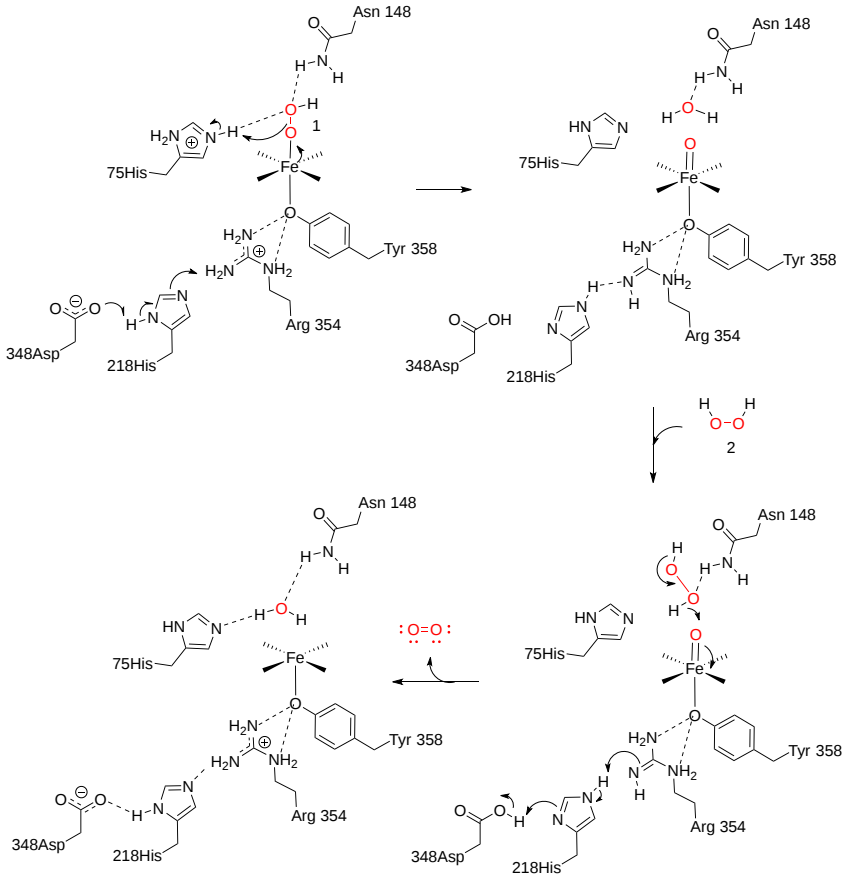

Figure 12.3.10: Human catalase reaction mechanism (adapter from Putnam et al. J. Mol. Biol. 296, 2000,https://doi.org/10.1006/jmbi.1999.3458)

Figure 12.3.11 shows an interactive iCn3D model of human erythrocyte catalase with bound ligand (CN^-) and NADPH (1DGG)

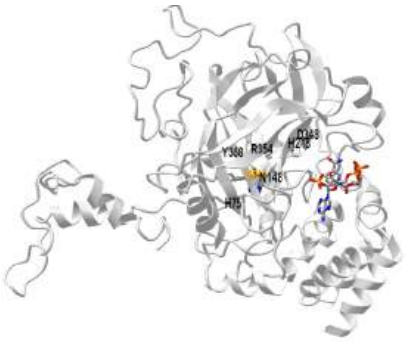

Figure 12.3.11: human catalase with bound ligand (CN^-) and NADPH (1DGG). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...TD7yJsfrNcwSJ7

The cyanide ligands in this structure bind to the heme in place of peroxide. The reaction in mammalian catalases appears to involve a tyrosine radical

H_2O_2 is very similar in structure to H_2O. How does the enzyme differentiate between them? Both approach the heme through a long 25 Å water channel with a hydrophobic constriction part way into the channel leading to the active site heme. Four waters in the crystal structure are positioned in the constricted opening and in a widened open just at the heme. The amino acid side chains forming the constriction are Val 74, Val 116, Pro 129, Phe 153, Phe154 and Trp 186. These allow only small molecules to enter. Two of the four waters form hydrogen bonds to side chains (one to His 75 and Asn 148 and another to Gln 168 and Asp12. The others don't form hydrogen bonds, are more dynamic, and more likely to leave the channel. H_2O_2 is bigger and can form bridging hydrogen bonds to side chains that the mobile waters can't. They probably leave the opening. H_2O_2 is more polar and has a higher dipole moment (2.26 Debye) compared to water (1.86 Debye) which implies that it would be differentially stabilized by hydrogen bonds in this hydrophobic site compared to the less polar water.

Figure 12.3.12 shows an interactive iCn3D model of human erythrocyte catalase (monomer) showing the hydrophobic constricture leading to the active site (1DGF**)**

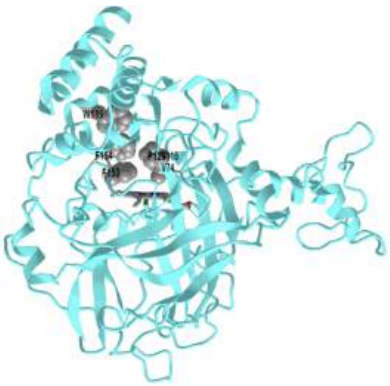

Figure 12.3.12: Human erythrocyte catalase (monomer) showing hydrophobic constriction leading to the active site (1DGF**)**. (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...e48pAa9X4zhcM7

12.3.5: HYDROXYL FREE RADICAL

We won't specifically discuss the reaction of the hydroxyl free radical ($\cdot OH^-$) since it will react with anything nearby to produce another free radical. General reactions of the radical are shown in Figure 12.3.13.

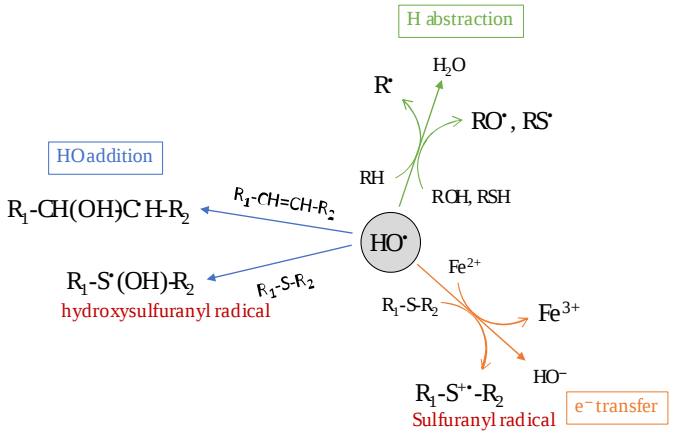

Figure 12.3.13: Chemical reactions of the hydroxyl radical. Fabrice Collin. Int. J. Mol. Sci. 2019, 20, 2407; doi:10.3390/ijms20102407. Creative Commons Attribution (CC BY) license (http://creativecommons.org/licenses/by/4.0/).

In summary, we reap the benefits of using dioxygen as an oxidizing agent as it allows the aerobic and hence complete oxidation of carbohydrates and lipids to CO_2 and H_2O. Yet we pay the price for using O_2 as an oxidizing agent as its partial reduction products, the superoxide radical, peroxides, and hydroxy free radical, collectively known as **reactive oxygen species (ROS)** can react with and damage proteins, nucleic acids, and lipids, as we will see below. Figure 12.3.13 shows a summary of their reactions.

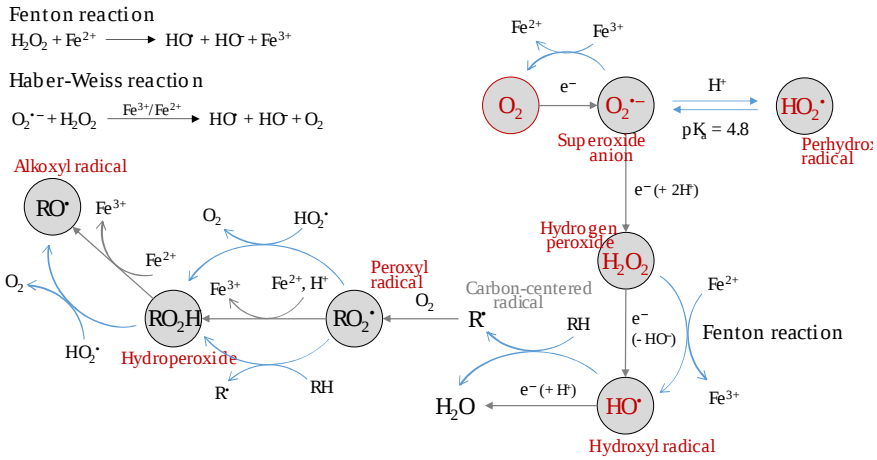

Figure (\PageIndex{14}\): Basis of Reactive Oxygen Species (ROS) generation. Fabrice Collin, ibid.

We have presented the role of superoxide dismutase and catalase in the removal of ROS in cells. In addition to these elegantly designed proteins, there is another simpler biomolecule, the tripeptide glutathione (γGlu-Cys-Gly), that can reduce ROS in cells and prevent oxidative damage. Glutathione serves as a major antioxidant in cells. It exists in reduced (GSH) and oxidized (GSSG) states, the ratio of which depends on the cellular oxidative stress. It can react with and detoxify peroxides and alkyl free radicals by the following net reactions:

$$2\ GSH + R_2O_2 \rightarrow GSSG + 2\ ROH$$

$$2GSH + 2R^{\cdot} \rightarrow GSSG + 2RH$$

12.3.6: PROTECTION FROM FE^{2+} - FERRITIN AND TRANSFERRIN

The Fenton reaction shows the potential problem with having free Fe^{2+} ions in a chemical state that would easily allow this reaction and the generation of ROS. Hence much of the Fe^{2+} in the body is sequestered in Fe^{2+} binding cofactors like heme and FeS clusters. It is transported in the blood by the protein **transferrin** and stored in cells like the erythrocyte in **ferritin**. The iron ions in both transferrin and ferritin are in the +3 oxidation state (Fe^{3+}). This strongly positive cation is quite insoluble in the presence of anions like hydroxide, phosphate, and carbonate. The K_{sp} values for the hydroxide salt of Fe^{3+} is $3.8x10^{-38}$. Let's detour for a bit and look at the structures of ferritin and transferrin and how they work, starting with ferritin.

12.3.6.1: FERRITIN

The biologically functional form of ferritin is a 24-mer. The structure encapsulates a large volume that can hold many Fe ions (up to 4500) in the central cavity. The ions are stored in the more insoluble form, Fe^{3+}, in complexes of oxide and hydroxide. Mammalian ferritin contains both heavy (H) and light (L) chains so they are hetero 24-mers.

Figure 12.3.15 shows an interactive iCn3D model of ferritin, the intracellular Fe storage protein (1fha).

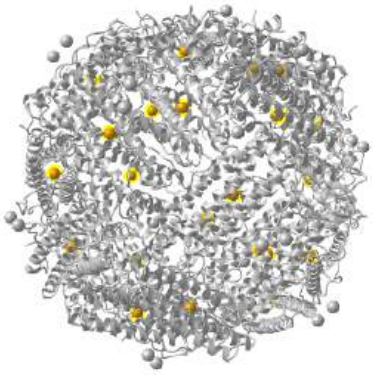

Figure 12.3.15: Ferritin, the intracellular Fe storage protein (1fha). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...MQXAbPAwNnVya8

The ferritin chains are shown in purple. This structure shows only 24 Fe ions (in orange spheres with yellow halo).

Two questions arise. How does Fe^{2+} get into the internal volume of ferritin and how does it get converted to Fe^{3+}? There must be a channel through which Fe^{2+} can diffuse. Its conversion to Fe^{3+} requires catalysis by an Fe cluster in the heavy chain (H) subunits. Figure 12.3.16s shows a generic diagram outlining the processes of uptake and conversion to Fe^{3+} salts inside the central cavity of ferritin.

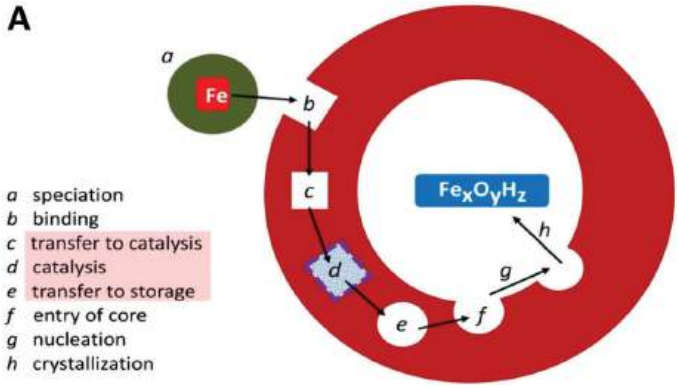

Figure 12.3.16: (A) Schematic outline of phases involved in the uptake, oxidation, and storage of Fe(II). Hagen et al. *Metallomics*, 9,(2017). https://doi.org/10.1039/c7mt00124j. Creative Commons Attribution Non-Commercial License (https://creativecommons.org/licenses/by/3.0/),

Heart and brain ferritin are enriched in the heavy (H) chain. These two organs clearly require safety from toxic Fe^{2+} ions. Ferritins in organs like the liver and spleen, which store lots of iron, are enriched in the light (L) chain. The two chains are about 50% homologous, but the H chain has a dinuclear **ferroxidase** iron site which catalyzes the Fe^{2+} to Fe^{3+} conversion. Once inside the L chain surface provides a nucleation site for the deposition of Fe^{3+} into a ferrihydrite "precipitate" ($(Fe^{3+})_2O_3 \bullet 0.5H_2O$). The general reaction is:

$$2Fe^{2+} + O_2 \rightarrow [Fe^{3+}\text{-O-O-}Fe^{3+}] \rightarrow [Fe^{3+}\text{-O(H)-}Fe^{3+}]$$

Figure 12.3.17 shows a possible generic mechanism for the oxidation of the Fe cluster from Fe^{2+} to Fe^{3+}.

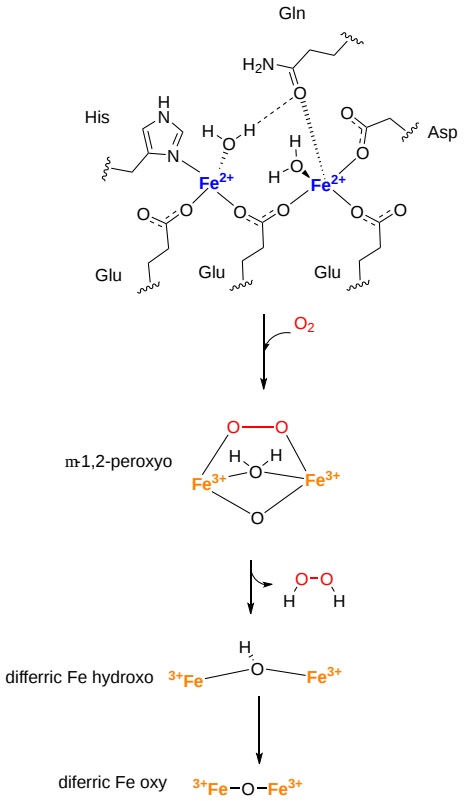

Figure 12.3.17: Possible mechanism for ferroxidase activity of ferritin heavy chain. (adapted from Hagen et al. *Metallomics*, 9 (2017). https://doi.org/10.1039/c7mt00124j)

It acts as a ferroxidase that suggests that dioxygen is involved as a ligand in the oxidation of the two Fe^{2+} ions in the cluster to Fe^{3+}.

Figure 12.3.18s shows a closeup of the interactions of the di-Fe cluster and two other Fe ions bound in the human H chain with water ligands.

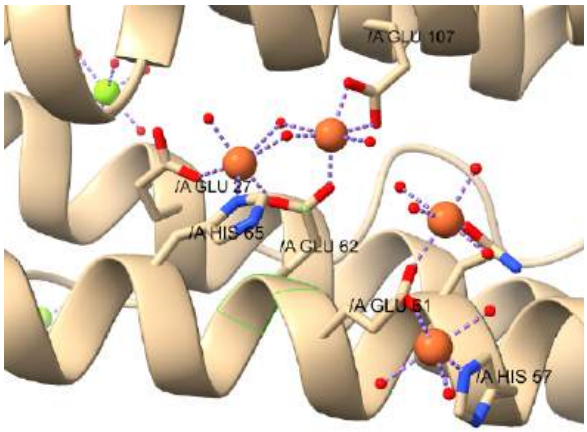

Figure 12.3.18: Interactions of the diFe cluster and two other Fe ions bound in the site with water ligands (image made with ChimeraX)

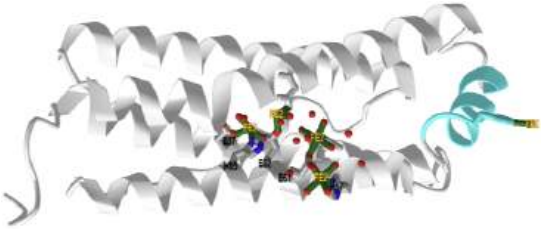
The dinuclear Fe core is shown in the central area of the figure.

Figure 12.3.19 shows an interactive iCn3D model of human heavy-chain ferritin monomer with bound Fe (4zjk)



NCBI iCn3D Figure 12.3.19: Human heavy-chain ferritin monomer with bound Fe (4zjk). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?Ux6ED11dT5dyBb2XA

The crystal structure of the full ferritin structure shows multiple binding sites and a channel to the oxidase site.

Now let's look at how the light chain L might nucleate the formation of the iron precipitates. Crystal structures show how mineralization probably occurs at a specific site on the light chains that present themselves on the inside surface of ferritin. Figure 12.3.20 shows a closeup of the interactions of a di-Fe cluster and two other Fe ions bound in the human L chain with water and peroxide ligands. This site probably represents the nucleation and mineralization site.

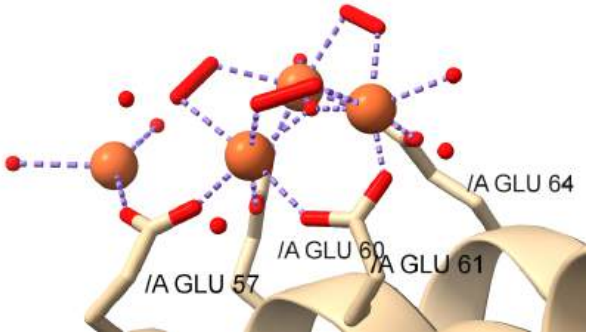


Figure 12.3.20: Closeup of the interactions of a di-Fe cluster and two other Fe ions bound in the human L chain with water and peroxide ligands at the probable mineralization site

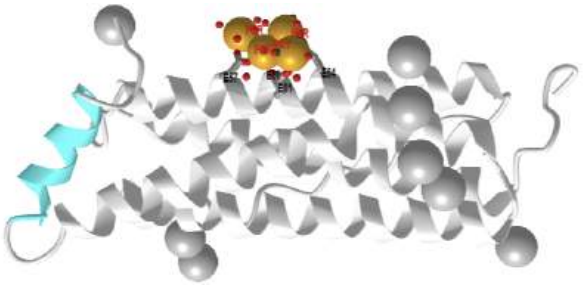
Figure 12.3.21 shows an interactive iCn3D model of human light chain ferritin with a possible nuclear site for mineralization (5LG8). The structure was made after 60 minutes of mineralization.



NCBI iCn3D Figure 12.3.21: Human human light chain ferritin with a possible nuclear site for mineralization (5LG8). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...LKo7WJtoHeLBq9

The structure suggests the presence of a μ(3)-oxo)Tris[(μ (2)-peroxo)] triiron(III) cluster assembled at subsite on the L chains containing the carboxylate ligands Glu60, Glu61, and Glu64 side chains. A Glu57, which is along the incoming path of Fe ions, is involved in Fe delivery and coordination. Figure 12.3.22 shows the electrostatic surface around the nucleation site.

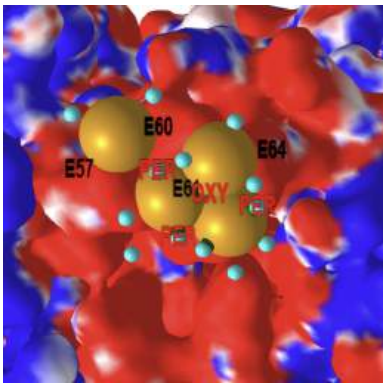


Figure 12.3.22: Electrostatic surface around the nucleation site in light chain ferritin. Here is a link to an interactive iCn3D model: https://structure.ncbi.nlm.nih.gov/i...9LKs4NFkurnhX8

Note that the Fe ions are embedded in a site of negative electrostatic potential arising, in part, from the localization of the glutamic acid side chains in the site. this

Why doesn't the heavy chain of ferritin perform the same nucleation function in preparation for the crystallization of ferrihydrite? A comparison of Figures 18 and 20 shows that the H chain (which has the ferroxidase activity) has a His 65 ligand instead of a glutamic acid

(position 60) as one of the coordinating ligands. This gives Glu 61 more flexibility which must inhibit the nucleation and mineralization process.

Figure 12.3.23 shows two top views (left and center image) and one side view of three contiguous subunits of human heavy-chain ferritin monomer with bound Fe (4zjk). The gray/black sphere is actually a Ca^{2+} ion (which is larger than Fe^{2+}) from the crystal structure. This three-monomer cluster would be replicated 8 times to form the full ferritin shell. There is a three-fold C3 axis going through the central calcium in the figure where all the monomers meet. Fe^{2+} must move through these central ions into the internal cavity.

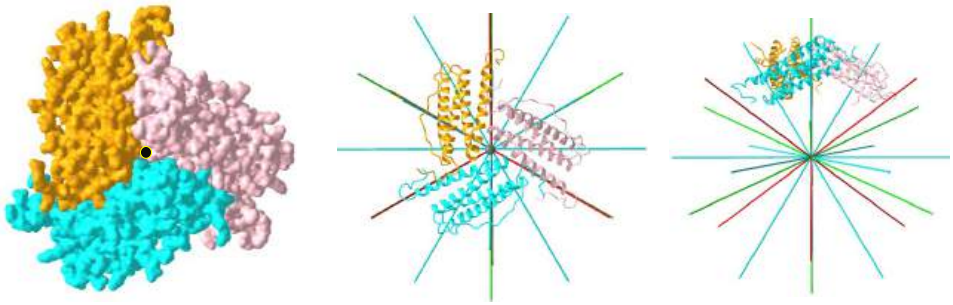

Figure 12.3.23: Opening in ferritin formed by 3 contiguous subunits of human heavy-chain ferritin monomer (4zjk)

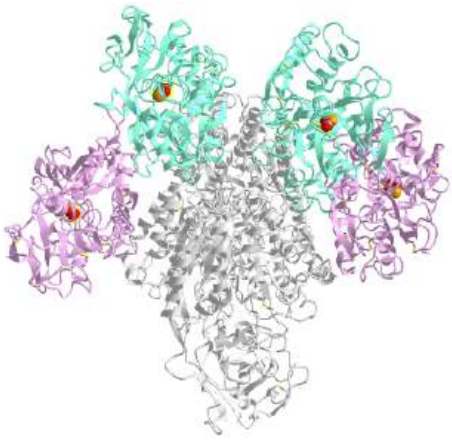
12.3.6.2: TRANSFERRIN

Iron ions are moved in the circulation bound to the iron-binding protein **transferrin**. It binds to a transferrin receptor and can be endocytosed into the cell, where the Fe ions are transferred and stored in ferritin. The transferrin receptor can also bind and internalize circulating ferritin (see pdb 6GSR).

Figure 12.3.24 shows an interactive iCn3D model of transferrin (2N and 2C-lobes) binding to the ectodomain of the transferrin receptor (1SUV).



NCBI iCn3D Figure 12.3.24: Transferrin (2N and 2C-lobes) binding to the ectodomain of the transferrin receptor (1SUV). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...cBhTyxoSDQgH47

The transferrin receptor is shown in gray (2 monomers) bound to the N-lobes (cyan) and C-lobes (magenta) of transferrin. Each transfer lobe has a bound CO_3^{2-} (spacefill with CPK colors) and a Fe^{3+} ion (orange).

12.3.7: OXIDATIVE MODIFICATION OF PROTEINS

Many amino acid side chains can be oxidized in cells, as shown in Table 12.3.1.

Table 12.3.1: Amino acid side chain oxidation products. Berlett and Stadtman. JBC, 272, 20313-20316 (1997).
DOI:https://doi.org/10.1074/jbc.272.33.20313.

Amino acids	Oxidation products
Cysteine	Disulfides, cysteic acid
Methionine	Methionine sulfoxide, methionine sulfone
Tryptophan	2-, 4-, 5-, 6-, and 7-Hydroxytryptophan, nitrotryptophan, kynurenine, 3-hydroxykynurinine, formylkynurinine
Phenylalanine	2,3-Dihydroxyphenylalanine, 2-, 3-, and 4-hydroxyphenylalanine
Tyrosine	3,4-Dihydroxyphenylalanine, tyrosine-tyrosine cross-linkages, Tyr-*O*-Tyr, cross-linked nitrotyrosine
Histidine	2-Oxohistidine, asparagine, aspartic acid
Arginine	Glutamic semialdehyde
Lysine	α-Aminoadipic semialdehyde
Proline	2-Pyrrolidone, 4- and 5-hydroxyproline pyroglutamic acid, glutamic semialdehyde
Threonine	2-Amino-3-ketobutyric acid
Glutamyl	Oxalic acid, pyruvic acid

We will focus just on one here, the oxidation of the ε-amino group of lysine by H_2O_2 to form α-aminoadipic semialdehyde, where the amine is replaced with an aldehyde. This reaction is called the Fenton reaction as is actually a **carbonylation** reaction. A hypothetical mechanism for the oxidation of lysine side chains is shown in Figure 12.3.25.

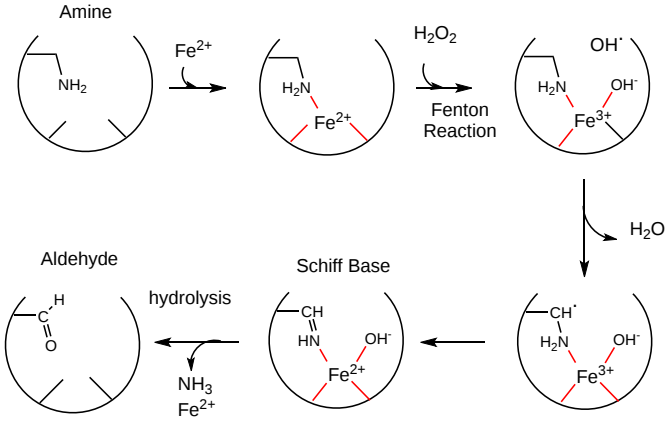


Figure 12.3.25

The next result is the oxidation of the lysine ε-amino group to an aldehyde. Oxidized levels of proteins (as evidenced by increased levels of carbonylation) increase dramatically with age (especially after age 40). The reactions seem to be catalyzed by metals and may proceed by the generation of hydroxy free radicals. Diseases associated with premature aging (Werner's Syndrome, another link to Werner's Syndrome, Progeria) show very high levels of oxidized proteins at an early age. Fibroblasts from 10 yr. old children with progeria have levels of oxidized proteins usually not seen until the age of 70. Beta-amyloid protein deposits (found in Alzheimer's and Down's Syndrome) cause neurotoxicity and death, partly by increasing superoxide production by endothelial cells, causing vasoconstriction/dilation, and ultimately disease progression. Beta-amyloid aggregates appear to increase H_2O_2 levels, in a process facilitated by Fe^{2+} and Cu^{+}. Free radical scavengers (antioxidants) may help to prevent this damage.

Carbonylation of proteins appears to be irreversible and nonrepairable. Increased carbonylation leads to misfolding and protein aggregation in ways in which protein chaperones can not reverse. The graphs in Figure 12.3.26 (the summation of many experiments) show the correlation (negative) of increasing carbonylation of proteins (red line), a measurement of oxidative damage, and the resulting decrease in protein function (green).

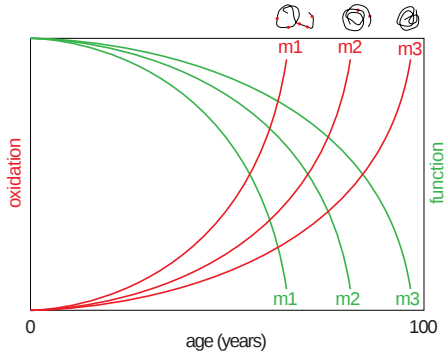

Figure 12.3.26: Susceptibility of proteoforms to oxidative modifications determines the onset of their oxidation over time and leads to their functional decline. Krisko and Radman, (2019) *Open Biol.***9.** http://doi.org/10.1098/rsob.180249. Creative Commons Attribution License http://creativecommons.org/licenses/by/4.0/.

Red dots in the top representations of protein show carbonylation. Variants of the same protein (proteoforms) that have more intrinsically disordered regions (m1) are more susceptible to carbonylation compared to more ordered variants (m3). Cancer starts to increase around 40 years of age, and the levels of carbonylation correlate with increased cancer rates and may, in part, cause it.

Lou Gehrigs Disease (Amyotrophic Lateral Sclerosis) is a disease of progressive motor neuron degeneration, which affects 1/100,000 people, and is 10-15% familial. Of the familial cases, about 25% have a mutation in superoxide dismutase I, a copper-zinc enzyme. About 2-3% of ALS patients carry 1 of 60 different dominant mutations in this enzyme. Mutations often decrease the stability of the protein which decreases Zn^{2+} affinity 5-50 fold. The A4V mutation (valine at amino acid 4 substituted for Ala) has the weakest Zn affinity and causes rapid disease progression. In the absence of Zn^{2+}, the apoprotein somehow seems to induce cell death in neurons. This superoxide dismutase also expresses a second activity. It also acts as a peroxidase which takes ROH + H_2O_2 to form an RHO (an aldehyde) plus water. In some cases, the enzyme retains normal activity against superoxide but altered peroxidase activity.

Figure 12.3.27s shows the extent of carbonylation of wild type (WT) and two mutant forms α-synuclein after exposure (in vitro) to increasing doses of γ-radiation. α-synuclein forms aggregates (Lewy bodies) in Parkinson's Disease.

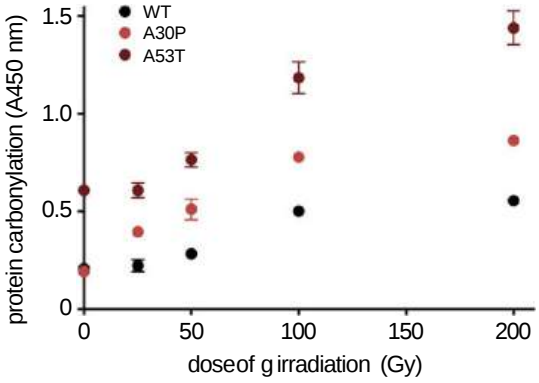

Figure 12.3.27: Wild-type version of α-synuclein is characterized by the highest oxidation resistance. The plot displays the differential resistance to γ radiation of human α-synuclein protein isomorph. Krisko and Radman, ibid.

The mutants, especially the A53T one, show significantly high extents of oxidative damage. This particular mutation is associated with the early onset (around 30) of Parkinson's Disease.

Is your hair going white?: Wood et al have shown that millimolar concentrations of hydrogen peroxide builds up in hairs that have grayed and whitened. This was associated with a decrease in catalase and in increases in Met oxidation (to Met-sulfoxide) in proteins, also associated with a decrease in the repair enzyme Met-sulfoxide reductase, Met 374 in the active site of tyrosinase, an enzyme required for the production of melanin in hair follicles, is also damaged, leading to lack of melanin, a pigment necessary for hair coloration and "senile hair graying".

ROS and Protein Folding

As discussed earlier, the cytoplasm has sufficient concentrations of "β-mercaptoethanol"-like molecules (used to reduce disulfide bonds in proteins in vitro) such as glutathione (γ-Glu-Cys-Gly) and reduced thioredoxin (with an active site Cys) to prevent disulfide bond formation in cytoplasmic proteins. Disulfide bonds in proteins are typically found in extracellular proteins, where they serve to keep multisubunit proteins together as they become diluted in the extracellular milieu. These proteins destined for secretion are cotranslationally inserted into the endoplasmic reticulum (see below) which presents an oxidizing environment to the folding protein and where sugars are covalently attached to the folding protein and disulfide bonds are formed (see Chapter 3D: Glycoproteins - Biosynthesis and Function). Protein

enzymes involved in disulfide bond formation contain free Cys which form mixed disulfides with their target substrate proteins. The enzymes (thiol-disulfide oxidoreductases, protein disulfide isomerases) have a Cys-XY-Cys motif and can promote disulfide bond formation or their reduction to free sulfhydryls. They are especially redox-sensitive since their Cys side chains must cycle between and free disulfide forms.

Reactive oxygen species (ROS) can significantly affect redox chemistry, and if present in excess can place the cell in a condition of "oxidative" stress. ROS can indiscriminately oxidize lipids, nucleic acids, and proteins, but more specifically, they may also oxidize proteins involved in creating and maintaining the normal disulfide bond formation in proteins. As the concentration of ROS increases, the concentration of cytoplasmic proteins with incorrect disulfides should increase. Using a two dimension PAGE system (first dimension run under nonreducing and the second reducing conditions) of neural cell proteins derived from cells exposed to normal and differing oxidative conditions (hydrogen peroxide or decreased intracellular glutathione levels, Cumming et al showed that oxidizing stress increased the levels of disulfide bonds in redox sensitive enzymes and, unexpectedly, among other cytoplasmic proteins involved in many aspects of life, affecting the activity of many cellular processes, suggesting that disulfide bond formation may have not only a structural but regulatory role.

12.3.8: OXIDATIVE MODIFICATION OF LIPIDS:

Figure 4 shows the most likely position in organic molecules that can form stable free radicals (allylic, benzylic position, and $3^o > 2^o >> 1^0$ carbons) are likely targets for reaction with ROS. Hence unsaturated fatty acids are extra reactive at the methylene C that separates the double bonds as shown in Figure 12.3.28.

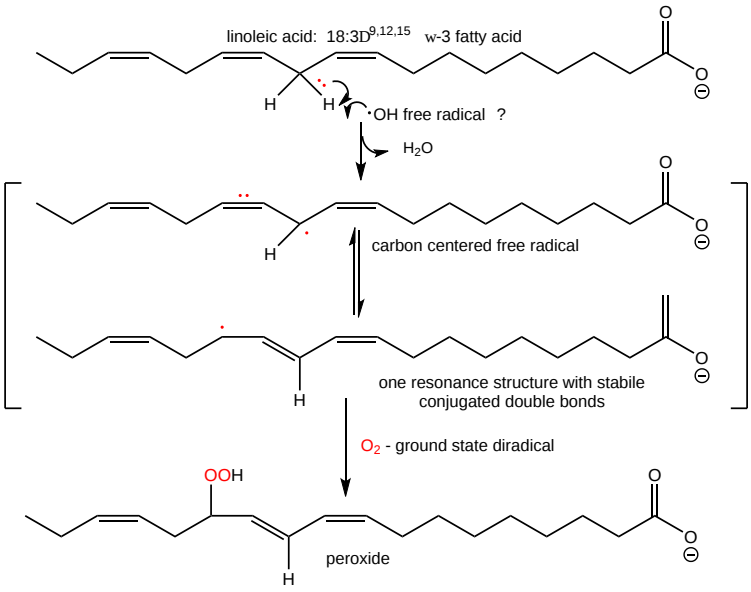

Figure 12.3.28: Reactions of fatty acids with ROS

12.3.9: LIPID AND PROTEIN OXIDATION - CARDIOVASCULAR DISEASE

The initial stages of cardiovascular disease appear to involve the development of fatty acid streaks under the artery walls. Macrophages are immune cells that have receptors that recognize oxidized lipoproteins in the blood, which they takeup. The cells then further differentiate into fat-containing **foam cells** which form the streaks. Oxidation of fatty acids in lipoproteins could produce lipid peroxides and along with the Fenton reaction lead to the oxidation of apoproteins in LDL. Cortical neurons from fetal Down's Syndrome patients show 3-4 times levels of intracellular reactive oxygen species and increased levels of lipid peroxidation compared to control neurons. This damage is prevented by treatment of the neurons in culture with free radical scavengers or catalase. Key events in atherosclerotic plaque initiation are shown in Figure 12.3.29.

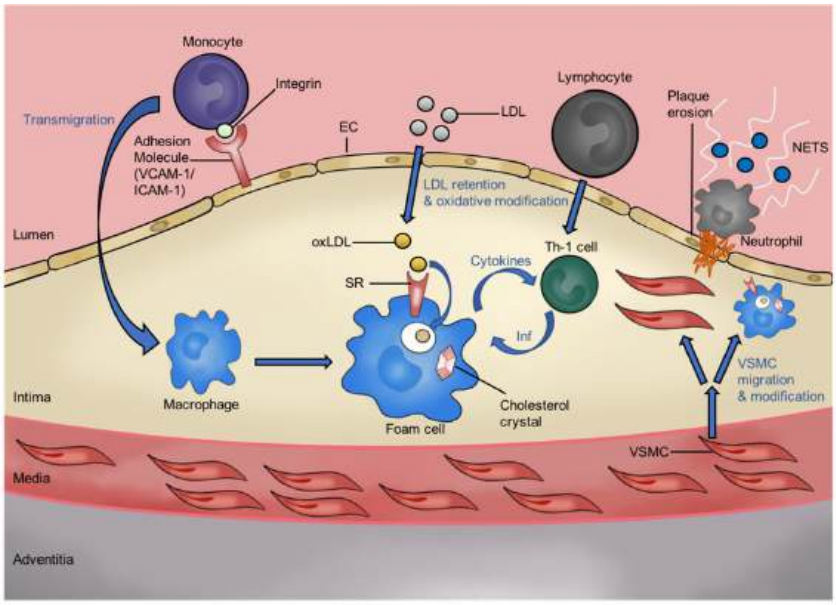

Figure 12.3.29: Key events in atherosclerotic plaque initiation. Blood LDL can accumulate within the arterial wall, in the sub-endothelial intima. This accumulated LDL can be chemically modified or oxidized: this new lipid particle species (e.g., oxLDL) promotes chronic inflammation, which promotes the trans-endothelial migration of immune cell types and foam cell development. Abbreviations: endothelial cell, EC; intercellular adhesion molecule-1, ICAM-1; interferon-γ, IFNγ; low-density lipoprotein, LDL; Neutrophil extracellular traps, NETS; oxidized low-density lipoprotein, oxLDL; scavenger receptor, SR; T- helper 1 cell, Th1; vascular cell adhesion molecule-1, VCAM-1; vascular smooth muscle cell, VSMC. Cuthbert et al. *Cells* **2020**, *9*(11), 2453; https://doi.org/10.3390/cells9112453. Creative Commons Attribution (CC BY) license (http://creativecommons.org/licenses/by/4.0/).

How do fatty streaks appear under the endothelial cells? LDL oxidized in the lipid monolayer and through carbonylation of lysine side chains of the apoproteins in LDL binds to "scavenger" receptors in macrophages which have moved into the intima below the endothelial cell barrier. Scavenger receptors were first recognized to bind acetylated LDL (conversion of ε-amino groups of lysines, for example, to acetylated and uncharged derivatives). This mimics to some degree the carbonylation of the ε-amino groups to aldehydes, as shown in Figure 12.3.30.

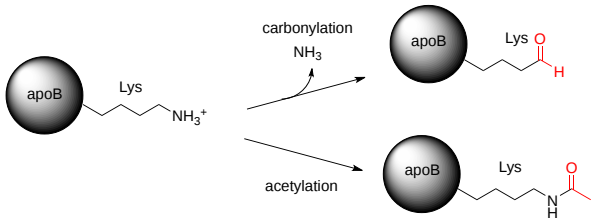

Figure 12.3.30: Carbonylation and acetylation of lysine side chains

Either modification would make the apoprotein more acidic with a lower isoelectric point since positive lysine side chains are replaced with neutral derivatives. Assuming an asymmetric distribution of the negatively charged side chains (Asp and Glu) on the apoprotein, any pre-modification negative electrostatic potential surfaces on the apoprotein would become more negative, enhancing binding to positive clusters displaying positive electrostatic potentials on scavenger receptors. Scavenger receptors often bind polyanions.

There are many 12 different classes (A-L) of scavenger receptor classes that have been identified. One, class C, is only found in drosophila. They bind a variety of polyanionic ligands and display broad binding specificity. Many in a single class have multiple names that makes their designation even more confusing. They bind a diverse set of ligands including those from bacteria and yeast (in a way similar to pathogen-associated molecular patterns - PAMPs - in the innate immune system) as well as self and modified self ligands (such as oxidized LDL - oxLDL). Once bound the ligand and scavenger receptors are taken into the cell by endocytosis for removal and degradation of the bound ligand. They can also act in signaling pathways.

The members of the scavenger receptor family are designated as illustrated in this example, **S**R-F1.1, where **S** is Scavenger, **R** is Receptor, **F** is Class, **1** is Order in class and **1** is alternatively spliced forms. Figure 12.3.31 shows domain structures of the different classes of scavenger receptors.

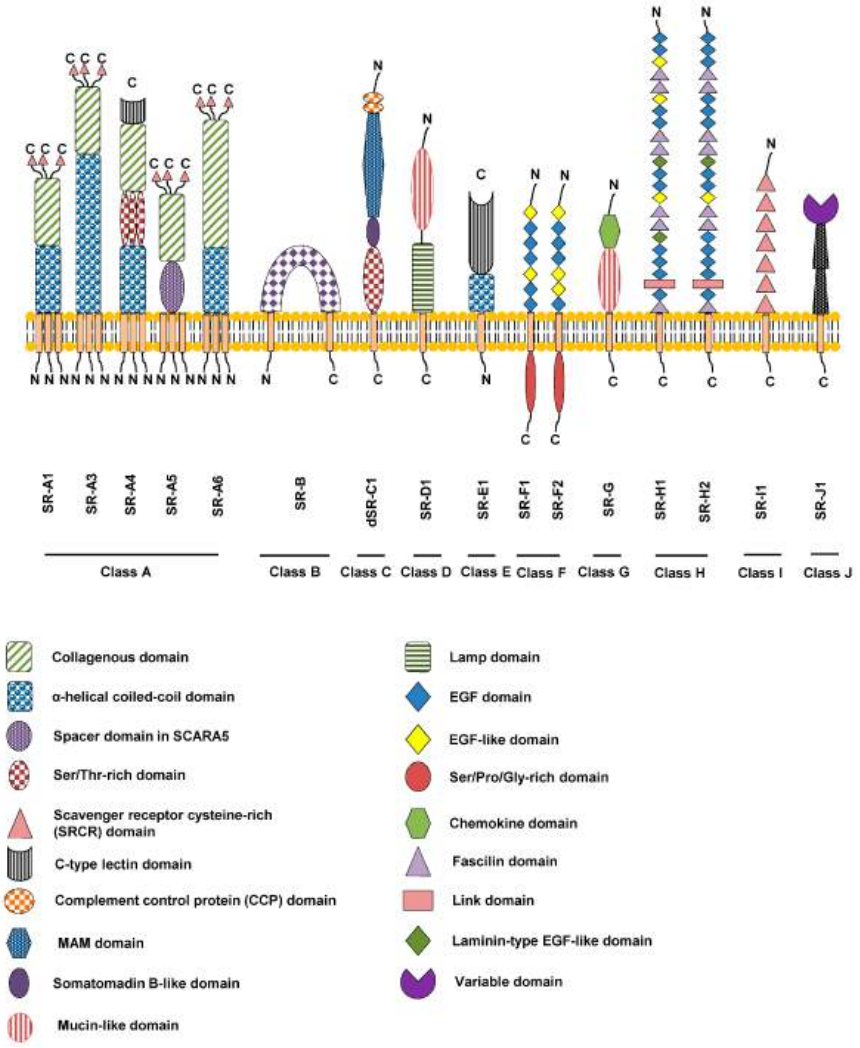

Figure 12.3.31: Domain structures of the different classes of scavenger receptors. Zani et al. *Cells* **2015**, *4*, 178-201. https://doi.org/10.3390/cells4020178. Creative Commons Attribution 4.0 International

A more detailed cartoon showing examples from a few different scavenger receptor classes involved in cardiovascular disease is shown in Figure 12.3.32.

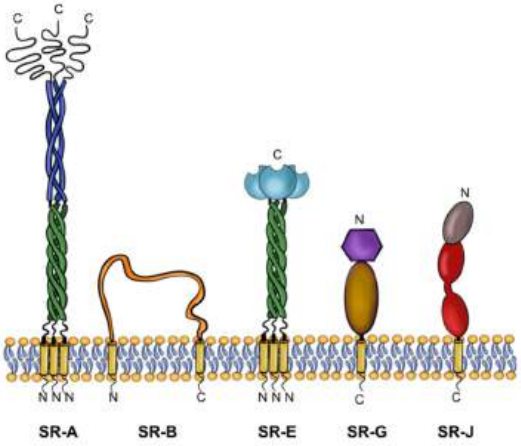

Figure 12.3.32 Five different SR classes (A, B, E, G, J) are most closely linked to the initiation and progression of atherosclerosis. These molecules are potential biomarkers and therapeutic targets. Their structures are represented in the sketches above. Abbreviations: N-terminus, N; C-terminus, C. Cuthbert et al. ibid.

Modified LDL binds to several different scavenger receptors, including SR-A1 (also called SCARA1 or CD204), SR-A2 (also called MARCO), and SR-E1 (also called Lectin-like oxidized LDL receptor 1 or LOX-1) binds oxidized and acetylated LDL.

Let's look in greater detail at two scavenger receptors that recognized oxLDL

SR-A2 (MARCO)

This scavenger receptor is a trimer that binds oxLDL, polyanions, and pathogens. It has an extracellular domain (ectodomain) formed from three monomers that are **c**ysteine **r**ich, so it's abbreviated SRCR. A five-stranded antiparallel β-sheet, and an α-helix with a large loop covering it, while the dimer has a larger 8-stranded eight-stranded β-sheet. The polyanion ligands bind presumably to the surface of the receptors with a positive (blue in figures) electrostatic potential associated with an arginine cluster. Crystal structures show that the protein also has a region of negative (red in figures) electrostatic potential which most likely is involved in metal ion binding and in the self-association of monomers to form trimeric receptors.

Given the size of the oxidized LDL (250 Å in diameter), it would not be unexpected that oxLDL binding would promote the formation of clusters of the normally trimer scavenger receptor. This is illustrated in Figure 12.3.33.

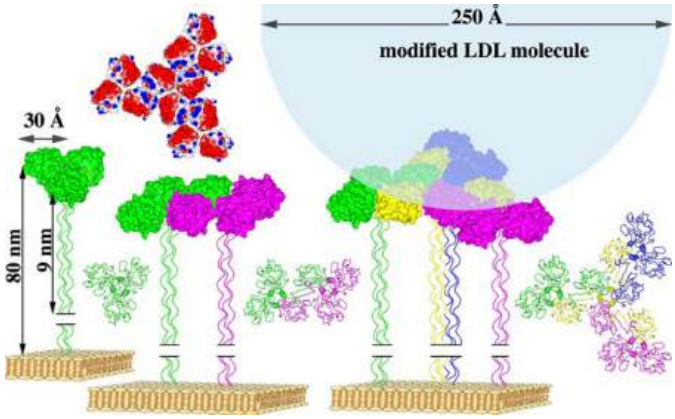

Figure 12.3.33: Model for dimerization and oligomerization of trimeric MARCO molecules. Ojalaet al. JBC **282,16654**-16666 (2007) DOI:https://doi.org/10.1074/jbc.M701750200. Creative Commons Attribution (CC BY 4.0)

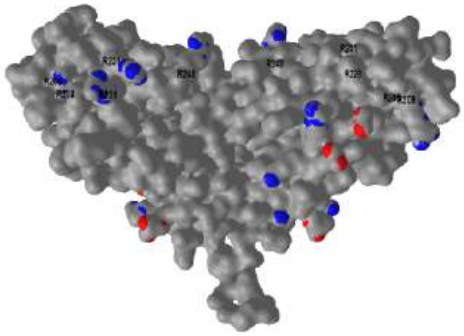
Monomeric, dimeric, and oligomeric forms of **SR-A2 (**MARCO) are shown in the bottom part of the figure. The trimeric receptor molecules can form dimers and multimers by swapping domains. Multiple interactions would promote tighter binding of large ligands such as LDL and even bacteria (0.2-2 μm diameter). The assembly could proceed to the formation of oligomers (the *yellow molecule* has swapped domains with three other molecules), thus resulting in the creation of a large surface capable of interacting with large ligands, such as modified LDL (250 Å in diameter) or bacteria (0.2-2 μm). The red and blue surfaces shown above the trimer represent the negative (red) and positive (blue) electrostatic surface electrostatic potential of the oligomeric from top down.

SR-E1 (Lox1 or Lectin-like oxidized LDLR or Oxidized low-density lipoprotein receptor 1.

LOX-1 is expressed on macrophages, dendritic cells, endothelial cells, platelets, smooth muscle cells, and adipocytes. It binds oxLDL, some bacteria (through their negatively charged cell walls), and even apoptotic cells. Figure 12.3.34 shows an interactive iCn3D model of the extracellular C-type lectin-like domain of dimeric human Lox-1 (1YPQ)

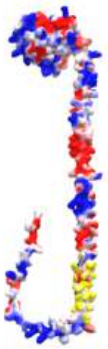


NCBI iCn3D Figure 12.3.34: Extracellular C-type lectin-like domain of dimeric human Lox-1 (1YPQ). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...qGY4HBzPjjs7P7

The dimer in this structure is connected by a disulfide bridge. The two monomers are shown in gray spheres. They come together to form a heart-like structure A series of arginines (with blue spheres for the surface Ns and labeled) are shown in the cradle of the heart shape. These most likely interact with the oxidized apoprotein B of the oxLDL. Other blue (N) and red (O) spheres near to each other can form salt

bridges and may interact with zwitterion heads of LDL surface lipids such as phosphatidylcholine, sphingomyelin, or phosphatidylethanolamine.

Figure 12.3.35 shows an interactive iCn3D model of an AlphaFold predicted model of human oxidized LDL receptor - LOX (P78380)



NCBI iCn3D Figure 12.3.35: . (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...rLoi7ZK4K3SsH8

The yellow spacefill indicates the transmembrane segment. Rotate the model along the long axis and you will see one face of the top domain has a red (negative electrostatic potential) face while the opposite side has blue (positive potential).

12.3.10: OXIDATIVE MODIFICATION OF DNA

Significant evidence suggests oxygen free radicals are linked to aging and diseases. Mutations caused by hydroxylation reactions (presumably from the generation of hydroxyl free radicals as shown above) can potentially lead to cancer. A particularly nasty reaction is the insertion of the hydroxy radical into bases in DNA. Figure 12.3.36 shows the hydroxylation at position 8 of guanine to produce 8-oxy-G and at positions 5 and 6 in thymine.

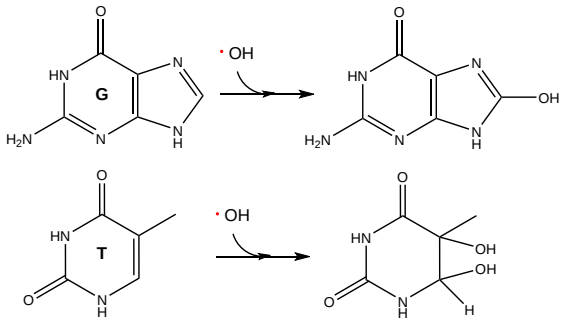


Figure 12.3.36 Hydroxylation of G and T bases by the hydroxyl free radical

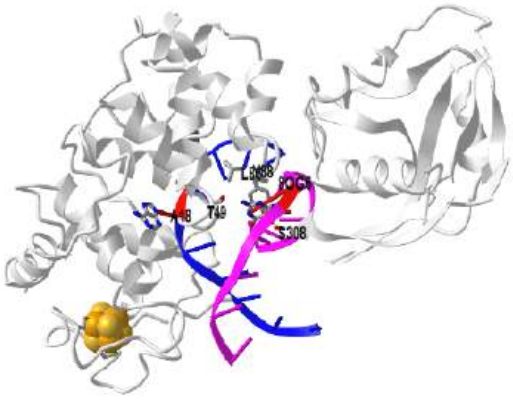
Mitochondrial DNA is more susceptible to oxidation than is nuclear DNA. The human mitochondrium has a small genome (16.5 Kb compared to the nuclear genome of 3 Gb) which code 13 protein subunits involved in respiration, 22 tRNAs and two ribosomal RNAs. (The mitochondria presumably are vestiges of a bacteria which invaded an early cell and established a symbiotic relationship with the cell). There is an inverse correlation of oxidized mitochondrial DNA [8-oxoG] with the maximal life span of an organism, but this correlation is not seen with nuclear DNA. Presumably, the nuclear DNA is somewhat protected from oxidative damage since it is bound to histone proteins (which form nucleosome core particles with DNA) and by DNA repair enzymes. DNA repair enzymes that are encoded in the nucleus are found in the mitochondria and mitochondrial DNA is packaged with mitochondrial transcription factor A (TFAM). Examination of human bladder, head and neck, and lung primary tumors reveals a high frequency of mitochondrial DNA mutations. In addition, most dioxygen use by the cell occurs in the mitochondria. Hence this organelle probably faces the highest concentration of toxic oxygen reduction products. Recently, the crystal structure of an enzyme, adenine DNA glycosylase (MutY), that repairs 8-oxyG modified DNA has been determined in complex with the oxidatively damaged DNA. If not repaired, the 8-oxyG base pairs with adenine instead of cytosine, causing a GC to AT mutation on DNA replication.

Figure 12.3.37 shows an interactive iCn3D model of adenine mispaired with 8-oxoguanine by MutY adenine DNA glycosylase (1RRQ)



NCBI iCn3D Figure 12.3.37: Adenine mispaired with 8-oxoguanine by MutY adenine DNA glycosylase (1RRQ) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?4RiEc6TuqmexiW1r7

The protein MutY, which catalyzes the base excision and repair, is shown in gray. The DNA strands are shown in magenta and blue. 8-OxyG on the magenta strand is labeled 8OG7 and is shown in CPK-colored sticks. Its mismatched adenine base pair partner, labeled A18 on the blue strand, is shown in CPK-colored sticks. Notice its orientation is kinked away from the orientation in a canonical base pair. Key amino acid side chains (Thr49, Leu86, Tyr88, and Ser308) interacting with the 8-oxyG are shown in CPK-colored sticks and labeled.

Although oxidative damage in mitochondria clearly can promote premature aging, other independent mechanisms may also. Kujoth et al. developed a mouse model that expressed a mutant form of mitochondrial DNA polymerase that was defective in the proofreading activity of the enzyme. These mice displayed premature aging but showed no increased levels of oxidized mitochondrial lipids or hydroxylated G residues in mitochondrial DNA. They did show significant activation of a cytosolic enzyme called caspase-3, which when active lead to the programmed death of cells (a process called apoptosis). This calcium-activated aspartic acid protease (with an active site Asp) is activated by binding mitochondrial cytochrome C that has "leaked" into the cytoplasm from its normal location in the intermembrane space in mitochondria. The process is usually associated with DNA damage (mutations, fragmentation) that would arise if the proofreading function of DNA polymerase was defective. This was indeed found in these mice.

Oxidative damage to biomolecules might not initiate aging and disease processes, but rather might be a secondary effect of other initiating events. .Reversing or preventing oxidative damage might slow the progression of aging and disease. Aging is a complex feature of organisms and would be expected to have complex causes and biological effects. At the organismal level, aging has been studied in the roundworm C. elegans which lives for only a few weeks. Genetic analyses can be easily used to find gene alterations associated with premature aging. One hormonal system that has recently been associated with aging in eukaryotes (and in C. elegans) involves the signaling pathways for insulin and insulin growth factor I (IGF-1), which regulate carbohydrate, lipid, and reproductive pathways in C. elegans. Mutations that decrease signaling from this pathway increase C. elegans life span. These mutations lead to increased activity of the DAF16 transcription factor, which upregulates the expression of many genes. In contrast, wild-type organisms, when exposed to insulin or IGF-1, decrease the activity of DAF16. Using DNA microarrays, investigators determined which DAF16-controlled genes were upregulated in mutant worms in the mid-life point of the organism. These genes included, among others, peroxisomal and cytosolic catalase, Mn-superoxide dismutase, cytochrome P450s, metallothionein-related Cd-binding protein, and heat shock proteins. We will investigate the function of several of these gene products in the next section, but needless to say, they are all involved in cellular responses to stress, often involving dioxygen metabolites. The over-expression of mitochondrial catalase in mice increased their lifespan by 20%. It has also been showed that decreased levels of insulin-like growth factor also promote longevity in mice, indicating again that mechanisms in addition to oxidative damage by ROS are involved in aging.

12.3.11: BENEFICIAL OXIDATION OF PROTEINS: OXIDATIVE BURST IN MACROPHAGES

There are cases in which oxidative damage to protein and lipids is desirable. One example involves the role of macrophages in the immune system in eliminating foreign microorganisms. When macrophages recognize and engulf microbes, one mechanism deployed in killing the microorganism is through oxidative damage. The stimulated macrophages undergo an oxidative burst which leads to increased oxygen

utilization. One outcome of this is the generation of ROS. The activation of the ROS-generating system can also kill the macrophage (which is OK).

In addition, immune function decreases with age. This probably also occurs through damage from ROS. Telomeres at the end of chromosomes are also shortened by oxidative stress and irradiation. They are enriched in guanine bases the have may repeat (thousands) of TTAGGG sequences and hence are susceptible to oxidation. However, as you might expect, macrophages have developed ways to limited self-damage by ROS.

In the presence of ROS, the macrophage or mitochondrial kinase Mst1/2 are recruited to their respective membranes from the cytosol. The enzyme acts as a ROS sensor and "attenuator" though the phosphorylation and stabilization of a protein Keap1 that binds to a transcription factor Nrf2 (also called NFE2L2), a transcription factor. When bound to unphosphorylated Keap1, the transcription factor Nrf2 is target for proteolysis. Keap1 phosphorylation prevents its binding to Nrf2. Free Nrf2 then can translocate to the nucleus where it promotes transcription of antioxidant proteins such as glutamate-cysteine ligase catalytic subunit (Gclc), which catalyzes the first step and rate-limiting step of glutathione (g-glutamyl-cysteinyl-glycine) synthesis. These processes are illustrated in Figure 12.3.38.

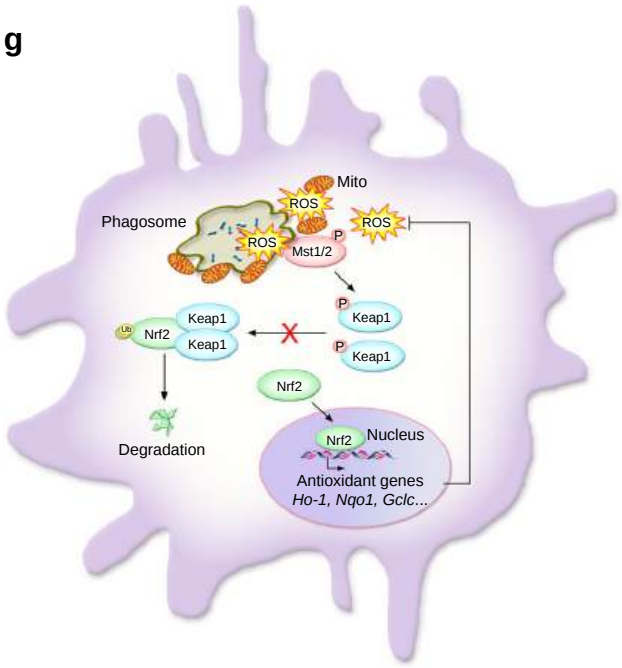


Figure 12.3.38 A proposed working model for kinases Mst1/2 sense ROS and maintain cellular redox balance by modulating the stability of Nrf2. Wang, P., Geng, J., Gao, J. *et al.* Macrophage achieves self-protection against oxidative stress-induced aging through the Mst-Nrf2 axis. *Nat Commun* **10,** 755 (2019). https://doi.org/10.1038/s41467-019-08680-6. Phagosomal or mitochondrial ROS release attracts Mst1/2 to the membrane of phagosome or mitochondrion from the cytosol and activates Mst1/2; Mst1/2
phosphorylate Keap1 to stabilize Nrf2 and regulate the expression of antioxidant enzymes to protect the cell against oxidative damage.

12.4: BIOLOGICAL OXIDATION-REDUCTION REACTIONS

12.4.1: GENERAL OXIDIZING AGENTS

Before we consider common biological oxidizing agents, lets look back at ones you saw in other chemistry classes. Oxidizing agents are required to oxidize organic molecules. In organic lab, you never used dioxygen as an oxidizing agent. It is difficult to limit the extent of oxidation using dioxygen. In addition, side reactions are likely given the nature of the reactive oxygen reduction products. The mechanisms of combustion reactions of organic molecules with dioxygen to produce carbon dioxide and water are very complicated. Table 12.4.1 belows some key steps in the combustion of methane.

Initiation

$$\mathrm{CH_4 \rightarrow CH_3^{\cdot} + H^{\cdot}}$$

$$\mathrm{O_2 \rightarrow 2\,O^{\cdot}}$$

Propagation

$$\mathrm{CH_4 + H^{\cdot} \rightarrow CH_3^{\cdot} + H_2}$$

$$\mathrm{CH_4 + HO^{\cdot} \rightarrow CH_3^{\cdot} + H_2O}$$

$$\mathrm{CH_3^{\cdot} + O^{\cdot} \rightarrow CH_2O + H^{\cdot}}$$

$$\mathrm{CH_2O + HO^{\cdot} \rightarrow CHO^{\cdot} + H_2O}$$

$$\mathrm{CH_2O + H^{\cdot} \rightarrow CHO^{\cdot} + H_2}$$

$$\mathrm{CHO^{\cdot} \rightarrow CO + H^{\cdot}}$$

$$\mathrm{CO + HO^{\cdot} \rightarrow CO_2 + H^{\cdot}}$$

Branching

$$\mathrm{H^{\cdot} + O_2 \rightarrow HO^{\cdot} + O^{\cdot}}$$

Termination

$$\mathrm{H\cdot + R^{\cdot} + M \rightarrow RH + M^{\cdot}}$$

In chemistry, other oxidizing agents are often used, including permanganate and chromate. Their mechanism of action is illustrated in Figure 12.4.1.

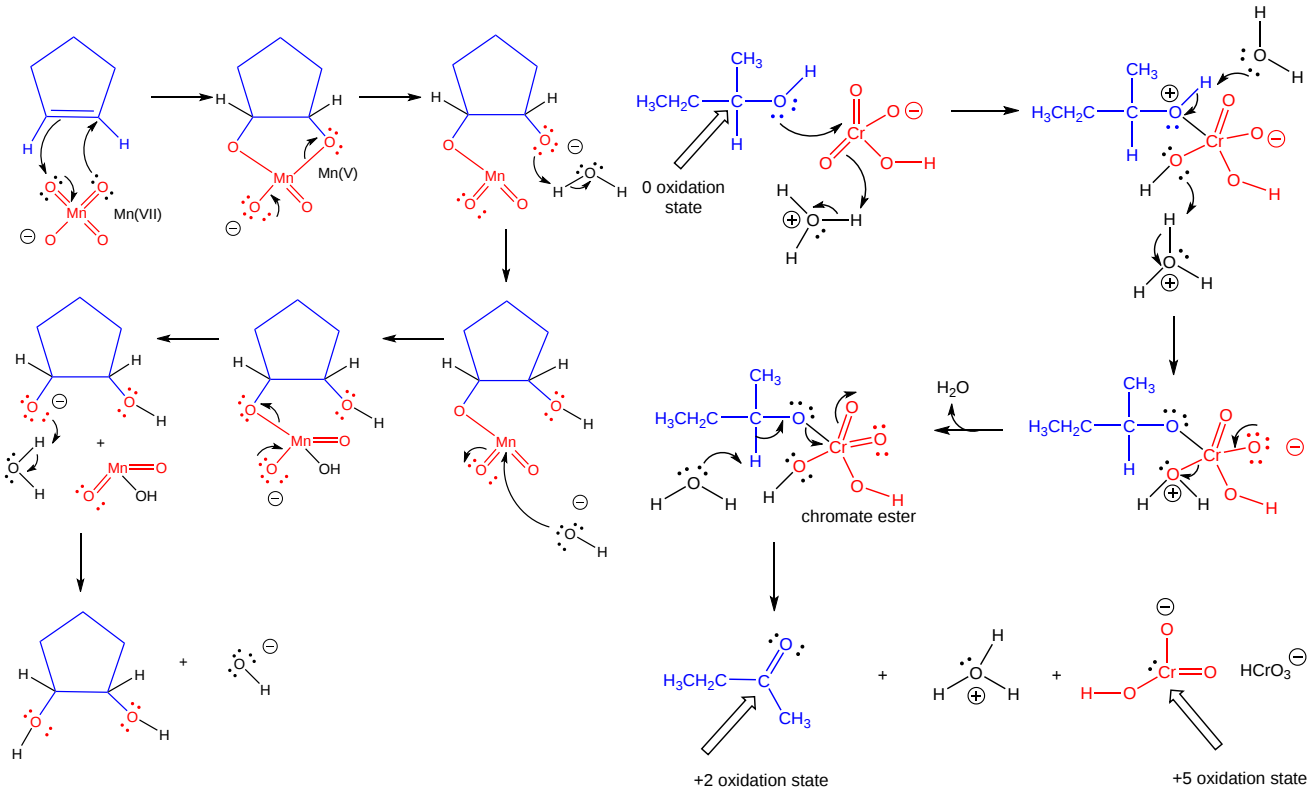

Figure 12.4.1: Mechanism of oxidation of organic molecules by permanganate and chromate

Oxygen can often be inserted into a molecule in a nonoxidative process by hydration of an alkene to an alcohol (a readily reversible reaction), which could then be oxidized to either an aldehyde/ketone or carboxylic acid using an appropriate oxidizing agent.

Most biological oxidation reactions (such as those found in glycolysis, Kreb Cycle, and fatty acid oxidation) do not use dioxygen as the immediate oxidizing agent. Rather they use nicotinamide adenine dinucleotide (NAD+) or flavin adenine dinucleotide (FAD) as oxidizing agents, which get reduced. Enzymes that uses these oxidizing agents are usually called **dehydrogenases**. Dioxygen can also be used to introduce oxygen atoms into biological molecules in oxidative reactions. Enzymes that introduce one oxygen atom of dioxygen into a molecule (and the other oxygen into water) are called **monooxygenases**. (Note: some monooxygenase that hydroxylate biomolecules are called **hydroxylases**.) Those that introduce both atoms of dioxygen into a substrate are called **dioxygenases**. These oxygenases are not usually used to oxidize organic molecules for energy production. Rather they introduce O atoms for other reasons, including increasing the solubility of nonpolar aromatics to facilitate secretion, and to produce new molecular species which have different biological activities. Finally, biological molecules can be oxidized by dioxygen in which no atoms of oxygen are added to the substrate. Rather, electrons lost from the oxidized substrate are passed via intermediate electron carriers to dioxygen , which get reduced to superoxide (if one electron is added), hydrogen peroxide (if two electrons are added) or water (if 4 electrons are added). These enzymes are called oxidases. (Note: The letters oxi- or oxygen- are used in all the enzymes that use dioxygen as the oxidizing agent.)

In this chapter section, we will discuss biological oxidation reactions. Most introductory biochemistry texts don't approach oxidation reactions in one cohesive chapter. Probably because of that, when I was learning biochemistry, I found the presentation of these different enzymes involved in redox reactions to be very confusing. Hopefully this section will alleviate that problem. First the chemistry of NAD^+ and FAD will be discussed. Then the enzymes using dioxygen in oxidative reactions (monooxygenases, dioxygenases, and oxidases) will be explored.

12.4.2: THE CHEMISTRY OF NAD^+ AND FAD

NAD^+ is a derivative of nicotinic acid or nicotinamide, as illustrated in Figure 12.4.2.

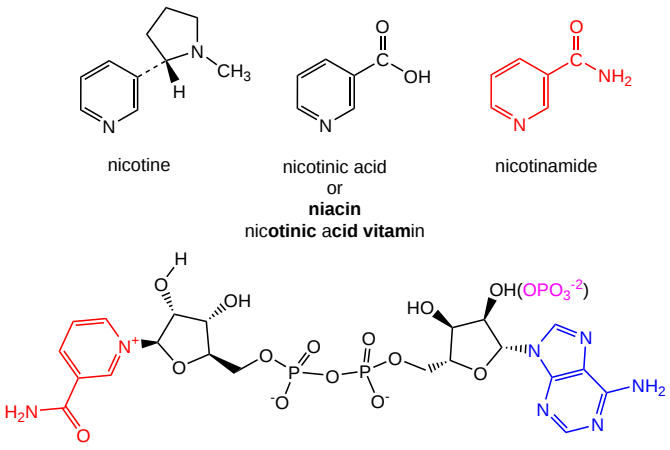

Figure 12.4.2: Structure of niacin derivatives

It and its reduction product, NADH, exists in the cells as interconvertible members of a pool whose total concentration does not vary significantly with time. Hence, if carbohydrates and lipids are being oxidized by NAD+ to produce energy in the form of ATP, levels of NAD+ would begin to fall as NADH rises. A mechanism must be be present to regenerate NAD+ from NADH if oxidation is to continue. As we will see later, this happens in the muscle under anaerobic conditions (if dioxygen is lacking as when you are running a 100 or 200 m race, or if you are being chased by a saber-toothed tiger) when pyruvate + NADH react to form lactate + NAD^+. The reaction is shown in Figure 12.4.3.

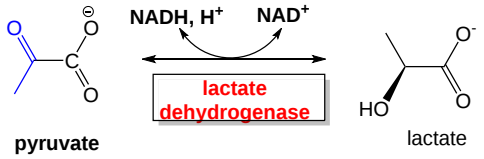

Figure 12.4.3: Conversion of pyruvate to lactate

Under aerobic conditions (sufficient dioxygen available), NADH is reoxidized in the mitochondria by electron transport through a variety of mobile electron carriers, which pass electrons to dioxygen (using the enzyme complex cytochrome C oxidase) to form water.

NAD^+/NADH can undergo two electron redox steps, in which a hydride is transferred from an organic molecule to the NAD^+, with the electrons flowing to the positively charged nitrogen of NAD^+ which serves as an electron sink. NADH does not react well with dioxygen, since single electron transfers to/from NAD^+/NADH produce free radical species which can not be stabilized effectively. All NAD^+/NADH reactions in the body appear to involve 2 electron hydride transfers. Figure 12.4.5 shows both 1 and 2 electrons to NAD^+.

Figure 12.4.4:

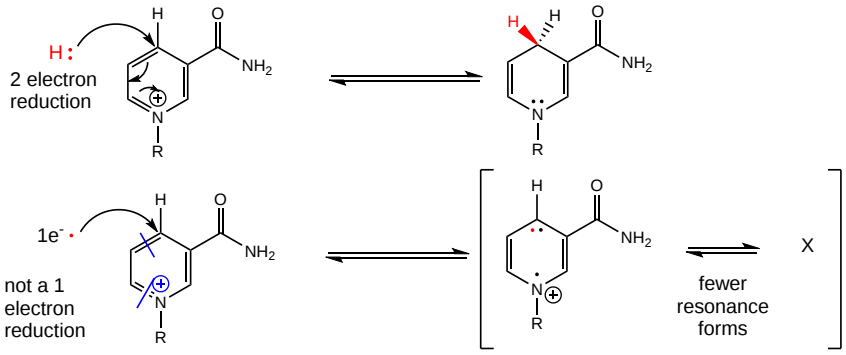

Figure 12.4.4: 1 and 2 electrons to NAD^+

FAD (or flavin mononucleotide-FMN) and its reduction product, $FADH_2$, are derivatives of riboflavin, as shown in Figure 12.4.5.

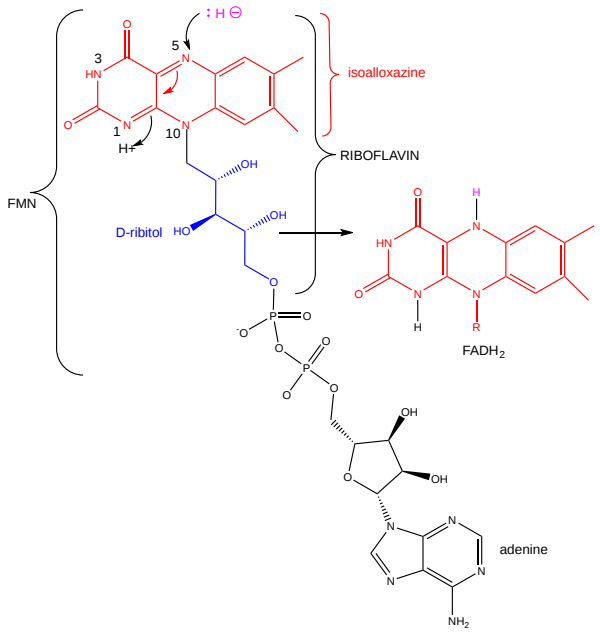

Figure 12.4.5: Structures of riboflavin, FMN and FAD

$FAD/FADH_2$ differ from $NAD^+/NADH$ since they are bound tightly (K_D approx 10^{-7} - 10^{-11} M) to enzymes which use them. This is because $FADH_2$ is susceptible to reactions with dioxygen, since $FAD/FADH_2$ can form stable free radicals arising from single electron transfers. $FAD/FADH_2$ can undergo 1 OR 2 electrons transfers. This is illustrated in Figure 12.4.6.

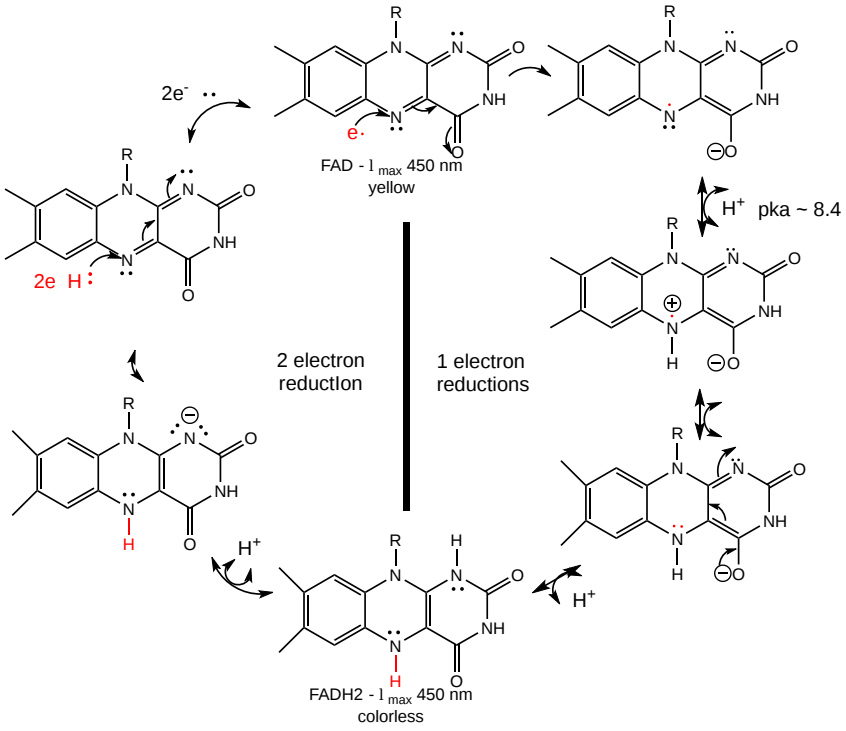

Figure 12.4.6: 1 and 2 electrons reduction of FAD

$FAD/FADH_2$ are tightly bound to enzymes so as to control the nature of the oxidizing/reducing agents that interact with them. (i.e. so dioxygen in the cell won't react with them in the cytoplasm.) If bound FAD is used to oxidize a substrate, the enzyme would be inactive in any further catalytic steps unless the bound $FADH_2$ is reoxidized by another oxidizing agent.

12.4.3: DEHYDROGENASES

These enzymes use NAD^+/NADH or FAD/$FADH_2$ and are named for the substrate that is oxidized. For instance in the reaction:

$$\text{pyruvate} + \text{NADH} \rightleftharpoons \text{lactate} + \text{NAD}^+$$

which is used to regenerate NAD^+ under anerobic conditions, the enzyme is named lactate dehydrogenase. As in acid/base reactions, when the preferred direction for the reaction (from a ΔG^o perspective) is from stronger acid to weaker (conjugate) acid, the preferred direction for a redox reaction is in the direction from strong to weak oxidizing/reducing agents. This can easily be determined from charts of standard reduction potentials, and using the equation: $\Delta G^o = -nFE^o$,

- where F is the Faraday constant (96,494 Coulombs/mol e^- = 96, 494 J/(V.mol) = 23.06 kcal/(V·mol) or 96 kJ/(V·mol). One Faraday is the charge per one mol of electrons).
- and E^o, the standard EMF or standard cell potential (total voltage at standard state conditions), which can be determined by adding the standard reduction potentials (**E^o**) for the two appropriate half-reactions, after reversing the equation for the half-reaction that represents the oxidation. Hence $E^o = E^o_{reduction} - E^o_{oxidation}$.

When n=2 (number of electrons) which is common for oxidations of organic molecules,

$$\Delta G^o \text{ (kcal/mol)} = -46.12E^o \text{ or approximately } -50E^0 \text{ (or } -193E^o \text{ kJ/mol)}$$

Notice when $E^o > 0$, $\Delta G^o < 0$, the reaction as written is favored under standard conditions. Note in the table below that many of the half reactions involve protons. For biological reactions involving free protons, the standard state concentration for the protons are not 1 M as for other solutes in solution, but defined to be the hydronium ion concentration at pH 7.0. The E^o and ΔG^o values for the reactions involving hydrogen ions at a standard state of pH 7.0 are usually written as $E^{o'}$ and $\Delta G^{o'}$.

Common standard reduction potentials are shown in Table 12.4.2 below.

Table 12.4.2: Standard reduction potentials for common biomolecules

oxidant	reductant	n (electrons)	$E^{o'}$ (volts), 25°C
Acetate + carbon dioxide	pyruvate	2	-0.70
succinate + CO_2 + $2H^+$	α−ketoglutarate + H_2O	2	-0.67
acetate	acetaldehyde	2	-0.60
glycerate-3-P	glyceraldehyde-3-P + H_2O	2	-0.55
O_2	O_2^-	1	-0.45
ferredoxin (ox)	ferredoxin (red)	1	-0.43
Carbon dioxide	formate	2	-0.42
$2H^+$	H_2	2	-0.42
α-ketoglutarate + CO_2 + $2H^+$	isocitrate	2	-0.38
acetoacetate	β-hydroxybutyrate	2	-0.35
Cystine	cysteine	2	-0.34
Pyruvate + CO_2	malate	2	-0.33
NAD^+ + $2H^+$	NADH + H^+	2	-0.32
$NADP^+$ + $2H^+$	NADPH + H^+	2	-0.32
FMN (enzyme bound)	$FMNH_2$	2	-0.30
Lipoic acid, ox	Lipoic acid, red	2	-0.29
1,3 bisphosphoglycerate + $2H^+$	glyceraldehyde-3-P + Pi	2	-0.29
Glutathione, ox	Glutathione, red	2	-0.23
FAD (free) + $2H^+$	$FADH_2$	2	-0.22
Acetaldehyde + $2H^+$	ethanol	2	-0.20
Pyruvate + $2H^+$	lactate	2	-0.19
Oxalacetate + $2H^+$	malate	2	-0.17
α-ketoglutarate + NH_4^+	glutamate	2	-0.14
FAD + $2H^+$ (bound)	$FADH_2$ (bound)	2	0.003-0.09
Methylene blue, ox	Methylene blue, red	2	0.01
Fumarate + $2H^+$	succinate	2	0.03
CoQ (Ubiquinone - UQ) + H^+	UQH	1	0.031
UQ + $2H^+$	UQH_2	2	0.06
Dehydroascorbic acid	ascorbic acid	2	0.06
Ubiquinone; ox	red	2	0.10
Cytochrome b2; Fe^{3+}	Cytochrome b2; Fe2+	1	0.12
Cytochrome c1; Fe3+	Cytochrome c1; Fe^{2+}	1	0.22
Cytochrome c; Fe^{3+}	Cytochrome c; Fe^{2+}	1	0.25
Cytochrome a; Fe^{3+}	Cytochrome a; Fe^{2+}	1	0.29
1/2 O_2 + H_2O	H_2O_2	2	0.30
Cytochrome a3; Fe^{3+}	Cytochrome a3; Fe^{2+}	1	0.35
Ferricyanide	ferrocyanide	2	0.36
Cytochrome f; Fe^{3+}	Cytochrome f; Fe^{2+}	1	0.37
Nitrate	nitrite	1	0.42
Photosystem P700	.	.	0.43
Fe^{3+}	Fe^{2+}	1	0.77
1/2 O_2 + $2H^+$	H_2O	2	0.816

The mechanism for the oxidation of a substrate by NAD^+ involves concerted hydride transfer to one face of NAD^+. Hydride transfer is possible since water is excluded from the active site. It is facilitated by removal of a proton from an oxygen on an alcoholic substituent, for example, adjacent to the departing hydride. The negative charge on the oxide acts as a "source" of electrons, which can then flow through the hydride transfer to the positively charged ring nitrogen of NAD^+, which acts as an electron "sink". This is crudely illustrated in the cartoon shown in Figure 12.4.7, which shows the oxidation of ethanol by the enzyme alcohol dehydrogenase.

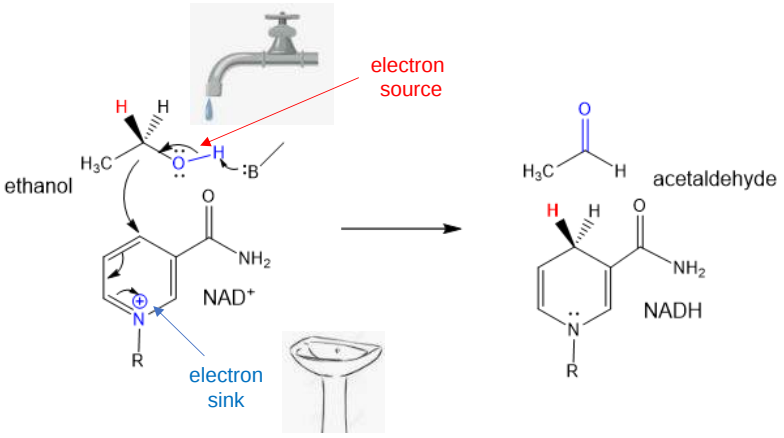

Figure 12.4.7: Source and sink analogy for hydride transfer in alcohol dehydrogenase

For substrates like ethanol that lose a hydride from a methylene carbon atom that has two hydrogens, only one of them is lost (either the proR or proS) from the prochiral center.

The site on NAD^+ that receives the hydride, as well as the entire ring, is planar with sp^2 hybridization. When bound to the enzyme, the hydride is transfer to the Re face of he ring. The same occurs in the reverse reaction when the hydride from NADH is transferred to the re face of acetaldehyde. Re and Si faces can be determined using by prioritizing the substituents attached to the sp^2 carbon using the Cahn-Ingold rules. The reversible transfer of the proR hydrogens to the Re faces of the reactants in the reversible conversion of ethanol to acetaldehyde are shown in Figure 12.4.8.

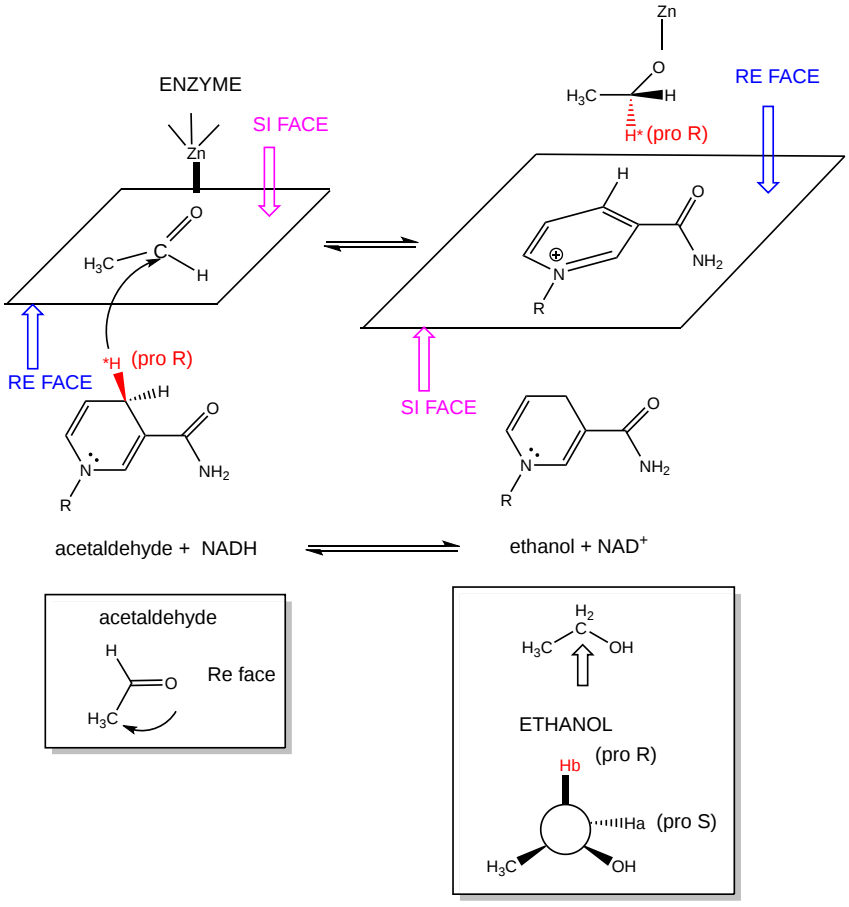

Figure 12.4.8: Reversible transfer of the proR hydrogens to the Re faces of the reactants in the alcohol dehydrogenase reaction

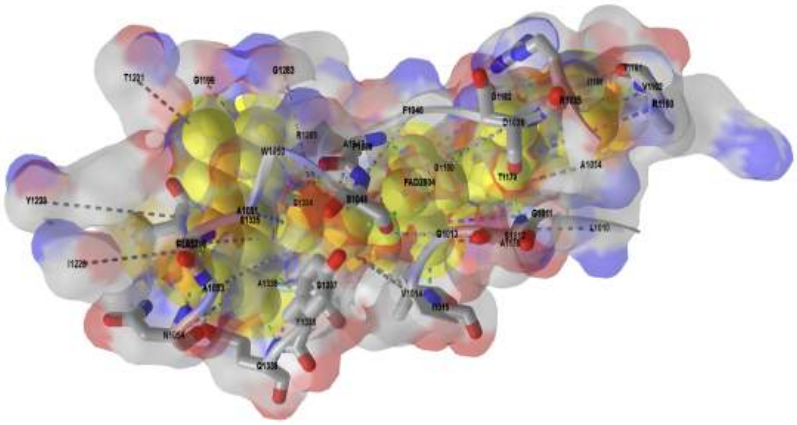
FAD has a more positive reduction potential than NAD^+ so it is used for more "demanding" oxidation reactions, such as dehydrogenation of a C-C bond to form an alkene. You will notice on standard reduction potential tables that the potential of FAD is often listed several times and depends on the enzyme. This is because the FAD is tightly bound to the enzyme so its tendency to acquire electrons depends on its

environment, in much the same fashion as the pKa of an amino acid side chain (which reflects is tendency to release protons) is affected by the environment of the amino acid side chain in the protein. The standard reduction potential for flavin enzymes varies from -465 mV to + 149 mV. Compare this to the reduction potential of free FAD/$FADH_2$, which in aqueous solution is -208 mV. The standard reduction potential of the flavin in D-amino acid oxidase, a flavoprotein, is about 0.0 V. Remember, the more positive the standard reduction potential, the more likely the reactant will be reduced and hence act as an oxidizing agent. Hence the FAD in D-amino acid oxidase is a better oxidizing agent than free FAD. The K_D for binding of FAD to the enzyme is 10^{-7} M compared to the K_D for binding of $FADH_2$, which is 10^{-14} M. By gaining electrons, the flavin binds more tightly, which preferentially stabilizes the bound $FADH_2$ compared to the bound FAD. This shifts the equilibrium of FAD ↔ $FADH_2$ to the right, making the bound FAD a stronger oxidizing agent.

A mechanism for the 2-electron hydride reduction of FAD is shown in Figure 6 above.

Figure 12.4.9 below shows an interactive iCn3D model of D-amino acid oxidase bound to FAD and a trifluoroalanine (1C0L) .



NCBI iCn3D **Figure 12.4.9 :** D-amino acid oxidase bound to FAD and a trifluoroalanine (1C0L). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...wYfRAK9TBSt2c8

FAD is shown in spacefill and colored yellow. Only the amino acids interacting with FAD are shown as a surface with underlying CPK colored sticks. The noncovalent interactions are shown as sticks. Note that you rotate the molecule, you will see the the FAD is almost completely buried which, along withe the extensive interactions with protein contributes to its low K_D.

Can the standard reduction potential of a redox active center in a protein be tuned by changing the environment of that center, much as the pKa of an acid side chain can by changing the polarity of the environment? The answer is yes. The active site of azurin, a cupredoxin, has a redox active copper ion coordinated by a Cys and two His residues in a trigonal planar fashion. Met 121 serves as a weak axial ligand. Marshall et al. have reported a feasible method to manipulate the redox potential (E^o) of this active site. The wild type azurin was mutated to alter the hydrophobicity and hydrogen bonding capabilities, while maintaining the overall architecture of the metal binding site. Ser 46 was selected for mutation since it occupied a position similar to Asn in another cupredoxin that was involved in an important H bond binding two ligand binding loops. An N47S-mutation, which strengthened the hydrogen bond between the two ligand-containing loops increased E^o by ~130 mV while preserving metal binding site architecture as determined by UV-Vis spectroscopy. They also compared a M121Q mutant with wild-type M121 and with a M121L mutant. A plot of E^o vs log partition coefficient for transfer of the side chain from water to octanol was essentially linear with a positive slope, showing that the standard reduction potential depended on the hydrophobicity of the weakly coordinating ligand in the metal binding region. This behavior extended to double mutants (where one set of mutants involved M121). The investigators were able to tune the E^o over a 700 mv range!

12.4.4: MONOOXYGENASES

An examples of monooxygenases are the hydroxylases which hydroxylate amino acids like tryptophane and tyrosine to form 5-hydroxytryptophan and 3-4-dihydroxyphenylalanine or dopa, respectively. These latter two substances can be decarboxylated using PLP-dependent enzymes to form the neurotransmitters 5 hydroxytryptamine (5HT or serotonin) and dopamine. The latter can be hydroxylated again to form norepinephrine, and subsequently methylated to form epinephrine. LSD and amphetamine are analogs of serotonin and dopamine, respectively. The derivative of tryptophan and tyrosine are shown in Figure 12.4.10.

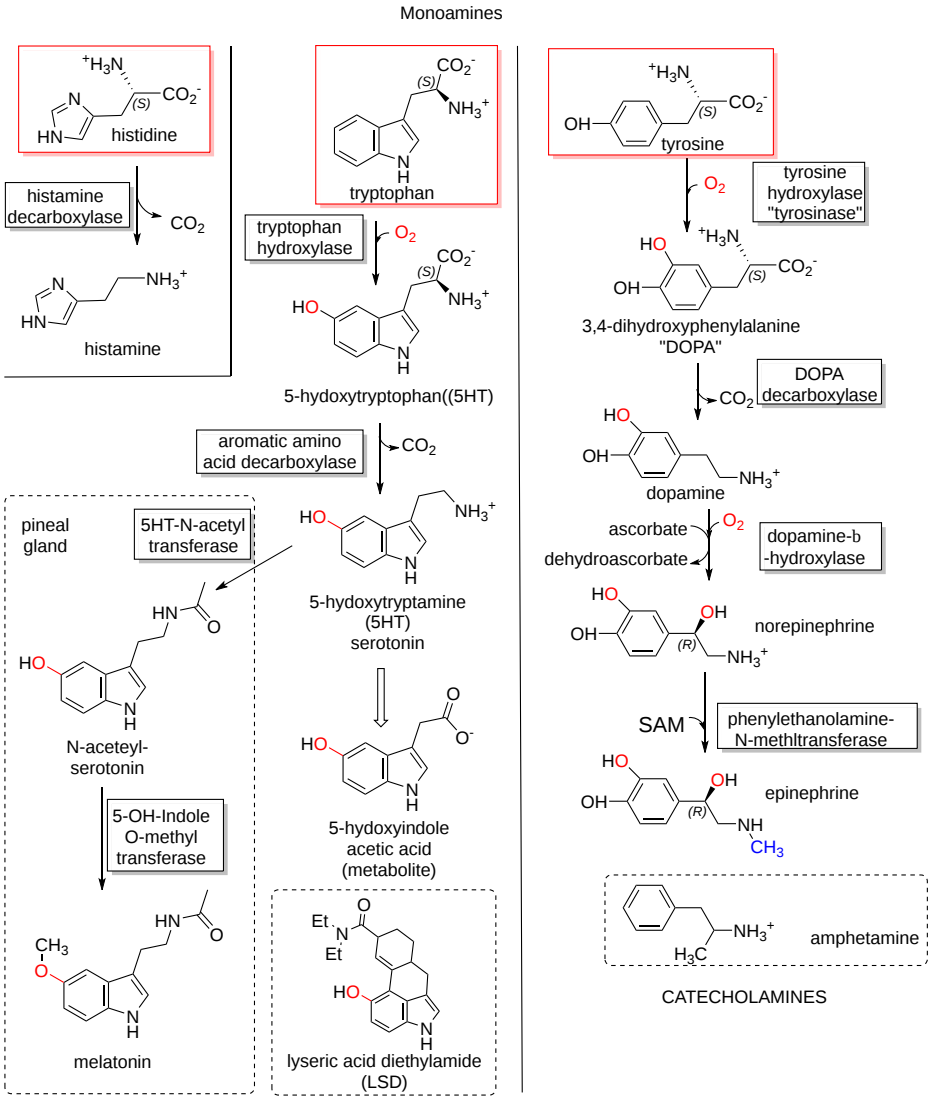


Figure 12.4.10: Derivative of tryptophan and tyrosine derived from monooxygenases

Since these monooxygenases use dioxygen, you might expect that the enzymes would use the motifs described in the previous section to facilitate its reaction with dioxygen. In fact, the enzyme contains a metal ion (Fe2+) bound to a heme in the protein. In addition, the reduction products of dioxygen that are eventually used to hydroxylate the substrate stay bound to the enzyme.

Tyrosine 3-monooxygenase (Tyrosine hydroxylase)

Tyrosine hydroxylase is a homotetramer which uses an Fe ion and biopterin cofactor for hydroxylation. In the central nervous system is used in the biosynthesis of dihydroxyphenylalanine (DOPA), which is the rate limiting step in the catecholamine synthesis.

A possible mechanism for the rat enzyme is shown in Figure 12.4.11.

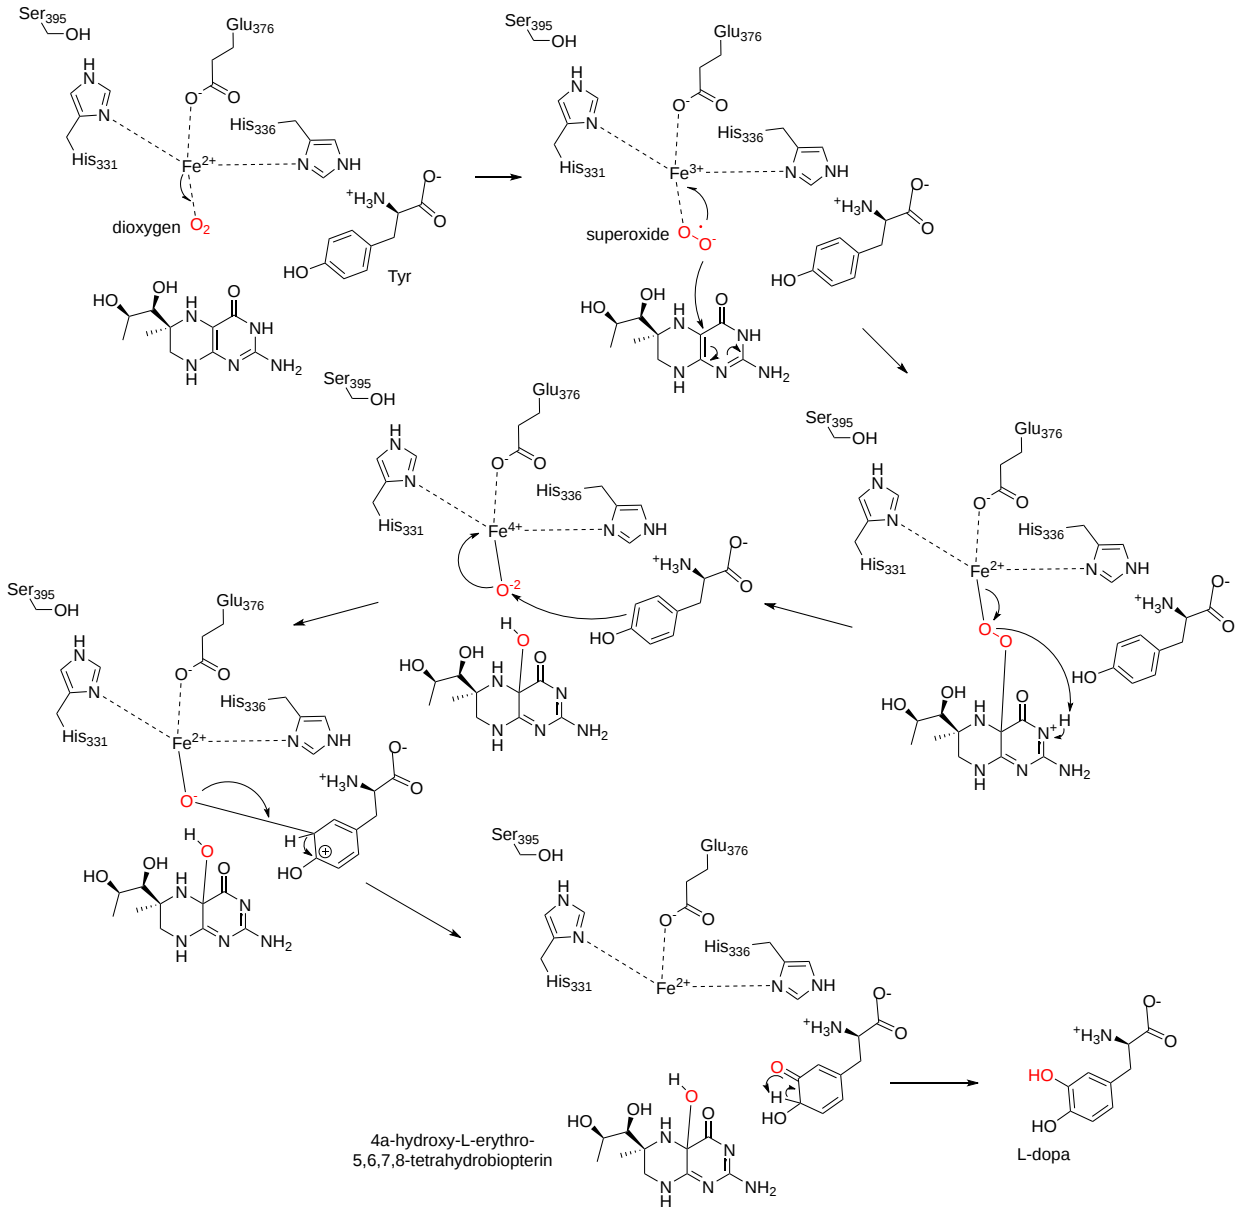

Figure 12.4.11: A possible mechanism for rat tyrosine hydroxylase, a monooxygenase. https://www.ebi.ac.uk/thornton-srv/m-csa/entry/134/

The Fe^{2+} ion binds O_2. Some mechanisms show a single electron transfer to the bound O_2 from the pterin ring to form Fe^{2+}-$O2^-$(bound superoxide) and a radical cation pterin. This is unstable and forms Fe^{2+}-μ-peroxypterin, followed by heterolytic cleaves of the peroxo O-O bond. Ultimately, hdroxpternin and an $Fe^{4+}O$ oxospecies form which then hydroxylates tyrosine.

Figure 12.4.12 below shows an interactive iCn3D model of rat tyrosine hydroxylase with bound cofactor analogue and iron (2TOH).

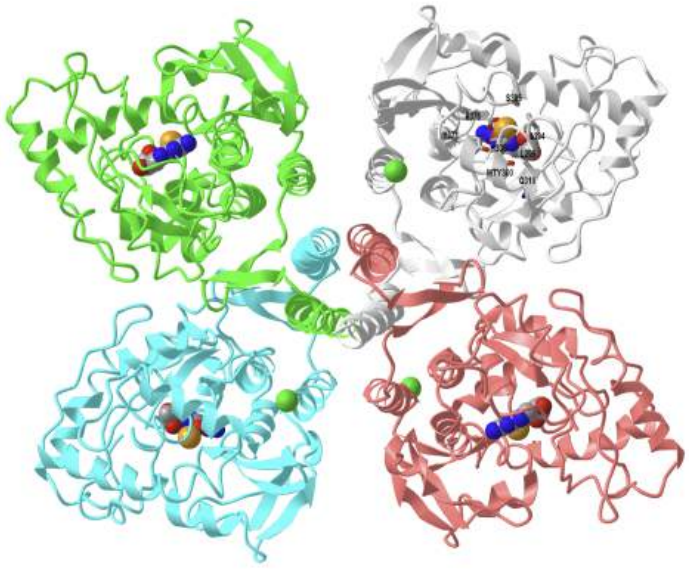

Figure 12.4.12 : Rat tyrosine hydroxylase with bound dihydrobiopterin analogue and iron (2TOH). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...KeKiLDfmeNFfr7

Four monomers in the homotetramer are shown. The cofactor analog (HBI), 7,8-dihydrobiopterin, is shown in spacefill. Phenylalanine 300 has been self-hydroxylated by the enzyme to produce meta-tyrosine (MTY300), which along with the other key amino acids in the active site are shown labeled in CPK-colored sticks in the gray monomer. The pterin ring interacts through pi stacking with Phe 300, which facilitates self-hydroxylation. The Fe ion is far (5.6 Å) from the carbon on pterin which gets phosphorylated. This suggests that O_2 might bridge the reacting pterin C- and the Fe ion in a Fe^{2+}-μ-peroxypterin complex.

Tryptophan hydroxylase

This enzyme also uses a tetrahyropterin cofactor and Fe ion in the formation of he hydroxylating intermediates As in the case of tyrosine hydroxlase, both the amino acid substrate and the cofactor must be present for oxygen to be activated. Other, it only oxidizes Fe^{2+} to Fe^{3+}. This serves as a protective mechanism so that O_2 is not activated unnecessarily, which avoids the formation of soluble ROS.

Figure 12.4.13 shows a possible mechanism without catalytic residues for tryptophan hydroxylase

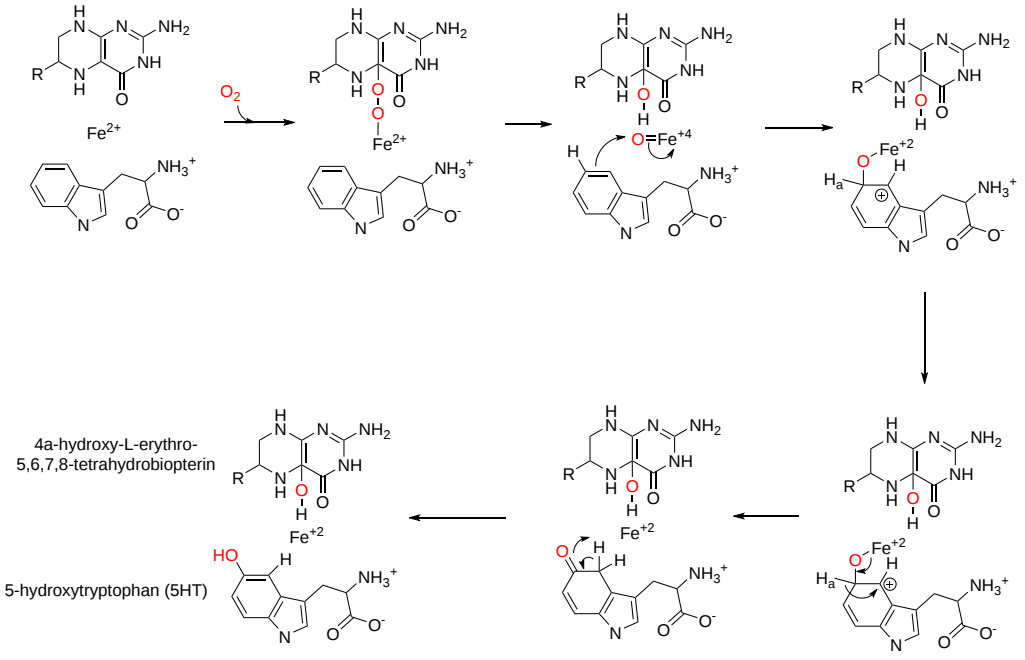

Figure 12.4.13: possible mechanism without catalytic residues for tryptophan hydroxylase adapted from Kenneth M. Roberts, Paul F. Fitzpatrick, https://doi.org/10.1002/iub.1144

Cytochrome P450s

The **cytochrome P450 (CYP)**consists of a large group of monooxygenases that contain a heme that absorbs maximally at 450 nm. They catalyze the following reaction:

$$RH + NAD(P)H + H^+ + O_2 \rightarrow ROH + NAD(P)^+ + H_2O$$

An example includes cytochrome P450cam that hydroxylates camphor, a large aromatic completely nonpolar molecule. The enzyme has been called the"biological equivalent of a blowtorch" as it can, at room temperature, stereospecific hydroxylate nonactivated hydrocarbons at physiological temperature. This reaction proceeds without stereospecificity only at high temperatures in the absence of a catalyst. Remember from the previous chapter section that dioxygen is a ground state triplet radical which can't react well with carbons atoms (which are singlets) unless converted to a singlet state, a process which requires significant energy. Cytochrome P450s get around this problem by binding to an Fe ion in the heme to form common intermediates such as oxos, oxides, and peroxides. The molecular orbitals of the bound dioxygen are "singlet-like".

Remember from introductory chemistry that transition metal ligands are names with a specific nomenclature. Some are shown in Figure 12.4.14.

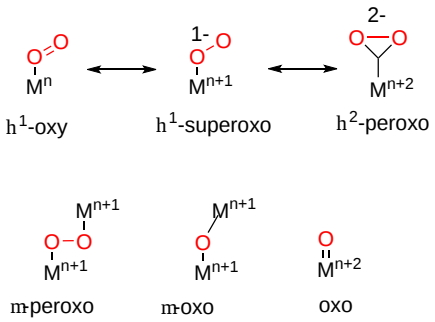

Figure 12.4.14: Common oxygen transition metal ligands

In naming η is the hapticity (the number of atoms of a ligand attached to a metal) and μ is the number of metal atoms bridged by a ligand.

For Fe ions and oxygen ligands, some examples include $Fe^{III}–O_2^-$ (superoxo) and Fe^{IV}=O (ferryl-oxo)

If the aromatic substrate get oxidized, something must get reduced. That something is of course O_2. Electrons for the reduction of O_2 come from the oxidized substrate but also by injection of electrons through NAD(P)H. Cytochrome P450 are microsomal protein and most require another protein, **NADPH-cytochrome P450 reductase (CPR)**. Before we look at the structure and mechanism of cytochrome P450, lets looks at this microsomal protein first. CPR catalyzes this reaction:

$$NADPH + \text{oxidized CytoP450 } (Fe^{3+}\text{-heme b}) + H^+ \leftrightarrow NADP^+ + \text{Oxidized CytoP450 } (Fe^{2+}\text{-heme b})$$

The protein contains multiple domains and resulted from a fusion of gene from flavodoxin, which binds FMN) and a FAD reductases. In addition is contains an NADP binding domain. It ultimately accepts a hydride ion (2 electrons) from NADPH and then transfers electrons to FMN (in one electron steps). These are used to reduce the heme which then activates dioxygen (oxidation number of 0) for hydroxylation reactions by cytochrome P450. In the hydroxylated organic product and in water, oxygen has an oxidation number of -2.

Figure 12.4.15 below shows an interactive iCn3D model of rat NADPH-cytochrome P450 reductase (1AMO).

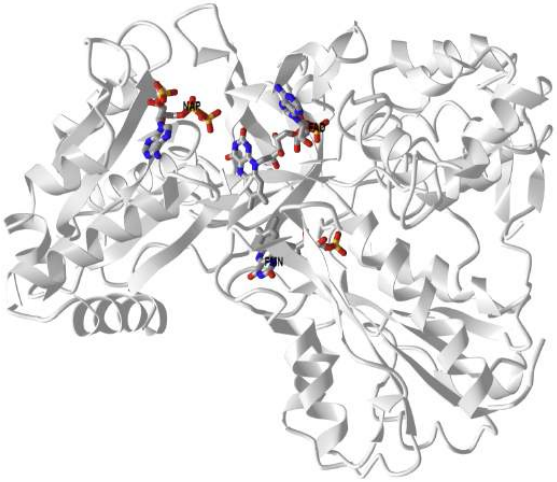

Figure 12.4.15 : Rat NADPH-cytochrome P450 reductase (1AMO). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...nMh9ByRbsWk4B8

$NADP^+$ is labeled as NAP. The enzyme is quite unique in that it has binding sites for both FAD and FMN (similar to nitric-oxide synthase). The flavins are aligned for electron transfer. The cleft in the enzyme presumably binds cytochrome P450. The protein has short (20 amino acid) lumenal sections, followed by 20 amino acid membrane-spanning helix (not shown in the above structure) followed a large cytosolic domain, where it can interact with cytochrome P450, which is found in multiple places including the ER, microsomal, and mitochondrial membranes as well as the cytoplasm..

The cytochromes P450s containing a heme, which instead of reversibly carrying dioxygen (as in myoglobin and hemoglobin), activates dioxygen for hydroxylation reactions involving aromatic, nonpolar substrates. Hydroxylation of these substrates increases their solubility which facilitates their elimination from the body. Epoxide intermediates or products are often produced, which can open up through nucleophilic attack using an alcohol (sugar derivative), as illustrated in Figure 12.4.16.

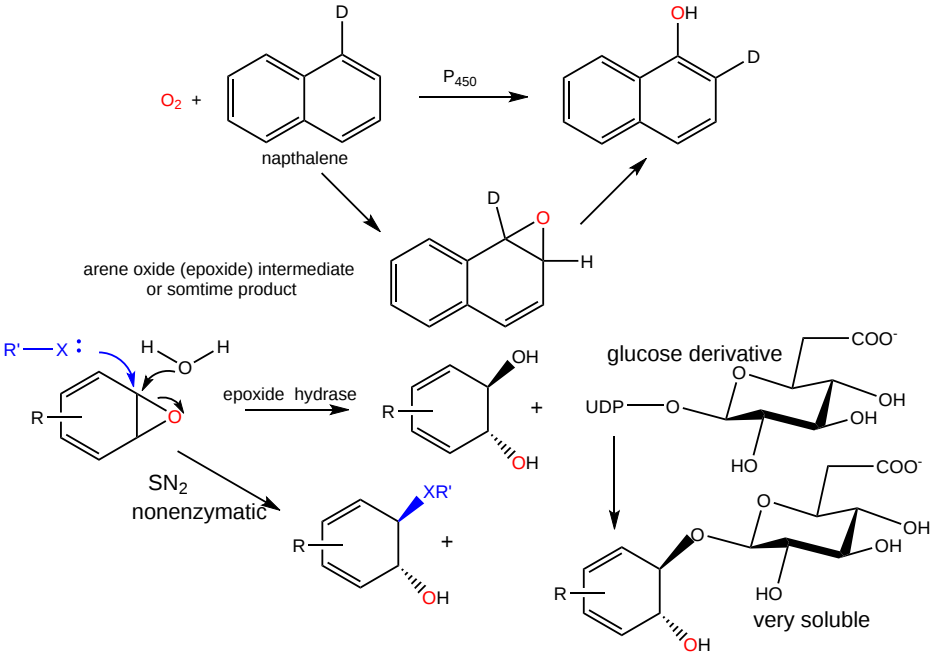

Figure 12.4.16: Cytochrome P450 hydroxylation reaction to increase target solubility

This type of reaction also converts steroids to different biologically active one.

The hydroxylation reaction and can also lead to reactions with amines, including those on nucleotide bases in DNA, resulting in the formation of large adducts, as illustrated in Figure 12.4.17.

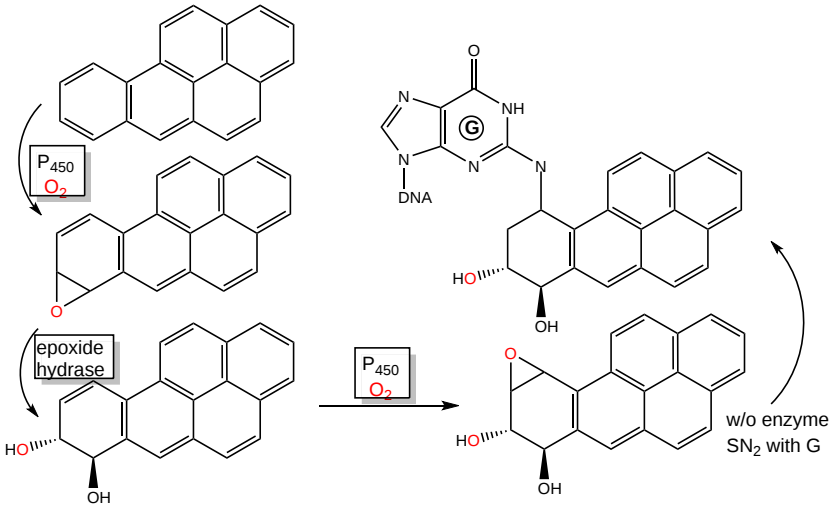

Figure 12.4.17: Cytochrome P450-mediated formation of carcinogens.

Hence cytochrome P450 can actually activate aromatic substrates to become carcinogens.

The cytochrome P450s family of genes/proteins are inducible on exposure to nonpolar aromatic molecules such as dioxin. These nonpolar molecules can enter the cytoplasm where they bind to the arylhydrocarbon receptor (AhR) which is bound to a heat shock protein, Hsp90. Upon binding of dioxin, TCDD, for example, the AhR.TCCD complex dissociates from Hsp90, and migrates to the nucleus where it binds a protein called Amt. The AhR-Amt complex serves as an enhancer/transcription factor, facilitating the transcription of the cytochrome P450 genes.

Figure 12.4.18 illustrates the activation of cytochrome P450 gene expression on exposure to nonpolar aromatic molecules such as dioxin.

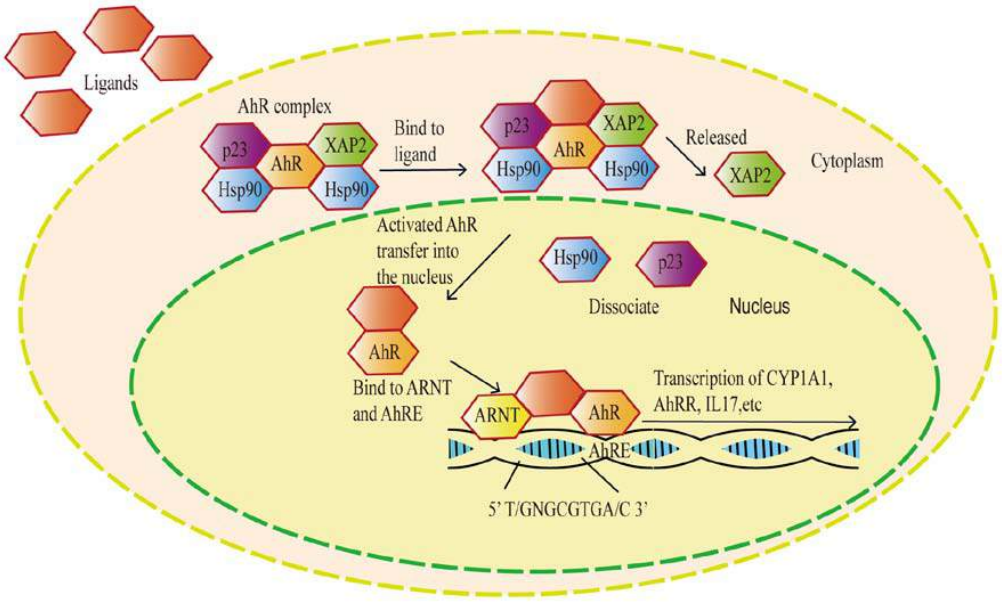

Figure 12.4.18: Activation of cytochrome P450 and other gene expression on exposure to nonpolar aromatic molecules such as dioxin

On binding to a ligand, the AhR is activated and enters the nucleus, where it binds to ARNT on the aryl hydrocarbon response element (AhRE) and promotes transcription of downstream genes including cytochrome P450 family 1 subfamily A member 1 (CYP1A1) and interleukin-1 (IL-1). CYP1A1 is in the CYP1A family that promotes activation of procarcinogens a well as hydroxylation of steroid hormones like estrogens. It also participates in the metabolism of steroidal hormones including estrogens. ARNT is the aryl hydrocarbon receptor nuclear translocator, AhRE the aryl hydrocarbon response element; CYP1A1, XAP2 is the aryl hydrocarbon receptor interacting protein, AHRR is the aryl-hydrocarbon receptor repressor, IL-11 is interleukin 17, Hsp90 is heat shock protein 90 and p23 is prostaglandin E synthase 3

Dioxin has been shown to affect estrogen-mediated activities. Estrogens, small hydrophobic hormones derived from cholesterol, enter cell and bind to cytoplasmic estrogen receptors, which then dimerize and bind to the estrogen response element (ERE), initiating transcription. Tamoxifen, a drug derived from the yew plant, blocks the biological effects of the estrogen receptor. Although it binds to the estrogen receptor, it doesn't elicit the same conformational changes in the protein, which prevents the bound receptor from binding to the estrogen response element and recruiting other proteins needed for estrogen-dependent gene transcription. It is used in chemotherapy and prevention of estrogen-dependent breast cancer cells.

How does dioxin interfere with estrogen signaling? Ahr and ARnt contain a basic helix-loop-helix motif which mediate their interaction with DNA. Upon binding of the complex, detoxification genes are activated. The dioxin-Ahr-Arnt complex can also bind to the estrogen receptor, which can then lead to activation of genes containing an estrogen response element (ERE) in the absence of estrogen. However, if estrogen is present, inhibition of gene expression from ERE is observed. Dioxins can be potent dysregulators of estrogen-induced gene expression. Such changes in estrogen activity could help to explain the pro- and inhibitory effects of dioxin on estrogen-mediated cellular responses and possible effects of dioxin on the immune system and on cancer development.

Given the importance of the cytochrome P450s, we'll offer two variant portrayals of their mechanism. Figure 12.4.19 shows the overall catalytic cycle of the enzyme with associated redox changes in the generic substrate, RH, and the Fe heme ion.

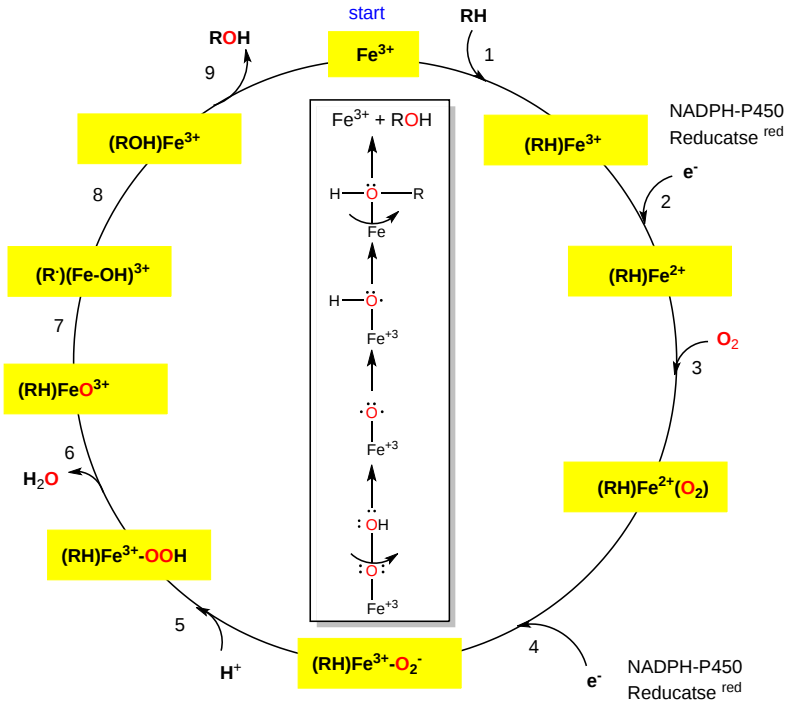

Figure 12.4.19: Catalytic cycle of cytochrome P450 with the generic substrate RH and the Fe heme ion

The key hydroxylating agent appears to be formal FeO^{3+} shown in step 7.

A possible mechanism for the hydroxylation of estrone by cytochrome P450 from Bacillus megaterium is shown below in Figure 12.4.20. It follows the general catalytic cycle shown above.

$$\text{Estrone} + \text{NADH} + H^+ + O_2 \rightarrow \text{2-hydroxyestrone} + NAD^+ + H_2O$$

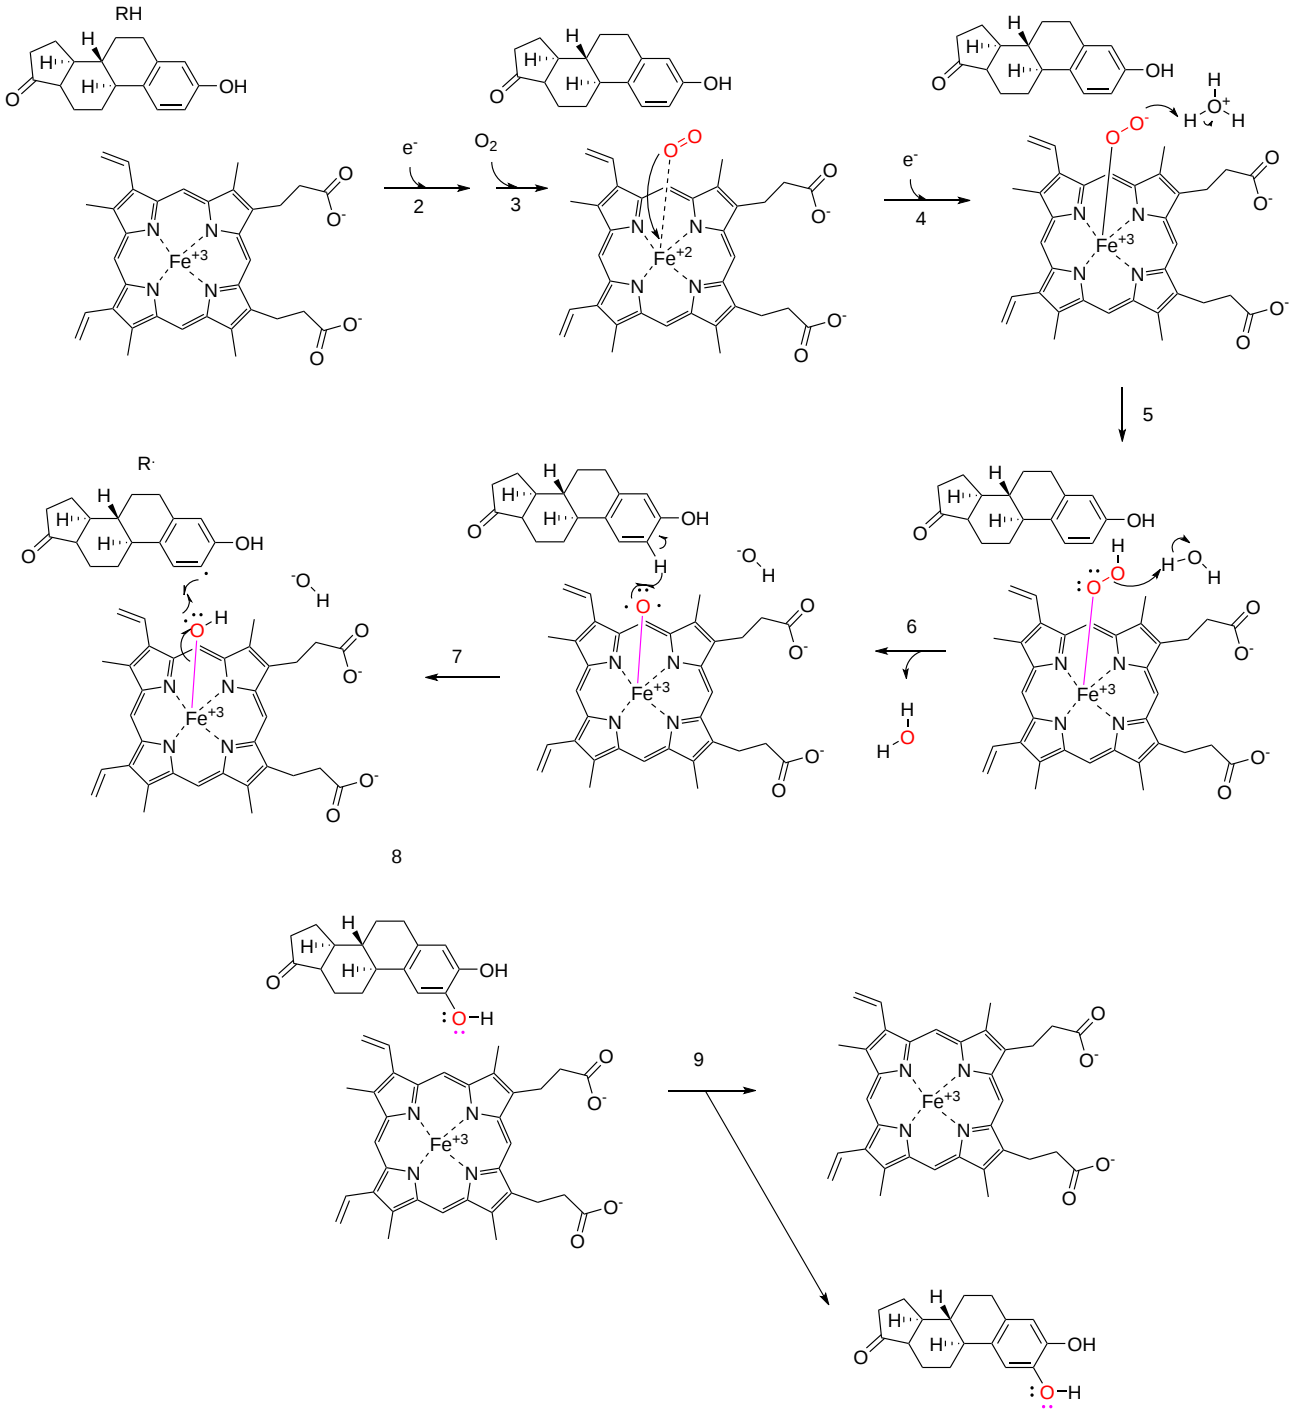

Figure 12.4.20: Possible mechanism for the hydroxylation of estrone by cytochrome P450 from Bacillus megaterium after https://www.ebi.ac.uk/thornton-srv/m...csa/entry/699/

As with the previous generic mechanism, the two added electrons derive from NADH which passed a hydride to FAD which passes single electrons on to FMN which them passes them onto the heme. The exact species for several parts of the mechanism are not completely clear. For instance, a Fe^{4+}-oxo complex has been proposed.

Let's shown the structure of a human cytochrome P450 1A1 that is active in drug metabolism and also in the activation of benzo[a]pyrene, a component of cigarette smoke, into a carcinogen. **Figure 12.4.21** below shows an interactive iCn3D model of Human Cytochrome P450 1A1 in complex with alpha-naphthoflavone (4I8V).

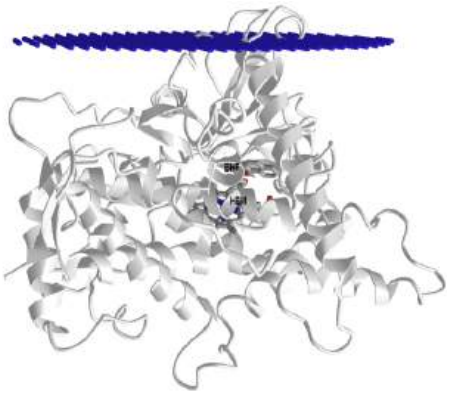

Figure 12.4.21 : Human Cytochrome P450 1A1 in complex with alpha-naphthoflavone (4I8V). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...JGtJeHG1qswN59

The shows in sticks and labeled the active site heme and an inhibitor, α-naphthoflavone (labeled BHF) bound and enclosed in the active site. It's 2-phenyl group points toward the heme Fe ion.

12.4.5: DIOXYGENASES

An example of a dioxygenase is the cyclooxygenase activity of prostaglandin synthase. This enzyme, often just called cyclooxygenase or COX, is an integral membrane protein found in the ER membrane, and is a homodimer (with two hemes). It catalyzes two different reactions. One is the addition of two dioxygens to arachidonic acid - 20:4$^{\Delta}$5, 8, 11, 15 (which is liberated from the C2 position of phospholipid membranes by phospholipase A2 upon appropriate signaling) to form prostaglandin PGG2. This molecule, with 5 chiral centers, arises from arachidonic acid, which has one. The cyclooxygenase activity is buried in the membrane, from where the arachidonic acid can readily access its active site. The active site is at the end of a hydrophobic channel (arachidonic acid binding site) and stretches from the membrane-binding region to a buried heme. PGG2 can be further metabolized to PGH2 by the addition of two electrons to PGG2 by the hydroperoxidase activity of the enzyme, located at the other end of the enzyme. This activity forms an alcohol from the peroxide functional group in PGG2. There is one heme per monomer, which acts in both the cyclooxygenase and peroxidase activities. Each monomer of the dimer has both enzymatic activities. A possible abbreviated reaction mechanism is shown in Figure 12.4.22.

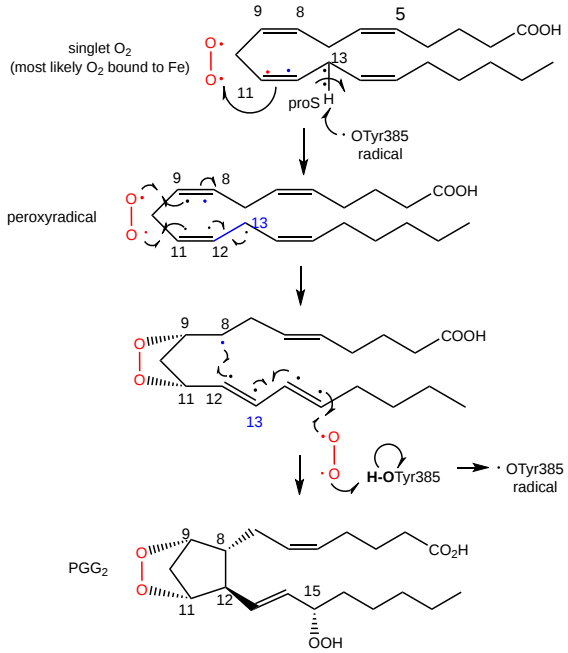

Figure 12.4.22: A possible abbreviated reaction mechanism for dioxygenase cyclooxygenase.

In summary:

- The carboxylate of arachidonic acid is coordinated to Arg 120 and Tyr 355.
- The C13 pro(S) H atom of arachidonic acid is close to Tyr 385 which allows its abstraction.
- This results in a radical centered on C11 that reacts with dioxygen to form a peroxyl radical

- Attack by dioxygen at C11 occurs from the side of the substrate opposite to that of hydrogen abstraction
- The oxygen radical at C11 cyclizes by attacking C9.

The C13 proS hydrogen atom (not proton) is remove from bound arachidonic acid by a free radical form of Tyr 385, which acts as an oxidizing agent. A site-specific mutants in which Tyr 385 is replaced by Phe is inactive. How is the Tyr free radical formed? Based on single electron standard reduction potential (0.9 V for Tyr and -0.2 to + 0.2 V for Fe^{3+} in the bound heme), it appears that the heme iron is not a potent enough oxidizing agent to accomplish this task. However, oxygen bound to the heme iron could be converted to a peroxide and form an Fe^{4+}-oxo complex (which has also been proposed for cytochrome P450). The Fe^{4+} ion is a more potent oxidizing agent (standard reduction potential of approximately 1 V, sufficient for oxidation of Tyr 385. Another possibility is that the peroxide activator (in the formation of the ferryl-oxo ligand) is NO (nitric oxide, a free radical). NO is formed by immune cells (like macrophages) on immune activation. The NO might react with superoxide (also a radical, possibly formed during an oxidative burst in macrophages during immune stimulation) to form peroxynitrite (NO^{3-}). This can donate an oxo group to the Fe^{3+} to form the Fe^{4+}-oxo complex, which could then oxidize Tyr to the free radical form. There might be other mechanisms as well to generate the Tyr free radical, since just adding organic peroxides to the enzyme will generate it.. After abstraction of the proS H atoms, a carbon-centered free radical at C11 results which reacts with oxygen as shown below. The exact form of oxygen that reacts is unclear, but presumably is either a peroxy or activated singlet form.

12.4.6: OXIDASES

This class of enzymes does not incorporate dioxygen into an organic substrate. Rather it accepts electrons released from an organic substrate, through intermediate electron carriers (such as ubiquinone and cytochrome C) to form superoxide (as in NADPH-oxidase), hydrogen peroxide (as in xanthine oxidase) or water (as in cytochrome C oxidase). The mechanism of cytochrome C oxidase again supports our expectations about enzymes that use dioxygen. Dioxygen binds metals in the enzyme. One oxygen atom binds a heme Fe^{2+} of cytochrome a3 which is bound to the enzyme, while the other binds a Cu^{1+} of Cu B. All oxygen reduction intermediates remain bound to the enzyme. Four electrons are added from four different cytochrome C molecules, which serve as mobile carriers of electrons.

We will explore cytochrome C oxidase in great detail in Chapter 19.1: Electron-Transfer Reactions in Mitochondria. Figure 12.4.23 shows cartoon versions of several oxidases.

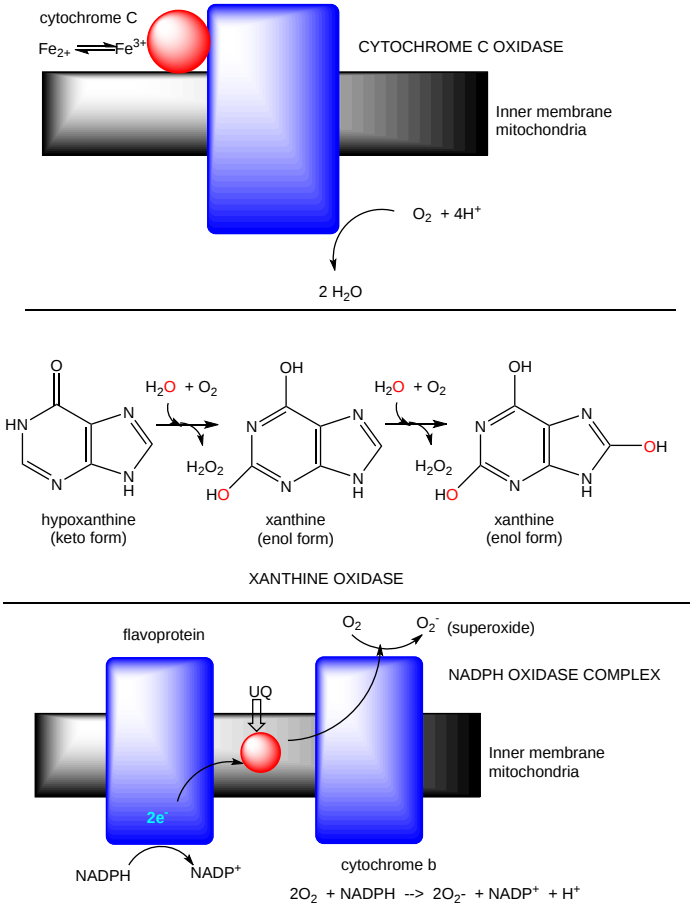

Figure 12.4.23: Examples of oxidases

Another example of an oxidase is monoamine oxidase. Mitochondrial monoamine oxidase catalyzes the oxidative deamination of certain neurotransmitters after they have been taken up by post-synaptic neurons, in a process of inactivation. The reaction is shown in Figure 12.4.24.

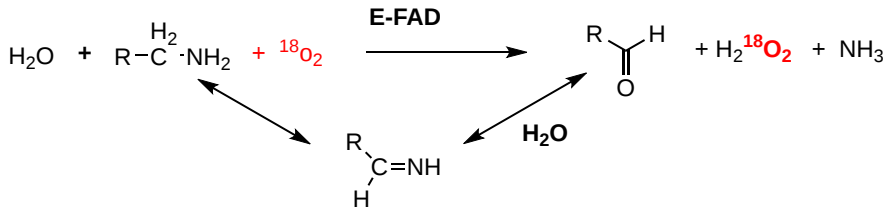

Figure 12.4.24: Monoamine oxidase reaction

A Schiff base is formed which is then hydrolyzed, incorporating unlabeled oxygen into the oxidized molecule.

12.4.7: BIOLOGICAL OXIDATIONS: METHANE TO CO_2

In the previous chapter section, we discussed the progressive oxidation of methane by 2 electron loses to form methanol, formaldehyde, formic acid and CO_2, with a progressive increase in oxidation number for the C by +2 (from -4 in methane to +4 in CO_2), as reviewed in Figure 12.4.25.

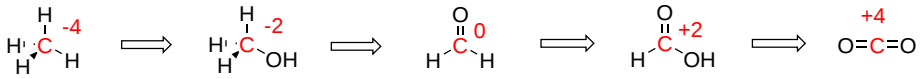

Figure 12.4.25:: Progressive stages in the oxidation of methane

Methanotrophs are aerobic bacteria that use methane as a source of energy, converting it in a series of two electron oxidations as shown above, to carbon dioxide. The enzymes involved in this sequential process are methane monooxygenase, methanol dehydrogenase, formaldehyde dehydrogenase, and formate dehydrogenase. Methane monooxygenase exists in a soluble and membrane form, both of which are part of a larger complex. Both have a hydroxylase (which uses dioxygen to add O to methane) and the membrane form has recently been shown to be associated with have methanol dehydrogenase in a larger complex consisting of trimers of each enzyme (the hydroxylase and the dehydrogenase).

12.4.8: HEME PROTEINS

So far in this course, we have examined three different kinds of heme proteins..

- The first, hemoglobin (and myoglobin) serve as carriers of **dioxygen**. Even though they bind one of the best oxidizing agents around (dioxygen), the heme Fe^{2+} does not get oxidized to Fe^{3+}. If it does, as in the case of met-Hb, the protein looses it ability to carry oxygen.
- Cytochrome C, on the other hand, does not bind dioxygen but rather serves as a carrier of **electrons** which get passed to dioxygen in Cytochrome C oxidase. Its Fe ion readily cycles between the 2+ and 3+ states as it serves as an electron carrier.
- Finally, the Fe^{2+} in the heme of the cytochrome P450s (so named since they have an absorbance maximum at 450 nm when they bind CO) does **both**. It binds dioxygen and cycles between the 2+ and 3+ states as it activates dioxygen for hydroxylation reactions.

The structure of the heme and amino acid ligands, along with their absorbance spectra, are shown in Table 12.4.3 below.

How could heme serve such diverse functions? We can explain this by referring to one of the main themes of the course - structure mediates function. The environment of each heme must be different. Clearly the protein ligands coordinating the Fe ions are different. The 5th ligand is the proximal His in hemoglobin while dioxygen binds to the 6th site. In cytochrome C, the 5th and 6th ligands are His and Met, respectively. In cytochrome P450, the 5th site is occupied by Cys, and the 6th by dioxygen. Presumably the environments surrounding the hemes are different as well. Once again, we have seen analogous example in which chemical properties are influenced by the microenvironment. The pKa of a given amino acid side chain can vary considerably depending on the polarity of the local environment. Likewise, the standard reduction potential of tightly bound FAD/FADH2 depends on the microenvironment.

As we have seen (from the study of heme proteins and the oxidative enzymes of cells), transition metals such as Fe, Zn, and Cu have vital biological roles as binding sites and cofactors in many reactions. Yet they also pose problems since they can lead to oxidative damage in cells. As we saw with cytoplasmic metallothioneins, which bind to heavy metals and protect the cell from such damage, many proteins are involved in binding and regulation of transition metals in the cell. Integral membrane proteins are required to bind and transport these cations into the cytoplasm. Other proteins act as sensors of transition ion concentration (such as latent transcription factors which bind heavy metals and become active transcription factors for metallothioneins. Others act as chaperone proteins which bind metal ions and transfers them to apometalloproteins. Recent work has suggested transporters and chaperones involved in metal ion biology bind these ions with unusual coordination geometry, which presumably facilitates transfer of the ion to the apo-target protein.

The transition metals Zn and Fe are often found in E. Coli at a concentration of 0.1 mM, compared to Cu and Mn which are present at concentrations from 10 to 100 μM. Also, about one third of all proteins demonstrate specific binding of metal ions and can be classified as metalloproteins. Mass balance suggests that metal ions would be distributed in proteins with low, intermediate, and high metal binding affinity as well as in free pools, which which potentially be toxic to cells. Metalloproteins, depending on their Kd for metal ion binding, would hence be in various state of ligation. The free concentration of some ions (Cu and Zn) is so low that newly synthesized apoproteins which bind these ions would not obtain the ion from the free pool. In such cases, metal chaperones would be required.

CHAPTER OVERVIEW

13: GLYCOLYSIS, GLUCONEOGENESIS, AND THE PENTOSE PHOSPHATE PATHWAY

13.1: Glycolysis

13.2: Fates of Pyruvate under Anaerobic Conditions- Fermentation

13.3: Gluconeogenesis

13.4: Pentose Phosphate Pathway of Glucose Oxidation

Thumbnail: Due to its role in the pentose phosphate pathway and the Calvin cycle, D-Ribose-5-phosphate isomerase is highly conserved in most organisms, such as bacteria, plants, and animals. It plays an essential role in the metabolism of plants and animals, as it is involved in the Calvin cycle which takes place in plants, and the pentose phosphate pathway which takes place in plants as well as animals. (CC BY-SA 4.0; Ishikawa, K., Matsui, I., Payan, F., Cambillau, C., Ishida, H. et al. via Wikipedia)

13.1: GLYCOLYSIS

13.1.1: INTRODUCTION

In this chapter, we will provide you with a historical overview of glycolysis and introduce you to the 10 enzymatic reactions in the pathway. Our main goal is to understand how the oxidation of our major food molecules, sugars in the case of glycolysis, can lead to ATP synthesis.

Before we begin our journey into the glycolytic pathway, it is useful to review the concept of free energy within reactions. For a reaction to be spontaneous, the change in the free energy within the system must be negative. From the equation in **Figure 13.1.1** you can see that the change in free energy of a reaction is dependent on the concentration of the reactants and the products, as well as the temperature within the system.

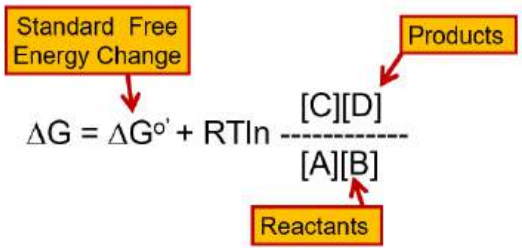

Figure 13.1.1 : The Change in Free Energy of a Reaction. The change in the free energy of a reaction is equal to the standard free energy change for the reaction plus the gas constant (R) multiplied by the Temperature in Kelvin (T) and the natural log (ln) of the concentrations of the products of the reaction (noted as C and D in the example) over the concentration of the reactants (noted as A and B in the example).

You will note that some reactions of glycolysis and other metabolic pathways that we will investigate are not favored. Thus, it is necessary to drive the reaction to become spontaneous by either coupling the reaction with a spontaneous reaction that can generate enough free energy to drive the nonspontaneous reaction forward, or by using Le Chatelier's principle and removing the products from the enzyme's area as soon as they are made. This will help drive the reaction in the forward direction as it will reestablish equilibrium. In this way, a small amount of product can be formed spontaneously. Essentially, the continued removal of the product or the addition of excess reactant will drive the reaction forward. It is of note that the temperature of the reaction can also influence the change in free energy. However, in biological systems, temperature changes that will significantly affect the change in free energy usually are not compatible with maintaining most life forms. Thus, it will not be a large consideration in the context of our metabolic discussions, here.

When reactions are coupled together to obtain a spontaneous reaction, the overall free energy change for a chemically coupled series of reactions is equal to the sum of the free energy changes of the individual steps, as noted in **Figure 13.1.2 .**

Figure 13.1.2 : The Coupling of Two Reactions. The top reaction is nonspontaneous with a positive change in free energy of 21 kJ/mol. This reaction can be driven in the forward direction, by coupling it with a strongly spontaneous reaction that releases -34 kJ/mol. The overall net reaction has a negative change in free energy and is spontaneous

The metabolic reactions of carbohydrates and other food molecules play an important role in generating energy within living systems in the form of ATP. For carbohydrates, this begins with the metabolic process known as glycolysis (or the breakdown, "lysis", of sugars, "glyco") At the end of the 1910s Otto Meyerhof mapped some of these metabolic conversions by measuring heat trends and oxygen consumption in frog muscles. When the muscle is working, lactic acid is formed from carbohydrates, and Otto Meyerhof showed that during recovery, this is followed partly by the burning of lactic acid and partly by reprocessing of lactic acid to carbohydrates.

Concurrently, Archibald Hill was also outlining these processes in the muscles of frogs. In opposition to the prevailing view that mechanical movement and chemical processes were parallel sequences, Hill was able to show through measurements of heat generated by the mechanical processes that these were delayed compared to the movements. The chemical sequence consists of a work phase, which is not dependent on oxygen supply, and a recovery phase when oxygen is required. Together, their work has opened the door to understanding aerobic and anaerobic metabolism beginning with the process of glycolysis. They both shared the Nobel Prize in Physiology and Medicine in 1922 for their work in these processes **Figure 13.1.3** .

Figure 13.1.3: The Nobel Prize for Physiology and Medicine in 1922. Archibald V. Hill and Otto Fritz Meyerhof received this award for their work on sugar metabolism and breakdown. Photos from Nobel Prize.Org

The glycolytic pathway consists of 10 enzymatic steps that convert glucose to pyruvate. This conversion generates a small amount of energy. The pyruvate can then be converted to lactic acid (lactate) in vertebrates or to ethanol in yeast in an anaerobic (or oxygen-independent) pathway or it can be fully oxidized to carbon dioxide in an aerobic (or oxygen-requiring) pathway that takes place within the mitochondria (which is shown in green in **Figure 13.1.4:**). Aerobic oxidation yields about 18 times as much energy as the anaerobic pathways causing them to be favored over anaerobic pathways. Most animal tissues can only survive short anaerobic bursts that occur in isolation and don't involve the entire organism. The aerobic pathway is required to sustain life. Yeast also prefers to grow using the aerobic, mitochondrial pathway. However, if oxygen is unavailable, yeast and other fungi can switch to anaerobic growth and produce ethanol as a byproduct. The production of alcoholic beverages through this fermentation process is quite popular.

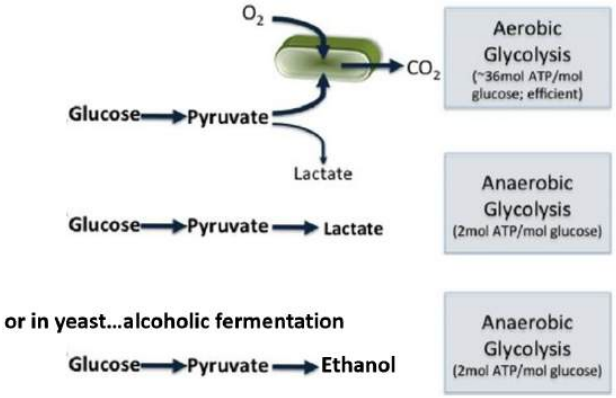

Figure 13.1.4: Overview of Aerobic and Anaerobic Oxidation of Glucose. Figure modified from Kim, Y. et al (2011) PLoS ONE 6(12):e28293

Figure 13.1.5 provides a summary of the glycolytic pathway coupled to the oxidative phosphorylation pathway that occurs within the mitochondria.

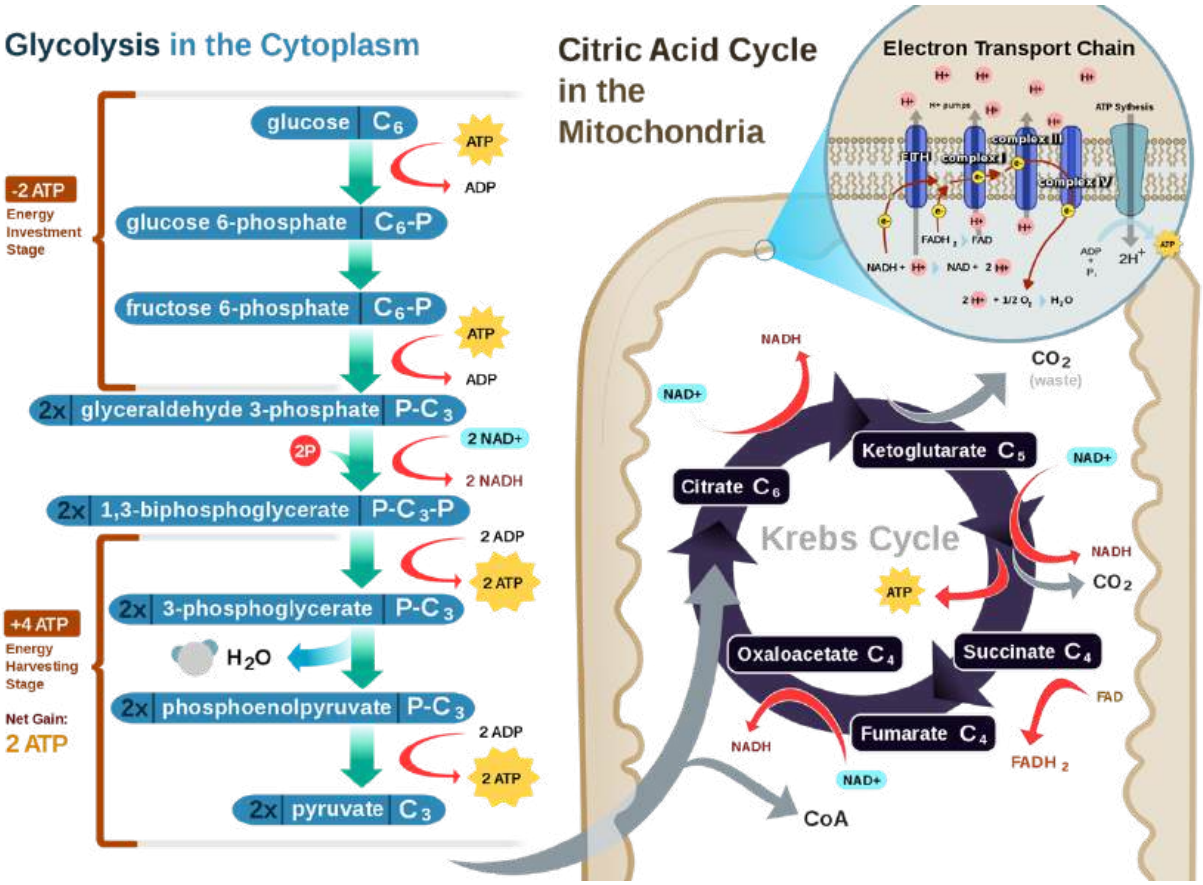

Figure 13.1.5 : A Summary of the Glycolytic and Oxidative Phosphorylation Pathways. The glycolytic pathway is shown on the left-hand side in blue. During aerobic metabolism, pyruvate would be converted to acetyl-CoA which then enters the Kreb cycle within the matrix of the mitochondria. Future chapters will focus on the reactions inside the mitochondria. Our focus in this chapter will be on the cytosolic reactions of the glycolytic pathway.

The major reactions of glycolysis are shown in **Figure 13.1.6** . The pathway can be broken down into two major sections: (1) the energy-consuming reactions and the (2) the energy-generating reactions. An adage states that 'It takes money to make money'. The same can be thought about the glycolytic pathway. The first section requires an investment of energy to generate energy in the second half of the reaction pathway. In this pathway, glucose, a 6-carbon hexose, is converted to two, 3C molecules - pyruvate. Note that **Figure 13.1.6** shows the entire pathway using Lewis wedge/dash representations plus the anaerobic conversion of pyruvate to lactate.

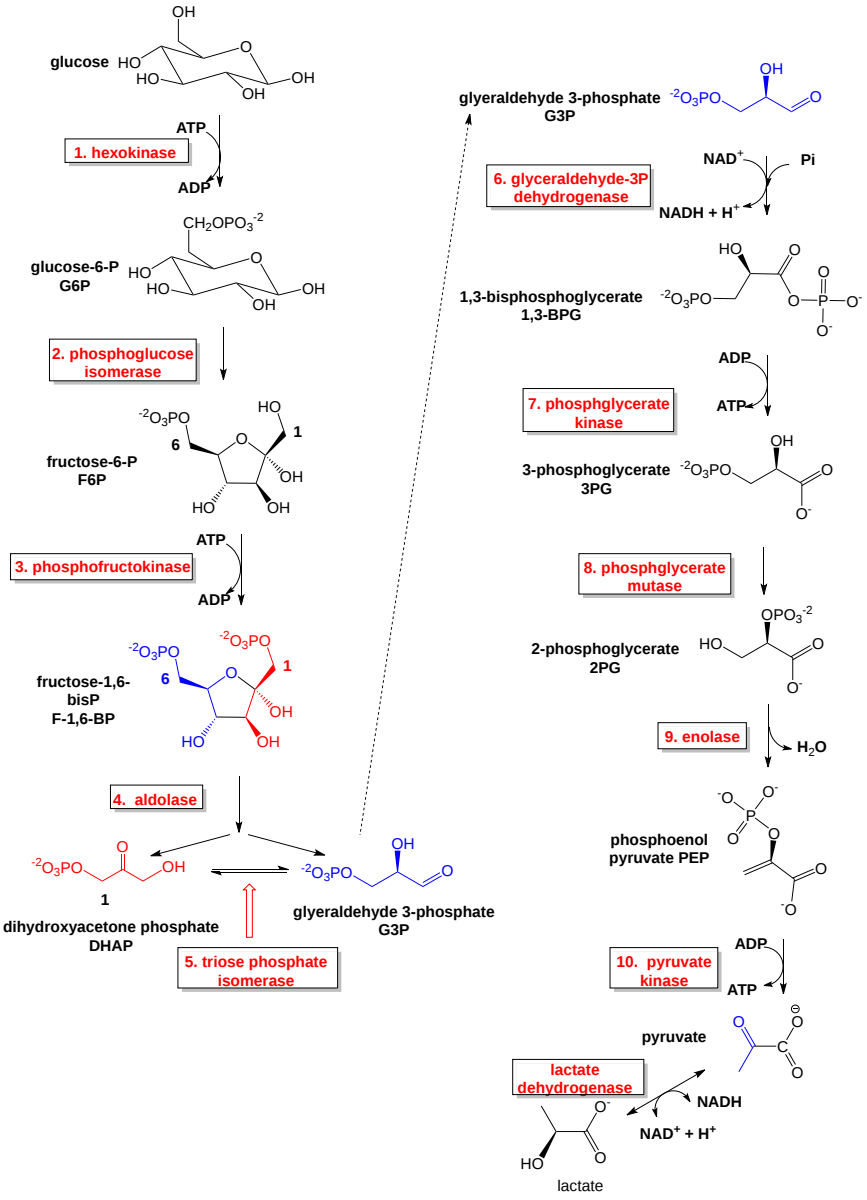

Figure 13.1.6 : Glycolytic pathway. The chemical steps of the glycolytic pathway are shown using Lewis wedge/dash representations. Enzymes required at each step are labeled in red. The energy-consuming steps encompass reactions 1 - 3, whereas the energy-producing steps occur in the second half of the pathway from reactions 4 - 10. The conversion of pyruvate to lactate by lactate dehydrogenase represents anaerobic respiration as it occurs within mammalian species.

Glycolysis is the key anaerobic pathway for energy products in all organisms, except in lithotropes that use the oxidation of inorganic molecules for energy production. In aerobic systems, glycolysis provides the release of fast energy within the body as glycogen metabolism can quickly release free glucose for utilization. Given the centrality of glycolysis to all of life, we will explore each of the reactions in detail below.

13.1.2: **REACTION 1: GLUCOSE → GLUCOSE-6-PHOSPHATE**. ΔG^{O}=-4.0 KCAL/MOL (-16.7 KJ/MOL).

The first step in glycolysis is catalyzed by enzymes known as hexokinases. The hexokinase family enzymes typically have broad specificity for various hexoses and catalyze the phosphorylation of carbon 6. Hexokinase phosphorylates glucose using ATP as the source of the phosphate, producing glucose-6-phosphate, a more reactive form of glucose. Notably, this reaction prevents the phosphorylated glucose molecule from continuing to interact with the GLUT transport proteins that can shuttle glucose into and out of the cell. Thus, once glucose is phosphorylated it can no longer leave the cell. Do note that both of these sugar forms (the free sugar and the phosphorylated version) can shift back and forth between the ring-closed and ring-opened conformation. Hexokinases require glucose to be in the closed conformation

for the phosphorylation reaction. **Figure 13.1.7** shows the reaction which is catalyzed by **hexokinase** (a kinase that transfers the γ-phosphate from ATP to a hexose in the closed-ring form).

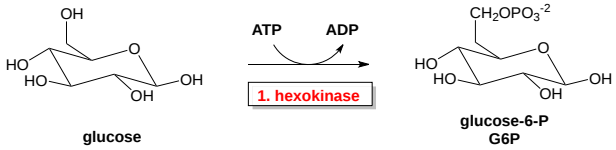

Figure 13.1.7 : Summary reaction - hexokinase

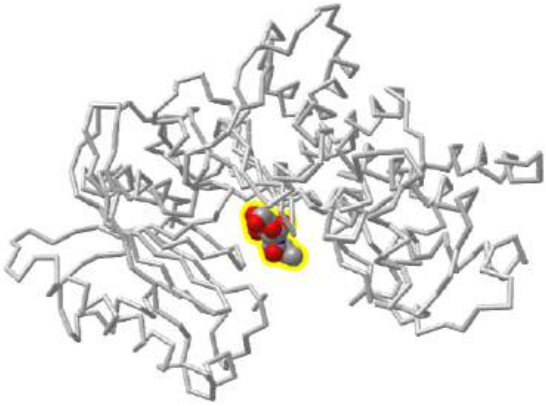
This reaction is a nucleophilic substitution reaction on the gamma phosphate of ATP. A phosphoanhydride bond is broken in ATP as a phosphoester bond is made producing glucose 6-phosphate. Hence the reaction proceeds with a negative ΔG^o.

Vertebrates have 4 different types of hexokinases, I-IV (also called A-D). The regulation of these enzymes is presented in more detail in Chapter 15.5. Hexokinases I-III bind glucose more tightly as reflected by low K_M values. Type IV or glucokinase binds it less tightly, and is found in high concentrations in vertebrate livers. Yeast has 3 isozymes, P1, PII or hexokinase B, and glucokinase. Most prokaryotic hexokinases are in the glucokinase (Type IV) class.

In addition to hexokinases, there are also many other different types of sugar kinase enzymes. Notably, all sugar kinases must prevent the spurious hydrolysis of ATP by water, which can also be considered a phosphotransfer to water, instead of the preferred transfer of the γ phosphate of ATP to a sugar ROH (alcohol), an "alcoholysis" reaction. Hexokinase does this through an "induced fit" mechanism, in which glucose binding triggers a large conformation change to close off the active site to water.

This conformational change is illustrated in **Figure 13.1.8** below which shows an interactive iCn3D model of the yeast hexokinase PI in the absence (2YHX) and presence (3B8A) of glucose.



NCBI iCn3D **Figure 13.1.8 : Yeast hexokinase PI in the absence (2YHX) and presence (3B8A) of glucose.** (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...84YGEd1ob3th7A

Within **Figure 13.1.8 ,** the gray structure is hexokinase without glucose (2YHX). However, it has a glucose analog bound, o-tolyoylglucosamine (spacefill, yellow highlights), which binds at the glucose binding site but does not cause a subsequent conformation change. The cyan structure (in the actual iCn3D model) show the enzyme with glucose shown as colored sticks. Note the large conformational change on the actual binding of glucose, a classical example of an "induced fit" mechanism.

Figure 13.1.9 shows the surface of both enzymes using the same color coding as in the above figure These images better show how the active site of hexokinase is occluded in the glucose-bound form. This prevents water access and hydrolysis of bound ATP instead of "alcoholysis" of ATP (transfer of phosphate to glucose). The gray structure on left has the glucose analog bound which doesn't alter the global conformation of the protein.

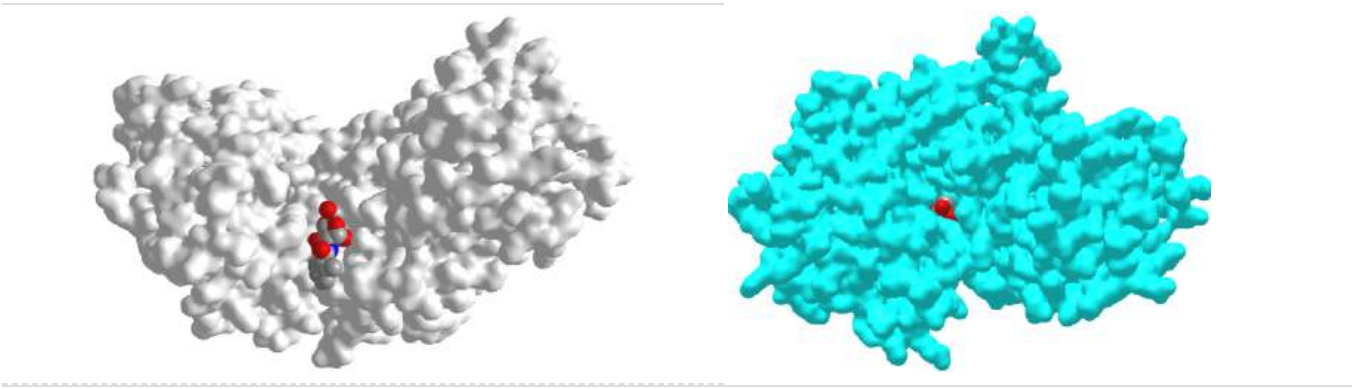


Figure 13.1.9 : Surface of human hexokinase I with bound o-tolyoylglucosamine (spacefill, left, 2YHX) and with bound glucose (spacefill, right, 3B8A)

Hexokinase I is the key form in the brain. It forms a complex with porin in the mitochondrial outer membrane and ATP/ADP translocase or carrier protein in the mitochondrial inner membrane which facilitates the hexokinase reaction. The mechanism for the reaction of human hexokinase I is shown in **Figure 13.1.10** below.

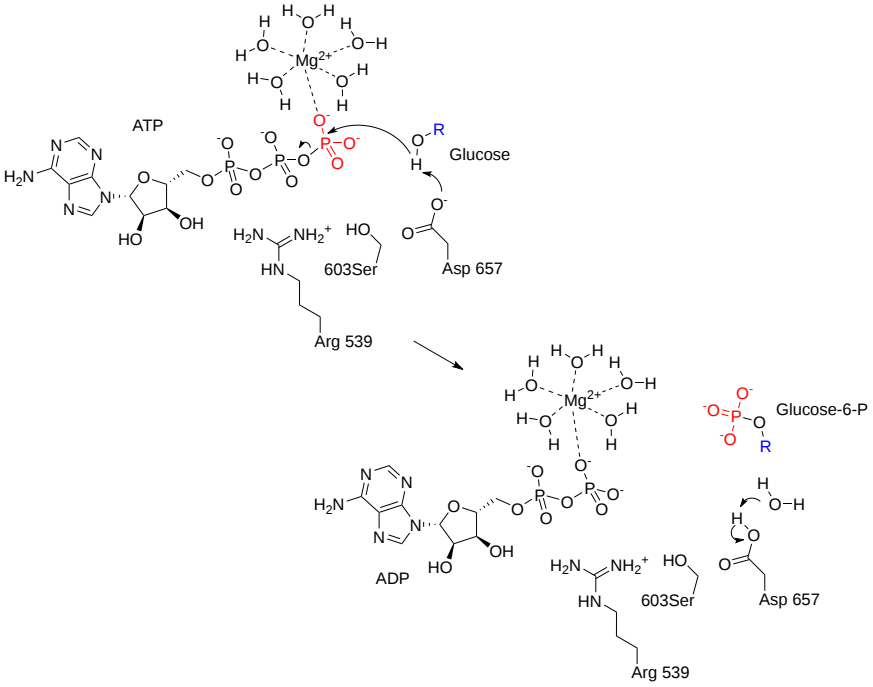

Figure 13.1.10 : Mechanism of human hexokinase I.

Ribeiro AJM *et al.* (2017), *Nucleic Acids Res*, **46**, D618-D623. Mechanism and Catalytic Site Atlas (M-CSA): a database of enzyme reaction mechanisms and active sites. DOI:10.1093/nar/gkx1012. PMID:29106569. https://www.ebi.ac.uk/thornton-srv/m-csa/entry/696/. Creative Commons Attribution 4.0 International (CC BY 4.0) License.

Figure 13.1.11 below shows an interactive iCn3D model of human hexokinase I with glucose and ADP in the active site (1dgk).

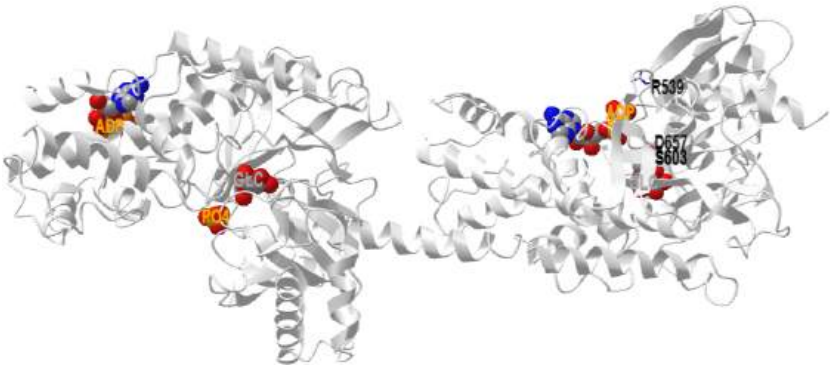

Figure 13.1.11 : Human hexokinase I with glucose and ADP in the active site (1dgk). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...aQy4gf6A2bWtp8

The key catalytic residues are shown in colored sticks and labeled. Glucose, ADP, and PO_4^{2-} are shown as colored spheres.

Note that hexokinase I, as well as forms II and III, have spatially distinct halves similar to those in the yeast enzymes. Forms I-III have a molecule weight of about 100K. Form IV (glucokinase) has a molecular weight of 50K and is similar to the distinct halves of I-III. suggesting that I-III arose through gene duplication.

Each half also binds glucose and ADP but the N-terminals of I and III are catalytically inactive. Hexokinase II, with both halves active, is the main enzyme involved in glycolysis in most mammalian tissues. Other differences are that glucose-6-phosphate, a product, inhibits I-III. PO_4^{2-} relieves G6P product inhibition in form I but not the others. ADP binding at multiple sites in hexokinase I likely causes a conformational change that affects structure and activity.

13.1.3: SUGAR KINASES IN GENERAL

We will see many kinases that use ATP to phosphorylate sugars, so it is useful to explore both their differences and similarities at the beginning of our studies on carbohydrate metabolism.

Figure 13.1.12 below shows the comparative structures of the five carbohydrate kinase classes.

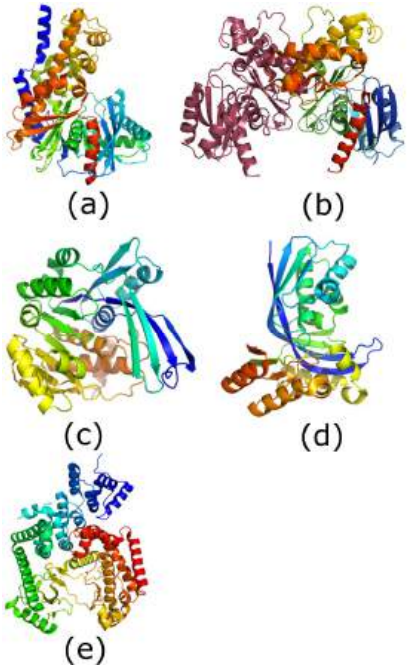

Figure 13.1.12 : Structures of the five carbohydrate kinase classes. All images are shown in rainbow format (blue: *N*-terminus, red: *C*-terminus). Roy, S.; Vivoli Vega, M.; Harmer, N.J. Carbohydrate Kinases: A Conserved Mechanism Across Differing Folds. *Catalysts* **2019**, *9*, 29. https://doi.org/10.3390/catal9010029. **Creative Commons Attribution License**

Panel (**a**) shows the structure of human glucokinase (hexokinase class; PDB (protein data bank) ID: 4IWV).

Panel (**b**) shows the structure of *Bacillus subtilis* fructokinase dimer: the second molecule shown in raspberry (ROK kinase class; PDB ID: 1XC3 [17]).

Panel (**c**) shows the structure of *Escherichia coli* ribokinase (ribokinase class; PDB ID: 1RKD; [18]).

Panel (**d**) shows the structure of *Aquifex aeolicus* IspE (GHMP kinase class; PDB ID: 2V2Z; [19]).

Panel (**e**) shows the structure of human PIK3C3 (phosphatidylinositol phosphate kinase class; PDB ID: 3IHY).

Table 13.1.1 : Overview of the Five Carbohydrate Kinase Classes.

Carbohydrate Kinase Family	Common Substrates	Native Phosphate Donors (Minor Donors in Parentheses)	Pfam ID
Hexokinase	Glucose, mannose, fructose	ATP (ITP)	PF00349, PF03727, PF02685
ROK Kinase	Glucose, allose, fructose, *N*-acetylglucosamine, *N*-acetylmannosamine	ATP (polyphosphate)	PF00480
Ribokinase	Ribose, 2-deoxy-d-ribose, adenosine	ATP, ADP (GTP, ribonucleotide)	PF00294
GHMP Kinase	Galactose, *N*-acetylgalactosamine,	ATP (GTP, ITP)	PF00288
Phosphatidylinositol kinase	Phosphatidylinositol, phosphatidylinositol phosphates	ATP (GTP)	PF00454, PF01504

ROK is a bacterial Repressor, Open reading frame, Kinases are predominantly bacterial enzymes. Ribokinases include adenosine kinases, fructokinases, and phosphofructokinases. GHMP Kinases include Galactokinase, Homoserine kinase, Mevalonate kinase, and Phosphomevalonate kinase. Roy et al. Ibid

Many of these kinases are regulated by the binding of allosteric effectors.

Figure 13.1.13 shows a common mechanism for all, using glucose as an example substrate.

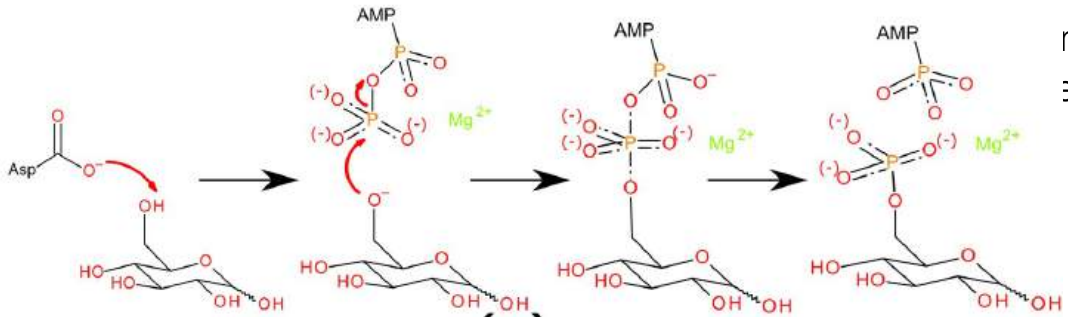

Figure 13.1.13 : Generic reaction mechanism for carbohydrate kinases (hexokinase shown). Roy et al, Ibid. The generic reaction is initiated by a catalytic base abstracting a proton from the reactive hydroxyl (left). The oxygen atom then attacks the -phosphate of ATP (second left), forming a pentacoordinate transition state (second right). This is stabilized by a divalent cation, and by the protein (not shown). This transition state resolves, leaving ADP and the phosphorylated carbohydrate (right).

13.1.4: **REACTION 2**: **GLUCOSE-6-PHOSPHATE ↔ FRUCTOSE-6-PHOSPHATE**. ΔG^{O}=+0.4 KCAL/MOL (+1.7 KJ/MOL)

In the second step of glycolysis, the **phosphoglucose isomerase (PGI)** converts glucose-6-phosphate into one of its isomers, fructose-6-phosphate. Recall that an isomerase is an enzyme that catalyzes the conversion of a molecule into one of its isomers. In this reaction, the aldose, glucose-6-phosphate, is converted to the ketose, fructose-6-phosphate. This conversion is essential to allow the eventual split of the sugar into two three-carbon molecules. We'll present this reaction, catalyzed by **phosphoglucose isomerase (PGI)**, in several different types of representations (chair, wedge/dash, and Fischer projection), as shown in **Figure \(\PageIndex{14}\)** below.

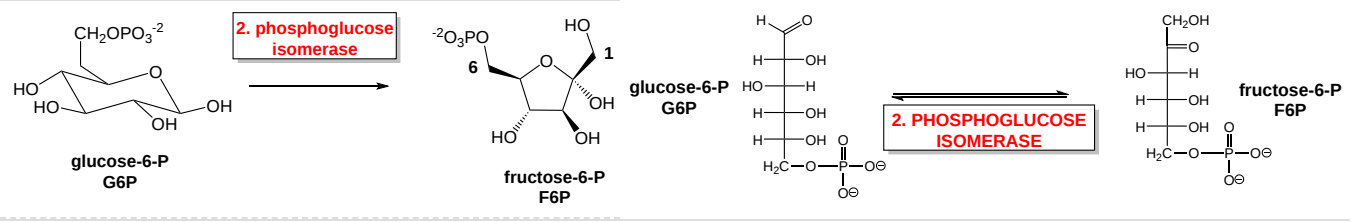

Figure 13.1.14 : Summary reaction, phosphoglucoisomerase

From a functional perspective, seen more clearly from the linear Fischer structure, it is evident that the C=O has been moved to the C2 position to create the ketose structure. The carbonyl O is now positioned to be an electron sink facilitating electron flow for reaction 4. This isomerization reaction would be expected to have a ΔG^o of about 0.

It has been proposed that the mechanism of PGI requires the enzyme to open the Glucose-6-Phosphate ring before the actual isomerization step, which proceeds through the formation of a cis-enediol intermediate and keto-enol tautomers before conversion back to the cyclic form.

Figure 13.1.15 below shows a proposed mechanism for rabbit phosphoglucose isomerase

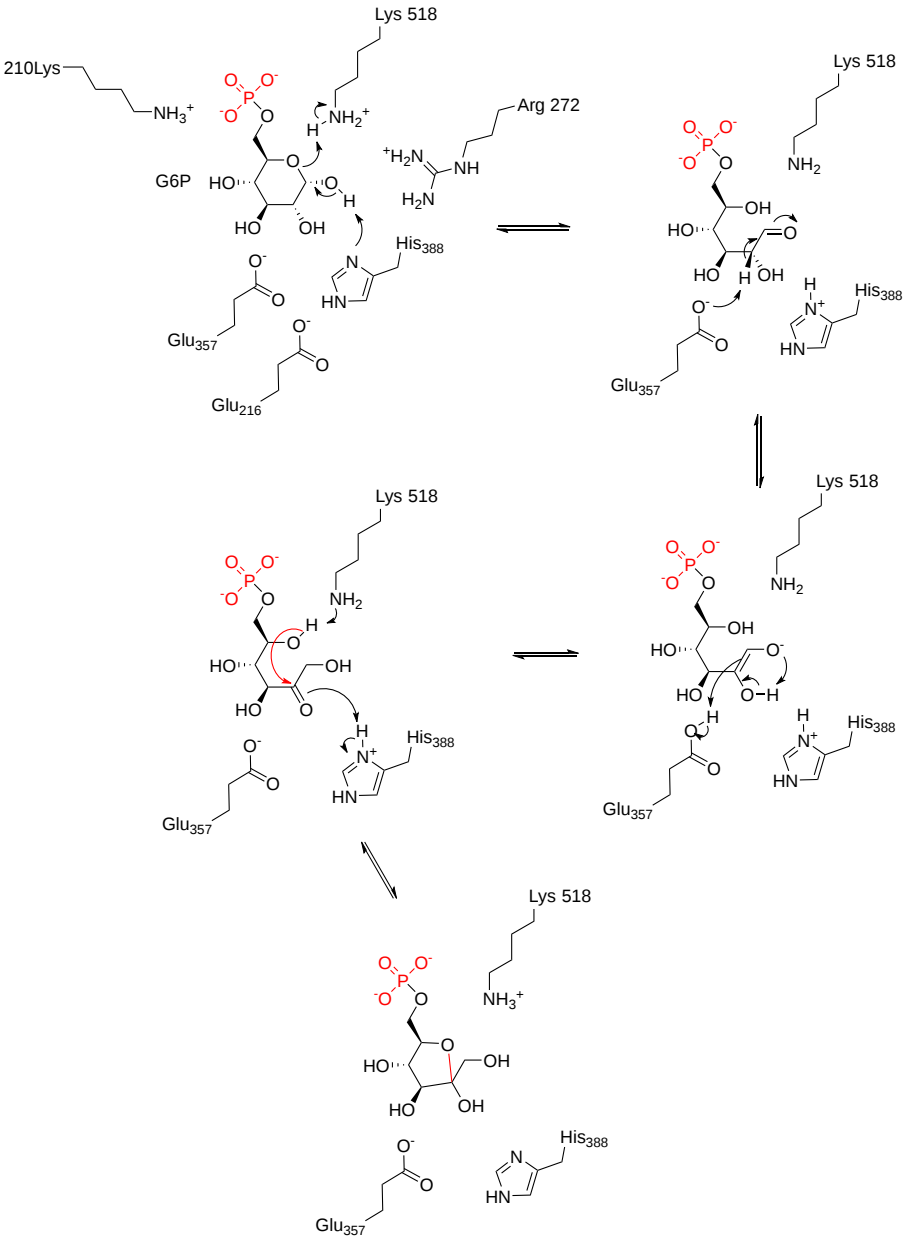

Figure 13.1.15 : Mechanism for phosphoglucose isomerase. Ribeiro AJM *et al. Ibid*

Figure 13.1.16 below shows an interactive iCn3D model of rabbit phosphoglucose isomerase with bound 6-phosphogluconic acid (1DQR)

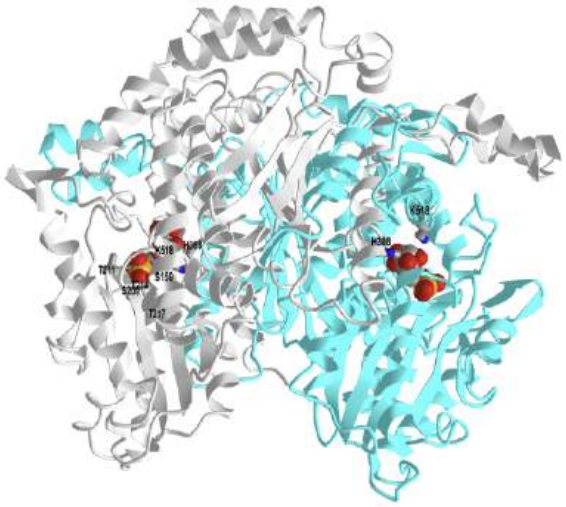

Figure 13.1.16 : Rabbit phosphoglucose isomerase with bound 6-phosphogluconic acid (1DQR). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...xo1SgF1ZpAySm9

One monomer of the dimer is shown in gray and the other in cyan. The catalytic residues Lys518 and His388 are shown in both subunits in colored sticks and labeled. Additional residues that contribute to specificity (Ser209, Ser159, Thr214, Thr217, and Thr211) are shown in the gray subunit with color sticks and labeled. 6-phosphogluconic acid, a competitive inhibitor, is shown in color spacefill.

The enzyme also has other functions in addition to its role in glycolysis, so it is a member of a group called "moonlighting" (a term that refers to working at a secondary job). proteins. Outside of the cell, phosphoglucoisomerase acts as a nerve growth factor and cytokine. It is also called autocrine motility factor (PGI/AMF) and its cytokine activity is associated with aggressive cancers.

13.1.5: **REACTION 3: FRUCTOSE-6-PHOSPHATE → FRUCTOSE-1,6-BISPHOSPHATE.** ΔG^{O}=-3.4 KCAL/MOL (-14 KJ/MOL)

The third step is the phosphorylation of fructose-6-phosphate, catalyzed by the enzyme **phosphofructokinase-1 (PFK1)**. A second ATP molecule donates a high-energy phosphate to fructose-6-phosphate, producing fructose-1,6-bisphosphate. The term bisphosphate is used when two phosphate groups are joined to a molecule at different positions on the molecule. In this case, one phosphate is at the 1-carbon position and the other is at the 6-carbon position. This differs from the term diphosphate, which is used when the phosphate groups are joined in a sequence, as in the molecule ADP. In ADP, both phosphate groups are joined in tandem from the 5-carbon position on the ribose ring structure.

In the glycolytic pathway, PFK1 is a rate-limiting enzyme. The mechanism of PFK1 regulation is discussed in greater detail in Chapter 15.5. However, we will introduce the process here. Essentially, the enzyme is sensitive to the energy load within the cell. Recall that ATP is a recycled molecule and exists in a pool of interconverting ATP, ADP, and AMP. A chief outcome of glycolysis is to shift the pool towards increased levels of ATP to drive endergonic processes like muscle contraction. PFK1 activity is sensitive to the ATP:ADP ratio within the cell. PFK1 is more active when the concentration of ADP is high and the concentration of ATP is low, and it is conversely less active when ADP levels are low and the concentration of ATP is high. This is a type of end-product inhibition since ATP is the end product of glucose catabolism. Note, however, that ATP is also a substrate for PFK1. ATP serves as the phosphate donor in the reaction and is required in the process. This is the second energy-intensive step in the glycolytic pathway. At the end of the PFK1 step, a total of 2 ATP molecules have been broken down in the glycolytic pathway.

The PFK1 enzymatic step is also important within the glycolytic pathway as it is the committed step in the pathway. Glucose-6-phosphate may be used for other purposes within the cell, and the isomerase step that converts glucose-6-phosphate to fructose-6-phosphate is readily reversible. The PFK1 enzyme only works in the forward direction to create fructose 1,6-bisphosphate. It cannot in the reverse direction and recover the reactant. Thus, it is thought of as the committed step in the glycolytic pathway as the fructose-1,6-bisphosphate will predominantly be converted into pyruvate through the remaining enzymatic steps.

The reaction catalyzed by PFK1 is shown in **Figure 13.1.17** below.

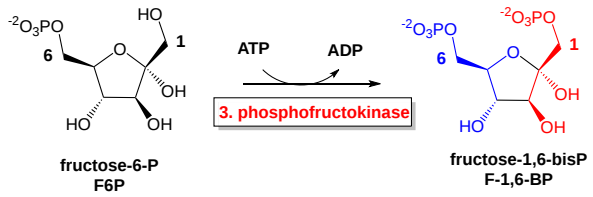

Figure 13.1.17 : Summary reaction - phosphofructokinase

By phosphorylating this intermediate, both products of the cleavage of this 6C molecule will be phosphorylated, keeping both more readily inside the cell. This reaction is a nucleophilic substitution reaction on the gamma phosphate of ATP. A phosphoanhydride bond is broken in ATP as a phosphoester bond is made producing fructose-1,6-bisphosphate. As in reaction 1, this reaction proceeds with a negative ΔG^o

The PFK1 enzyme exists as a tetramer and as with another "famous" tetramer, hemoglobin, it can exist in T and R symmetry states. Hence it is an allosteric enzyme and has many allosteric regulators. One important allosteric activator of eukaryotic (but not prokaryotic) PFK is fructose-2,6-bisphosphate. This is formed by a separate **phosphofructokinase enzyme named PFK2**. This regulatory pathway will be described in greater detail in Chapter 15.5. Hence the number 1 is added to the name of the glycolytic enzyme, PFK1, that forms fructose 1,6-bisphosphate, to indicate the position of phosphorylation. Mammals have three isoforms of PFK1, muscle (PFKM), liver (PFKL), and platelet (PFKP).

The mechanism for E. Coli phosphofructokinase is shown in **Figure 13.1.18** below. A metal cofactor (Mg2+) coordinates the positioning of the ATP and stabilizes the gamma phosphate for nucleophilic attack by the fructose alcohol group at position-1. Activation of the fructose alcohol group is mediated by proton abstraction with a coordinated Asp_{127} of PFK1.

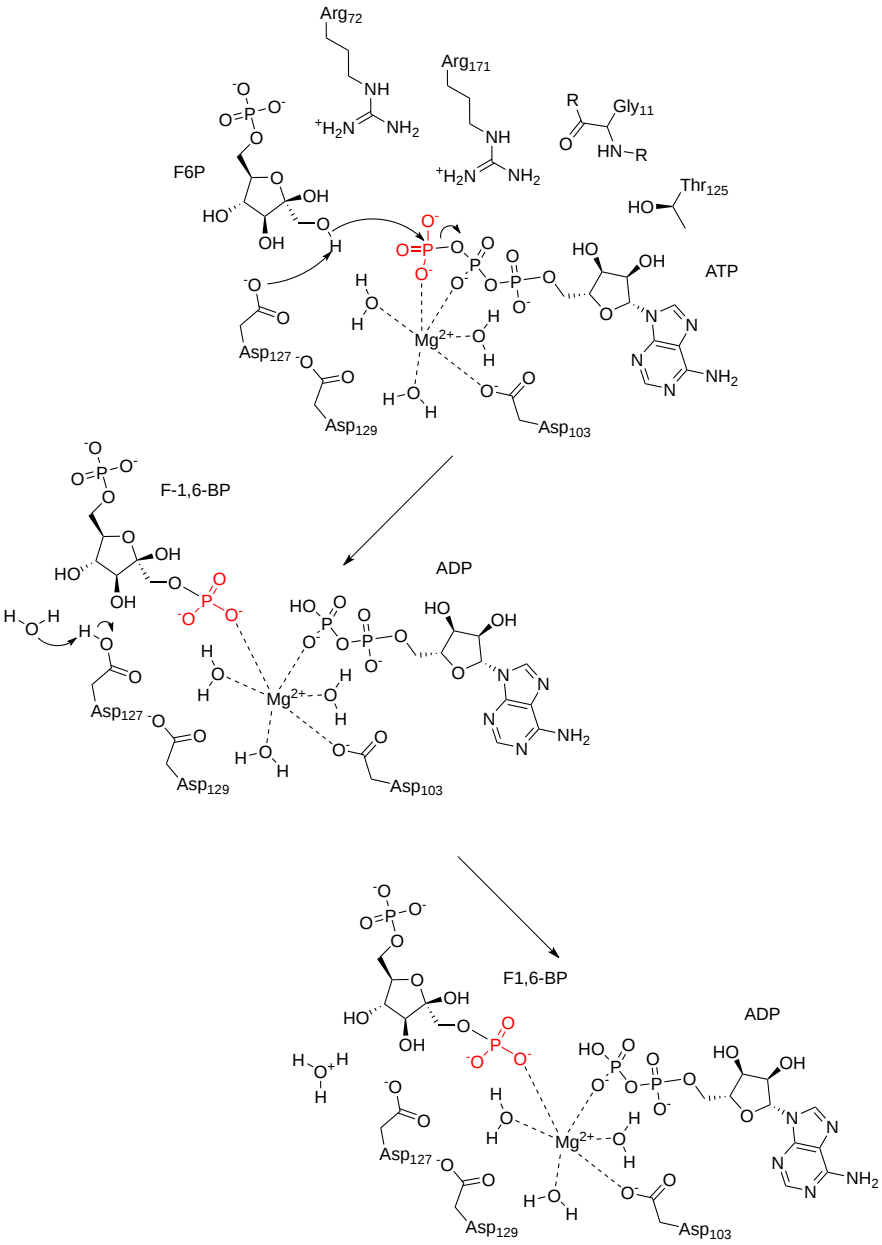

Figure 13.1.18 : Proposed mechanism for E. Coli phosphofructokinase. Ribeiro AJM *et al. Ibid*

Figure 13.1.19 below shows an interactive iCn3D model of the *E. Coli* phosphofructokinase with bound F1,6-bisphosphate and ADP products (1PFK). (long load)

Figure 13.1.21 : Conformation changes in the active site of PFK on ATP hydrolysis

13.1.6: REACTION 4: **FRUCTOSE-1,6-BISPHOSPHATE → DIHYDROXYACETONE PHOSPHATE (DHAP) + GLYCERALDEHYDE 3-PHOSPHATE (G3P).** ΔG^{O} = + 5.7 KCAL/MOL (+24 KJ/MOL)

The newly added high-energy phosphates further destabilize fructose-1,6-bisphosphate. The fourth step in glycolysis employs an enzyme, aldolase, to cleave fructose-1,6-bisphosphate into two three-carbon isomers: dihydroxyacetone phosphate and glyceraldehyde-3-phosphate. This reaction is shown in **Figure 13.1.22** below in both wedge dash and Fischer projections.

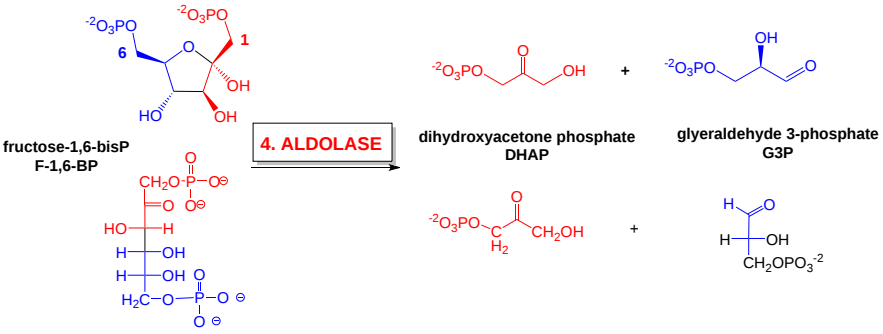

Figure 13.1.22 : Summary reaction - aldolase

This is the first C-C bond cleavage within glucose on the path to complete cleavage during aerobic respiration and release of 6 carbon dioxide molecules per glucose metabolized. This reaction is the reverse of an aldol condensation when an enol or enolate reacts with a carbonyl C to form an adduct. Note that both products are phosphorylated. The reaction is not thermodynamically favored but is pulled in the forward direction by the utilization of the product in subsequent reactions in the pathway.

Table 13.1.2 Characteristics of the Three Classes of Aldolases (I, IA, and II) and the Organisms in Which They are Found.

Aldolase class	Organisms	Characteristics
I	Higher eukaryotes (plants, animals), some protozoans (e.g., Trypanosoma brucei, Leishmania donovani, Plasmodium falciparum), some bacteria, some algae	• Mechanism of action: Schiff base forms substrate intermediate • Structure: Typically forms homo-tetramers, contains TPI β/α-barrel fold
IA	Archaea	• Mechanism of action: Schiff base forms substrate intermediate • Structure: Typically forms homo-octamers/ decamers/higher oligomers, contains TPI β/α-barrel fold
II	"Lower" eukaryotes (some protozoans (e.g., Giardia lamblia), fungi, yeasts, algae), most bacteria, some archaea	• Mechanism of action: Divalent ion forms substrate intermediate, metal-dependent • Structure: Typically forms homo-dimers, contains TPI β/α-barrel fold

Class I Aldolase

These enzymes proceed through a Schiff base intermediate between a reactive lysine and the reactant/product. The enzyme is favored in the reverse direction and it's perhaps easier to see the mechanism presented in that fashion. In rabbits, the muscle Class I aldolase (RAMA) uses Lys-229 to form a Schiff base with DHAP as shown in a mechanism presented in **Figure 13.1.23** below.

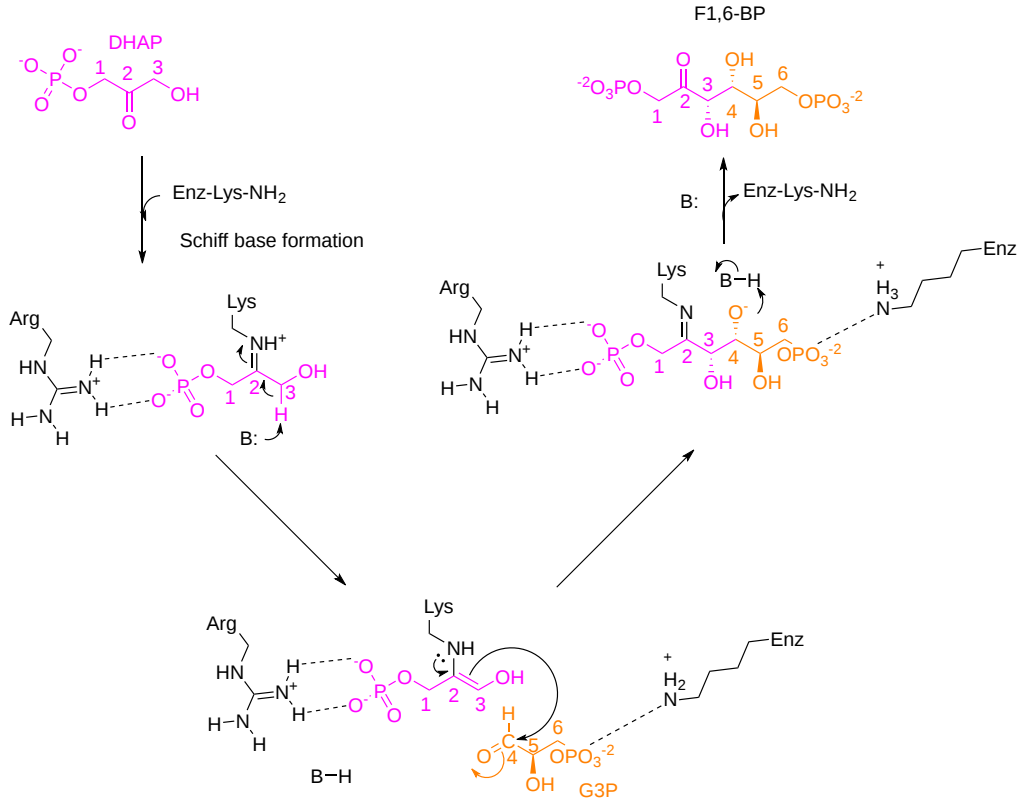

Figure 13.1.23 : Class I aldolases - general mechanism (after Bolt et al., Arch Biochem Biophys. 2008 June 15; 474(2): 318–330)

Only the pro(S) proton of the dihydroxyacetone phosphate C3 carbon is removed and effectively exchanged with the glyceraldehyde-3-phosphate substrate. **Figure 13.1.24** below reviews how the pro(R) and pro(S) hydrogens can be visually differentiated by replacing one

with a deuterium and determining the stereochemistry of the now chiral C3.

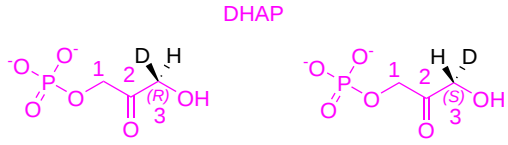

Figure 13.1.24 : Visualization of the Pro(R) and Pro(S) Hydrogens on DHAP

Figure 13.1.25 shows key active site residues in the active site of a Class I aldolase from rabbit muscle. The first step in Schiff base formation with Lys229 is shown.

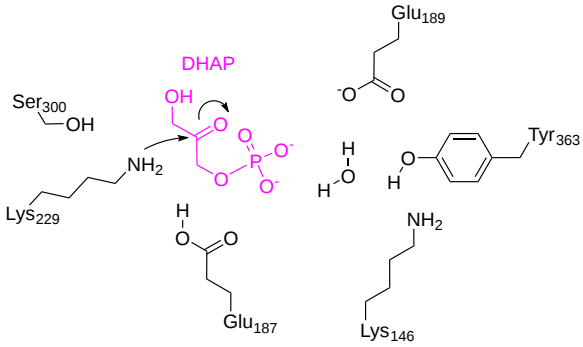

Figure 13.1.25: Catalytic residues in rabbit muscle Class I enolase.

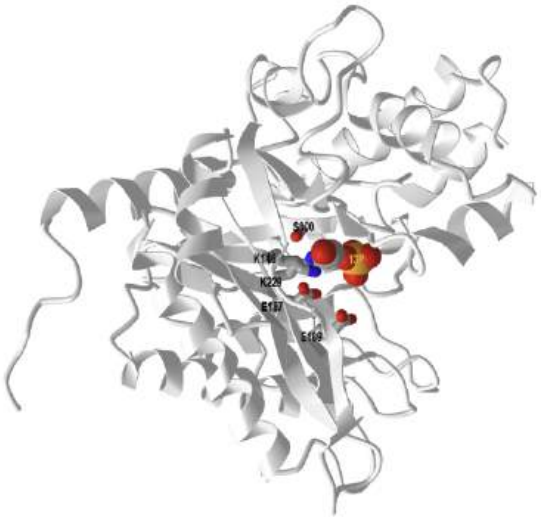
Figure 13.1.26 shows an interactive iCn3D model of the dihydroxyacetone phosphate enamine intermediate in fructose-1,6-bisphosphate aldolase from rabbit muscle (2QUT)



NCBI iCn3D Figure 13.1.26: Dihydroxyacetone phosphate enamine intermediate in fructose-1,6-bisphosphate aldolase from rabbit muscle (2QUT). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...uR5KZBsfN8QQh9

Only one monomer of the four in the homotetramer is shown. The ligand, 1,3-dihydroxyacetonephosphate, is shown in spacefill with CPK colors. It is Schiff base linkage with Lys229. The key catalytic residues are shown and labeled.

The reaction proceeds between eneamine and iminium covalent intermediates. A K146M mutation (in the active site) decreases enzyme activity and allows the trapping of the K229 eneamine intermediate. A key tyrosine (Y363) in its deprotonated state formed in the presence of the iminium phosphate and a local water appears to abstract the C3 pro(S) proton to form the enamine.

Class II Aldolase

Figure 13.1.27:

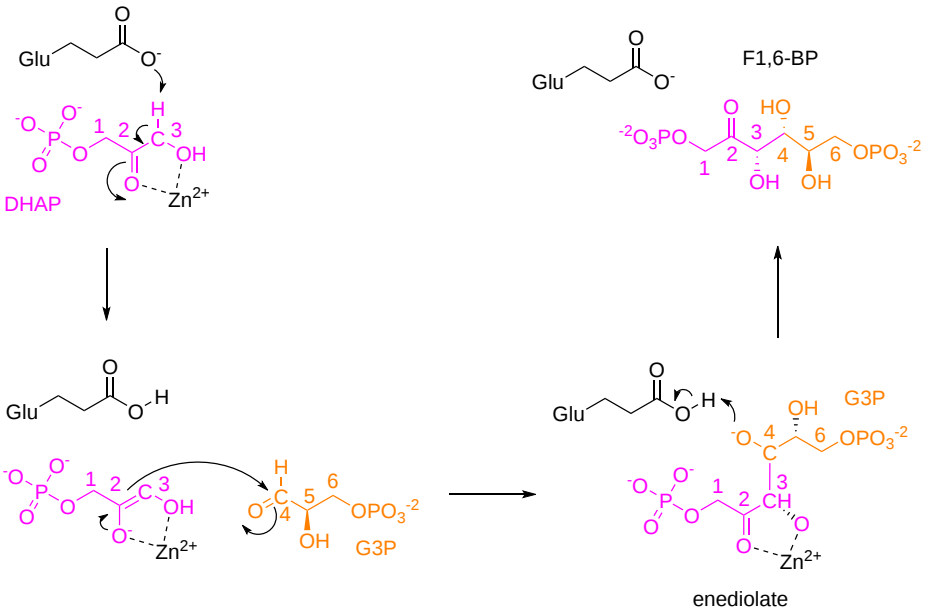


Figure 13.1.27: Class II aldolases - general mechanism (after Bolt et al, ibid)

13.1.7: **REACTION 5: DHAP ↔ G3P**. ΔG^{O}= +1.8 KCAL/MOL (+7.5 KJ/MOL)

This reaction, catalyzed by triose phosphate isomerase (TPI), is shown in Figure 13.1.28.

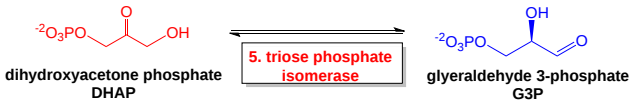

Figure \(\PageIndex{28}\: Summary reaction - triose phosphate isomerase.

This is another simple isomerization reaction. Only one product, glyceraldehyde-3P continues on in glycolysis, so only one enzyme is needed to metabolize the cleavage products of this reaction further. As in other isomerization reactions, the ΔG^{o} is close to 0.

A proposed mechanism for this reaction is shown in Figure \(\PageIndex{29} below.

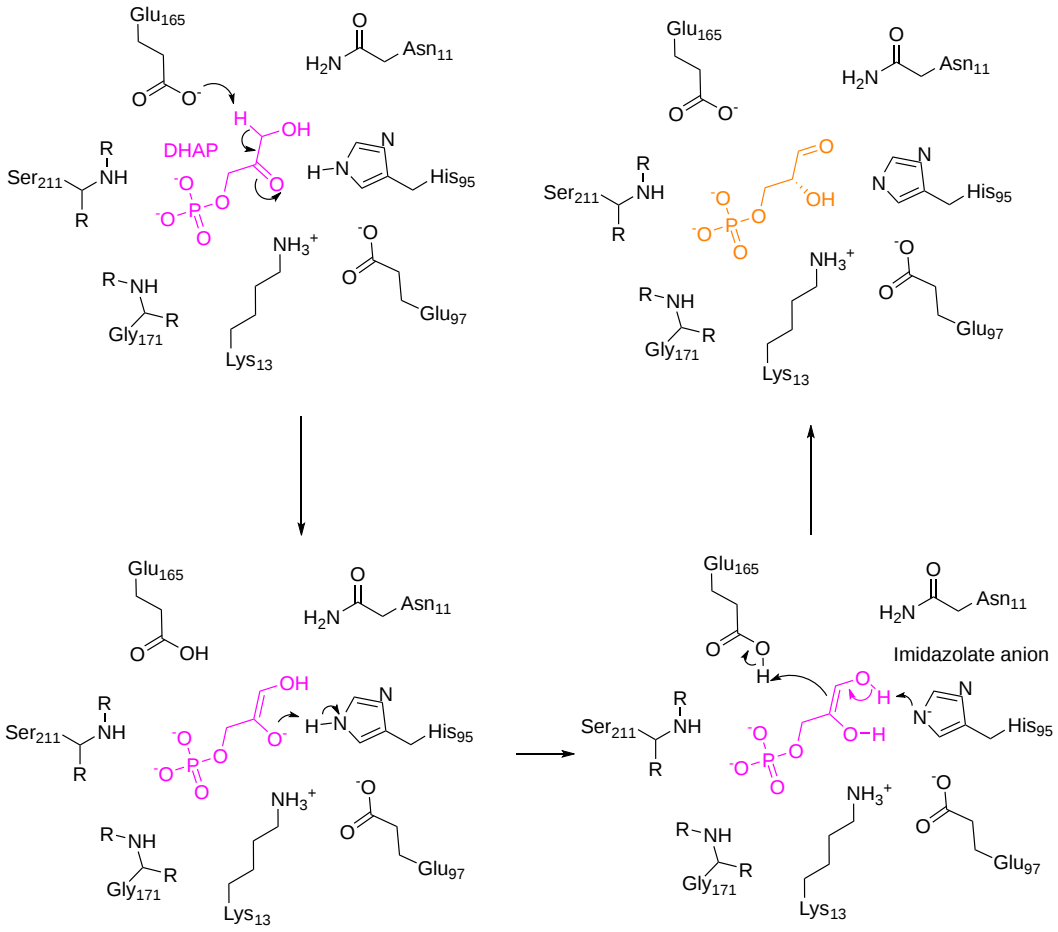

Figure 13.1.29: Proposed mechanism for triose phosphate isomerase (after Bolt et al, ibid)

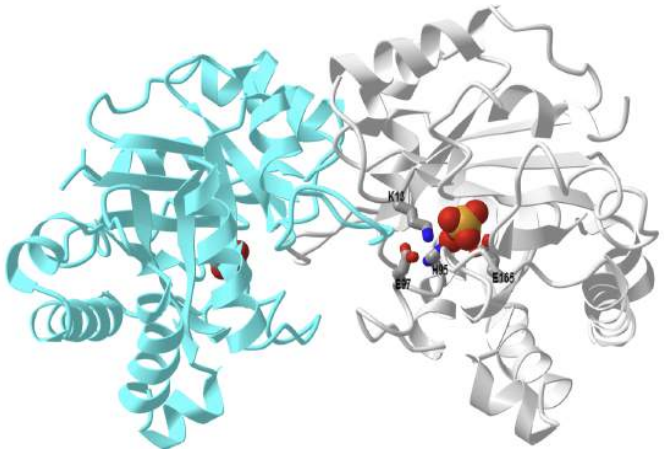
Note that the reaction employees the deprotonation of a neutral imidazole side chain to form an imidazolate anion. This would not likely be favorable, given its pKa value.

The are four possible conserved proton donors with more reasonable pKas in the active sites of TPIs, including K12, H95, E97, and E165. Mutations of E97 to E97Q and E97D lead to a 4000-fold reduction in k_{cat} (E97Q) but only a 100-fold reduction for E97D suggesting tha30}\) shows an interactive iCn3D model of the chicken triosephosphate isomerase-phosphoglycolohydroxamate complex (1TPH)



NCBI iCn3D Figure 13.1.30: Chicken triosephosphate isomerase-phosphoglycolohydroxamate complex (1TPH). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...AFXpt9kg5aki5A

The four key conserved residues are shown in the gray monomer of the homodimer.

13.1.8: **REACTION 6: G3P ↔1,3 BPG.** ΔG^{O}= +1.5 KCAL/MOL (+6.1 KJ/MOL)

This reaction, catalyzed by **glyceraldehyde-3-phosphate dehydrogenase**, is shown in Figure 13.1.31

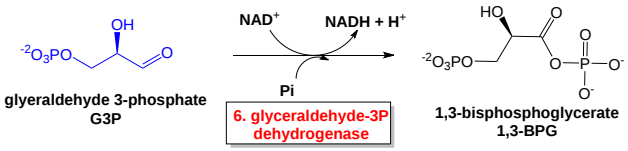


Figure \(\PageIndex{31}\: Summary reaction - glyceraldehyde-3-phosphate dehydrogenase

This is a big reaction! Note that the ΔG^{o} is close to 0 but look at what happened. The carbonyl O in G3P has been oxidized to the form of a mixed anhydride which can donate a phosphate to ADP (in the next step) to form ATP. That this is an oxidation reaction should be obvious from the fact that the carbonyl C in G3P has two bonds to O but 3 bonds in 1,3 BPG.

To carry out an oxidation reaction, you need an oxidizing agent. In comes NAD^{+}, a modest but very prevalent oxidizing agent in biology. When glucose is oxidized completely by O_2 to CO_2 during combustion, much energy is released so we can surmise that oxidation reactions, if carried out by powerful oxidizing agents like O_2, proceed with a large negative ΔG^{o}. For every oxidation reaction, the oxidizing agent is reduced. All reactions are potentially reversible so the products formed are new potential oxidizing and reducing agents. As in acid/base reactions, which proceed from stronger acid to weaker conjugate acid, redox reactions proceed from a stronger to a weaker oxidizing agent. For reaction 6, we must use tables of redox potentials to calculate the actual ΔG^{o}. It turns out to be close to 0, which is great since in the same reaction, a substrate-level phosphorylation reaction (using inorganic phosphate - P_i instead of ATP) occurs. In summary, this reaction catalyzes the first and only oxidation of glucose in glycolysis which has paid (thermodynamically) for the generation of a mixed anhydride whose phosphorylating potential is higher than that of ATP.

Figure 13.1.32 shows a proposed mechanism for glyceraldehyde-3-phosphate dehydrogenase from Trypanosoma cruzi

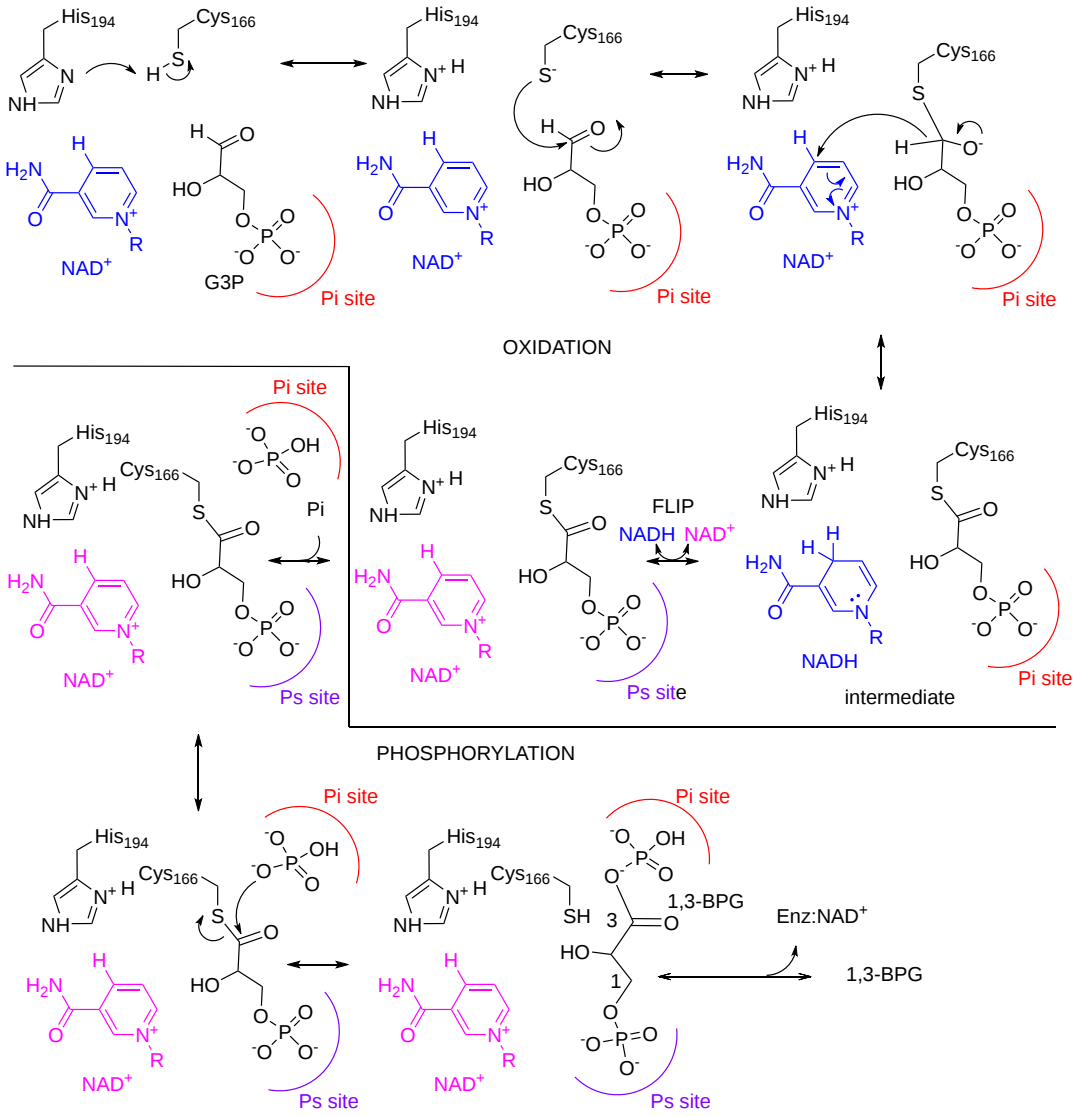

Figure 13.1.32: Proposed mechanism for glyceraldehyde-3-phosphate dehydrogenase from Trypanosoma cruzi (after Reis et al. Phys. Chem. Chem. Phys., 2013, 15, 3772. https://pubmed.ncbi.nlm.nih.gov/23389436/)

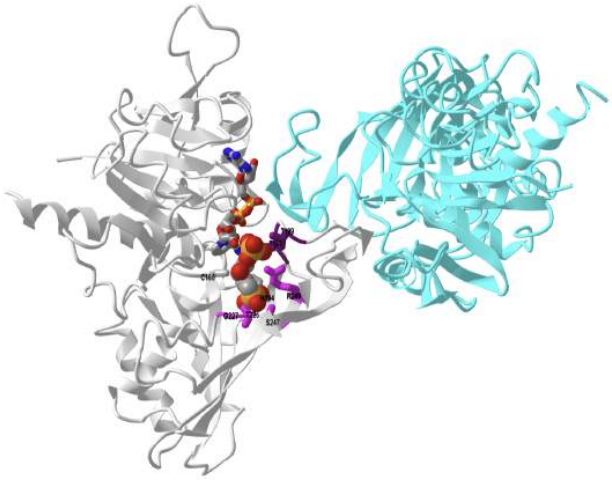
The reaction proceeds in two parts. The first (top section) is the oxidation of glyceraldehyde-3-phosphate (G3P) by NAD^+ to the state of a thioester attached to Cys166. The now reduced NADH dissociates and is replaced by a new NAD^+ for another cycle of catalysis. In the meantime, inorganic phosphate, Pi, binds and reacts with the thioester to form 1,3-bisphosphoglycerate (1,3-BPG).

The mechanism is not entirely clear. There are two phosphate binding sites, Pi (red) and Ps (purple) which interact with phosphate groups on the substrates. The oxidation part of the reactions appears to take place at the Pi site. Pi is composed of the side chains of Thr197, Thr199, and the 2-hydroxyl group of the ribose in NAD^+. The Pi site in the T. cruzi enzyme consist of Thr226 and Arg249, Gly227, and Ser 247. The mechanism appears to involve a flip of the orientation of substrates and intermediates after the dissociation of NADH from the enzyme.

Figure 13.1.33 shows an interactive iCn3D model of the Trypanosoma cruzi glyceraldehyde-3-phosphate dehydrogenase with bound NAD and a 1,3-bisphosphoglycerate analogue (1QXS)



NCBI iCn3D Figure 13.1.33: Trypanosoma cruzi glyceraldehyde-3-phosphate dehydrogenase with bound NAD and a 1,3-bisphosphoglycerate analogue (1QXS) . (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...WnsNSgmA3AJyw6

Only two monomers of the homotetramer are shown for clarity. The Pi site is shown in magenta and the Ps site is in purple. The phosphonic acid analog is shown in spacefill and NAD in sticks. The active site His194 and Cys166 are also shown in sticks and labeled.

13.1.9: **REACTION 7: 1,3 BPG + ADP + H^+ → 3PG + ATP** ΔG^O= -4.5 KCAL/MOL (-19 KJ/MOL)

This reaction, catalyzed by **phosphoglycerate kinase**, is shown in Figure 13.1.34

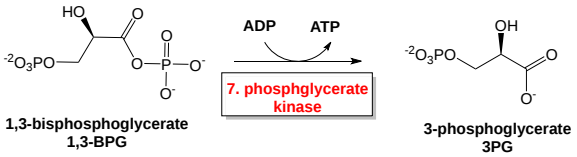


Figure 13.1.34: Summary reaction - phosphoglycerate kinase

It's finally happened! An ATP has been made for each of the two 1,3-BPG molecules derived from glucose. We've made back the ATP used in steps 1 and 3. A mixed phosphoanhydride bond is broken in 1,3 BPG as a phosphoanhydride bond is made in ATP. As the mixed phosphoanhydride has higher energy than its hydrolysis product compared to the phosphoanhydride in ATP, the reaction proceeds with a negative ΔG^o

A mechanism for the reaction is shown in Figure 13.1.35.

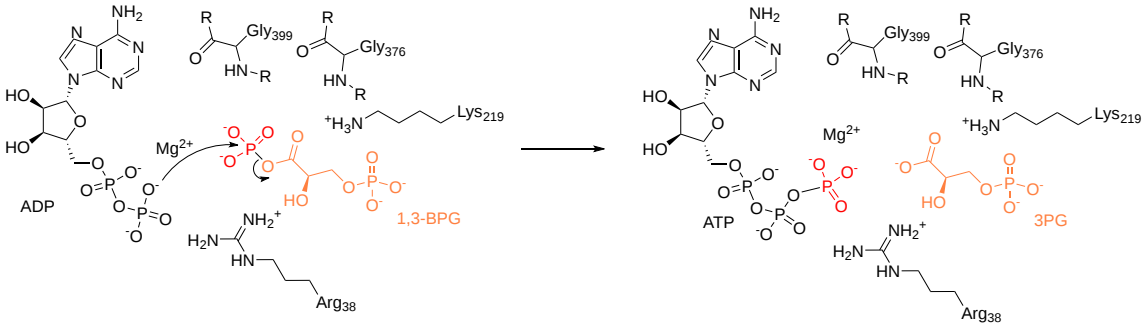

Figure 13.1.35: Reaction mechanism for phosphoglycerate kinase

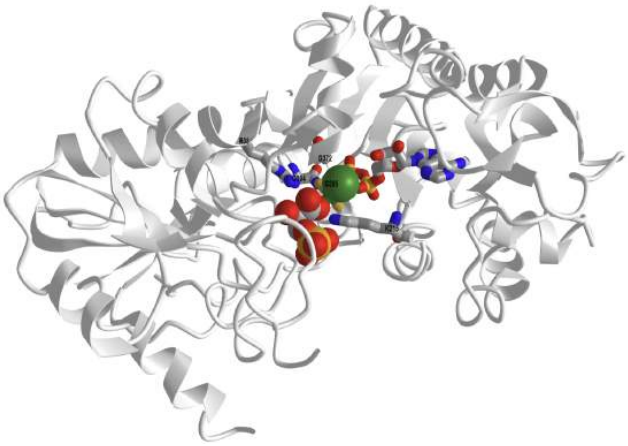
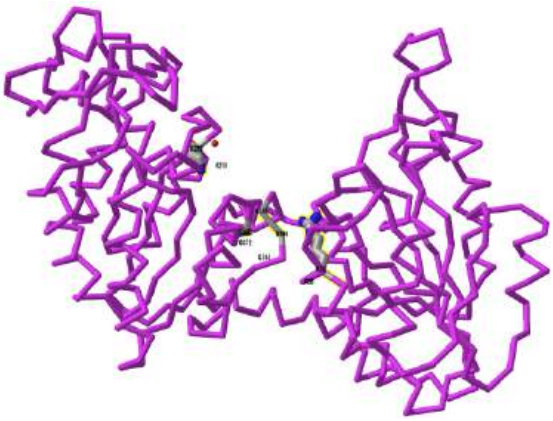
Figure 13.1.36 shows an interactive iCn3D model of human phosphoglycerate kinase in complex with ADP, 3PG, and magnesium trifluoride (2WZB).



NCBI iCn3D Figure 13.1.36: Human phosphoglycerate kinase in complex with ADP, 3PG, and magnesium trifluoride (2WZB). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...w5yvu2VuGhmQXA

3-phosphoglycerate is shown in spacefill with CPK colors. ADP plus the adjacent MgF_3 is a mimetic for the transition state for ATP synthesis. Hence this structure shows the products/transition state in a closed active site, which as we have seen before prevents spurious hydrolysis of 1,3-BPG or ATP.

Figure 13.1.37 shows an interactive iCn3D model of the alignment of the open form of human phosphoglycerate kinase (2XE7) with bound 3PG and ADP with the closed form with bound 3PG, ADP, **and MgF_3** (2WZB).



NCBI iCn3D Figure 13.1.37: Alignment of the open form of human phosphoglycerate kinase (2XE7) with bound 3PG and ADP with the closed form with bound 3PG, ADP, **and MgF_3** (2WZB). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...n5FfsJeYitiWr9

Use the "a" key to toggle back between the open form (magenta) and closed forms (cyan). In the closed state most closely representing the bond transition state of ATP, the two lobes of the enzyme clamp together.

13.1.10: **REACTION 8: 3PG ↔ 2PG** ΔG^{O}= +1.1 KCAL/MOL (4.6 KJ/MOL)

This reaction, catalyzed by **phosphoglycerate mutase (PGM)**, is shown in Figure 13.1.38

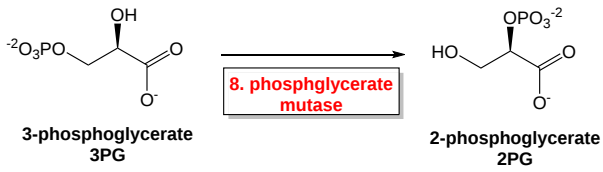


Figure 13.1.38: Summary reaction - phosphoglycerate mutase

This isomerization reaction proceeds with little thermodynamic barrier. Its function is to locate the phosphate on C2 which on the next reaction (dehydration) will form a molecule whose phosphoryl transfer potential is greater than ATP. It seems so simple but the enzymes that catalyze this reaction are diverse and quite complicated from a mechanistic perspective.

There are two types of PGMs, bisphosphoglycerate and monophosphoglycerate mutases that carry out three different reactions involving shuffling of phosphates from one position to another in 3C sugars or cleavage of a phosphate from a sugar

- 3-phosphoglycerate ↔ 2-phosphoglycerate (reaction 8 of glycolysis) catalyzed by bisphosphoglycerate and monophosphoglycerate (the glycolytic enzyme) mutases
- 1,3-bisphosphoglycerate ↔ 2,3-bisphosphoglycerate by bisphosphoglycerate mutases
- 2,3-phosphoglycerate ↔ 3-phosphoglycerate + Pi by bisphosphoglycerate mutases

Within the monophosphoglcyerate mutases, and more specifically the phosphoglycerate mutase (PGM) of glycolysis, there are two types

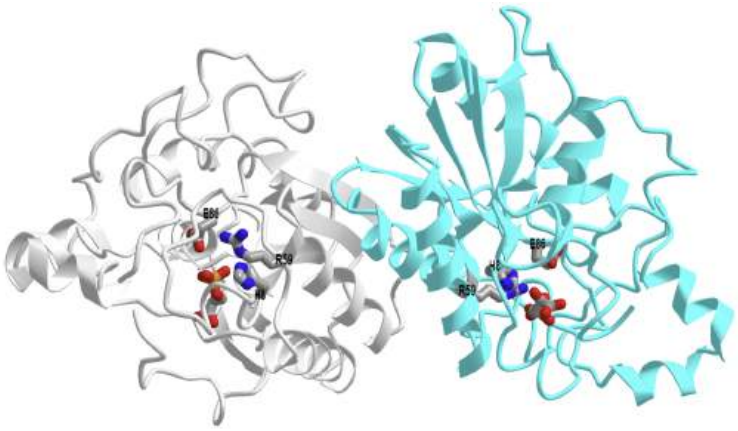
- one that depends on the cofactor 2,3-phosphoglycerate. These are called cofactor-dependent phosphoglycerate mutase (dPGM) and are found in mammals, yeast, and some bacteria. They do not require metal ions.
- one that does not depend on the cofactor 2,3-phosphoglycerate. These are called cofactor-independent phosphoglycerate mutase (iPGM) and are found in plants and some bacteria. These can only interconvert 3PGA and 2PGA. One family of enzymes in the class requires Mn^{2+} while the other requires Mg^{2+} or Zn^{2+}. These enzymes are often structurally similar to alkaline phosphatases

The cofactor-independent and cofactor-dependent monophosphoglycerates (such as the phosphoglycerate mutase of glycolysis) are very different structurally and mechanistically so we will look at both types of mechanisms. Within each type, the enzyme sequences are very conserved.

Mechanism of cofactor (2,3-BPG) dependent phosphoglycerate mutase (dPGM)

The reaction is much less complicated than the cofactor-independent PGM. In E. Coli, the reaction involves the transfer of the phosphate on the C3-OH to the nucleophilic nitrogen on histidine 8 (His 10 in other enzymes) in the active site to form a covalent pHis8 intermediate. The phosphate on pHis could then be transferred to the O on carbon C2 of the substrate. An active His 181in E. Coli may also act as a general acid/base and is adjacent to the Glu 88 in the active site.

Figure 13.1.39 shows an interactive iCn3D model of yeast phosphoglycerate mutase (cofactor dependent) bound to 3-phosphoglycerate (1QHF)



NCBI iCn3D Figure 13.1.39: Yeast phosphoglycerate mutase (cofactor dependent) bound to 3-phosphoglycerate (1QHF). (Copyright; author via source). A dimer of the active tetramer is shown. Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...9F4oc6mmr5DFs9

Mechanism of cofactor-independent phosphoglycerate mutase (iPGM)

Let's consider the mechanism for the Mn^{2+}-requiring iPGM from Geobacillus stearothermophilus. Two Mn^{2+} ions are in the active site. The mechanism for the first half of the cofactor-independent phosphoglycerate mutase (iPGM) reaction is shown in Figure 13.1.40.

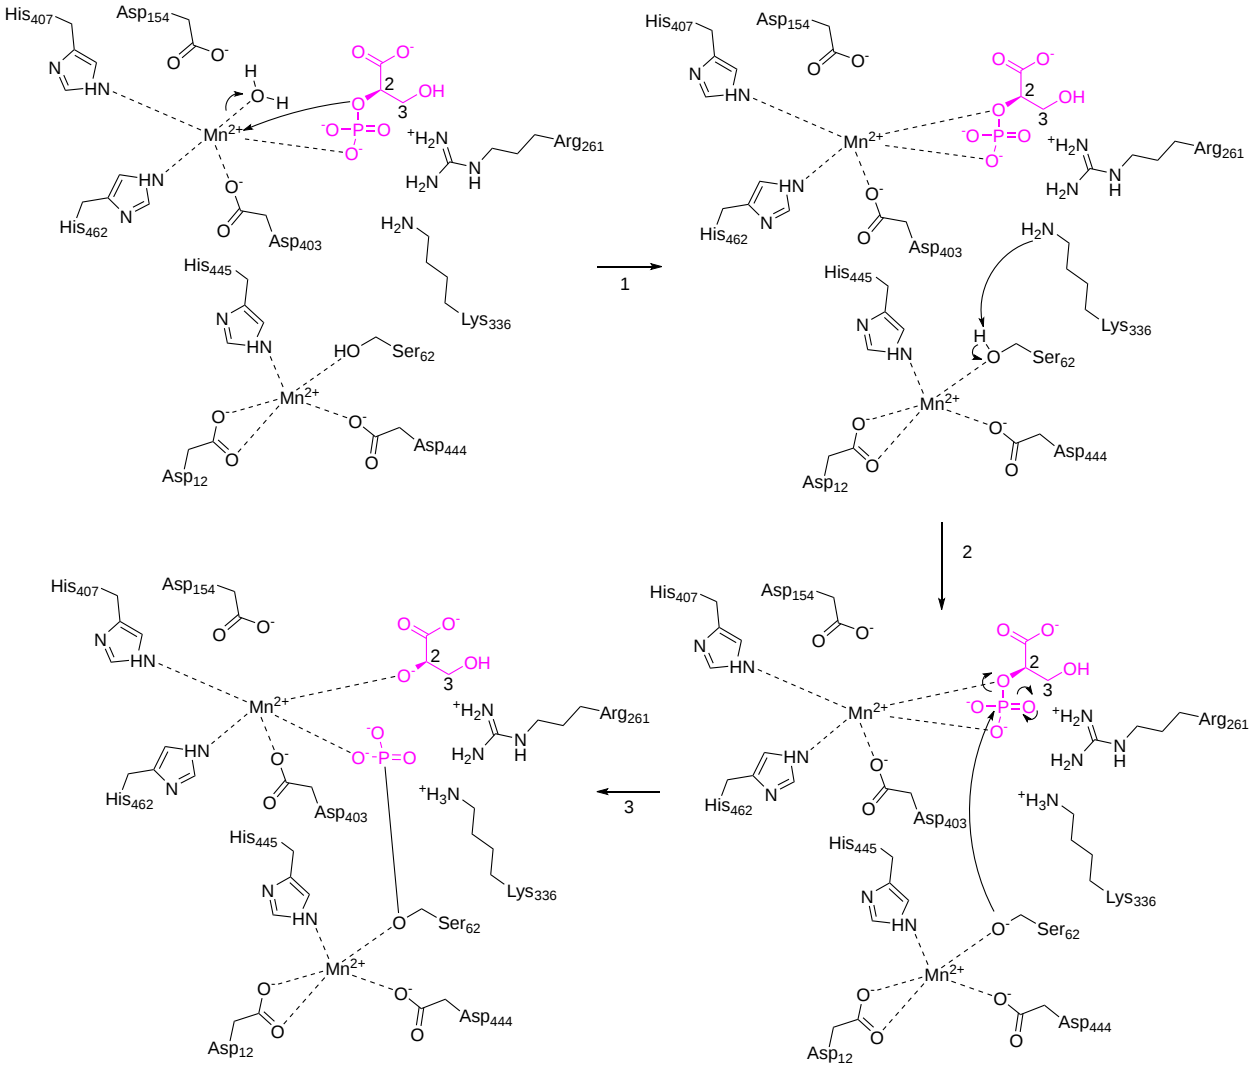


Figure 13.1.40: Part A - Mechanism for cofactor independent phosphoglycerate mutase (iPGM) from Geobacillus stearothermophilus (after Bolt et al, ibid)

Arg 261 interacts with the substrate, stabilizing the negative charge in it and its transition state. It also makes the target phosphorous more electrophilic. Ser62 is activated by a Mn^{2+} ion to become more nucleophilic on the abstraction of a proton by Lys336. Reaction 3 probably proceeds through an S_N2 mechanism.

The rest of the mechanism is shown in Figure 13.1.41.

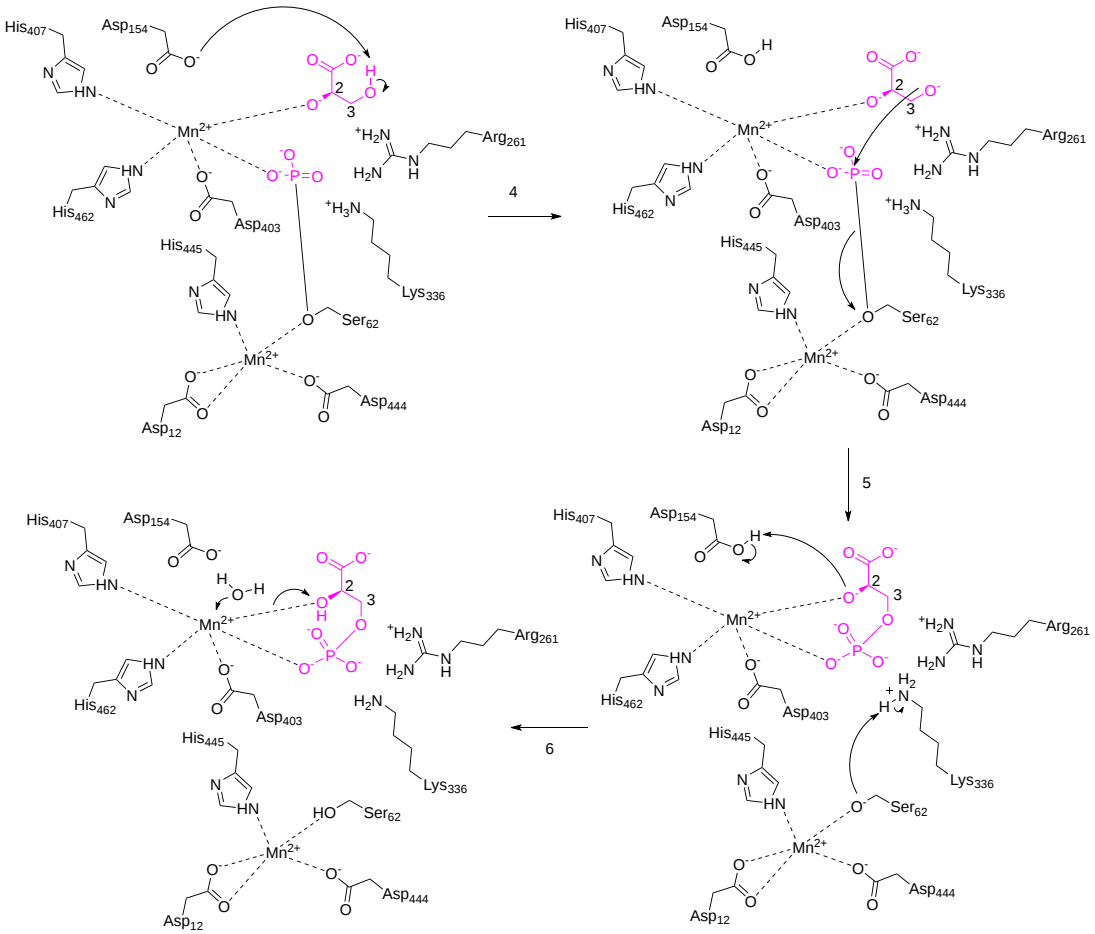

Figure 13.1.41: Part B - Mechanism for cofactor independent phosphoglycerate mutase (iPGM) from Geobacillus stearothermophilus (after Bolt et al, ibid)

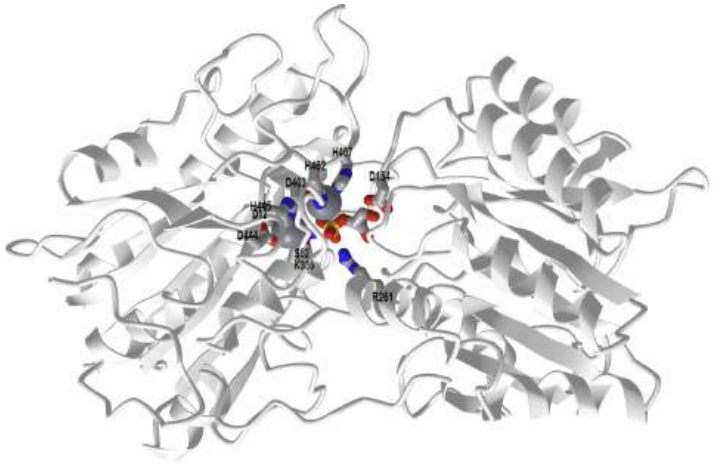
The iPGMs are monomers with two distinct domains (lobes) containing a substrate binding site separated from an active site. They are connected by flexible sequences that bend to produce either an open or closed form of the enzymes (as we have seen before). In some enzymes, the two sites are merged at the interface between the domain. The active site Ser62 becomes phosphorylated and then transfers its phosphate to the new site in the substrate which is oriented differently in the enzyme.

Figure 13.1.42 shows an interactive iCn3D model of the Geobacillus stearothermophilus cofactor-Independent Phosphoglycerate Mutase (iPGM) with bound 2-phosphoglycerate (product) (1O98)



NCBI iCn3D Figure 13.1.42: Cofactor-Independent Phosphoglycerate Mutase with bound 2-phosphoglycerate (product) (1O98). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...71iYHXAEKMGsEA

13.1.11: **REACTION 9: 2PG ↔ PEP + H_2O** ΔG^O= +0.4 KCAL/MOL (+1.7 KJ/MOL)

This reaction, catalyzed by **enolase**, is shown in Figure 13.1.43

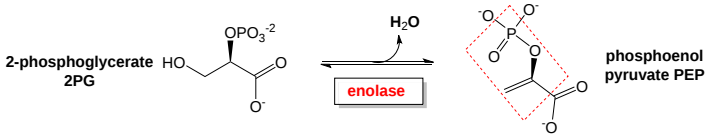


Figure \(\PageIndex{43}\: Summary reaction - enolase

Now you can see the rationale for reaction 8. With a simple dehydration, a molecule with high phosphoryl transfer potential has been produced which in the next and final step of glycolysis produces ATP.

This enzyme has an active site Mg^{2+} that is required for catalysis. Mammals have three forms of the enzyme, α-enolase (ENO-1) found in most tissues, β-enolase (ENO-3) found mostly in muscle, and γ-enolase (ENO-2) found in neurons. A possible mechanism for yeast enolase is shown in Figure 13.1.44.

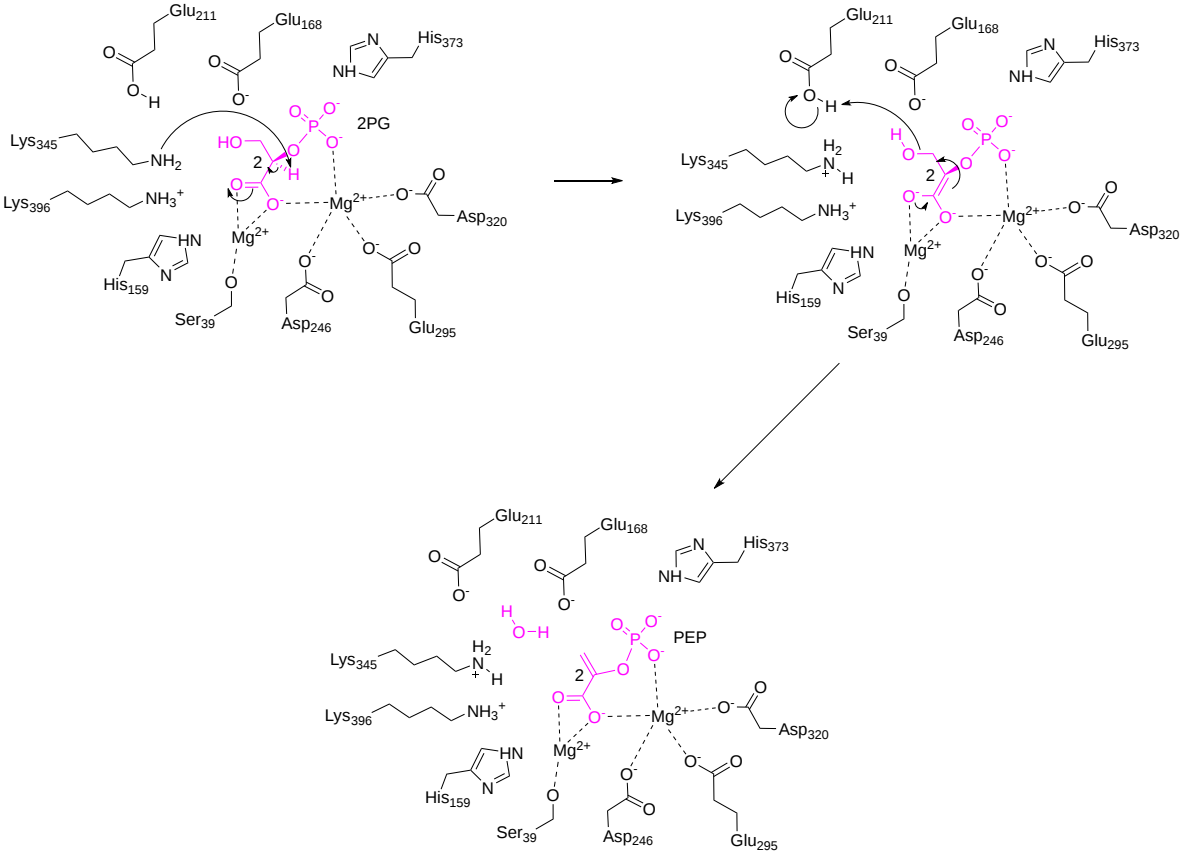

Figure 13.1.44: A possible mechanism for yeast enolase

Figure 13.1.45 shows an interactive iCn3D model of Yeast enolase with bound 2-phosphoglycerate (7ENL)

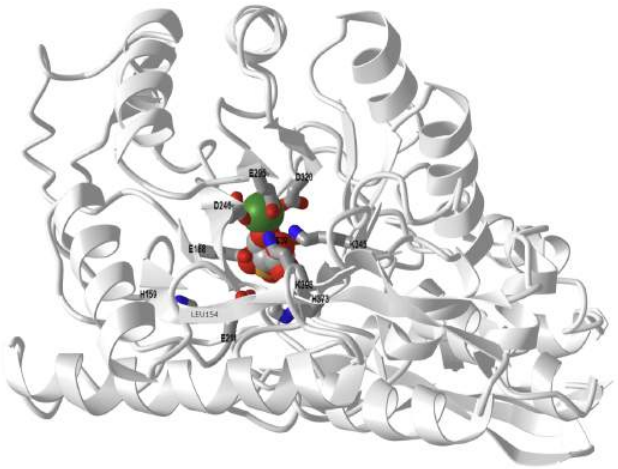

Figure 13.1.45: Yeast enolase with bound 2-phosphoglycerate (7ENL). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...TgwYV9vF8cYtPA

13.1.12: **REACTION 10: PEP + ADP → PYR + ATP** ΔG^{O}= -7.5 KCAL/MOL (-31 KJ/MOL)

This reaction, catalyzed by **pyruvate kinase**, is shown in Figure 13.1.46

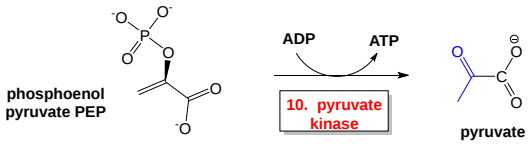

Figure 13.1.46: Summary reaction - pyruvate kinase

In this step, 1 more ATP is made for each PEP consumed (hence 2 ATPs for both 3C PEPs). The phosphoryl transfer potential for PEP is higher than for ATP, which allows this reaction to proceed with a large negative ΔG^{o} (-7.5 kcal/mol, -31 kJ/mol).

The mechanism for rabbit pyruvate kinase is shown in Figure 13.1.47.

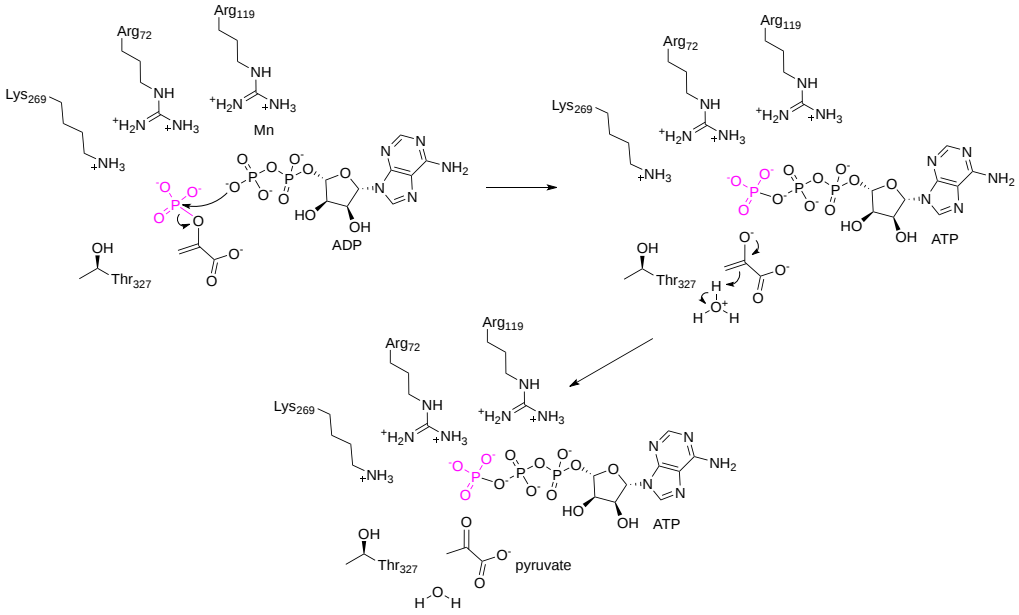

Figure 13.1.47: Mechanism for rabbit pyruvate kinase

Figure 13.1.48 shows an interactive iCn3D model of rabbit muscle pyruvate kinase complexed with Mn^{2+}, K^{+}, and pyruvate (1PKN)

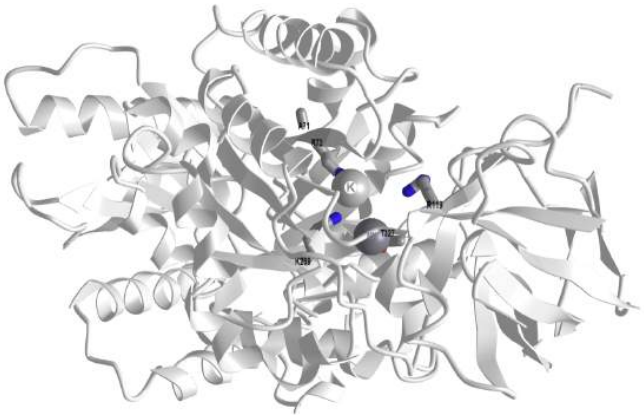

Figure 13.1.48: **Rabbit muscle pyruvate kinase complexed with Mn^{2+}, K^{+}, and pyruvate (1PKN)**. (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...cZkm8DdEw2N3C6

We are done! Given that glycolysis is the central anaerobic energy-extracting pathway in all life, it is important that we examined each enzyme in detail.

This is the net reaction of the glycolytic pathway:

$$\mathrm{Glc} + \mathrm{Pi} + 2\,\mathrm{ADP} + 2\,\mathrm{NAD}^{+} \longrightarrow 2\,\mathrm{Pyr} + 2\,\mathrm{ATP} + 2\,\mathrm{NADH} + 2\,\mathrm{H}^{+} + 2\,\mathrm{H_2O}$$

13.1.13: UNCOUPLING GLYCOLYTIC OXIDATION AND PHOSPHORYLATION (ATP FORMATION)

Since we are most interested in energy transduction at this point, let's consider just two important steps in glycolysis that directly lead to ATP synthesis. Only one oxidative step is found in this pathway, namely the oxidative phosphorylation of the 3C glycolytic intermediate glyceraldehyde-3-phosphate, to 1,3-bisphosphoglycerate, a mixed anhydride (see link below for mechanism). The oxidizing agent is NAD^{+} and the phosphorylating agent is NOT ATP but rather Pi. The enzyme is named glyceraldehyde-3-phosphate dehydrogenase. It contains an active site Cys, which helps explain how the enzyme can be inactivated with a stoichiometric amount of iodoacetamide. A general base in the enzyme abstracts an H+ from Cys, which attacks the carbonyl C of the glyceraldehyde, forming a tetrahedral intermediate. Instead of the expected reaction (which would be the protonation of the alkoxide in an overall nucleophilic addition reaction at the aldehyde), a hydride leaves from the former carbonyl C to NAD+ in an oxidation step. Notice, this is a two-electron oxidation reaction similar to that seen in alcohol dehydrogenase. An acyl-thioester intermediate has formed, much like the acyl intermediate that formed in Ser proteases. Next inorganic phosphorous, Pi, attacks the carbonyl C of the intermediate in a nucleophilic substitution reaction to form the mixed anhydride product, 1,3-bisphosphoglycerate. Although we have formed a mixed anhydride, we cleaved a sulfur ester, which is destabilized with respect to its hydrolysis products (since the reactant, the thioester, is not stabilized by resonance to the extent of regular esters owing to the poor donation of electrons from the larger S to the carbonyl-like C.) In the next step, catalyzed by the enzyme phosphoglycerate kinase, ADP acts as a nucleophile that attacks the mixed anhydride of the 1,3-bisphosphoglycerate to form ATP. Note that the enzyme is named for the reverse reaction. We have coupled the oxidation of an organic molecule (glyceraldehyde-3-phosphate) to phosphorylation of ADP through the formation of a "high" energy mixed anhydride, 1,3-bisphosphoglycerate.

The linkage between the oxidation of glyceraldehyde-3-phosphate and the phosphorylation of ADP by 1,3-bisphosphoglycerate can be artificially uncoupled by adding arsenate, which has a similar structure as phosphate. The arsenate can form a mixed anhydride at C1 of glyceraldehyde-3-phosphate, but since the bringing O-As bond is longer and not as strong as in the mixed anhydride, it is easily hydrolyzed. This prevents the subsequent transfer of phosphate to ADP to form ATP.

Figure 13.1.49 shows a summary of oxidation and substrate-level phosphorylation in glyceraldehyde-3-phosphate dehydrogenase.

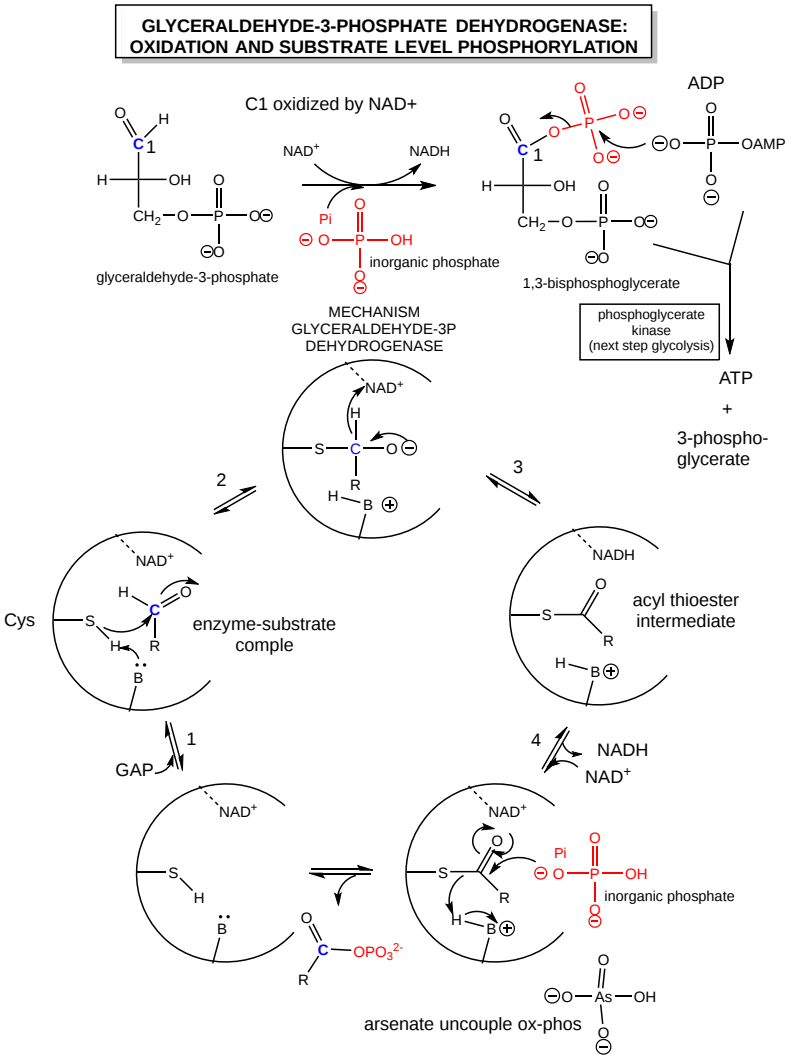

Figure 13.1.49: Oxidation and substrate-level phosphorylation in glyceraldehyde-3-phosphate dehydrogenase (after Voet and Voet)

Summary: Under anaerobic conditions, glucose (6Cs) is metabolized through glycolysis which converts it to two molecules of pyruvate (3Cs). Only one oxidation step has been performed when glyceraldehyde 3-phosphate is oxidized to 1,3-bisphosphoglycerate. To regenerate NAD^+ so glycolysis can continue, pyruvate is reduced to lactate, catalyzed by **lactate dehydrogenase**. These reactions take place in the cytoplasm of cells actively engaged in the anaerobic oxidation of glucose (muscle cells for example during sprints). Note that t50}\).

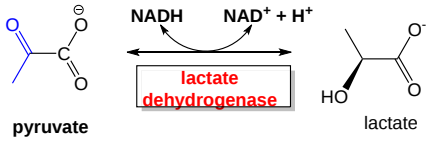

Figure 13.1.50: Conversion of pyruvate to lactate

We will explore the fate of pyruvate under anaerobic conditions more in the next chapter section.

13.2: FATES OF PYRUVATE UNDER ANAEROBIC CONDITIONS- FERMENTATION

13.2.1: INTRODUCTION TO FERMENTATION

Fermentation is a process in which a fuel molecule is broken down anaerobically (or without oxygen) to meet ATP demands. One of the most notable pathways that can utilize fermentation is glycolysis, which we have just described. During glycolysis, glucose is converted to pyruvate, yielding a total of 2 ATP energy-rich molecules. This occurs in anoxic conditions (or without the requirement of oxygen). However, the process of glycolysis cannot be sustained if the end product is pyruvate. This is because the production of pyruvate also yields 2 molecules of reduced NADH in addition to the production of the two ATP molecules. The pool of available NAD^+/NADH is limited within the body, and thus, this electron acceptor/donor molecule must continually be recycled for metabolic pathways to remain functional. For example, if NADH is not oxidized back into NAD^+ in a timely manner, the glycolytic pathway can slow. Therefore, to be able to maintain the process of energy generation through glycolysis, the pool of NADH needs to be converted from the reduced form, back into the oxidized form (NAD^+) form where it can then accept electrons from intermediates in the glycolytic pathway. This process of recycling NADH to NAD^+ can occur aerobically through the Citric Acid Cycle, which is described in more detail in Chapter 16, or it can be processed via anaerobic fermentation (Figure 13.2.1).

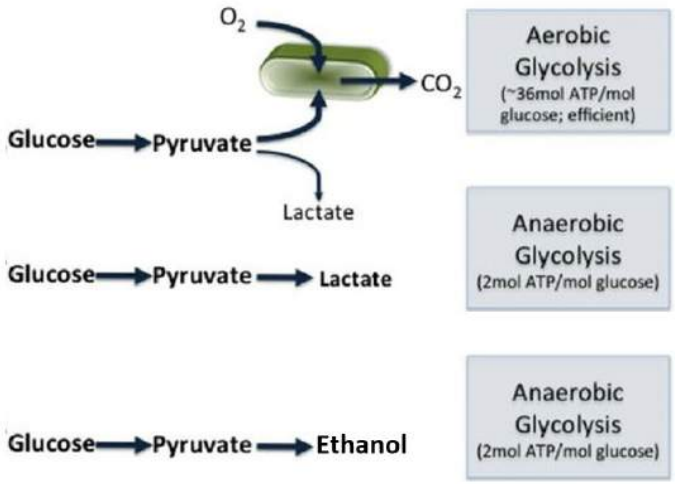

Figure 13.2.1 : Fates of Pyruvate via Aerobic or Anaerobic Pathways.

In the 1860s, Louis Pasteur first described fermentation very narrowly, as the process that yeast use to convert glucose into ethanol when they are grown in the absence of air. Subsequently, it was discovered that other microorganisms could convert pyruvate to lactate (or lactic acid), instead of ethanol, during the process of anaerobic respiration. These microorganisms became known as lactic acid bacteria and are currently utilized heavily within the food industry to produce a wide array of fermented food products including cheese, yogurt, and sauerkraut, to name a few. As the enzymes within the glycolytic pathway were discovered, it became apparent that muscle tissue could also engage in anaerobic respiration-producing lactate. Thus while fermentative processes are most often described in microbial organisms, the definition of fermentation has since been broadened to include any enzymatic, energy-yielding pathways that occur in the absence of oxygen, including the production of lactate in muscle tissue of animals during the glycolytic process.

Thus, NADH recycling to NAD^+ typically occurs in anaerobic systems by two different routes: ethanolic fermentation or lactate fermentation (Figure 13.2.1). We will focus on the details of these two systems here.

13.2.2: LACTATE FERMENTATION

In lactate fermentation, pyruvate is converted to lactate by the enzyme lactate dehydrogenase. In the process, NAD^+ is regenerated. The reaction catalyzed by lactate dehydrogenase (LDH) is shown in Figure 13.2.2.

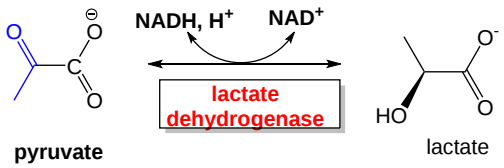

Figure 13.2.2: Reaction catalyzed by lactate dehydrogenase

It is named for the reverse reaction which, as with other dehydrogenases, uses NAD^+ as an oxidizing agent. The reaction is reversible with the ΔG^0 for conversion of pyruvate to lactate of -3.76 kcal/mol (-15.7 kJ/mol). Under anaerobic conditions when glycolysis is the major source of ATP, pyruvate levels increase, further driving the reaction towards lactate formation and NAD^+ regeneration so glycolysis can continue.

The enzyme is found in the cytoplasm but a mitochondrial form also exists. It is most abundant in muscle, liver, kidney, and also in erythrocytes. Interestingly, mature red blood cells are enucleated and do not contain any mitochondria. Their lifespan is limited to approximately two weeks. During this time, their primary energy resources are generated through the process of anaerobic fermentation via the glycolysis-lactate pathway.

The active enzyme is a tetramer of various compositions of two different subunits, the heart (H) and muscle (M) forms. The quaternary structures consist of 5 different isozyme forms containing the H and M subunits. LDH-1, found most abundantly in the heart, is a tetramer of 4H subunits (H_4). The other forms are as follows: LDH-2 (H_3M, prevalent in RBCs), LDL-3 (H_2M_2, prevalent in lungs), LDH-4 (HM_3, prevalent in the kidney), and LDH-5 (M_4, prevalent in muscle).

During anaerobic metabolism, lactate is produced by muscle tissue and released into the bloodstream where it can travel back to the liver. Once in the liver, lactate is converted back into pyruvate and can be utilized to produce glucose through a pathway called gluconeogenesis. The liver can then export the glucose into the blood from where it can be taken up by the muscle for ATP production. This cycle is called the **Cori cycle** and is illustrated in Figure 13.2.3.

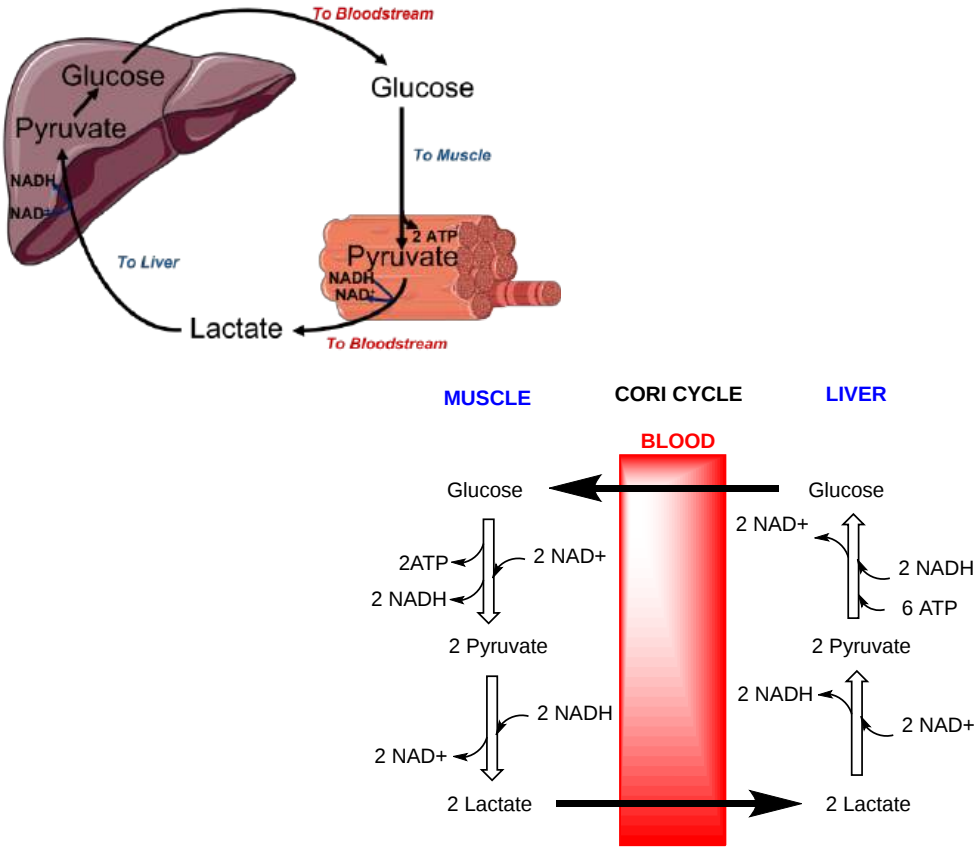

Figure 13.2.3 : Cori cycle *Upper diagram* is a cartoon image of the Cori cycle and the *lower diagram* demonstrates the recycling of NAD^+/NADH in different locations within the body. Figure modified from Servier Medical Art

Notably, anaerobic metabolism can only be sustained for short periods in animals due to its high energy demand. Aerobic respiration is required to maintain an adequate ATP supply. However, the production of lactate by certain tissues, such as white, or fast-twitch muscle cells occurs regularly and releases lactate into the bloodstream, where it can be taken up and used as an energy source by other neighboring tissues such as red, slow-twitch muscle. Brain tissue can also effectively use lactate as an energy source as well. Within these 'consumer' tissues, lactate is converted back into pyruvate using the mitochondrial LDH enzyme where it can then be processed by aerobic respiration producing high levels of ATP.

Thus, the production of lactate can be thought of as a strain response that occurs during times of metabolic stress, such as intense cardiovascular exercise. It has also been noted that after an injury or head trauma, the activation of epinephrine will cause an increase in lactate production and blood levels of lactate will increase. Thus, it has been hypothesized that lactate may play a role in the repair of

damaged tissue. Clinical trials and experiments are currently underway to determine if lactate can help in the healing and recovery process for conditions such as traumatic brain injury, myocardial infarction, and sepsis. Early studies have shown that lactate can increase the production of Brain-Derived Neurotropic Factor (BDNF) which supports neuronal growth, providing further support for the role of lactate in recovery and repair.

Spectroscopy analyses show the geometry and electrostatics of the active sites of LDHs from all organisms are essentially the same. The mechanism for the reverse oxidation of lactate by NAD^+ by spiny dogfish lactate dehydrogenase (LDH) is shown in Figure 13.2.4

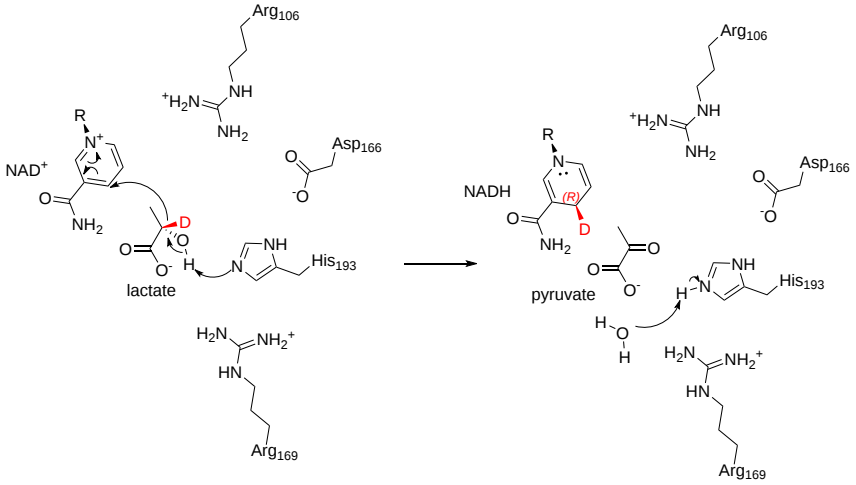

Figure 13.2.4 : Mechanism for the reduction of lactate by NAD^+ by spiny dogfish lactate dehydrogenase (LDH)

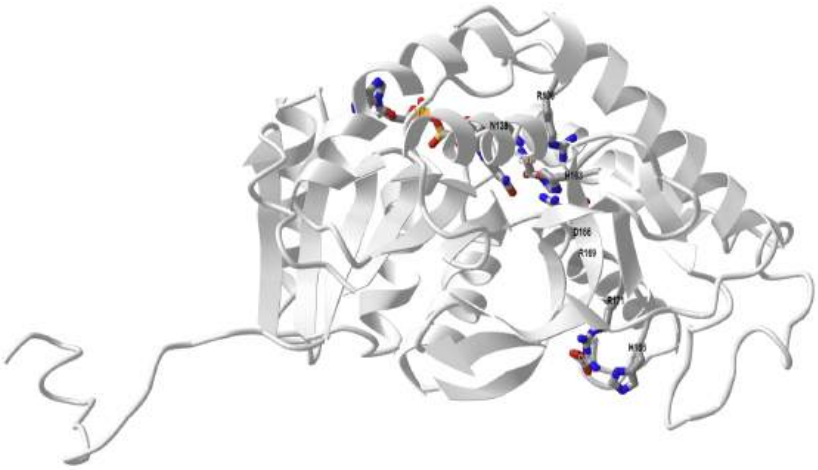
Lactate is shown with a deuterium (D), which moves as a deuteride to NAD^+ to form NADH, simply to illustrate the stereochemistry of the reaction. In the reverse reaction, the reduction of pyruvate to lactate (to regenerate more NAD^+ so anaerobic glycolysis can continue), the deuterium (or the proR H of non-deuterated NADH) is removed.

Figure 13.2.5 shows an interactive iCn3D model of dogfish M4 apo-lactate dehydrogenase (1LDM).



NCBI iCn3D **Figure 13.2.5 : Dogfish M4 apo-lactate dehydrogenase (1LDM).**(Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...FBzuqJ2gEPUHM8

Only the monomer of the active tetramer is shown. NAD and oxamic acid, structurally similar to lactate/pyruvate and a competitive inhibitor of the enzyme, are labeled. His193, the active site general base/acid, is near Arg 169 and to Asp 166 and Asn 138, to which it is hydrogen bonded.

LDH exists in two major conformational states, T (inactive) and R (active) state, as we have seen with other allosteric proteins. Figure 13.2.6 shows an interactive iCn3D model of the T state (2ZQY) and R state (2ZQZ) of Lacticaseibacillus casei L-lactate dehydrogenase.

Figure 13.2.6 : T state (2ZQY) and R state (2ZQZ) of Lacticaseibacillus casei L-lactate dehydrogenase. (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...zjrtVYjLXdhDp8

Toggle between the magenta T state and cyan R state using the "a" key. Orient the proteins to see the best view of the allosteric changes caused by binding regulators. The spheres show Arg 171 whose disposition changes significantly in the T and R states. Pyruvate (a reactant/product) activates the enzyme (conversion of T to R state) and is considered a **homotropic regulator** since it is a substrate. This is similar to the allosteric "activation" of hemoglobin by its ligand O_2, which preferentially binds to the R state and promotes the T-to-R state transition. Fructose 1,6-bisphosphate, a glycolytic intermediate, also activates the Lacticaseibacillus casei L-lactate dehydrogenase and since it is not a reactant/product of the enzyme, it is considered a heterotropic allosteric regulator. The enzyme hence is effectively regulated by the concentration of substrate (pyruvate) and by NADH levels. High concentrations of ethanol consumption lead to high levels of NADH through the activity of alcohol dehydrogenase. High levels of NADH would lead to increased lactate production as well.

13.2.3: ETHANOL FERMENTATION IN YEAST

In this process, pyruvate is decarboxylated first to acetaldehyde by the thiamine pyrophosphate (TPP)-requiring enzyme **pyruvate decarboxylase**. The resulting product, acetaldehyde, is then reduced by NADH to form ethanol by the enzyme **ethanol dehydrogenase** in a process that reforms NAD^+. Yeast are facultative (not obligate) anaerobes in that they can produce energy by glycolysis and ethanol fermentation in the absence of oxygen Figure 13.2.7:. Of course, in the presence of oxygen, the pyruvate produced from glycolysis in yeast is preferentially converted to acetyl-CoA which enters the citric acid cycle and oxidative phosphorylation pathways to maximize ATP production.

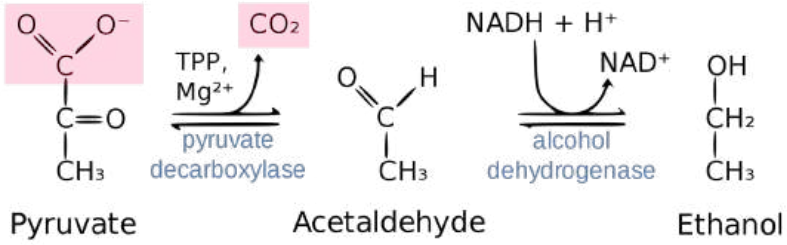


Figure 13.2.7 : Summary of Ethanol Fermentation in Yeast

Figure from Thomas Baldwin

Pyruvate decarboxylase

Pyruvate decarboxylase catalyzes the first step in the alcoholic fermentation pathway converting pyruvate into acetaldehyde and carbon dioxide. Interestingly, in addition to yeast, some species of fish, such as goldfish and carp, have a homologous enzyme that allows for the production of ethanol when oxygen is scarce. Pyruvate decarboxylase is tetrameric occurring as a dimer of dimers with two active sites shared between the monomer subunits of each dimer. The decarboxylation reaction requires two cofactors, thiamine pyrophosphate (TPP) and magnesium (Figure 13.2.8). Within the active site, the acidic Glu-477 and Glu-51 residues and the Mg^{2+} cofactor interact with and stabilize the TPP cofactor. The aminopyrimidine ring on TPP acts as a base and enables the formation of the TPP nucleophile with the removal of the C2 proton. This reaction is stabilized by the protonation of Glu-51. The nucleophilic attack of pyruvate causes the release of carbon dioxide. The acetaldehyde intermediate is still covalently attached to the TPP cofactor following the release of carbon dioxide.

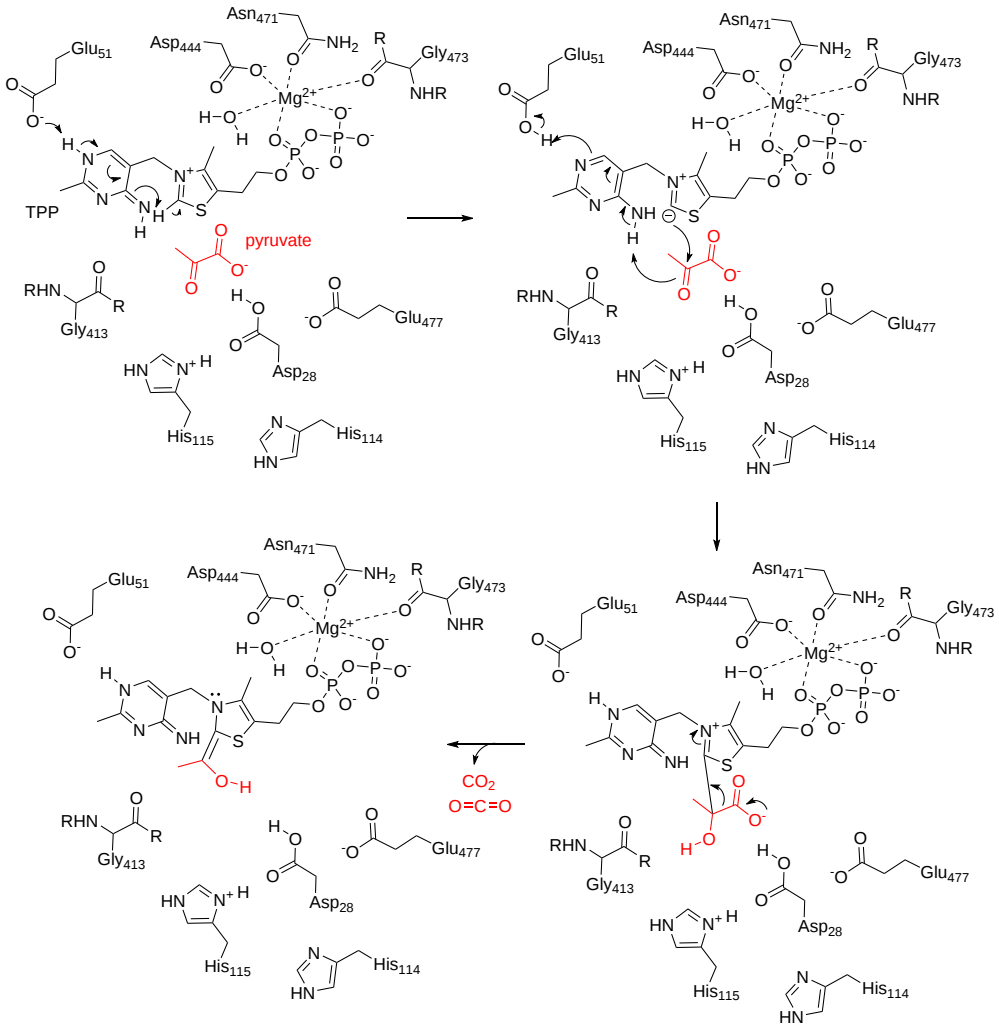

Figure 13.2.8 : Part 1 Pyruvate Decarboxylase mechanism - decarboxylation

Once carbon dioxide diffuses away from the active site, the double bond of the enol-intermediate abstracts a proton from Asp-28, which is stabilized by a neighboring His-115 residue. TPP can then serve as a good leaving group during the formation of the carbonyl functional group and causes the release of acetaldehyde (Figure 13.2.9:).

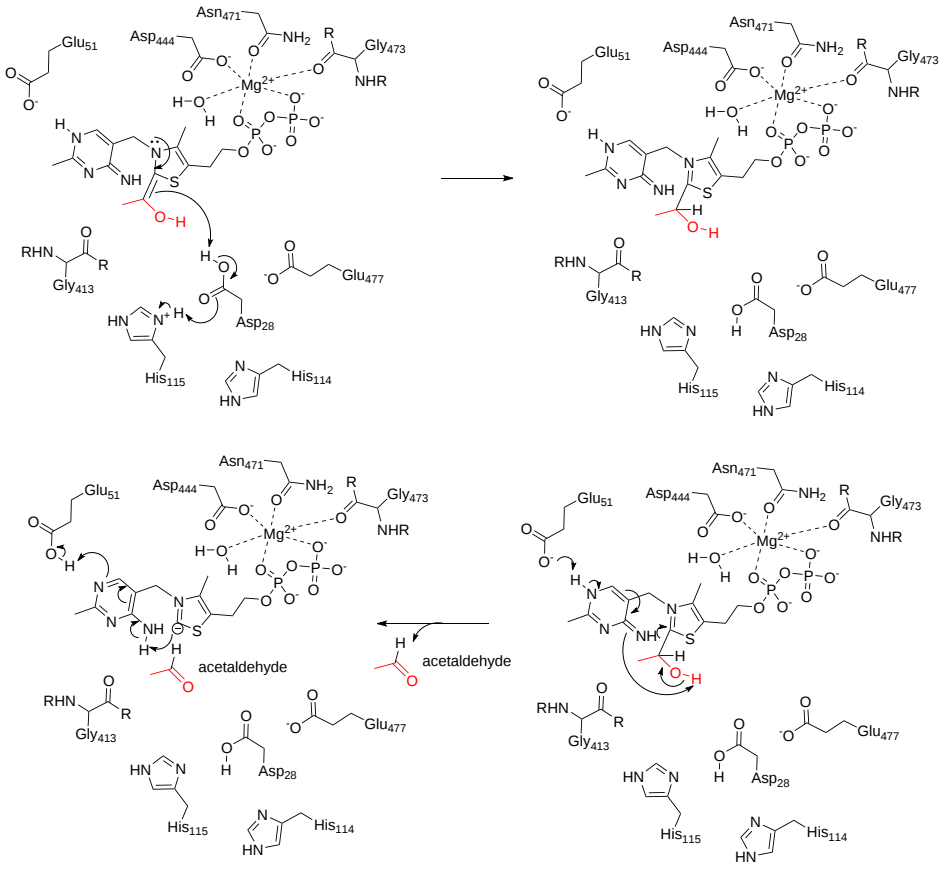

Figure 13.2.9 : Part 2 Pyruvate Decarboxylase mechanism - acetaldehyde generation

Figure 13.2.10 shows an interactive iCn3D model of the thiamin diphosphate-dependent enzyme pyruvate decarboxylase from the yeast Saccharomyces cerevisiae (1PVD).

Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...DMM4gjodX4q1G9 TTP is shown in spacefill. The enzyme is a homotetramer.

Alcohol dehydrogenase (ADH)

Alcohol dehydrogenase enzymes catalyze the interconversion of aldehydes or ketones with alcohol functional groups. In humans and other animals, they are utilized to break down alcohols that are ingested, as well as participate in the biosynthesis of numerous metabolites. There are at least 5 classes of alcohol dehydrogenases that use NAD^+ as an oxidizing agent to convert alcohols to aldehydes or ketones. We are

mainly concerned with the yeast ADH, a member of Family I, that is involved in ethanol fermentation. Figure 13.2.11 shows the reaction catalyzed by alcohol dehydrogenase.

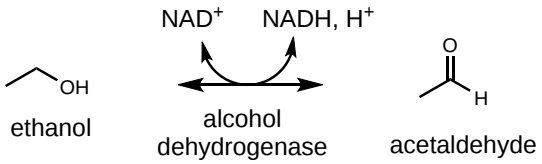

Figure 13.2.11 : Reaction catalyzed by alcohol dehydrogenase

Figure 13.2.12A below shows a mechanism for yeast alcohol dehydrogenase (ADH1). ADH1 requires zinc as a metal cofactor and utilizes NADH as the reducing agent in the conversion of acetaldehyde into ethanol.

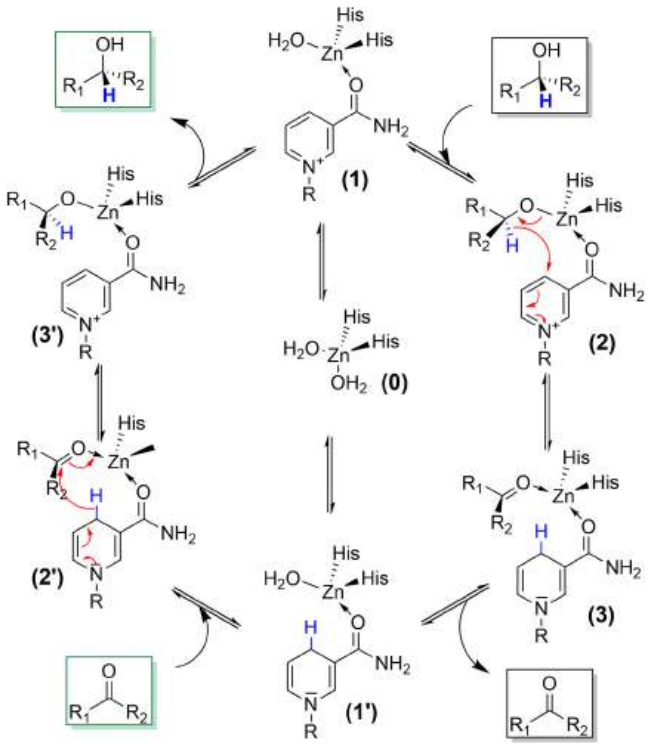

Figure 13.2.12A : Simplified catalytic mechanism of ADH reactions. Upon binding of both substrates (e.g., NAD(P)$^+$ and alcohol; 0->1->2) a hydride transfer occurs from the alcohol-carbon atom to the oxidized nicotinamide moiety yielding the Zn-coordinated carbonyl product and NAD(P)H (3). Both can dissociate from the active site yielding apo-ADH (0). Alternatively, only NAD(P)H stays bound and the reduced ADH can undergo a reductive conversion (1'->2'-> 3'-> 1). Amanda Silva de Miranda, et al. Front. Catal., 10 May 2022. Sec. Biocatalysis. https://doi.org/10.3389/fctls.2022.900554. Creative Commons Attribution License (CC BY).

Figure 13.2.12B shows key amino acids in the active site of yeast ADH1. Note that in this figure, two cysteines are the coordinating ligands.

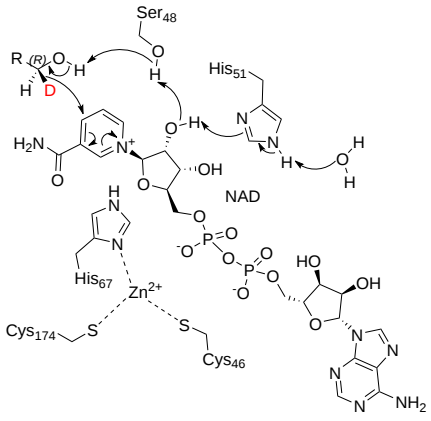

Figure 13.2.12B : Abbreviated mechanism for yeast alcohol dehydrogenase (ADH1)

If you look at the reverse reduction reaction, the acetaldehyde (or a ketone for 2^0 alcohols) carbonyl is sp^2 hybridized and planar, so the hydride could be added to either of the two faces, re or si, of the plane (using the same rules used to define R or S enantiomers). Likewise, the methylene carbon atom with two hydrogens, one of which is transferred as a hydride, is prochiral. Hence four different stereochemical hydride transfer pathways are possible, as shown in **Figure 13.2.13A** below. Hydride transfers from the *si*-face of the prochiral aldehyde/ketone result in (*R*)-configured alcohols whereas hydride attacks from the *re*-face yield (*S*)-alcohols. In both cases, the hydride transferred can stem from either the *re*- or *si*-face of the nicotinamide ring.

Figure 13.2.13A : Possible stereochemical courses of the hydride transfer from NAD(P)H to the ketone. Attacks from the *si*-face of the ketone result in (*R*)-alcohols (E1 and E2) whereas hydride attacks from the *re*-face (E3 and E4) result in (*S*)-alcohols.

ADHs catalyzing hydride addition from the *re*-face of the ketone (or abstraction of a hydride from (*S*)-alcohols) are termed Prelog-selective ADHs whereas those ADHs attacking from the *si*-face (or abstracting a hydride from the (*R*)-alcohol) are termed *anti*-Prelog ADHs. Different ADHs are available for the different reaction stereochemistries.

The stereochemistry for the reaction of ADH1 with ethanol is shown in **Figure 13.2.13B** below**.** Deuterium (**D**) is shown in the figure to better illustrate the stereochemistry of the reaction. With the **deuterium** label, the carbon is now chiral and the enantiomer shown is the R isomer. The corresponding **H** in the undeuterated and prochiral form of ethanol is removed by the enzyme, as shown in Figure 13.2.13B below.

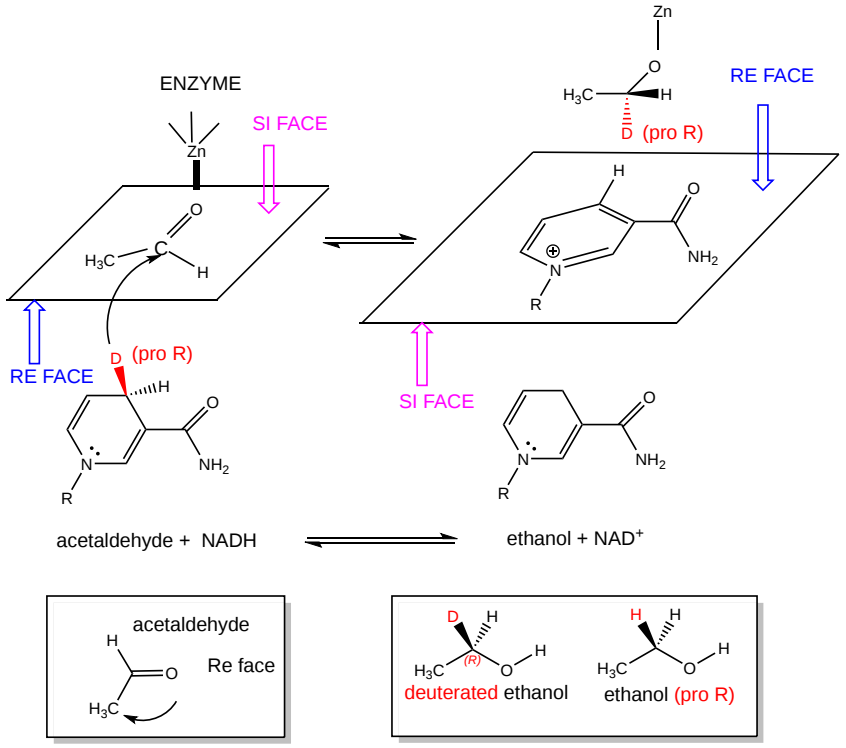

Figure 13.2.13*B* : Stereochemistry of human alcohol dehydrogenase reaction.

Figure 13.2.14 shows an interactive iCn3D model of the Yeast alcohol dehydrogenase (ADH I) with bound substrate analogs- ADH1 (4W6Z).

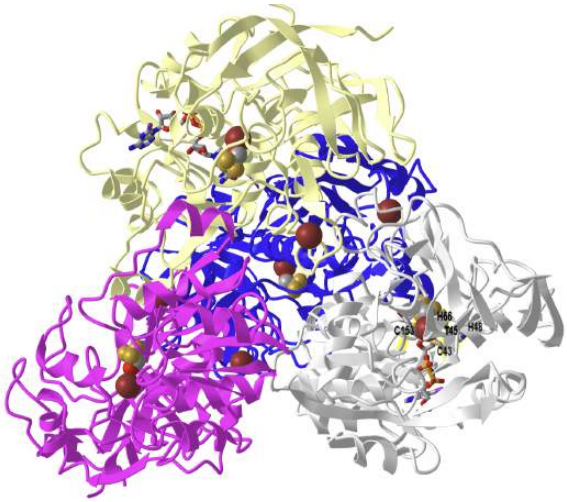

Figure 13.2.14 : Yeast alcohol dehydrogenase structure with bound substrate analogs (4W6Z). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...feE7toF6wU6MB9

All four monomers of the homotetramer are shown. The light gray subunit has the key catalytic and binding residues shown in sticks and labeled. The numbering for the key residues is a bit different than in the mechanism shown above. The cofactor analog, nicotinamide-8-iodo-adenine-dinucleotide, is shown in sticks and the substrate analog, trifluoroethanol is shown in spacefill.

Only two subunits (a homodimer) have both bound cofactor and substrate. The substrate trifluoroethanol in these subunits is ligated to the catalytic Zn^{2+} through its oxygen, with the other ligands provided by the side chains of Cys 43, Cys 153, and His 66. The other two monomers (the other homodimer) have a different conformation and use Glu 67 to coordinate the Zn^{2+} instead of His 66 and no substrate is bound. This may be an intermediate in the process that displaces water bound to Zn^{2+} with the substrate.

13.2.4: ALCOHOL METABOLISM IN HUMANS:

When ethanol is consumed, it is oxidatively metabolized primarily in the liver. Cytosolic Alcohol Dehydrogenase (ADH) and mitochondrial Acetaldehyde Dehydrogenase 2 (ALDH2) are the main enzymes involved in this metabolic pathway, first converting ethanol to acetaldehyde and then acetaldehyde to acetate (Figure 13.2.15:). Liver mitochondria have a limited capacity to use the acetate in the Kreb cycle because the enzyme needed to convert acetate to acetyl-CoA (acetyl-CoA synthase 2) is almost absent in the liver, but is abundant in the heart and skeletal muscles. Thus, most of the acetate resulting from ethanol metabolism escapes the liver into the blood circulation and is eventually metabolized to CO_2 by way of the Kreb cycle in cells with mitochondria that contain enzymes to convert acetate to acetyl CoA, such as heart, skeletal muscle, and brain.

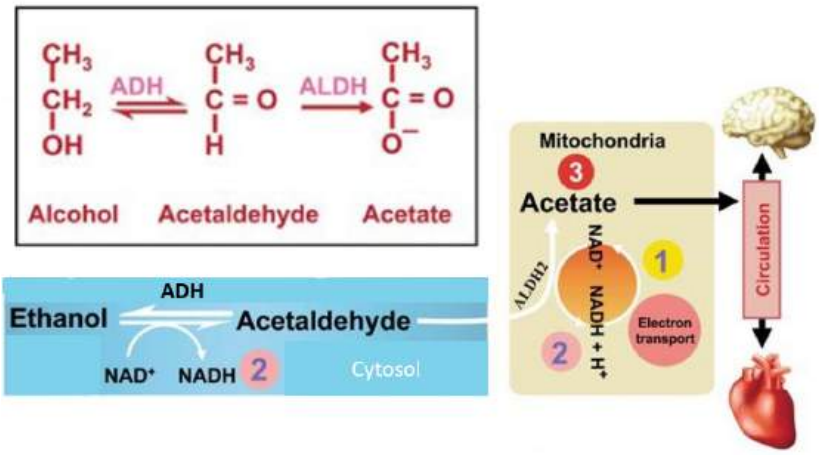

Figure 13.2.15 : Summary of Ethanol Metabolism in Humans

Figure modified from Zakhari, S. (2013) Alcohol Research: Current Reviews 35(1):6-16

Like many substances, the consumption of alcohol can be both beneficial and detrimental, depending on the quantity and frequency of consumption. This is known as a hormetic response (Figure 13.2.16:). At low doses (up to 2 daily drinks for men and 1 daily drink for women) the consumption of alcohol can be cardioprotective. At higher consumption rates this protective effect is lost and the detrimental effects of alcohol consumption become apparent and include cardiotoxicity, liver damage, and increased cancer risk. Not to mention the debilitation that can accompany addiction.

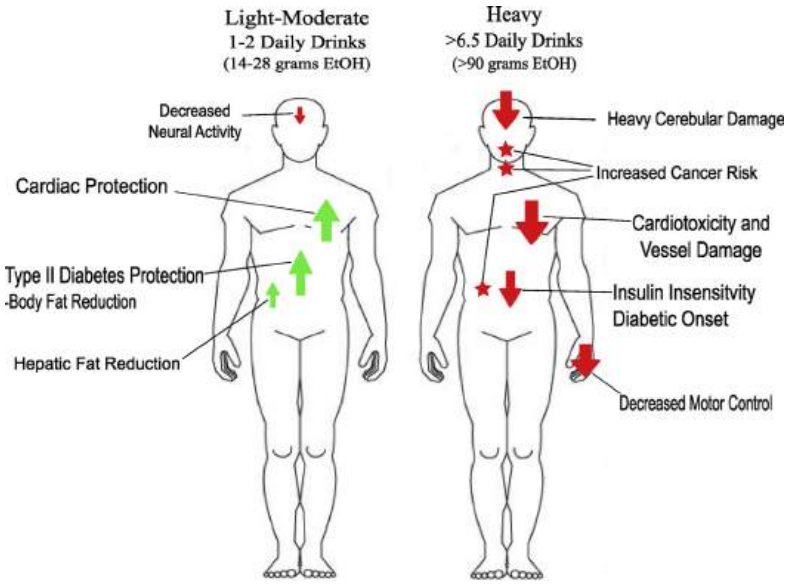

Figure 13.2.16 : Alcohol Consumption and Hormesis

Figure from Adamson, S.S., et al (2017) Translational Medicine of Aging 1:18-23.

The graph presented in Figure 13.2.17 exemplifies the hormetic nature of alcohol consumption. Maintaining ethanol consumption between one (for women) and two (for men) daily drinks will significantly reduce the overall risk of mortality. However, mortality risk skyrockets at high ethanol consumption.

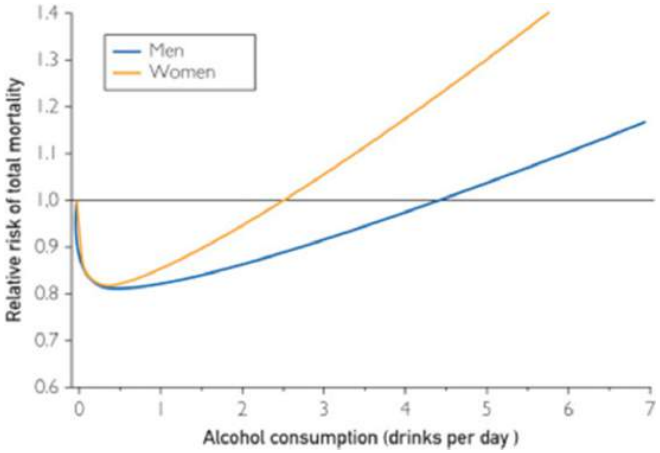

Figure 13.2.17 : Risk of Mortality and Alcohol Consumption

Figure from Adamson, S.S., et al (2017) Translational Medicine of Aging 1:18-23.

Moderate alcohol use of no more than 2 drinks per day for men, and no more than 1 drink per day for women can reduce the risk of coronary artery disease by 29%, and reduce the risk of dying from any cardiovascular disease by 25%. These statistics are significant. Do note that at these levels that there is an increased risk of dying from hemorrhagic stroke. Increased alcohol consumption, however, can have dire effects on health and can lead to unwanted addiction. The Centers for Disease Control estimates that alcohol abuse leads to approximately 80,000 deaths annually in the United States and that up to 40% of deaths related to liver disease are caused by alcohol abuse.

Harvard Medical School has evaluated thousands of studies and has tried to come up with a method for alcohol risk assessment. They categorize low-risk drinking behavior for men as no more than four drinks in a single day or 14 drinks in a week and no more than 3 drinks in a single day or a total of 7 drinks in a single week for women. Women have lower drinking tolerance due to their smaller sizes, but also due to metabolic differences. Women have less ADH and typically higher fat levels which disperse and retain ethanol longer. Addiction and damage to the liver tend to occur more quickly in women as well. Harvard ranks people at increased risk if their drinking is above either the single day or the weekly limit (which is estimated at 29% of drinkers). High-risk drinkers break both the daily and weekly limits (estimated at 14% of drinkers).

During ethanol metabolism, when circulating ethanol is in the millimolar range, acetaldehyde is in the micromolar range, and acetate is in the millimolar range (Figure 13.2.18:). When heavy drinking or chronic drinking occurs the Acetaldehyde Dehydrogenase enzyme cannot keep up with the Alcohol Dehydrogenase enzyme and the pool of Acetaldehyde increases. This aldehyde has many toxic effects within biological systems (Figure 13.2.19:).

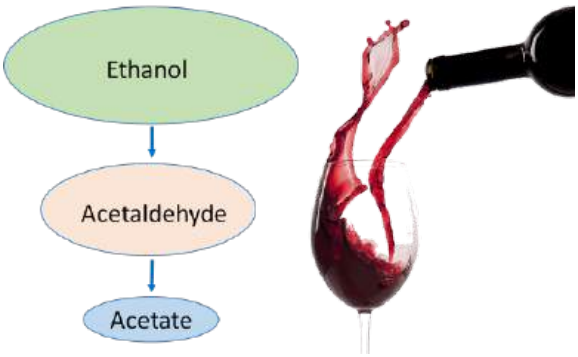

Figure 13.2.18 : The Effects of Binge or Chronic Drinking on Ethanol Metabolites.

Figure modified from Zakhari, S. (2013) Alcohol Research: Current Reviews 35(1):6-16

Acetaldehyde can form adducts with proteins. For example, acetaldehyde adducts on cytoskeletal components such as microtubulin, lead to the swelling of hepatocytes (liver cells). If secreted from the cell, these protein adducts can also be recognized as foreign by the immune system and cause an autoimmune response causing further inflammation and damage to the liver. Acetaldehyde also causes oxidative damage to lipids and DNA and can alter mitochondrial function. Overall, the liver is stressed and unhappy when too much ethanol is consumed.

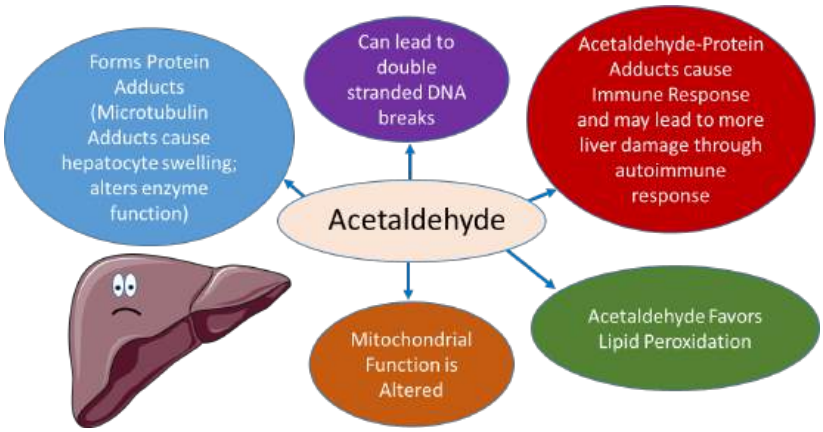

Figure 13.2.19 : Acetaldehyde Toxicity

Figure modified from Servier Medical Art

Heavy chronic drinking can also lead to epigenetic modifications that alter protein expression patterns within the cell. Due to the oxidation of alcohol to acetate, the metabolism of alcohol also leads to an increase in the NADH: NAD+ ratio altering carbohydrate metabolism. Heavy ethanol consumption promotes the formation of reactive oxygen species and can also promote apoptosis. Overall, heavy drinking is extremely hard on liver function. It can lead progressively from the formation of a fatty liver to liver cirrhosis and increased risk of liver cancer. The risk for several other types of cancer is also heightened with heavy alcohol use.

Chronic heavy alcohol use can also alter gene expression, especially in the liver. Figure 13.2.20 is a schematic representation of DNA methylation, which converts cytosine to 5′methyl-cytosine via the actions of DNA methyltransferase (DNMT). DNA methylation typically occurs at cytosines that are followed by a guanine (i.e., CpG motifs). Within the liver, chronic heavy drinking reduces pools of S-adenosylmethionine (SAM) while increasing homocysteine and S-adenosylhomocysteine (SAH). SAH further inhibits DNA methyltransferases (DNMTs) by negative feedback inhibition, ultimately resulting in global hypomethylation of DNA. This hypomethylation leads to the inappropriate expression of many genes, especially within the liver tissue.

Figure 13.2.20 : Effects of Chronic Alcohol Use on DNA Methylation

Figure modified from Zakhari, S. (2013) Alcohol Research: Current Reviews 35(1):6-16

Two genes that are upregulated due to this hypomethylation express the Catalase enzyme and the p450 oxidoreductase enzyme, CYP2E1. Both of these enzymes are involved in oxidative pathways of alcohol metabolism that produce the toxic acetaldehyde intermediate (Figure 13.2.21). Expression of both of these proteins become more prevalent in chronic alcohol consumption or when blood alcohol levels are high, as in cases of binge or heavy drinking. The activity of these enzymes can also lead to the formation of reactive oxygen species that contribute to global cellular damage (lipid peroxidation, DNA damage, protein damage, etc).

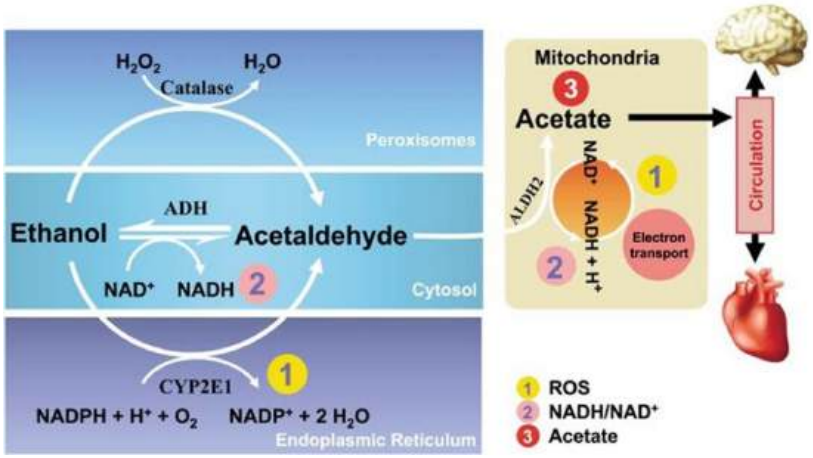

Figure 13.2.21 : Oxidative Pathways of Alcohol Metabolism

Figure from Zakhari, S. (2013) Alcohol Research: Current Reviews 35(1):6-16

Gene regulation in other areas of the body is also affected in response to chronic heavy alcohol consumption. This is due to the production of acetate during the metabolic pathway of alcohol that is released from the liver into the bloodstream. In other areas of the body, acetate is converted to acetyl-CoA by the enzyme Acetyl-coenzyme A (acetyl-CoA) synthetase (AceCS). AceCS is activated by Sirtuin 1, also known as NAD-dependent protein deacetylase (SIRT1). Acetyl-CoA is used by histone acetyltransferase (HAT) to acetylate the lysine residues in histone proteins. Histone acetylation causes these proteins to release the bound DNA, allowing regions to be opened up for transcription (Figure 13.2.22). Thus, higher levels of acetate promote histone acetylation and increased gene expression.

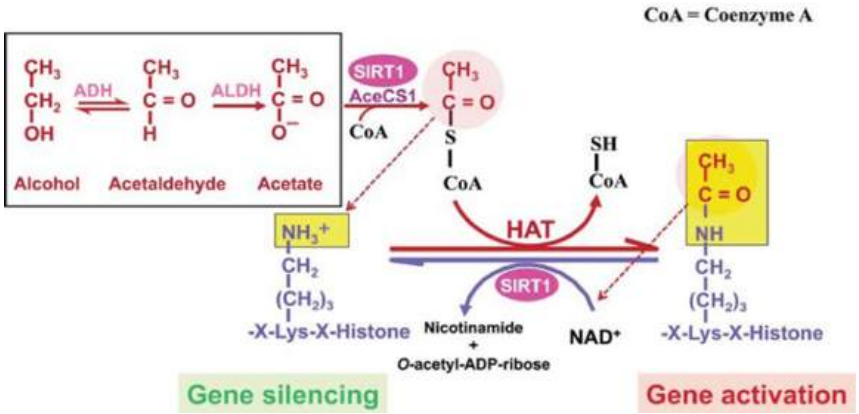

Figure 13.2.22 : The Effects of Chronic Alcohol Consumption on Histone Acetylation. Note in the diagram shown, that SIRT1 also deacetylates histones, resulting in gene silencing. Thus, SIRT1 is a sensor that balances gene activation and silencing in the cell based on the cell's energy status. Alcohol metabolism results in acetate formation, which is used in ***extrahepatic tissues*** to produce acetyl-CoA, upregulating histone acetylation within those tissues. NOTES: AceCS1 = Acetyl-CoA synthase 1; ADH = alcohol dehydrogenase; ALDH = Aldehyde dehydrogenase. Figure from Zakhari, S. (2013) Alcohol Research: Current Reviews 35(1):6-16

In addition to these effects, both ADH and ALDH utilize the cofactor nicotinamide adenine dinucleotide (NAD+), which is reduced to NADH; as a consequence, during ethanol oxidation the ratio NADH/NAD+ is significantly increased, altering the cellular redox state and triggering several adverse effects, related to alcohol consumption. Glycolysis and the Kreb Cycle are downregulated due to low NAD+ levels. This results in lower pyruvate levels, and lower conversion of pyruvate to acetyl-CoA and also causes a decrease in gluconeogenesis (ie there is not enough pyruvate to drive glucose production). Thus, the pyruvate that does form favors anaerobic conversion to lactate and can result in lactic acidosis or lowering of the blood pH levels. Low rates of gluconeogenesis can also contribute to hypoglycemia which can be seen during binge drinking.

Hyperuricemia or an increase in blood levels of uric acid can also occur due, in part, to increased production of ketone bodies and lactic acid. Both the ketone bodies and lactate can compete with uric acid for excretion into the urine within the kidney. The uric acid gets retained and heightens blood levels.

Ketone bodies typically form during periods of starvation when carbohydrate stores have been depleted. When the liver can no longer efficiently maintain blood glucose levels, it will break down fatty acids into ketone bodies and secrete these into the bloodstream (Figure

13.2.23). Ketone bodies, such as acetoacetate, acetone, and D-beta-hydroxybutyrate (which isn't a real ketone, but is still referred to as a ketone body) are released into the bloodstream to compensate for the reduced glucose levels. Brain, heart, and skeletal muscle tissue can utilize ketone bodies as an energy source and this is a good short term solution to starvation. However, the formation of lactate and ketone bodies can severely reduce blood pH levels and induce a life-threatening state known as ketoacidosis. In addition to starvation, heavy alcohol consumption can induce ketogenesis inappropriately.

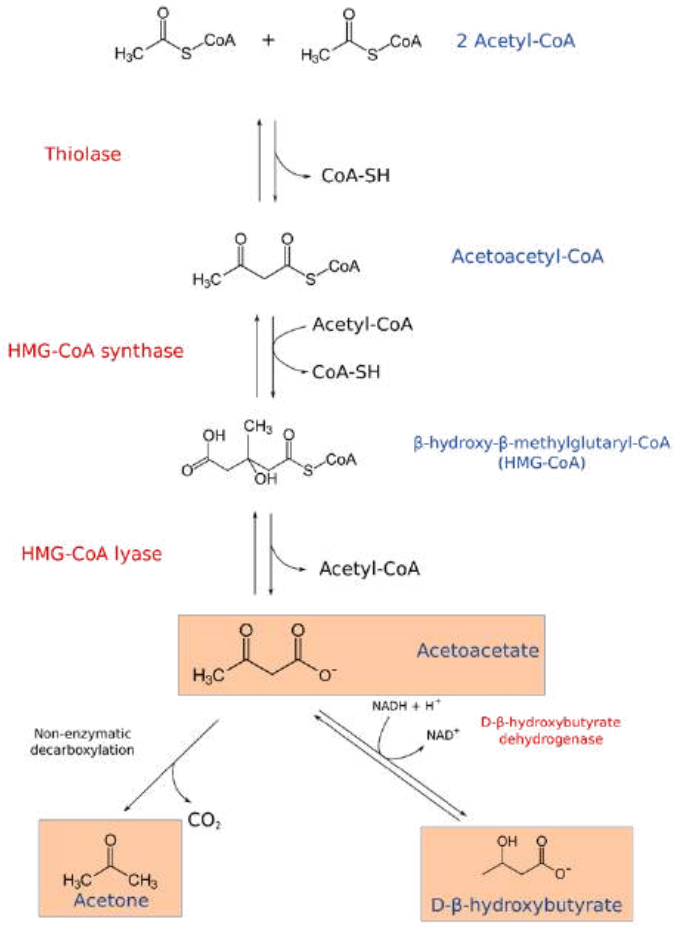

Figure 13.2.23 : Formation of Ketone Bodies. Figure from Sav vas

As noted before, high levels of lactate and ketone bodies within the bloodstream can result in dehydration and reduced excretion of uric acid, leading to hyperuricemia. Over time, high uric acid levels can cause uric acid to precipitate, especially in joints where it causes painful gout flare-ups (Figure 13.2.24).

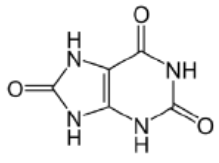

Figure 13.2.24 : Hyperuricemia and Gout. Image from www.scientificanimations.com

According to the American Cancer Society, excessive alcohol use can also increase the risk for several different forms of cancer.

- **Cancers of the mouth, throat, voice box, and esophagus:** Alcohol use raises the risk of these cancers. Drinking and smoking together raise the risk of these cancers even more than drinking or smoking alone. This might be because alcohol can help harmful chemicals in tobacco get inside the cells that line the mouth, throat, and esophagus. Alcohol may also limit how these cells can repair damage to their DNA caused by the chemicals in tobacco.
- **Liver cancer:** Long-term alcohol use has been linked to an increased risk of liver cancer. Regular, heavy alcohol use can damage the liver, leading to inflammation and scarring. This might raise the risk of liver cancer.
- **Colon and rectal cancer:** Alcohol use has been linked with a higher risk of cancers of the colon and rectum. The evidence for this is generally stronger in men than in women, but studies have found the link in both sexes.
- **Breast cancer:** Even a few drinks a week are linked with an increased risk of breast cancer in women. This risk may be especially high in women who do not get enough folate (Vitamin B12) in their diet or through supplements. Alcohol can also raise estrogen levels in the body, which may explain some of the increased risks. Cutting back on alcohol may be an important way for many women to lower their risk of breast cancer.

So how does alcohol consumption contribute to increased risks of cancer? Alcohol may help other harmful chemicals, such as those in tobacco smoke, enter the cells lining the upper digestive tract more easily. This might explain why the combination of smoking and drinking is much more likely to cause cancers in the mouth or throat than smoking or drinking alone. In other cases, alcohol may slow the body's ability to break down and get rid of some harmful chemicals. Alcohol might affect the body's ability to absorb some nutrients, such as folate. Folate is a vitamin needed as a cofactor for enzymes involved in amino acid biosynthesis. Absorption of nutrients can be even worse in heavy drinkers, who often have low levels of folate. These low levels may play a role in the risk of some cancers, such as breast and colorectal cancer. Alcohol can raise the levels of estrogen, a hormone important in the growth and development of breast tissue. This could affect a woman's risk of breast cancer. Too much alcohol can also add extra calories to the diet, which can contribute to weight gain in some people. Being overweight or obese is known to increase the risks of many types of cancer.

Overall, heavy ethanol consumption produces a wide spectrum of hepatic lesions (Figure 13.2.25). Fatty liver (i.e., steatosis) is the earliest, most common response that develops in more than 90 percent of problem drinkers who consume 4 to 5 standard drinks per day. With continued drinking, alcoholic liver disease can proceed to liver inflammation (i.e., steatohepatitis), fibrosis, cirrhosis, and even liver cancer (i.e., hepatocellular carcinoma). Heavy drinking can also damage other organs, such as the pancreas and the brain, and can raise blood pressure. It also increases the risk of heart disease and stroke. In pregnant women, alcohol use, especially heavy drinking, may lead to birth defects or other problems with the fetus.

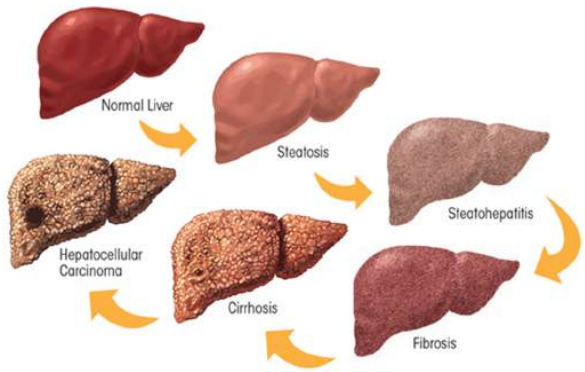

Figure 13.2.25 : The Effects of Heavy Chronic Drinking on the Liver

Figure from Osna, N.A. et al (2017) Alcohol Research: Current Reviews 38(2)

In 1951, the FDA approved disulfiram for the treatment of alcoholism in the US (Figure 13.2.26). Initially, the drug was prescribed in very high doses, often as high as 3,000 mg per day. The high doses led to reports of severe reactions to alcohol, some of which were fatal. It is an inhibitor of the ALDH-2, which will lead to an even higher increase in acetaldehyde concentration if alcohol is consumed. Thus, alcoholics that are taking this drug to quit drinking need to maintain sobriety. If they drink while taking this drug, they will become very ill due to the accumulation of acetaldehyde. Overall, the use of this drug supports abstinence, which is often hard to realistically achieve.

Figure 13.2.26 : Disulfiram

At one time it was thought that before prescribing disulfiram to people, patients should experience mixing the drug with alcohol in a supervised setting. Researchers felt it was important for the individuals to have full knowledge of what would happen if they mixed disulfiram and alcohol. This practice is no longer used, but every person must be educated on the reactions of combining alcohol with disulfiram before a prescription is written.

Along with these effects, alcohol may contribute to cancer growth in other, unknown ways.

and other mammals, various ADHs are used to oxidatively metabolize ethanol to acetaldehyde (also toxic) which is converted to acetate by the enzyme aldehyde dehydrogenase which catalyzes the following reaction:

$$\mathbf{CH_3CHO + NAD^+ + H_2O \rightarrow acetate + NADH + H^+}$$

They can also convert methanol to the very toxic and reactive formaldehyde, which makes methanol poisoning so dangerous if not fatal. Mammalian enzymes are dimers of up to nine different monomers.

13.3: GLUCONEOGENESIS

13.3.1: INTRODUCTION

Gluconeogenesis is a metabolic pathway that results in the generation of glucose from non-carbohydrate carbon substrates such as lactate, glycerol, and glucogenic amino acids. It is one of the two main mechanisms humans and many other animals use to keep blood glucose levels from dropping too low (hypoglycemia). The other means of maintaining blood glucose levels is through the degradation of glycogen (glycogenolysis). Gluconeogenesis is a ubiquitous process, present in plants, animals, fungi, bacteria, and other microorganisms. In animals, gluconeogenesis takes place mainly in the liver and, to a lesser extent, in the cortex of the kidneys. This process occurs during periods of fasting, starvation, low-carbohydrate diets, or intense exercise and is highly endergonic. For example, the pathway leading from phosphoenolpyruvate to glucose-6-phosphate requires 6 molecules of ATP. Gluconeogenesis is often associated with ketosis. Gluconeogenesis is also a target of therapy for type II diabetes, such as metformin, which inhibits glucose formation and stimulates glucose uptake by cells.

Lactate is transported back to the liver where it is converted into pyruvate by the Cori cycle using the enzyme lactate dehydrogenase. Pyruvate, the first designated substrate of the gluconeogenic pathway, can then be used to generate glucose (Figure 13.3.1). All citric acid cycle intermediates, through conversion to oxaloacetate, amino acids other than lysine or leucine, and glycerol can also function as substrates for gluconeogenesis. Transamination or deamination of amino acids facilitates the entry of their carbon skeleton into the cycle directly (as pyruvate or oxaloacetate), or indirectly via the citric acid cycle. Glycerol, which is a part of the triacylglycerol molecule, can be used in gluconeogenesis.

Gluconeogenesis is a pathway consisting of eleven enzyme-catalyzed reactions. The pathway can begin in the mitochondria or cytoplasm, depending on the substrate being used. Many of the reactions are the reversible steps found in glycolysis (Figure 13.3.1). In humans, gluconeogenesis is restricted to the liver and a lesser extent the kidney.

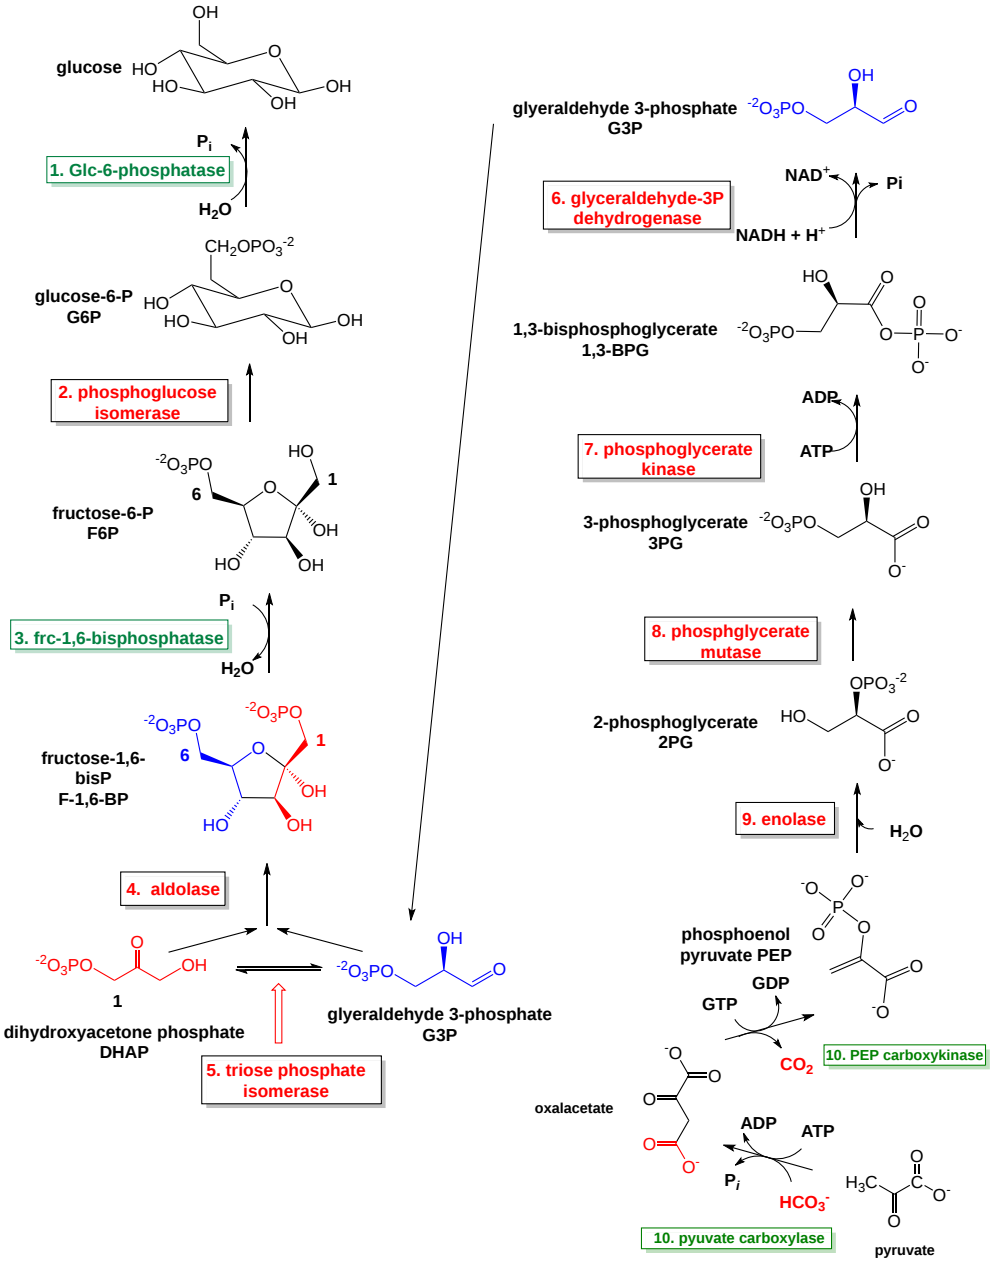

Figure13.3.1 : Gluconeognesis

13.3.2: BYPASS I (REVERSE OF STEP 10 IN GLYCOLYSIS): PYRUVATE TO PHOSPHOENOLPYRUVATE

The conversion of pyruvate into phosphoenolpyruvate requires two enzymatic steps and the formation of oxaloacetate as the intermediate. In all species, the formation of oxaloacetate from pyruvate and any other TCA cycle intermediates is restricted to the mitochondrion, and the enzymes that convert PEP to glucose are found in the cytosol. The location of the enzyme that links these two parts of gluconeogenesis by converting oxaloacetate to PEP, PEP carboxykinase, is variable by species: it can be found entirely within the mitochondria, entirely within the cytosol, or dispersed evenly between the two, as it is in humans. Transport of PEP across the mitochondrial membrane is accomplished by dedicated transport proteins; however, no such proteins exist for oxaloacetate. Therefore in species that lack intra-mitochondrial PEP, oxaloacetate must be converted into malate or aspartate, exported from the mitochondrion, and converted back into oxaloacetate to allow gluconeogenesis to continue.

Here is the net reaction: Pyruvate + ATP + HCO_3^- + GTP → PEP + ADP + GDP + CO_2 $\Delta G^{o'}$ = +0.2 kcal/mol (0.8 kJ/mol)

Figure13.3.2 shows the overall reaction for the conversion of pyruvate to phosphoenol pyruvate.

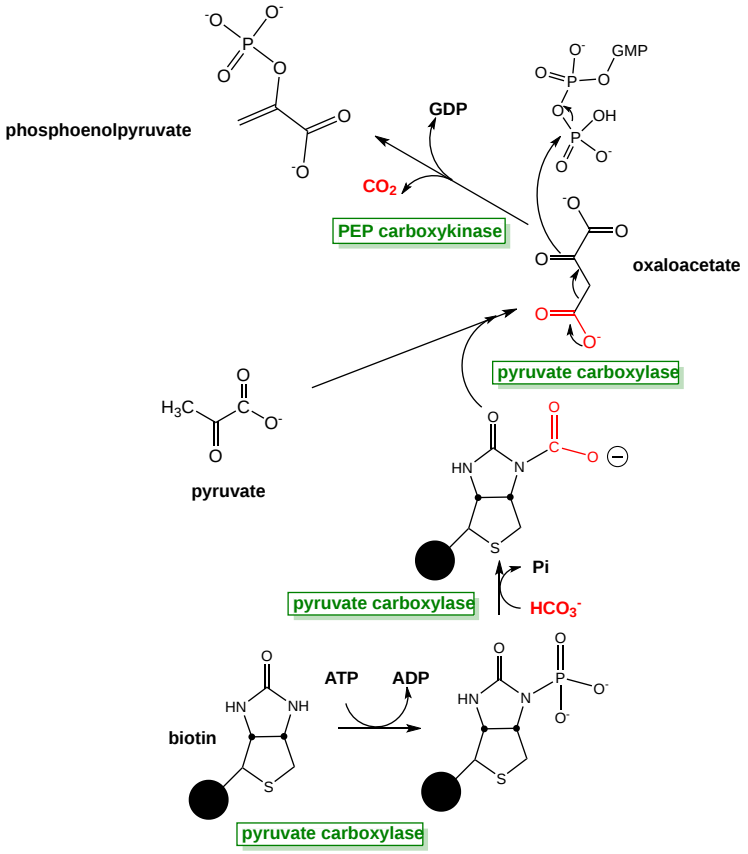

Figure 13.3.2 : Overall reaction for the conversion of pyruvate to phosphoenol pyruvate

In systems that produce oxaloacetate in the mitochondria and then need to transport it to the cytosol to be converted into phosphoenolpyruvate, three enzymes are needed for the process: pyruvate carboxylase (PC) located in the mitochondrial matrix, aspartate aminotransferase (AAT), located in the matrix and the cytosol, and the phosphoenolpyruvate carboxykinase (PCK) located in the cytosol. Oxaloacetate and aspartate are intermediate compounds formed in the process.

In the first reaction, pyruvate carboxylase converts pyruvate into oxaloacetate, based on the following reaction:

Pyruvate carboxylase: pyruvate + HCO_3^- + ATP → oxaloacetate + ADP + P_i

The pyruvate carboxylase enzyme requires biotin as a cofactor and has two major enzymatic functions: 1) carbon fixation from carbon dioxide, and 2) carbon transferase activity, placing the carbon dioxide that has been fixed, onto the molecule of pyruvate to create oxaloacetate. The biotin cofactor is shown in Figure (\PageIndex{3}\). Biotin is a water-soluble vitamin (known as D-biotin or vitamin B7) and is a cofactor in many enzymatic reactions, especially those involving carboxylation (or carbon fixation reactions). It is part of the vitamin B2 complex and is an essential vitamin for mammals. Deficiency results in dermatitis, loss of hair, and neurologic symptoms.

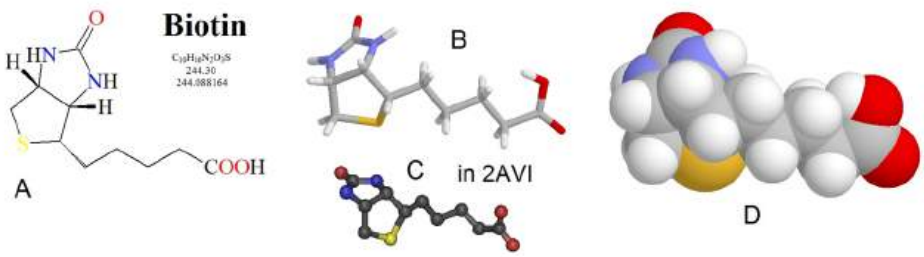

Figure (\PageIndex{3}\): Chemical Structure of Biotin. Biotin is shown in several different formats, (A) line structure, (B) stick model, (C) ball and stick model, and (D) spacefilling model.

Figure from: Biosynthesis

The biotin cofactor forms an amide linkage with the pyruvate carboxylase enzyme at a lysine residue (Figure (\PageIndex{4}\)). This creates a flexible linker region within the pyruvate carboxylase that is capable of dipping the biotin cofactor into the different catalytic domains of the enzyme to obtain the biological activity of the protein. Attaching the biotin to the enzyme requires the energy of ATP.

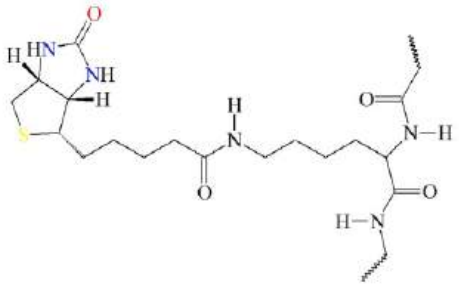

Figure (\PageIndex{4}\) Attachment of Biotin Cofactor to Lysine Residue in Pyruvate Carboxylase.

Image from: Biosynthesis

The pyruvate carboxylase enzyme is a tetramer that contains four functional protein subunits as shown in Figure 13.3.5. The BCCP flexible arm is capable of extending into the biotin carboxylation (BC) domain where biotin is first carboxylated, and then the BCCP shifts over to the carboxyl transferase (CT) domain where the fixed molecule of carbon dioxide can be transferred to pyruvate forming oxaloacetate.

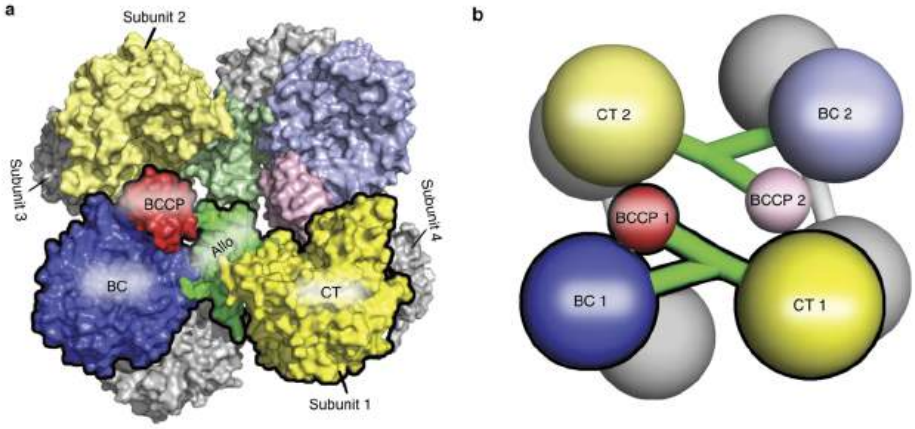

Figure 13.3.5 Structure of the Pyruvate Carboxylase Enzyme. The overall structure of the Pyruvate Carboxylase is a tetramer that contains four functional protein subunits. Two subunits are shown in color, with the other two indicated in gray at the back of the structure. (a) shows the space-filling model while (b) shows the major domains as a cartoon graphic. Each subunit contains a biotin carboxylase (BC) domain shown in blue, a carboxytransferase (CT) domain shown in yellow, and the biotin-carboxyl carrier protein (BCCP) domain shown in red and green.

Figure modified from Liu, Y., et al (2018) Nat Commun 9:1384

In the first part of the reaction, the biotin cofactor is carboxylated using bicarbonate as a substrate with ATP to drive the formation of a molecule with high energy with respect to its hydrolysis product intermediate. (**Remember, there is no such thing as a "high energy" bond.**) Thus, biotin is acting as an intermediate carrier of the carboxy group that will be added to pyruvate during the formation of oxaloacetate. This occurs in the biotin carboxylase domain (BC) with biotin bound to a biotin carboxyl carrier protein (BCCP) domain. The carboxyl group is then transferred to pyruvate to form oxaloacetate in the carboxyl transferase (CT) domain. Let's break up the mechanism of the enzyme from *Rhizobium etli* into three figures.

Figure13.3.6 below shows the first steps in the carboxylation of biotin in the biotin carboxylase domain, using bicarbonate as a substrate. In Figure13.3.6, you can see that an oxygen from bicarbonate mediates nucleophilic attack on the outer phosphate group of the ATP molecule forming the carbonyl-phosphate intermediate + ADP. The carbonyl-phosphate decomposes to release carbon dioxide and phosphate. The negatively charged phosphate activates the biotin cofactor to enable a nucleophilic attack on the carbon of the carbon dioxide producing the carboxybiotin intermediate, shown in the upper part of Figure13.3.7.

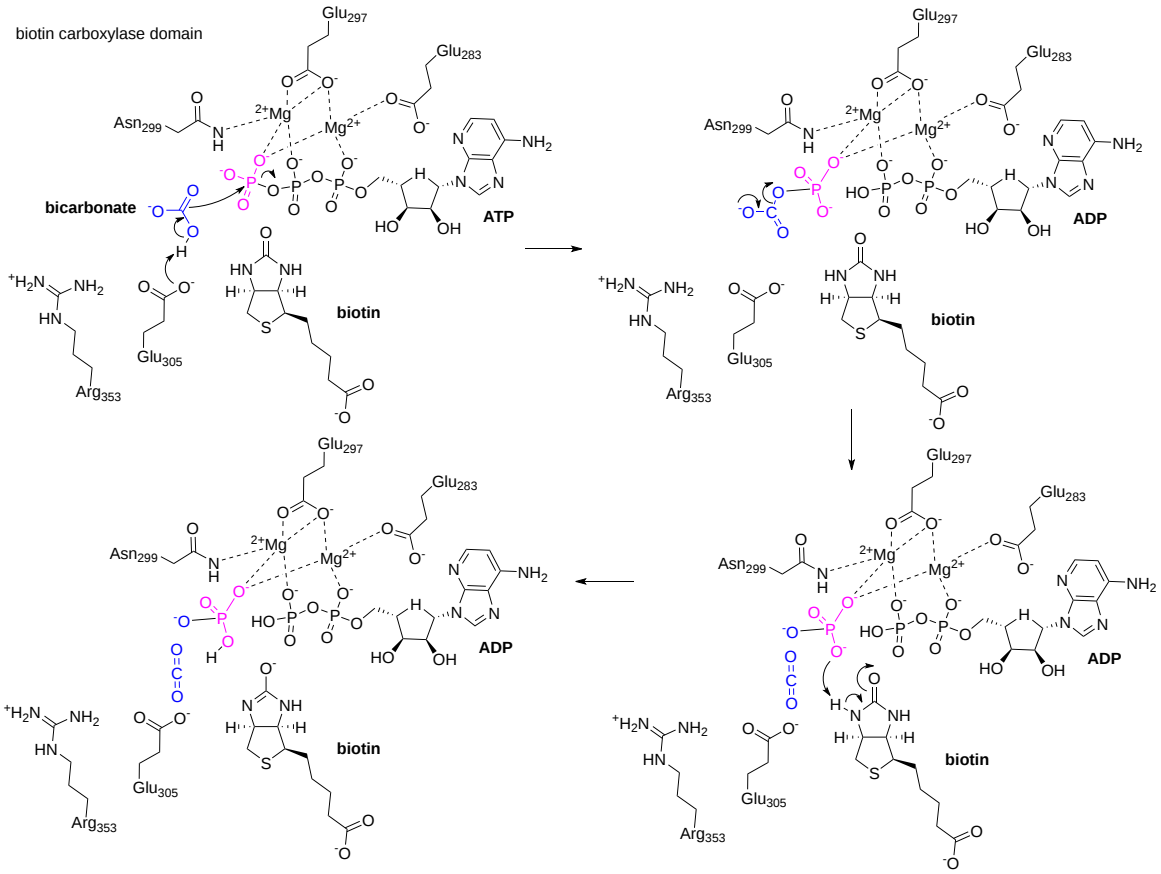

Figure 13.3.6 : The Carboxylation of Biotin during the Pyruvate Carboxylase Reaction Mechanism. Bicarbonate, shown in blue, enters the active site of the enzyme and reacts with the terminal phosphate of ATP forming a phosphorylated intermediate. This reaction is stabilized by two Mg^{2+} cofactors. The carboxyphosphate intermediate decomposes to release carbon dioxide and phosphate.

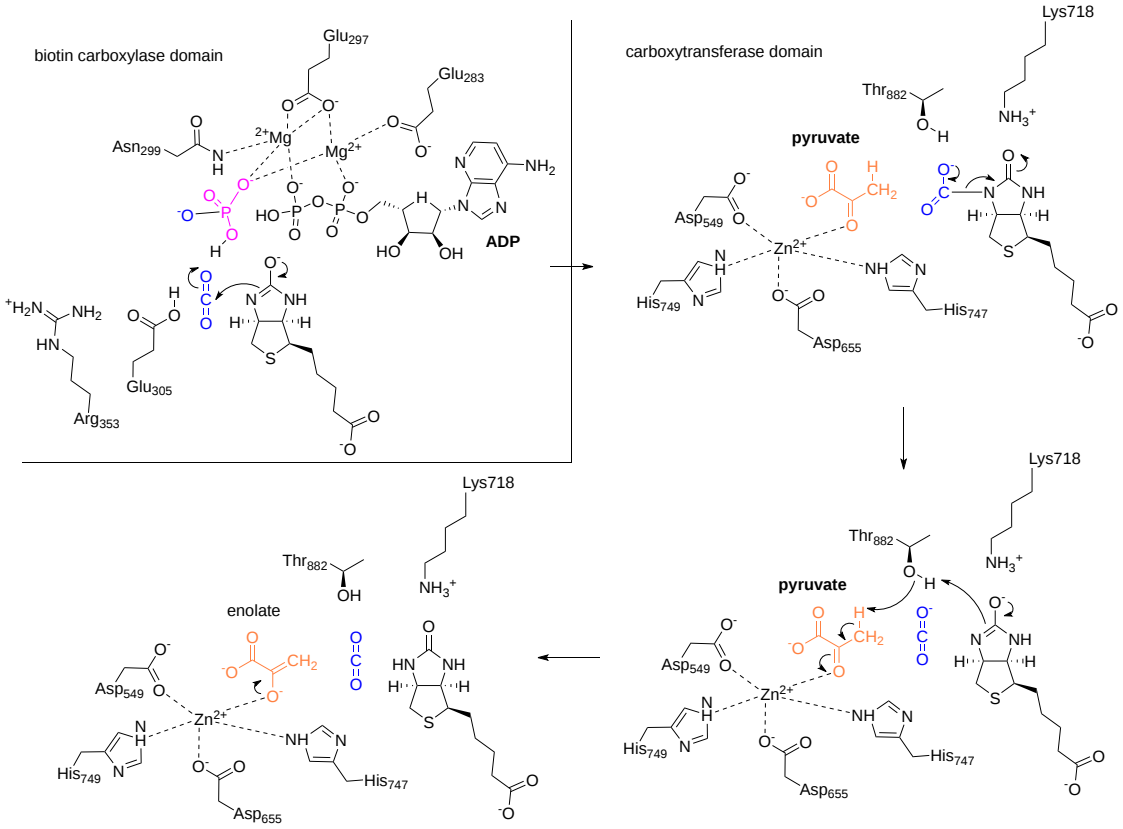

Figure13.3.7 : Carboxylation of biotin in pyruvate carboxylase. The upper diagram shows the actual carboxylation of biotin, which occurs in the BC domain. The carboxybiotin intermediate then shifts on the flexible arm and enters the carboxytransferase (CT) domain. Pyruvate enters the active site and this begins the steps involved in the carboxylation of pyruvate to form oxaloacetate. Ribeiro, ibid

The carboxyltransferase activity is housed in the CT domain of the enzyme and requires the formation of a carbanion intermediate to occur on the pyruvate molecule to make it reactive enough to cause the addition of the carboxyl group. A base from the enzyme eliminates a proton from the C3 position of pyruvate causing the formation of an enol reaction intermediate. As the electrons on the oxygen from the pyruvate molecule reform the carbonyl group, the electrons from the carbon-carbon double bond shift onto the carbon, creating a reactive carbanion intermediate. At this point, the carboxybiotinyl complex swings into the CT domain, providing the carboxyl group that will be incorporated into pyruvate. The carbanion intermediate mediates a nucleophilic attack onto the carboxyl carbon from the BCCP complex, and carbon dioxide is transferred to the pyruvate, creating oxaloacetate. The biotin cofactor is restored by the donation of the proton from the basic residue in the enzyme. This also restores the Pyruvate Carboxylase enzyme for another round of activity. Figure13.3.8 below shows the carboxylation of the enolate form of pyruvate to form oxaloacetate.

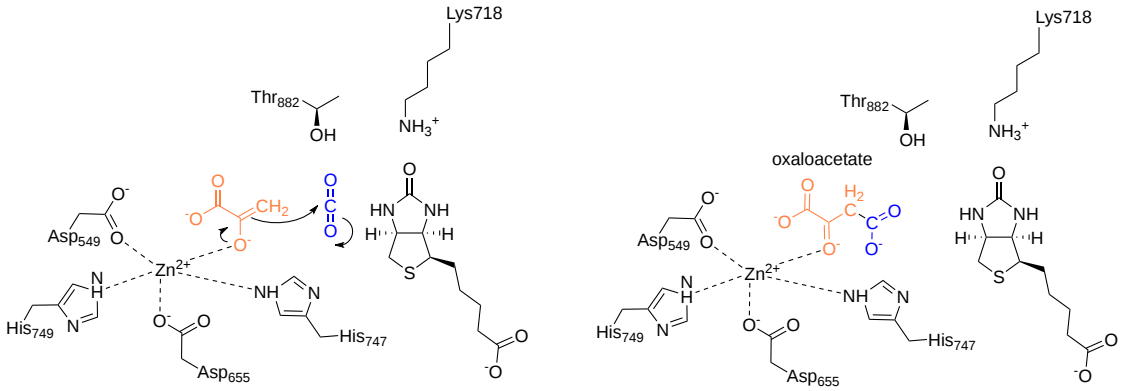

Figure13.3.8 : Carboxylation of the enolate form of pyruvate to form oxaloacetate by pyruvate carboxylase. Ribeiro et al, ibid

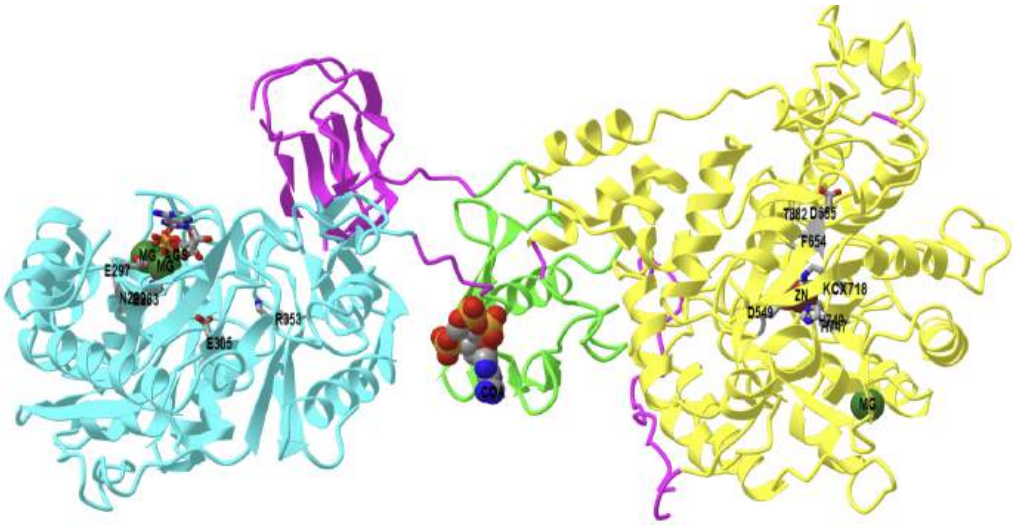
Figure13.3.9 below shows an interactive iCn3D model of the biotin-dependent multifunctional enzyme pyruvate carboxylase from Rhizobium etli (2QF7)



NCBI iCn3D **Figure13.3.9 : Biotin-dependent multifunctional enzyme pyruvate carboxylase from Rhizobium etli (2QF7).** The enzyme is a homotetramer with C2 symmetry but only one subunit chain is shown for clarity. The biotin carboxylase domain (BC) is shown in cyan, the carboxytransferase domain (CT) in yellow, a C-terminal biotin carboxyl carrier protein (BCCP) domain (disconnected in parts) in magenta, and the allosteric domain in green. AGS in the cyan domain is a phosphothiophosphoric acid-adenylate ester, an ATP analog. It is shown interacting with the 2 Mg^{2+} ion and it is represented in sticks and labeled. Acetyl-CoA and a nonhydrolyzable analog, ethyl-CoA, are allosteric activators. CoASH (ethyl group not shown) is illustrated in spacefill bound to the green allosteric domain. Acetyl-CoA binding leads to a conformational change that decreases the distance between the two active sites on the BT (cyan) and CT (yellow) domains. Biotin, not shown, is tethered, in the BCCP domain, which transfers biotin between the two catalytic domains not within a single monomer (as shown above), but between different monomers in the homo 4-mer.

Figure13.3.10 shows the flexible nature of the biotin flexible arm of the enzyme during the catalytic process.

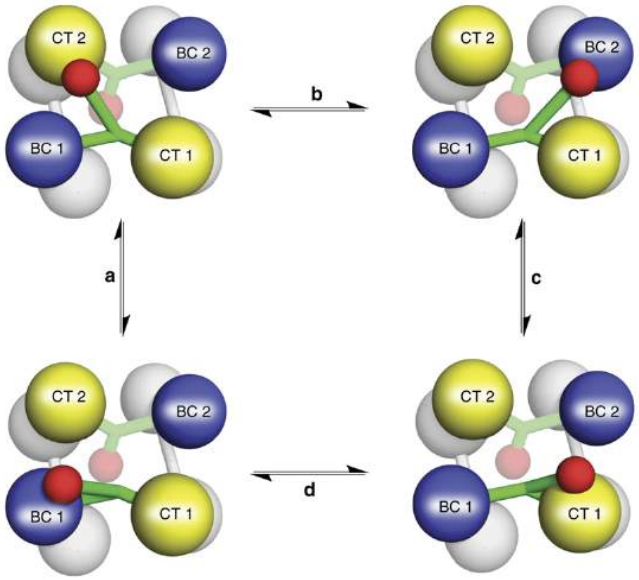

Figure13.3.10 The Catalytic Activity of Pyruvate Carboxylase. The Biotin-Carboxyl Carrier Protein Domain (BCCP) is a flexible arm of the protein structure that can swing from one catalytic domain to the other during the reaction process. As shown in the diagram, the BCCP domain of subunit 1 will be fixed with carbon dioxide at the biotin carboxylase domain from subunit 1 (BC1). The BCCP will then translocate to the carboxyltransferase domain from subunit 2 (CT2) where it will create one molecule of oxaloacetate and reset the biotin cofactor. The BCCP will then swing into the BC2 domain where carbon fixation will occur. BCCP then shifts to the CT1 domain where it creates a second oxaloacetate molecule and resets the biotin. While this is going on with the BCCP from subunit 1, the other BCCP arms from subunits 2, 3, and 4 are also active. Thus, one full sequence of the enzyme activity will produce 8 molecules of oxaloacetate.

Image from: Liu, Y., et al (2018) Nat Commun 9:1384

The next reaction in the process requires the conversion of oxaloacetate to phosphoenolpyruvate by phosphoenolpyruvate carboxykinase (PEPCK). However, the major human PEPCK enzyme, PCK1, resides in the cytoplasm of the cell. Thus the oxaloacetate produced in the matrix of the mitochondria by pyruvate carboxylase must be transported into the cytosol. However, there are no oxaloacetate transporters that can mediate the transfer directly. To leave the mitochondrial matrix, oxaloacetate has to first be converted to aspartate by the aspartate aminotransferase enzyme (AAT). It can then be transported to the intermembrane space of the mitochondria through an antiporter that transports one molecule of aspartate out of the matrix and one molecule of glutamate into the matrix Figure13.3.11. Once in the intermembrane space, the aspartate can pass freely through a pore in the outer mitochondrial membrane. When it reaches the cytoplasm, aspartate is reconverted to oxaloacetate using the cytoplasmic aspartate aminotransferase enzyme (AAT). Oxaloacetate can then be used as a substrate by the phosphoenolpyruvate carboxykinase enzyme (PEPCK).

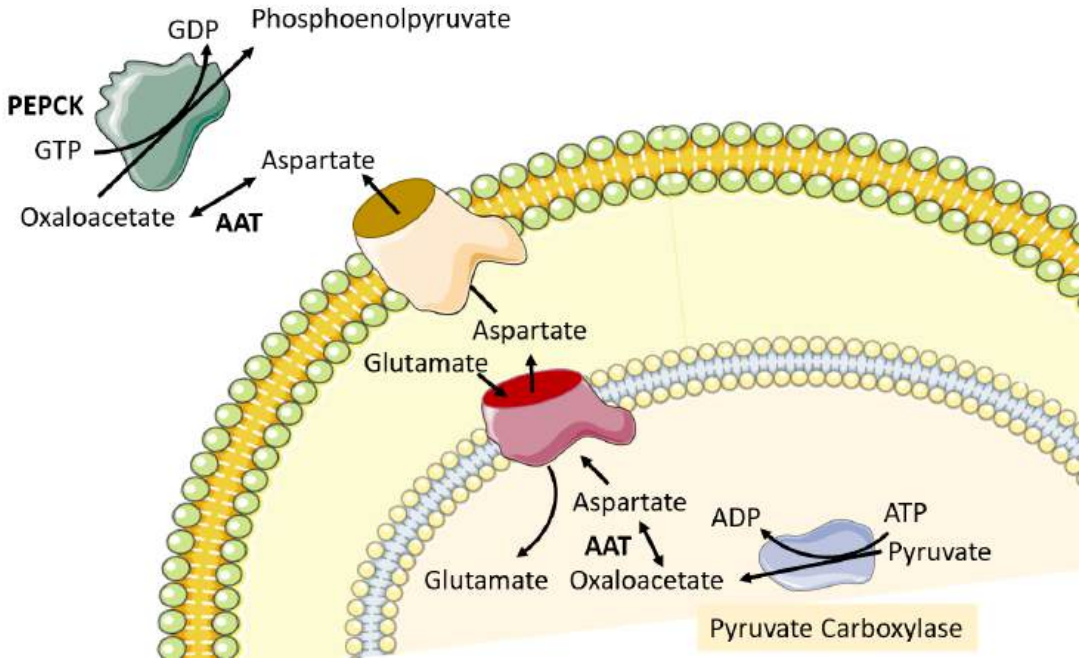

Figure13.3.11 Conversion of Oxaloacetate to Aspartate and Transfer to the Cytoplasm.

Image modified from SMART Servier Medical Art

The glutamate/aspartate transporter has some additional complexities associated with it. It cannot function on its own. It requires the coordinated functioning of the malate/alpha-ketoglutarate antiporter. Together, these antiporters are known as the Malate-Aspartate Shuttle System.

The Malate-Aspartate Shuttle System is dependent on the functioning of two enzymatic processes. The first is the aspartate aminotransferase that was indicated more simplistically in Figure13.3.11. The aspartate aminotransferase enzyme can utilize glutamate as an amine donor to generate aspartate from oxaloacetate. Alpha-ketoglutarate is also formed in this process. Depending on substrate concentrations and other regulatory mechanisms, this enzyme can also work in the reverse reaction to produce glutamate and oxaloacetate. In a different reaction using Malate Dehydrogenase, oxaloacetate can be reduced to form malate using a molecule of NADH as the electron donor.

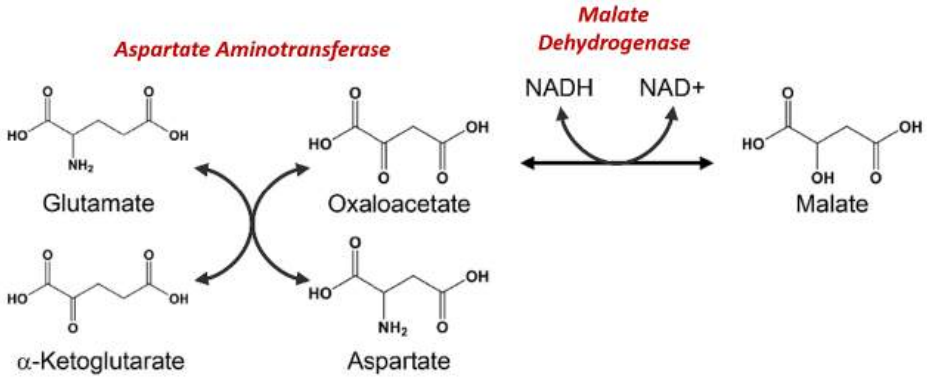

Figure13.3.12 Chemical Reactions of the Malate-Aspartate Shuttle System

Figure modified from Son, H.F. and Kim, J-J. (2016) PLoS One 10.1371

The malate dehydrogenase enzyme is expressed to high levels in the cytoplasm of liver cells as well as in the matrix of the mitochondria. This enzyme is a component of the Kreb Cycle where it mediates the formation of oxaloacetate in the last step of the cycle. Within the cytoplasm, it predominantly converts oxaloacetate to malate. The malate can then be shuttled into the matrix of the mitochondria through the malate/alpha-ketoglutarate antiporter (Figure13.3.13). In this antiporter, malate moves into the mitochondrial matrix while alpha-ketoglutarate moves into the intermembrane space (and subsequently into the cytosol of the cell). Together with aspartate, it can be used by cytoplasmic aspartate aminotransferase to produce glutamate and oxaloacetate. This is the oxaloacetate pool that is then utilized in the gluconeogenic pathway when PEPCK is active. The glutamate generated from this reaction is transported back into the matrix of the mitochondria through the aspartate/glutamate antiporter. The pool of aspartate in the matrix of the mitochondria is supplied by the reaction of the aspartate aminotransferase enzyme, which completes the reverse reaction from the one seen in the cytoplasm. In the matrix, aspartate aminotransferase uses glutamate and oxaloacetate as substrates to generate aspartate and alpha-ketoglutarate. This enables the transport of aspartate and glutamate through their specific antiporter. Within the gluconeogenic pathway, heightened levels of oxaloacetate are produced in the matrix of the mitochondria. Oxaloacetate is then converted to aspartate and transported across the inner membrane, where it can subsequently be converted back into oxaloacetate and used for the production of glucose.

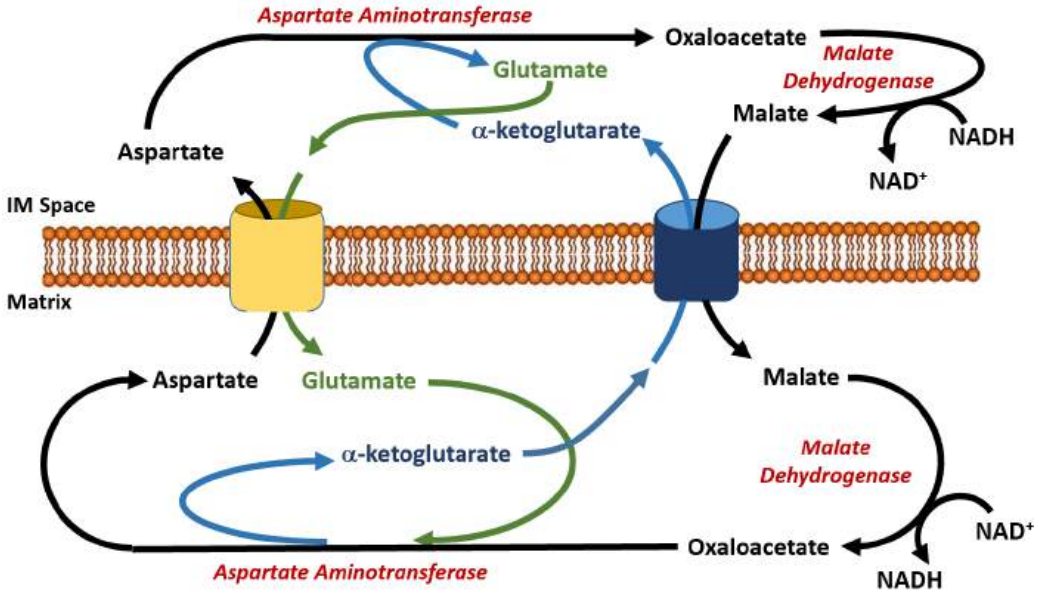

Figure13.3.13 : The Malate-Aspartate Shuttle System.

Once oxaloacetate has been effectively transported via the Malate-Aspartate Shuttle into the cytoplasm, it is converted to phosphoenolpyruvate (PEP) by the PEP carboxykinase (PEPCK). The overall reaction mediated by PEPCK is:

PEP carboxykinase (PEPCK): oxaloacetate + GTP → phosphoenol pyruvate + GDP

PEPCK is classified as a lyase enzyme and exists in two isozymes, a cytoplasmic PEPCK, and a mitochondrial PEPCK. The cytoplasmic form is the one that is predominantly used in the gluconeogenic pathway and requires the action of the Malate-Aspartate Shuttle. However, small amounts of PEP can be made directly by the mitochondrial PEPCK and then transported across the mitochondrial membrane. The conversion of oxaloacetate to phosphoenolpyruvate by PEPCK mediates the removal of carbon dioxide and the addition of a phosphate group. A molecule of GTP is used during this process as the phosphate donor and magnesium ions serve as a cofactor. Figure 13.3.14 shows the reaction mechanism for the human PEP carboxykinase.

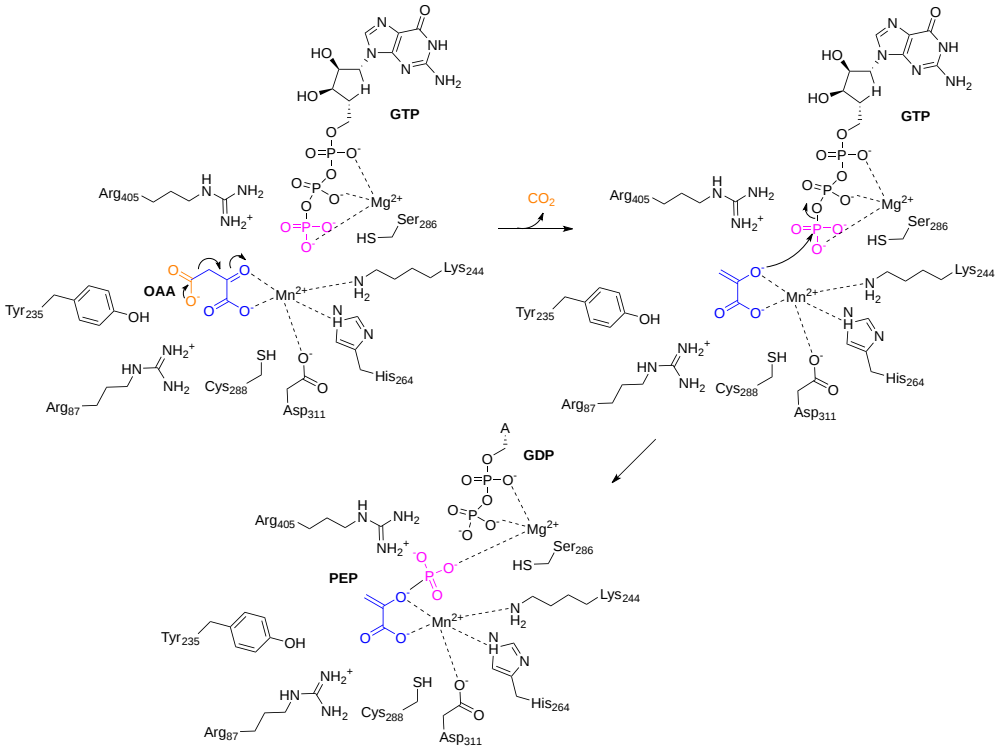

Figure 13.3.14 : Reaction mechanism for human PEP carboxykinase (PEPCK)

13.3.3: PHOSPHATASE REACTIONS OF GLUCONEOGENESIS (REVERSE OF STEPS 1 AND 3 IN GLYCOLYSIS):

The last two unique enzymes of the gluconeogenic pathway are both phosphatase enzymes. Fructose 1,6-bisphosphatase converts fructose 1,6-bisphosphate to fructose 6-phosphate. The same phosphoglucoisomerase used in glycolysis can convert fructose 6-phosphate back into glucose 6-phosphate. A unique glucose 6-phosphatase enzyme will then convert glucose 6-phosphate to free glucose. The unique phosphatase reactions are shown in Figure13.3.16.

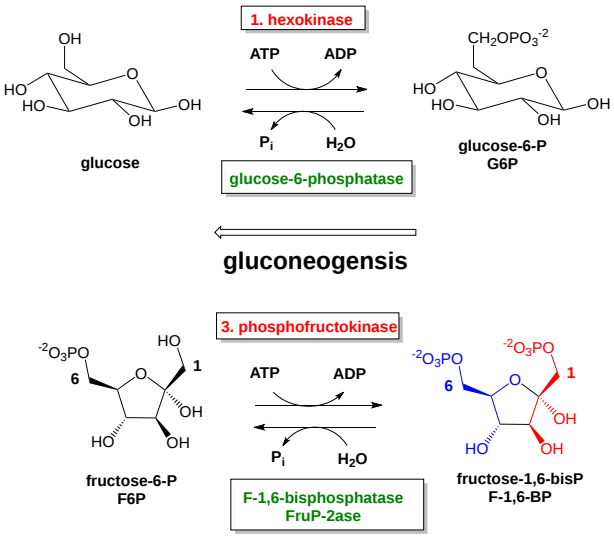

Figure 13.3.16 : Phosphorylase Enzymes utilized during Gluconeogenesis

First, let's consider the dephosphorylation of fructose 1,6-bisphosphate. The gluconeogenic enzyme is named fructose-1,6-bisphosphatase, (FBP or FBPase-1). FBP requires a metal cofactor and is competitively and allosterically regulated. Fructose 2,6-bisphosphate and low energy load (AMP and ADP) inhibit the enzyme. The overall reaction is shown below:

Fructose-1,6-bisphosphatase: F1,6BP + H_2O → F6P + P_i

Figure 13.3.17 shows the mechanism of mouse fructose,1-6-bisphosphatase (FBPase-1)

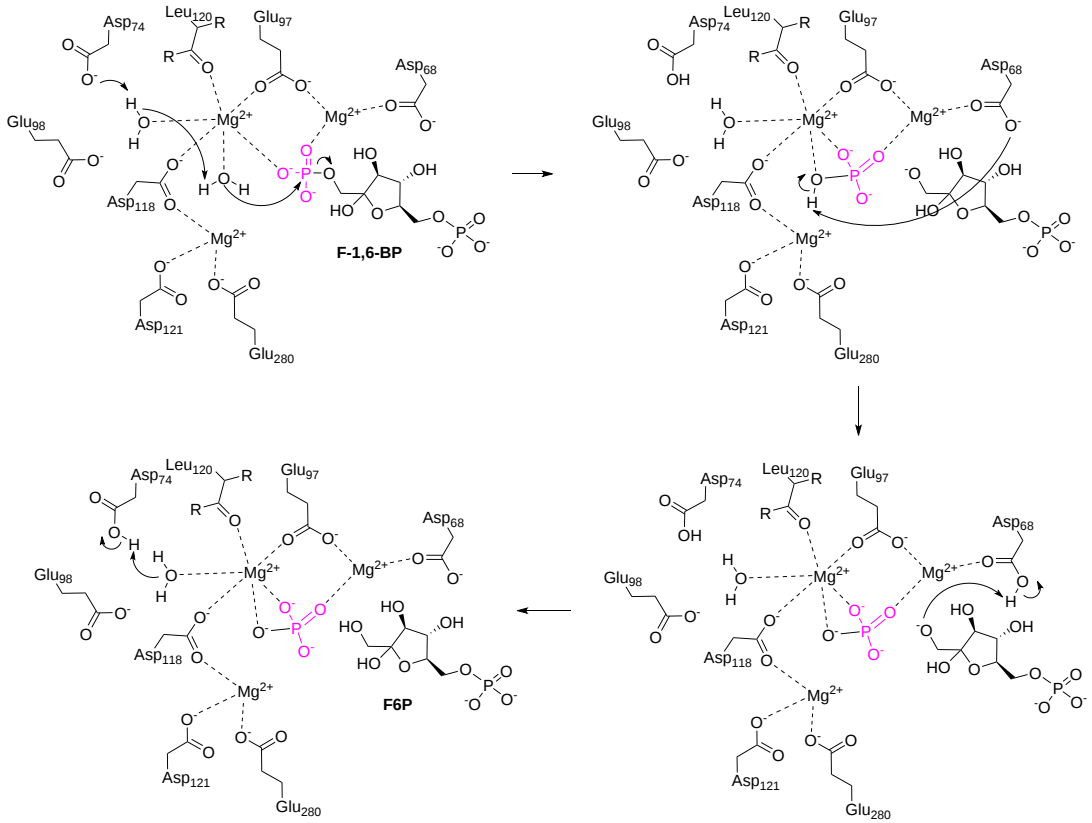

Figure 13.3.17 : Mechanism of mouse fructose,1-6-bisphosphatase. Mg^{2+} ions coordinate the positioning of F-1,6-BP near an activated water molecule that mediates nucleophilic attack on the 1-position phosphate group. This leads to the cleavage of the phosphate group from the sugar molecule, F6P, which can then leave the active site.

Figure13.3.18 below shows an interactive iCn3D model of pig fructose-1,6-bisphosphatase with bound Mg^{2+}, fructose-6-phosphate, and phosphate in the R state (1EYI).

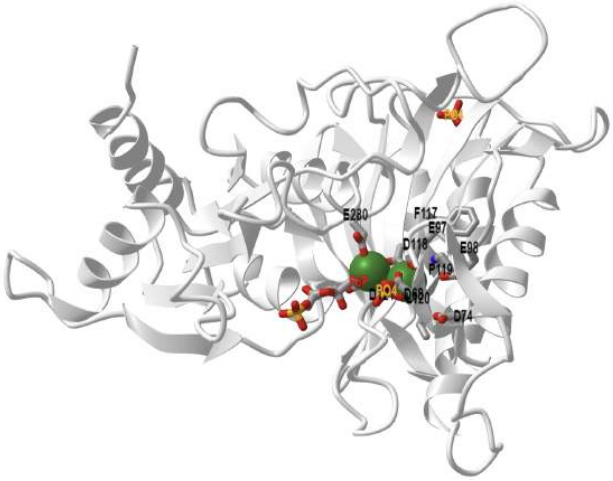

Figure 13.3.18 : Fructose-1,6-bisphosphatase with bound Mg, fructose-6-phosphate and phosphate in the R state (1EYI). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...DbWMHBRTdPGhJ8

FBP is an allosteric homotetramer and can exist in a tense (T) and relaxed (R) state. When the enzyme is in the R state, it has the highest catalytic activity. Figure13.3.18 shows only one monomer of the R state with bound ligands and substrates for clarity.

Figure 13.3.19 shows an interactive iCn3D model of tetrameric FBP enzyme in the T state with bound Mg^{2+}, fructose-6-phosphate, phosphate, and AMP, an allosteric inhibitor, in the T state (1EYJ).

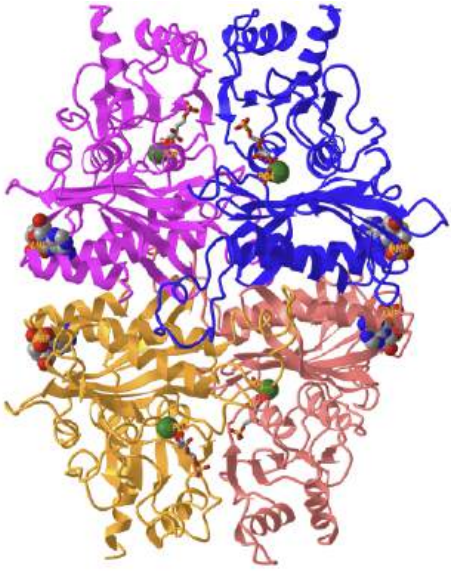

Figure 13.3.19 : Tetrameric fructose-1,6-bisphosphatase in the T state with bound Mg^{2+}, fructose-6-phosphate, phosphate and AMP in the T state (1EYJ). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...UAbjNtkPsoBdA9

FBPase is inhibited by AMP and fructose-2,6-bisphosphate, and activated by ATP. Allosteric changes control the catalytic activity of the enzyme and the transition from the T to the R state, or vice versa. As shown in Figure13.3.17, FBP has 3 metal binding sites. The mechanism shown in Figure 13.3.17 In the model, all of the binding sites are filled with Mg^{2+}, however, Zn^{2+} can also play a role. In the presence of AMP, only one site is occupied by Mg^{2+}, as shown in the model of the T state in Figure13.3.19. The T state form of FBP has a loop (52-72) that is disordered. In the R state (no AMP), the loop interacts with the active site and 1 Zn^{2+} and 2 Mg^{2+} ions are bound in the three sites. The binding of AMP leads to the dissociation of two of the bound metal cofactors and causes a decrease in enzyme activity.

The resulting fructose 6-phosphate is isomerized to glucose 6-phosphate. Glucose 6-phosphate is then converted by the last unique gluconeogenic enzyme, glucose 6-phosphatase, to generate free glucose. The overall reaction is shown below:

Glucose-6-phosphatase: G6P + H_2O → glucose + P_i

The dephosphorylation of glucose only occurs appreciably in liver cells, as this is the primary location for the regulation of blood glucose levels. This serves as the final step in the gluconeogenic pathway. The glucose 6-phosphatase enzyme is a transmembrane protein that resides in the inner membrane of the endoplasmic reticulum. Thus, for glucose 6-phosphate to be dephosphorylated, it must first be transported from the cytoplasm into the lumen of the endoplasmic reticulum (ER) through transporter 1 (T1) (Figure13.3.20). The glucose 6-phosphatase (G-6-Pase) then cleaves the phosphate from the substrate, releasing inorganic phosphate (P) and glucose (red molecule). The inorganic phosphate is then transported back into the cytoplasm through transporter 2 (T2) and glucose is transported through Transporter 3 (T3). Free glucose is then transported back into the bloodstream through a glucose (GLUT) transporter (not shown in Figure13.3.20).

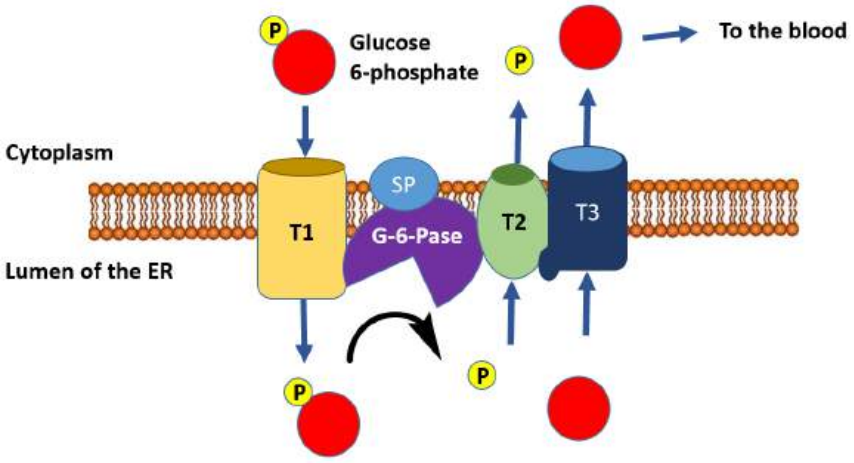

Figure13.3.20 Dephosphorylation of Glucose 6-Phosphate in the Lumen of the Endoplasmic Reticulum.

The catalytic site of this hydrolase enzyme is comprised of Lys76, Arg83, His119, Arg170, and His176. His 176 acts as a nucleophile that attacks the phosphorous of G6P in an S_N2-like reaction to form a His-PO_3^{2-} intermediate. Hydrolysis follows restoring the enzyme to its original state. Figure 13.3.21 shows an abbreviated mechanism for the reaction.

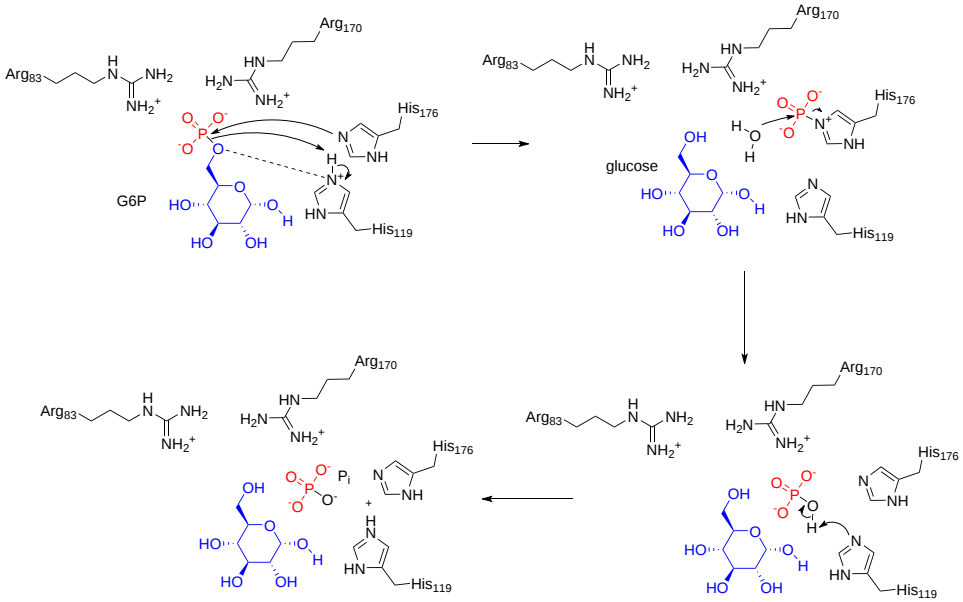

Figure 13.3.21 : Abbreviate mechanism for human glucose-6-phosphatase

Figure 13.3.21 shows an interactive iCn3D model of the AlphaFold predicted structure of human glucose-6-phosphatase (P35575). The enzyme contains nine transmembrane helices that dock the protein in the inner membrane of the ER. The active site faces the ER lumen.

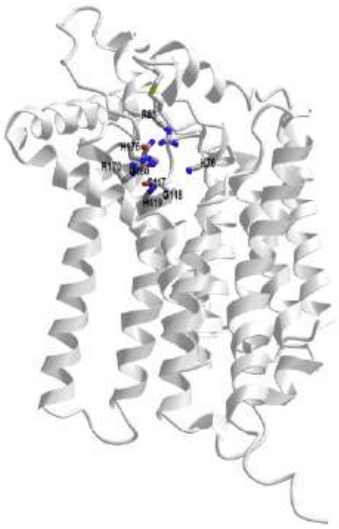

Figure 13.3.14: AlphaFold predicted structure of human glucose-6-phosphatase (**P35575)**(Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...jmcQAo49eZ8p16

13.3.4: SUMMARY:

It is noteworthy that the process of gluconeogenesis is energy intensive. For example, the phosphatase hydrolysis reactions that liberate glucose are not reverse kinase reactions and they do not produce substrate-level phosphorylation the way reactions occur in the second half of the glycolytic pathway. Overall, there are approximately 6 molar equivalents of ATP required to make 1 mole of glucose. Over 3 times as much energy is consumed during glucose formation than is generated from glycolysis during the breakdown of glucose. Per glucose molecule made, 2 ATP are used in the pyruvate carboxylase step, 2 GTP are used in the phosphoenolpyruvate carboxykinase step, and 2 ATP are used in the kinase reaction to create 1,3-bisphosphoglycerate from 3-phosphoglycerate. There is also the loss of 2 moles of NADH during the reverse reaction to create glyceraldehyde 3-phosphate from 1,3-bisphosphoglycerate, which reduces energy potential through oxidative phosphorylation in the mitochondria. Plus there are energy costs to changing the metabolite pools in the matrix of the mitochondria and for transporting molecules across the mitochondrial membrane that we have not considered here.

13.4: PENTOSE PHOSPHATE PATHWAY OF GLUCOSE OXIDATION

13.4.1: INTRODUCTION

The pentose phosphate pathway (PPP), also known as the pentose phosphate shunt, is an important part of glucose metabolism. The PPP branches after the first step of glycolysis and consumes the intermediate glucose 6-phosphate (G6P) to generate fructose 6-phosphate (F6P) and glyceraldehyde 3-phosphate (G3P) through the oxidative and non-oxidative branches of the PPP. Unlike glycolysis and glucose aerobic oxidation, the PPP does not provide adenosine 5′-triphosphate (ATP) to meet the energy demands of cells. Instead, it supplies NADPH and ribose 5-phosphate (R5P). These two metabolites are vital for the survival and proliferation of cells. R5P is a building block for nucleic acid synthesis. NADPH is the reducing power required for the synthesis of fatty acids, sterols, nucleotides, and non-essential amino acids. Moreover, NADPH-derived conversion of oxidized glutathione (GSSG) to reduced glutathione (GSH) *via* glutathione reductase is important for cellular antioxidant defenses. Interestingly, NADPH also serves as the substrate of NADPH oxidases (NOXs) which produce reactive oxygen species (ROS).

Both the oxidative branch and non-oxidative branch of the PPP take place in the cytosol (Figure 13.4.1). Glucose 6-phosphate dehydrogenase (G6PD) is the rate-limiting enzyme of the oxidative PPP, determining the flux of G6P directed into the pathway. G6PD catalyzes the conversion of G6P to 6-phosphogluconolactone, accompanied by NADPH production. 6-phosphogluconolactonase (6PGL) is the enzyme that hydrolyzes 6-phosphogluconolactone to produce 6-phosphogluconate (6PG). 6-phosphogluconate dehydrogenase (6PGD) converts 6-PG to ribulose 5-phosphate (Ru5P) and generates NAPDH (Figure 13.4.1). The largest contributor to cytosolic NADPH is the oxidative PPP in mammalian cells.

The non-oxidative branch is composed of a series of reversible transfer reactions of chemical groups. Ribose 5-phosphate isomerase (RPI) and ribulose 5-phosphate epimerase (RPE) catalyze reversible reactions converting Ru5P to R5P and xylulose 5-phosphate (Xu5P), respectively. TKT catalyzes two reversible reactions. One is the conversion of Xu5P and R5P to G3P and sedoheptulose 7-phosphate (S7P). The other is the conversion of Xu5P and erythrose 4-phosphate (E4P) to G3P and F6P. Therefore, TKT can bi-directionally regulate the carbon flux between the non-oxidative PPP and glycolysis or gluconeogenesis. Transaldolase (TALDO) reversibly converts G3P and S7P to E4P and F6P. The non-oxidative branch not only replenishes metabolites of the oxidative branch (by their reversal), but also regulates the flux of glycolysis or gluconeogenesis by providing F6P and G3P (Figure 13.4.1).

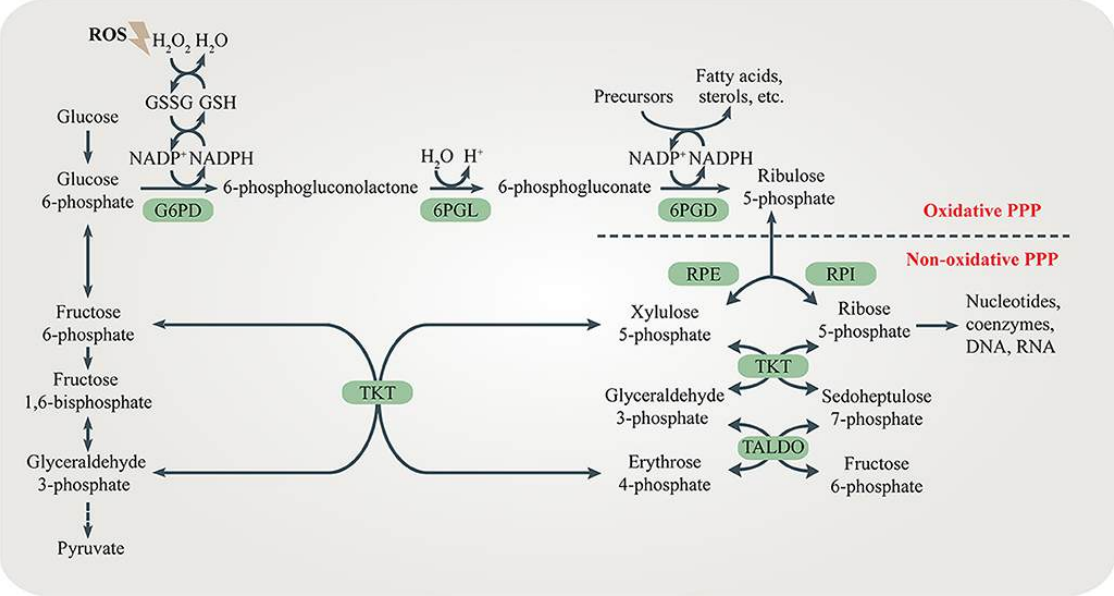

Figure 13.4.1 : The pentose phosphate pathway (PPP). The PPP branches after the first step of glycolysis and goes back to fructose 6-phosphate and glyceraldehyde 3-phosphate in the glycolytic and gluconeogenic pathway. The PPP produces R5P and NADPH for biosynthesis and redox regulation. Enzymes in the oxidative and non-oxidative PPP are shaded in green. Figure from: Ge, T., et al. (2020) Cellular Endocrinology DOI:10.3389

13.4.2: OXIDATIVE BRANCH

The oxidative branch of PPP (ox-PPP) is a non-reversible metabolic pathway where glucose-6-phosphate (G6P) is transformed into 6-phosphoglucono-δ-lactone by glucose-6-phosphate dehydrogenase (G6PD) and, subsequently, to ribulose-5-phosphate by 6-phosphogluconate dehydrogenase (6PGD) with the concomitant production of nicotinamide adenine dinucleotide phosphate (NADPH). The resulting ribulose-5-phosphate is then converted to ribose-5-phosphate and used for the biosynthesis of nucleotides (Figure13.4.2).

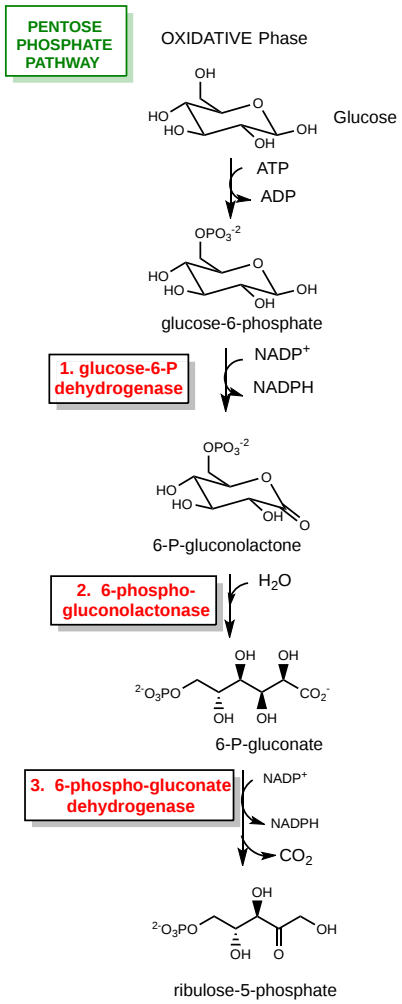

Figure 13.4.2 : Summary of the oxidative branch of phosphopentose pathway

The first enzyme in the oxidative branch is the glucose-6-phosphate dehydrogenase enzyme. It is also the first committed enzyme in the pathway and is involved in the regulation. PPP metabolizes from 5 to 30% of glucose depending on the tissue type. The enzymatic reaction is:

1. Glucose-6-phosphate dehydrogenase: Glc6P + $NADP^+$ → 6-phosphogluconolactone + NADPH

The oxidative branch produces NADPH for reductive biosynthesis and it also maintains the reducing condition of the cell to protect it against oxidative stress, which is especially important in erythrocytes (Figure13.4.3). It also starts the pathway to produce 5-carbon sugars for nucleotide biosynthesis.

G6PDH AND ROS

G6PDH is very important for the protection of free radicals in red blood cells since they don't have mitochondria that could provide another source of NADPH for protection. NADPH is involved in protection against ROS through the three cycles shown in Figure 13.4.3.

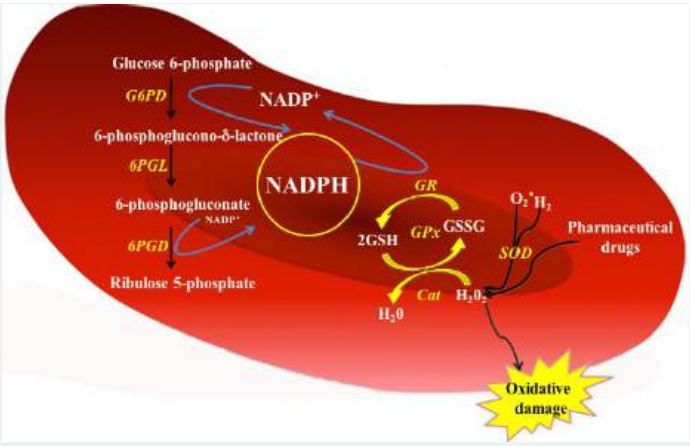

Figure 13.4.3 : Function of G6PD enzyme in the PPP from red blood cells. In G6PD-normal red cells, the NADPH is produced by the action of glucose 6-phosphate dehydrogenase (G6PD) and 6-phosphogluconate dehydrogenase (6PGD) enzymes. The NADPH serves as a proton donor to regenerate the GSSG oxidized. Cat = Catalase; GPx = Glutathione peroxidase; GR = Glutathione reductase; G6PD = glucose 6-phosphate dehydrogenase; 6PGL = 6-phosphogluconolactonase; 6GPD = 6-phosphogluconate dehydrogenase; SOD = Superoxide dismutase; GSH = Reduced glutathione; GSSG = Oxidized glutathione; H_2O_2 = Peroxide; O_2^- = Superoxide. Gomez-Manzo et al. Int J Mol Sci. 2016 Dec; 17(12): 2069. doi: 10.3390/ijms17122069. Creative Commons Attribution (CC-BY) license (http://creativecommons.org/licenses/by/4.0/).

NADPH can keep glutathione in its reduced form, which as a substrate for catalase can help rid the cell of hydrogen peroxide and indirectly other ROS.

The enzyme is active as a dimer or tetramer. Each monomer in the complex has a substrate binding site that binds to G6P, and a catalytic coenzyme binding site that binds to $NADP^+$/NADPH. For some higher organisms, such as humans, G6PD contains an additional $NADP^+$ binding site, called the $NADP^+$ structural site, that does not seem to participate directly in the reaction catalyzed by G6PD. The evolutionary purpose of the $NADP^+$ structural site is unknown, however, it does play a role in the overall stability of the enzyme.

Mutations that cause dysfunction or deficiencies are very common, especially in males and in Africa, Asia, the Mediterranean, and the Middle East, in a geographic distribution that parallels the incidence of malaria. Interestingly, many of the mutations occur near the $NADP^+$ structural site. Glucose-6-phosphate dehydrogenase deficiency is very common worldwide and causes acute hemolytic anemia in the presence of simple infection, ingestion of fava beans, or reaction with certain medicines.

An abbreviate mechanism for glucose-6-phosphate dehydrogenase from *Leuconostoc mesenteroides* is shown in Figure 13.4.4.

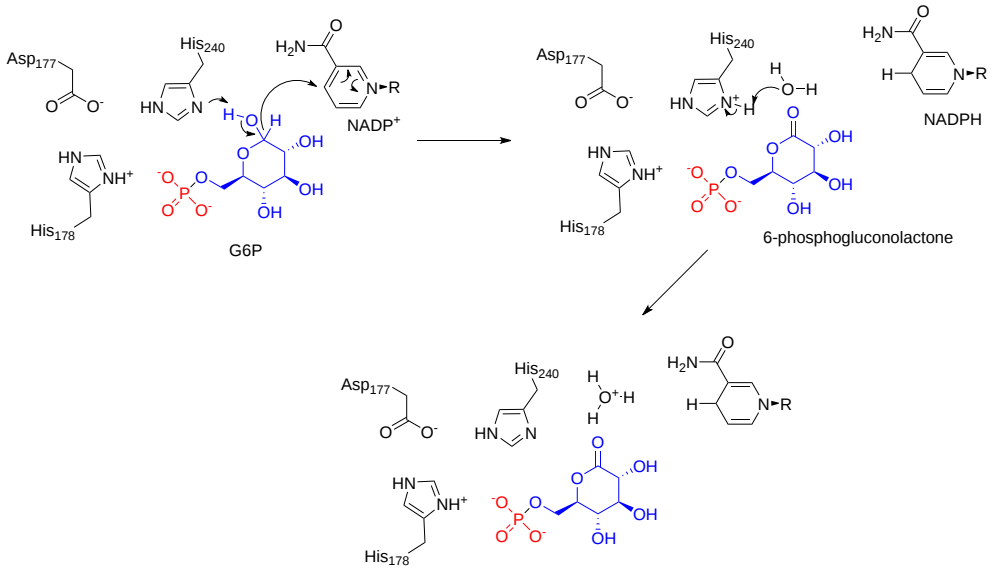

Figure 13.4.4 : Mechanism of *Leuconostoc mesenteroides* glucose-6-phosphate dehydrogenase. Ribeiro AJM *et al.* (2017), *Nucleic Acids Res*, **46**, D618-D623. Mechanism and Catalytic Site Atlas (M-CSA): a database of enzyme reaction mechanisms and active sites.

Figure 13.4.5 shows an interactive iCn3D model of the glucose 6-phosphate dehydrogenase from Leuconostoc mesenteroides (1DPG).

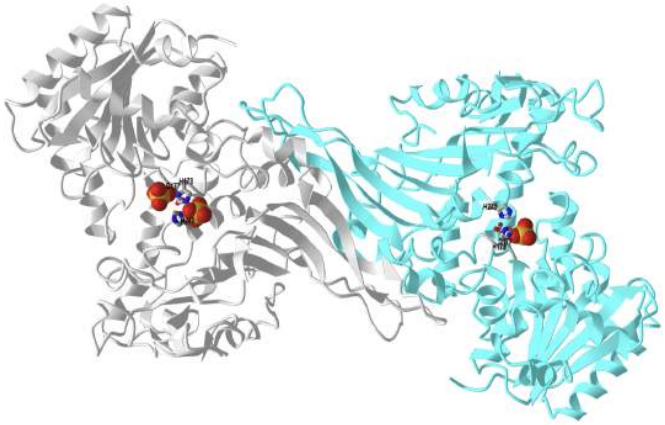

Figure 13.4.5 : Glucose 6-phosphate dehydrogenase from Leuconostoc mesenteroides (1DPG). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...m8NCXiBuQbTQb7

Interestingly, this bacteria has an incomplete glycolytic pathway and can use this enzyme with either $NADP^+$ for anabolism or NAD^+ for catabolism.

Each monomer can bind two $NADP^+$, one at a site that promotes structure integrity and stability and the other at the catalytic site where $NADP^+$ serves as a substrate (or cofactor). The other substrate, glucose-6-phosphate bind between the two.

Figure 13.4.6 shows an interactive iCn3D model of the human glucose 6-phosphate dehydrogenase with bound structural and substrate $NADP^+$ (2BH9).

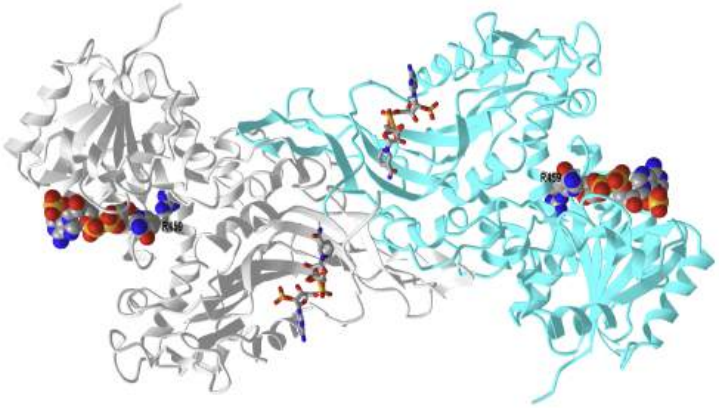

Figure 13.4.6 : Human glucose 6-phosphate dehydrogenase with bound structural and substrate NADP (2BH9). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?NFJnS7UtUt3Uwu2D7

The biological unit shown is a dimer. The structural $NADP^+$ is shown in spacefill bound in the N-terminal end of each monomer, while the substrate (cofactor) $NADP^+$ is shown in sticks. Arg 459 is shown in spacefill.

A common disease-causing mutation of G6PDH is the Canton R459L mutation. It's common in China and Southeast Asia. The activity of the enzyme is significantly decreased and the enzyme is less able to form tetramers. It unfolds at a lower temperature. This suggests that the mutation causes a significant conformation change. The Arg459 is shown in the above model. Its contribution to interhelical noncovalent attractions between it and D181 and N185. D181 is shown in proximity to Arg459 in the above model.

Figure 13.4.7s shows a static image of glucose 6-phosphate dehydrogenase with bound structural and substrate $NADP^+$ as well as glucose-6-phosphate.

Figure 13.4.7 : Glucose 6-phosphate dehydrogenase with bound structural and substrate $NADP^+$ as well as glucose-6-phosphate (2BHL and 2BH9). Structural $NADP^+$ (**blue** molecular surface), catalytic $NADP^+$ (dark **purple** molecular surface), and G6P substrate (**yellow** molecular surface) in the dimer are shown. The two monomers are shown in **cyan** and **green**. Right inset, close-up of the dimer interface and both structural $NADP^+$ molecules. Gomez-Manzo et al., ibid.

The second reaction of the oxidative branch is mediated by the phosphogluconolactonase (6PGL, PGLS) enzyme. The overall reaction is shown here:

2. 6-phosphogluconolactamase: 6-phosphogluconolactone + H_2O → 6-phosphogluconate

6PGL is a cytosolic enzyme found in all organisms that catalyzes the hydrolysis of 6-phosphogluconolactone to 6-phosphogluconic acid in the oxidative phase of the pentose phosphate pathway. 6PGL hydrolysis of 6-phosphogluconolactone to 6-phosphogluconic acid has been proposed to proceed via proton transfer to the O5 ring oxygen atom (Figure 13.4.8). The reaction initiates via the attack of a hydroxide ion at the C5 ester. A tetrahedral intermediate forms and the elimination of the ester linkage follows, aided by the donation of a proton from an active site histidine residue.

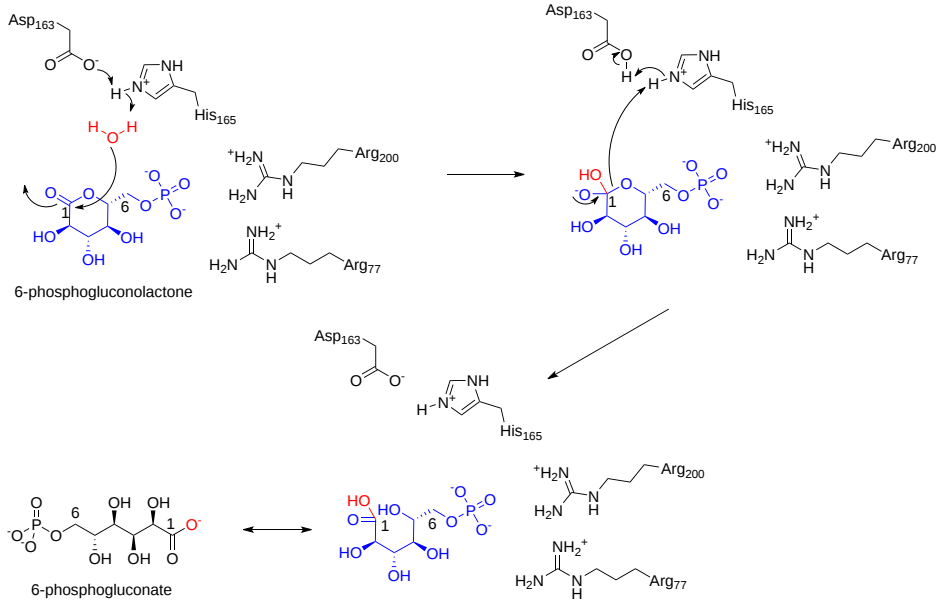

Figure 13.4.8 : Mechanism for6-phosphogluconolactamase His 165 and Asp 163 appear to be involved in a proton relay scheme. His 163 is conserved in lactonase. Arg 77 and 200 are involved in binding the substrate.

Figure 13.4.9 shows an interactive iCn3D model of the 6-phosphogluconolactonase from Trypanosoma brucei complexed with 6-phosphogluconic acid (3E7F). This enzyme is a target for developing drug treatment strategies for African sleeping sickness.

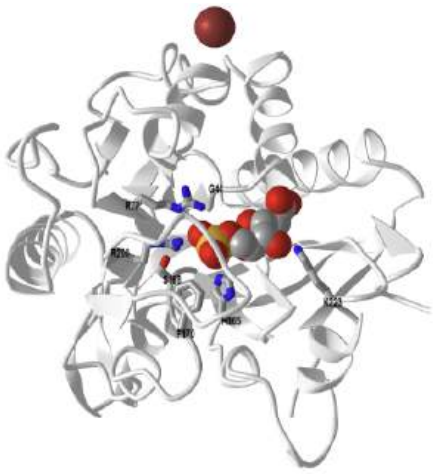

Figure 13.4.9 : 6-phosphogluconolactonase from Trypanosoma brucei complexed with 6-phosphogluconic acid (3E7F). The key residues involved in binding and the charge relay system are shown in sticks and labeled. The product, 6-phosphogluconic acid, is shown in spacefill. The single sphere is a Zn^{2+} which does not appear to be involved in catalysis. (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?jRgi1nfrSGGgTYWo8

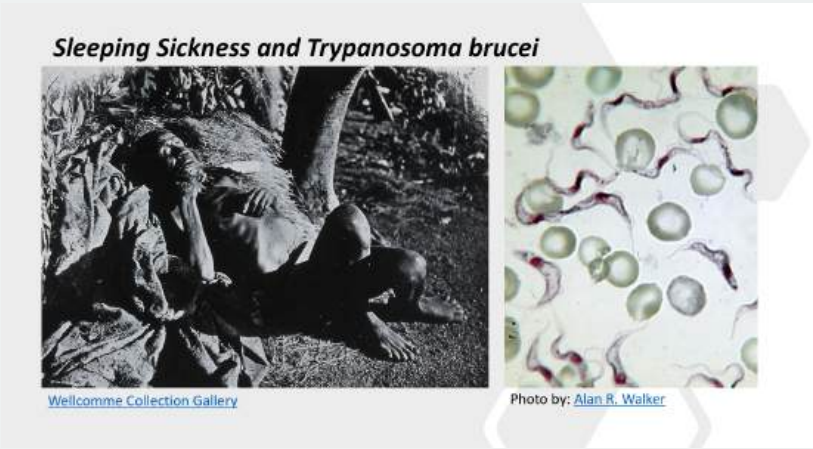
GLYOXOSOMES AND GLYCOSOMES



Trypanosomiasis is a disease usually referring to African human trypanosomiasis or African sleeping sickness. This infectious disease is caused by the parasites *Trypanosoma brucei gambiense or Trypanosoma brucei rhodesiense* cause this infectious disease, and the tsetse fly transmits the disease.

The vector tsetse fly, *Glossina*, carries the trypanosome within the midgut after a blood meal. These protozoa then migrate to the salivary glands of the fly whereby they can be transmitted during the next feeding. After inoculation within the host, the parasite can live freely within the bloodstream and evade mammalian host defenses through variable surface glycoproteins (VSG). The clinical disease has 2 stages. These are characterized by an early/first hemolymphatic stage and a late /second meningoencephalitis stage with an invasion of the central nervous system (CNS). In stage 1, systemic symptoms develop including intermittent fever, headache, pruritus, and lymphadenopathy. Undulating fevers reflect parasites multiplying within the blood. Less frequent hepatosplenomegaly may occur in the early stage. In the late/second stage, CNS symptoms manifest as sleep disturbances or neuropsychiatric disorders. A sleep disorder is the most common symptom of the second stage, and it is from this that the term “African sleeping sickness” was ascribed.

13.4.3: NEW DRUG TARGETS:

Enzymes involved in the pentose phosphate pathway provide a new set of drug targets to help combat parasitic infections such as those caused by trypanosomes. In this context, a focus for new therapeutics has been on the disruption of glycosomes within these organisms. Glyoxosomes are specialized peroxisomes found in plants and some fungi. They all have enzymes for the glyoxylate shunt and can hence create some glucogenic intermediates. In trypanosomes and Leishmania, another internal organelle called the glycosome is

found. This houses most of the glycolytic enzymes and also the oxidative enzymes of the pentose phosphate pathway. This makes the enzymes in the glycosome unique drug targets.

The third enzyme utilized in the oxidative branch of the PPP is 6-phosphogluconate dehydrogenase (6PGDH). The overall reaction is shown here:

3. 6-phosphogluconate dehydrogenase: 6-phosphogluconate + $NADP^+$ ↔ ribulose-5-phosphate + NADPH + CO_2

6PGDH catalyzes a reversible oxidative decarboxylation reaction, as shown in Figure 13.4.10. Oxidation, followed by decarboxylation forms an endiol intermediate followed by conversion to product. Notably, $NADP^+$ serves as an electron acceptor in the reaction, leading to the production of a second molecule of NADPH. Essentially, an active center lysine abstracts a proton from the substrate, 6-phosphogluconate, and NADP+ is reduced, causing the formation of a ketone-intermediate. Decarboxylation leads to the formation of the enediol intermediate. The active site lysine abstracts a proton in the second half of the reaction causing the formation of ribulose 5-phosphate. The abstracted proton is transferred to the active site Glu_{190} resetting the enzyme for another catalytic cycle.

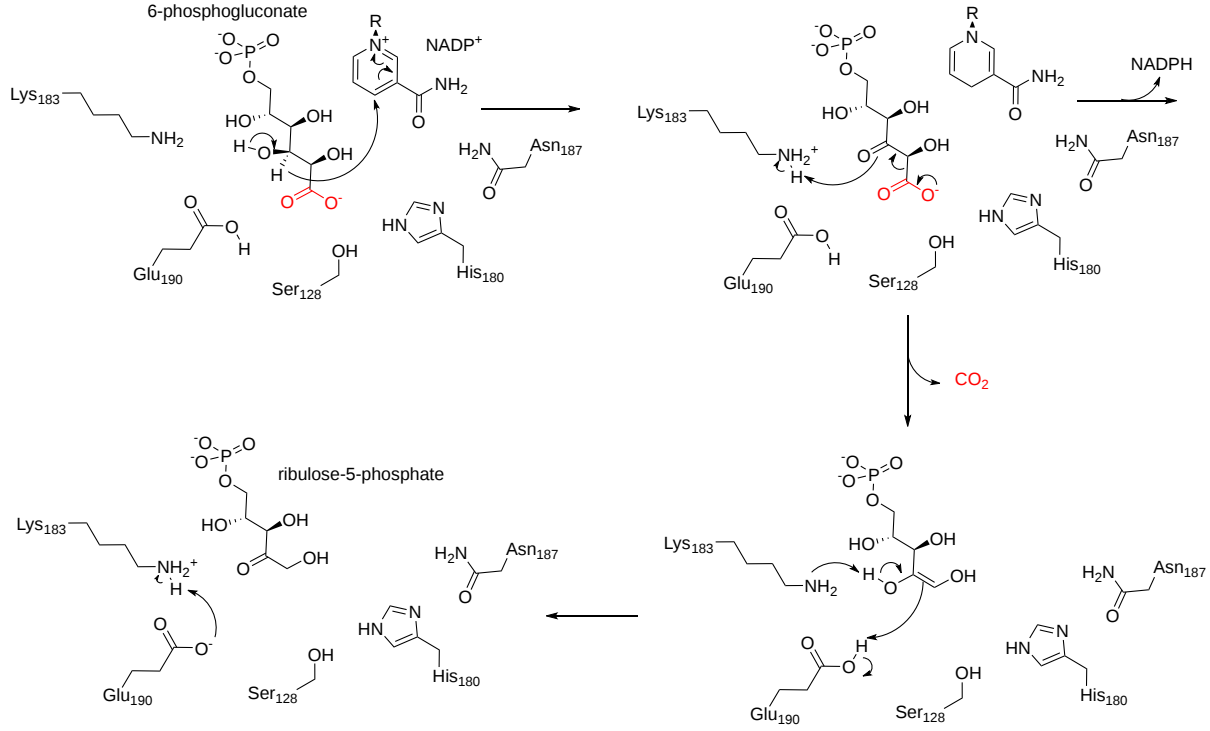


Figure 13.4.10 : Mechanism of 6-phosphogluconate dehydrogenase.

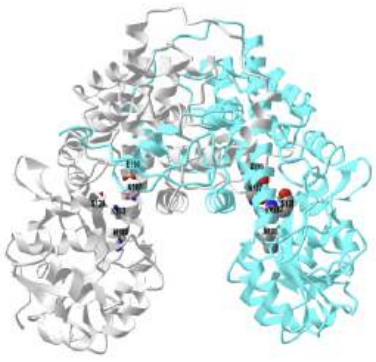
Figure 13.4.11 shows an interactive iCn3D model of sheep 6-phosphogluconate dehydrogenase (2PGD).



NCBI iCn3D **Figure 13.4.11 : Sheep 6-phosphogluconate dehydrogenase (2PGD).** (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...DqosWmFg1DqK16

The protein is a homodimer in which the monomers act independently: each contains a large, mainly alpha-helical domain and a smaller beta-alpha-beta domain, containing a mixed parallel and anti-parallel 6-stranded beta-sheet. $NADP^+$ is bound in a cleft in the small domain,

the substrate binding in an adjacent pocket.

13.4.4: NONOXIDATIVE BRANCH

The non-oxidative branch of the pentose phosphate pathway (nonox-PPP) is responsible for the formation of simple sugars within the cell and maintaining these building blocks in appropriate concentrations. The enzymes utilized in this pathway mediate a set of reversible reactions that lead to the production of ribose-5-phosphate, xylulose-5-phosphate, sedoheptulose 7-phosphate, and erythrose 4-phosphate, as well as intermediates utilized in the glycolytic pathway, including glyceraldehyde-3-phosphate and fructose-6-phosphate Major enzymes utilized include transketolase (TKT) and transaldolase (TALDO), as well as important isomerase and epimerase enzymes.

Ribose 5-phosphate is an important building block for the biosynthesis of nucleotides, and erythrose 4-phosphate is used in the synthesis of aromatic amino acids. When these simple sugars are in excess, they can also be converted into glycolytic intermediates and utilized for energy production.

The nonoxidative branch of the phosphopentose pathway is shown in Figure 13.4.12.

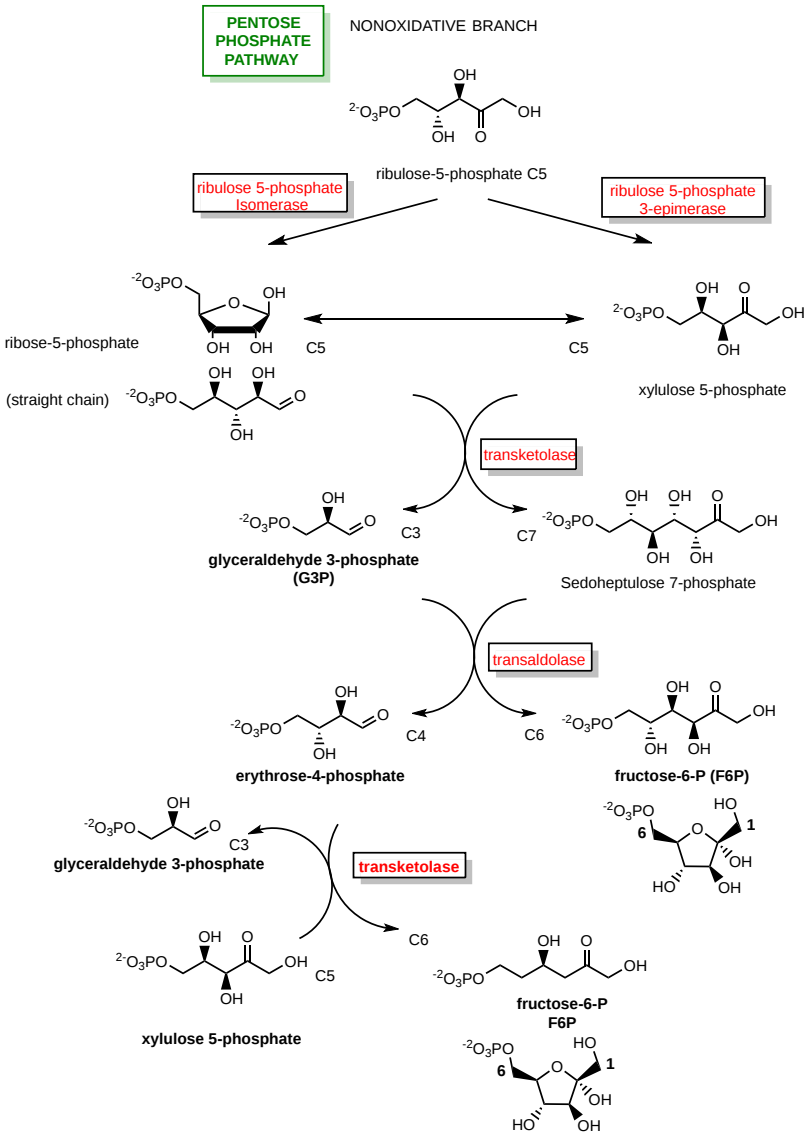


Figure 13.4.12 :Nonoxidative branch of the phosphopentose pathway

Now let's examine the individual enzymes. Ribulose 5-phosphate is the starting place for the non-oxidative portion of the PPP. It can be converted down two different pathways, either to ribose-5-phosphate or to xylulose-5-phosphate. The ribose 5-phosphate isomerase is involved in the ketose-aldose conversion and will be the first enzyme discussed.

Ribose-5-phosphate isomerase (Rpi)

This enzyme is fully reversible and is usually referred to as ribose-5-phosphate isomerase, although it can also be known as ribulose 5-phosphate isomerase, as it mediates the transition between this aldose-ketose pair. In addition to the PPP, this enzymatic reaction is also required in the Calvin cycle in photosynthesis.

There are two different Rpi enzymes, RpiA and RpiB, which have little sequence or structural similarities as well as different mechanisms. RpiA is found in all three kingdoms of life and is highly conserved due to its role in the PPP and the Calvin Cycle of photosynthesis. RpiB, on the other hand, is only found in some bacteria and protozoans. Thus, RpiB is a potential therapeutic target for the treatment of diseases such as African Sleeping Sickness, Chagas disease, and leishmaniasis. While RpiA and RpiB are structurally very different, both enzymes catalyze the isomerization reaction through an enediol intermediate using the linear form of the sugar. The reaction mechanism of RpiB is detailed below.

Figure 13.4.13 shows a mechanism for *Escherichia coli* RpiB.

Figure 13.4.13 : Mechanism for *Escherichia coli* RpiB. https://www.ebi.ac.uk/thornton-srv/m-csa/entry/680/. Creative Commons Attribution 4.0 International (CC BY 4.0) License.

RpiB is a homodimer that can form a tetramer. The monomer subunits are coordinated in a head-to-tail format, such that there are two active sites per dimer where side chains from each monomer contribute to each active site (Figure 13.4.14). The reaction mechanism requires two major steps: (1) ring opening of the furanose form of the sugar, and (2) isomerization through an enediol intermediate (Figure 13.4.13). Figure 13.4.14 shows an interactive iCn3D model of Ribose-5-phosphate isomerase (RPIB_AlsB) from Escherichia coli (1NN4).

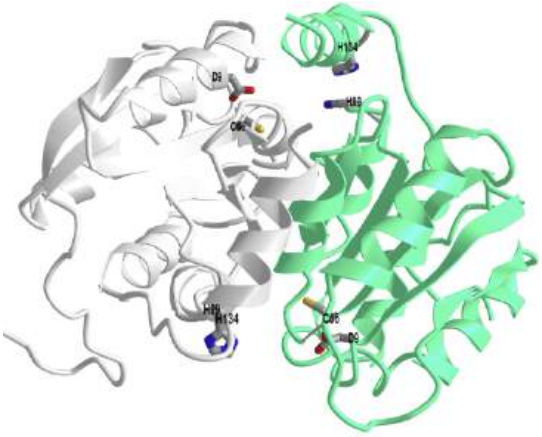

Figure 13.4.14 : Ribose-5-phosphate isomerase (RPIB_AlsB) from Escherichia coli (1NN4). Active site residues are indicated in each of the monomer subunits. (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...ByuLUqhhs9B8c9

The other major pathway for ribulose 5-phosphate conversion involves the ribulose 5-phosphate (3) epimerase (RPE) and the conversion to xylulose 5 phosphate.

Ribulose-5-phosphate (3) epimerase (RPE)

This enzyme is also called pentose-5-phosphate 3-epimerase or PPE. Sugar epimerase enzymes alter the stereochemistry of the sugar at one of the alcohol positions creating a different epimer. The RPE enzyme has a Zn^{2+} cofactor, however, its requirement for enzyme activity is not essential. A Zn^{2+} independent form can still function and stabilize an oxyanion intermediate with adjacent and conserved methionines. A mechanism of the Zn^{2+} dependent form of the enzyme is shown in Figure 13.4.15.

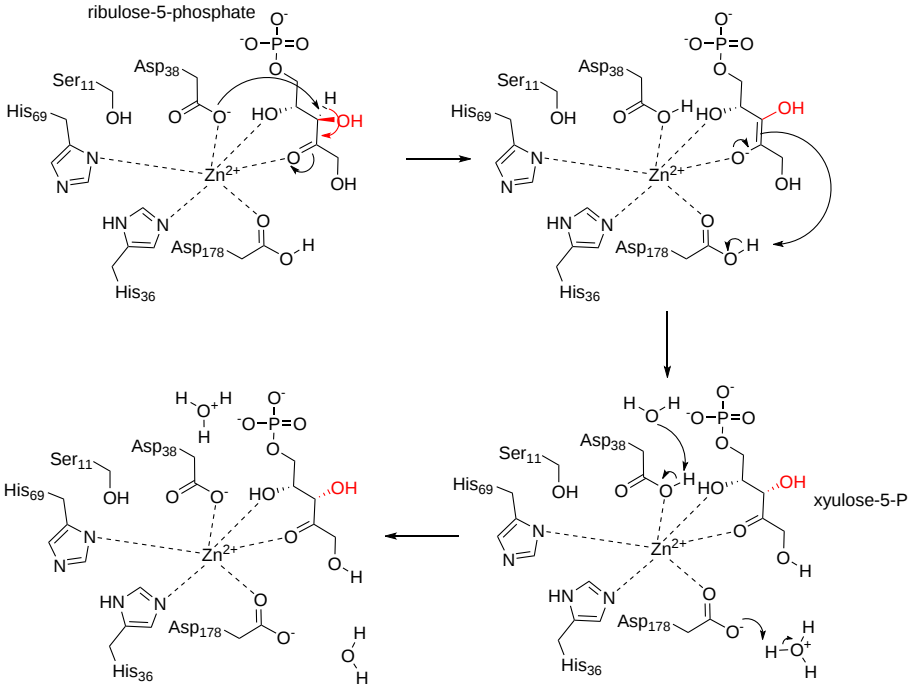

Figure 13.4.15 : Mechanism for rice ribulose-5-phosphate epimerase

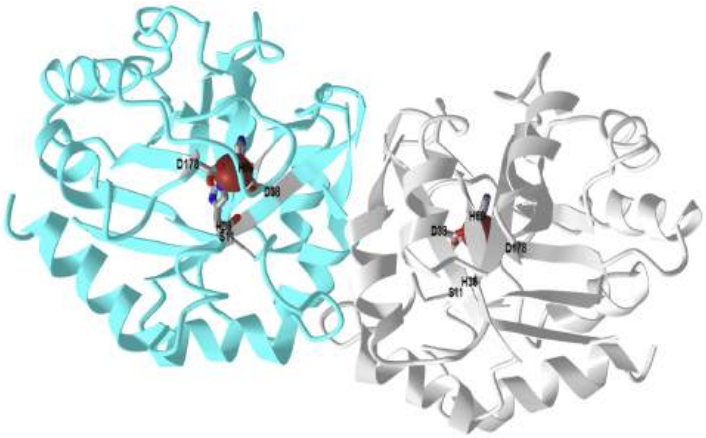
The enzyme utilizes an acid/base catalytic mechanism that mediates the formation of a trans-2,3-enediol phosphate intermediate. Key aspartic acid residues act as proton donors and acceptors during the reaction. A zinc metal cofactor helps stabilize charges during the reaction.

Figure 13.4.16 shows an interactive iCn3D model of cytosolic D-ribulose-5-phosphate 3-epimerase from rice (1h1z).



NCBI iCn3D **Figure 13.4.16 : Cytosolic D-ribulose-5-phosphate 3-epimerase from rice (1h1z).** (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...AH7uS2T8hsnpXA

Transketolase (TK)

The pool of ribose 5-phosphate that is created can be utilized for nucleotide production, or some of it can undergo a reaction with the xylulose 5-phosphate created in the RPE reaction. The transketolase enzyme converts two five-carbon sugars (ribose 5-phosphate and

xylulose 5-phosphate) into a 3-carbon and a 7-carbon sugar (glyceraldehyde 3-phosphate and sedoheptulose 7-phosphate). Essentially, transketolase enzymes transfer ketone functional groups from ketoses to aldoses, effectively creating a new ketose that is two carbons larger. The ketose donor then becomes an aldose with two fewer carbons. The basic transketolase reaction shown in Figure 13.4.17

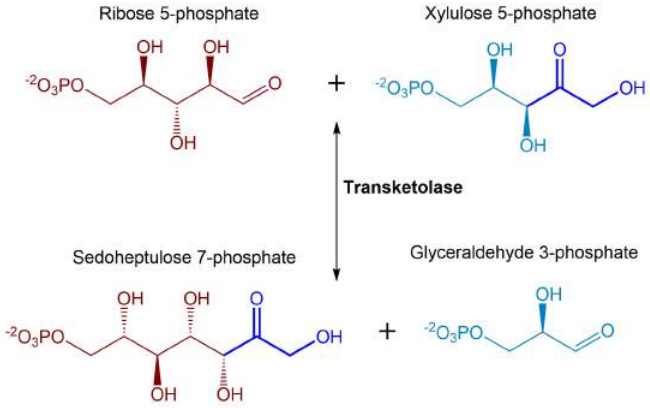


Figure 13.4.17 : Transketolase reaction. The reaction shows the reversible conversion of ribose 5-phosphate and xylulose 5-phosphate to sedoheptulose 7-phosphate and glyceraldehyde 3-phosphate.

Note the number of carbons in the reactants and products: 5C + 5C ↔ 3C + 7C. In this reversible reaction, the enzyme uses the cofactor thiamine pyrophosphate (TPP) and a divalent cation. The enzyme transfers a 2C ketol group from xylulose-5-phosphate to ribose-5-phosphate, an aldose. The product glyceraldehyde-3-phosphate is a glycolytic intermediate and can be used in the glycolytic pathway.

The mechanism for the reverse reaction (yeast numbering system) is shown in Figure 13.4.18. In this reaction, sedoheptulose 7-phosphate binds with the enzyme and the TPP cofactor is activated to form a carbanion. The carbanion mediates nucleophilic attack on the carbonyl carbon of the substrate forming a covalent intermediate. His_{263} serves as a base and abstracts a proton, enabling bond cleavage and the formation of ribose 5-phosphate. Ribose 5-phosphate leaves the active site and glyceraldehyde 3-phosphate enters. The two carbon intermediate covalently bound to the TPP mediates nucleophilic attack on the glyceraldehyde 3-phosphate enabling the formation of xylulose 5-phosphate and the restoration of the enzyme.

Figure 13.4.18 : Mechanism of the transketolase reaction during the pentose phosphate pathway.
https://www.ebi.ac.uk/thornton-srv/m-csa/entry/219/

Figure 13.4.19 shows an interactive iCn3D model of Human transketolase in a covalent complex with donor ketose D-xylulose-5-phosphate (4kxv).

Figure 13.4.19 : Human transketolase in covalent complex with donor ketose D-xylulose-5-phosphate (4kxv). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...WtGtQ7mKA6UYx7

The enzyme is a dimer (gray and cyan coloring). Numbering of key residues compared to yeast mechanism:

Human	Yeast
E366	E418
Q428	H481
H258	H262
H38	H30

Also shown are human active site residues H474, R318, and S345. The covalent xylulose-5-phosphate adduct is shown in spacefill and labeled DX5 (xylitol-5-phosphate). TPP is shown in sticks and labeled. The metal ion is Ca^{2+}. Structural analyzes show a 20^0 distortion in the planarity of the cofactor-substrate bond and a lengthening of the C-C bond in the substrate which breaks.

Transaldolase

In addition to being used as a resource in the glycolytic pathway, glyceraldehyde 3-phosphate can also be utilized as a substrate in a transaldolase reaction along with the sedoheptulose 7-phosphate that is produced in the previous reaction. This results in the formation of erythrose 4-phosphate and fructose 6-phosphate. A summary of the reaction is shown in Figure 13.4.20.

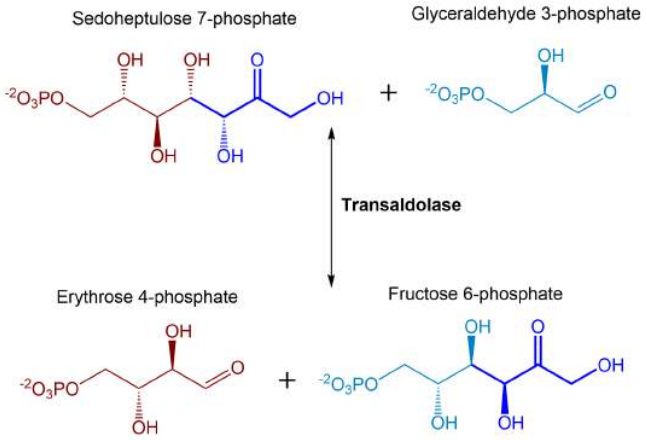

Figure 13.4.20 : Summary of transaldolase reaction

As with transketolase, the transaldolase enzyme is reversible. Again, note the number of carbons in the reactants and products: 3C + 7C ↔ 4C + 6C. Unlike the transketolase used in the last reaction, the transaldolase enzyme does NOT use TPP as a cofactor. Instead, it forms a Schiff base intermediate similar to that of the aldolase enzyme in the glycolytic pathway. The enzyme removes a 3C ketol group

(dihydroxyacetone) from sedoheptulose 7-phosphate and transfers it to glyceraldehyde 3-phosphate forming fructose 6-phosphate. Erythrose 4-phosphate is left from the original sedoheptulose 7-phosphate.

We will explore the mechanism for the *E. Coli* enzyme in the reverse direction. The first part of the mechanism of transaldolase is shown in Figure 13.4.21.

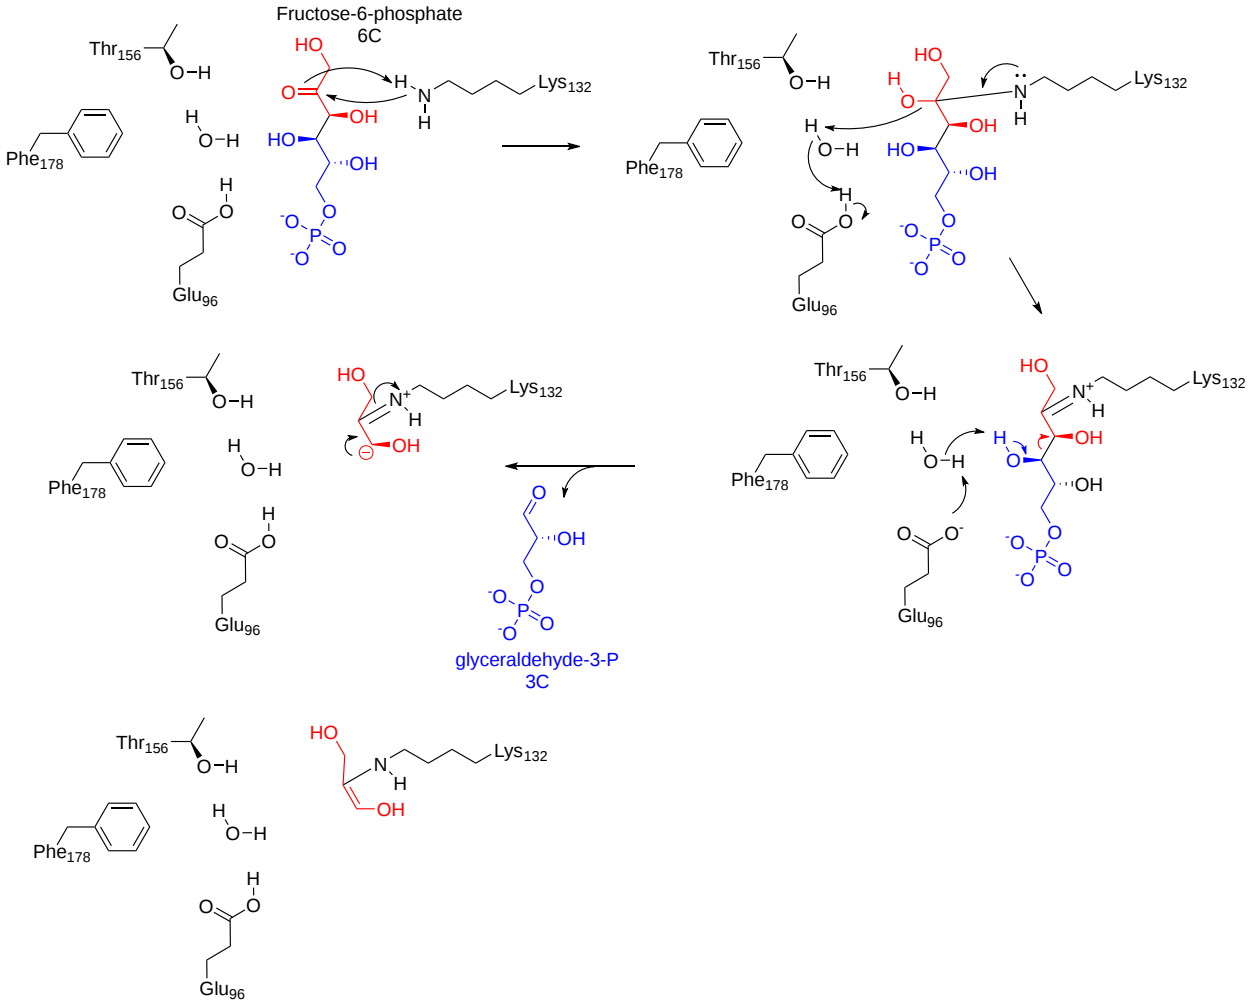

Figure 13.4.21 : Mechanism for the first half of the transaldolase reaction. https://www.ebi.ac.uk/thornton-srv/m-csa/entry/148/

In the first part of the reaction, fructose 6-phosphate binds to the active site of the enzyme, where an active site lysine residue mediates nucleophilic attack on the carbonyl carbon and forms a covalent intermediate with the enzyme. Formation of the Schiff base leads to dehydration of the intermediate. The Schiff base nitrogen becomes protonated and this leads to the oxidation of the C4 hydroxyl leads and subsequent bond cleavage releasing glyceraldehyde 3-phosphate. The remaining ES-complex rearranges to form an enol intermediate.

The mechanism for the second half of the transaldolase reaction is shown in Figure 13.4.22.

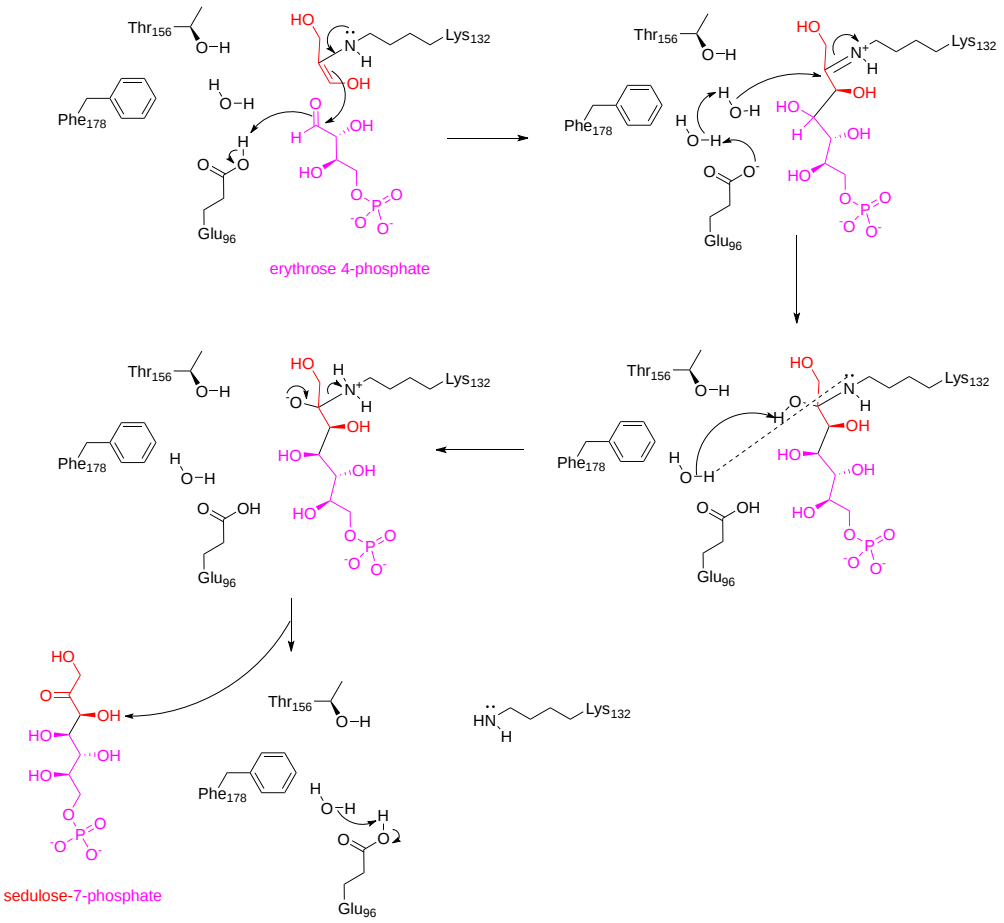

Figure 13.4.22 : Mechanism for the second half of the transaldolase reaction. https://www.ebi.ac.uk/thornton-srv/m-csa/entry/148/

Once glyceraldehyde 3-phosphate has left the active site of the enzyme, erythrose 4-phosphate can bind. The enol from the ES intermediate mediates nucleophilic attack on the aldehyde carbonyl group of erythrose 4-phosphate. This results in the formation of a Schiff base intermediate. Hydration at the Schiff base carbon atom ensues followed by the oxidation of the newly incorporated alcohol to form a ketone functional group. Formation of the ketone causes bond cleavage between the enzyme and the newly formed ketose, sedoheptulose 7-phosphate.

Figure 13.4.23 shows an interactive iCn3D model of transaldolase B from Escherichia coli (1ONR).

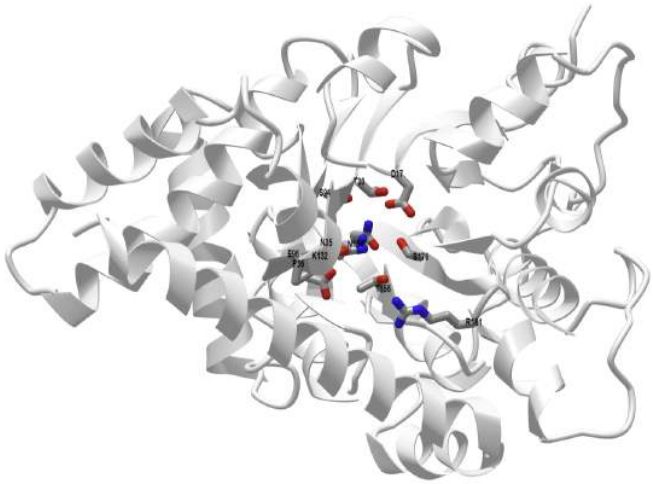

Figure 13.4.23 : 3D structure of Transaldolase B from E. coli (1ONR). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...7swLZVpNPe3eU9

Transketolase

As seen above, fructose 6-phosphate is a product of the transaldolase enzyme during the nonoxidative branch of the PPP. This sugar can feed back into the glycolytic cycle. The formation of fructose 6-phosphate can also occur using the transketolase enzyme when it transfers a 2C ketol group from xylulose 5-phosphate to the aldose, erythrose 4-phosphate. This reaction is summarized in Figure 13.4.24.

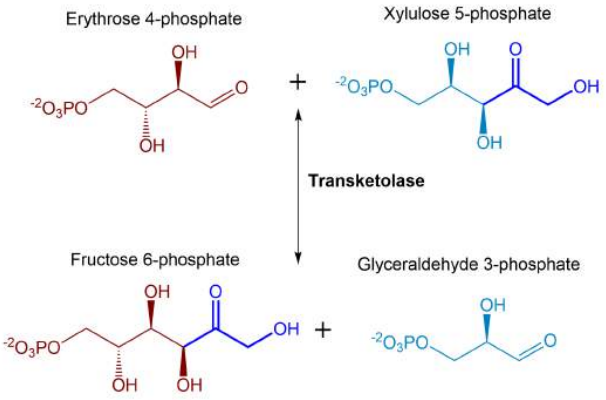

Figure 13.4.24 Summary of second transketolase reaction during the pentose phosphate pathway.

Both products of this final transketolase reaction can be utilized in energy formation through glycolysis. Thus, there are clear metabolic ties of the PPP with the energy-producing glycolytic pathway and intermediates from both pathways can easily be exchanged through the activity of these reversible enzymes. The PPP provides key intermediates, including ribose 5-phosphate that is used in the biosynthesis of nucleotides and ultimately nucleic acids, as well as, other important metabolic molecules such as FAD, NAD^+, $NADP^+$, and Coenzyme A. In addition to being a biosynthetic source for these molecules, the PPP also is the primary source for reducing $NADP^+$ to NADPH, during the oxidative reactions. NADPH is utilized in many biosynthetic processes as an electron donor. For example, the biosynthesis of many lipid molecules requires NADPH, including the production of triacylglycerols, phospholipids, and steroids. NADPH is also required for the biosynthesis of some amino acids (such as glutamate and proline) and is also involved in the reduction of ribonucleotides and deoxyribonucleotides during the synthesis of RNA and DNA. NADPH is also utilized by a number of oxidoreductases involved in detoxification reactions within the body. Within the immune system, NADPH oxidases or NOX enzymes are involved in the production of superoxide and utilized to damage invading pathogens nonspecifically. $NADP^+$/NADPH ratios also can play a regulatory role in cellular metabolic processes and are utilized as allosteric effectors for several enzymes and oxidation sensor proteins.

13.4.5: REGULATION OF THE PENTOSE PHOSPHATE PATHWAY

The cellular demand for the two major products of the PPP (ribose 5-phosphate and reduced NADPH) can be different depending on the cell type or the current cellular environment, such as times of increased metabolic demand or oxidative stress. Thus, the two major products may need to be produced in different quantities and independently of one another. For example, we can imagine times when the needs for ribose 5-phosphate and NADPH are in balance with the standard PPP reactions. However, we can also imagine times when the demand for ribose 5-phosphate may be much higher than the demand for NADPH, or vice versa, the demand for NADPH may be much greater than the demand for ribose 5-phosphate. Thus, there are regulatory strategies in place that enable the ability to regulate the production of these different pools independently of one another and adapt to cellular needs. This ability is largely dependent on the production of metabolic intermediates that can be easily interchanged within the glycolytic pathway.

For example, the ratio of $NADP^+$/NADPH serves as a key regulator of the oxidative branch of the PPP. The first enzymatic step of the pathway mediated by the glucose 6-phosphate dehydrogenase (G6PD) is regulated in this fashion and helps control the pool of glucose 6-phosphate that will be utilized within the PPP to produce reduced NADPH. Low levels of $NADP^+$ inhibit the G6PD enzyme. The G6PD reaction is essentially irreversible and serves as the committed step for glucose to enter into the oxidative portion of the PPP. Thus the regulation of this enzymatic step is key in the regulation of NADPH levels within the cell. When the ratio of $NADP^+$/NADPH increases, G6PD becomes more active and the reduction of $NADP^+$ to NADPH increases.

When ribose 5-phosphate is also in high demand, the pool of ribose 5-phosphate will be low and increase the activity of the ribose 5-phosphate isomerase in the forward direction to convert the ribulose 5-phosphate produced in the oxidative branch to generate more ribose 5-phosphate.

However, if more ribose 5-phosphate is required than can be supplied from the activity of the oxidative branch, the pool of ribose 5-phosphate can be fed from the conversion of intermediates from the glycolytic pathway in the nonoxidative branch of the PPP. The opposite occurs as well when there is a high need for NADPH in the cell but a low need for ribose 5-phosphate. In this situation, ribose 5-phosphate is converted to fructose and glyceraldehyde 3-phosphate and can be incorporated into the glycolytic pathway.

In addition, the activity of the PPP varies depending on the tissue type and location within the body. For example, skeletal muscle has very low PPP activity, as this tissue requires more energy production and activity of the glycolytic pathway. On the other hand, the PPP is highly

active in adipose tissue due to the heightened requirement for intermediates needed for lipid biosynthesis.

14.4: Concentration Control and Elasticity Coefficients
14.5: Metabolism and Signaling: The Steady State, Adaptation and Homeostasis

Thumbnail: Overview of regulatory interactions involved in metabolic regulatory networks. The function of metabolic networks are governed by constraints. The regulation of a metabolic network involves a tight interplay between different cellular networks such as signalling and gene networks and by interactions with its environment. The enzyme capacity is the net result of the amount of enzyme expressed and its activity as dictated by post-translational modification and allosteric regulation. Metabolite pools and fluxes are considered as the outputs of metabolic reaction networks and can be involved in various regulatory feedback loops to other networks within the metabolic reaction networks as indicated by the dashed arrows. (CC BY 3.0; Jan Berkhout, Frank J. Bruggeman, and Bas Teusink via MDPI)

14.1: REGULATION OF METABOLIC PATHWAYS

Exquisite mechanisms have evolved that control the flux of metabolites through metabolic pathways to insure that the output of the pathways meets biological demand and that energy in the form of ATP is not wasted by having opposing pathways run concomitantly in the same cell.

Enzymes can be regulated by changing the activity of a preexisting enzyme or changing the amount of an enzyme.

14.1.1: CHANGING THE ACTIVITY OF A PRE-EXISTING ENZYME

The quickest way to modulate the activity of an enzyme is to alter the activity of an enzyme that already exists in the cell. The list below, illustrated in the following figure, gives common ways to regulate enzyme activity

1. Substrate availability: Substrates (reactants) bind to enzymes with a characteristic affinity (characterized by a dissociation constant) and a kinetic parameter called Km (units of molarity). If the actual concentration of a substrate in a cell is much less than the Km, the activity of the enzyme is very low. If the substrate concentration is much greater than Km, the enzyme's active site is saturated with substrate and the enzyme is maximally active.
2. Product inhibition: A product of an enzyme-catalyzed reaction often resembles a starting reactant, so it should be clear that the product should also bind to the activity site, albeit probably with lower affinity. Under conditions in which the product of a reaction is present in high concentration, it would be energetically advantageous to the cell if no more product was synthesized. Product inhibition is hence commonly observed. Likewise, it is energetically advantageous to a cell if the end product of an entire pathway could likewise bind to the initial enzyme in the pathways and inhibit it, allowing the whole pathway to be inhibited. This type of feedback inhibition is commonly observed. Figure 14.1.1 shows product and end-product inhibition.

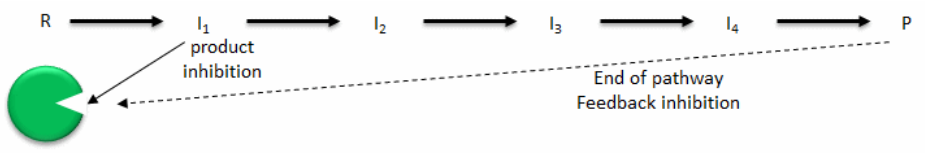

Figure 14.1.1 : Product and end product inhibition of an enzyme

3. Allosteric regulation: As many pathways are interconnected, it would be optimal if the molecules of one pathway affected the activity of enzymes in another interconnected pathway, even if the molecules in the first pathway are structurally dissimilar to reactants or products in a second pathway. Molecules that bind to sites on target enzymes other than the active site (allosteric sites) can regulate the activity of the target enzyme. These molecules can be structurally dissimilar to those that bind at the active site. They do so by conformational changes which can either activate or inhibit the target enzyme's activity.
4. pH and enzyme conformation: Changes in pH that can accompany metabolic processes such as respiration (aerobic glycolysis for example) can alter the conformation of an enzyme and hence enzyme activity. The initial changes are covalent (change in the protonation state of the protein) which can lead to an alteration in the delicate balance of forces that affect protein structure.
5. pH and active site protonation state: Changes in pH can affect the protonation state of key amino acid side chains in the active site of proteins without affecting the local or global conformation of the protein. Catalysis may be affected if the mechanism of catalysis involves an active site nucleophile (for example), that must be deprotonated for activity.
6. Covalent modification: Many if not most proteins are subjected to post-translational modifications which can affect enzyme activity through local or global shape changes, by promoting or inhibiting binding interaction of substrates and allosteric regulators, and even by changing the location of the protein within the cell. Proteins may be phosphorylated, acetylated, methylated, sulfated, glycosylated, amidated, hydroxylated, prenylated, or myristoylated, often in a reversible fashion. Some of these modifications are reversible. Regulation by phosphorylation through the action of kinases, and dephosphorylations by phosphates are extremely common. Control of the phosphorylation state is mediated through signal transduction processes starting at the cell membrane, leading to the activation or inhibition of protein kinases and phosphatases within the cell.

Figure 14.1.2 shows ways to regulate the activity of pre-existing enzymes.

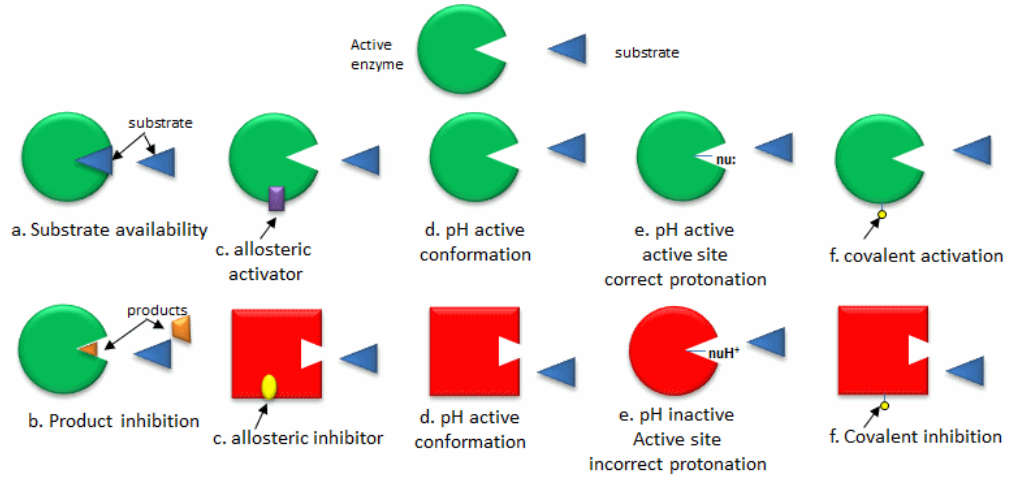

Figure 14.1.2: Ways to regulate the activity of pre-existing enzymes

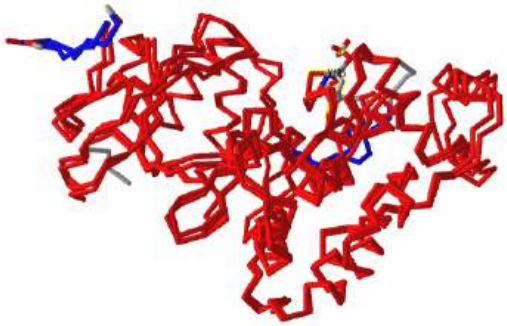
Extracellular regulated kinase 2 (ERK2), also known as mitogen-activated protein kinase 2 (MAPK2) is a protein that plays a vital role in cell signaling across the cell membrane. Phosphorylation of ERK2 on Threonine 183 (Thr153) and Tyrosine 185 (Tyr185) leads to a structural change in the protein and the regulation of its activity.

Figure 14.1.3 shows an interactive iCn3D model showing the structural alignment of ERK2 in the dephosphorylated (5UMO) and phosphorylated (pY185) forms (2ERK). Toggle back and forth between the two structures with the "a" key.



NCBI iCn3D Figure 14.1.3: Structural alignment of ERK2 in the dephosphorylated (5UMO) and phosphorylated (pY185) forms (2ERK). (Copyright; author via source). Click the image for a popup or use this external link:https://structure.ncbi.nlm.nih.gov/i...8iMQUVBbmMTRJ6

The residues that change significantly in conformation on phosphorylation are shown in blue. The side chain of tyrosine 185 in the unphosphorylated form is shown in CPK-colored sticks and labeled.

14.1.2: REGULATION OF SINGLE ENZYMES OR ENTIRE PATHWAYS: ENZYME CONDENSATES

Single enzymes or all the enzymes of a given pathway can be coordinately regulated to maximize end-product output by organizing the enzymes in one large complex built from soluble enzymes that produce a "condensate" through a process similar to phase separation. Such condensates are shown for a series of enzymes in Figure 14.1.4.

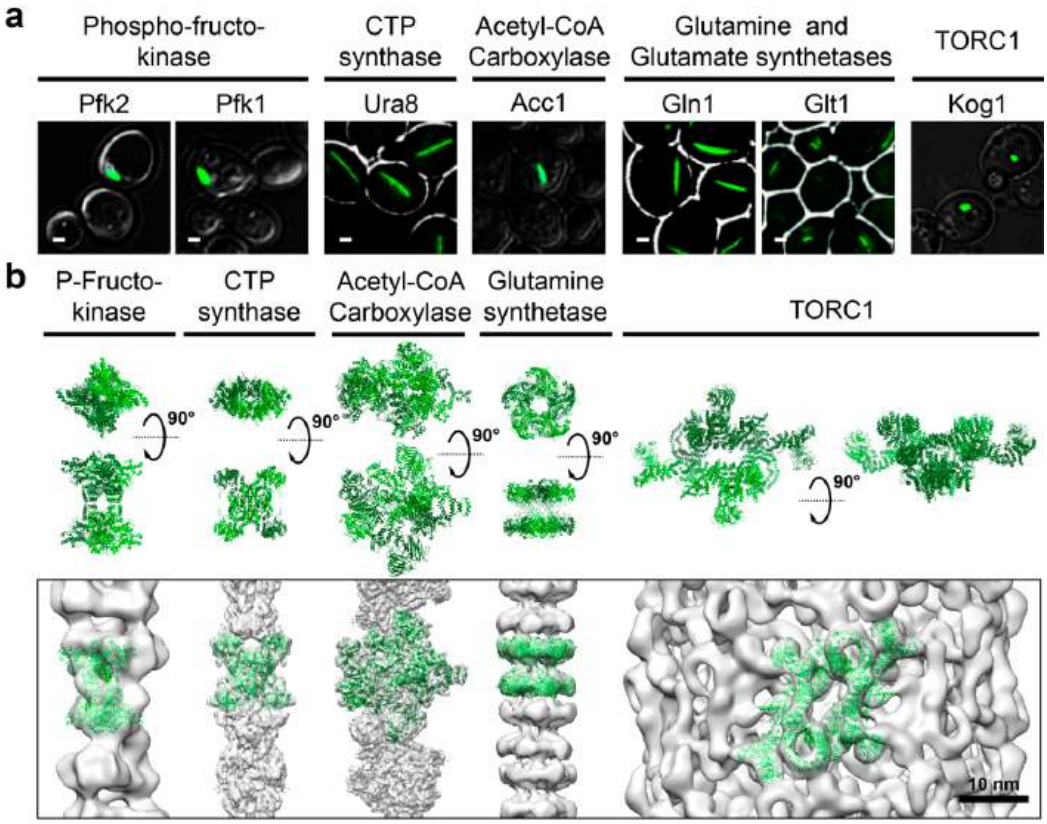


Figure 14.1.4: Supramolecular assembly of enzyme condensates. **Prouteau and Loewith.** *Biomolecules* **2018**, *8*(4), 160; **https://doi.org/10.3390/biom8040160.** Creative Commons Attribution (CC BY) license (**http://creativecommons.org/licenses/by/4.0/**).

The figure shows metabolism-related enzymes that form polymers in various organisms.

Panel (**a**) shows examples of metabolic enzymes observed to coalesce into cytosolic condensates.

Panel (**b**) top shows structures of metabolic enzymes that polymerize into filaments. The protomer of the polymer is shown above and placed into the filament below. These include P-Fructo-Kinase (4XYJ), cytidine triphosphate synthase (5U03), acetyl-CoA carboxylase (6G2D), glutamine synthetase (3FKY), mTORC1 (5FLC) from PDB files.

Panel (**b**) bottom shows the same structures from the Electron Microscopy Data Bank, including P-Fructo-Kinase filament (emd-8542), human CTP synthase filament (and-8474), human acetyl-CoA carboxylase with citrate (emd-4342), and the yeast glutamine synthetase filament.

14.1.3: CHANGING THE AMOUNT OF AN ENZYME

Another longer-duration method to modulate the activity of an enzyme is to alter the activity of an enzyme that already exists in the cell. Figure 14.1.5 shows ways in which enzyme concentrations are regulated.

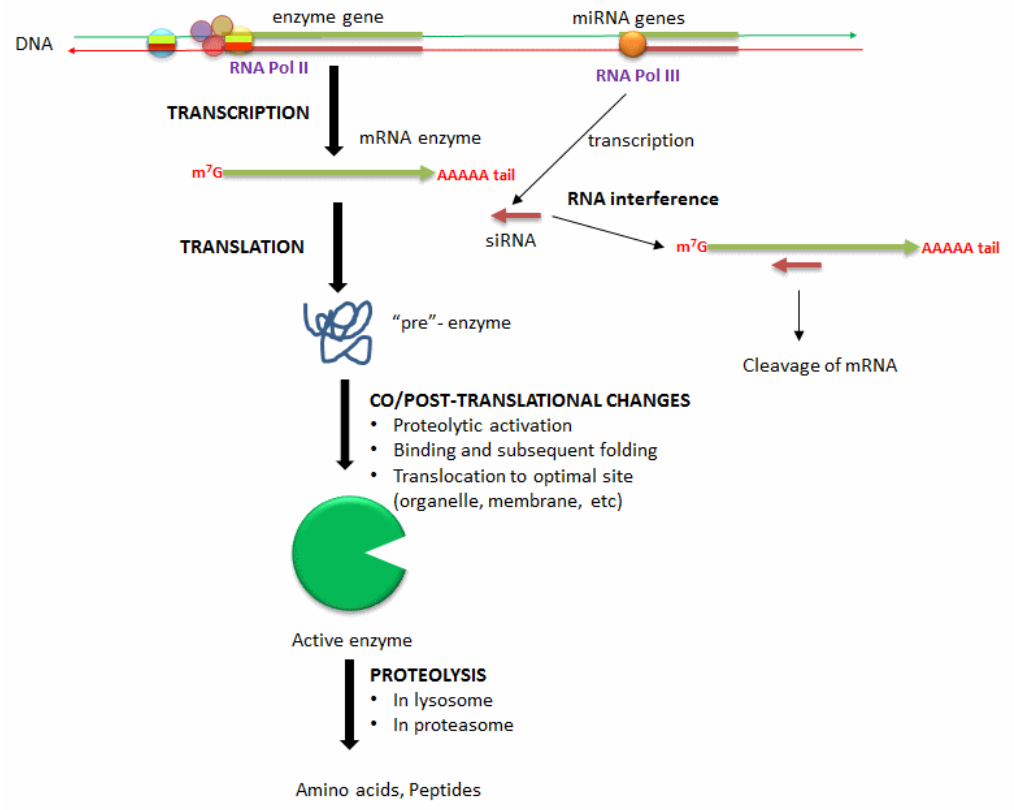

Figure 14.1.5: Ways to regulate the concentration of an enzyme

Methods include:

1. Alterations in the transcription of enzyme's gene: Extracellular signals (hormones, neurotransmitters, etc) can lead to signal transduction responses and ultimate activation or inhibition of the transcription of the gene for a protein enzyme. These changes result from the recruitment of transcription factors (proteins) to DNA sequences that regulate the transcription of the enzyme gene.
2. Degradation of messenger RNA for the enzyme: The levels of messenger RNA for a protein will directly determine the amount of that protein synthesized. Small inhibitor RNAs, derived from microRNA molecules transcribed from cellular DNA, can bind to specific sequences in the mRNA of a target enzyme. The resulting double-stranded RNA complex recruits an enzyme (Dicer) that cleaves the complex with the effect of decreasing the translation of the protein enzyme from its mRNA.
3. Co/Post-translational changes: Once a protein enzyme is translated from its mRNA, it can undergo many changes that regulate its activity. Some proteins are synthesized in a "pre" form which must be cleaved in a targeted and limited fashion by proteases to activate the protein enzyme. Some proteins are not fully folded and must bind to other factors in the cell to adopt a catalytically active form. Finally, fully active protein can be fully proteolyzed by the proteasome, a complex within cells, or in lysosomes, which are organelles within cells containing proteolytic enzymes.

All proteins are ultimately regulated, if only by modulating the rates of their synthesis and degradation. However, some enzymes positioned at key points in metabolic pathways are ideal candidates for regulation, as their activity can affect the output of entire pathways. These enzymes typically have two common characteristics, they catalyze reactions far from equilibrium and they catalyze early committed steps in pathways.

14.1.4: WHICH ENZYMES TO REGULATE: REACTIONS NOT AT EQUILIBRIUM

The optimal enzymes for regulation are those at the beginning of pathways that carry out thermodynamically favored reactions. Why is the latter so important? These enzymes control the flux of metabolites through pathways, so to understand their regulation we can use the analogy of flow (or flux) of water from one container to another as illustrated in Figure 14.1.6.

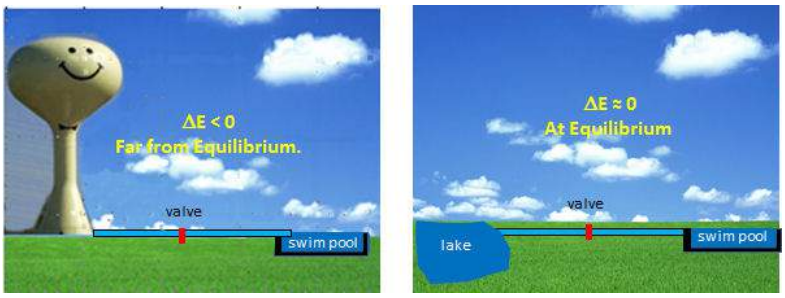

Figure 14.1.6: Regulation of water flow in pipe

Let's say you wish to fill a swimming pool at any desired height you wish and you have two ways to do so (see figure below). You could open a valve that controls the flow from your town's water tower to the pool. In this, the reaction (flow of water) is energetically (thermodynamically) favored given the difference in height of the water levels and the potential energy difference between the two. Even though flow (or flux) is cleared flavored, you can regulate it, from no flow to maximal flow, by opening and closing the valve (analogous to activating and inhibiting an enzyme). Your choices in the other scenario, filling the pool from a lake, are not so great. It would be hard to fill the water to the desired level (especially if it was an above-ground pool). It would be hard to regulate the flow.

By analogy, the best candidates for regulation are those enzymes whose reactions are thermodynamically favored (not at equilibrium) but which can be controlled by the mechanisms discussed in the previous section.

Which reactions are commonly not at equilibrium (i.e. $\Delta G<0$ and usually also $\Delta G^0<0$ if the ratio of products to reactants is not too high)? The answer is those that have reactants that are thermodynamically unstable compared to their reaction products. Several types of reactions often fit these criteria:

Hydrolysis (or similar reactions) of anhydride or analogous motifs: The figure below shows molecules with similar "anhydride" motifs and the ΔG^0 for hydrolysis of the molecules. Those with more negative ΔG^0 values can transfer their phosphate group to ADP to make ATP, which is necessary to drive unfavorable biological reactions. Metabolic reactions that involve hydrolysis (or other types of transfer reaction of these groups) usually proceed with a negative ΔG^0 and ΔG, making them prime candidates for pathway regulation. Many textbooks label these types of molecules as having "high energy" bonds. This is confusing to many students as bonds between atoms lower the energy compare to when the atoms are not bonded. It takes energy to break the "high" energy phosphoanhydride covalent bond. What make hydrolysis of the molecules below so exergonic is that more energy is released on bond formation within the new products than was required to break the bonds in the reactants. In addition, other effects such as preferential hydration of the products, lower charge density in the products, and less competing resonances in the products all contribute to the thermodynamically favorable hydrolysis of the reactants.

Figure 14.1.7 shows thermodynamically unstable molecules (compared to their reaction products in aqueous solutions).

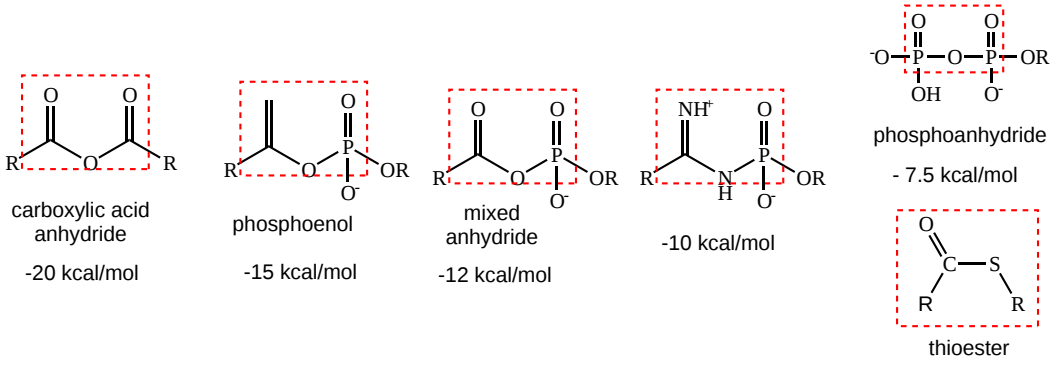

Figure 14.1.7: Molecules that are thermodynamically unstable compared to their hydrolysis products

Thioesters (such as Acetyl-SCoA) are also included as they have the same negative ΔG^0 of hydrolysis as ATP, even though they lack an "anhydride" motif. Thioesters are destabilized compared to their hydrolysis products and in comparison to esters made with alcohol since the C-S bond is weaker. Why?

Redox reactions: Everyone knows that redox reactions are thermodynamically favored if the oxidizing agent deployed is strong enough. The oxidation reactions of hydrocarbons, sugars, and fats by dioxygen are clearly exergonic (we do call these combustion reactions after all). What about redox reactions with less powerful oxidants? NAD^+ is used frequently as a biological oxidizing agent. Are all these reactions as favored as combustion? Hardly so. Remember that in every redox reaction, an oxidizing and reducing agent react to form another oxidizing and reducing agent. Consider the following reaction:

$$\text{Pyruvate} + \text{NADH} \leftrightarrow \text{Lactate} + \text{NAD}^+.$$

This reaction can go either way and is reversible. The above form is written in the favored direction in anaerobic metabolism when both Pyr and NADH levels are high. Although the ΔG^0 favors the oxidation of lactate, given the high concentration of Pyr and NADH, the reaction is driven in the opposite direction and proceeds as shown. To determine if a redox reaction is favored and likely to occur (and possibly be regulated), the ΔG^0 for a redox reaction should be calculated from standard reduction potentials, using the formula $\Delta G^0 = -nFE^0$.

14.1.5: WHICH ENZYMES TO REGULATE: THOSE CATALYZING COMMITTED STEPS IN PATHWAYS

The best enzymes to regulate are those that catalyze the first committed step in the reaction pathway. The committed step proceeds with a $\Delta G^0 < 0$ and is essentially irreversible. These reactions often occur from key metabolic intermediates that are immediately before or proximal to branches in reaction pathways. Two examples of key intermediates at branch points of metabolic pathways are shown in Figure 14.1.8 shows the reactions for the production and use of the intermediate glucose-6-phosphate.

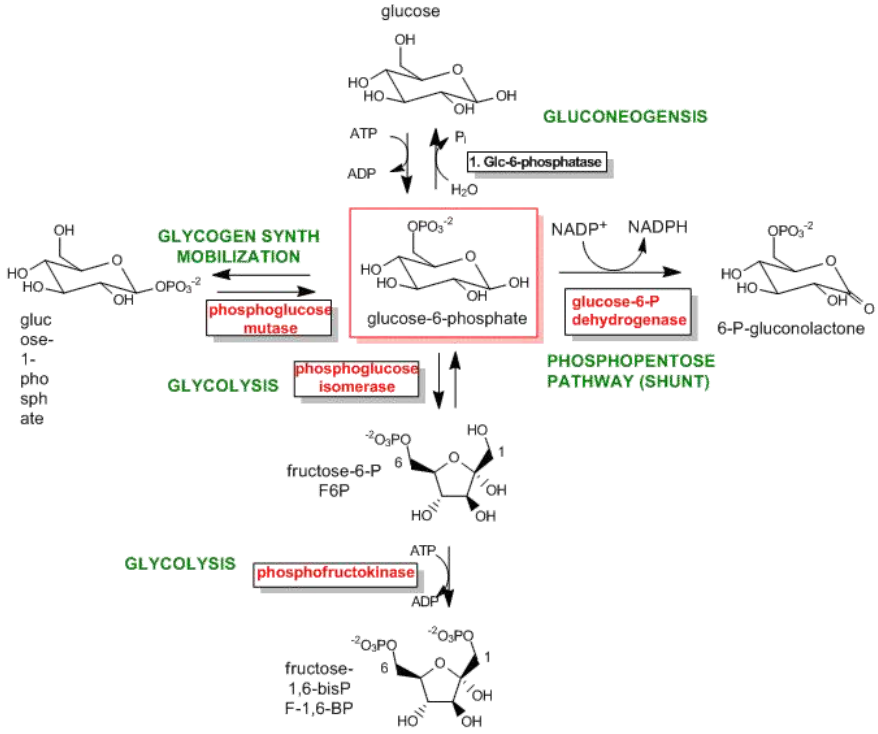

Figure 14.1.8: Reactions for the production and use of the intermediate glucose-6-phosphate

Figure 14.1.10 shows reactions for the production and use of the intermediate acetyl-CoA.

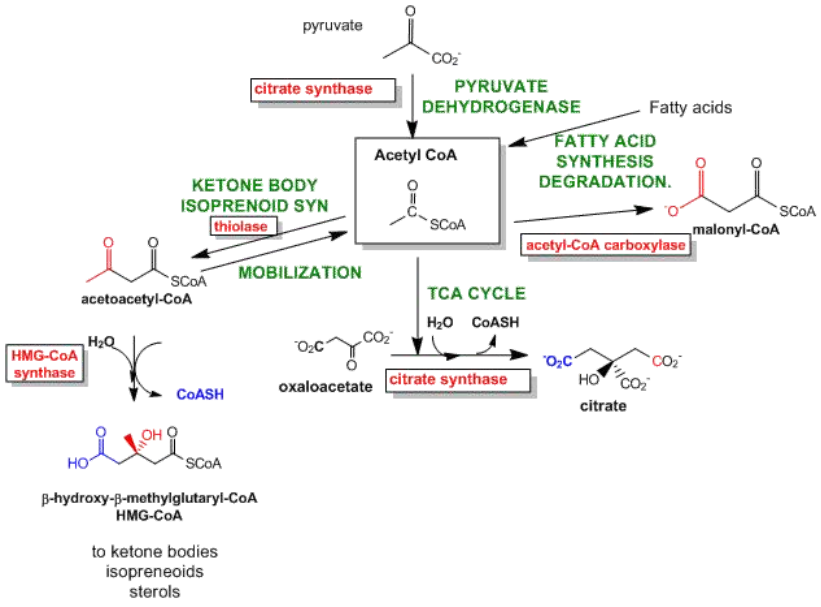

Figure 14.1.10: Reactions for the production and use of the intermediate acetyl-CoA

In reality, metabolic regulation is more complex and is distributed to many steps in a reaction pathway in ways that might not be evident without details mathematical analyses. We will discuss that in the next sections on metabolic control analysis.

14.2: BASIC PRINCIPLES OF METABOLIC CONTROL ANALYSIS (MCA)

14.2.1: INTRODUCTION TO METABOLIC CONTROL ANALYSIS

Enzyme kinetics may seem difficult given the complicated mathematical derivations, the number of chemical species involved (an enzyme and all its substrates and products), the number of steps in the mechanism, and a large number of rate, kinetic, and dissociation constants. An example of such a “complicated” reaction explored earlier is shown in Figure 14.2.1.

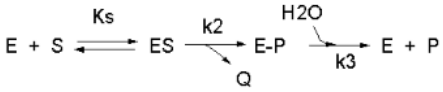

Figure 14.2.1: Chemical Equations for an enzyme-catalyzed reaction with a covalent E-intermediate

$$v = \frac{\frac{k_2 k_3}{k_2+k_3}(E_0)(S)}{\left[\frac{k_3}{k_2+k_3}\right]K_S + S} = \frac{k_{cat}(E_0)(S)}{K_M + S} \tag{14.2.1}$$

But single enzymes rarely act in isolation. They are components of complex pathways which have a multitude of steps, many of which are regulated. To fully understand a reaction, it is important to study the concentrations of all species in the entire pathway as a function of time. Imagine deriving the equations and determining all the relevant concentrations and constants of a pathway such as glycolysis!

To study enzyme kinetics in the lab, you have to spend much time developing assays to measure how the concentration of species changes as a function of time to be able to measure the initial velocities of an enzyme-catalyzed reaction. However, in networks of connected metabolic reactions, the concentration of some species in the system may not change. How can this happen? Two simple examples might help explain how.

Example 1: There is no change in input or output from a given reaction. This would occur in a closed system for a reversible reaction at equilibrium.

For a reversible reaction of reactant R going to product P (R ↔ P) with forward and reverse first-order rate constants, the following equation can be written at equilibrium:

$$\begin{aligned} v_f &= k_1 R = k_2 P \\ K_{eq} &= \frac{P_{eq}}{R_{eq}} = \frac{k_1}{k_2} \end{aligned} \tag{14.2.2}$$

At equilibrium, R and P don’t change.

Example 2: Consider the reaction as part of a pathway of reactions (like an open system). Now imagine a nonzero input to form reactant R and a nonzero output that consumes product P as shown in Figure 14.2.2.

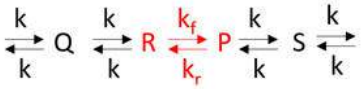

Figure 14.2.2: Reactant R conversion to Product P with preceding and following steps

If the input and output rates are the same, the concentrations of R and P would not change with time. That is the rate of formation of a reactant R for a given reaction is equal to the rate at which the product P of the given reaction is used. This would lead to a **steady state** but not equilibrium concentrations of the species.

14.2.1.1: THE STEADY STATE - A THRESHOLD BIOCHEMISTRY CONCEPT

Students have a difficult time understanding the steady state and recognizing when it may prevail under a set of conditions.

IN VITRO VS. *IN VIVO*

Cornish-Bowden in his book Fundamentals of Enzyme Kinetics talks about key differences between the enzyme kinetics we do in test tubes (*in vitro*) and what happens in cells (*in vivo*). We've discussed this previously but it is important to reconsider it now. The conditions under which the enzymes are studied (*in vitro*) and operate (*in vivo*) are very different.

- *In vitro* (in the lab), the enzyme is held at a constant concentration while the substrate is varied (i.e the substrate concentration is the independent variable). The velocity is determined by the *substrate* concentration. When inhibition is studied, the substrate is varied while the inhibitor is held constant at several different fixed concentrations.

- *In vivo* (in the cell), the velocity might be held at a relatively fixed level in a pathway with the substrate determined by the *velocity*. To avoid a bottleneck in flux, substrate can't build up at the enzyme, so the enzyme processes it in a steady-state fashion to produce the product as determined by the Michael-Menten equation

These differences are vastly underappreciated and not understood by students and instructors alike.

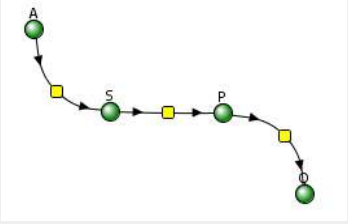
Additionally, we confound our efforts in helping students understand the steady state when almost **all** of our efforts are focused on presenting initial rate v_0 vs [S] curves when the substrate concentration is changed. Then instructors expect students to magically understand the steady state when substrate levels in pathways don't change. It's a big leap out of this box. We can help students better understand the steady state by shifting to progress curves (concentrations vs time), which are easily constructed by using programs such as VCell and Copasi.

Let's use Vcell to analyze a very simple reversible enzyme in isolation, S ↔ P. Then we will place that same enzyme into a "mini" pathway, A ↔ S ↔ P ↔ Q in which there is one preceding reactant A and one following product Q that help control S and P levels. We have to start the simulation at some specified concentration so the default for the simulations is set such that [S] and [A] at time t = 0, S_0 and A_0, are 5, and the rest are set at 0. Hence as the simulation starts, there will be a readjustment of concentration until equilibrium or steady state concentration is reached. The reaction diagrams and their parameters are shown in Figure 14.2.3.

A reversible enzyme in isolation, S ↔ P

J	reaction rate	$\frac{(\frac{S \cdot VmaxFwd}{KmFwd} - \frac{P \cdot VmaxRev}{KmRev})}{(1.0 + \frac{S}{KmFwd} + \frac{P}{KmRev})}$
KmFwd	Km forward	10.0
VmaxFwd	max forward rate	10.0
KmRev	Km reverese	20.0
VmaxRev	max reverse rate	5.0
Size	size	50000.0
initConc	initial concentration for S	5.0

A reversible enzyme for S ↔ P in a mini-pathway A ↔ S ↔ P ↔ Q



J	reaction rate	$\frac{(\frac{S \cdot VmaxFwd}{KmFwd} - \frac{P \cdot VmaxRev}{KmRev})}{(1.0 + \frac{S}{KmFwd} + \frac{P}{KmRev})}$
KmFwd	Km forward	10.0
VmaxFwd	max forward rate	10.0
KmRev	Km reverese	20.0
VmaxRev	max reverse rate	5.0
J	reaction rate	$(Kf \cdot P - Kr \cdot Q)$
Kf	forward rate constant	20.0
Kr	reverse rate constant	2.0
J	reaction rate	$(Kf \cdot A - Kr \cdot S)$
Kf	forward rate constant	2.0
Kr	reverse rate constant	2.0
Size	size	50000.0
initConc	initial concentration for S	5.0
initConc	initial concentration for P	0.0
initConc	initial concentration for Q	0.0
initConc	initial concentration for A	5.0

Figure 14.2.3: Reactions schemes and parameters for simple enzyme-catalyzed reversible reaction and the same reaction embedded in a "mini" pathway.

Vcell simulation for the isolated enzyme

Remember that an enzyme does not change the thermodynamics of a given reaction and hence doesn't alter K_{eq}. It just speeds up both the forward and the reverse reactions. Hence you can calculate the K_{eq} for the reaction condition from the Vcell model time course graph:

$$K_{eq} = \frac{[P]_{eq}}{[S]_{eq}} = \frac{4}{1} = 1 \tag{14.2.3}$$

Now you observe that in this reaction, S does change from its initial value, S_0 = 5 (since P_0 = 0). Soon, however, the reaction comes to a real dynamic equilibrium in that both S and P don't change with time.

You could choose a different initial concentration of S and P, rerun the simulation and calculate K_{EQ} for the new conditions using the csv-downloaded spreadsheet data fro each run you make. They should be the same.

VCell MODEL

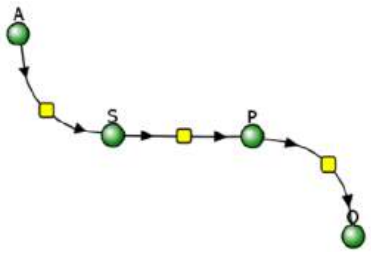
Vcell simulation for the the enzyme in a "mini-pathway"

Now compare this same reaction but in which S and P are part of the "mini-pathway" A ↔ S ↔ P ↔ Q, as shown in the Vcell model below. The enzyme kinetic parameters for S ↔ P ($K_{M\ forward}$, $V_{M\ forward}$, $K_{M\ reverse}$, $V_{M\ reverse}$) in the A ↔ S ↔ P ↔ O pathway were made the same as for the simple S ↔ P reaction since its the same enzyme. How do the A ↔ S and P ↔ Q reactions affect the apparent K_{EQ}? Run the Vcell model with the defaults automatically set to the values in the table above!

VCell MODEL



Initial Values

Name	Description	Global	
J	reaction rate	☐	$(Kf \cdot A - Kr \cdot S)$

Select Load [model name] below

Load EnzymeRev_Constant_S_Premoved

Select **Start** to begin the simulation.

Select **Plot** to change Y axis min/max, then **Reset** and **Play** | Select **Slider** to change which constants are displayed | Select **About** for software information.

Move the sliders to change the constants and see changes in the displayed graph in real-time.

Time course model made using Virtual Cell (Vcell), **The Center for Cell Analysis & Modeling**, at **UConn Health**. Funded by NIH/NIGMS (R24 GM137787); Web simulation software (miniSidewinder) from Bartholomew Jardine and Herbert M. Sauro, University of Washington. Funded by NIH/NIGMS (RO1-GM123032-04)

As in the first simulation, constant values for S and P are soon reached. Both are significantly lower than in the simple reaction of S ↔ P since P is being pulled toward Q faster than Q is converted back to S. Note also that Q reaches a higher concentration than either A or S but remember that the sum of the initial values of A and S is 10.

Run the simulation again only this time set k_r=2000 for the P ↔ Q reaction.

Now calculate the "$K_{EQ\ apparent}$" for the different k_f values of the conversion of P → Q from this equation. Again use the csv-downloaded spreadsheet data for each run you make.

$$K_{\text{eq apparent}} = \frac{[\text{P}]_{\text{steady state}}}{[\text{S}]_{\text{steady state}}} \tag{14.2.4}$$

Do they equal 4 as in case 1? No, they do not. You should see that the "$K_{EQ\ apparent}$" value deviates most from 4 (lower number) when the rate constant for removal of P is highest (k_f=2000).

14.2.2: ANIMATIONS

Now let's look at some animation for these reactions as an additional way to understand the dynamics of the reactions. Click the image in Figure 14.2.4 to view (in a new window) the animation of the chemical species and an inserted graph showing concentration vs time for the reversible enzyme-Catalyzed Reaction S ↔ P

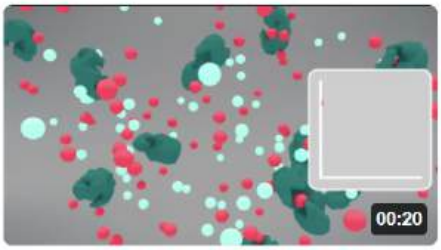

Figure 14.2.4: Animation of the reversible enzyme-Catalyzed Reaction: S ↔ P

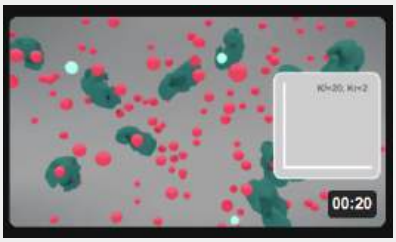
Pay attention to the disappearance of S (red) and the appearance of P (blue) species after interacting with the enzyme (green).

Now here are two animations for the S ↔ P reaction when its embedded in the "minipathway" A ↔ S ↔ P ↔ Q when k_f for the reaction P ↔ Q is **20** (left) and **2**00 (right). Click the images in Figure 14.2.5 to view (in a new window) an animation of the chemical species and inserted graphs showing concentrations vs time.

"mini-pathway" A ↔ S ↔ P ↔ Q, k_f for the reaction P ↔ Q = **20**



"mini-pathway" A ↔ S ↔ P ↔ Q, k_f for the reaction P ↔ Q = **200**

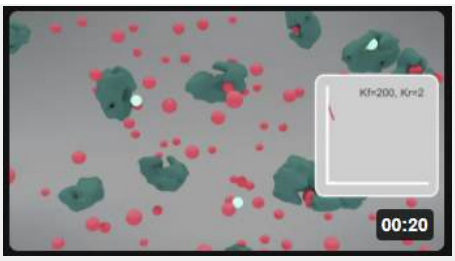


Figure 14.2.5: Animation of the reversible enzyme-Catalyzed Reaction embedded in a "minipathway" A ↔ S ↔ P ↔ Q when k_f for the reaction P ↔ Q is **200.**

These animations should reinforce your understanding of the differences between equilibrium and steady-state conditions, although you can calculate the actual $K_{EQ\ apparent}$ from the insert graphs without numerical data.

Understanding a pure enzyme in vitro and in vivo requires different approaches. Biochemists like to isolate and purify to homogeneity an enzyme found in some tissue and study its mechanism of action. In doing thermodynamic measurements to measure equilibrium constants (K_{eq}) or dissociation constants (K_D), from which ΔG^0 can be calculated, a protein concentration is usually held constant as the binding ligand concentration is varied (independent variable). A dependent variable signal (often spectroscopic) is measured. Measurements are made when equilibrium is reached.

For enzyme kinetic measurements *in vitro*, the enzyme concentration is usually held constant while substrate and modifiers are varied (independent variables) to determine how velocity (dependent variable) changes. The velocity is determined by the substrate concentration. When inhibition is studied, the substrate is varied while the inhibitor is held constant at several different fixed concentrations.

In vivo, the substrate concentration and even the enzyme concentration are determined by the velocity. Again compare this to in vitro kinetics when concentrations determine the velocity. For sets of reactions in pathways, it is better to use the term flux, J. In the steady state, the in and out fluxes for a given reaction are identical. Flux J is used to describe the rate of the system whereas rate or velocity v is used to describe the rate of an individual enzyme in a system.

Computer programs can find steady-state concentrations by finding the roots of the ordinary differential equations (ODE) when set to zero ($v_f = v_r$). To model a process at very low concentrations, programs can also use probabilistic or stochastic simulations to model probability distributions for species and their change with time for a finite number of particles. In such simulations, concentrations (mM) are placed with the number of particles. ODEs don't work well to describe these conditions since changes in concentrations are not continuous.

Now back to our earlier rhetorical question of deriving the equations and determining all the relevant concentrations and constants of a pathway such as glycolysis! It has been done by Teusink et al for glycolysis in yeast. Many such complicated metabolic and signal transduction pathways have been mathematically modeled in the hopes of better understanding cellular and organismal responses. Quantitatively modeling and predicting input, outputs, and concentrations of all species in complex pathways is the basis of systems biology.

14.2.2.1: BASIC PRINCIPLES OF METABOLIC CONTROL ANALYSIS - GLYCOLYSIS

Let's use a more complex example, glycolysis, to illustrate the powers of computational modeling of entire pathways. The reference for this model is shown below.

Can yeast glycolysis be understood in terms of in vitro kinetics of the constituent enzymes? Testing biochemistry, Bas Teusink, Jutta Passarge, Corinne A. Reijenga, Eugenia Esgalhado, Coen C. van der Weijden, Mike Schepper, Michael C. Walsh, Barbara M. Bakker, Karel van Dam, Hans V. Westerhoff, and Jacky L. Snoep, 2000, *European Journal of Biochemistry*, 267, 5313-5329. PubMed ID: 10951190.

Databases containing curated models with all the above information have been developed for many pathways. The yeast glycolysis model described in the reference above and the material below is found in the Biomodels Database. The model, BIOMD0000000064, can be downloaded as a systems biology markup language (SBML) file and imported into any of the programs described above.

A variety of inputs are required for such computational analyses:

a. **Defined pathways.** These are available in many databases. An example from the KEGG pathways for yeast glycolysis is shown in the left panel of Figure 14.2.6 below. The right panel shows a more familiar representation, with glucose on the outside of the cell (Glc_o) entering the cell.

b. A **computational modeling program** to input all parameters, equations, and models and calculate concentrations for all species as a function of time. We have been using Vcell throughout this book. A **reaction diagram** is constructed that connects all of the species. Two are shown in Figure 14.2.7 below.

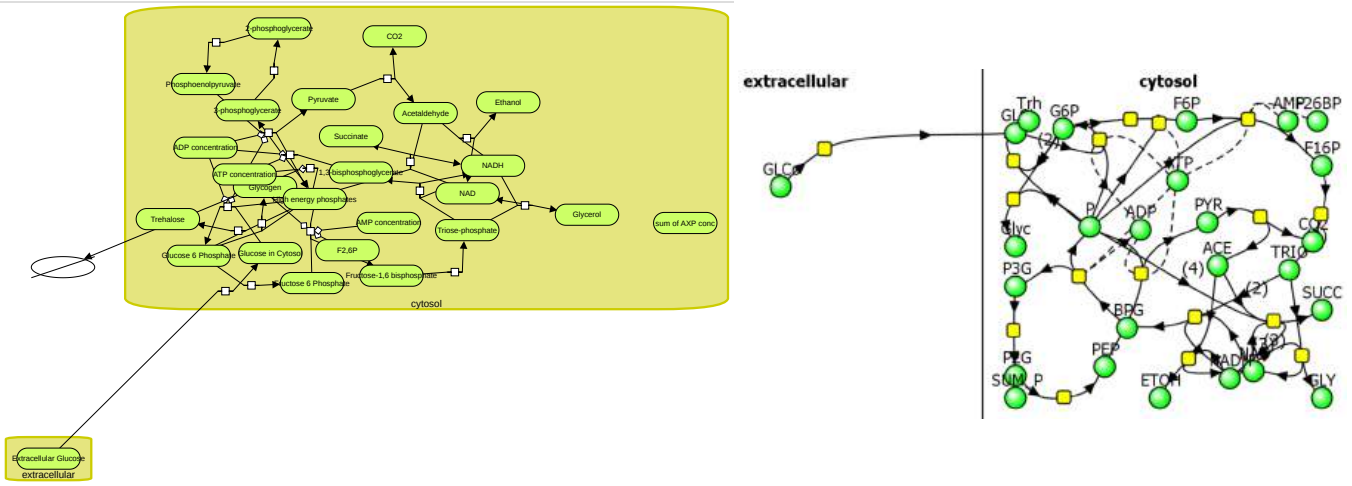

Figure 14.2.7: Reaction Scheme for Yeast Glycolysis. Left made using NEWT Pathway Viewer using Systems Biological Graphical Notation (SBGN) for BIOMD0000000006. Right is a reaction diagram using Vcell. P represents ATP and ACE acetaldehyde.

The computational results from the analyzes for yeast glycolysis were able to fit experimental data only if corrected by the addition of several branching reactions (shown in the figures above and Figure 14.2.8) and in the dotted boxes in Figure 6 (Right)

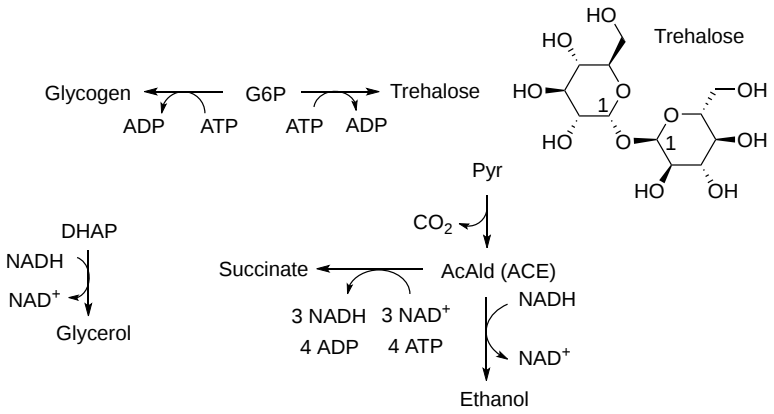

Figure 14.2.8: Branching reactions for Yeast Glycolysis model (Teusink)

Trehalose is the non-reducing disaccharide Glc-(α 1,1)-Glc. It is a reserve carbohydrate that also protects yeast against the effects of stress (desiccation, dehydration, temperature extremes) as well as lethal levels of ethanol. These effects arise from its effects on protein stability which likely arise by its preferential exclusion from the hydration sphere of protein. A similar mechanism accounts for the stabilizing effect of glycerol on protein stability, as described in Chapter 4.9.

c. A l**ist of all reactions** as shown in Figure 14.2.10 for glycolysis and branching reactions (taken from COPASI).

Reaction	Name	Structure
ACE + NADH -> NAD + ETOH	vADH	cytosol
F16P -> 2TRIO	vALD	cytosol
P ->	vATP	cytosol
P2G -> PEP	vENO	cytosol
TRIO + NADH -> NAD + GLY	vG3PDH	cytosol
NAD + TRIO -> NADH + BPG	vGAPDH	cytosol
P + GLCi -> G6P	vGLK	cytosol
GLCo -> GLCi	vGLT	extracellular
G6P + P -> Glyc	vGLYCO	cytosol
PYR -> ACE + CO2	vPDC	cytosol
P + F6P -> F16P	vPFK	cytosol
G6P -> F6P	vPGI	cytosol
BPG -> P + P3G	vPGK	cytosol
P3G -> P2G	vPGM	cytosol
PEP -> P + PYR	vPYK	cytosol
3NAD + 4P + 2ACE -> 3NADH + SUCC	vSUC	cytosol
2G6P + P -> Trh	vTreha	cytosol

Figure 14.2.10: List of reactants and concentrations for yeast glycolysis. P is ATP, ACE is acetaldehyde, a reactant/product of the enzyme alcohol dehydrogenase.

d. **Parameters** (concentrations, rate, enzyme kinetic, and equilibria constants) of all species. Figure 14.2.11 below shows the initial concentrations for the glycolysis model.

Species	Structure	Depiction	Clamped	Rules	
GLCo	extracellular		☑		50.0 [mmol.litre⁻¹]
GLCi	cytosol		☐		0.087 [mmol.litre⁻¹]
G6P	cytosol		☐		2.45 [mmol.litre⁻¹]
F6P	cytosol		☐		0.62 [mmol.litre⁻¹]

Figure 14.2.11: Parameters for hexokinase reactions

e. **Equations** that can be used to compute the change in concentrations of all species with time. These are usually ordinary differential equations (ODE) as described in Chapter 6B - Kinetics of Simple and Enzyme-Catalyzed Reactions, Sections B1: Single Step Reactions.) ODEs are easy to write but require a computer to solve as the number of interacting species increases.

For a quick review, consider the relatively simple reaction scheme shown in Figure 14.2.12 below. The set of ODEs for each species is shown below that.

$$A + B \underset{k_2}{\overset{k_1}{\rightleftharpoons}} C \xrightarrow{k_3} D$$

Figure 14.2.12: Chemical reactions for ODEs

This set of ODEs for each species can be written.

$$\begin{aligned}
\frac{d[A]}{dt} &= -k_1[A][B] + k_2[C] \\
\frac{d[B]}{dt} &= -k_1[A][B] + k_2[C] \\
\frac{d[C]}{dt} &= +k_1[A][B] - k_2[C] - k_3[C] = +k_1[A][B] - (k_2 + k_3)[C] \\
\frac{d[D]}{dt} &= +k_3[C]
\end{aligned} \tag{14.2.5}$$

If a reaction removes species X, the right side of the ODE for the disappearance of that species has a – sign for that term. Likewise, if a reaction increases species X, the right-hand side has a + sign. The above examples show unimolecular (C to D, C to A + B) and bimolecular (A+B to C) reactions.

Now let's look at the equations just for the change in the concentration of glucose-6-phosphate. One reaction forms it and 3 remove it, as shown in Figure 14.2.13 below.

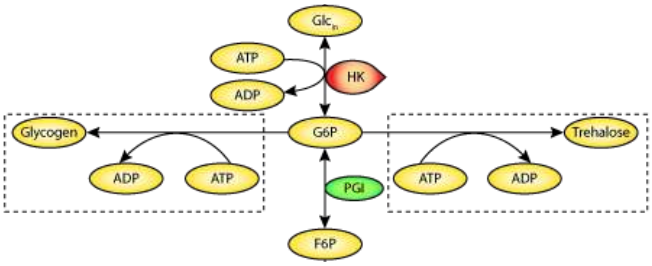

Figure 14.2.13: The reactions that change [G6P] in the Teusink yeast glycolysis model

An ODE can be written for the change in concentration of glucose-6-phosphate.

$$\mathrm{d[G6}P\mathrm{]/dt} = v_{\mathrm{HK}} - v_{\mathrm{PGI}} - 2v_{\mathrm{trehalose}} \ - v_{\mathrm{glycogen}} \ ) \tag{14.2.6}$$

where HK is hexokinase and PGI is phosphoglucoisomerase.

Let's look at the terms more closely and how the terms are written in Vcell.

Formation of G6P

Only one reaction goes towards G6P. Its the reaction catalyzed by hexokinase (G + ATP → G6P + ADP). In the Vcell reaction diagram, ATP is represented by P. Flux J =

$$\frac{VmGLK \cdot \left(GLCi \cdot ATP - \frac{G6P \cdot ADP}{KeqGLK}\right)}{KmGLKGLCi \cdot KmGLKATP \cdot \left(1.0 + \frac{GLCi}{KmGLKGLCi} + \frac{G6P}{KmGLKG6P}\right) \cdot \left(1.0 + \frac{ATP}{KmGLKATP} + \frac{ADP}{KmGLKADP}\right)} \tag{14.2.7}$$

Removal of G6P

3 reactions go away from G6P.

i. G6P → F6P. Flux J =

$$\frac{VmPGI\_2 \cdot \left(G6P - \frac{F6P}{KeqPGI\_2}\right)}{KmPGIG6P\_2 \cdot \left(1.0 + \frac{G6P}{KmPGIG6P\_2} + \frac{F6P}{KmPGIF6P\_2}\right)} \tag{14.2.8}$$

ii. G6P → Glycogen

Flux J = KGLYCOGEN_3

iii. G6P → Trehalose

Flux J = KTREHALOSE

Now let's run a simulation of the model of yeast glycolysis (*Teusink,B et al.: Eur J Biochem 2000 Sep;267(17):5313-29*). The actual model is available from Biomodels (BIOMD0000000064).

Yeast Glycolysis

Teusink et al., 2000. BIOMD0000000064

Species conditions

Parameters

SUBMIT OMEX

Simulation ran using VCell & Tellurium and powered by https://run.biosimulations.org

For Figure 14.2.14 below, the model above model was run and the CSV file was used to plot the concentration vs time plots for each species. Two of the species, EtOH (50 mM) and GLCo - glucose outside (50 mM), have fixed concentrations much larger than the rest, so they are omitted from the graph for clarity. When you run the simulation above, do the same when you download the csv file and plot the progress curves. Also, note that when you run the simulation, the y-axis values are not shown correctly. Rescale them in the spreadsheet based on the correct values of EtOH and GLC0, which were held constant (clamped) throughout the time course at 50 mM.

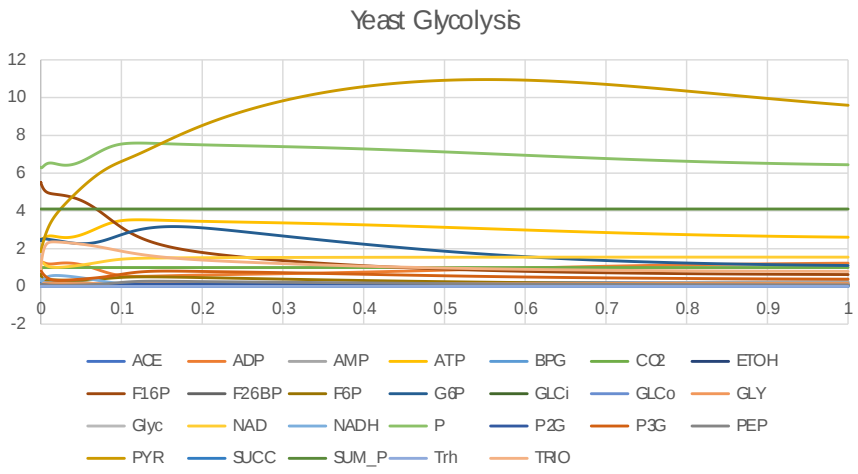

Figure 14.2.14: Time course graphs of all glycolytic species vs time

How close does simulation replicate fluxes found experimentally in vivo? As mentioned above, without the additions of the branch reaction, steady state was not achieved in the simulation. Fluxes in the model were within a factor of two for only about half of the enzymes so the model needs improvement. Other discrepancies could be accounted for generically by differences in kinetics in vivo compared to in vitro measurements. Additional products (glycogen, trehalose, glycerol and succinate) were derived from glucose, which mainly entered glycolysis and was converted to ethanol, showing the complexity in modeling even a relatively "simple" pathway as glycolysis.

14.2.2.2: METABOLIC CONTROL ANALYSIS AND SIMPLE ENZYME INHIBITION

Biochemists model complex enzyme-catalyzed reactions in the presence and absence of modifiers (either activators or inhibitors) to develop mechanisms for the reactions. The following kinetic parameters are experimentally determined by fitting initial velocity (vo) vs substrate concentration ([S]) through nonlinear fitting algorithms.

- K_m – the Michaelis Constant, the concentration of substrate at half-maximal velocity;
- V_m – the velocity at saturating substrate concentration;
- k_{cat} - the turnover number for conversion of bound reactant to product;
- K_{ix} – inhibition dissociation constants.

An example of competitive inhibition, shown in Figure 14.2.15, illustrates a common type of analysis for such reactions.

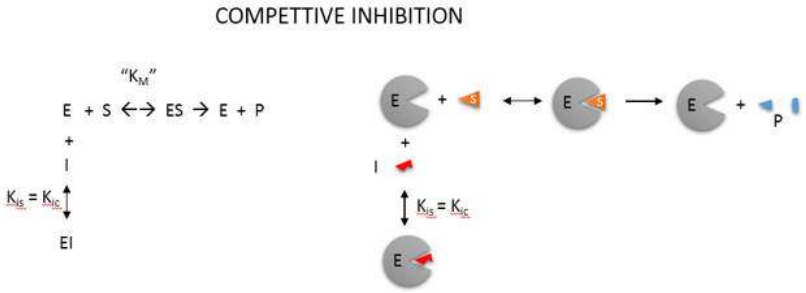

Figure 14.2.15: Chemical reactions for competitive inhibition

One modern pictorial depiction of a simple irreversible, enzyme-catalyzed reaction of substrate S going to product P with inhibition by the product and by an added inhibitor is shown in Figure 14.2.16. The square, a "node" in the reaction diagram, represents the enzyme.

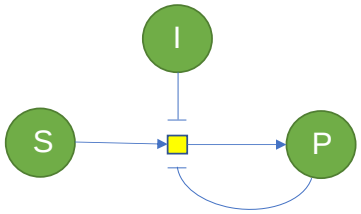

Figure 14.2.16: Pictorial Description for product and separate competitive inhibitor

Consider the simple enzyme-catalyzed reaction for a reversible conversion of substrate S to product P that has 3 reversible steps., as shown in Figure 14.2.17

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} EP \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} E + P$$

Figure 14.2.17: Three step reversible enzyme-catalyzed reaction

If the forward (f) and reverse (r) chemical reaction steps were irreversible and written separately, simple Michaelis-Menten equations could be written for each.

$$\begin{aligned} v_f &= \frac{V_f S}{K_{MS} + S} = \frac{\frac{V_f S}{K_{MS}}}{1 + \frac{S}{K_{MS}}} \\ v_r &= \frac{V_r P}{K_{MP} + P} = \frac{\frac{V_r P}{K_{MP}}}{1 + \frac{P}{K_{MP}}} \end{aligned} \tag{14.2.9}$$

For the actual reversible reactions, the net forward rate cannot be found by simple subtraction of the two equations above as the differential equations describing the simple forward and reverse rates don't account for the reverse steps

$$v \neq \left[\frac{\frac{V_f S}{K_{MS}}}{1 + \frac{S}{K_{MS}}} - \frac{\frac{V_r P}{K_{MP}}}{1 + \frac{P}{K_{MP}}} \right] \tag{14.2.10}$$

A simple derivation (assuming rapid equilibrium for both forward and reverse steps) can be made for the net forward reaction. Again consider the following enzyme-catalyzed reaction (Figure 17 above):

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} EP \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} E + P$$

? A DERIVATION OF THE RAPID EQUILIBRIUM, FULLY REVERSIBLE MICHAELIS-MENTEN EQUATION CONVERSION OF SUBSTRATE S TO PRODUCT P

Here it is!

Derivation

You may remember that for the isolated E + S ↔ ES and for the E + P ↔ EP reactions, the simple dissociation constants, K_S and K_P are given by

$$\begin{aligned} K_S &= \frac{E_{eq}S_{eq}}{ES_{eq}} = \frac{k_{-1}}{k_1} \text{ or } ES = \frac{[E][S]}{K_S} \\ K_P &= \frac{E_{eq}P_{eq}}{EP_{eq}} = \frac{k_3}{k_{-3}} \text{ or } EP = \frac{[E][P]}{K_P} \end{aligned} \tag{14.2.11}$$

The rapid equilibrium assumption states that the rate of dissociation of ES and EP, which are both physical steps, is much faster than the rate of the chemical conversion steps for each complex. Hence $k_{-1} \gg k_2$ and $k_3 \gg k_{-2}$, so the relative amounts of ES and EP can be determined from the dissociation constants as shown above.

Mass conservation of enzymes gives

$$E_0 = E + ES + EP = E + \frac{[E][S]}{K_S} + \frac{[E][P]}{K_p} = E\left[1 + \frac{[S]}{K_S} + \frac{[P]}{K_p}\right] \tag{14.2.12}$$

From this, we can get the fractional amount of both ES and EP

$$\begin{aligned} \frac{ES}{E_0} &= \frac{\frac{[E][S]}{K_S}}{E\left[1 + \frac{[S]}{K_S} + \frac{[P]}{K_p}\right]} \text{ or } ES = \frac{E_0\frac{[S]}{K_S}}{\left[1 + \frac{[S]}{K_S} + \frac{[P]}{K_p}\right]} \\ \frac{EP}{E_0} &= \frac{[E][P]}{E\left[1 + \frac{[S]}{K_S} + \frac{[P]}{K_P}\right]} \text{ or } EP = \frac{E_0\frac{[P]}{K_P}}{\left[1 + \frac{[S]}{K_S} + \frac{[P]}{K_P}\right]} \end{aligned} \tag{14.2.13}$$

Now we can derive the rate equation for the net forward reaction for the rapid equilibrium case:

$$v = k_2[ES] - k_{-2}[EP] = k_2\frac{E_0\frac{[S]}{K_S}}{\left[1 + \frac{[S]}{K_S} + \frac{[P]}{K_p}\right]} - k_{-2}\frac{E_0\frac{[P]}{K_p}}{\left[1 + \frac{[S]}{K_S} + \frac{[P]}{K_p}\right]} \tag{14.2.14}$$

Knowing that k_2E_0 and $k_{-2}E_0$ represent the maximal velocities, V_f and V_r, respectively, the equation becomes:

$$v = k_2[ES] - k_{-2}[EP] = \frac{V_f\frac{[S]}{K_S}}{\left[1 + \frac{[S]}{K_S} + \frac{[P]}{K_p}\right]} - \frac{V_r\frac{[P]}{K_p}}{\left[1 + \frac{[S]}{K_S} + \frac{[P]}{K_p}\right]} = \frac{V_f\frac{[S]}{K_S} - V_r\frac{[P]}{K_p}}{\left[1 + \frac{[S]}{K_S} + \frac{[P]}{K_p}\right]} \tag{14.2.15}$$

Here is the derived equation.

$$v = k_2[ES] - k_{-2}[EP] = \frac{V_f\frac{[S]}{K_S}}{\left[1 + \frac{[S]}{K_S} + \frac{[P]}{K_p}\right]} - \frac{V_r\frac{[P]}{K_p}}{\left[1 + \frac{[S]}{K_S} + \frac{[P]}{K_p}\right]} = \frac{V_f\frac{[S]}{K_S} - V_r\frac{[P]}{K_p}}{\left[1 + \frac{[S]}{K_S} + \frac{[P]}{K_p}\right]} \tag{14.2.16}$$

An equation of a similar form can be derived from the steady state assumption. Hence the net forward rate can't be determined by simple substration of the backward rate from the forward rate as shown in Equation 10 above.

14.2.3: COMMON FORMS OF KINETIC EQUATIONS

Programs like COPASI and VCell have many built-in equations for the velocities of many enzyme-catalyzed reactions that have similar forms. Two are shown below:

Reversible Michaelis-Menten:

$$\frac{\frac{V_f[\text{substrate}]}{K_{Ms}} - \frac{V_r[\text{product}]}{K_{Mp}}}{1 + \frac{[\text{substrate}]}{K_{Ms}} + \frac{[\text{product}]}{K_{Mp}}} \tag{14.2.17}$$

Competitive Inhibition Reversible:

$$\frac{\frac{V_f[\text{substrate}]}{K_{Ms}} - \frac{V_r[\text{product}]}{K_{Mp}}}{1 + \frac{[\text{substrate}]}{K_{Ms}} + \frac{[\text{product}]}{K_{Mp}} + \frac{[\text{inhibitor}]}{K_I}} \tag{14.2.18}$$

What is most important for readers to understand is not detailed derivations or how to solve the differential equations on their own. However, you should be able to:

- write the differential equation of a given reaction;
- recognize the common equations used for nonenzyme-catalyzed reactions (mass action) and enzyme-catalyze ones;
- change parameters in programs that use numerical methods to solve systems of linked differential equations for a system and see how the time course graphs are affected.

14.3: THE FLUX CONTROL COEFFICIENT

14.3.1: INTRODUCTION

Metabolic control analysis (MCA) is one method used to address the complexity of dynamic changes of species in a complex metabolic system. As such, an understanding of MCA would apply to complex signal transduction pathways as well as to other emerging areas in systems biology. In MCA, external inputs (source) and outputs (exits), and pools and reservoirs exist which are connected to the internal metabolic enzymes, reactants, and products of the pathway connecting the two external reservoirs.

In studying complex metabolic systems, what is interesting to know is not just the K_m or V_m of particular enzymes (such as those far from equilibrium or catalyzing "rate limiting" steps based on in vitro studies), but rather the control parameters, known as **control coefficients**, for the system. These coefficients are properties of the whole pathway as an emerging system with properties different from those of the individual steps. For another example of an emergent property, consider consciousness. It must emerge from the incredible assembly of around 90 billion neurons in the brain forming around 10^{15} synapses. It cannot simply be predicted from the properties of isolated neurons. Three especially relevant parameters are used in metabolic control analyses, the Flux Control Coefficient, the Concentration Control Coefficient, and the Elasticity Coefficient

To understand how a pathway is regulated and how scientists modify it to meet their demands, one needs to understand these coefficients. In particular, we would like to know which:

- parameters have the greatest effect (increase or decrease) on a preferred outcome;
- properties of the system make it most resilient or fragile;
- parameters should be measured most accurately

14.3.2: THE FLUX CONTROL COEFFICIENT

The **Flux Control Coefficient** (C^J_{Ei}) gives the relative fractional change in pathway flux J (dJ/J) (a system variable) with fractional change in concentration or activity of an enzyme Ei (du_i/u_i). The change in the concentration of an enzyme can arise from increased synthesis or degradation of the enzyme, a change in a modifier (an inhibitor or activator), a covalent modification, the presence of inhibitor RNA, mutations, etc. Again, the word flux J is used to describe the rate of the system whereas rate or velocity v is used to describe an individual enzyme in the system. Think of u as "units" of activity".

The **Flux Control Coefficient** (C^J_{Ei}) can also be written as

$$C^J_{Ei} = \frac{dJ}{du}\frac{u}{J} \tag{14.3.1}$$

The dJ/du in Equation 14.3.1 suggests that the C^J_{Ei} is equal to the slope of a plot of J vs u multiplied by u/J at that point. Alternatively, it is the actual slope of an ln-ln plot of $\ln J$ vs $\ln u$. A more formal definition would be obtained using partial derivatives (a normal derivative like dy/dx with everyother variable held constant - in this case all other enzyme concentrations or activities other than the one under study :

$$C^J_{Ei} = \frac{\dfrac{\partial J}{J}}{\dfrac{\partial u}{u}} = \frac{\partial \ln J}{\partial \ln u_i} \tag{14.3.2}$$

C^J_{Ei} clearly shows how the system flux changes with changes in the activity of a single enzyme. The variable ui is a property of an enzyme (a local property) but J and concentrations (for the concentration coefficient – see below) are systems variables. Every enzyme in a pathway hence has a flux control coefficient. How are they related? It makes sense that the sum of all of the individual $C^J_{Ei} = 1$ as the fractional change in flux, $\partial J/J$, is equal in magnitude to the fractional change in all enzyme activities. This relationship, shown below, is called the **Summation Theorem**.

$$\sum_{i=1}^{n} C^J_{Ei} = 1 \tag{14.3.3}$$

This equation would predict that if there were one magical enzyme X that was truly rate limiting and as such completely controlled that rate, then C^J_{Ex} = 1 for that enzyme and 0 for all the rest of the enzymes. Yet this is counterintuitive since if all the enzymes are linked their responses should also be linked. Hence the control of flux is shared by all enzymes.

Another way to think about this is to consider a linear set of connected reactions. For these enzymes, C^J_{Ei} would vary between 0 and 1. If one enzyme was completely rate limiting, its C^J_{Ei} would be 1 indicating that the fractional change in flux, $\partial J/J$, is equal to the fractional change in enzyme concentration (or activity) u, $\partial u/u$, for enzyme X. This implies that all change in flux is accounted for by the change in the concentration of enzyme X. This is a bit difficult to believe so it would make sense to think of the control of a pathway as being

distributed over all the enzymes in the pathway. Plots of flux J vs enzyme activity u are similar to rectangular hyperbolas. Hence the flux coefficient changes with enzyme activity and with flux so at different fluxes, different enzyme flux coefficients would change as well. “Control” gets redistributed in the pathway.

Textbooks often describe that ideally the first step of a linear pathway would be the committed step and be rate limiting. But think of this. If the end product of a pathway feeds back and inhibits the first enzyme in the pathway, then the last enzyme influences the first even though the last is not considered “rate limiting”. Now if another enzyme removes the last product and hence first enzyme's feedback inhibitor of the pathway, that enzyme determines flux as well. This again shows that flux control is distributed throughout the system. The classical “rate limiting” enzyme might still have the largest C_{Ei}^{J} of the pathways, but if the system is in a steady state, all enzymes have the same rate. Hence the term “rate-limiting” is a bit useless in a pathway. Analysis of flux control coefficients gives a truly quantitative analysis of the system pathway.

Phosphofructokinase is said to be a “key” enzyme in glycolysis as it is one of three enzymes in the pathway that is characterized by a large negative free energy difference. Figure 14.3.1:

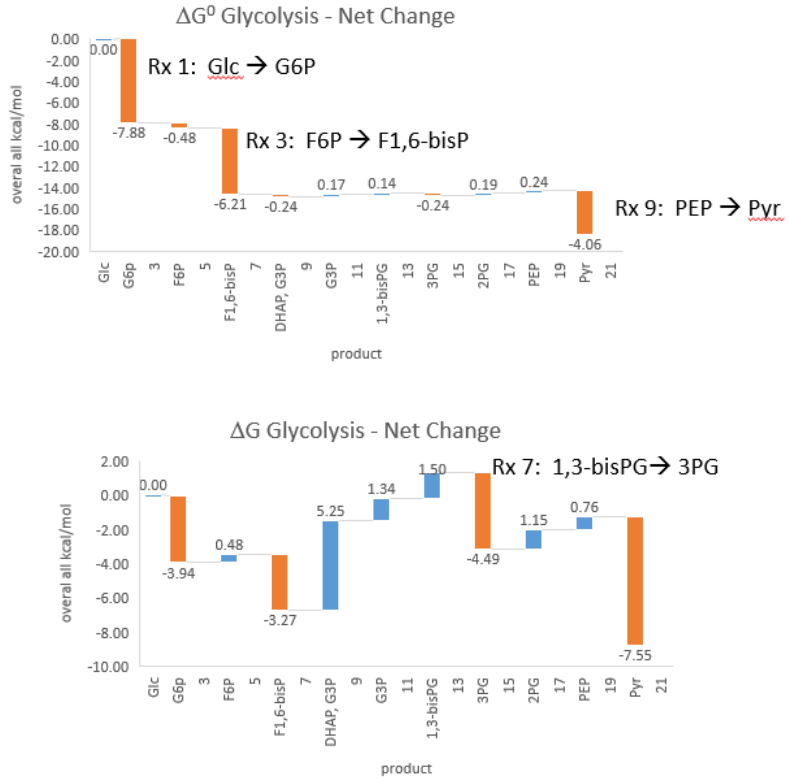

Figure 14.3.1: ΔG^0 and ΔG values for enzymes in glycolysis

It is also highly regulated. However, Heinisch et al (Molecular and General Genetics, 202, 75-82) found that increasing its concentration 3.5 fold in fermenting yeast did not affect the flux of ethanol production.

Here are some results of "sensitivity analyses" of yeast glycolysis showing the effect of small changes (up to 5%) on the flux control coefficients of glycolytic enzymes. The changes in the enzymes for these analyses are 1%. The numbers are scaled values that represent a relative change. A value of + 0.5 means that if the parameter is increased by 10%, the target value will increase by 5%. A column shows the rate of a reaction that is changed and the row indicates the flux of the reaction that has been affected. Green represents positive values and red negative with the intensity of the color correlating with the extent of the change. The table is split with column 1 of the first table applying to tables 2 and 3 as well.

Some things to note:

- almost everything has changed in each column, which shows that a change in one enzyme affects all enzymes;
- 2 adjacent rows often have identical numbers since they describe two connected reactions (without branches) so their steady state fluxes will be the same;
- the sum of the C^{J}_{Ei} values across the same row in both tables is 1 (summation theorem);
- perturbations of the "big 3" enzymes for steps 1,3, and 10 in glycolysis (hexokinase, phosphofructokinase, and pyruvate kinase), all of which proceed with a significant $-\Delta G^0$ and $-\Delta G$, have **minor effects** on the flux.

It should be clear from these results that you can't predict the enzymes that control the flux without this kind of mathematical analysis. Don't rely on just your "biochemical intuition"

14.3.3: FLUX CONTROL IN AEROBIC GLYCOLYSIS

Let's look at another pathway for which we can run a full simulation using Vcell - aerobic glycolysis. We have mostly encountered glycolysis as a central anaerobic pathway in almost all organisms. In some cases, it can also run aerobically. One prime example is in cancer cells in which there is a need for energy in the form of ATP but also for anabolic building blocks so cells can proliferate - a hallmark of cancer cells. Aerobic glycolysis was noted by Warbug and this effect now has his name.

Aerobic glycolysis has been modeled in yeast cells. The pathway is shown in Figure 14.3.2 below.

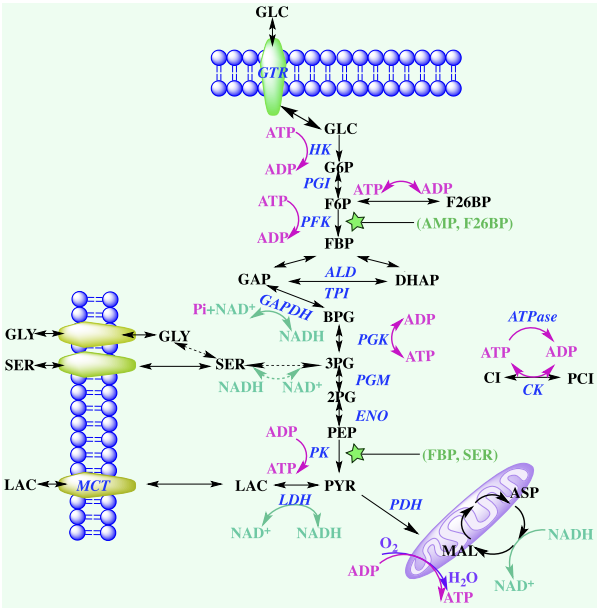

Figure 14.3.2: Schematic of the glycolysis model with chemical reactions and allosteric points of regulation described. Alexander A Shestov et al. (2014) Quantitative determinants of aerobic glycolysis identify flux through the enzyme GAPDH as a limiting step. eLife 3:e03342. https://doi.org/10.7554/eLife.03342. Creative Commons Attribution License

Abbreviations: GLC—glucose, G6P—glucose-6-phosphate, F6P—fructose-6-phosphate, FBP—fructose-1,6,-bisphosphate, F26BP—fructose-2,6,-bisphosphate, GAP—glcyceraldehyde-3-phosphate, DHAP—dihydroxyacetone phosphate, BPG—1,3 bisphosphoglycerate, 3PG—3-phosphoglycerate, 2PG—2-phosphoglycerate, PEP—phosphoenolpyruvate, PYR—pyruvate, SER—Serine, GLY—glycine, Lac—lactate, MAL—malate, ASP—aspartate, Pi—inorganic phosphate, CI—creatine, PCI—phosphophocreatine, GTR—glucose transporter, HK—hexokinase, PGI—phosphoglucoisomerase, PFK—phosphofructokinase, ALD—aldolase, TPI—triosephosphoisomerase, GAPDH—glyceraldehyde-phosphate dehydrogenase, PGK—phosphoglycerate kinase, PGM—phosphoglycerate mutase, ENO—enolase, PK—pyruvate kinase, LDH—lactate dehydrogenase, MCT—monocarboxylate transporter, PDH—pyruvate dehydrogenase, CK—creatine kinase.

The Warburg Effect **W** can be quantitatively described by the ratio of the flux of pyruvate to lactate (J_{Lac}) compared to the flux of pyruvate entry into the mitochondria and subsequent consumption of O_2 by mitochondrial oxidative phosphorylation (J_{ox}), so $\mathbf{W} = J_{Lac}/J_{ox}$).

Usually in normal conditions for healthy cells, W <0.10, which means that less than 10% of glucose is converted (or diverted) to lactate. On average for different tissues, W < 0.3. Hence some lactate is always being made. High values of W (> 1) mean that most glucose is diverted to lactate synthesis. The W values is determined by lots of factors that determine the energy state of cells, including rates of glucose uptake, ATP hydrolysis, and biosynthesis, as well as the balance of cytoplasmic and mitochondrial NAD^+/NADH, hence the redox state of the cell. Key to the balance leading to aerobic glycolysis is the need to reoxidize cytosolic NADH back to NAD^+ under aerobic conditions so glycolysis can continue under conditions when there is a high growth rate.

How does a cell know which path to take, pyruvate to lactate (anaerobic), pyruvate to CO_2 with ATP synthesis (aerobic), or some of both? In terms of metabolic control analysis, what controls the flux of pyruvate through these paths? This is where computational modeling informed by experimental data helps. We can determine the flux control coefficient (C^J_{Ei}), more easily written as **FCC**, for each enzyme in glycolysis to help us understand what controls the flux. Figure 14.3.3 metaphorically describes these different paths. In a way, the flux of pyruvate through these 3 choices, anaerobic, aerobic, and both (as reflected by the Warburg effect W) is then perhaps the best example to use to discuss flux control since the readers are likely very familiar with the concept of anaerobic and aerobic metabolism and the "switch" between them when running short sprints vs marathons.

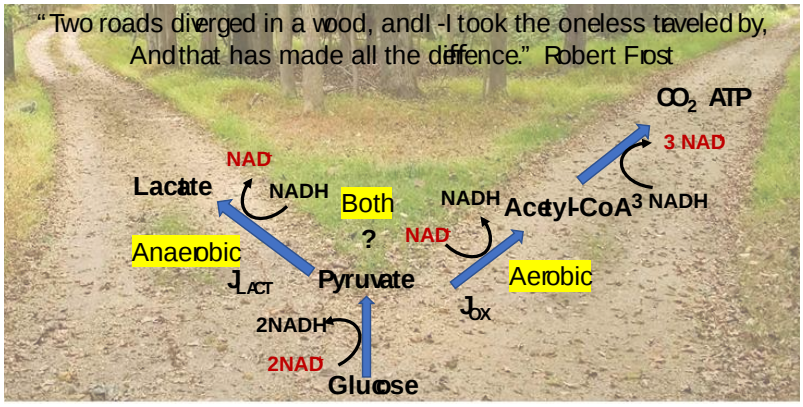

Figure 14.3.3: Fluxs of pyruvate through multiple paths

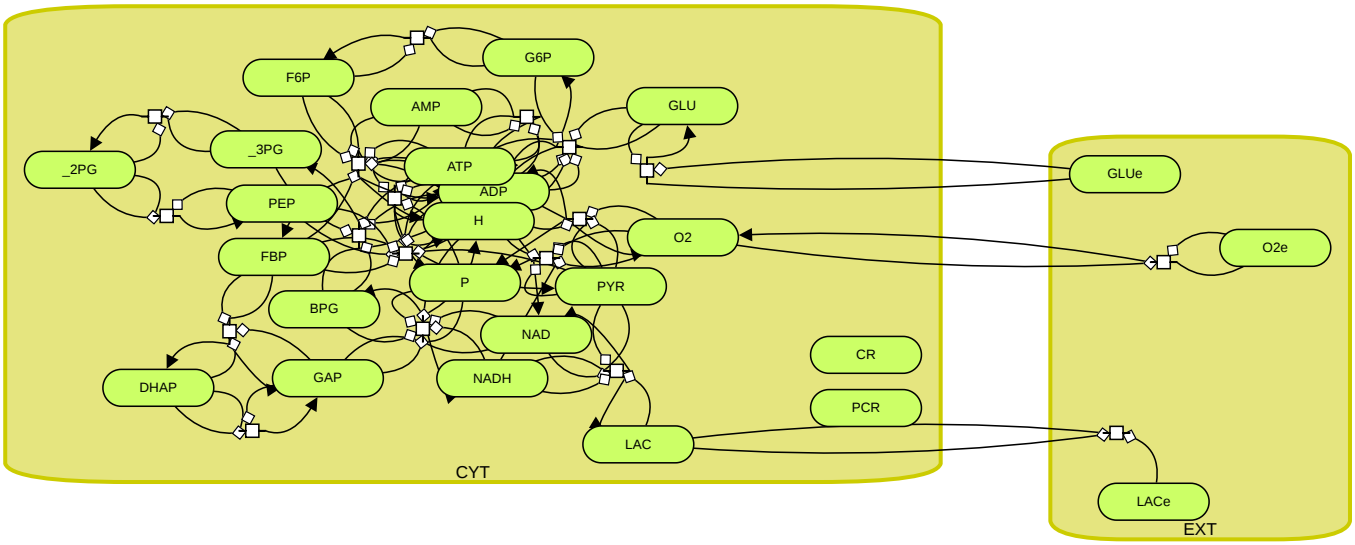
Now let's run the Vcell model for aerobic glycolysis in yeast.

VCell MODEL

AerobicGlycolysis

Quantitative determinants of aerobic glycolysis identify flux through the enzyme GAPDH as a limiting step. .Shestov AA, Liu X, Ser Z, Cluntun AA, Hung YP, Huang L, Kim D, Le A, Yellen G, Albeck JG, Locasale JW. *eLife* , 7/ 2014 , Volume 3 , PubMed ID: 25009227. Biomodel MODEL1504010000



Select Load [model name] below

Load AerobicGlycolysis

Select **Start** to begin the simulation.

Select **Plot** to change Y axis min/max, then **Reset** and **Play** | Select **Slider** to change which constants are displayed | Select **About** for software information.

Move the sliders to change the constants and see changes in the displayed graph in real-time.

Time course model made using Virtual Cell (Vcell), **The Center for Cell Analysis & Modeling**, at **UConn Health**. Funded by NIH/NIGMS (R24 GM137787); Web simulation software (miniSidewinder) from Bartholomew Jardine and Herbert M. Sauro, University of Washington. Funded by NIH/NIGMS (RO1-GM123032-04)

Where did all the parameters in the model come from? They are derived experimentally and the goal of modeling is to produce a computational model that is consistent with the experimental findings which are fed into the model.

The result of the model suggests that the Warburg effect is determined by the growth rate of the cells as well as the activity of mitochondria. The model does **not** support the idea that aerobic glycolysis results as a balance between energy needs and new biosynthesis as cells proliferate. Rather, the cells that proliferate the most have the most active mitochondria and hence lower levels of lactate production. Redox balance appears to be key in pushing cells toward lactate synthesis and aerobic glycolysis.

A key step is catalyzed by glyceraldehyde-3-phosphate dehydrogenase (**GAPDH**), the glycolytic enzyme that separates the top and bottom halves of glycolysis. Experimental data shows that in fact, flux through this enzyme is rate-limiting with the levels of F1,6-BP also being very important. Some key steps that were thought to be rate-limited in fact had negative fluxes through them. Negative flux control coefficients were found and confirmed for several steps thought to be rate-limiting in glycolysis.

The flux control coefficients, given by the formula

$$C_{Ei}^{J} = \frac{\frac{\partial J}{J}}{\frac{\partial u}{u}} = \frac{\partial \ln J}{\partial \ln u_i} \tag{14.3.4}$$

were calculated for each enzyme in the glycolytic pathway. The authors of the study used this equation for the Flux Control Coefficient:

$$FCC = \frac{d\ln[J_{LACT}]}{d\ln[E_i]} \tag{14.3.5}$$

The fluxes were measured for lactate production by using ^{13}C-labeled lactate to get the absolute concentration of lactate, and then measuring the fluxes by measuring the changes in ^{13}C-lactate production with time. Using these data and the selective inhibition by small drugs of each step in glycolysis to effectively alter the "concentration/activity of the enzyme", the FCC of each enzyme could be calculated. The results are shown in Figure 14.3.4 below.

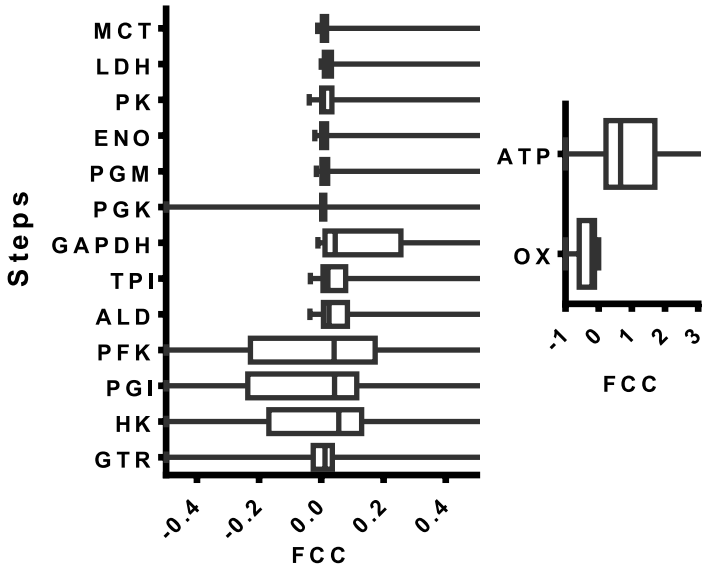


Figure 14.3.4: (left) Box plots of flux control coefficient (FCC) for lactate production for each enzymatic step in glycolysis (FCC = $dlnJ_{lac}/dln\ E_i$) where J_{lac} is the rate of pyruvate conversion to lactate, and E_i is the i^{th} enzyme in glycolysis for each step of glycolysis. (right) Box plots of flux control coefficient (FCC) for lactate production for Oxygen consumption (OxPhos) and ATP consumption (ATP). Shestov et al., ibid

The left-hand side of Figure 4 shows that two of the key enzymes that are thermodynamically favored in glycolysis, PFK (phosphofructokinase) and HK (hexokinase), both driven by ATP hydrolysis, have essentially *negative* flux coefficients, so they are **NOT** key in driving flux toward lactate. Only one enzyme, GAPDH, is characterized by a positive flux coefficient. (Remember we are talking about flux coefficients, not the Warburg effect factor W.)

Also important, as mentioned above, is the concentration of F1,6BP (FBP in the figure below). The model and data show that high levels of FBP and associated higher concentrations of the reactants in the first half of glycolysis (denoted by ↑↑ and large font size), and a corresponding depletion of substrates in the bottom half (denoted by ↓↓) actually cause a bottleneck in glycolysis and inhibit flux through GADPH. Hence GADPH determines the flux through glycolysis. This "bottleneck" is associated with the redox and energy states of the cell. This outcomes are illustrated in Figure 14.3.1 below.

Figure 14.3.5:

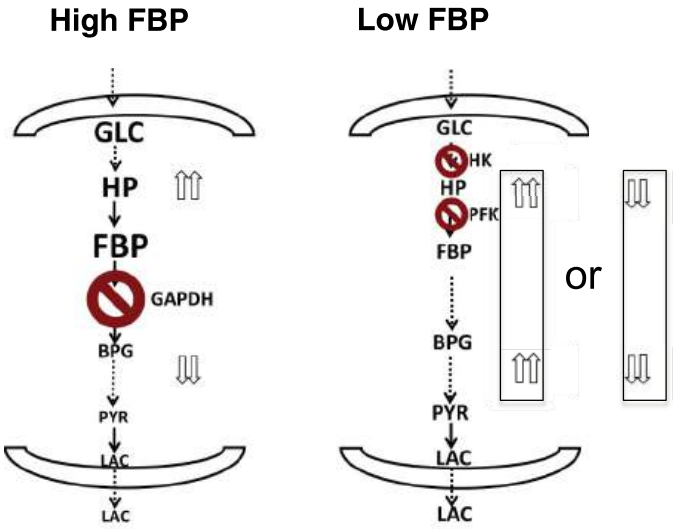

Figure 14.3.5: **A unified model of aerobic glycolysis.** Shestov et al., ibid

When there is a balance of metabolites in the top and bottom halves of glycolysis (right hand size), including both high levels in both top and bottom (denoted by ↑↑ and font size) or low levels in both (denoted by ↓↓ and font size), no bottleneck at GAPDH exists and flux through glycolysis is determined by the usual "suspects", hexokinase and phosphofructokinase.

The results described above are those predicted by computational modeling. Do experimental data support the model? The only way to know is to test the model. This was done by using drugs to inhibit each of the enzymes in glycolysis. This offers an effective way to change the "effective" concentration or activity in the enzyme. From this data, flux changes due to changes at each step could be determined. These data supported the computation results - GADPH regulates aerobic metabolism in normal as well as. When the top half substrates were elevated, the blockade of flux was determined by GADPH. In Chapter 13, we studied all of the glycolytic enzymes and the myriad of small molecules that control the activity of the 3 major enzymes that have the biggest thermodynamic push, HK, PFK and PK. GADPDH appears to be equally important. It is known to be regulated by many mechanisms, including post-translational modifications, such as nitrosylation, and modification of its active site cysteine with ROS. Perhaps this helps regulate the balance between anaerobic and aerobic glycolysis. Also, there are high levels of expression of GADPH in cells engaged in aerobic glycolysis.

14.4: CONCENTRATION CONTROL AND ELASTICITY COEFFICIENTS

14.4.1: CONCENTRATION CONTROL COEFFICIENTS

The **Concentration control coefficient** ($C^S_{E_i}$), a global property of the system, gives the relative fractional change in metabolite concentration $S_j(dS_j/S_j)$, where S_j is the concentration of any metabolite in the system and as such is a system variable, with fractional change in concentration or activity of enzyme $E_i(du_i/u_i)$. Similar equations as section 15.3 apply.

$$C^S_{E_i} = \frac{\frac{\partial S_i}{S_i}}{\frac{\partial u_i}{u_i}} = \frac{\partial \ln S_i}{\partial \ln u_i} = \frac{\partial S_i}{\partial u_i}\frac{u_i}{S_i} \tag{14.4.1}$$

It can be shown that the sum of all of the individual $C^S_{E_i} = 0$ (another summation theorem), is not 1 as in the case of flux control coefficients. This again would make sense in the steady state. Flux coefficients usually vary from 0 to 1, but concentration coefficients can vary from negative to positive and small to large.

$$\sum_{i=1}^{n} C^S_{Ei} = 0 \tag{14.4.2}$$

The concentration control coefficients can have large values as seen in a simple example. For a given enzyme, at low [S], for example, when [S] << Km,

$$v = \frac{V_m S}{K_M + S} = \frac{V_m S}{K_M} = \frac{k_{cat} E_{tot} S}{K_M} \text{ when } S \ll Km \tag{14.4.3}$$

If the enzyme had only 0.1x of its normal activity (due to a mutation for example), then to maintain constant flux, the [S] would have to increase 10-fold.

The tables below show the C^S_{Ei} values for incremental changes in the substrate (1%).

14.4.2: ELASTICITY COEFFICIENT

The **Elasticity Coefficient**, in contrast to the flux and concentration control coefficients, which are properties of the system, is a local property and can be measured using isolated enzymes and substrates. It makes sense that some kinetic property of the isolated enzyme would affect its propensity to affect system flux. The elasticity coefficient gives a measure of how much a substrate S (or other substance) can change the reaction rate (v) of an isolated enzyme. (Note we use v and not flux J, which describes a system property.) Hence

$$\varepsilon_S^v = \frac{\frac{\partial v}{v}}{\frac{\partial S}{S}} = \frac{\partial \ln v}{\partial \ln S} = \frac{\partial v}{\partial S}\frac{S}{v} \tag{14.4.4}$$

PRICE ELASTICITY

The term elasticity is also used in economics and is especially useful in times when inflation is high. If the price of your favorite product, such as a Starbucks Latte coffee goes up, consumers might either buy them less frequently or buy another cheaper latte from a competitor. If a small rise for a Starbucks latte leads to a large drop in demand, the Starbucks latte is characterized by a high elasticity. If however, people don't change their latte buying behavior when there is a big price rise on the latte, the product is said to be inelastic. If you are the CEO of a company, it is good to know the elasticity of your products to maximize your profits.

Hence the elasticity coefficient can be determined using basic enzyme kinetics of the isolated enzyme. Note that the coefficient at each S concentration is the slope of the v vs S curve multiplied by the S/v at that tangent point. The elasticity coefficient must be evaluated at the same concentration of enzyme and substrate as found in vivo in the steady state. Velocity (v), not flux, is used. In the above case, S is the substrate, but it could be a product or modifier. There is a different elasticity coefficient for each parameter. There is no summation theory for elasticities. Values can be positive for species that increase the velocity or negative for those that decrease it. Hence there can be multiple elasticities.

The tables below show the elasticity coefficients (relative or scaled) for yeast glycolysis determined using COPASI.

Things to note:

- the columns show substrates not enzymes;
- green cells (with positive elasticities) are generally substrates for their target enzymes (for example, glucose-6-phosphate for phosphoglucomutase);

Other "generic" sensitivities can be determined as well. For example, incremental changes in K_m, V_m, or K_{ix} for specific enzymes could affect fluxes in a pathway.

A link between system control coefficients and local coefficients:

You would think that there should be some relationship between a system variable such as the flux control coefficient and a local variable such as the elasticity coefficient. There is and it is expressed by the Connectivity Theorem (below). If a substrate S is acted upon by many different enzymes ($i \ldots\ldots n$), which is very likely, especially for branch points in metabolic pathways, then it can be shown that

$$\sum_{i=1}^{n} C_{vi}^{J} e_{s}^{vi} = 0 \tag{14.4.5}$$

14.5: METABOLISM AND SIGNALING: THE STEADY STATE, ADAPTATION AND HOMEOSTASIS

14.5.1: INTRODUCTION

We have studied binding interactions in Chapter 5, kinetics in Chapter 6, and principles of metabolic control in this chapter. We've learned the following:

Binding Reactions

- for simple binding of a ligand to a macromolecule, graphs of fractional saturation of the macromolecule vs free ligand concentration are hyperbolic and demonstrate saturation binding. In the initial part of the binding curve, when [L] << K_D, the fractional saturation shows a linear dependence on free ligand concentration. Figure 14.5.1 shows [ML] vs L, which is the same basic equation as a plot of Y vs L.

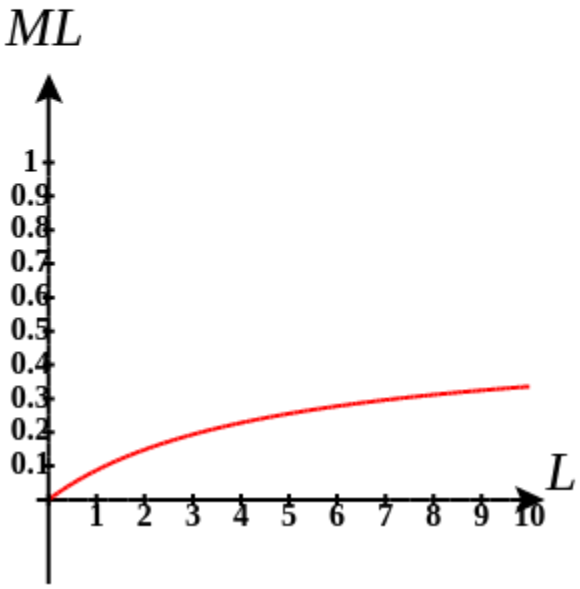

Figure 14.5.1

- for allosteric binding of a ligand to a multimeric protein, graphs of fractional saturation vs free ligand concentration are sigmoidal and also display saturation binding. In the first parts of the binding curve, the fractional saturation is much more sensitive to ligand concentration than in simple binding of a ligand to a macromolecule with one binding site. Figure 14.5.2 below shows graphs for the allosteric binding of a ligand to a macromolecule using the Hill Equation (instead of the MWC equation we used to model O_2 binding to tetrameric hemoglobin).

Figure 14.5.2

In these two plots, the system (in this case a single macromolecule) displays different sensitivities to ligand concentration, allowing the system to have different responses to changes in physiological conditions.

Binding and Chemical Reactions

As with the case for binding interactions, we have seen hyperbolic and sigmoidal plots of initial velocity (v_0) vs [substrate] for enzyme-catalyzed reactions. These also allow appropriate responses to a single substrate in a physiological setting.

But what if you put the same macromolecule and ligand into a larger metabolic or signal transduction pathway in vivo? What kinds of responses would they make to a change in input? As we have just seen in our discussion of the steady state, the ligand or substrate concentration might not change at all as flux continues through the pathway. One could imagine a lot of scenarios with different inputs and different optimal outputs. For example, what if the input (a reactant or small signaling molecule) comes in pulses? Ultimately a system should return to its basal state since a prolonged response (such as cell proliferation) could be detrimental to the health of the organism.

Let's look at some simple examples and see how different inputs lead to specific outputs. We'll just construct some very simple reaction diagrams in Vcell and see how varying them leads to different outputs. Here are two simple cases for **isolated** chemical species and reactions, analogs to the simple binding reactions described above.

Linear Response: A Signal S and a Response R; S → R

If no enzyme is involved, the rate doubles as the signal (substrate) doubles since dR/dt = k[S] for the first-order reaction. If S is the stimulus and R is the response, a plot of R vs S is linear. Hence the system responds linearly with increasing S. Here is the simple chemical equation

$$S \underset{k_2}{\overset{k_1}{\rightleftarrows}} R \tag{14.5.1}$$

As a concrete example, consider the synthesis and degradation of a protein, characterized by the following equation derived from mass action.

$$\frac{dR}{dt} = k_0 + k_1 S - k_2 R \tag{14.5.2}$$

where S is the signal (ex. concentration of mRNA) and R is the response (ex concentration of the transcribed protein). A constant k_0 has been added to account for any basal rate of the reaction. (This is a vastly oversimplified way to model a complex process like mRNA translation to a protein as it omits 100s of steps.)

Here is the simplified derivation under steady state (SS) conditions typically found for enzymes embedded in a pathway.

$$\begin{aligned} \frac{dR_{SS}}{dt} &= k_0 + k_1 S - k_2 R = 0 \\ R_{SS} &= \frac{k_0 + k_1 S}{k_2} \end{aligned} \tag{14.5.3}$$

The equation is a linear function of S.

Hyperbolic Response: E+S ↔ ES → E + R

In a simple enzyme-catalyzed reaction with a fixed concentration of enzyme, as S increases the initial velocity saturates. Hence there is a limit on the response, so the response R is a hyperbolic function of S. Increasing S ever more after saturation won't lead to more R (in a given amount of time).

As a concrete example of this consider the phosphorylation/dephosphorylation of a protein R. R_P represents the phosphorylated and active form of the protein R with concentration $[R_P]$. The reaction is simply written as R ↔ R_P, where R_P is the response. Mass action shows that the total amount of R, $R_T = R + R_P$. A simple mass action equation can be derived.

Here is the chemical equation

$$\mathrm{R} + \mathrm{S} \underset{k_2}{\overset{k_1}{\rightleftarrows}} \mathrm{R_P} \tag{14.5.4}$$

Here is the math equation, again for the steady state (SS), when $dR_P/dt = 0$. (We derived the same equation for the steady-state version of the Michaelis-Menten equation in Chapter 6.

$$\frac{dR_P}{dt} = k_1 S\left(R_T - R_P\right) - k_2 R_P \tag{14.5.5}$$

? DERIVATION: STEADY STATE HYPERBOLIC RESPONSE TO A STIMULUS S

Click below to see the derivation

Derivation

$$\frac{dR_P}{dt} = k_1 R[S] - k_2 R_P \tag{14.5.6}$$

then in the stead state:

$$\begin{aligned} \frac{dR_P}{dt} &= k_1 S\left(R_T - R_P\right) - k_2 R_P = 0 \\ k_2 R_{P,SS} &= k_1 S\left(R_T\right) - k_1 S\left(R_{P,SS}\right) \\ k_2 R_{P,SS} + k_1 S\left(R_{P,SS}\right) &= k_1 S\left(R_T\right) \\ R_{P,SS}\left(k_2 + k_1 S\right) &= k_1 S\left(R_T\right) \end{aligned} \tag{14.5.7}$$

Finally, we get

$$R_{P,Ss} = \frac{k_1 S\left(R_T\right)}{\left(k_2 + k_1 S\right)} = \frac{\left(R_T\right) S}{\left(\frac{k_2}{k_1} + S\right)} \tag{14.5.8}$$

In the steady state, $dR_P/dt = 0$, and the steady state equation can be written as:

$$R_{P,ss} = \frac{k_1 S\left(R_T\right)}{\left(k_2 + k_1 S\right)} = \frac{\left(R_T\right) S}{\left(\frac{k_2}{k_1} + S\right)} \tag{14.5.9}$$

Sigmoidal Response

Consider this simple reaction for a homotetramer in which each monomer can bind a substrate S: $nS + E_n \leftrightarrow E_nS_n \rightarrow E_n + nR$: If E_n is a multimeric allosteric enzyme, as S increases the initial velocity also saturates but the response R is a sigmoidal function of S (in analogy to the above example). The equation is too complicated to derive there, but the result reproduces a sigmoidal curve for the steady state, much as the Hill equation does for cooperative binding.

14.5.2: ADAPTATION AND HOMEOSTASIS

The above examples show that the response of proteins or enzymes to increasing levels of a stimulus like a ligand or a substrate can be linear, hyperbolic, or sigmoidal, with quite a varied set of outcomes. However, in many biological conditions, an ever-increasing or increasing and plateauing response might be too much. The cell needs a way to turn off the response and settle back to a basal state, even in the presence of constant or changing stimuli. This allows the **adaption** of a system to a stimulus and the maintenance of **homeostasis**. Every system needs to be able to respond and return to a homeostatic basal level. The maintenance of homeostasis is critical to life.

HOMEOSTASIS - ASBMB

The American Association for Biochemistry and Molecular Biology (ASBMB) describes both homeostasis and evolution as key underlying concepts for all biology. Homeostasis shapes both form and function from the molecular to organismal levels. Homeostasis is needed to maintain biological balance. The steady state at the molecular to organismal levels in metabolic and signaling pathways is a hallmark of homeostasis. Here are the learning goals for homeostasis designated by the ASBMB

1. Biological need for homeostasis

Biological homeostasis is the ability to maintain relative stability and function as changes occur in the internal or external environment. Organisms are viable under a relatively narrow set of conditions. As such, there is a need to tightly regulate the concentrations of metabolites and small molecules at the cellular level to ensure survival. To optimize resource use, and to maintain conditions, the organism may sacrifice efficiency for robustness. The breakdown of homeostatic regulation can contribute to the cause or progression of disease or lead to cell death.

2. Link steady-state processes and homeostasis

A system that is in a steady state remains constant over time, but that constant state requires continual work. A system in a steady state has a higher level of energy than its surroundings. Biochemical systems maintain homeostasis via the regulation of gene expression, metabolic flux, and energy transformation but are never at equilibrium.

3. Quantifying homeostasis

Multiple reactions with intricate networks of activators and inhibitors are involved in biological homeostasis. Modifications of such networks can lead to the activation of previously latent metabolic pathways or even to unpredicted interactions between components of these networks. These pathways and networks can be mathematically modeled and correlated with metabolomics data and kinetic and thermodynamic parameters of individual components to quantify the effects of changing conditions related to either normal or disease states.

4. Control mechanisms

Homeostasis is maintained by a series of control mechanisms functioning at the organ, tissue, or cellular level. These control mechanisms include substrate supply, activation or inhibition of individual enzymes and receptors, synthesis and degradation of enzymes, and compartmentalization. The primary components responsible for the maintenance of homeostasis can be categorized as stimulus, receptor, control center, effector, and feedback mechanism.

5. Cellular and organismal homeostasis

Homeostasis in an organism or colony of single-celled organisms is regulated by secreted proteins and small molecules often functioning as signals. Homeostasis in the cell is maintained by regulation and by the exchange of materials and energy with its surroundings.

In the rest of the chapter section, we will describe chemically and mathematically simple circuits/motifs that are employed that allow perfect or near-perfect adaptation to a stimulus, a hallmark of homeostasis. We will define adaptation as a complete or almost complete return to a basal state after the introduction of a stimulus. In all the cases below we will consider not a single application of a stimulus but a pulse application (a repetitive step wave function). The pulsed stimuli could be of constant magnitude or an increasing/decreasing pulse of a signal such as a substrate. All responses must be transient to avoid uncontrolled responses such as proliferation (a hallmark of tumor cells) or cell death.

Adaptation is commonly found in sensory systems like vision, hearing, pressure, taste, etc. Think of eating your favorite cookie. The first bite is delicious but by the tenth bite, there is significant attenuation in the positive sensory response, which helps keep most from adding significant weight continually.

Ma et al. conducted simulations on three component/nodes (proteins, enzyme) systems to see which might display the potential for perfect or near-perfect adaption. The simple 3-component motifs or circuits were modeled using simple mass action kinetic equations, ordinary differential equations (which we learned to write in Chapter 6.2), or a combination of both. The systems that displayed adaption had to conform to three criteria:

1. The stimulus had to initially induce a response of high magnitude
2. The system had to return to a basal or near basal state.
3. The return to a basal state had to be mostly parameter-independent. That is, the return to the basal state must occur for many different combinations of parameters.

The possible 3-component components (nodes) and the links among the nodes are shown in Figure 14.5.3 below.

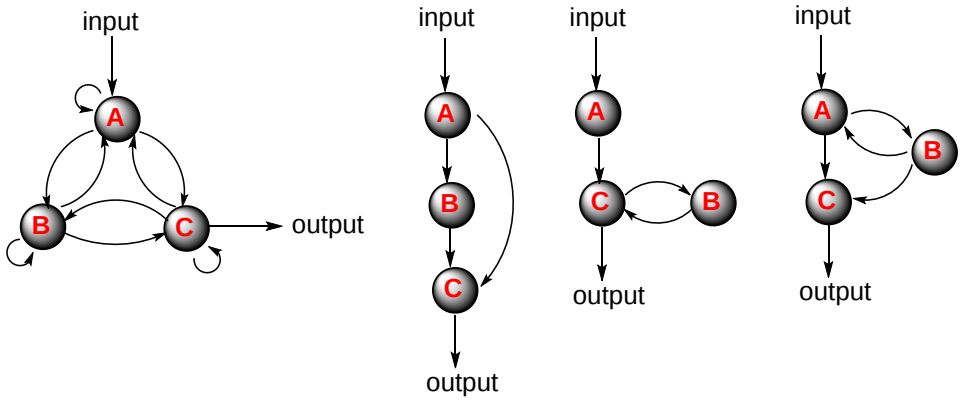

Figure 14.5.3: Possible 3-component components (nodes) and the links among the nodes. After Ma et al. Cell Theory,138, 760-773 (2009) https://www.cell.com/fulltext/S0092-8674(09)00712-0. DOI:https://doi.org/10.1016/j.cell.2009.06.013.

Out of over 16,000 models, several hundred were found that met the criteria. Most were variations of simple motifs that we will show below. The most common motifs were the **negative feedback loop** and the **incoherent feedforward system**.

Much of the discussions, models, and equations used below are from two articles:

- John J Tyson, Katherine C Chen, Bela Novak, Sniffers, buzzers, toggles and blinkers: dynamics of regulatory and signaling pathways in the cell, Current Opinion in Cell Biology, Volume 15, Issue 2, 2003, Pages 221-231, https://doi.org/10.1016/S0955-0674(03)00017-6.
- James E. Ferrell, Perfect and Near-Perfect Adaptation in Cell Signaling, Cell Systems, Volume 2, Issue 2, 2016, Pages 62-67, https://doi.org/10.1016/j.cels.2016.02.006.

By adding a third component to form a mini pathway, we can now change the response R to a stimulus S from linear, or hyperbolic/sigmoidal in the steady state, to one that exhibits perfect or near-perfect adaptation. Again we see this kind of response in signaling pathways in sensation and also in responses like chemotaxis, in which a cell moves toward a stimulus (a chemoattractant molecule).

14.5.2.1: SIMPLE 3-NODE MOTIF/CIRCUIT FOR PERFECT ADAPTATION

Figure 14.5.4 below shows our first example of a 3-component system that displays perfect or near-perfect adaption. The right-hand side shows a Vcell reaction diagram. In this example, a stimulus S (could be a reactant, neurotransmitter, mRNA, etc) leads to the synthesis of X and also of R, a response molecule. Both X and R get degraded. The yellow squares represent the nodes through which the flux of S to X and R proceeds. Each node has an equation for the flux, J, through the node. The left part of Figure 4 shows the periodic pulse of stimuli S that increases the concentration of S from an initial value of S_0 = 1 uM to S + 0.2 uM for each step. Note that the flux equations for J are very simple and are based on mass action, and are not derived through Michaelis-Menten kinetic equations.

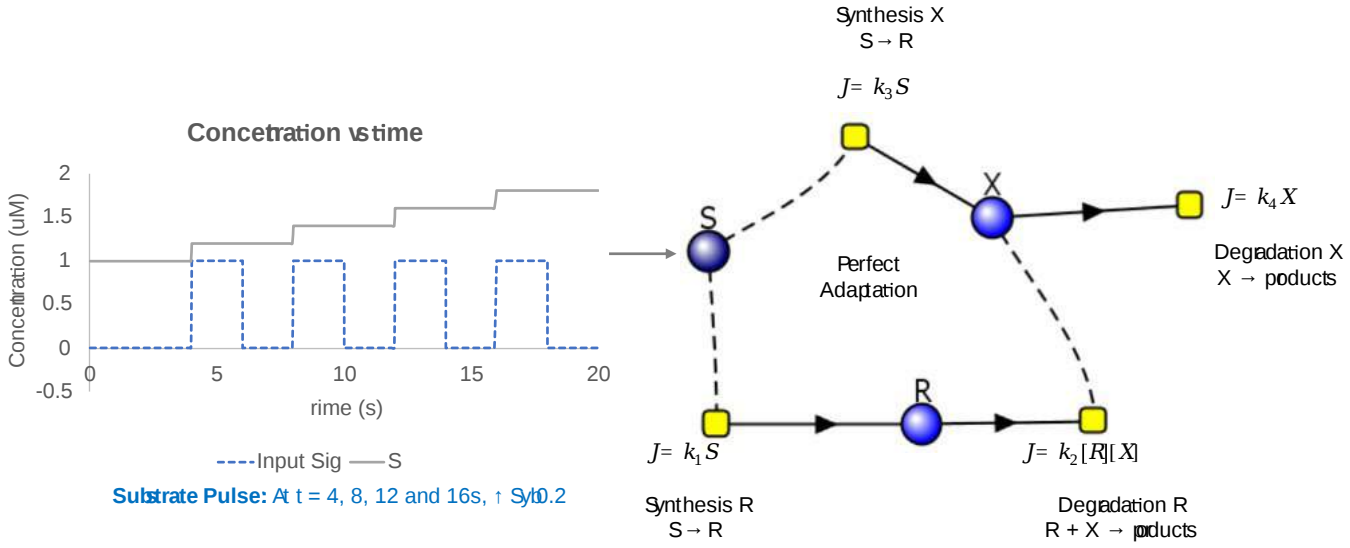

Figure 14.5.4: Simple 3-component system that displays perfect or near-perfect adaption.

Note that S, the stimulus (or substrate for example) is a square wave step function varying from 0 to 1 over the time interval shown in the graph. The dotted blue line simply shows when the pulse is delivered. The initial S concentration is 1 uM and increases by 0.2 for each step (as shown in the gray line). Hence S increases in a stepwise fashion.

Figure 14.5.5 below is a time course graph that shows the stepwise (=0.2 uM) increase in S from 1 uM and the concentration of R (the response) over 20 seconds. Even though S continues to increase in a stepwise fashion, R rises substantially only from the initial input of S (1 uM) and subsequent increases in S with each increment of S are damped out!

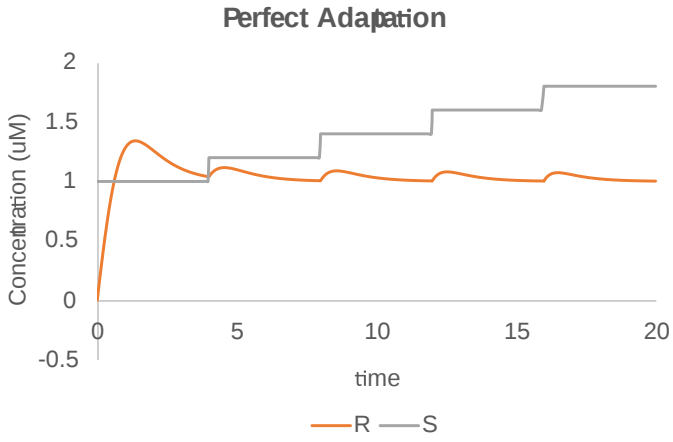

Figure 14.5.5: Time course for a 3-Component Perfect Response system. Model by ModeBrick from VCell: CM-PM12648679_MB4:Perfect_Adaptation; Biomodel 188456707

RUNNING ADAPTIVE VELL MODELS IN THIS BOOK

The present version of Vcell release (as of 4/28/23) does not yet allow the export of a file compatible with the software used to run simulations with this book. The Vcell model includes an "event" which allows for the production of stepwise changes in stimuli. A future release will allow users to run the simulations within this book (as is the case for the other Vcell simulations throughout the book).

14.5.2.2: NEGATIVE FEEDBACK LOOP

The negative feedback loop is one of the simplest circuits/motifs to generate perfect or near/perfect adaptation. It has only two nodes (yellow dots) and two proteins. An example is bacterial chemotaxis. Figure 14.5.6 below shows a Vcell reaction diagram (left), and another representation (middle) and the time course graphs for all species. This model works especially well with certain parameters assigned.

Figure 14.5.6

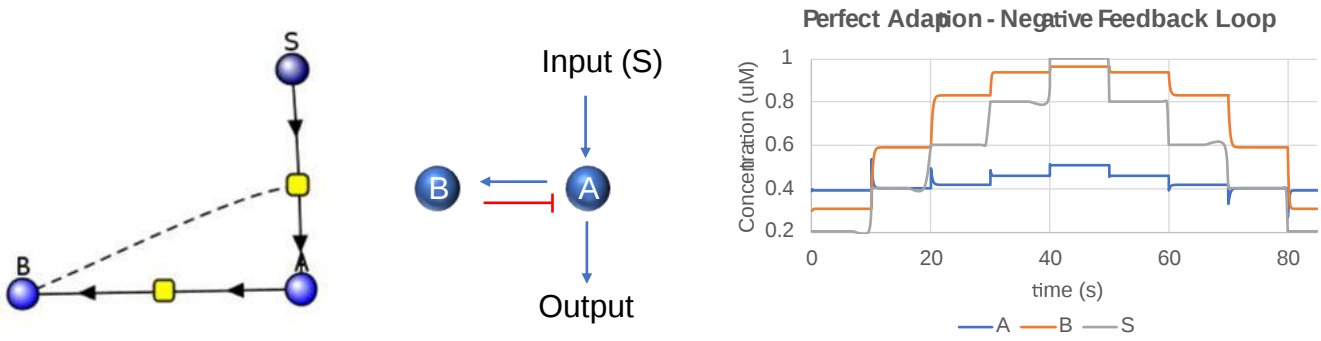

Figure 14.5.6: Near-Perfect Adaptation from Negative Feedback. Adapted from Ferrell (ibid)

The gray line in the graph is the stimulus S (substrate). The blue line is the response, designated in this model as A. B acts as an inhibitor (note the dotted line to the input node in the left diagram and the blunt-ended red bar in the middle diagram. Note that the stimulus goes from 0.2 uM (initial concentration) at t=0 to 1 uM (a 5-fold increase) at 40 seconds, but the response A increases at most from 0.4 (initial condition) to 0.5 (a 1.25-fold increase).

If we say the [A] is the output, then the differential equation for dA/dt is given by

$$\frac{dA}{dt} = k_1 \, \mathrm{S} \cdot (1 - A) - k_2 A \cdot B \tag{14.5.10}$$

dB/dt is given by

$$\frac{dB}{dt} = k_3 A \frac{1 - B}{K_3 + 1 - B} - k_4 \frac{B}{K_4 + B} \tag{14.5.11}$$

The constants for the graph (right) produced by the Vcell model are:

- $k_1 = k_2 = 200$
- $k_3 = 10$; $k_4 = 4$
- $K_3 = K_4 = 0.01$

14.5.2.3: INCOHERENT FEEDFORWARD SYSTEMS

In this circuit/motif, the stimulus S increases the concentration of A (the output) but also forms a negative modulator, B, which with a bit of a time lag decreases the concentration of A through inhibition. There is no feedback inhibition from A in this simple system. If you're reading carefully, you'll see that the reaction scheme and inhibition are the same as the first circuit/motif we introduced. Here we simplify the diagram and give it an official name. The word incoherent in the name makes sense since the stimulus S is converted both to the output A, and to the inhibitor B, which on the surface seems like a crazy thing to do.

Figure 14.5.7 below shows the Vcell reaction diagram (left) and more classical reaction diagram (middle) and progress curves showing S, the stimulus, A the output or response, and B, the inhibitor. The dashed line in the left diagram from B to the reaction node for the S → A reaction shows that B affects the rate of that reaction. The equations used account for the inhibitory effect of B.

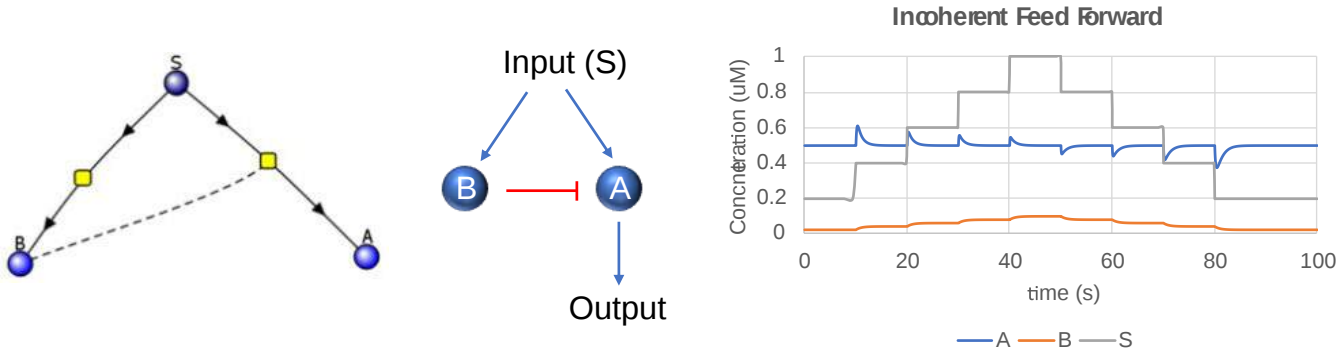

Figure 14.5.7: Near-Perfect Adaptation from an Incoherent Feedforward System. Adapted from Ferrell (ibid)

Note that the response A goes up or down a bit with each new step in concentration of S but to a very minimal degree. The system is certainly almost perfectly adapted.

The differential equation for dA/dt (where A is the response) is

$$\frac{dA}{dt} = k_1 \, \mathrm{S} \cdot (1 - A) - k_2 A \cdot B \tag{14.5.12}$$

The equation for dB/dt (the inhibitor generated from A) is

$$\frac{dB}{dt} = k_3 \, \mathrm{S} \, \frac{1 - B}{K_3 + 1 - B} - k_4 B \tag{14.5.13}$$

The constants for the graph (right) produced by the Vcell model are:

- $k_1 = 10$; $k_2 = 100$
- $k_3 = 0.1$; $k_4 = 1$
- $K_3 = 0.001$

14.5.3: STATE-DEPENDENT INACTIVATIONS SYSTEMS.

There are two simple circuits/motifs in this system that were found after the initial analyses that showed all possible interactions in a 3-component system (see Figure 3). The motif was patterned after the inhibition of proteins in neuron stimulation, specifically in ion channels in neural cell membranes that open up on a change in the transmembrane potential but then close again quickly to avoid constant neuronal stimulation (or inhibition). In the Na^+ ion channel, there are both fast (1-2 ms) and slow (100 ms) inactivation mechanisms. The fast one allows for repetitive firing, the development of action potentials, and the control of the excitation of neurons, and at the neuromuscular junction. Neuronal signaling is discussed in Chapter 28.9. Figure 14.5.8 below shows a simplified model for one type of inactivation of the Na^+ ion channel

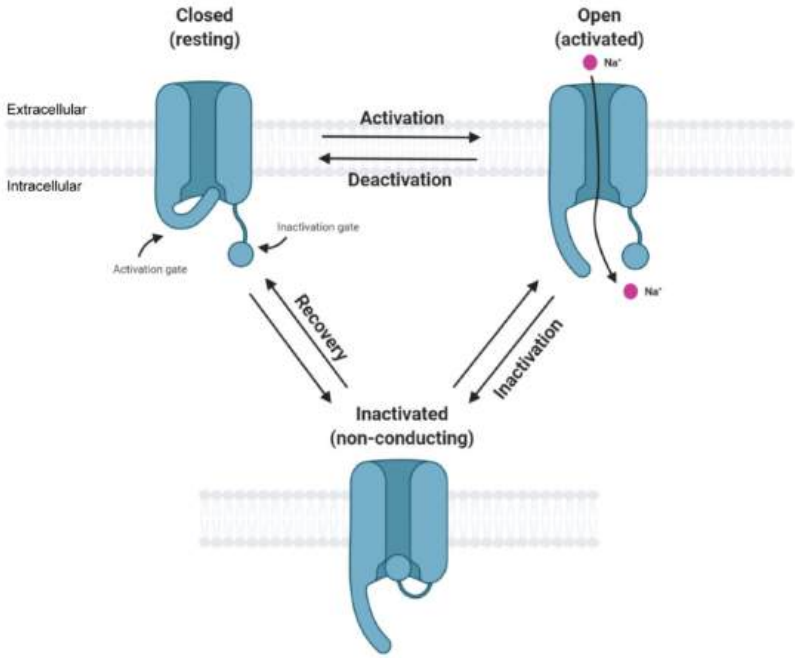

Figure 14.5.7: Simplified state transition model of voltage-gated sodium channels featuring closed, open, and inactivated states. Zybura, A. et al. *Cells* **2021**, *10*, 1595. https://doi.org/10.3390/cells10071595. Creative Commons Attribution (CC BY) license (**https://creativecommons.org/licenses/by/4.0/**).

The figure implies that there are at least 3 conformational states of the channel so the inactivation for the channel and the circuit/motif for adaptation we will now discuss are called **state-dependent inactivations**. The slow return to the original state is observed in many ion channels as well as in the return of G protein-coupled receptors to the normal state after their desensitization. Also, some protein kinases (kinases that use ATP to phosphorylate protein substrates) can be inactivated by internalizing the membrane kinase into vesicles where they can be reactivated and returned to the plasma membrane in a slow process.

For the construction of a perfect or near-perfect adaption state, we will assume the protein A exists in an off state (A_{off}) which binds the stimulus (B or S), an on state (A_{on}) which is viewed as the response (or A produces the response), and an inactivated state (A_{in}) which slowly reverts to the A_{off} state which can be activated again. The inactive state can be produced by conformational transitions with the

protein itself or another molecule produced downstream of it in a metabolic or signaling pathway. For example, a GPRC could be phosphorylated or bind to another species to produce an inactive state.

There are two different circuits/motifs that can produce state-dependent inactivation. We'll refer to these as Type A and Type B

Type A

Figure 14.5.9 shows the Vcell reaction diagram (top left), a classical reaction diagram (bottom left) and time course graphs for Type A state-dependent inactivation.

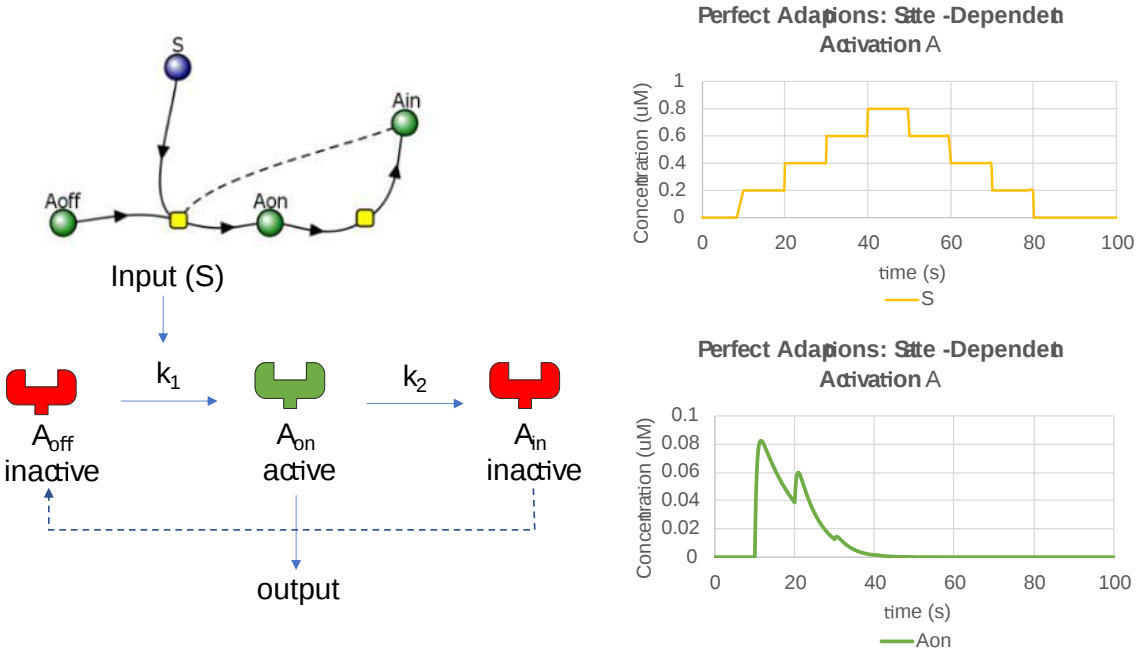

Figure 14.5.9: Perfect Adaptation for Type A State-Dependent Inactivation. Adapted from Ferrell (ibid).

A_{on} represents the active state of the protein. This mechanism applies well to the Na^+ channel. The differential equations for dA_{on}/dt and dA_{off}/dt are shown below.

For dA_{on}/dt

$$\frac{dA_{on}}{dt} = k_1 \,\text{Input} \cdot (1 - A_{on} - A_{in}) - k_2 A_{on} \tag{14.5.14}$$

dA_{in}/dt

$$\frac{dA_{in}}{dt} = k_2 A_{on} \tag{14.5.15}$$

with constants $k_1 = k_2 = 1$.

Again, as with the other cases, the stimulus S is pulsed. The different colors in the bottom left reaction diagram imply an off and inactive red state and a green active state, each of different conformations. The graphs were produced using Vcell. There is a slight anomaly in the graph of A_{on} which shows two additional small peaks as the system returns to the basal state. This contrasts to just 1 peak which returns to the basal state in a simple exponential fashion as described in the Ferrell paper. We are uncertain as to the source of the discrepancy.

Type B

In this case, the periodic stimulus, abbreviated as B, is a binding partner for A_{off} which produces an active complex B-A_{on}. Figure 14.5.10 below shows the Vcell reaction diagram (top left), a classical reaction diagram (bottom left), and time course graphs for Type B state-dependent inactivation

Figure 14.5.10

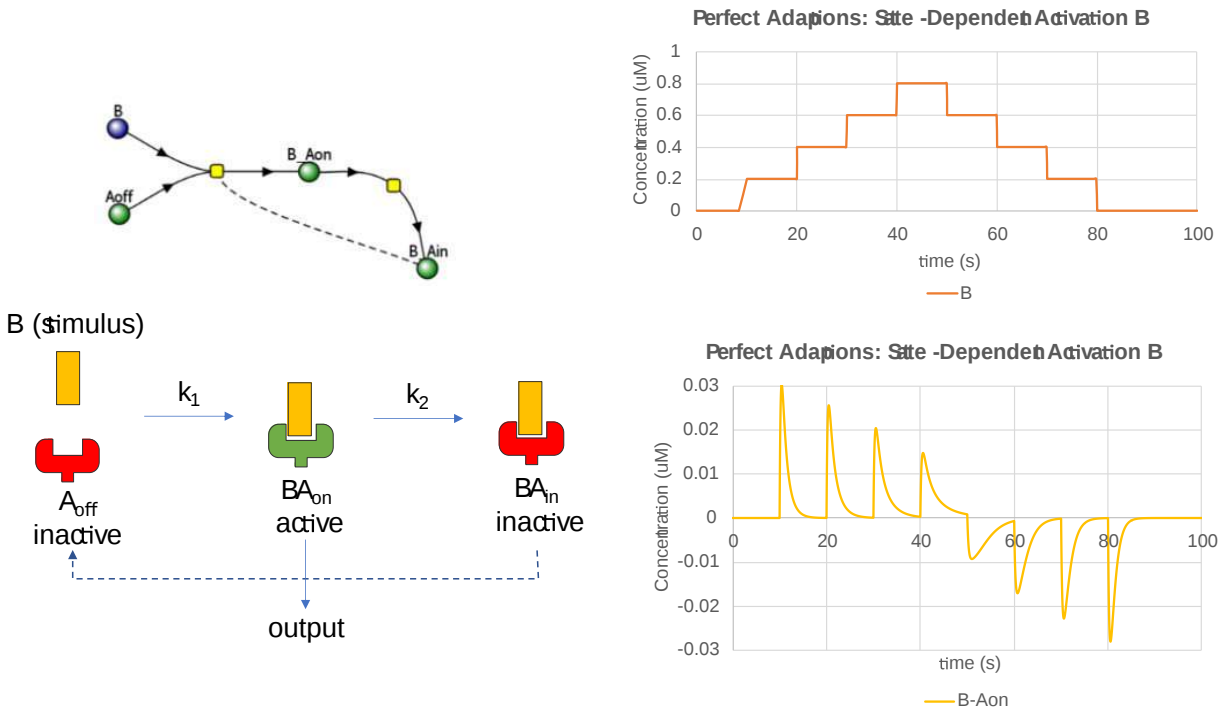

Figure 14.5.10: Perfect Adaptation for Type B State-Dependent Inactivation. Adapted from Ferrell (ibid)

BA_{on} represents the active state of the protein bound to B while BA_{in} represents the inactive complex.

The equation of dBA_{on}/dt for the formation of the active state is

$$\frac{dBA_{on}}{dt} = k_1 \left(B_{tot} - BA_{on} - BA_{in}\right) * \left(1 - BA_{on} - BA_{in}\right) - k_2 BA_{on} \tag{14.5.16}$$

and the equation for dBA_{in}/dt for the formation of the inactive state is

$$\frac{dA_{in}}{dt} = k_2 AB_{on} \tag{14.5.17}$$

with constants $k_1 = k_2 = 4$.

The graphs (note the different time concentration scales on the left) show a fairly quick return to the basal state after each pulse of stimuli (B).

CHAPTER OVERVIEW

15: GLUCOSE, GLYCOGEN, AND THEIR METABOLIC REGULATION

15.1: Insulin Signaling in the Liver
15.2: Glycogenesis
15.3: Glycogenolyis and its Regulation by Glucagon and Epinephrine Signaling
15.4: Regulation of Glycolysis
15.5: Regulation of Gluconeogenesis

15.1: INSULIN SIGNALING IN THE LIVER

15.1.1: INTRODUCTION

In this section, we will discuss insulin signaling and glycogen synthesis. Insulin is released in the fed state, and leads to glucose uptake where it can be stored, if not needed, for glycogen synthesis. Recall that glycogen is a large polymer of glucose residues connected in the main chain by alpha 1 → 4 linkages and with branching side chains about every 12 – 15 residues at the alpha 1 → 6 positions. The reducing ends of the carbohydrate (two for each polymer) are connected to the glycogenin dimeric protein at the center of the macromolecule (Figure 15.1.1). With the branching nature of the polymer, many non-reducing ends of the molecule are present, allowing easy access and fast release of glucose for energy utilization.

Most of the body's pools of glycogen are stored in the liver, with 10% of the liver biomass in glycogen granules, and in the skeletal muscle, with glycogen comprising 2% of the biomass of the muscle. Each glycogen polymer may have upwards of 30,000 glucose residues, making the glycogen polymer visible using standard microscopic techniques. Storage of glycogen within muscle tissue is used by the muscle cells as a source of energy to fuel muscle contraction. In the liver, the purpose of glycogen storage is different. Glycogen stored at this location is used to maintain the homeostatic balance of blood glucose levels. The liver is the primary organ that can actively transport glucose into the bloodstream. Our only other major source of glucose within the blood is our diet.

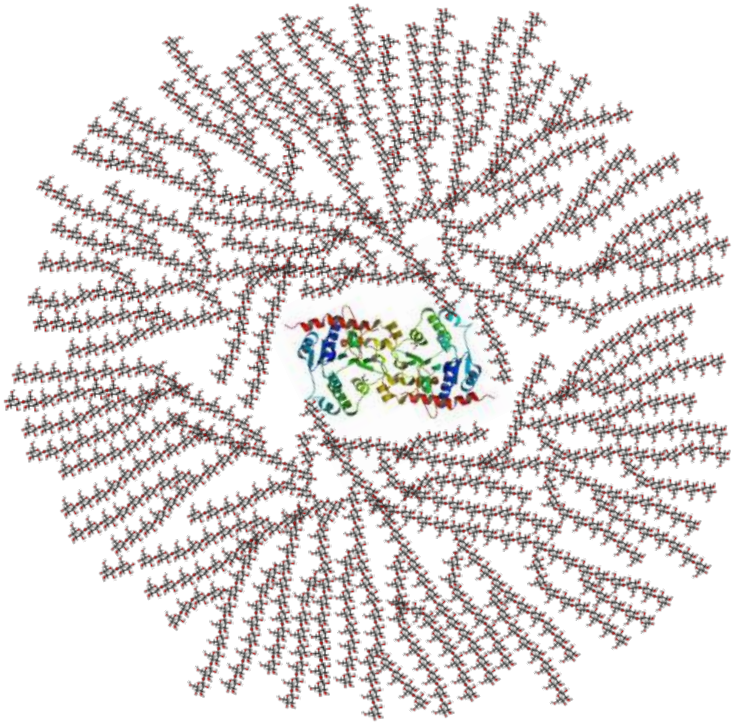

Figure 15.1.1: The Glycogen Polymer. The glycogen-reducing ends of the glycogen polymer are connected with the dimeric glycogenin protein shown at the center of the diagram using the ribbon projection. The polymer is constructed predominantly of glucose monomers connected through alpha 1 --> 4 linkages. Alpha 1 --> 6 branches are apparent about every 12 - 15 residues. (Public Domain; Mikael Häggström via Wikipedia.

Blood glucose homeostasis is critical for brain function (Figure 15.1.2). The brain has a huge energy demand, but nearly zero storage of key energy molecules required for ATP production. Furthermore, glucose and ketone bodies are the only energy sources that can pass the blood-brain barrier and be utilized by the brain for ATP production. Note that ketone bodies are only produced during starvation, or disease states such as diabetes, and are not a regular source of energy for the brain. Thus, glucose is critical for brain function. Nearly 10% of the whole body's energy is used for nerve impulse transmission by the brain. If blood flow to the brain carrying critical oxygen and glucose is impeded, people will lose consciousness within approximately 20 seconds! And brain death/permanent damage occurs within 4 minutes of blood flow cessation. This exemplifies the importance of the liver in maintaining blood glucose levels, as well as the importance of oxygen maintenance.

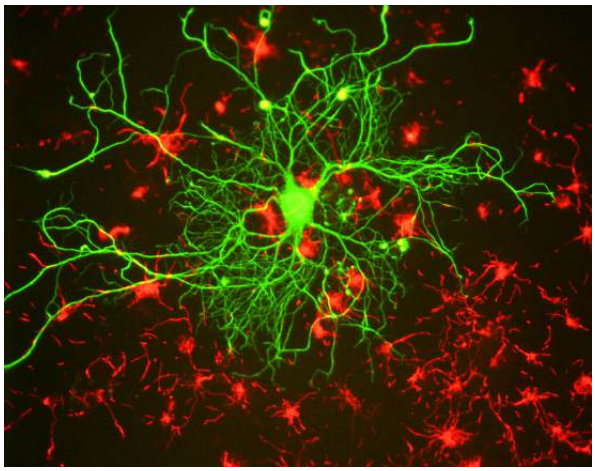

Figure 15.1.2: Cortical neuron stained with antibody to neurofilament subunit NF-L in green. In red are neuronal stem cells stained with antibodies to alpha-internexin. Image created using antibodies from EnCor Biotechnology Inc. (CC BY-SA 3.0 Unported; GerryShaw via Wikipedia)

Glycogen in the liver or muscle can be broken down into glucose 1-phosphate (Figure 15.1.3). This can be interconverted to glucose 6-phosphate which is then readily used in many cellular processes. The process of glycolysis (or the breakdown of glucose into pyruvate) occurs in all cells and produces a small amount of ATP in the process. Further processing of pyruvate can occur anaerobically (or in the absence of oxygen) to produce lactate, or the process can continue to occur in the aerobic pathway to complete oxidation to carbon dioxide and water in the Kreb cycle. Note that oxygen from breathing is used to create the water within this pathway. This fuels the process of oxidative phosphorylation within the mitochondria and produces large quantities of ATP (from 30-36 molecules/glucose). Within the liver, glucose can be freed from glycogen and released back into the bloodstream to maintain homeostatic levels. Glucose 6-phosphate can also be utilized as a precursor for other major macromolecules such as ribose and deoxyribose, as well as the hexosamine compounds commonly found cushioning joints or attached to proteins of the plasma membrane.

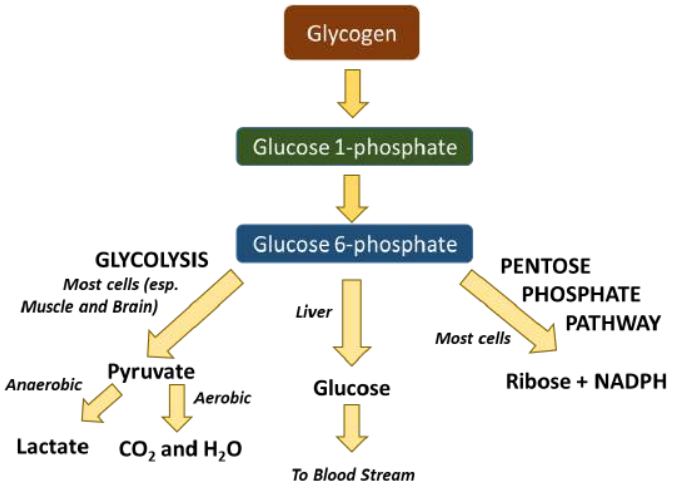

Figure 15.1.3: Pathways of Glycogen Utilization.

In healthy individuals, hormone signaling is critical to maintaining blood glucose homeostasis. Within this system, the hormones glucagon and insulin work together to maintain normal plasma glucose levels (Figure 15.1.4). During hyperglycemia, pancreatic beta (β) cells release insulin, which stimulates glucose uptake by energy-consuming cells and the formation of glycogen in the liver. During hypoglycemia, pancreatic alpha (α) cells release glucagon, which stimulates gluconeogenesis and glycogenolysis in the liver and the release of glucose to the plasma.

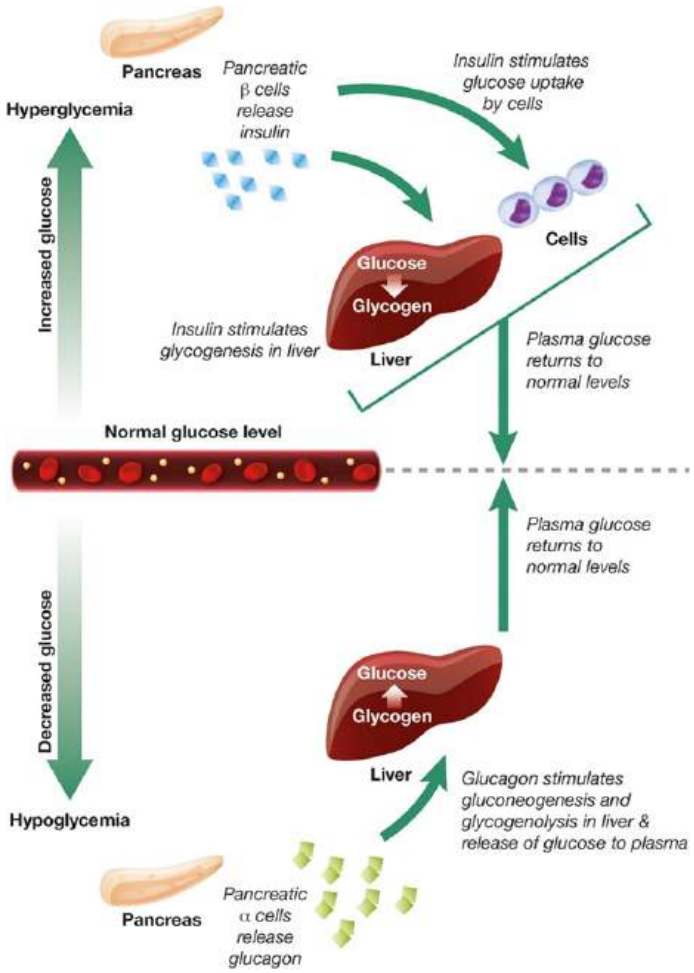

Figure 15.1.4: Hormone Signaling Involved in Blood Glucose Homeostasis. The hormones, glucagon, and insulin, released by the pancreas are critical for regulating the release or the uptake of glucose from the bloodstream by the liver. In the *upper diagram*, when blood glucose levels rise, beta cells within the pancreas secrete the insulin hormone. Insulin signaling causes the liver to increase the uptake of glucose from the bloodstream and promotes its storage as glycogen. Alternatively, when blood glucose levels are low, as shown in the *lower diagram*, alpha cells in the pancreas release the hormone, glucagon. Glucagon signaling in the liver leads to the breakdown of glycogen and the release of stored glucose into the bloodstream. Hædersdal, S., et al (2018) Mayo Clinic Proceedings 93(2):217-239

The first area we will focus our attention on will be the mechanism utilized by insulin to reduce blood glucose levels. Figure 15.1.5 shows the structure of the pancreas and its anatomical relationship with the liver and the stomach. The pancreas is the sensor organ that detects blood glucose levels. It is responsible for signaling to the liver to either remove or release glucose in response to changing levels. Notably, the pancreas also produces most of the digestive enzymes utilized by the body, including proteases, amylases, and lipases.

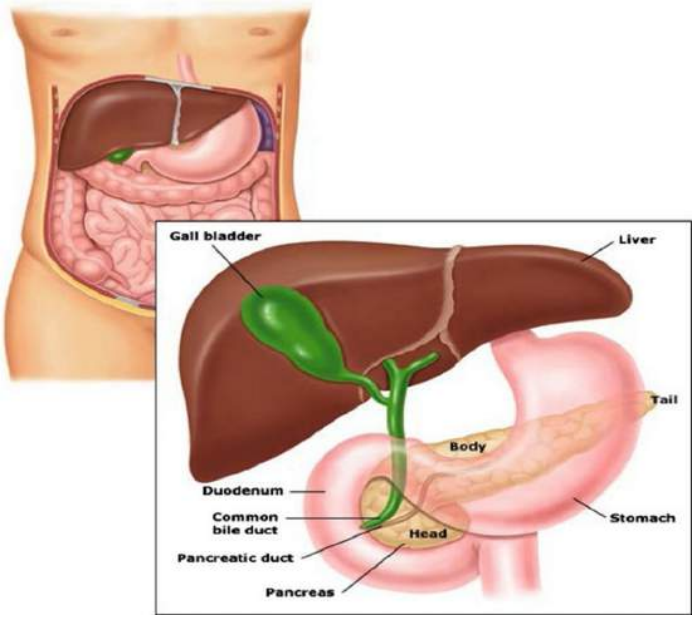

Figure 15.1.5: The Anatomy of the Liver and Pancreas. Akinlade, A., et al (2014) Int. Archives of Med 7(50):28

Figure 15.1.6: shows a light microscope image of the pancreatic islet cells. They are responsible for the production of glucagon and insulin. The islets are distinguished from the surrounding tissue by a continuous connective tissue capsule and extensive vascularity.

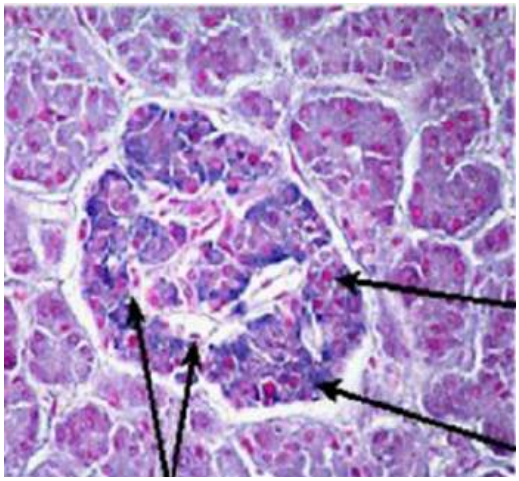

Figure 15.1.6: Pancreatic Islet Cells. In this diagram, the islet cells that secrete glucagon (known as alpha cells) are stained in red, while the beta cells that produce insulin are stained in blue. Akinlade, A., et al (2014) Int. Archives of Med 7(50):28

Insulin is a peptide hormone composed of 51 amino acids as shown in Figure 15.1.7. It is initially synthesized as preproinsulin, which is converted to proinsulin after the signal peptide is removed. Two disulfides are made in the ER (catalyzed by protein disulfide isomerase) along with selective proteolytic cleavage to form insulin. Mature insulin consists of A and B chains that were connected in proinsulin by the C-peptide.

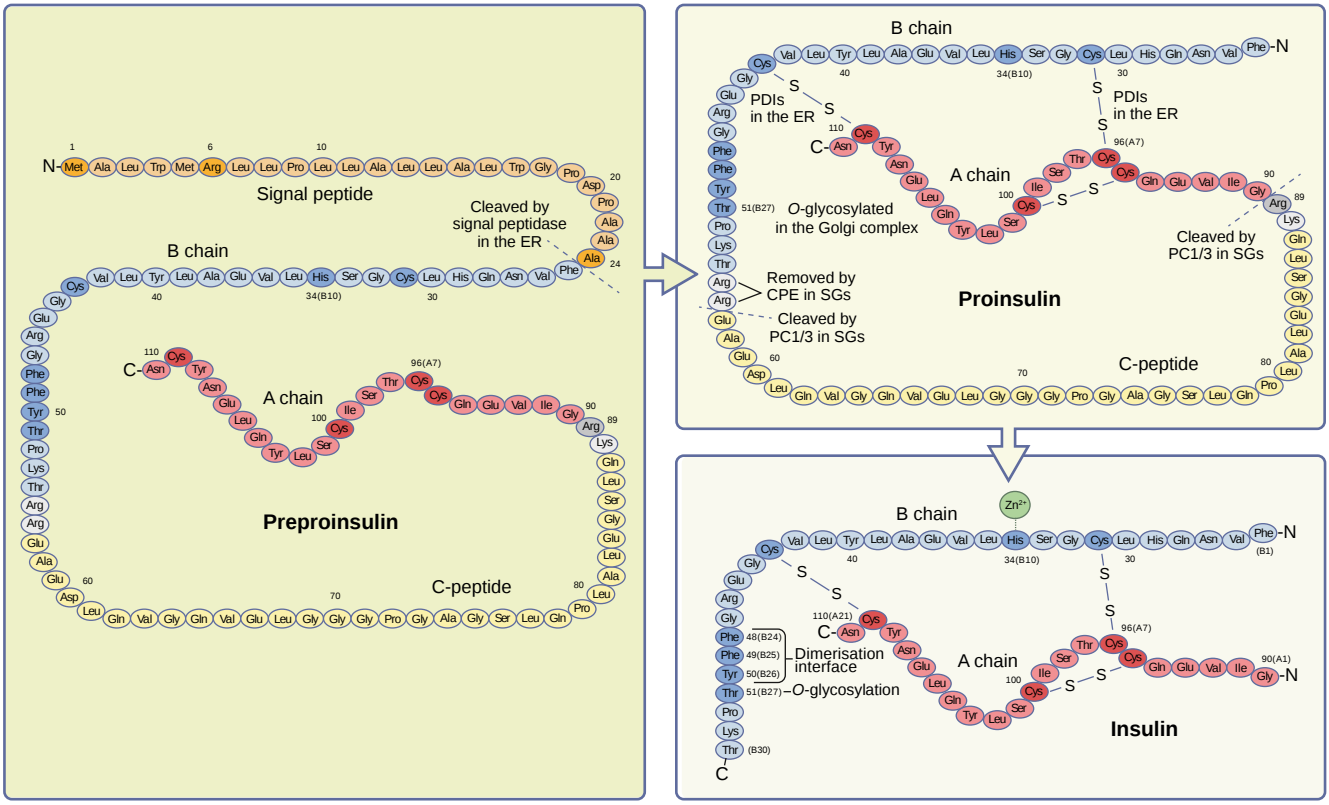

Figure 15.1.7: Conversion of preproinsulin to mature insulin. Vasiljević, J. *et al. Diabetologia* **63**, 1981–1989 (2020). https://doi.org/10.1007/s00125-020-05192-7. http://creativecommons.org/licenses/by/4.0/.

External link: https://structure.ncbi.nlm.nih.gov/i...nQJXhrEfHD1GH9

The maturation of preproinsulin to insulin is shown in more detail in Figure 15.1.9. The peptide is first translated on ribosomes linked to the rough endoplasmic reticulum (ER), where a signal peptide docks the peptide to the ER membrane. The proinsulin is folded and the signal peptide is cleaved. It is transported to the Golgi where it is further packaged into secretory vesicles. Within the secretory vesicles, the proinsulin is cleaved to release the C-peptide. The A and B peptides are held together by disulfide bridges and form the active insulin component.

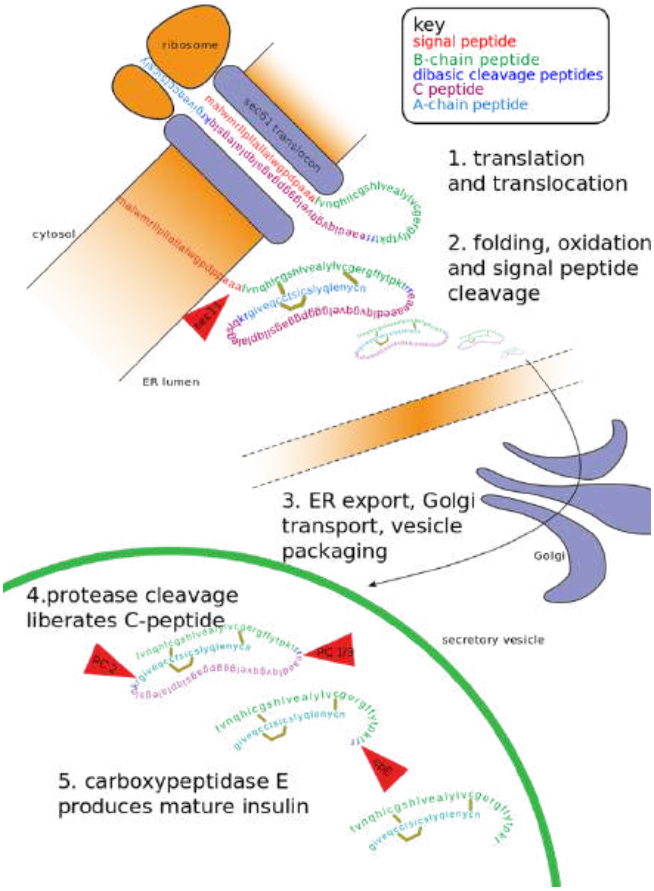

Figure 15.1.9: Insulin Production. The process of insulin production includes the translation of the insulin mRNA into the rough endoplasmic reticulum. The peptide is transported through the Golgi and packaged into secretory vesicles where protease cleavage by carboxypeptidase E produces the mature insulin peptide and peptide C. Image from Fred the Oyster

The C-peptide is a bioactive peptide secreted at the same time and in equimolar amounts to the insulin hormone. It also has a longer half-life than insulin and is excreted by the kidneys into the urine, making detection easy. Furthermore, it allows for the detection of patient-produced insulin, even if they are receiving insulin injections. Thus, C-peptide detection is often utilized to help distinguish between patients with type 1 diabetes from patients with type 2 diabetes (or Maturity onset diabetes). Details about the different forms of diabetes will be discussed in greater detail later.

Once insulin is released from the pancreas, it travels throughout the body and binds with cellular targets that contain the insulin receptor. The Insulin Receptor is a tyrosine kinase receptor that dimerizes upon insulin binding, as shown in Figure 15.1.10. Insulin receptors are located on most cell types throughout the body causing pleiotropic effects during insulin response. Primary targets of insulin action are the liver, where it promotes the uptake of glucose and the production of the glycogen storage molecule, as well as skeletal muscle and fat. The tyrosine kinase portion of the receptor located on the internal side of the plasma membrane is quite flexible.

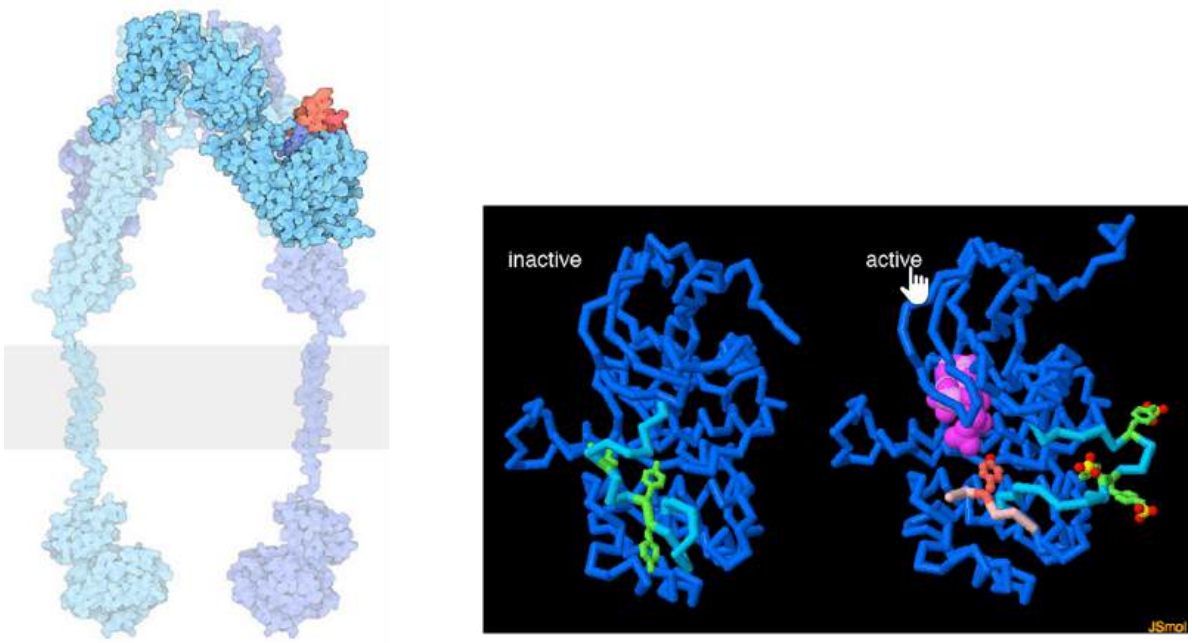

Figure 15.1.10: The Insulin Receptor. Images from Goodsell, D., et al (2015) RCSB PDB-101 'Molecule of the Month'

The *lefthand diagram* shows a space-filling model of the activated insulin receptor dimer embedded into the plasma membrane (shown as the gray bar). The tyrosine kinase portion of the receptor is shown on the inside of the cell whereas the insulin binding domain is present on the external side of the plasma membrane. The *middle and right-hand diagrams* show the inactive *(middle)* and active forms *(far right)* of the tyrosine kinase domain of an insulin receptor monomer. When activated the tyrosine kinase domain binds to ATP (hot pink) and phosphorylates downstream targets, including several of its tyrosine residues (green). In the inactive state (middle), a mobile loop (turquoise) binds in the ATP binding site and prevents ATP association. When the insulin receptor is activated, the mobile loop opens, allowing for the binding of ATP and self-phosphorylation of tyrosine residues, as well as other signaling proteins (a small peptide from one is shown in light pink).

Figure 15.1.11 below which shows an interactive iCn3D model of the **Full-length mouse insulin receptor bound to four insulins (7SL7)**.

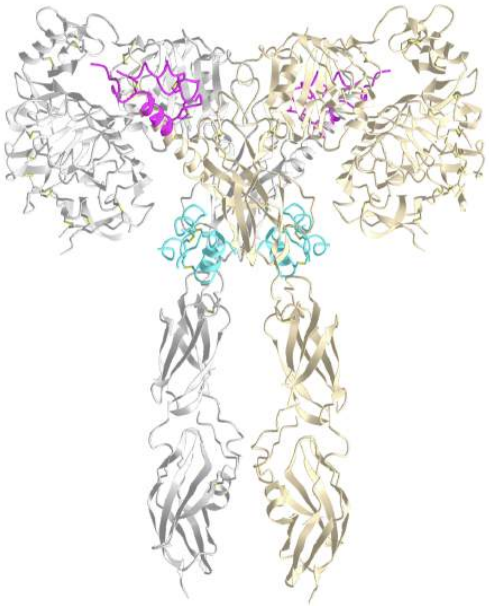

Figure 15.1.11 : Full-length mouse insulin receptor bound to four insulins (7SL7). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...gkTrtvaqQF6o2A

The receptor is a dimer (one monomer gray and the other light brown). Four insulins are bound in maximally activated insulin receptors. Two insulins (magenta) are bound at the same respective place in each monomer (site-1, the primary site) and the two others are bound at a second parallel site (site-2). The full active state is a symmetric T-shape. Less active receptors have fewer bound insulins with receptor geometry more asymmetric (one insulin bound at site 1 gives a Γ-shaped conformation, while two produce a T-shaped conformation as the second insulin binds). When 4 insulins are bound at both sites, the asymmetric conformation can't be formed. Although the structure is described as full-length, both monomers end at amino acid 910. The single membrane-spanning alpha-helix membrane occurs at amino acids 947-967 and is NOT shown in the model.

Activation of the insulin receptor in the liver when insulin is present initiates a phosphorylation signaling cascade, as shown in Figure 15.1.12. One function of the signaling cascade results in the activation of the Rab10 protein. Rab 10 promotes the fusion of GLUT4-containing secretory vesicles (GSVs) with the plasma membrane allowing for increased surface expression of GLUT4. GLUT4 is a glucose transporter protein. Thus, an increased concentration of the protein in the plasma membrane results in the upregulation of glucose import into the cell. Having GLUT4 proteins stored within secretory vesicles makes it available more readily than having to activate gene transcription pathways and production of the protein *de novo*. This allows a faster response to help lower blood glucose levels. The result is increased glucose uptake from the bloodstream into liver cells and other cellular targets, reducing blood glucose levels.

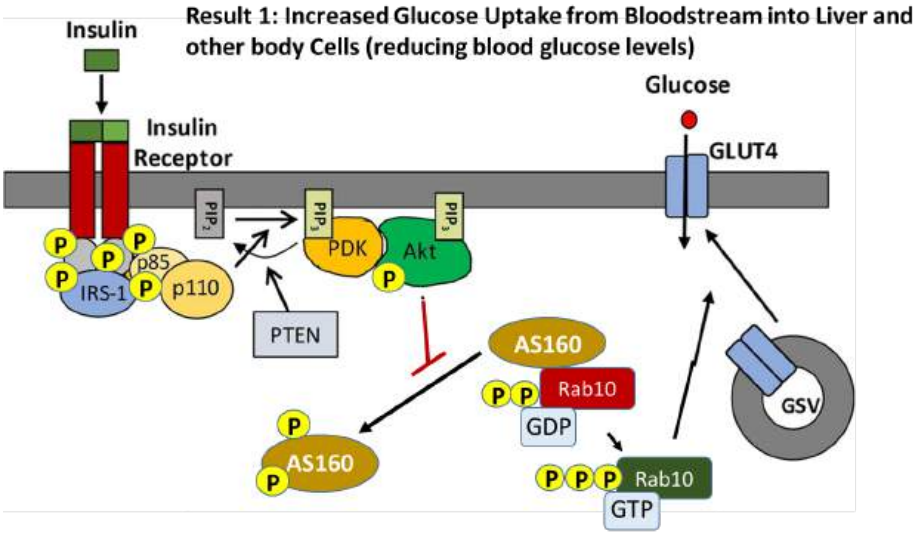

Figure 15.1.12 Insulin Activation of Liver Cells and Glucose Uptake. Image from Carmichael, R.E., et al (2019) Scientific Reports 9:6477

The insulin receptor is a receptor tyrosine kinase, which undergoes dimerization and autophosphorylation of Tyr residues upon insulin binding. The phosphorylated receptor also recruits and phosphorylates the insulin receptor substrate 1 (IRS-1) on tyrosine residues, which then recruits dimeric Phosphoinositol (PI)3-kinase (p85/p110 in the diagram above) and phosphorylates the p85 regulatory subunit. The PI3 kinase catalyzes the phosphorylation of phosphatidylinositol bisphosphate (PIP2) within the plasma membrane to form phosphoinositol, 3,4,5-triphosphate (PIP3). PIP3 then recruits PIP3-dependent kinase (PDK) which phosphorylates and activates Akt. Once activated, Akt dissociates from the membrane into the cytosol where one of its downstream targets is AS160. AS160 is a GTPase that normally binds with Rab10 (a G-protein) causing the cleavage of GTP to GDP. Thus, AS160 downregulates the activity of Rab10. In the phosphorylated state, AS160 cannot bind or inhibit Rab10, enabling Rab10 to release GDP and bind with a molecule of GTP. In the activated state, Rab10 helps promote the fusion of GLUT4-containing secretory vesicles (GSVs) secretory vesicles with the plasma membrane.

Figure 15.1.13 provides a deeper look at some of the initial activation steps in the insulin signaling pathway. This step shows the phosphorylation of Phosphoinositol 4,5-bisphosphate (PIP2) to Phosphatidylinositol 3,4,5-triphosphate (PIP3). PIP2 is a common phospholipid within the lipid bilayer structure. In future lectures, we will see the utilization of this phospholipid in other signaling pathways as well.

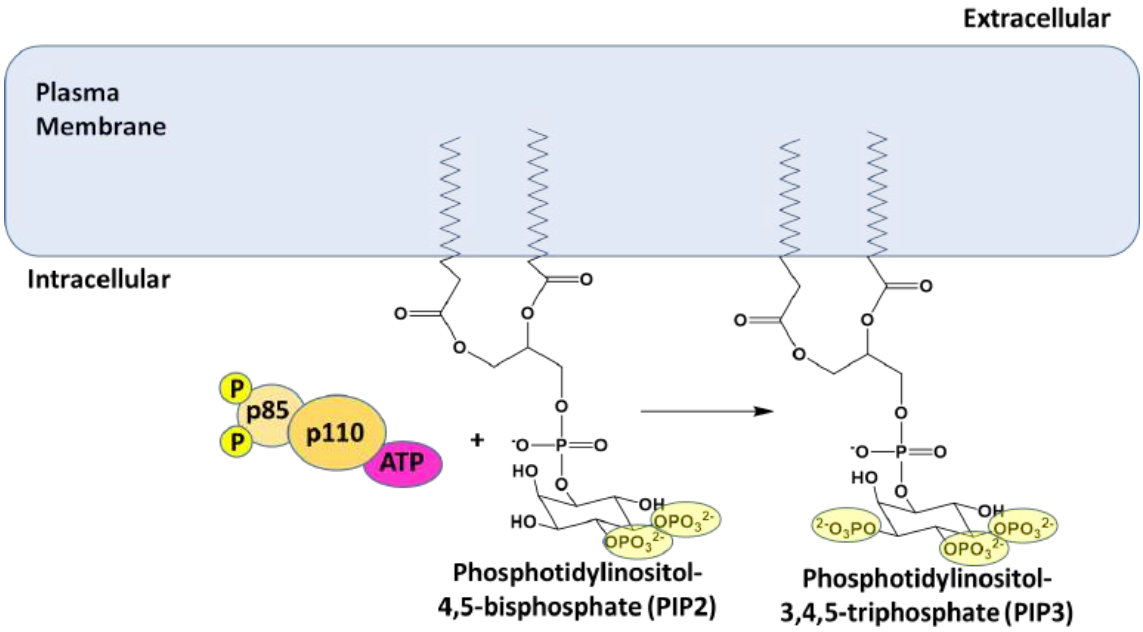

Figure 15.1.13 Phosphorylation of phosphotidylinositol-4,5-bisphosphate During Insulin Signaling.

Once glucose enters a cell, it is rapidly converted to glucose 6-phosphate via the enzyme hexokinase, as shown in Figure 15.1.14 below. This enzyme is covered in more detail in our section on glycolysis. Importantly, phosphorylation traps the glucose inside the cell and does not allow it to be redistributed back into the bloodstream. This helps to maintain the homeostasis of glucose within the bloodstream. In addition, glucose 6-phosphate is the first step in many pathways utilizing glucose, including energy utilization and the formation of building blocks such as ribose and deoxyribose used in RNA and DNA synthesis.

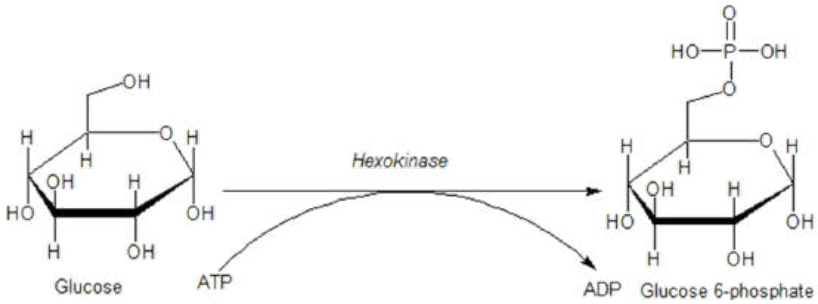

Figure 15.1.14 Conversion of Glucose to Glucose-6-Phosphate by Hexokinase. Image from Jmun7616

Insulin signaling increases the number of GLUT4 transporters in the plasma membrane causing an increased uptake of glucose into the cell. Within liver and muscle tissue, if glucose is not required for energy or other metabolic intermediates, it is then converted to glycogen for storage. The major enzyme required for glycogen synthesis is also activated via insulin signaling, as shown in Figure 15.1.15. In addition to phosphorylating the AS160 protein, Activated Akt also phosphorylates the Glycogen Synthase Kinase enzyme (GSK-3) which inactivates this protein. This allows protein phosphorylase 1 (PP1) to dephosphorylate the Glycogen Synthase enzyme shifting it into a more active state, and causing glycogen synthesis to commence.

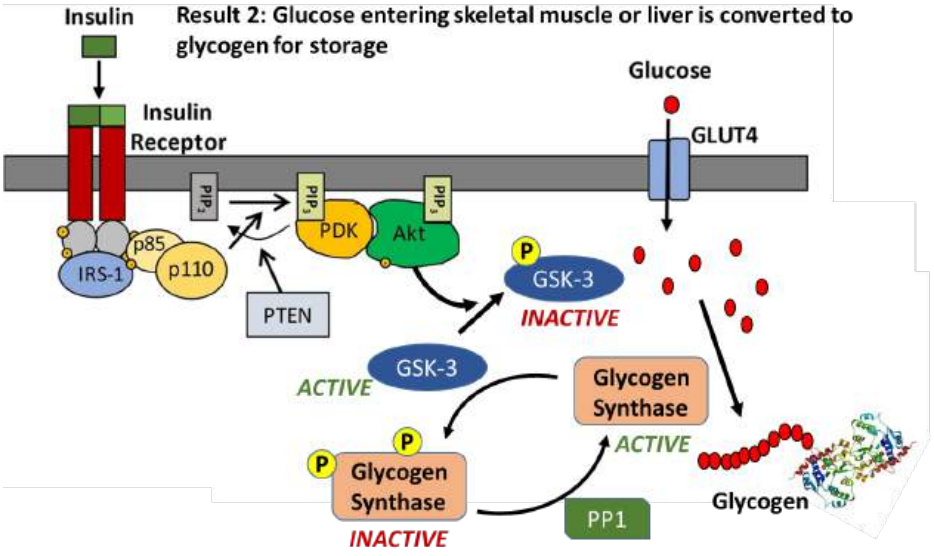

Figure 15.1.15 Activation of Glycogen Synthase During Insulin Signaling. Image modified from Carmichael, R.E., et al (2019) Scientific Reports 9:6477

In this section, we have covered two pathways activated during cellular response to insulin signaling, and I am sure that you are feeling a bit overwhelmed with the complexity. However, biological processes are incredibly complex and signaling pathways have multiple pleiotropic downstream effects. For insulin signaling, we have only touched the tip of the iceberg, as evidenced in Figure 15.1.16. This figure gives a more complete representation of the chemical changes induced within a liver cell in response to insulin signaling. For our purposes, we will restrict coverage to the two downstream effects: an increase in GLUT4 transporters in the plasma membrane and increased activity of glycogen synthase.

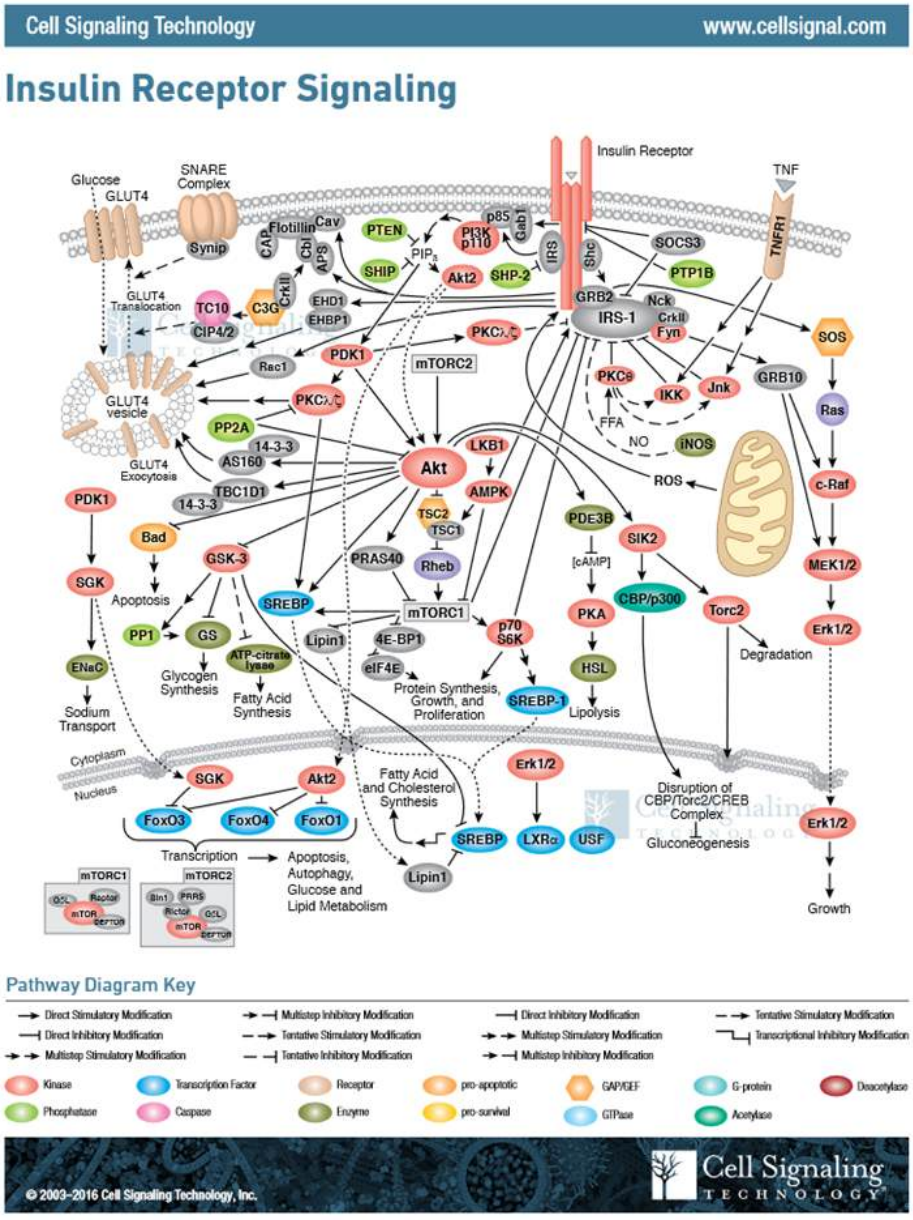

Figure 15.1.16: Insulin Signaling Pathway. Image by Cell Signaling Technology

15.2: GLYCOGENESIS

15.2.1: INTRODUCTION

The process of forming glycogen is called **glycogenesis** and it requires the activity of six enzymes as illustrated in Figure 15.2.1. We have already discussed several including hexokinase which phosphorylates the 6'-OH of glucose and phosphoglucomutase which converts glucose-6-phosphate to the glucose-1-phosphate isomer. In this section, we will discuss the remaining four enzymes and their role in glycogen biosynthesis. They are Glycogen Synthase, UDP-Glucose Pyrophosphorylase (preferred name UTP-glucose-1-phosphate uridylyltransferase), Glycogenin, and Glycogen Branching Enzyme.

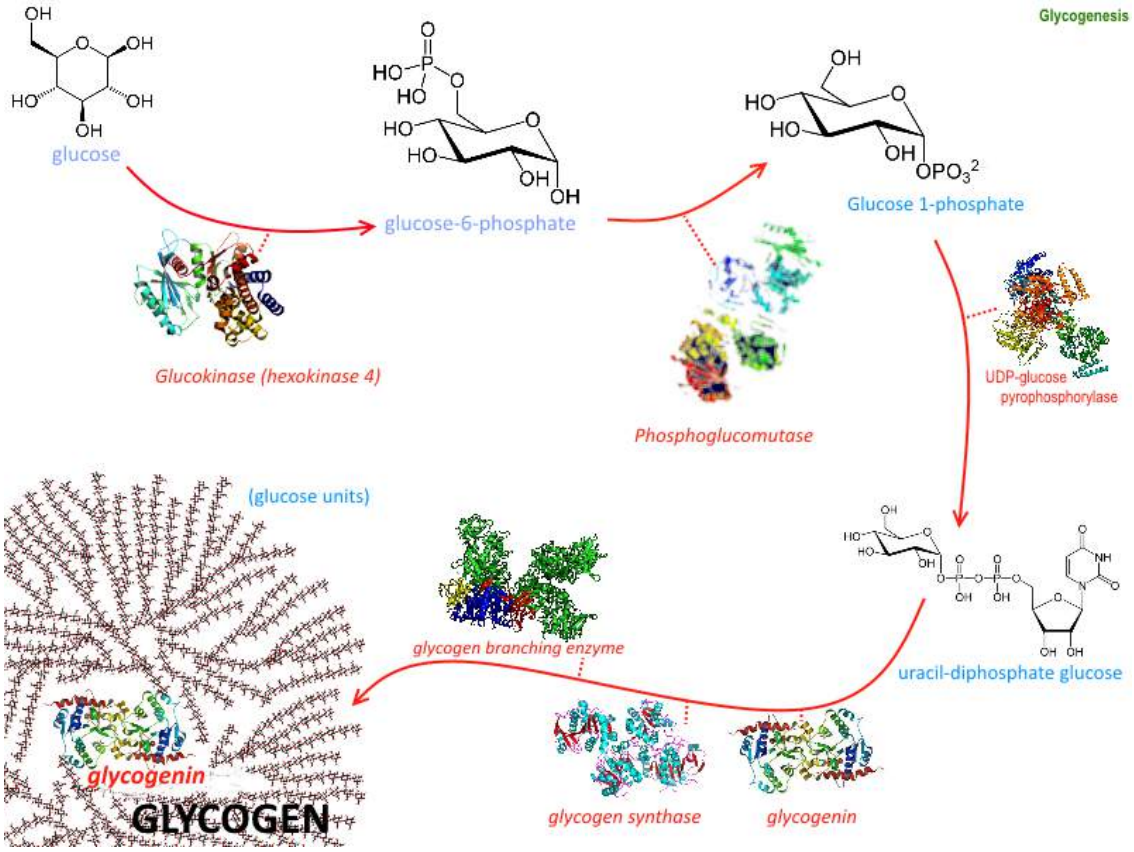

Figure 15.2.1: Enzymes involved in Glycogenesis. Image from Mark Cidade

Given the importance of these enzymes in the synthesis of the second main energy storage molecule, we must probe the enzymes in detail.

Glycogen synthase (GS) is a key enzyme and its activity is highly regulated. In Chapter 15.1, we have already explored how insulin signaling upregulates the activity of this enzyme by inhibiting phosphorylation by GSK-3. Other effectors include the allosteric binding of glucose-6-phosphate, which also increases the activity of the GS. In a later section, we will also see that the hormone glucagon can also regulate the activity of the GS through protein kinase A (PKA) in a fashion that decreases glycogen synthesis and increases glycogen breakdown.

In the glycogenesis pathway, GS is responsible for building the majority of the main alpha 1 → 4 chain glucose acetal linkages. The GS does require a primer of 4 -6 glucose residues linked together by alpha 1 → 4 bonds to begin synthesis. Since GS can only form alpha 1 → 4 linkages in the main chain, it CANNOT create the alpha 1 --> 6 branches inherent to the core structure of glycogen.

To build the glycogen main chain, GS uses the glycogen primer and glucose that has been activated through covalent attachment to uridine diphosphate (UDP) at the 1-position. Upon completion of one round of synthesis, the 1 position of the incoming UDP-glucose is covalently attached to the 4-position of the nascent glycogen molecule, releasing the UDP as a leaving group.

$$\text{Glycogen}_{(n)} + \text{UDP-glucose} \rightarrow \text{Glycogen}_{(n+1)} + \text{UDP}$$

15.2.2: **UTP--GLUCOSE-1-PHOSPHATE URIDYLYLTRANSFERASE (OR** UDP-GLUCOSE PYROPHOSPHORYLASE)

The formation of the UDP-glucose required for the synthesis of the main chain of glycogen is mediated by **UTP-glucose-1-phosphate uridylyltransferase (preferred name), which is also called UDP-glucose pyrophosphorylase** (GalU or UGPase; EC 2.7.7.9). UGPase catalyzes the reversible reaction of glucose 1-phosphate and UTP into UDP-glucose and inorganic pyrophosphate (PP_i) (Figure 15.2.2). Enzymes of the UGPase family are ubiquitous and can be found in the tree of life.

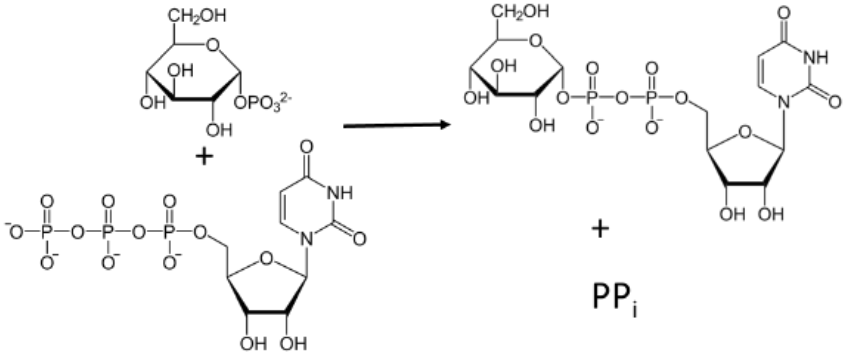

Figure 15.2.2: Formation of UDP-Glucose

UDP-glucose is an activated form of glucose used in the synthesis of other glycans including sucrose, cellulose, start, and glycogen, and the glycan parts of glycoproteins, glycolipids, and proteoglycans. Hence it is a key metabolite, which gives more importance to understanding UGPase.

Like many other nucleotidyl transferases, UGPase requires divalent cations to promote the reaction (Figure 15.2.3). In most cases, magnesium ions are employed. The reaction mechanism follows a sequential bi-bi-mechanism starting with the binding of UTP to the active site, in presence of a magnesium ion, followed by the binding of glucose 1-phosphate. The octahedral coordination sphere of the magnesium positions the substrates in the right way and enables the nucleophilic attack of glucose 1-phosphate on UTP. A lysine, an aspartate, and several water molecules within the active site help to stabilize the position of the substrates and cofactor for the proper nucleophilic attack of the phosphoryl oxygen of glucose 1-phosphate towards the α-phosphorous atom of UTP. Finally, PP_i is released from the UGPase/Mg^{2+}/UDP-glucose complex. UDP-Glucose then dissociates from the complex restoring the active site of the enzyme for another round of synthesis.

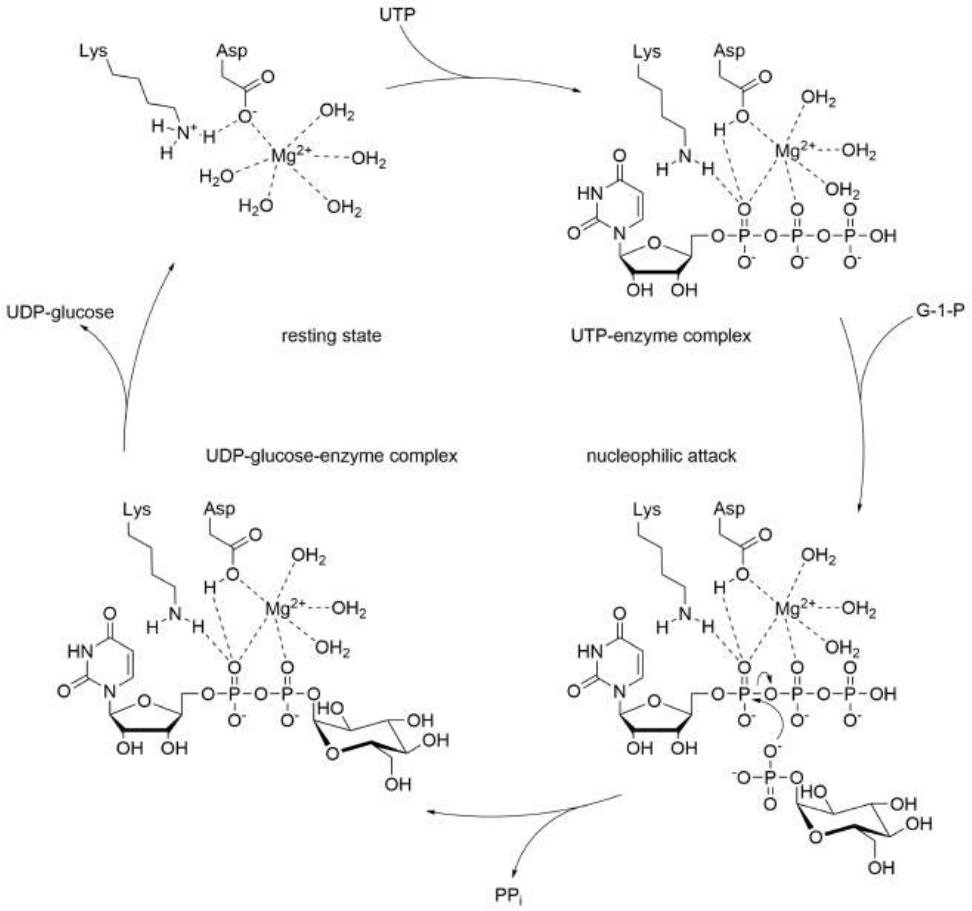

Figure 15.2.3: Proposed Reaction Mechanism of UTP--glucose-1-phosphate uridylyltransferase (UDP-Glucose Pyrophosphorylase). Image from Kumpf, A., et al. (2019) *Int. J. Mol. Sci. 20(22)* 5809; **https://doi.org/10.3390/ijms20225809**

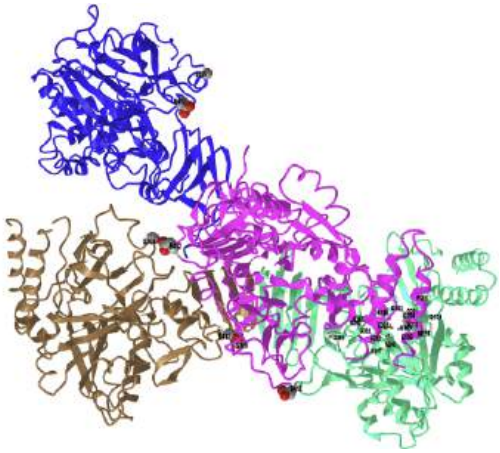
Figure 15.2.4 shows an interactive iCn3D model of the human UDP-glucose pyrophosphorylase tetramer (3R2W).



NCBI iCn3D Figure 15.2.4: Human UDP-glucose pyrophosphorylase tetramer (3R2W). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?9yq9STPGvq87Wnbt8

Substrate binding and active site residues are shown as CPK-colored sticks and labeled in one of the subunits. Three key loops whose correct positioning is required for catalysis are colored as follows:

- Latch Loop: 406-416, yellow, which contains Glu 412 (shown in spacefill)
- SB Loop: 275-282, red
- 309 Loop: 309-311, cyan, which contains Ser 309 (shown in spacefill).

Only four of the eight subunits are shown for clarity. Note the proximity of the interacting loops positioned between the brown and magenta subunits. The SB and 309 loops at that location are part of the brown subunit, while the yellow latch loop is part of the magenta subunit. The latch loop is between the SB and 309 loops. The cyan 309 loop hence is prevented from interacting with the substrate and with the movements of the SB and 309 loops needed for catalysis. In other species, it has been observed the SB loop moves down UDP-glucose on binding to the active site. The structure above is for the apo-enzyme without bound substrate, and hence the inactive or **closed** form of the protein.

Mutations in the 309 loop (S309N/S311R) still had 84% of normal activity. Glu412 in the latch loop is highly conserved in vertebrates (but not present in yeast). Mutations in Glu 412 didn't affect the formation of oligomers of the enzyme but did affect activity.

- replacing E412 with a short aspartate (E412D) significantly increase activity (176%)
- E412Q, which eliminates the charge while retaining the approximate size of the side chain showed just a marginal increase in activity (19%)
- E412K, which flips the charge and increases the length of the side chain decreased activity to 22%.

These mutations generally suggest that steric effects in the region of subunit interaction are most important in activity.

15.2.3: GLYCOGEN SYNTHASE

UDP-glucose is then utilized by **glycogen synthase** (GS) to extend the main chain of glycogen by one glucose residue. In this reaction, the 4'-OH group of the glycogen main chain attacks the anomeric carbon of UDP-glucose (Figure 15.2.5). The UDP functional group serves as a good leaving group allowing for the formation of the alpha 1 --> 4 bond.

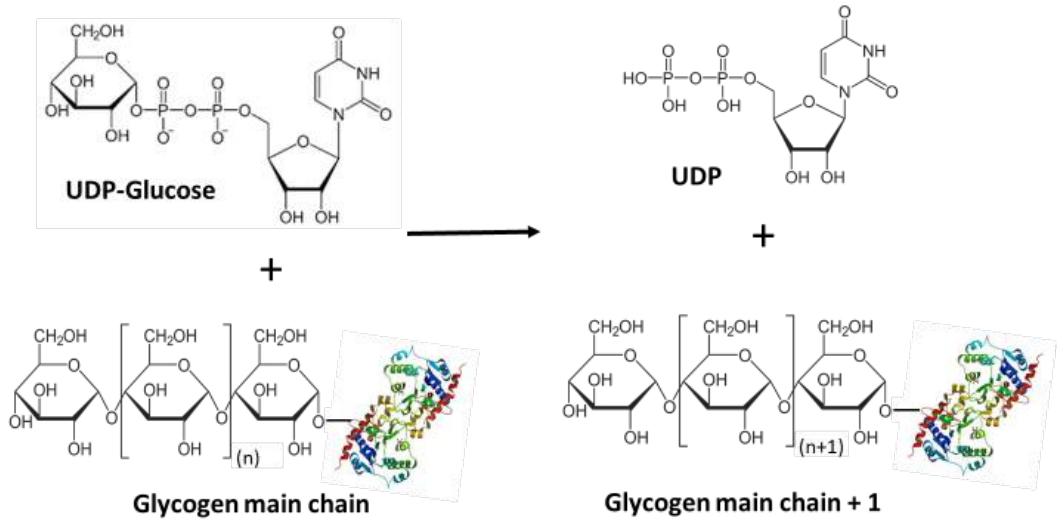


Figure 15.2.4: Formation of the Glycogen Mainchain by Glycogen Synthase. Image modified from Mikael Häggström

Glycogen synthase has two isoforms, GS1 expressed in tissue where glycogen is present (for example muscle) and GS2 expressed only in the liver. We will explore its mechanism more fully below.

15.2.4: GLYCOGENIN

Previously, we mentioned that GS requires a glycogen primer of 4 – 6 glucose residues to begin adding new residues to the main chain. This primer is provided by the small docking protein, **Glycogenin (GN or GYG)**. This protein is a homodimer that self-catalyzes its own glycosylation at amino acid Tyr-194. In this reaction, UDP-glucose is coordinated by a Mn^{2+} metal cofactor and critical aspartate residues (Figure 15.2.6). The –OH group of Tyr-194 then mediates nucleophilic attack on the anomeric carbon of UDP-glucose. Thus, glycogenin is tethered to the reducing end of the glycogen molecule.

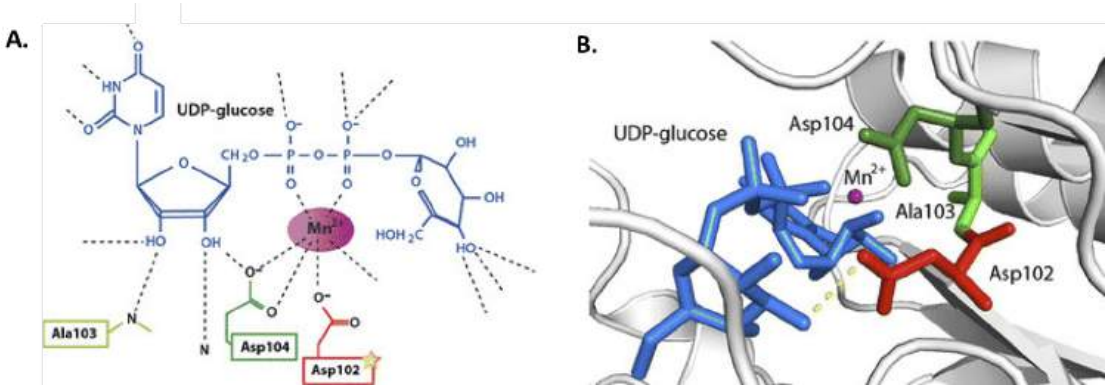

Figure 15.2.6: Coordination of UDP-Glucose by Glycogenin. Critical aspartic acid residues and a manganese ion cofactor are required for the coordination of UDP-glucose by glycogenin. Image from Hedberg Oldfors, C., Glamuzina, E., Ruygrok, P. and Anderson, L. (2016) *J. Inherit. Met. Dis.* 40(1) DOI: 10.1007/s10545-016-9978-1

As with glycogen synthase, glycogenin (GN or GYG) has two isoforms, with GN2 (or GYG2) expressed mostly in the liver, pancreas, and heart.

15.2.5: MECHANISMS FOR GLYCOGEN SYNTHESIS BY GLYCOGENIN AND GLYCOGEN SYNTHASE

How do glycogenin and glycogen synthase cooperate in the synthesis of glycogen? Structures of the complex of glycogenin-1 (GYG1), which seeds the molecule by starting glycogen synthesis by autoglucosylation, and glycogen synthase-1 (GS1 or GYS1), which extends the molecule, show allosteric transitions between three main states, the closed/inactive, partially open, and open active complex, as shown in Figure 15.2.7:

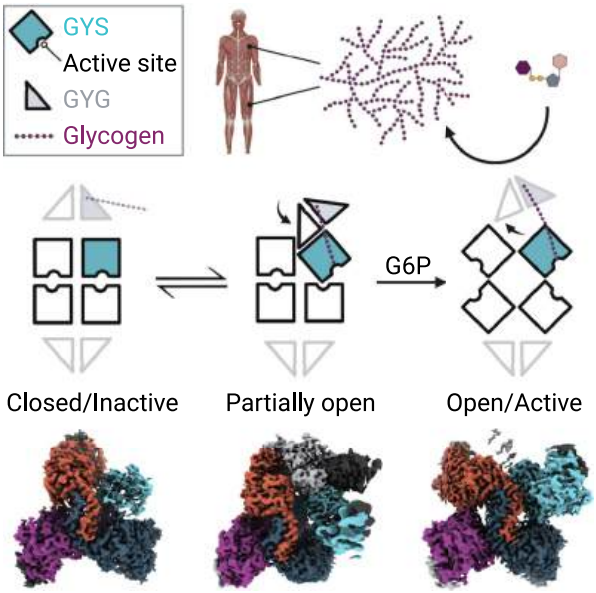

Figure 15.2.7: GYS1 chains A, B, C, and D are colored orange, turquoise, purple, and navy respectively. GYG1 globular domains and the GYG1-tail fragment are colored in gray shades for all chains. The left bottom structure shows the apo GYS1:GYG1 mobile complex. The bottom middle structure is the apo GYS1:GYG1 ordered complex. The bottom right structure is the +G6P GYG1:GYS1 complex. Fastman et al., 2022, Cell Reports 40, 111041 July 5, 2022, 2022. https://doi.org/10.1016/j.celrep.2022.111041. Creative Commons Attribution (CC BY 4.0)

It makes sense that both enzymes bind to each other and cooperate in the synthesis of glycogen. In the closed state, GS (GYS) is a tetramer, which like hemoglobin can be described as a T or closed/inactive state. In a slight difference, one of the GS (GYS) subunits appears to display an asymmetric conformation which leads to close interactions with GN (GYG) allowing the glycogen seed polymer on GN (GYG) to move to GS (GYS) for elongation (a partially open state). Multiple conformations of the complex have been resolved. Further conformational changes lead to the open/active state and a more open binding groove for GN (GYG).

Figure 15.2.8 shows an interactive iCn3D model of the Human glycogenin-1 and glycogen synthase-1 complex in the presence of glucose-6-phosphate (8CVX). Glucose-6-phosphate is an allosteric activator of glycogen synthase.

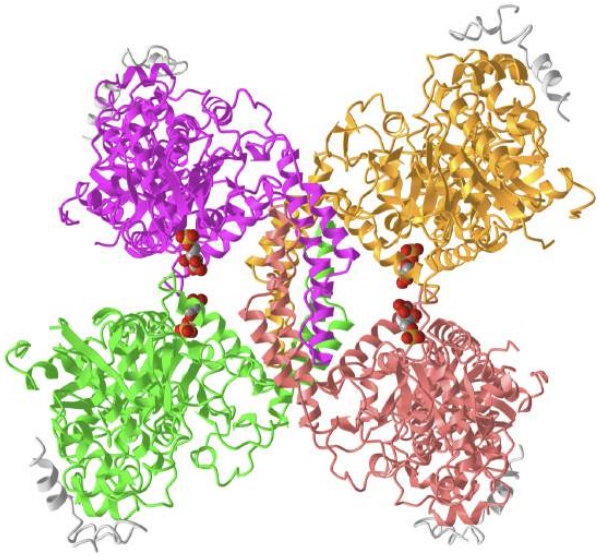

Figure 15.2.8: Human glycogenin-1 and glycogen synthase-1 complex in the presence of glucose-6-phosphate (8CVX). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...ivh4gZCupGcXZ7

The larger glycogen synthase subunits in the tetramer are shown in various colors while the glycogenin fragments bound to each monomer of GS (GYS) are shown in gray.

Figure 15.2.9 illustrate in greater detail the conformational changes induced on the binding glucose-6-phosphate to glycogen synthase.

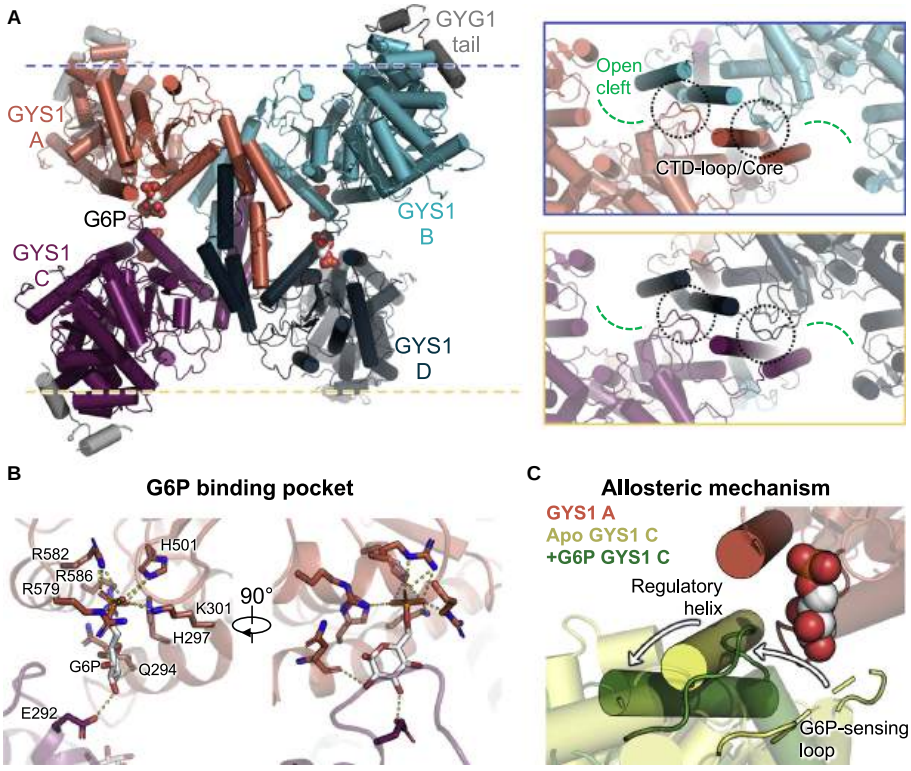

Figure 15.2.9: G6P binding induces a conformational change across the GYS1 tetramer leading to an open conformation for all four active sites. Fastman et al, ibid.

Panel (A) shows a cartoon representation of the +G6P GYS1:GYG1 complex (left) with GYS1 and GYG1 chains colored as in the previous figure. G6P is shown as spheres colored by heteroatom. Blue and yellow lines and boxes (right) indicate relative positions for perpendicular views. A black dotted circle indicates the oligomeric interface between the CTD-loop region and tetramerization core domains. The CTD-

loop, residues 484–488, forms cross-protomer interactions on the other side of the active site. Green dashed semicircles indicate open active sites.

Panel (B) shows G6P-binding site interactions. G6P (white) and proximal interacting residues are shown as sticks and colored by heteroatom. Polar interactions are indicated by yellow dotted lines.

Panel (C) shows changes at the G6P-binding site across conformations. A G6P-bound protomer is highlighted in orange with G6P shown as spheres. The adjacent active state protomer (chain C) is shown as a green cartoon. A basal state protomer (chain C) is modeled relative to the orange G6P-bound protomer and shown in yellow. Key changes to the G6P-sensing loop and a regulatory helix are highlighted by outline and non-transparent representation with arrows indicating the relevant motions. The rest of each chain is shown in a transparent cartoon representation.

We will return to the mechanism after exploring the last enzyme in the pathway.

15.2.6: GLYCOGEN BRANCHING ENZYME

The final enzyme, the **glycogen branching enzyme** (GBE), catalyzes the hydrolytic cleavage of an α(1→4) glycosidic linkage and subsequent inter- or intra-chain transfer of the non-reducing terminal fragment to the C6 hydroxyl position of an α-glucan (Figure 15.2.10). In this example, an inter-chain transfer is occurring. At the top of the scheme, above the arrow, you can see that the GBE enzyme transiently removes several glucose residues (usually around 7) from one linear glycogen chain and then attaches it as an alpha 1→ 6 branch to the other chain. In this process, an additional non-reducing end is created which can act as a primer site for Glycogen Phosphorylase (the main enzyme that breaks down glycogen). Thus, glucose residues can be released very quickly when needed.

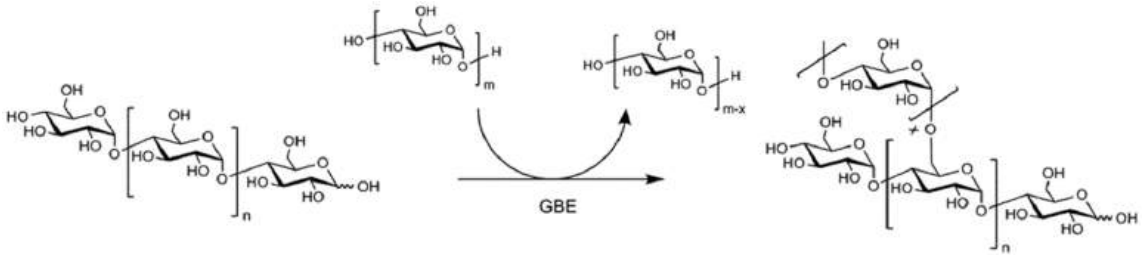

Figure 15.2.10: Formation of Glycogen alpha 1 --> 6 Branches. Image from van der Vlist, J., et al (2012) Polymers 4(1) 674-690. DOI: 10.3390/polym4010674

Details of the structure and domain organization of the human glycogen branching enzyme are shown in Figure 15.2.11. The four domains include N1, CBM48, the catalytic domain, and the C-terminal domain.

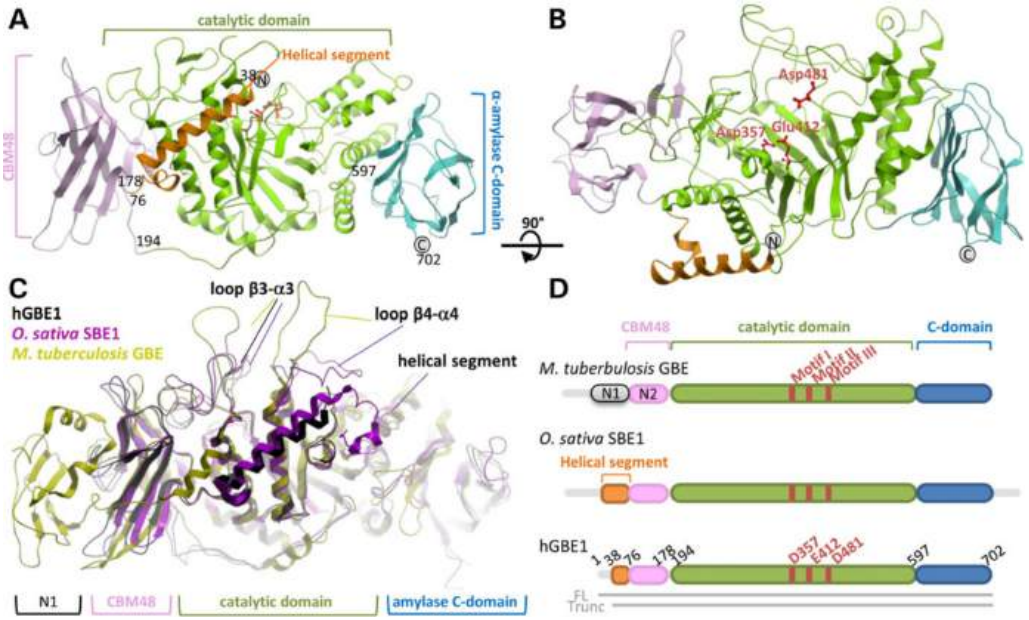

Figure 15.2.11: Crystal structure of hGBE1. Froese et al. *Human Molecular Genetics*, Volume 24, Issue 20, 15 October 2015, Pages 5667–5676, https://doi.org/10.1093/hmg/ddv280. Creative Commons Attribution License (http://creativecommons.org/licenses/by/4.0/)

Panels (**A** and **B**) show orthogonal (perpendicular) views of hGBE1 showing the N-terminal helical segment (orange), CBM48 (pink), central catalytic domain (green), and C-terminal domain (blue). The catalytic triad Asp357-Glu412-Asp481 is shown as red sticks. Numbers refer to domain boundaries. N- and C-termini are labeled as grey spheres.

Panel (**C**) shows the superposition of branching enzyme structures from human (hGBE1, this study), *O. sativa* SBE1, and *M. tuberculosis* GBE, highlighting the conserved domain architecture and three regions of structural variation.

Panel (**D**) shows the domain organization of hGBE1, *O. sativa* SBE1, and *M. tuberculosis* GBE revealing differences in the N-terminus between prokaryotic and eukaryotic polypeptides. Prokaryotic GBEs contain two N-terminal carbohydrate-binding domains (N1, N2) whereas eukaryotes contain only one (CBM48) and replace the prokaryotic N1 domain with a helical extension.

Figure 15.2.12 shows an interactive iCn3D model of the **human glycogen branching enzyme (GBE1)**

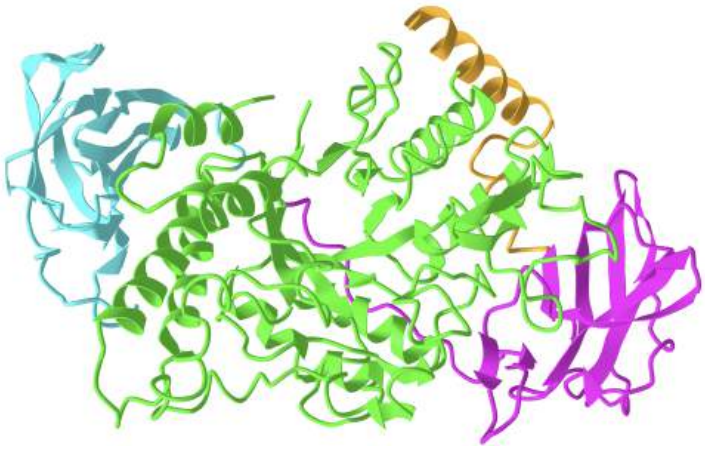

Figure 15.2.12: **human glycogen branching enzyme (GBE1)**. (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...47aqw5qto8hkU7

The domains in the iCn3D module are colored similarly to that of the previous figure.

The enzyme core is similar to amylase with the conserved active site. Diseases of glycogen storage often result from mutations in the amylase core domain. For example, late-onset adult polyglucosan body disease (APBD) arises from a common mutation, Y329S. The effect of this mutation may arise from misfolding. A tetrapeptide, Leu-Thr-Lys-Glu, given to patients, increased activity twofold, probably by acting as a chaperone to facilitate proper folding.

15.2.7: PUTTING IT ALL TOGETHER: GLYCOGEN SYNTHESIS AND ITS REGULATION

Figure 15.2.13 shows the steps involved in the addition of glucose from the donor UDP-glucose to glycogenin and through glycogen synthase to the growing glycogen polymer which becomes branched through the activity of the glycogen branching enzyme.

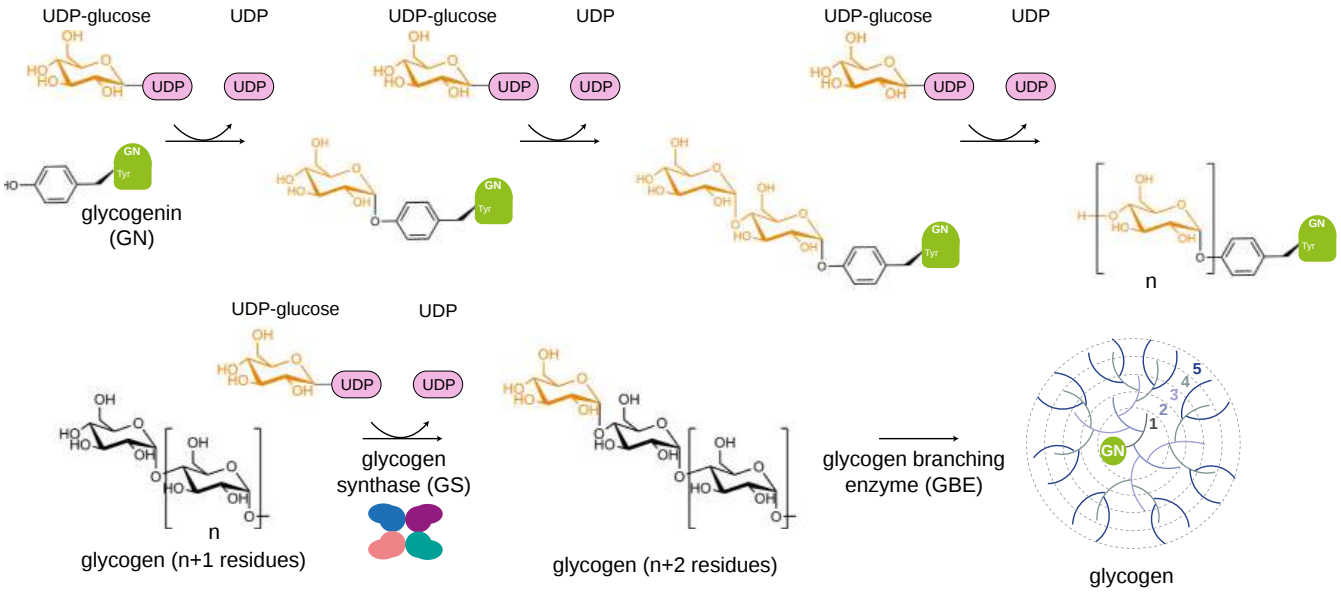

Figure 15.2.13: Summary of glycogen synthesis. Marr, L., Biswas, D., Daly, L.A. *et al. Nat Commun* **13**, 3372 (2022). https://doi.org/10.1038/s41467-022-31109-6. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/

The top reaction shows the step catalyzed by glycogenin (GN), while the bottom reactions are those catalyzed by glycogen synthase and the glycogen branching enzyme.

Regulation of glycogen synthesis occurs in part through the phosphorylation of key residues in both GS (GYS) and GN (GYG). Those sites are shown in Figure 15.2.14.

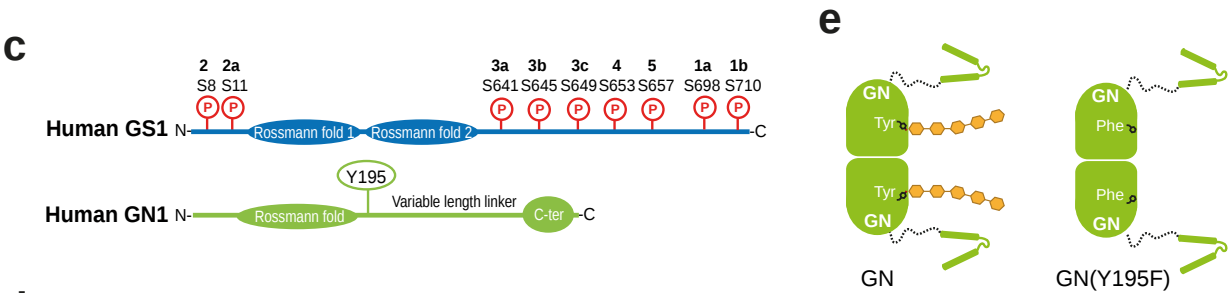

Figure 15.2.14: Domain and phosphorylation sites for glycogen synthase 1 (GS1) and glycogenin 1 (GN1). Marr et al, ibid

Panel c shows the domain architecture of human GS (top) and GN (bottom). Known in vivo phosphorylation sites of GS are shown in red and are labeled with residue number and classical nomenclature (in bold). GN tyrosine 195 that becomes auto-glucosylated and was mutated to phenylalanine (Y195F) in this study is indicated. Not to scale. **Panel e** shows the cartoon representation of GN WT and Y195F.

As we showed above, glycogen synthase is allosterically activated on the binding of glucose-6-phosphate, which can be thought to activate the enzyme by a T to R state change. The enzyme is inactivated by phosphorylation at multiple sites as shown above. Activation hence can also occur through dephosphorylation. Phosphorylation of a site can provide a binding site that leads to more phosphorylations. This can lead to a flexible "spike" of hyperphosphorylated residues forming from two of the monomers. Particularly important is pSer641 (site 3A) which interacts with a series of arginine residues in a regulatory helix of glycogen synthase. This arginine cluster has been called the arginine cradle. The interaction sites are illustrated in Figure 15.2.15.

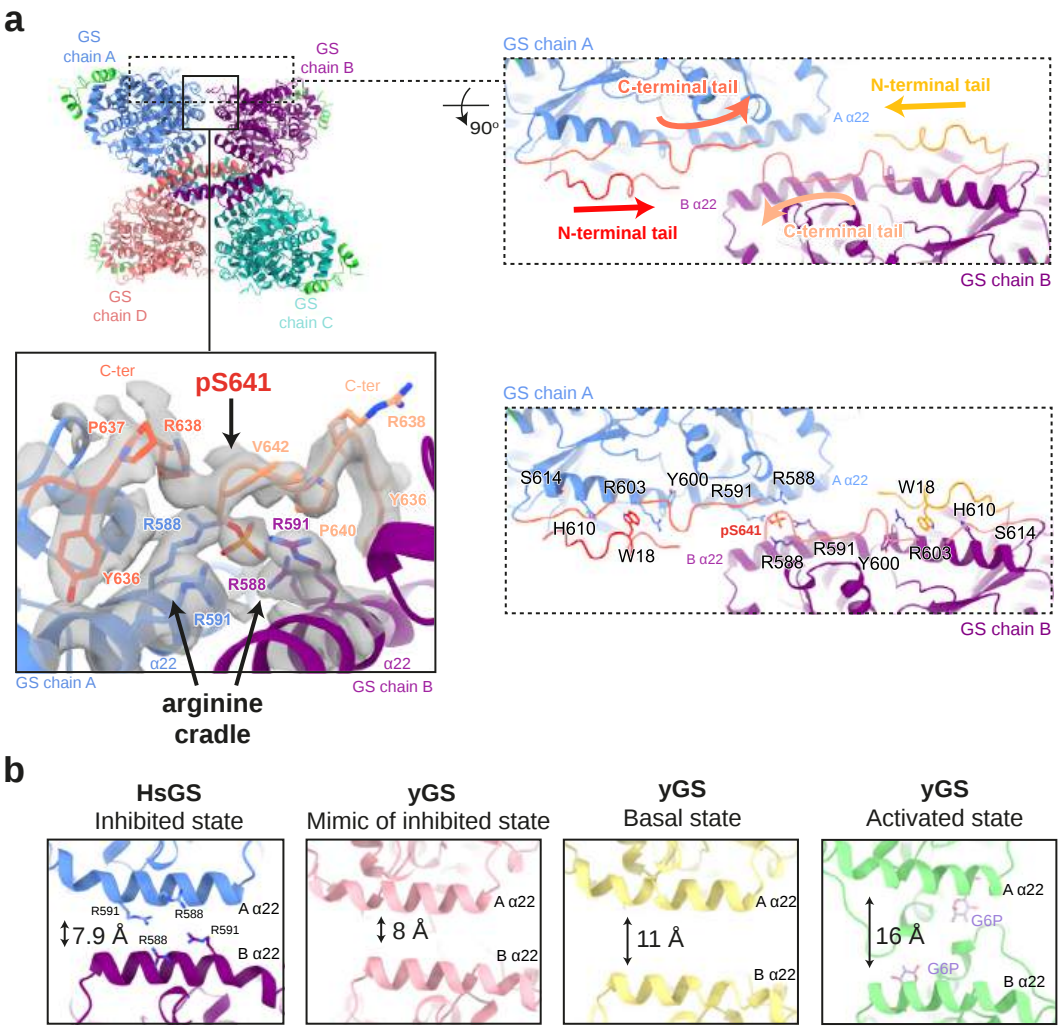

Figure 15.2.15: **The phosphoregulatory region of human GS.** Marr et al, ibid

Panel a shows the human (Hs)GS-GN[34] structure in ribbons (top left). The N- and C- terminal tails of one GS protomer (chain A) lie next to one another and move towards the adjacent protomer, meeting the N- and C-terminal tails from chain B. Arrows indicate a continuation of cryo-EM density (top right). Electron density (C1 symmetry) for phosphorylated S641 (pS641) interacting with R588 and R591 on the regulatory helices α22 (bottom left). Residues that are interacting with the N- and C-terminal tails that are mutated in this study are shown (bottom right).

Panel b shows a comparison of distances between regulatory helices of adjacent monomers of HsGS (reported here), low activity inhibited mimic (PDB ID 5SUL), basal state (PDB ID 3NAZ), and G6P activated (PDB ID 5SUK) yeast GS (yGS) crystal structures. Quoted distances were measured from Cα of Arg591 (chain A) and -Cα of Arg580 (chain B) of HsGS and corresponding yeast residues.

The strong electrostatic arginine-pSer interactions lock the tetramer into the inactive T state.

A cartoon model illustrating the regulation of glycogen synthase by phosphorylation/dephosphorylation and interconversion between T and R state is shown in Figure 15.2.16.

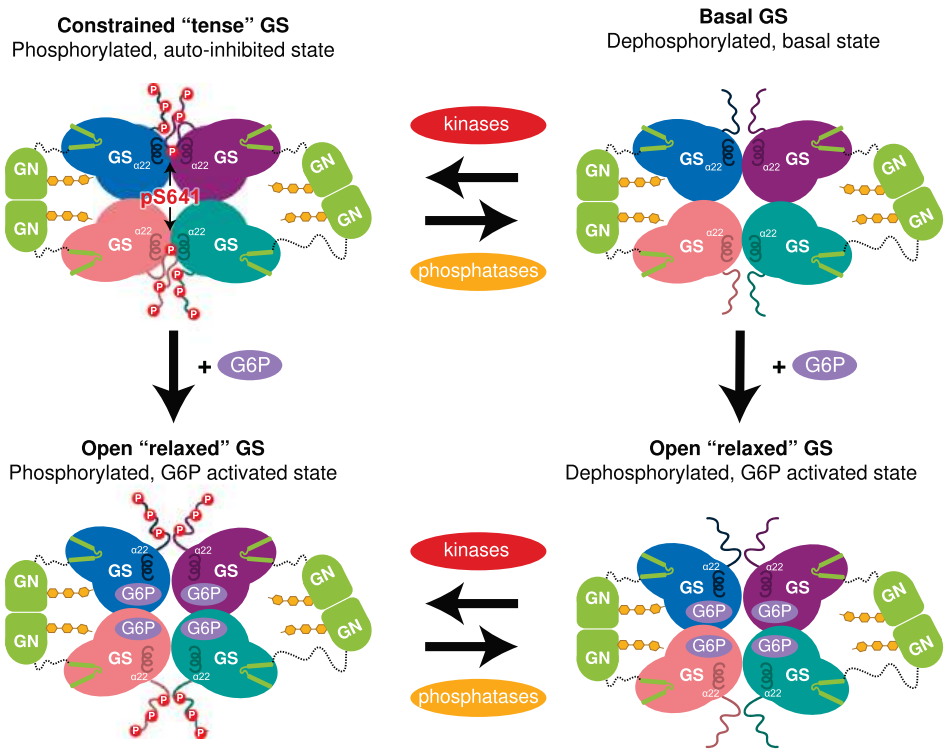

Figure 15.2.16: **GS and GN cooperate to synthesize glycogen.** Marr et al, ibid

The inhibition by phosphorylation can be relieved by binding the allosteric effector glucose-6-phosphate and does not require phosphatases,

15.3: GLYCOGENOLYIS AND ITS REGULATION BY GLUCAGON AND EPINEPHRINE SIGNALING

In the previous section, you learned that glucagon signaling down-regulates glycogen synthesis. Now let's look at glycogen breakdown, called glycogenolysis, and its control by two hormones, glucagon, and epinephrine. Only two enzymes are required for the breakdown of glycogen, the glycogen phosphorylase enzyme, and the glycogen debranching enzyme.

15.3.1: GLYCOGENOLYSIS: AN OVERVIEW

Two key enzymes are required for the stepwise catabolism of glycogen, glycogen phosphorylase, and glycogen debranching enzyme. In the liver, the ultimate end product is glucose-1-phosphate, which is dephosphorylated in the liver to enable the export of free glucose into the circulation. In contrast, in the respiring skeletal muscle, it is converted to glucose-6-phosphate for use in glycolysis. Glycogenolysis is also activated by the hormones glucagon and epinephrine.

Glycogen Phosphorylase

Glycogen phosphorylase (GP) catalyzes the release of glucose 1-phosphate from the alpha 1→ 4 non-reducing ends of glycogen. An overview of this reaction is shown in Figure 15.3.1.

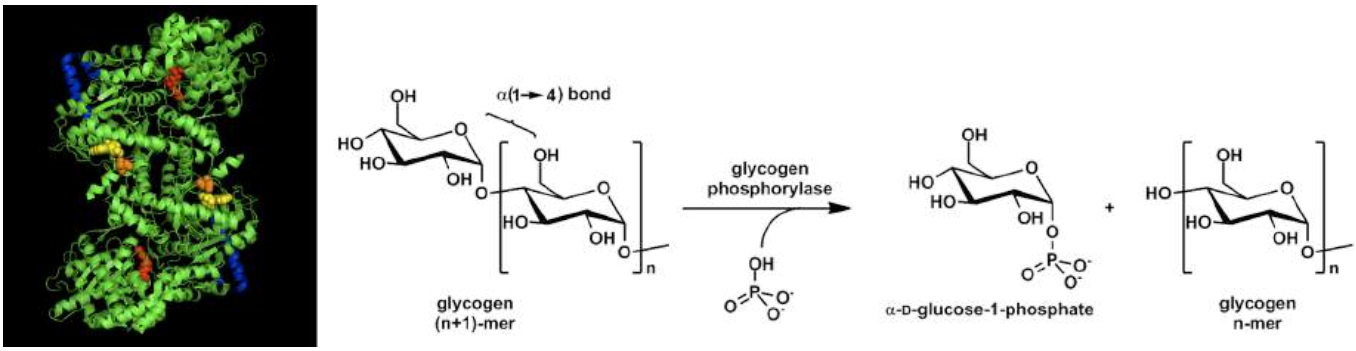

Figure \(\PageIndex{1}\): Overview of Glycogen Phosphorylase Reaction. Images from Ascherer730 and Michal Sobkowski

Glycogen phosphorylase is a homodimer with two active sites. It also requires a cofactor, pyridoxal phosphate (PLP) to be functional (Figure 15.3.2). The PLP is derived from Vitamin B6. You may have heard previously that low levels of B vitamins are associated with lethargy or a lack of energy. We will continue to see that the B vitamins provide essential cofactors for enzymes involved in the production of ATP. Thus, if you lack B vitamins, you are not efficiently producing ATP. The PLP cofactor of GP is attached covalently to the enzyme through a Schiff-base linkage with a Lysine (K) residue.

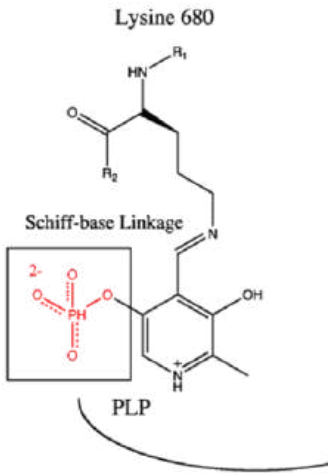

Figure 15.3.2: Pyridoxyl Phosphase Cofactor Associated with Glycogen Phosphorylase Image modified from Ascherer730

The reaction mechanism of glycogen phosphorylase is detailed in Figure 15.3.3. When glycogen phosphorylase binds with glycogen a free inorganic phosphate anion is positioned by the PLP and the enzyme active site in proximity with the anomeric carbon position of the non-reducing end residue of the glycogen molecule. The oxygen involved in the glycosidic bond attacks the partially charged hydrogen

associated with the phosphate ion, leading to the cleavage of the glycosidic bond. The cleaved glycogen chain leaves the active site and one of the phosphate oxygens attacks the carbocation intermediate created during the cleavage. This results in the release of the terminal glucose residue as glucose 1-phosphate

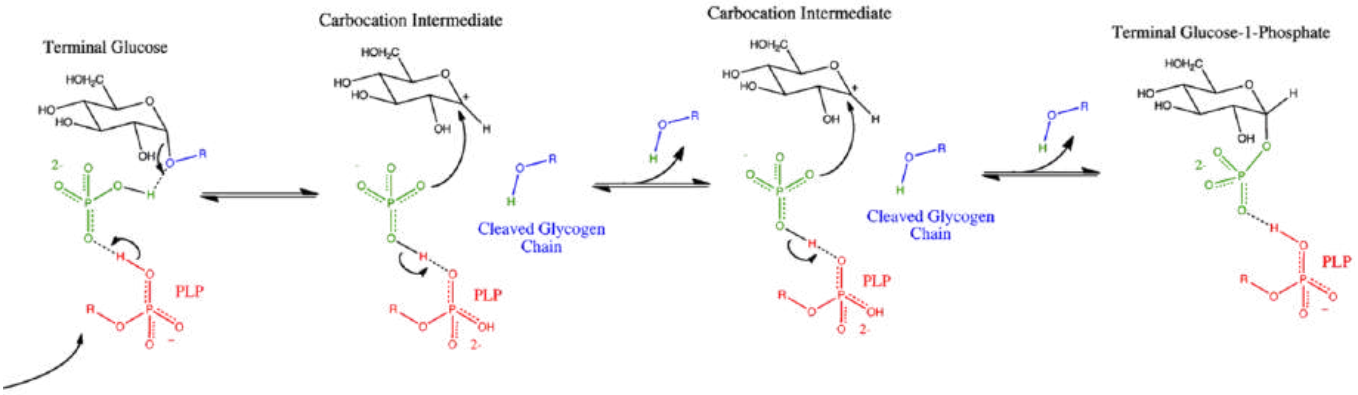

Figure \(\PageIndex{3}\): Glycogen Phosphorylase Reaction Mechanism. Image from Ascherer730

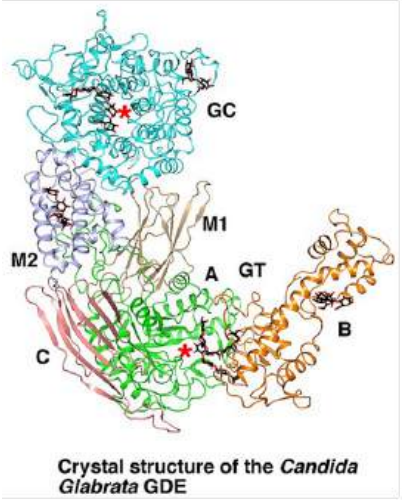
Glycogen Debranching Enzyme

Glycogen phosphorylase cannot cleave the alpha 1 → 6 linkages, and it also cannot cleave alpha 1 --> 4 linkages that are within 4 residues of an alpha 1→ 6 linkage (the glycogen chain will no longer fit into the active site of the enzyme) The Glycogen Debranching Enzyme (GDE) has two catalytic activities that enable it to deal with this problem. The first catalytic activity is a Glycosyl Transferase (GT) activity. In this process, the three remaining alpha 1 → 4 extended units on the branch site (colored in green) are clipped off of the branch site and attached to a straight chain of alpha 1 → 4 extended glucose residues. The second part of the reaction requires the Glucosidase (GC) activity that mediates the hydrolysis of the alpha 1 → 6 glycosidic bond and the release of free glucose in the process. Glycogen Phosphorylase can then resume the breakdown of the remaining alpha 1 → 4 chain. An overview of glycogen breakdown is shown in Figure 15.3.4.



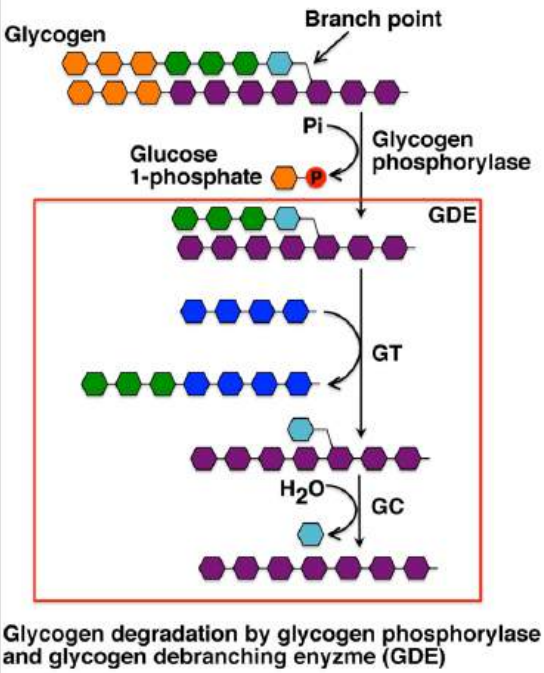


Figure \(\PageIndex{4}\): Biological Activity of the Glycogen Debranching Enzyme. Image modified from XiangSong

Dephosphorylation of Glucose 1-Phosphate

Following the activation of glycogenolysis, the liver cell has now released large quantities of glucose 1-phosphate from glycogen, as well as a smaller amount of free glucose from the clipped branch residues. The free glucose can be transported to the bloodstream straight away, but the glucose 1-phosphate must be dephosphorylated prior to release (Figure 15.3.5).

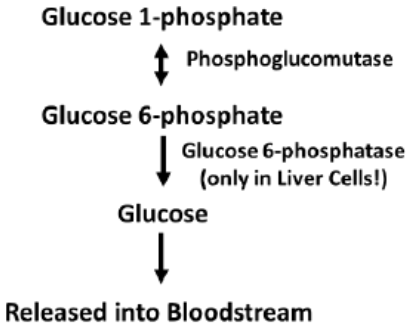

Figure 15.3.5: Process of Glucose Dephosphorylation in Liver Cells

The dephosphorylation of glucose only occurs in liver cells, as this is the primary location for the regulation of blood glucose levels. Free glucose can exit the cell while phosphorylated forms are trapped inside the cell. Figure 15.3.6 outlines the process of glucose dephosphorylation in the liver. To mediate the dephosphorylation of glucose, glucose 6-phosphate is transported from the cytoplasm into the lumen of the endoplasmic reticulum (ER) through transporter 1 (T1). The glucose 6-phosphatase (G-6-Pase) then cleaves the phosphate from the substrate, releasing inorganic phosphate (P) and glucose (red molecule). The inorganic phosphate is then transported back into the cytoplasm through transporter 2 (T2) and glucose is transported through Transporter 3 (T3). Free glucose is then transported back into the bloodstream through a glucose (GLUT) transporter located in the plasma membrane.

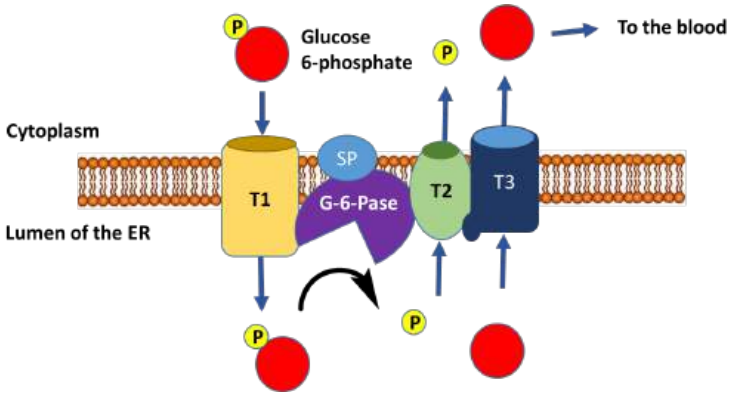

Figure 15.3.6: Dephosphorylation of Glucose 6-phosphate in Liver Cells.

15.3.2: HORMONAL CONTROL OF GLYCOGEN BREAKDOWN

In the previous sections, we've discussed insulin signaling and the process of building glycogen (glycogenesis) in detail. Now let's take a look at the other side of the homeostatic balance which begins with glucagon signaling. During hypoglycemia (or low blood glucose levels), pancreatic alpha (α) cells release the hormone peptide, glucagon, which stimulates gluconeogenesis (the formation of glucose) and glycogenolysis (the breakdown of glycogen) in the liver, resulting in the release of glucose to the plasma, and the raising of blood glucose levels, as shown in Figure 15.3.7.

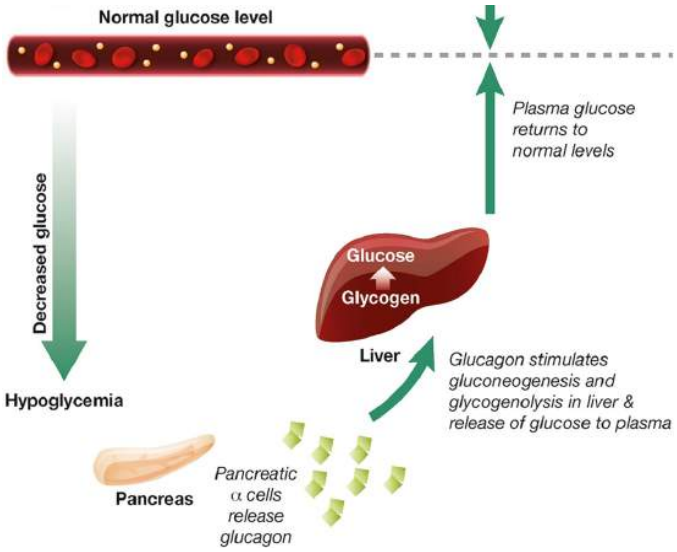

Figure 15.3.7: Summary of Glucagon Signaling During Low Blood Glucose Levels. Image from Hædersdal, S., et al (2018) Mayo Clinic Proceedings 93(2):217-239

Let's review a few terms before we begin. In the last section, we were introduced to glycogenesis, the synthesis of glycogen. We saw that this pathway was activated during insulin signaling. In glucagon signaling, this pathway is inhibited and the opposite pathway, glycogenolysis (glycogen breakdown) is activated. Glucagon signaling in the liver also down-regulates glycolysis (the utilization of glucose for energy production), as the liver is trying to use glucose to maintain blood glucose levels. It doesn't utilize it for its own energy needs during this time. Instead, lipids can be used by liver cells to generate ATP, and in fact, glucagon signaling increases lipolysis or the breakdown of lipids. Finally, glucagon also up-regulates the process of gluconeogenesis or the generation of glucose from non-sugar metabolites. We will address the mechanisms of glycolysis and gluconeogenesis regulation in a later section. Here we will only take a cursory look at these pathways and will focus more on the process of glycogenolysis.

Overview of Glucagon Signaling

Glucagon signaling begins when the hormone binds with its receptor on liver cells as shown in Figure 15.3.8. Glucagon receptors are not widespread within the body as insulin receptors. Since the purpose of this hormone is to cause the release of glucose back into the bloodstream, this process is highly controlled and only the liver can deliver glucose back into the bloodstream to maintain homeostasis. Thus, other target tissues such as skeletal muscle do not need to have these receptors expressed and are not sensitive to glucagon signaling.

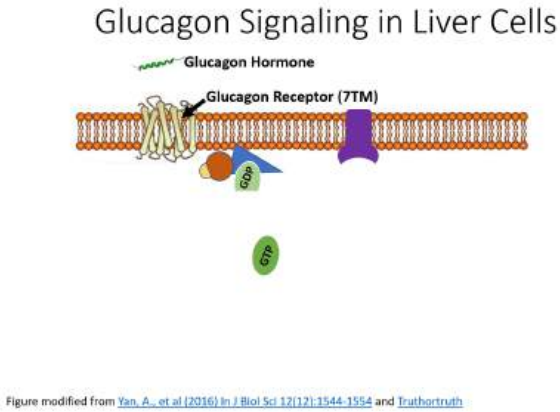

Figure 15.3.8: Overview of Glucagon Signaling Cascade

The glucagon receptor is a G-protein-coupled receptor and is also referred to as a 7TM receptor (as it contains 7 transmembrane domains that span the plasma membrane). This family of receptors is widespread throughout the body and responsible for many of the pharmaceutical mechanisms of action seen in our treatment of different disease conditions. With regards to this pathway, once glucagon binds to the receptor, the receptor moves laterally in the plasma membrane and binds with a G-protein that is stationed as a peripheral protein to the plasma membrane. The G-protein contains three major domains, the alpha, the beta, and the gamma domain. The alpha domain is capable of binding to the GDP/GTP cofactor. When the G-protein is inactive, all three subunits stay together and the alpha subunit remains inactive and bound to GDP.

When the G-protein associates with an activated receptor, the alpha subunit exchanges GTP for the bound GDP cofactor, and the gamma and beta subunits dissociate into the cytoplasm. The activated alpha subunit moves laterally on the periphery of the plasma membrane until it contacts the adenylyl cyclase enzyme (also called adenylate cyclase). This activates the adenylyl cyclase that converts ATP into cyclic AMP (cAMP). cAMP production is an amplification step within this pathway. That means that more cAMP is produced than G-proteins are activated.

After some time a G-protein hydrolase will cause the hydrolysis of the GTP to GDP and inactivate the G-protein. At this point, the G-protein will associate with the gamma and beta subunits reforming its inactive state. Another glucagon signaling event will be required to reactivate the process. The cyclic AMP produced in the process serves as a second messenger in the process and activates a myriad of downstream targets. We will focus on two of the major targets.

The first is Protein Kinase A, which becomes activated upon binding with cAMP. The second target is a cAMP Response Element-Binding *Protein* (CREB). The CREB protein is also activated when bound to the cAMP molecule. This causes the CREB protein to translocate from the cytosol into the mitochondria and the nucleus. In both of these locations, the activated CREB binds to specific response element sequences in the DNA and activates the transcription of genes that are involved in gluconeogenesis. These genes and their encoded proteins have been discussed in more detail in chapter 14. What is important to note now is that glucagon signaling in the liver results in the upregulation of glucose production *de novo* from non-carbohydrate precursors. This is NOT a favored pathway in the body. It is expensive energetically for the liver to manufacture glucose. In fact, more expensive in the cost of ATP than can be produced from the newly formed molecule. However, organs like the brain can only utilize free glucose as an energy resource. Thus, the liver will engage in this energy deficit to build glucose for use by the brain and other cellular targets.

Glucagon signaling also leads to the downregulation of glycolysis, which we will cover in more depth in section 15.4 and glycogenesis. It also leads to an increase in glycogenolysis or the breakdown of glycogen. Let's take a further look at the regulation of both of these processes.

15.3.3: REGULATION OF GLYCOGENESIS -

Since glycogen synthase (GS) is the primary enzyme required for glycogenesis, it is also the primary target for the regulation of this pathway. Recall that GS is active in the dephosphorylated state. Thus, PKA down-regulates the activity of this enzyme through the phosphorylation of GS, as shown in Figure 15.3.9. Phosphorylation of GS causes it to shift into its inactive conformation and inhibits glycogenesis.

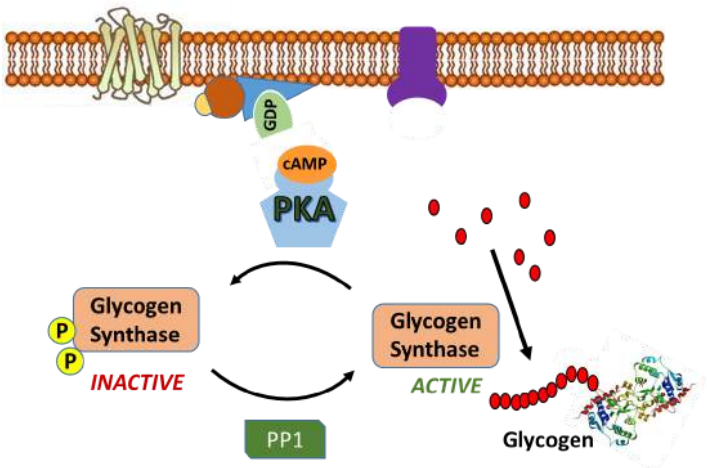

Figure 15.3.9: Inactivation of Glycogen Synthase through Phosphorylation. When bound to cAMP, protein kinase A (PKA) phosphorylates and inactivates the glycogen synthase enzyme. The activity of protein phosphorylase 1 (PP1) is required to dephosphorylate GS and restore its activity. Image modified from Yan, A., et al (2016) In J Biol Sci 12(12):1544-1554 and Servier Medical Art

In addition, activated PKA also phosphorylates the protein phosphatase 1 (PP1) enzyme leading to the inactivation of the phosphatase. PP1 normally dephosphorylates GS, helping to retain the active conformation of GS. Thus, phosphorylation of PP1 by PKA helps to maintain the GS in the phosphorylated, inactive state. The inhibition of PP1, is quite complicated, as shown in Figure 15.3.10. PP1 contains a regulatory domain and a catalytic domain. Normally the regulatory domain of PP1 binds with glycogen, keeping the molecule close to the location where GS will be present. Thus, when GS is near its substrate it can also bind with PP1 and be dephosphorylated into its active state. This is more efficient than diffusing in the cell and trying to find the PP1 randomly. When PKA phosphorylates the regulatory domain of PP1, it dissociates from the catalytic domain, causing the catalytic domain to float away from the glycogen molecule. This makes PP1 less efficient at dephosphorylating GS because it is harder for the molecules to randomly come into contact with one another. Thus, PP1 is less active. PKA reduces this activity even further, by phosphorylating an allosteric inhibitor (I) of PP1. In the phosphorylated state, the inhibitor can bind to PP1 fully inactivating the phosphatase. Both phosphorylation events need to be reversed to regain full PP1 activity.

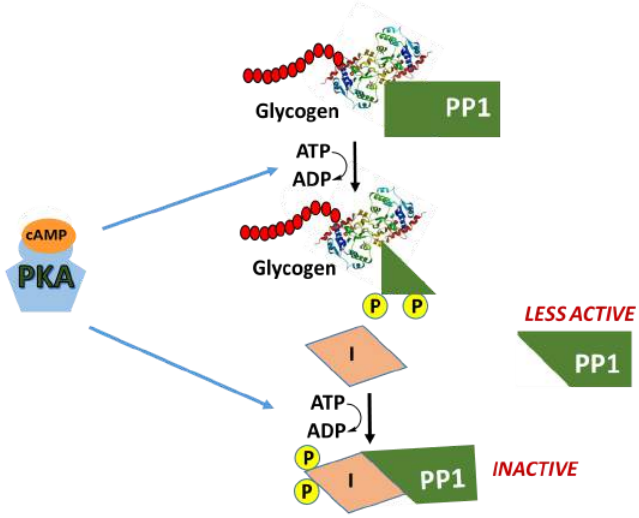

Figure 15.3.10: Inactivation of Phosphorylase 1 (PP1) by Protein Kinase A (PKA). PKA phosphorylates PP1 causing it to dissociate from glycogen and become less active. PKA also phosphorylates an allosteric inhibitor (I) of PP1 which increases its binding affinity for PP1. The phosphorylated inhibitor maintains PP1 in an inactive conformation. Image Modified from Yan, A., et al (2016) In J Biol Sci 12(12):1544-1554 and Servier Medical Art

In summary, glucagon signaling in the liver downregulates glycogenesis through the activation of PKA. PKA phosphorylates GS directly, inactivating the enzyme, and maintains it in the inactive state by also inhibiting the PP1 responsible for dephosphorylating GS.

15.3.4: ACTIVATION OF GLYCOGENOLYSIS

In addition to phosphorylating GS and PP1 during the inactivation of glycogenesis, PKA also phosphorylates the enzyme **Phosphorylase Kinase**, which is upstream of glycogen phosphorylase, the primary enzyme involved in glycogen breakdown. As its name implies, phosphorylase kinase is a protein kinase that phosphorylates the enzyme to activate it. Figure 15.3.11 offers a first view of the phosphorylation cascade required for glycogen phosphorylase activation.

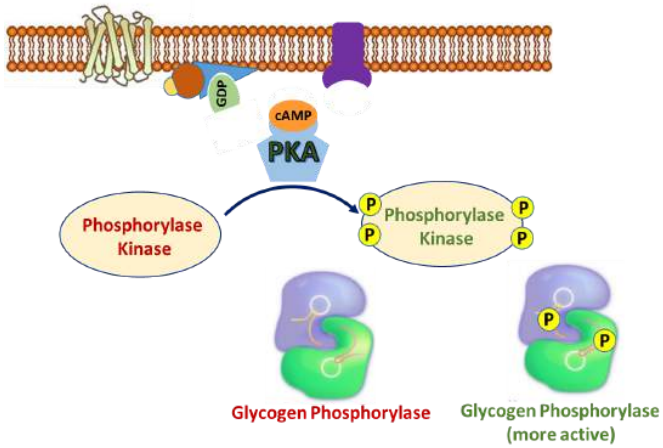

Figure 15.3.11: Activation of Glycogen Phosphorylase by Protein Kinase A (PKA) Signaling. PKA upregulates the activity of Phosphorylase Kinase through direct phosphorylation. The activated kinase enzyme phosphorylates its downstream target, Glycogen Phosphorylase (GP). In the phosphorylated state, GP is more active. Image modified from Yan, A., et al (2016) In J Biol Sci 12(12):1544-1554 and Llavero, F., et al (2019) Int. J. Mol. Sci. 20(23):5919

The phosphorylase kinase enzyme is a complex enzyme that is a tetramer of a tetrameric complex, αβγδ, so the full holoenzyme has an $(\alpha\beta\gamma\delta)_4$ structure. It is large with a molecular weight of around $1.3x10^6$. As you would expect, it is highly regulated in multiple ways, including phosphorylation by PKA, ADP (an allosteric effector), divalent cations like Ca^{2+}, and pH. The α and β are regulatory subunits that affect activity through their phosphorylation. The δ is calmodulin, a calcium-binding protein we discussed in Chapter 12.7, and its binding of calcium affects the holoenzyme activity. The γ subunit has kinase activity and has an N-terminal catalytic domain and a C-terminal calmodulin-binding domain. This is primarily regulated by phosphorylation through the PKA pathway as shown in Figure 15.3.5.

"PHK is one of the largest of the protein kinases and is composed of four types of subunit, with stoichiometry $(\alpha\beta\gamma\delta)_4$, and a total mol. wt of 1.3×10^6 Da. Activity is regulated by cyclic AMP-dependent protein kinase phosphorylation, autophosphorylation, allosteric effectors (e.g. ADP), metal ion concentration (Ca^{2+} and Mg^{2+}), proteolysis and pH (Pickett-Gies and Walsh, 1986). The α and β subunits are regulatory

and are the targets for control by phosphorylation. The δ subunit is essentially identical to calmodulin and confers Ca^{2+} sensitivity. The 386 amino acid γ subunit is the catalytic subunit which comprises an N-terminal kinase domain (residues 1–298) and a regulatory calmodulin-binding domain (residues 299–386)"

Calcium, an allosteric regulator, may be present within cellular targets due to nerve impulse firing, muscle contraction, or through hormone signaling. The presence of calcium in the cell generally indicates that there is high energy demand on the cell at that time and that energy production is needed. Thus, calcium binding to the phosphorylase kinase is a positive effector of the enzyme and upregulates activity. Maximal activity of the enzyme is achieved through combined phosphorylation and calcium binding. Thus, phosphorylase kinase can exist in 4 different states of activity as shown in linked equilibria in Figure 15.3.12.

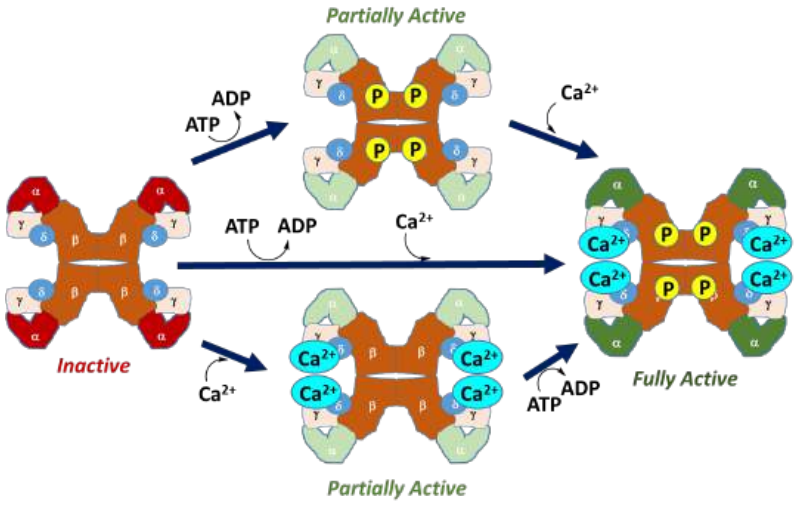

Figure 15.3.12 Activation States of Phosphorylase Kinase (PK). In the left-hand diagram, PK is in the inactive state, with the kinase-containing alpha domains shown in red. The upper diagram shows the activation of PK through phosphorylation by Protein Kinase A during hormone signaling. This leads to a partially active enzyme. Similarly, calcium binding, shown in the lower diagram, also results in a partially active enzyme. Calcium plays a particularly important role in the activation of this enzyme in skeletal muscle. The process of muscle contraction causes the release of high levels of calcium into the cytoplasm. Thus, the presence of calcium within the cytoplasm of muscle cells indicates high energy demand, as the muscle is being called into action. This activates PK and stimulates the breakdown of glycogen within muscle tissue to help meet energy demands. Maximal activity is obtained with both calcium binding and phosphorylation.

This diagram by now should be quite familiar. It is yet another example of a tetrameric enzyme (where the "enzyme" composition is αβγδ) existing in two major states, an inactive T state and an active R state, with the interconversion regulated by allosteric effectors (Ca^{2+}) and post-translationally phosphorylation.

A mechanism for the phosphorylation of a Ser in a substrate target protein (i.e glycogen phosphorylase) by the catalytic domain of the γ subunit of phosphorylase kinase is shown in Figure 15.3.13.

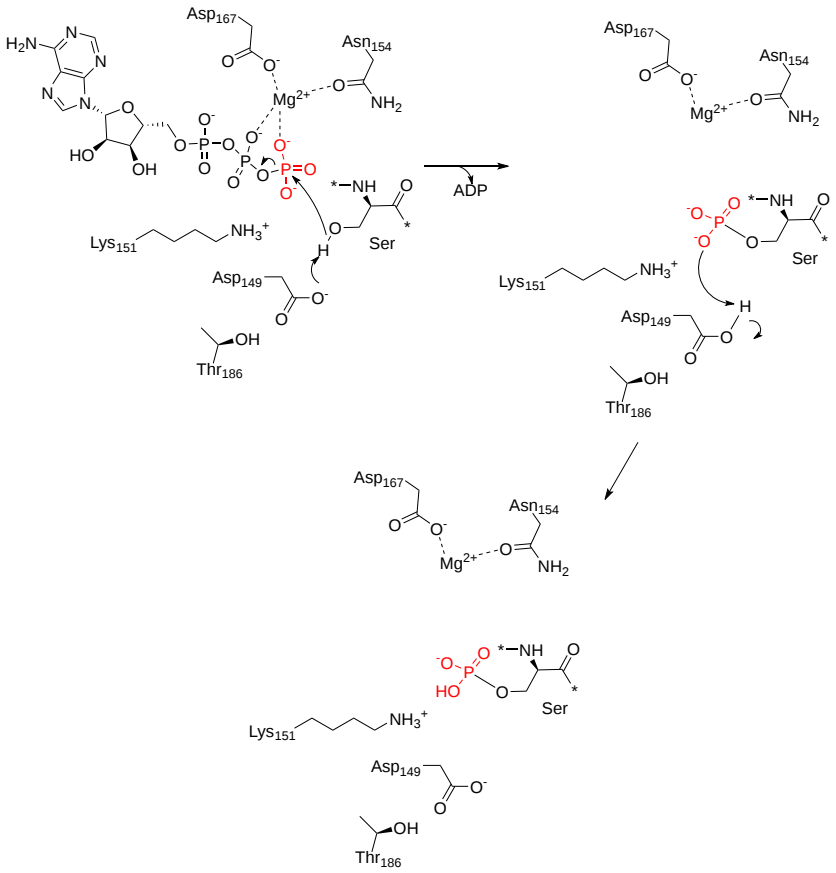

Figure 15.3.13: A mechanism for the phosphorylation of a Ser in a substrate target protein (i.e glycogen phosphorylase) by the catalytic domain of the γ subunit of phosphorylase kinase. https://www.ebi.ac.uk/thornton-srv/m-csa/entry/35/. Creative Commons Attribution 4.0 International (CC BY 4.0) License.

The * in the mechanism denotes the serine of the target protein.

Figure 15.3.14 below which shows an interactive iCn3D model of a truncated form of the rabbit phosphorylase kinase gamma subunit dimer bound to a peptide substrate complex (2PHK).

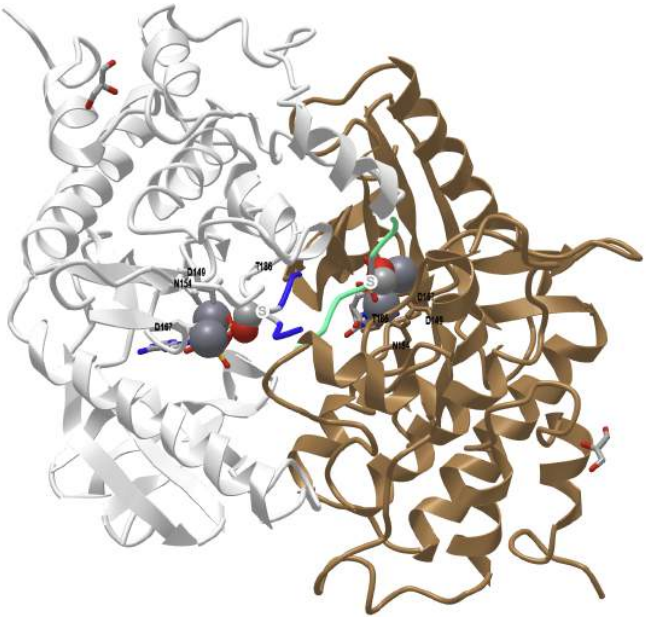

Figure 15.3.14 : Rabbit phosphorylase kinase gamma subunit dimer bound to a peptide substrate complex (2PHK). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...3wHapyHWEy7qi9

The phosphorylase kinase dimer is shown (gray and brown subunits). A non-hydrolyzable ATP analog (adenylyl imidodiphosphate, AMPPNP) in each subunit is shown as CPK-colored sticks. The backbone of two identical peptide substrates (blue and cyan) with the sequence RQMSFRL (similar to the target sequence in glycogen phosphorylase and an ideal peptide substrate) is shown as a backbone trace, with the central Ser which gets phosphorylated shown as CPK-colored spheres. Active site residues are shown as CPK-colored sticks and labeled in each subunit.

We have been primarily discussing the regulation of glycogenolysis in the liver. However, in considering the activity of PK and its reactivity with Ca^{2+} ions, we should also consider the activation of glycogenolysis in skeletal muscle, as well. Of note, glycogenolysis in liver tissue and skeletal muscle has many differences. First, the G-protein coupled pathway is activated by different hormones. Liver tissue is responsive to Glucagon stimulation, as well as stimulation through the Epinephrine hormone signaling pathway. Glycogenolysis in skeletal muscle tissue, on the other hand, is only activated by the Epinephrine signaling pathway, but not by glucagon. This is because the liver is the primary organ responsible for regulating blood glucose levels. Thus, pancreatic signaling due to low blood glucose levels primarily targets glycogenolysis within the liver tissue. Both systems are responsive to Epinephrine, which is described in more detail below.

15.3.5: EPINEPHRINE SIGNALING

Epinephrine is a small amino acid-derived hormone (can you guess the amino acid?? Yes it is Tyrosine!!), as shown in Figure 15.3.15. It is also called adrenaline, as it is secreted from the adrenal glands located just above the kidneys, during the flight or fight response. It is also secreted during heavy or sustained exercise. Epinephrine has pleiotropic responses in the body, which include the activation of glycogenolysis in the liver and skeletal muscles. Epinephrine also promotes fat breakdown in adipose tissue, which releases this energy reserve into the bloodstream for utilization by muscle tissue. It also causes the relaxation of smooth muscles in the lungs and respiratory tract enabling better oxygen absorption. Cardiac contractility is also increased to increase blood flow to skeletal muscles. This supports the generation of ATP from glucose and fatty acids for sustained muscle utilization. It also reduces blood flow to the skin and causes the contraction of smooth muscles in the skin causing goosebumps.

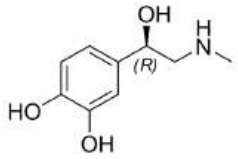

Figure 15.3.15: Structure of Epinephrine

Within the liver and skeletal muscle, the epinephrine signaling pathway overlaps with the glucagon signaling pathway seen in the liver. The epinephrine receptor is also a G-protein coupled receptor related to the glucagon receptor. However, it is specific for epinephrine and cannot bind with glucagon. It does activate the same G-protein pathway leading to Protein Kinase A activation, as shown in Figure 15.3.16. The body is very efficient at reusing machinery in different parts of the body, in this case, it does so under different regulatory parameters.

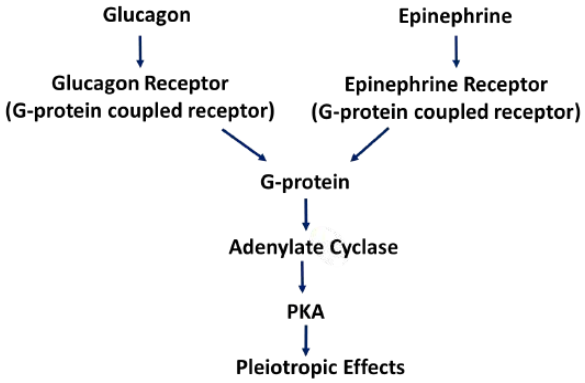

Figure 15.3.16: Similarities of Glucagon and Epinephrine Signaling Pathways

The Glycogen Phosphorylase enzymes are also encoded by different genes within the Liver and Skeletal Muscle. These are known as isozymes. Recall, that isozymes have the same biological function, but since they are expressed from different genes, they have different enzyme kinetics and they are regulated in different and unique ways within each tissue.

The liver and skeletal muscle forms of Glycogen Phosphorylase share approximately 90% sequence identity. Yet again, both isozymes can exist in two major conformations, the a-form, and the b-form. The protein adopts the a-form when it is phosphorylated at Ser 12 by

phosphorylase kinase, as shown in Figure 15.3.17. The Glycogen Phosphorylase enzyme can also be in two different states, the relaxed, flexible state which is the active form of the enzyme, and the tense or rigid state which is inactive. When the protein is in the a-conformation, it favors the relaxed and active state of the protein. Therefore, phosphorylation of Glycogen Phosphorylase leads to an increase in the activity of the enzyme. This is depicted in the following diagram.

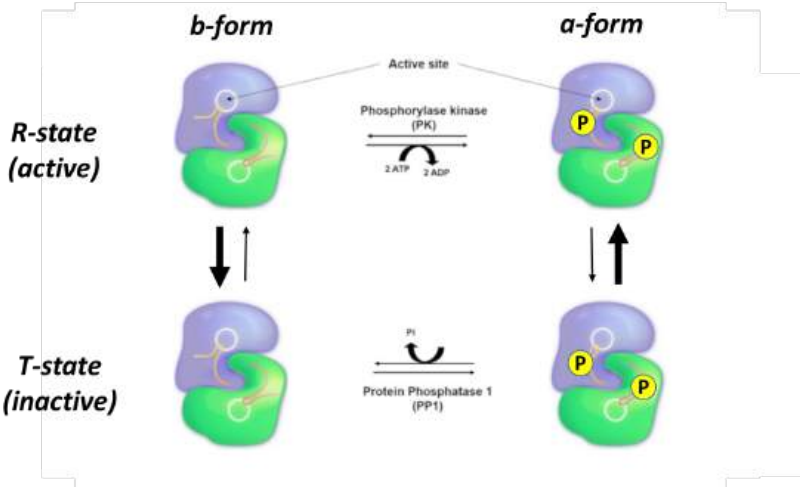

Figure 15.3.17: Enzymatic States of Liver and Skeletal Muscle Glycogen Phosphorylase. Both isozymes of Glycogen Phosphorylase are responsive to phosphorylation by phosphorylase kinase. Phosphorylation of Glycogen Phosphorylase causes it to shift from the b-form to the a-form of the protein. The a-form of the protein favors the relaxed, active state of the protein, whereas the b-form of the protein favors the tense and inactive state of the protein. Image modified from Llavero, F., et al (2019) Int. J. Mol. Sci. 20(23):5919

Another way to think about these four different enzyme states is that they exist in a dynamic equilibrium, with the population of each state determined by the phosphorylation state AND the presence of allosteric inhibitors and activators which we will explore below. In Figure 17 above, the R state is on top and the T state is on the bottom. The equilibrium between just those two states is indicated by the vertical arrows. The thickness of the arrows indicates the preferred direction of the reversible reaction. In the absence of phosphorylation (left-hand vertical states), the equilibrium favors the T or inactive form. When phosphorylated (right-hand vertical states) on Ser12 by the enzyme phosphorylase kinase, the R or active form is favored. The horizontal equilibria show the phosphorylation of the Ser12 by phosphorylase kinase (top, shown reversibly but the enzyme is not acting physiologically to remove phosphate) and dephosphorylation of Ser 12 by the enzyme protein phosphatase 1 (which acts physiologically only as a phosphatase).

The different isozymes of the Glycogen Phosphorylase enzyme are also regulated by different, tissue-specific allosteric effectors. Within the liver, glucose is a negative regulator of Glycogen Phosphorylase, which makes sense, as the role of this pathway in liver tissue is to promote the release of glucose into the bloodstream. The presence of free glucose in the cytoplasm of the liver would indicate either the fed-state when blood glucose levels are high, or that high levels of glycogenolysis have released substantial glucose. Within liver tissue, the presence of free glucose will cause the a-form of Glycogen Phosphorylase to shift to the Tense state, reducing the activity of the enzyme. This is shown in Figure 15.3.18.

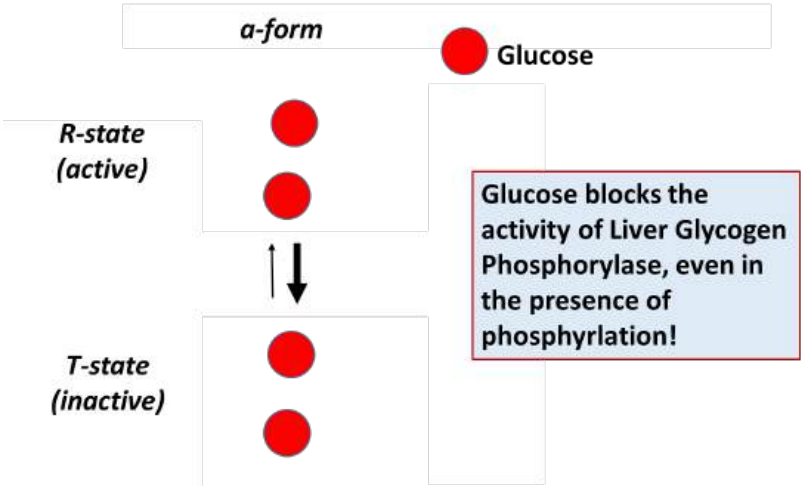

Figure 15.3.18: Regulation of Liver Glycogen Phosphorylase by Free Glucose. When the liver isoform of Glycogen Phosphorylase is in the a-form (phosphorylated), it can be shifted into the Tense state in the presence of high levels of free glucose. This blocks the glycogen binding site of the enzyme, essentially serving as a competitive inhibitor of the enzyme. Image modified from Llavero, F., et al (2019) Int. J. Mol. Sci. 20(23):5919

Skeletal muscle glycogen phosphorylase (or Myophosphorylase, as it is sometimes called), is more responsive to allosteric effectors that indicate the energy state of the cell. This makes sense, as the main purpose of glycogen breakdown in muscle tissue is to fuel the energy demand for the muscle tissue. Thus, the energy housed in glucose will be used to produce ATP within these cells. The presence of either glucose 6-phosphate or ATP within skeletal muscle indicates high levels of energy are present. Thus, glycogen breakdown will be inhibited. The presence of AMP, on the other hand, indicates a low energy state and is an activator of Glycogen Phosphorylase. This is shown in Figure 15.3.19 to Figure 15.3.21 below.

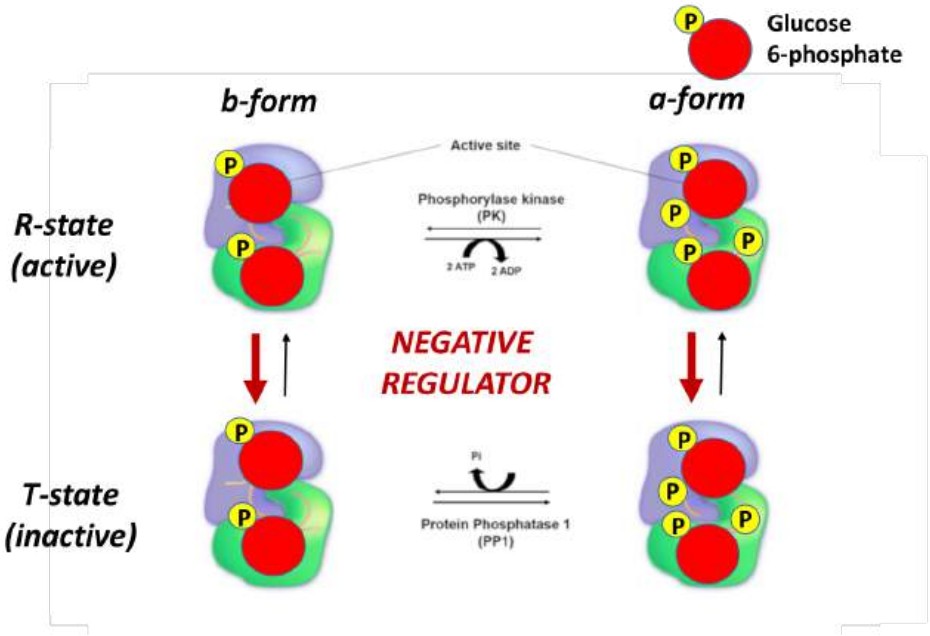

Figure 15.3.19: Regulation of Skeletal Muscle Glycogen Phosphorylase by Glucose 6-phosphate. Muscle Glycogen Phosphorylase is negatively regulated by the presence of high levels of Glucose 6-phosphate. Regardless of the form (a or b) the enzyme is shifted into the Tense state. Image modified from Llavero, F., et al (2019) Int. J. Mol. Sci. 20(23):5919

Again, note that the bold red arrows point downward, showing that on the addition of glucose-6-phosphate, the T state (inactive) is favored even if glycogen phosphorylase has been phosphorylated.

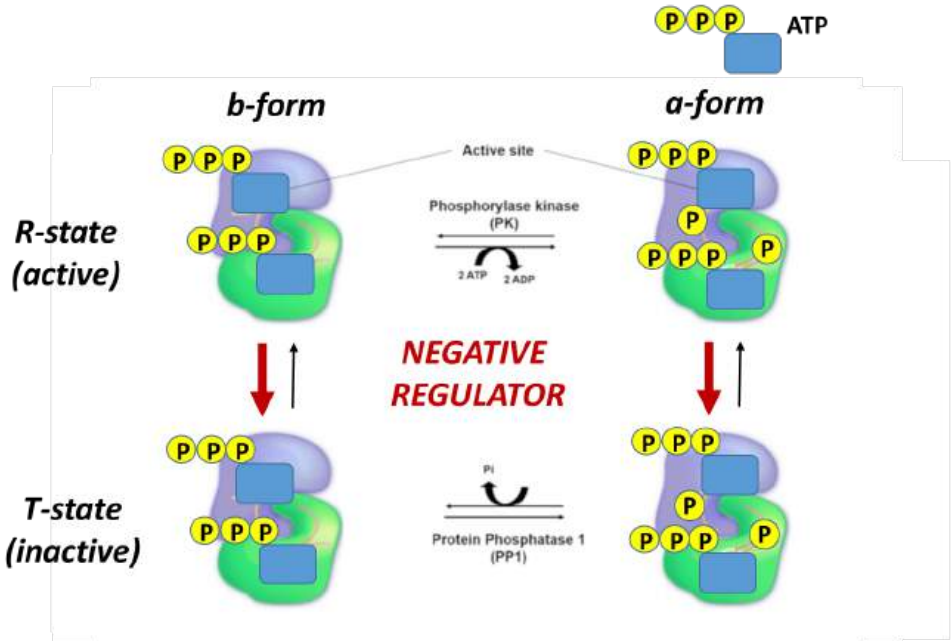

Figure 15.3.20: **Regulation of Skeletal Muscle Glycogen Phosphorylase by ATP.** In the presence of high levels of ATP, GP is converted to the Tense state, showing the inhibition of the enzyme in the presence of high levels of energy. Image modified from Llavero, F., et al (2019) Int. J. Mol. Sci. 20(23):5919

Again, note that the bold red arrows point downward, showing that when the ATP levels are high, the T state (inactive) is favored even if glycogen phosphorylase has been phosphorylated. Again, under conditions of a high energy state (as reflected by high ATP), there is no need to cleave glycogen to enter glycolysis.

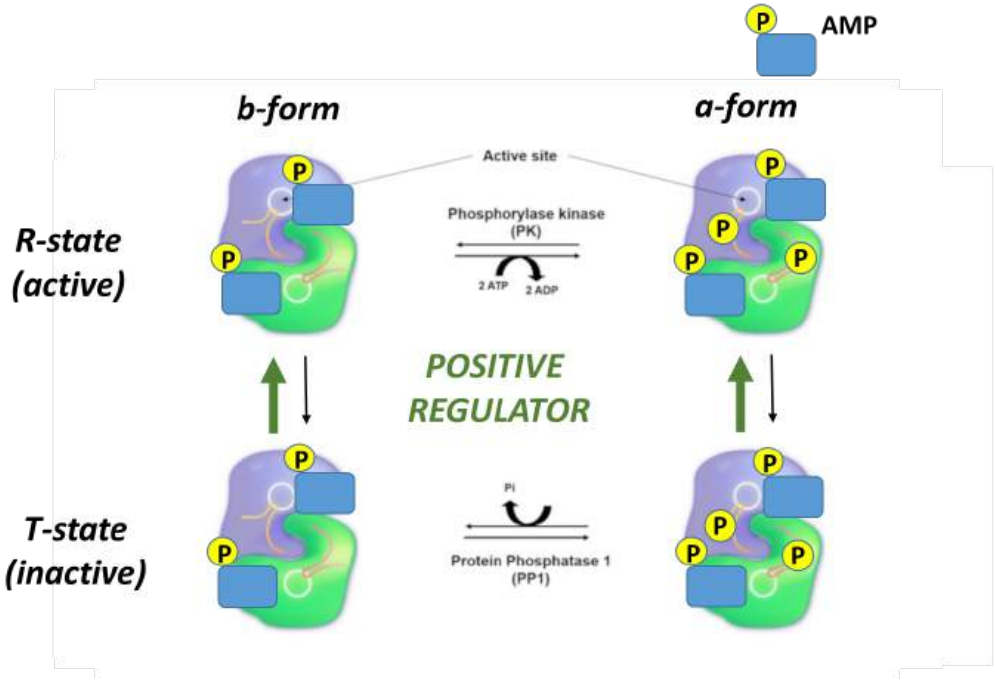

Figure 15.3.21: Regulation of Skeletal Muscle Glycogen Phosphorylase by AMP. In the presence of low-energy indicators, such as AMP, the glycogen phosphorylase enzyme is activated, even in the absence of phosphorylation. Thus, when AMP is bound, the b-form of glycogen phosphorylase is converted into the relaxed and active state. Image modified from Llavero, F., et al (2019) Int. J. Mol. Sci. 20(23):5919

In contrast, note that the bold green arrows point upward showing that when the AMP levels are relatively high, the R state (active). Higher levels of AMP reflect a need to activate glycogen breakdown to increase ATP production.

A mechanism for the phosphorolysis of Glc_{n+1} to Glc_n and glucose-1-phosphate is shown in Figure 15.3.22. Note the unusual presence of a molecule of pyridoxal phosphate covalently attached through a Schiff base linkage to Lys 568 (rabbit phosphorylase).

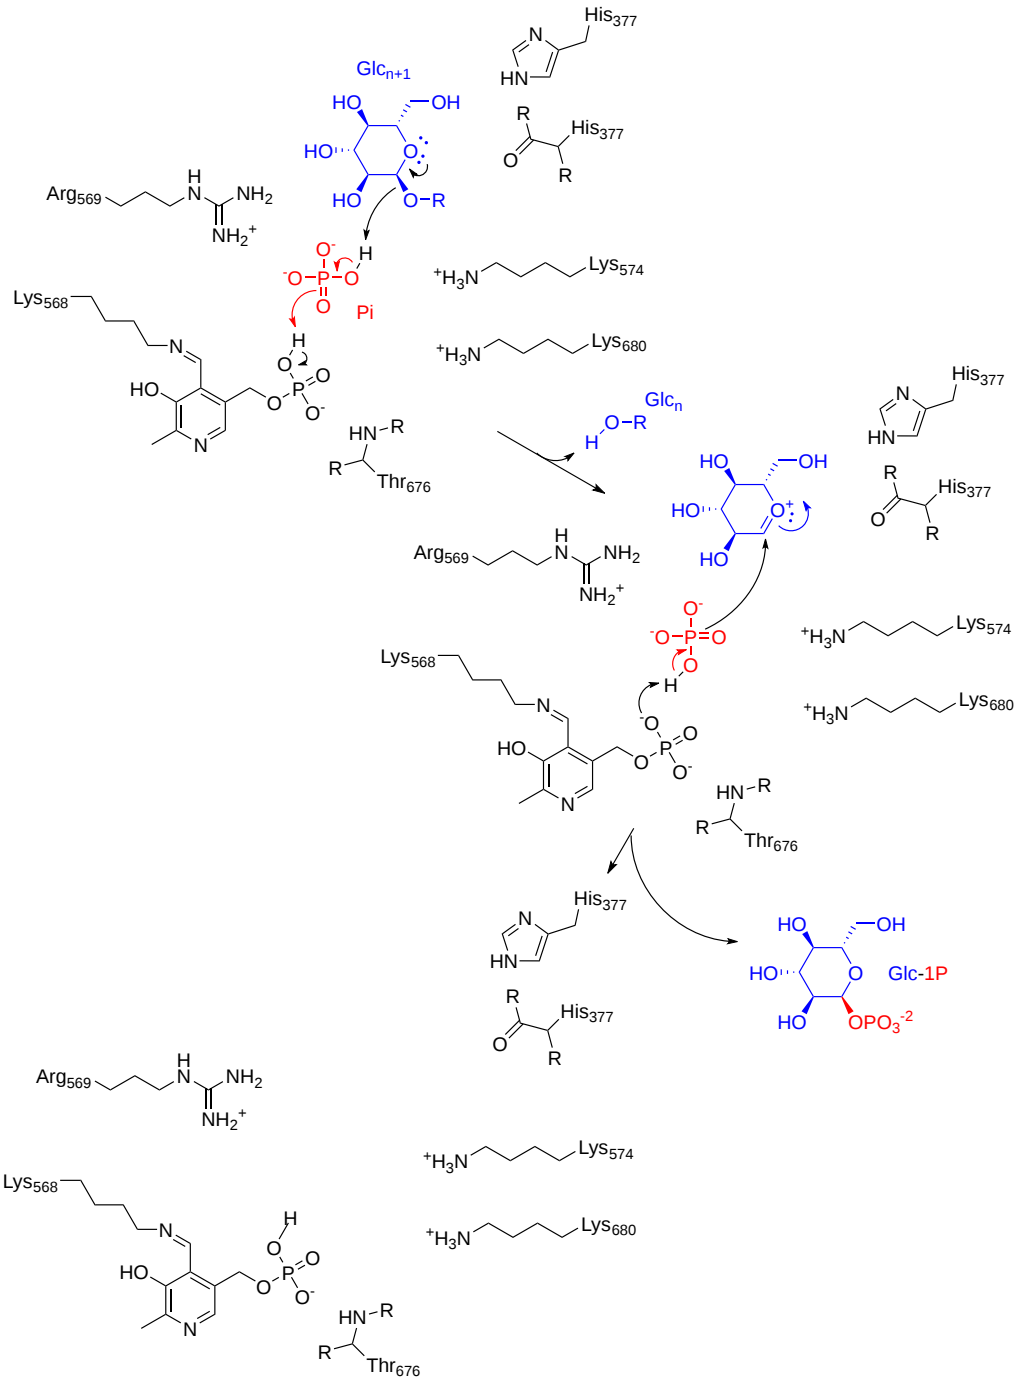

Figure 15.3.22: A mechanism for the phosphorolysis of Glc_{n+1} to Glc_n and glucose-1-phosphate. https://www.ebi.ac.uk/thornton-srv/m-csa/entry/205/. Creative Commons Attribution 4.0 International (CC BY 4.0) License

PLP, which is covalently attached through a Schiff base, functions in this enzyme as a general acid and base, and not as a cofactor that facilitates covalent bond cleavage in amino acid substrates that are covalently attached to it (Chapter 6.8: Cofactors and Catalysis - A Little Help From My Friends).

It is important to note that the reaction is a phosphorolysis, not a hydrolysis, which would leave free glucose, which would more readily leave the cell and hence be less available for cellular energy needs and less available for glycolysis.

Figure 15.3.23 below which shows an interactive iCn3D model of a dimer of rabbit glycogen phosphorylase (1GDB).

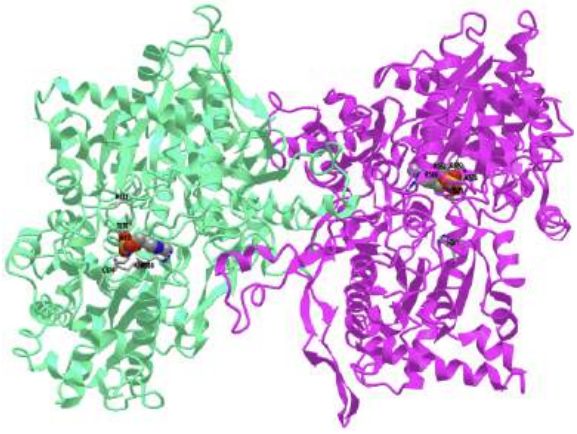

Figure 15.3.23 : Dimer of rabbit glycogen phosphorylase (1GDB). (Copyright; author via source). Click the image for a popup or use this external link:https://structure.ncbi.nlm.nih.gov/i...s1LosR5TJLjru9

The subunits in the dimeric form are shown in different colors. PLP is shown in spacefill. Active site residues are shown in both subunits as CPK-colored sticks and labeled.

Let's look at a monomer (from the tetramer) of 2 nonphosphorylated states of glycogen phosphorylase. Since they are both unphosphorylated, they both represent the **b state**. One (**2GPB**) has glucose bound, so it represents the inactive (T state). The other (**3E3N**) has AMP bound, so it represents the active (the R state). Figure 15.3.24 shows the conformation differences between the monomeric states

Figure 15.3.24: Conformational differences between the monomeric unphosphorylated b state of glucose-bound GP (T state, inactive) and AMP-bound GP (R state, active)

Now let's look at the conformations of two different GP activated by different means. In one, the nonphosphorylated form of GP (the b state, and inactive T state,) binds AMP, an allosteric activator (pdb 8GPA), and converts to the active, b state (unphosphorylated R state). Let's compare its active conformation to a form of GP activated by phosphorylation (the phosphorylated **a** state, and active R state) to which just SO_4^{2-} is also bound. In the 1st case, GP-b T state is driven to the active Gp-b R state by binding of the allosteric activator AMP. In the second case, GP-a is already in the R active state since it is phosphorylated. Figure 15.3.25 compares their conformations.

Figure 15.3.25: Comparison of the conformations of two active forms of GP - phosphorylase b bound to the allosteric activator AMP (R state) and phosphorylase a activated by phosphorylation of Ser 14.

The cyan monomer is glycogen phosphorylase b which is not phosphorylated but driven into the **R state** on the binding of AMP (note that two are bound at the periphery). The dark blue monomer is glycogen phosphorylase a which is phosphorylated at Ser14 (a different number in this crystal file which is shown in spacefill and labeled SEP-14) which is also in the R state. It also has two SO_4^{2-} bound that help stabilize the state. Look carefully! the conformations are very similar to each other, in contrast to the different conformations for the T and R states shown in Figure 24.

Figure 15.3.26 below which shows an interactive iCn3D model of unphosphorylated (b state) rabbit glycogen phosphorylase with bound glucose (inactive T state, **2GPB).**

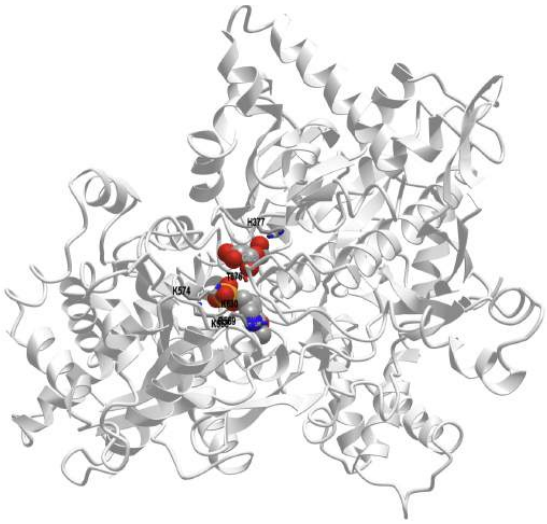

Figure 15.3.26 : Unphosphorylated (b state) rabbit glycogen phosphorylase with bound glucose (inactive T state, 2GPB). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...eXQciAPczmQpLA

Only 1 monomer of the tetramer is shown. PLP and glucose are shown in spacefill, CPK colors, and labeled. Key active site residues are shown as colored sticks and labeled.

Figure 15.3.27 below which shows an interactive iCn3D model of unphosphorylated (b state) rabbit glycogen phosphorylase with bound AMP (active R state, 3E3N).

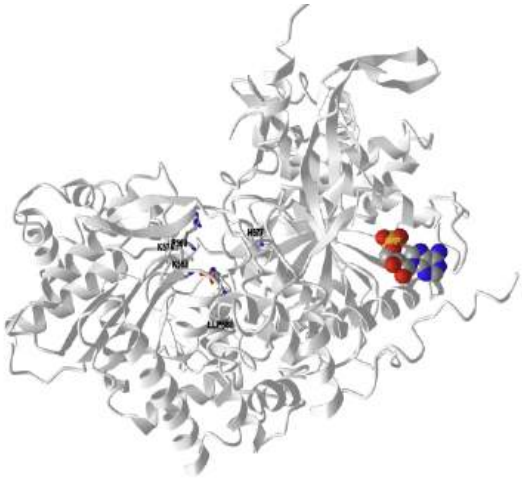

Figure 15.3.27 : Unphosphorylated (b state) rabbit glycogen phosphorylase with bound AMP (active R state, 3E3N). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...WDZJc1CcpFqEG7

Note the different locations for the binding site of the allosteric activator AMP compared to the inhibitor glucose in the previous model.

MCARDLE'S DISEASE

McArdle's Disease, also referred to as myophosphorylase deficiency or type V glycogen storage disease, is a recessive inherited disorder characterized by an inability to metabolize glycogen due to the absence of a functional myophosphorylase (PYGM). In Figure 15.3.28 shown below, the normal functional pathway is shown in blue, on the left, while the mutant pathway is shown on the right in red. Patients with this disease lack sufficient glucose-1-phosphate (G1P) monomers needed for glycolysis and the hexosamine biosynthetic pathway (HBP). This results in lower ATP and, consequently, lower muscle contraction, as well as in lower post-translational modifications by O-GlcNAcylation in comparison to normal conditions. This is especially pronounced during extended or heavy workouts, where people with McArdle's Disease will sustain painful cramping of their muscle tissue during workouts, can have dark red/brown urine, and can easily tire during activity. Some patients also note a second-wind phenomena occur during workouts as

the body shifts from carbohydrates to lipids as a primary energy source. The dark red/brown color in the urine happens if muscle tissue is damaged during the workout. The damaged muscle releases the protein myoglobin into the bloodstream. This is filtered out by the kidneys and excreted in the urine, causing the color change. The severe uncontrolled disease can cause life-threatening kidney problems.

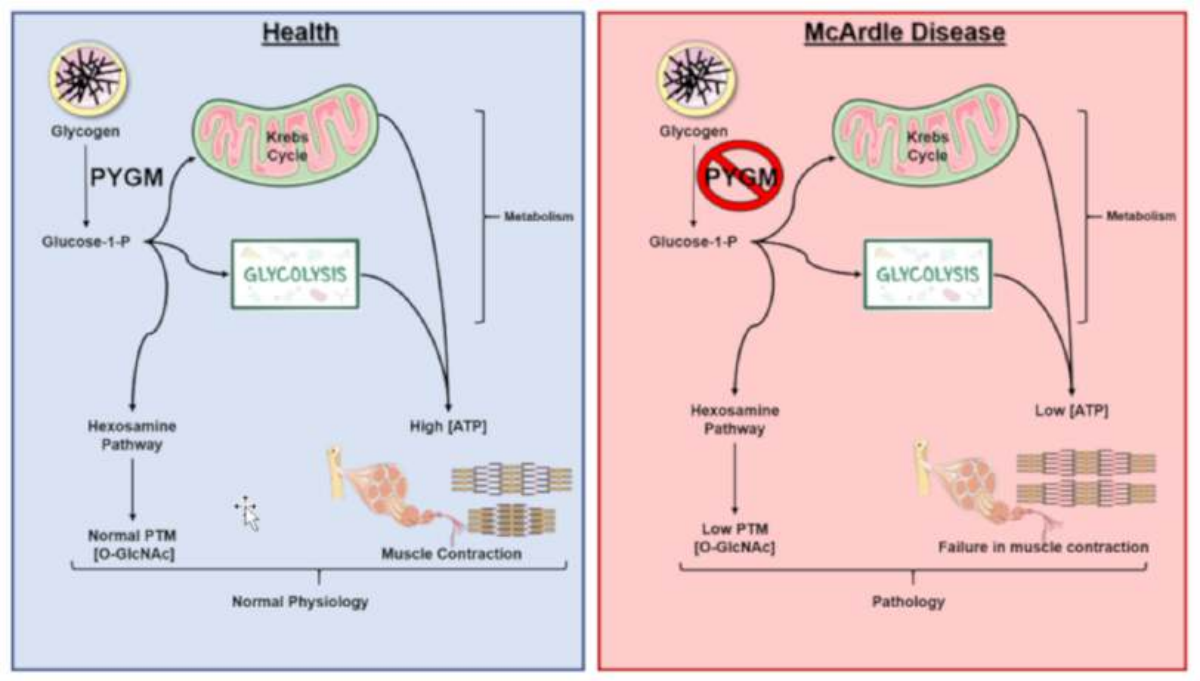

Figure 15.3.28 McArdle's Disease. *Left hand side (blue)* represents the normal pathway, whereas the *right hand side (red)* notes the deficiency of muscle glycogen phosphorylase. Image from Llavero, F., et al (2019) Int. J. Mol. Sci. 20(23):5919

Figure 15.3.29 presents an overview of glucose metabolism in skeletal muscle. Both glucose-1-phosphate (G1P) released from the intracellular glycogen stores by glycogen phosphorylase (GP), as well as the glucose introduced into the cell through glucose transporters (GLUT) are converted to glucose-6-phosphate (G6P) by phosphoglucomutase (PGM) and hexokinase (HK), respectively. The G6P can be directed to different destinations. One of them is the pentose phosphate pathway for the formation of nucleic acid building blocks (ribose and deoxyribose). Another is in the formation of ATP. Here G6P enters the metabolic pathway of glycolysis. The glycolytic reactions culminate in the production of pyruvate and adenosine triphosphate (ATP). Pyruvate can be fermented to lactate by the catalysis of the lactate dehydrogenase (LDH), as happens during anaerobic muscle exercise. On the other hand, pyruvate can be used to obtain ATP through full oxidation in the Kreb Cycle. In total, oxidative phosphorylation produces between 30-36 molecules of ATP (depending on the organism and tissue), 6 molecules of carbon dioxide (CO_2), and 6 molecules of water (H_2O) from 1 glucose molecule. Glycolysis alone only produces two net ATP molecules per glucose. Glucose, in addition to being the main fuel of the cell's energy metabolism, is also used by the cellular machinery as a vitally important substrate for the production of key intermediaries of the hexosamine biosynthetic pathway (HBP) forming O-GlcNAc, β-linked N-acetylglucosamine. And finally, in times of plenty, glucose will be utilized by glycogen synthase (GS) to make glycogen.

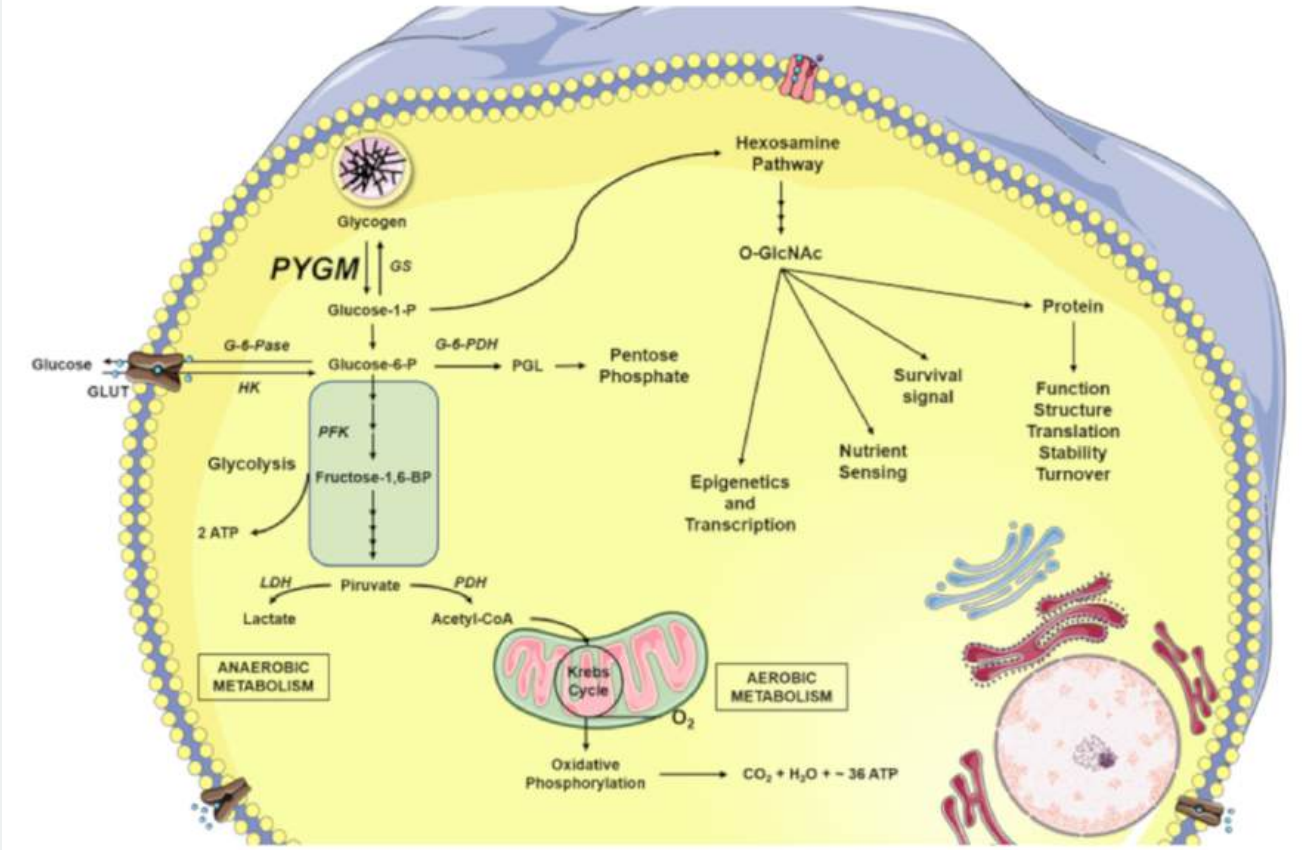

Figure 15.3.29 Summary of Glucose Metabolism in Skeletal Muscle. Image from Llavero, F., et al (2019) Int. J. Mol. Sci. 20(23):5919

15.4: REGULATION OF GLYCOLYSIS

There are three major enzymatic control points within the glycolytic pathway. These include hexokinase, phosphofructokinase, and pyruvate kinase reactions. Key drivers for regulating the pathway are energy demand within the cell as determined by local indicators such as ATP and AMP, as well as energy demand within the organism as a whole, which can be influenced by hormone signaling pathways. We will also see that the regulation of the pathway can vary depending on cell type and cellular needs.

15.4.1: HEXOKINASE REGULATION

One of the primary mechanisms that control the regulation of the hexokinase step in glycolysis is the presence of different hexokinase enzymes in different cellular types. Essentially, these are proteins that are encoded by different genes but perform the same function within the cell. They are known as isozymes. Isozymes can have different enzyme kinetics, different expression patterns in different tissues, different post-translational modifications, and bind with different allosteric effectors. This affords the body to have differential control over the same processes in different locations within the body. Within vertebrates, four important hexokinase isozymes vary in subcellular locations and kinetics parameters. This allows the differential phosphorylation of hexoses depending on local conditions, and physiological function. They are designated hexokinases I, II, III, and IV. All of the Hexokinases can use multiple hexoses as substrates, in addition to glucose. These include mannose, fructose, and 2-deoxyglucose. Hexokinase IV is also often referred to as Glucokinase and is specific to the Liver and Pancreas.

Recall that hexokinase enzymes mediate the first step in the glycolytic pathway with the formation of glucose 6-phosphate, as shown in Figure 15.4.1 below. They also require ATP as a cofactor in the process.

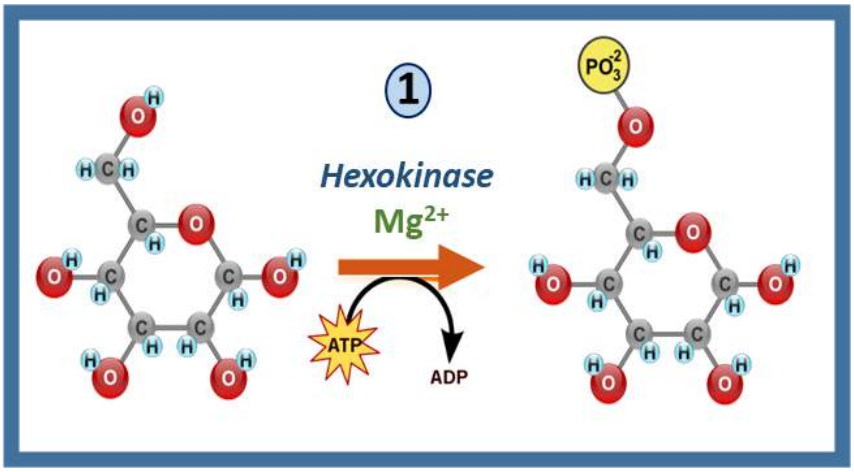

Figure 15.4.1: Glucose Phosphorylation by Hexokinase Enzymes. Figure modified from YassineMrabet

Recall that glucose-6-phosphate (G6P) has several potential fates within the body, as shown in Figure 15.4.2. It can be used as an energy source through the pathways of glycolysis and aerobic respiration. Short bursts of anaerobic respiration can also be sustained in animals that convert pyruvate into lactate. G6P can also be dephosphorylated in the liver and released back into the bloodstream to maintain homeostatic balance. The pancreas uses G6P as a sensor to determine when to secrete insulin and glucagon. The G6P can also serve as a building block for anabolic processes. It can be converted to ribose through the Pentose Phosphate Pathway where it will be used in the construction of nucleotide monomers. It can also be used for the formation of hexosamines used in proteoglycan and glycoprotein formation.

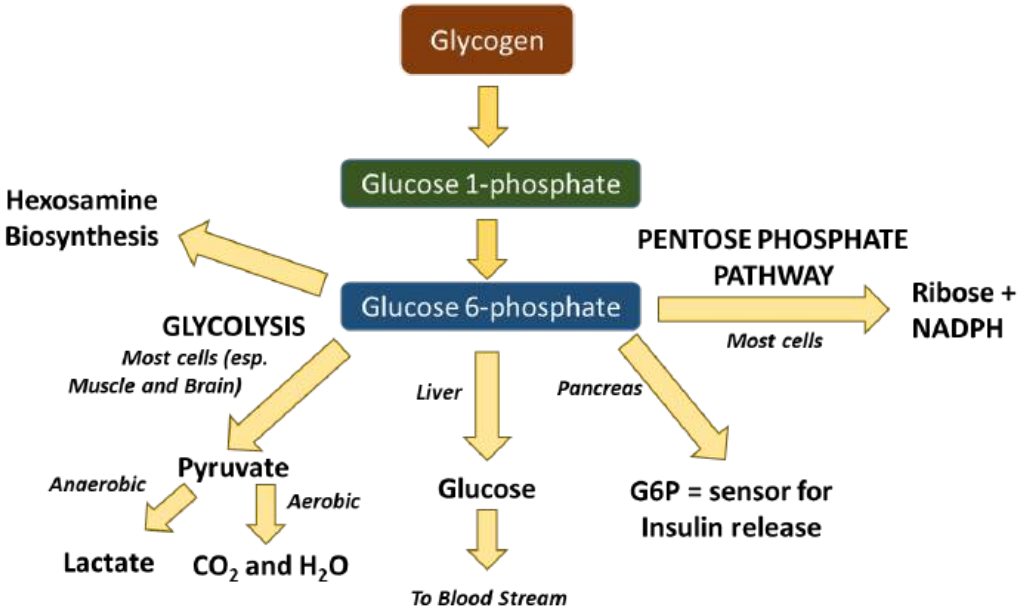

Figure 15.4.2: Cellular Fates of Glucose 6-Phosphate

Now let's take a look at the different isozymes of hexokinase in a little more detail. Hexokinase I (HKI) is found widely distributed throughout the body and is the main form expressed in brain tissue and red blood cells, as shown in Figure 15.4.3. In brain cells, this protein is localized to the mitochondria. This colocalization aids in the efficient coupling of glycolysis and the Krebs' cycle and oxidative phosphorylation pathways inside the mitochondria. It also ties the activity of HKI with oxidative phosphorylation and energy load, as HKI preferentially uses mitochondrially-derived ATP in its reaction mechanism. HK association with the mitochondria also has a cellular protective effect, reducing the potential for programmed cell death or apoptosis to occur. Red Blood Cells (RBCs), on the other hand, are highly differentiated cells with a very short lifespan. They are replaced in humans approximately every two weeks. RBCs are enucleated and do not have mitochondria, and thus, only generate ATP through the process of glycolysis. the HKI protein is free floating in the cytoplasm in this system. HKI has a low Km, meaning that it has a high affinity for glucose and is active at low substrate concentrations. It is also inhibited by the product Glucose-6-Phosphate (G6P) in the process of ***negative feedback inhibition.*** Essentially, you do not want to waste time and energy making more than you need. Low to moderate levels of free inorganic phosphate can overcome this negative feedback inhibition.

Figure 15.4.3: Localization of Hexokinase I. Hexokinase I (HKI) is found widely throughout the body and is the primary hexokinase found in brain tissue and red blood cells. Within the brain tissue, HKI is localized to the mitochondria. Images from Smart Servier Medical Art and Jessica Polka

HKI and HKII are expressed in Skeletal Muscle, Heart Muscle, and insulin-sensitive tissues. While it is thought that HKI is providing a predominantly catabolic role for the use of G6P in energy production, HKII may play a more pertinent role in anabolic processes, providing G6P for conversion to G1P and subsequent utilization in Glycogenesis. Both HKI and HKII are localized to the outer membrane of the mitochondria. However, while 95% of HKI is associated with mitochondria, only about 70% of HKII is associated, with the remaining HKII fractionating with the cytosolic proteins. This could help to explain the heightened role of HKII in anabolic glycogenesis processes within skeletal muscle, and why it is not found in brain tissue. HKII is also often overexpressed in tumor cells, where it is associated with higher mortality rates. It has also been linked with the processes of metastasis and with the development of drug resistance. Similar to HKI, HKII also has a low Km and is inhibited by G6P, although this inhibition is not released by the presence of inorganic phosphate.

Not a lot is known about the functions of HKIII. It may be an inactive gene duplication or remnant. Under basal conditions, it is not expressed to appreciable levels in any major tissues, and studies on its biological activity it is inhibited by glucose at physiological concentrations. However, some studies suggest that it may be expressed during cellular stress responses, such as hypoxia, although its function in these types of responses is not currently understood.

Hexokinase IV or Glucokinase is specifically expressed within the liver and pancreas. HKIV is cytoplasmic and not tethered to the mitochondria. Activity within the pancreas serves as a sensor for the release of insulin, and in the liver for the production of G6P that will fuel glycogen production. HKIV has a higher Km than HKI and HKII, thus it does not work efficiently at low concentrations of glucose. However, it is NOT inhibited by the product, G6P. Thus, it will continue to make G6P, even when levels are high. This helps to explain the high levels of glycogen that are stored within liver tissue, but not elsewhere in the body. This also ensures that the sensor system in the pancreas will accurately read blood glucose levels.

The four isozymes of HK share high homology with one another and appear to have arisen from gene duplication events, as shown in Figure 15.4.4. The left-hand panel of Figure 15.5.4 shows the linear protein domains of the different HK isozymes. Both HKI and HKII contain an N-terminal domain that localizes the protein to the mitochondrial membrane. HKI, II, and III all contain two repeating catalytic domains in the N- and C-terminals. However, mutations in the N-terminal domain in HKI and HKIII render them inactive. Both catalytic domains in HKII retain activity. HKIV (Glucokinase) is the most truncated isozyme, only containing the C-terminal catalytic domain. The lower right diagram shows the ribbon diagram of HKIV. Upstream promoter regions of HKIV (not shown in this diagram) also differ, allowing for controlled expression in the liver and pancreas. Feedback inhibition in HKI and HKII occurs through the N-terminal catalytic domain. The upper diagram on the right shows an HKI dimer complex with an ATP analog, glucose, G6P, and Mg2+ ion. HKI dimerizes when concentrations of the inhibitor, G6P, are high enough. Dimerization reduces the biological activity of the enzyme in brain tissue. Dimerization of HKI can be reversed in the presence of low levels of inorganic phosphate.

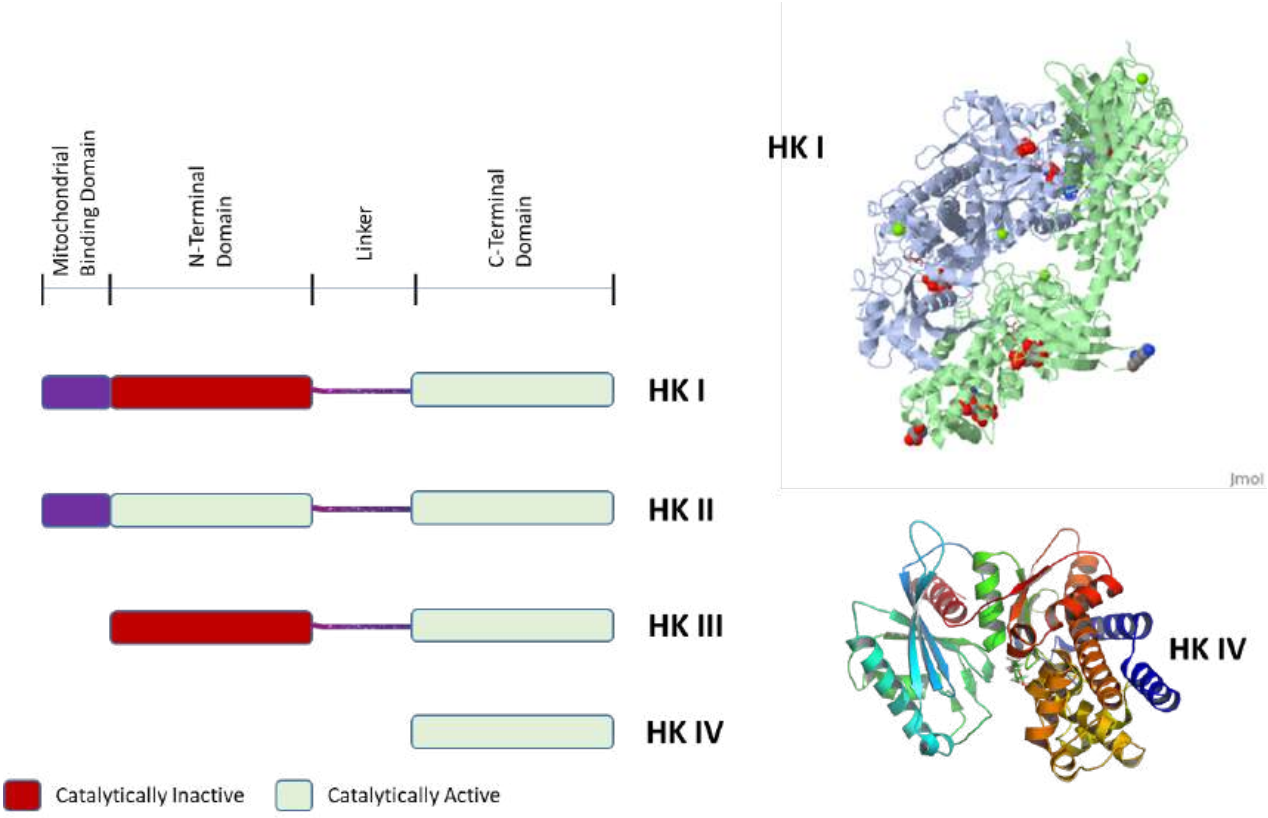

Figure 15.4.4: Protein Comparison of the Four Major Hexokinases in Vertebrates. The left-hand panel shows the linear protein domains of the hexokinases I - IV. The upper right diagram shows a dimer of HKI complexed with an ATP analog, glucose, glucose 6-phosphate, and Mg^{2+}. The lower panel depicts a ribbon diagram of HKIV. Figures modified from Proteopedia and JAG123

HKIV is also a good model for understanding enzyme conformation change during the reaction. HKs change shape by induced fit upon substrate binding. HKIV has a large induced fit motion that closes over the substrates ATP and xylose, as shown in Figure 15.4.5. The binding sites are shown in blue, substrates in black, and the Mg^{2+} cofactor in yellow (PDBs:2E2N,2E2Q).

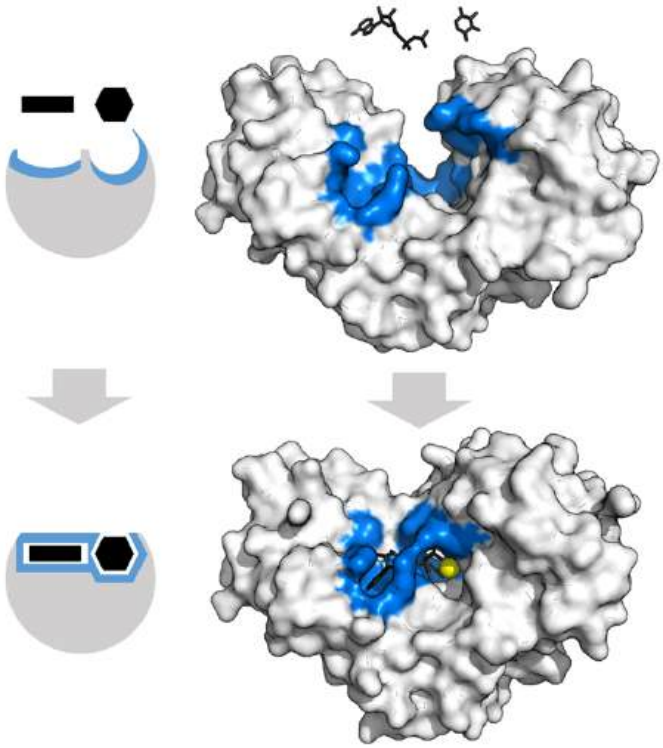

Figure 15.4.5: HKIV Conformational Change During Substrate Binding. The upper diagram shows the enzyme before substrate binding whereas the lower diagram shows the conformational change upon binding with xylose, ATP, and the Mg^{2+} cofactor. Mg^{2+} is shown in yellow and the substrate binding pocket in the enzyme in blue. Xylose and ATP are shown in black. Figure from Thomas Shafee

In summary, the isozyme expression patterns of HKs differentially regulate the fate of glucose within those tissues. Within brain tissue and red blood cells where only HKI is present, glucose is predominantly used in the glycolytic pathway for energy production. In muscle tissue, the presence of HKII allows for increased use of glucose for the formation of glycogen. HKIV expression in the pancreas and liver allows for the homeostatic regulation of blood glucose levels and stockpiling of glucose in the form of glycogen.

15.4.2: PHOSPHOFRUCTOKINASE-1 REGULATION

Recall that phosphofructokinase-1 (PFK1) mediates the third step in the glycolytic pathway with the conversion of fructose 6-phosphate to fructose 1,6-bisphosphate, as shown in Figure 15.4.6. The PFK1 reaction is the first irreversible reaction of glycolysis. It also represents the committed step within the pathway. The phosphorylation of fructose-6-phosphate (F6P) to fructose-1,6-bisphosphate (F1,6BP) commits the F1,6BP to continue through the glycolytic pathway. It cannot be utilized for any other purpose at that point. F6P, on the other hand, could be converted back into glucose-6-phosphate and used for many different purposes (ie glycogen synthesis, nucleotide synthesis, or hexosamine synthesis). Because of the committed nature of this step, PFK1 is one of the most important control points in the glycolytic pathway.

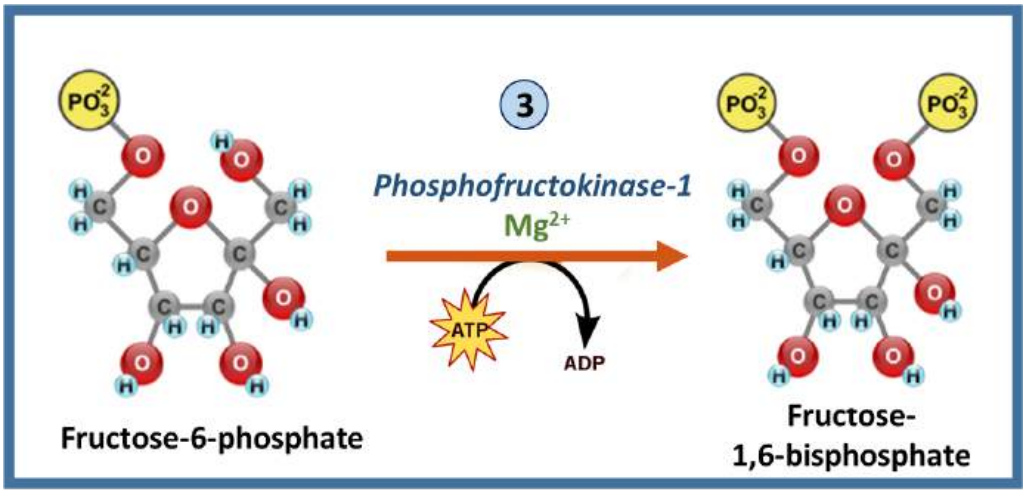

Figure 15.4.6: Phosphofructokinase-1 Activity During Glycolysis. Image modified from YassineMrabet

The PFK1 enzyme is composed of a tetramer that can contain different combinations of three types of subunits: muscle (M), liver (L), and platelet (P). The composition of the PFK1 tetramer differs according to the tissue type it is present in. For example, mature muscle expresses only the M isozyme, therefore, the muscle PFK1 is composed solely of homotetramers of M4. The liver and kidneys express predominantly the L isoform. In erythrocytes, both M and L subunits randomly tetramerize to form M4, L4, and the three hybrid forms of the enzyme (ML3, M2L2, M3L). As a result, the kinetic and regulatory properties of the various isoenzymes pools are dependent on subunit composition. Tissue-specific changes in PFK1 activity and isoenzymes content contribute significantly to the diversities of glycolytic and gluconeogenic rates which have been observed for different tissues

PFK1 is an allosteric enzyme and has a structure similar to that of hemoglobin in so far as it is a dimer of a dimer, as shown in Figure 15.4.7. One half of each dimer contains the ATP binding site, whereas the other half the substrate (fructose-6-phosphate or (F6P)) binding site, as well as a separate allosteric binding site, that can bind with ADP or AMP. All isoforms of PFK1 are activated by the allosteric binding of ADP or AMP. This indicates a low energy state within the cell and the need for glycolysis and energy generation. Allosteric inhibitors include high levels of ATP and Citrate. Note that ATP is a substrate of this enzyme and has the normal substrate binding site. When there is enough ATP present that it can also bind allosterically to the enzyme, it will act as an inhibitor. Citrate, the first molecule in the Kreb's Cycle (Citric Acid Cycle), can also act as an allosteric inhibitor of PFK-1. High levels of citrate that no more pyruvate is needed to generate ATP through oxidative phosphorylation. We are also going to see that Fructose 2,6-bisphosphate is predominantly a regulator of PFK1 in Liver Cells, where it serves as an activator.

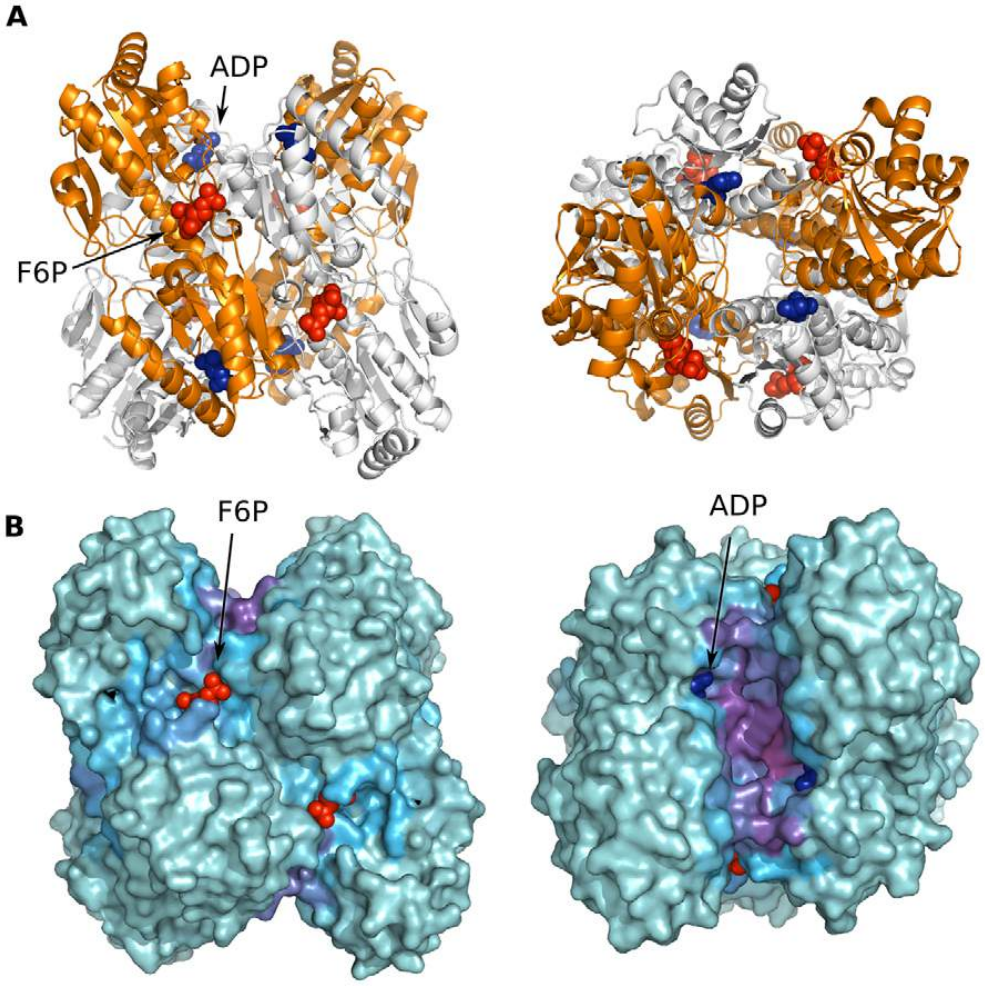

Figure 15.4.7: Structure of Phosphofructokinase-1. Lefthand diagrams show the ribbon and space-filling models from a side view whereas the right-hand diagrams has been rotated 90 degrees to show the top-down view. The ATP binding sites are shown in dark blue and the fructose 6-phosphate binding sites are shown in red. A separate allosteric binding site for ADP is also shown. Image modified from Mitternacht, S., and Berezovsky, I.N. (2011)

Before we discuss the formation and use of Fructose 2,6-bisphosphate and its role in the regulation of PFK1, let's review opposing glucose utilization/production pathways within the liver, as shown in Figure 15.4.8. Two opposing pathways within the liver are glycolysis (the breakdown of glucose) and gluconeogenesis (the formation of glucose). It would be unproductive to have both of these pathways operating at the same time. Thus, if one pathway is needed, then the other one needs to be turned off. We previously saw this same type of control for

glycogenesis (the formation of glycogen) and glycogenolysis (the breakdown of glycogen). When one of these pathways is upregulated, the other needs to be downregulated.

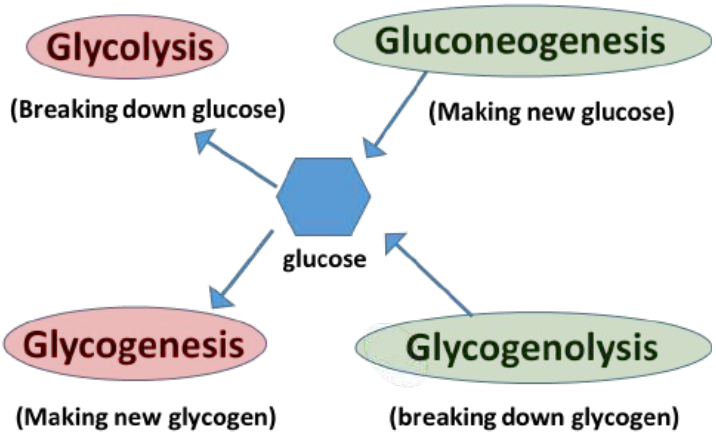

Figure 15.4.8: Opposing Pathways of Glucose in the Liver. Image modified from Yan, A., et al (2016) In J Biol Sci 12(12):1544-1554 and Servier Medical Art

In the resting state of the liver, when blood glucose levels are in the homeostatic range, gluconeogenesis will be shut off, as it is very expensive to make glucose and the liver will only invest in making glucose if blood glucose levels fall critically low (ie extreme exercise or long term fasting). In the resting state, the liver will use the glycolytic pathways to supply normal levels of ATP energy for the maintenance of housekeeping processes. Glycogenesis and glycogenolysis will be in balance or equilibrium as needed to augment the supply of glucose entering the system from the bloodstream.

If glucose in the blood drops below homeostatic levels, the pancreas will release glucagon and begin this hormone-signaling pathway that causes the liver to release glucose into the bloodstream. Thus, glucagon signaling leads to the downregulation of glycolysis and glycogenesis, so it can shunt glucose pools to the bloodstream. It also leads to an increase in glycogenolysis or the breakdown of glycogen. During this time, liver cells are predominantly generating ATP from lipids, rather than carbohydrates. Thus, glycolysis can be inhibited to promote the release of glucose into the bloodstream.

If cellular demand for glucose is high, liver cells will also turn on the gluconeogenesis pathway and make glucose new from non-carbohydrate precursors (which it then exports into the bloodstream for delivery to tissues). This is an energy-intensive pathway. The major site of gluconeogenesis is the liver, with a small amount also taking place in the kidney. Little gluconeogenesis takes place in the brain, skeletal muscle, or heart muscle. It just does not make energetic sense to do that! It costs more energy for cells to make glucose than they can get from breaking it down in oxidative phosphorylation. This cost can be dealt with by doing it in the liver and then releasing it into the bloodstream to fuel activities in the brain, heart, and skeletal muscles.

To do this, glucagon stimulates that lovely signaling pathway that you are all now familiar with (reviewed in Figure 15.4.9)! Within the liver, it activates the G-protein coupled receptor which in turn activates the downstream G-protein. Adenylate Cyclase is activated and produces the second messenger, cAMP. cAMP binds with the CREB protein and activates the transcription of proteins involved in gluconeogenesis. The cAMP also binds with Protein Kinase A and upregulates the activity of glycogen phosphorylase resulting in the breakdown of glycogen. It also down-regulates the activity of glycogen synthase to inhibit glycogenesis. In this section, we will also see how PKA activation will down-regulate the activity of the glycolytic pathway as well.

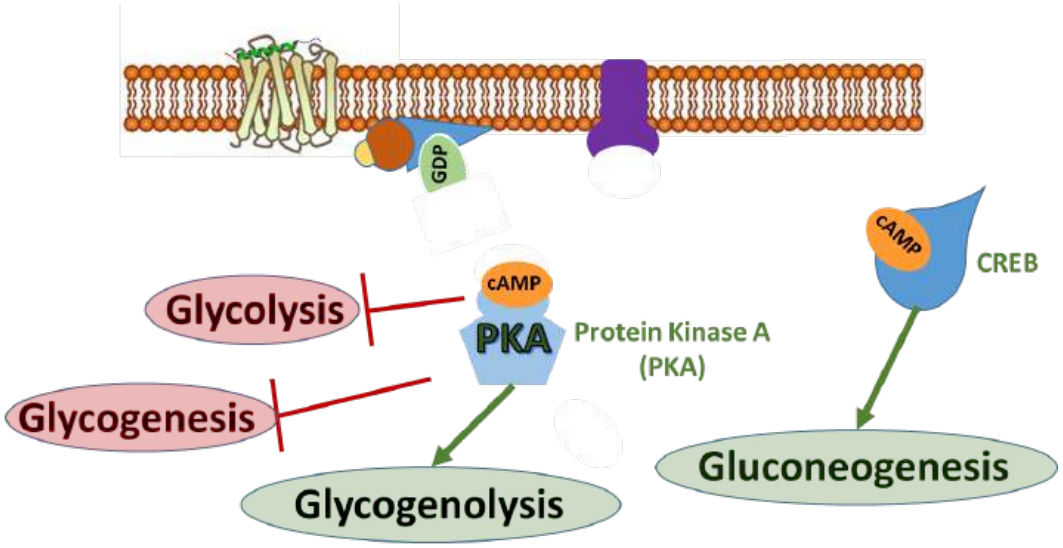

Figure 15.4.9: Overview of Glucagon Signaling Pathways within the Liver. Image modified from Yan, A., et al (2016) In J Biol Sci 12(12):1544-1554 and Servier Medical Art

Regulation of the glycolytic pathway in response to this signaling occurs through the regulation of the PFK-2/FBPase-2 Enzyme. The activity of this enzyme is controlled through the PKA signaling cascade. This enzyme is responsible for phosphorylating fructose 6-phosphate to the fructose 2,6-bisphosphate form. Note that this bisphosphate form of fructose is ***DIFFERENT*** than the bisphosphate form utilized in the glycolytic pathway. The glycolytic pathway requires fructose 1,6-bisphosphate that is formed from the PFK1 enzyme (or Step 3 of the glycolytic pathway). The PFK-2/FBPase-2 is a separate enzyme altogether and not involved directly in the glycolytic pathway. However, we noted previously that fructose 2,6-bisphosphate can serve as an allosteric activator of the PFK1 enzyme.

The PFK-2/FBPase-2 Enzyme is a dual-purpose enzyme, as shown in Figure 15.4.10. Half of the protein has kinase activity and can phosphorylate fructose-6-phosphate to fructose-2,6-bisphosphate. The other half of the enzyme contains a phosphatase that can cleave off the phosphate group from the 2-position and restore fructose-6-phosphate. Note that both activities are not functional at the same time! The enzyme activity is determined by the phosphorylation state. When the protein is dephosphorylated, the PFK-2 enzyme is active, leading to the production of fructose-2,6-bisphosphate. This molecule can then bind with PFK-1 in the glycolytic pathway and increase its activity. If the protein is phosphorylated by PKA during glucagon signaling, the FBPase is activated and the kinase activity is inhibited. This leads to the dephosphorylation of fructose at the 2-position and the release of fructose-6-phosphate.

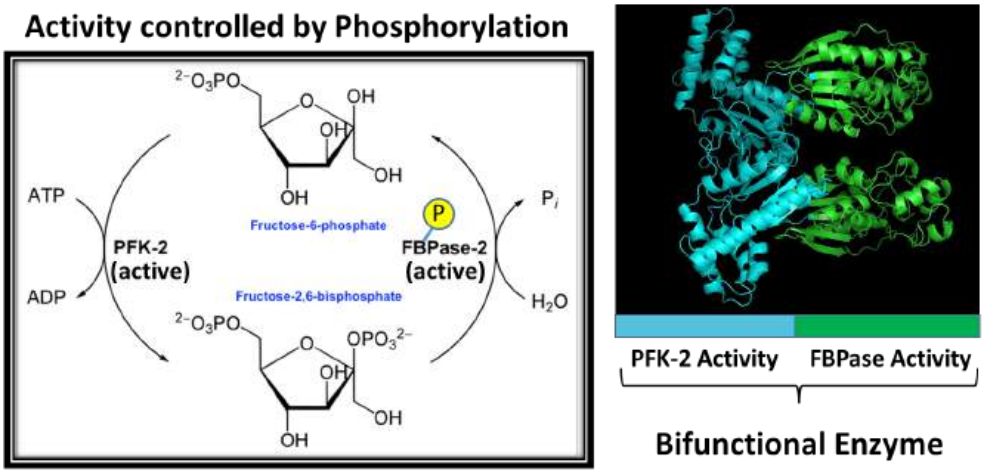

Figure 15.4.10: Biological Activity of the PFK-2/FBPase-2 Enzyme. The PFK-2/FBPase-2 is a dual functional enzyme that is capable of phosphorylating the 2'-position of fructose 6-phosphate using the kinase activity, whereas the FBPase activity can be used to remove the phosphoryl group from position 2' of fructose 2,6-bisphosphate, yielding fructose 6-phosphate. The PFK-2 component is active when the protein is in the dephosphorylated state while the FBPase remains inactive. However, following phosphorylation, the FBPase component becomes active and the kinase domain is inhibited. Image modified from Kedrosolan and Hyunsuky

As shown in Figure 15.5.10, the PFK-2/FBPase-2 Enzyme is responsible for phosphorylating fructose 6-phosphate to the fructose 2,6 bisphosphate form. Note again that this bisphosphate form of fructose is ***DIFFERENT*** than the bisphosphate form utilized in the glycolytic pathway. The glycolytic pathway requires fructose-1,6-bisphosphate that is formed from the PFK1 enzyme (or Step 3 of the glycolytic

pathway). If there is a lot of fructose-6-phosphate around (ie you just drank high fructose corn syrup in your sugary energy drink) it can support both the formation of fructose 1,6-bisphosphate by PFK1 and the production of fructose 2,6-bisphosphate by PFK-2. Fructose 2,6-bisphosphate will then bind with PFK1 and increase its activity converting fructose 6-phosphate into fructose-1,6-bisphosphate, as shown in Figure 15.4.11.

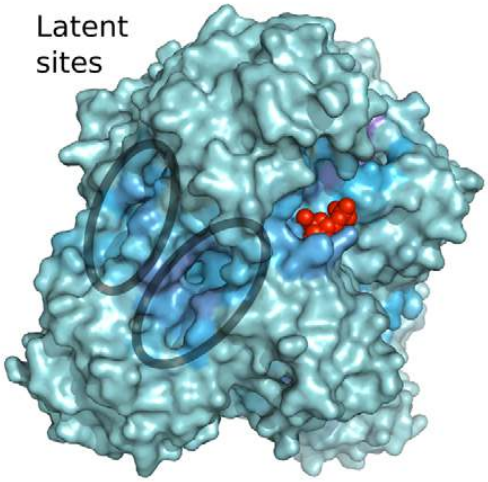

Figure 15.4.11: Fructose 2,6-bisphosphate is a positive allosteric effector of the PFK1 Enzyme. The upper diagram shows a space filling model of PFK1 with the fructose 2,6-bisphosphate binding sites indicated. Mitternacht, S., and Berezovsky, I.N. (2011), ibid

However, during glucagon signaling, you need to shut down this fast-track upregulation of PFK1 by fructose-2,6-bisphosphate and turn down the glycolytic pathway. To do this, Protein Kinase A will phosphorylate the PFK-2/FBPase-2 enzyme and alter its activity. The kinase activity is inhibited and the phosphorylase activity is turned on. Figure 15.4.12 provides a summary of this pathway control. In the presence of glucagon, PKA will phosphorylate the PFK-2/FBPase-2 enzyme causing the kinase activity to be switched off and the phosphatase activity to be switched on. Dephosphorylation of fructose-2,6-bisphosphate recovers fructose-6-phosphate (F6P). F6P can then go through the reverse isomerase reaction and recover glucose-6-phosphate (G6P). G6P will then be transported to the rER where it will be dephosphorylated and then free glucose can be released back into the blood.

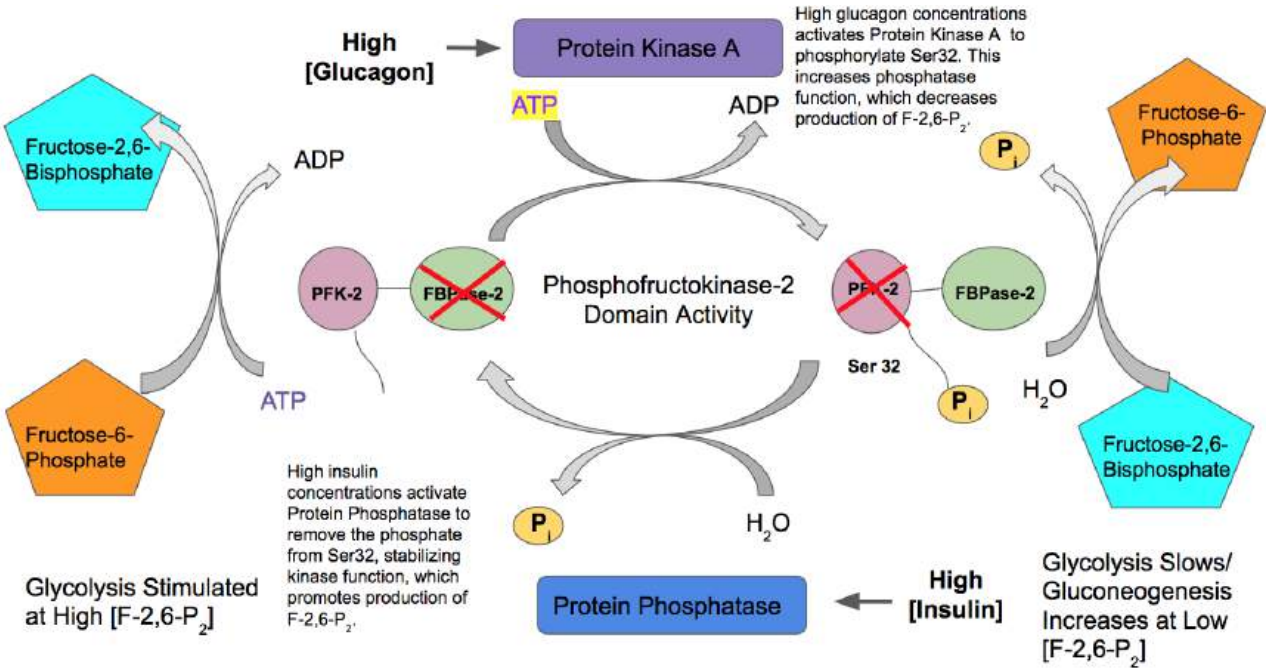

Figure 15.4.12: Allosteric Regulation of PFK1 in the Liver in Response to Glucagon Signaling. Image from Kedrosolan

The opposite holds for insulin signaling. High insulin concentrations result in the activation of protein phosphatase and the dephosphorylation of the PFK-2/FBPase-2 enzyme. In the dephosphorylated state, PFK-2 activity is high and the FBPase-2 activity is low, which will stimulate PFK1 and the glycolytic pathway.

15.4.3: PYRUVATE KINASE

Recall that pyruvate kinase mediates the final reaction during glycolysis resulting in the production of pyruvate and ATP as shown in Figure 15.4.13. Similar to PFK1 this enzyme is also a key regulatory component within the pathway.

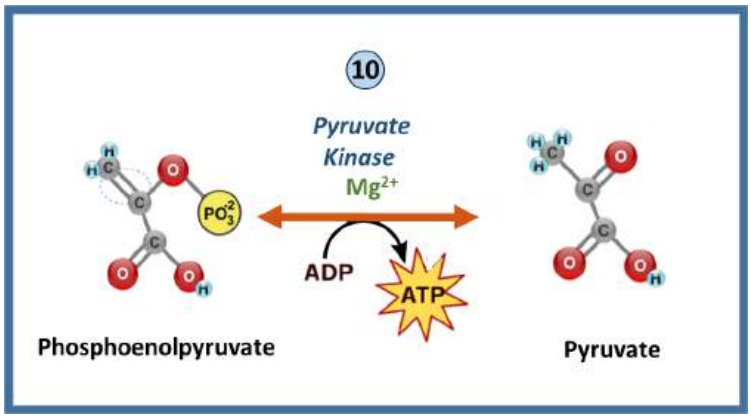

Figure 15.4.13: Review of the Pyruvate Kinase Reaction. Image modified from YassineMrabet

The pyruvate kinase enzyme exists as a tetramer, that is built from the combination of different isozymes expressed in different tissues. There are three major isozymes of pyruvate kinase, the L form that is predominantly found in the liver, the R form that is predominantly found in erythrocytes, and the M1 form in muscle and brain, and the M2 form that is expressed in fetal tissue and at some level in most adult tissues. The L and R forms are splice variants that arise from the same gene locus, and the M1 and M2 forms are also splice variants that arise from the same gene locus.

We will focus on some of the general regulatory mechanisms common to most of the isozymes of pyruvate kinase, starting with the activator, fructose 1,6-bisphosphate (FBP). Because FBP is an earlier product within the same metabolic cascade, the activation of pyruvate kinase enzymes by FBP is known as ***feedforward stimulation***. All of the isozymes, except for the M1 form are stimulated by the binding of FBP to the enzyme. Similarly, all of the pyruvate kinase isozymes are inhibited by the product of the reaction, ATP (or high energy load), and high levels of alanine. Alanine can be converted to pyruvate in one enzymatic step. Thus, pyruvate serves as a metabolic intermediate in the formation of alanine. If high levels of alanine are present, this indicates that there is a high energy load within the cell (ie that the cell is full of building blocks to make new macromolecules and is not in the need of more energy). Thus, high levels of alanine serve as a negative regulator of the pyruvate kinase family of enzymes.

The liver isozyme of pyruvate kinase is also regulated through protein phosphorylation, as shown in Figure 15.4.14. Similar to the PFK-2 activity of the PFK-2/FBPase-2 enzyme, the liver isozyme of Pyruvate Kinase is also downregulated during glucagon signaling. Protein kinase A phosphorylates Pyruvate Kinase inhibiting its activity and preventing the conversion of phosphoenolpyruvate to pyruvate. Dual regulation of the glycolytic pathway during glucagon signaling helps to ensure that glucose resources will be diverted away from cellular use by the liver and released into the blood stream to restore homeostatic blood glucose levels.

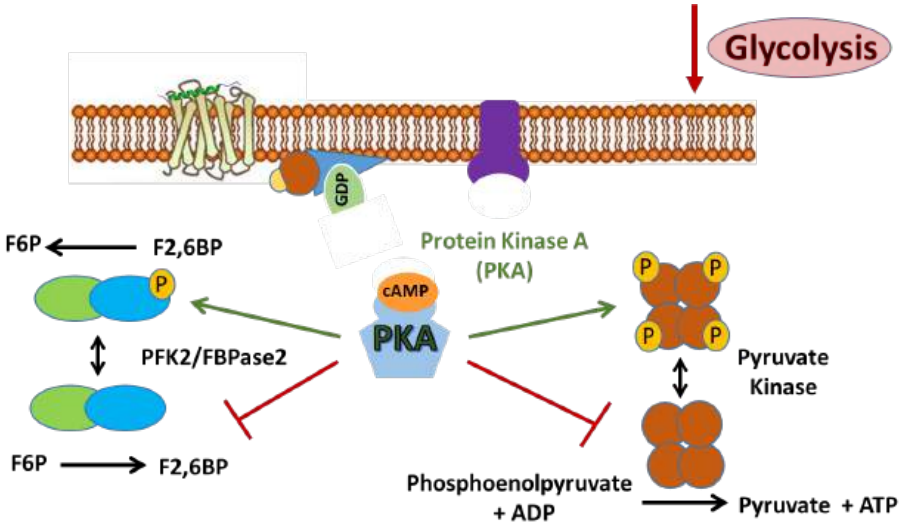

Figure 15.4.14: Glucagon Signaling in Liver Cells Down Regulates PFK2 Activity and Pyruvate Kinase Activity. Image modified from Yan, A., et al (2016)

15.4.4: FRUCTOSE REGULATORY BYPASS

Other sugars from the diet can also enter into the glycolytic pathway, as shown in Figure 15.4.15. Galactose is converted in a four-step process to Glucose-6-phosphate and mannose can be converted to fructose-6-phosphate. Within most of the body's tissues, fructose can also be converted into fructose-6-phosphate by hexokinase. However, in the liver and kidneys, there is an alternative route that fructose from the diet can take to enter into the glycolytic pathway. This pathway is concerning because it bypasses two of the major regulatory steps of the glycolytic pathway, the hexokinase step and the PFK1 step. Within the liver and kidneys, fructose can also be converted into fructose-1-phosphate by the enzyme fructokinase. The other isozyme of Aldolase, Aldolase B, can cleave the fructose-1-phosphate into 2 three carbon units, dihydroxyacetone phosphate, and glyceraldehyde. Dihydroxyacetone phosphate can be converted to glyceraldehyde 3-phosphate by Triose Isomerase and then continue into the glycolytic cascade. Glyceraldehyde can be phosphorylated to Glyceraldehyde 3-phosphate by Triokinase. This is an unregulated system that can flood the Kreb Cycle with high levels of pyruvate if high levels of fructose enter the cell (i.e. from high fructose corn syrup, sucrose, and other sweeteners common to the Westernized diet). The excess pyruvate can then be shunted into fatty acid biosynthesis for long-term storage in the form of triglycerides. If the pathway is overutilized by consuming too much sucrose and high fructose corn syrup, this can lead to the development of Hypertriglyceridemia (or the heightened increase of body fat). With this, we will end our discussions of glycolysis. In the next section, we will look at the complementary and opposite pathway, gluconeogenesis.

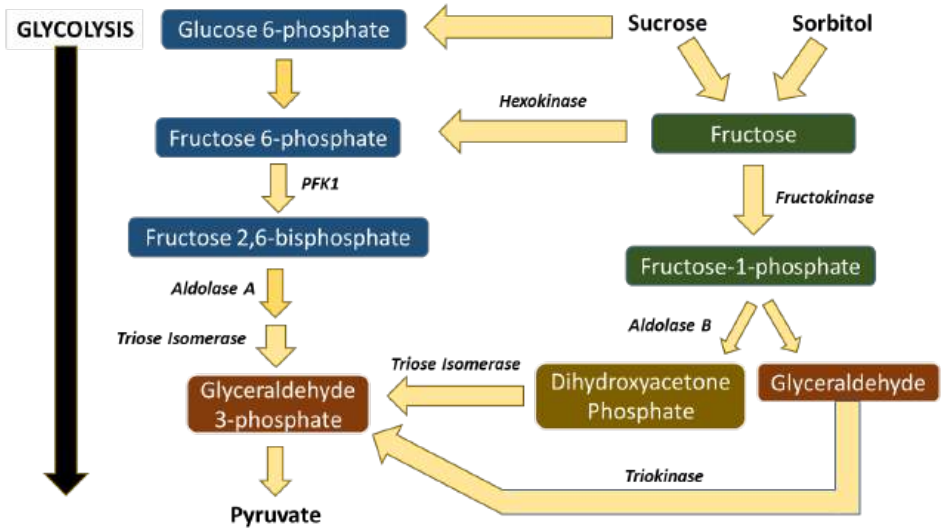

Figure 15.4.15: Alternate Sugar Sources for Glycolysis

15.5: REGULATION OF GLUCONEOGENESIS

Within the regulation of the gluconeogenic pathway, three of the major enzymatic steps are regulated. The first two are the pyruvate carboxykinase enzyme and the phosphoenolpyruvate carboxykinase (PEPCK). Recall that these two enzymes are required to convert pyruvate back into phosphoenolpyruvate via an oxaloacetate intermediate as shown in Figure 15.5.1. The third enzyme regulated in this pathway is Fructose 1,6-Bisphosphatase which converts fructose 1,6-bisphosphate into fructose 6-phosphate. We will explore the regulation of these three enzymes in more detail.

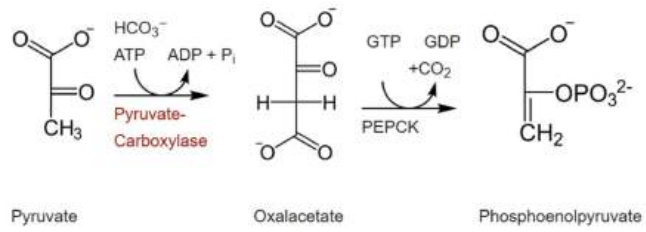

Figure 15.5.1: Conversion of Pyruvate to Phosphoenolpyruvate during Gluconeogenesis. Image modified from Principles of Biochemistry (2019) Wikibooks

15.5.1: PYRUVATE CARBOXYKINASE

Pyruvatecarboxykinase is one of the primary regulation points. It is primarily regulated by two allosteric effectors, Acetyl-CoA and ADP, as shown in Figure 15.5.2. When pyruvate enters into the Kreb Cycle, it is first converted to Acetyl-CoA. If abundant pyruvate is present, an ample supply of acetyl-CoA will also be available, indicating a high energy load for the cell. Acetyl-CoA, can bind with pyruvate carboxylase and act as an activator of the protein, stimulating the production of oxaloacetate. ADP, on the other hand, is a low-energy indicator and an inhibitor of the enzyme. In the next section, we will discover how oxaloacetate moves into the cytoplasm.

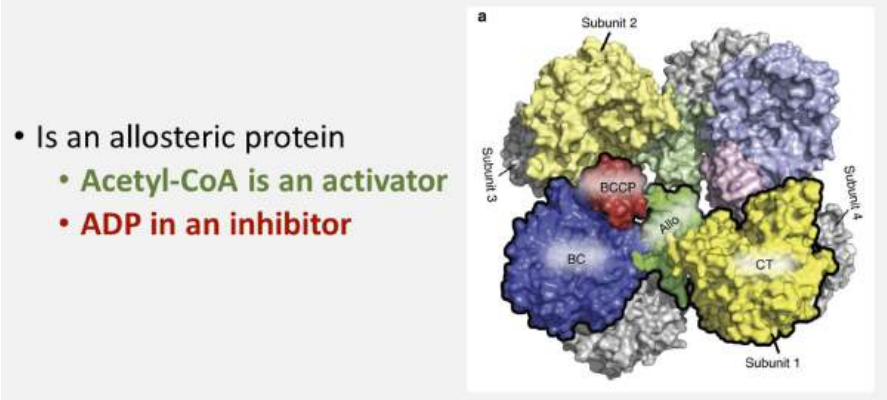

Figure 15.5.2: Allosteric Regulation of Pyruvate Carboxykinase. Figure modified from Liu, Y., et al (2018) Nat Commun 9:1384

15.5.2: PHOSPHOENOLPYRUVATE CARBOXYKINASE

Cytoplasmic PEPCK is largely regulated at the transcriptional level. Increases in gene expression are seen in response to elevated cAMP levels, increased glucocorticoids, and increased thyroid hormone levels, as shown in Figure 15.5.3. The activated CREB transcription factor plays a role in this response. Alternatively, decreased gene expression is caused by insulin signaling. ADP also acts as an allosteric effector of the protein, causing it to have lower activity. This indicates that when energy is low, the cell cannot afford to use its reserves to remake glucose and inhibits the pathway.

Figure 15.5.3: Regulation of Phosphoenolpyruvate Carboxykinase at the Transcriptional and Allosteric Levels. Image from ProteinBoxBot

15.5.3: FRUCTOSE 1,6-BISPHOSPHATASE

Fructose 1,6-bisphosphatase is both competitively and allosterically regulated, as shown in Figure 15.5.4. Fructose 2,6-bisphosphate serves as a competitive inhibitor of the enzyme reducing the overall activity of the enzyme for fructose 1,6-bisphosphate. Competitive inhibitors bind within the active site and compete for binding with the regular substrate. Thus, they lower the overall Km of the reaction and make the enzyme less effective at lower substrate concentrations. However, the Vmax of the enzyme is not affected during the process.

In addition to competitive inhibition, low energy load (AMP and ADP) also inhibits the enzyme. ADP and AMP will bind allosterically with the enzyme and inhibit its activity.

CHAPTER OVERVIEW

16: THE CITRIC ACID CYCLE

The citric acid cycle – also known as the TCA cycle or the Krebs cycle – is a series of chemical reactions to release stored energy through the oxidation of acetyl-CoA derived from carbohydrates, fats, and proteins.

16.1: Production of Acetyl-CoA (Activated Acetate)

16.2: Reactions of the Citric Acid Cycle

16.3: Regulation of the Citric Acid Cycle

16.4: Variants of the Citric Acid Cycle

16.1: PRODUCTION OF ACETYL-COA (ACTIVATED ACETATE)

16.1.1: INTRODUCTION

Let's do a short review of the metabolic processes for the extraction of energy from the oxidation of glucose (i.e. glycolysis). Glycolysis is a universal pathway used to anaerobically extract energy from glucose, a six-carbon. In this linear pathway, 2- 3 carbon molecules of pyruvate are formed as glucose is cleaved and converted to two molecules of glyceraldehyde-3-phosphate, form through an oxidation reaction using the oxidizing agent NAD^+. As glycolysis continues, NADH builds up. Using lactate dehydrogenase, pyruvate, the end product of glycolysis, can be converted to lactate, regenerating NAD^+ so the pathway can continue. The reactions are illustrated in Figure 16.1.1.

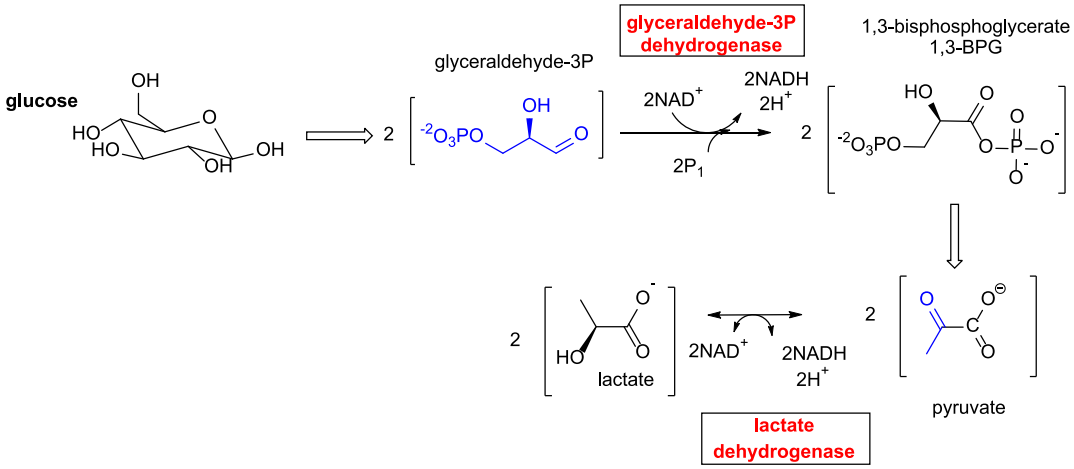

Figure 16.1.1: Anaerobic production of pyruvate and lactate

A careful glance at the structure of the 3-carbon pyruvate molecule shows that much more energy could be extracted from it, presumably through oxidative decarboxylation reactions, converting the carbons to 3 CO_2 molecules. A problem arises immediately when examining pyruvate. It is an α-ketoacid and there is no easy route to decarboxylate it as an electron "sink" is not available to receive the electrons and in the process stabilize the transition state and intermediate in the reaction. This stands in contrast to the decarboxylation of β-keto acids, which have a built-in electron "sink", an electronegative carbonyl carbon, to receive the electrons. This is illustrated in Figure 16.1.2.

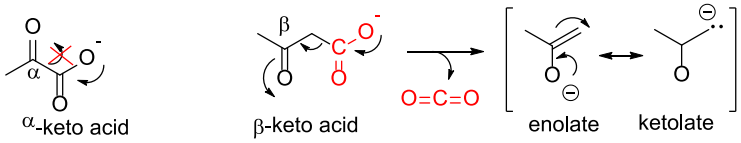

Figure 16.1.2: Comparison of the decarboxylation of α and β keto acids

To begin the process of complete oxidation of the remnants of glucose, pyruvate enters the mitochondria and starts the process of oxidative decarboxylations by interacting with the pyruvate dehydrogenase complex (PHC). This catalyzes a complicated reaction to attach an electron "sink" beta to the carboxylate, which is subsequently released as CO_2. The end products of the PHC oxidative decarboxylation reaction are the two-carbon acetyl-CoAs, NADH, and CO_2. The acetyl-CoA then enters a cyclic, non-linear pathway called the citric acid cycle, tricarboxylic acid (TCA) cycle, or Kreb's cycle, named after Hans Krebs who discovered it. We'll talk about that in section 16.2.

A glance reveals that we have taken glucose a small fraction along the way of oxidizing every carbon in it to CO_2 and H_2O. Complete oxidation happens under aerobic conditions when the glycolytic pathway is followed by the Kreb's cycle. Pyruvate formed in glycolysis enters the mitochondrial matrix where it gets oxidatively decarboxylated while reacting with a small thiol, Coenzyme A (CoASH) to form a 2C "activated acetate" acetyl group connected through a thioester link to CoASH, forming acetyl-CoA.

The third carbon from pyruvate is released as CO_2. The reaction is catalyzed by the enzyme **pyruvate dehydrogenase complex (PDC)**.

16.1.1.1: PYRUVATE DEHYDROGENASE MECHANISM

This enzyme complex is enormous. The E. Coli complex has a molecular weight of almost 4 million with at least 16 chains each of three different enzymes catalyzing part of the reaction. The components are pyruvate dehydrogenase (E1), dihydrolipoamide dehydrogenase (E2), and dihydrolipoamide dehydrogenase (E3). The molecular weight of the bovine complex is almost 8 million, and it has 22 E_1, 60 E_2, and 6 E_3 subunits. Nature often uses the same solution for identical problems. For example, many proteases have an active site nucleophilic

serine, which works with the assistance of histidine and aspartate to cleave peptide bonds. There are three α-ketoacid dehydrogenase complexes in many organisms. Each has a common E3 but specific E1 and E2 enzymes. Figure 16.1.3 shows an image of the structure so you can get an overview before we dive into the activity of each of the substrates.

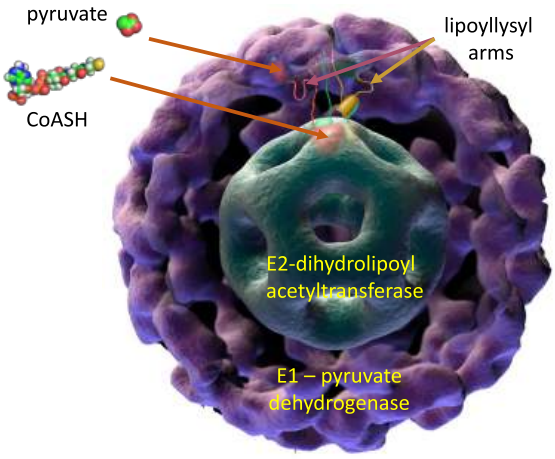

Figure 16.1.3: View of pyruvate dehydrogenase. https://electron.med.ubc.ca/2018/07/...dehydrogenase/

The E3 subunit is not readily seen in the image below. Why has nature produced such a monstrous enzyme complex to simply catalyze the oxidative decarboxylation of a small three-carbon molecule? We will explore that at the end of this section.

The complex also employs collectively 5 substrates/cofactors derived from vitamins.

- Thiamine in the form of thiamine pyrophosphate (TPP), which is covalently attached to E1
- lipoic acid, in the form of lipoamide, which is covalently attached to a lysine side chain in E2
- riboflavin the in the form of flavin adenine dinucleotide ($FAD/FADH_2$), which is bound very tightly (and not released) to E3
- pantothenic acid, incorporated into the structure of CoASH/Acetyl-CoA, a substrate/product pair for the reaction
- niacin, nicotinic acid, in the form of NAD^+/NADH, a substrate/product pair for the reaction

The structures for the five are shown in Figure 16.1.4, along with some additional descriptions that summarize some of the chemistry of these molecules.

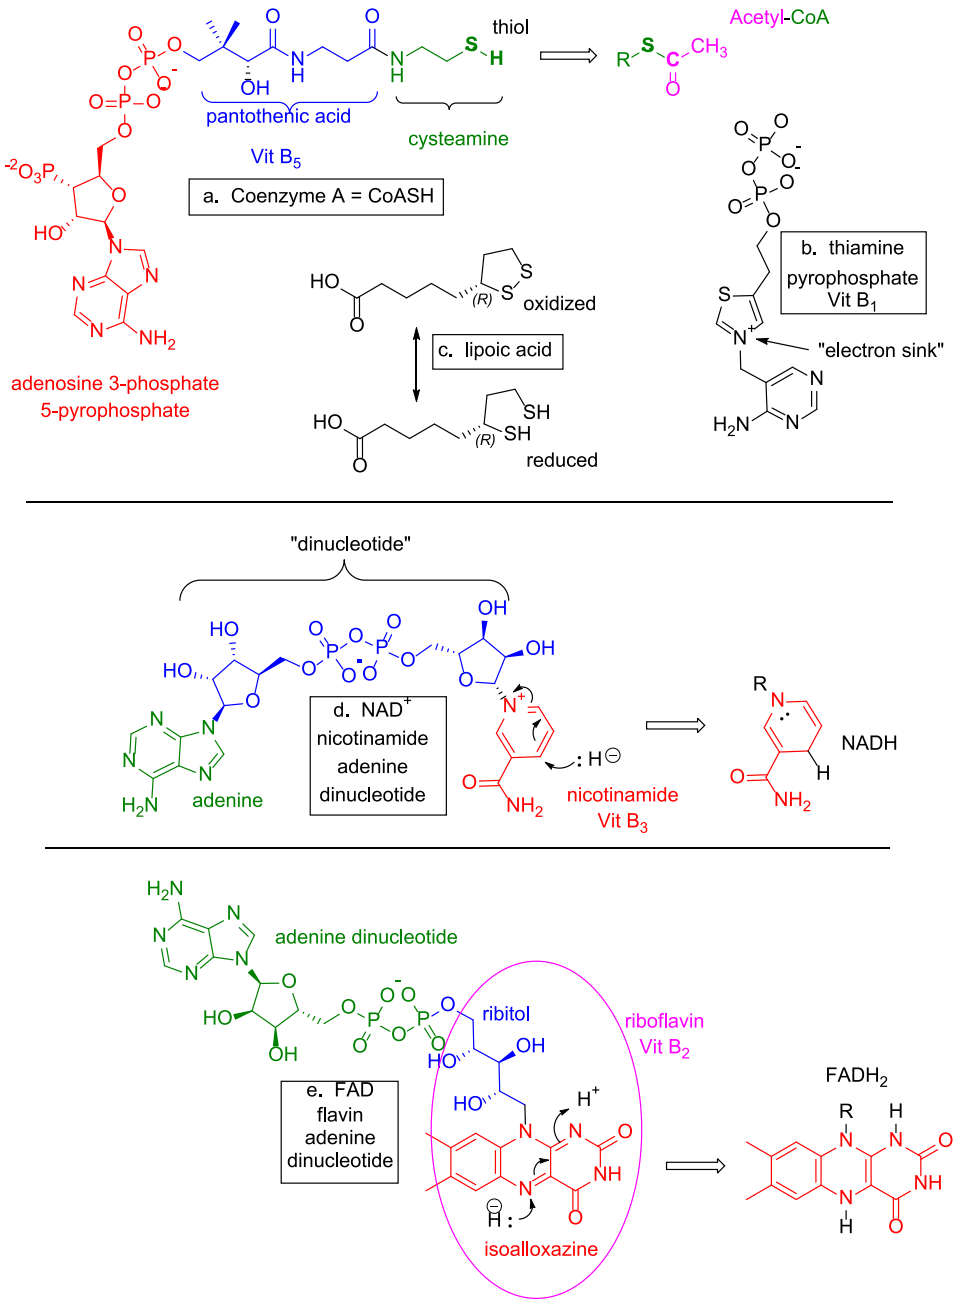

Figure 16.1.4: Structure of the cofactors in pyruvate dehydrogenase

Figure 16.1.5 shows a schematic of the overall reaction.

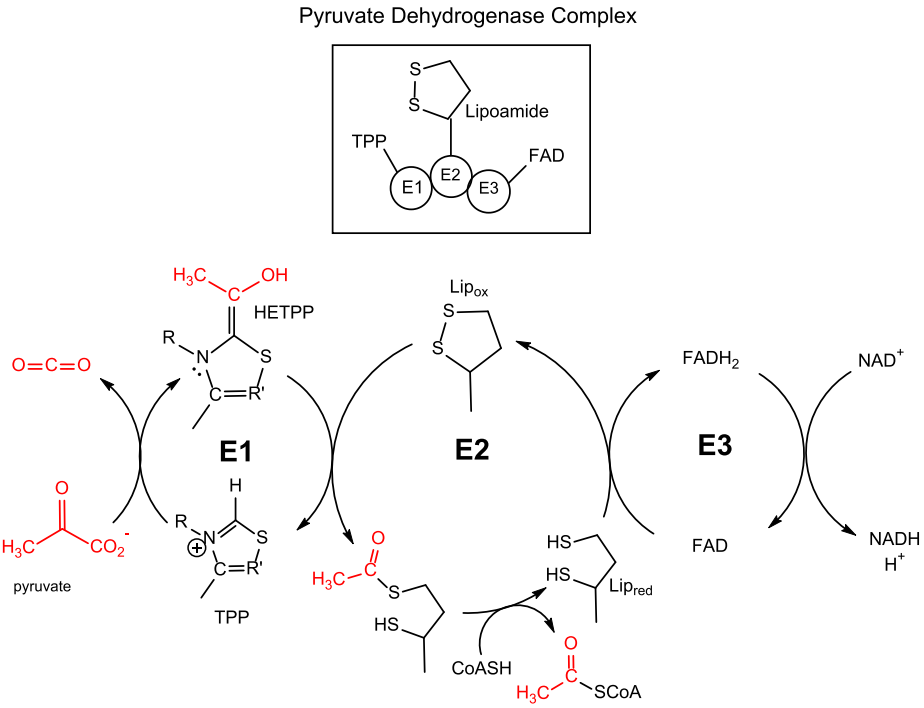

Figure 16.1.5: Overall reactions catalyzed by pyruvate dehydrogenase

The net reaction is

$$\text{pyruvate} + \text{CoASH} + \text{NAD}^+ \longrightarrow \text{Acetyl}-\text{CoA} + \text{CO}_2 + \text{NADH} + \text{H}^+$$

16.1.2: PART 1: OXIDATIVE DECARBOXYLATION - PYRUVATE DEHYDROGENASE (E1P)

So let it begin. We need to get rid of one carbon as CO_2 and transfer the other two carbons of pyruvate to CoASH to form acetyl-CoA, the thioester of CoASH. Thioesters are "high energy" with respect to their hydrolysis products as the thioester is destabilized compared to a normal carboxylic acid ester. (**Remember, there is no such thing as a "high energy" bond**). Since the sulfur atom is larger than the O in the C-S and C-O bond in their respective esters, the thioester as a reactant can not be stabilized well as the C-S single bond length is longer, as shown in Table 16.1.1 below.

bond	length (Angstroms)
C-O	1.43
C=O	1.21
C-S	1.82
C=S	1.56

Table 16.1.1: Bond lengths of carbon-oxygen and carbon-sulfur single and double bonds

This minimizes resonance stabilization compared to the carboxylic acid ester, as shown in the figure below. The products of hydrolysis of both a carboxylic and thiol ester are of comparable energy. Hence only the thioester is relatively destabilized compared to its hydrolysis product, with the $\Delta G^0_{\text{hydrolysis}}$ = -7.5 kcal/mol (-31 kJ/mol), the same as for the hydrolysis of a phosphoanhydride bond of ATP. Additionally, a resonance structure shows a positive charge on the carbonyl C and a negative on the oxygen allowing the carbonyl carbon to be more electrophilic. Another more sophisticated reason for the relative destabilization of the thiol ester is that the overlap between the carbonyl C p orbital is the larger S p orbital is less, hindering the delocalization of electrons needed to stabilize the thiol ester.

Figure 16.1.6 illustrates these points.

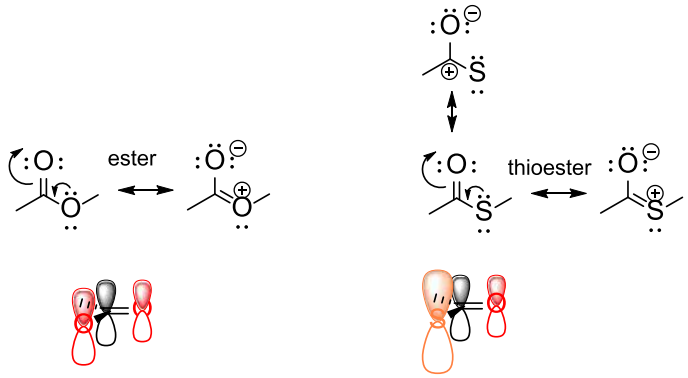

Figure 16.1.6: Comparison of resonance stabilization of carboxylic esters and thioesters

Now we can explore the mechanism of CO_2 release and acetyl-CoA production by E_1. The carbon atom directly between the N and S in the ring has a reduced pKa, so it can be deprotonated to form a carbanion. The negative charge can't be stabilized by resonance but it is adjacent to the positively-charge N, which stabilizes it. This zwitterion is called an **ylide**, which is a net neutral species with a positive charge (usually on a N, P, or S) and a negative charge (usually on a C) on adjacent atoms.

The carbanion on the ylid attacks the electrophilic C=O of pyruvate, forming a TPP intermediate with a wonderful electron sink (N^+) beta to the carboxyl carbonyl C. This is the essence of the entire reaction as this enables the decarboxylation event. The rest of the reactions catalyzed by E2 and E3 allow the release of the other 2 Cs of pyruvate as acetyl-CoA (E2) and the return of the enzyme to its original state (E2 and E3).

Figure 16.1.7 shows the reaction mechanism of E1.

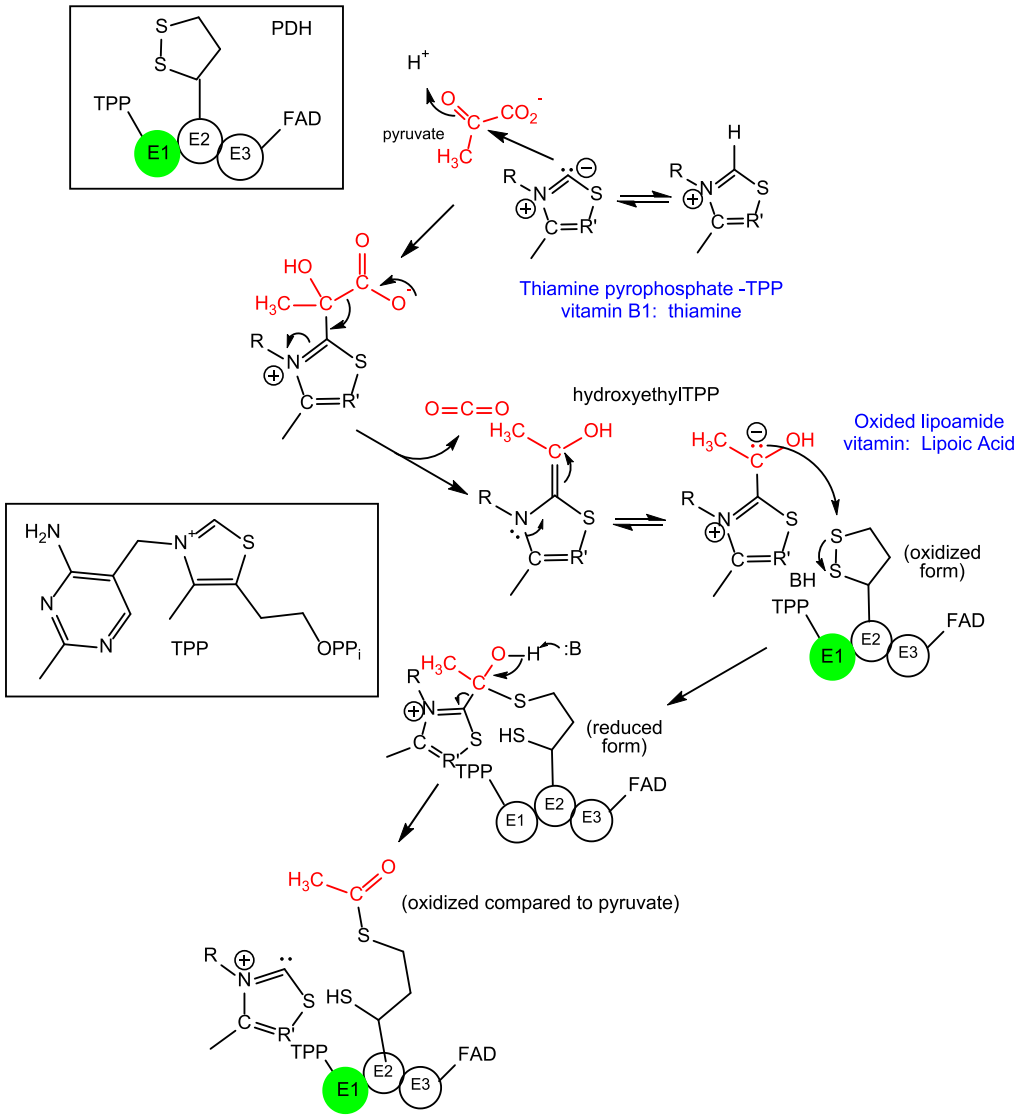

Figure 16.1.7: Reaction mechanism of E1 of pyruvate dehydrogenase

Note that the carbonyl C in pyruvate has two single bonds to two other carbon atoms, while in the final covalently attached form it has one bond to carbon and one to sulfur. Sulfur is under oxygen in the periodic table so by analogy, the replacement of one C-C bond with a C-S bond is an oxidation reaction, which requires an oxidizing agent. The covalently attached ring of the lipoamide with an S-S bond similar to that of a disulfide bond, an oxidized form of sulfur, is the oxidizing agent. On the formation of acetyl-lipoamide, the S-S bond is cleaved and a thioester is formed. Other sulfur is a free reduced thiol.

There are 22 E1 subunits in the bovine PDC. Here is an iCn3D model of one human pyruvate dehydrogenase E1 component complex that has TPnP (TDP acetyl phosphonate, a TPP analog, covalently attached (PDB ID: 6CFO). One E1 subunit is an $\alpha_2\beta_2$ heterodimer. The two alpha chains are shown in cyan while the beta chains are in dark blue. Orient the model to view along the C2 rotational symmetry axes shown.

Figure 16.1.8 shows an interactive iCn3D model of the human pyruvate dehydrogenase E1 covalently bound to TDP acetyl phosphonate (TpnP), a TPP analog (6CFO)

16.1.2.1:

16.1.3: PARTS 2 AND 3: FORMATION OF ACETYL-COA (E2) AND REGENERATION OF THE ACTIVE COMPLEX.

The next part of the reaction produces acetyl-CoA (E2), but after that, the enzyme is "dead" as it no longer has an oxidized form of lipoamide to serve as an oxidizing agent (which gets reduced) in another round of catalysis. To regenerate enzyme activity, the reduced

lipoamide, after the release of the attached acetyl group, must be reoxidized by another oxidizing agent. That oxidizing agent is FAD, which is covalently attached to E3, and is converted to $FADH_2$. It must be reoxidized back to FAD to restore activity to the enzyme complex. The final oxidizing agent used for that is solution-phase NAD^+, which is released by the enzyme as a product. So it's a bit complicated. Three oxidizing agents are used in the PDH, two of which are covalently attached to the enzyme (oxidized lipoamide on E2 and oxidized FAD on E3).

Figure 16.1.10 shows the transacetylation reaction and formation of reduced lipoamide

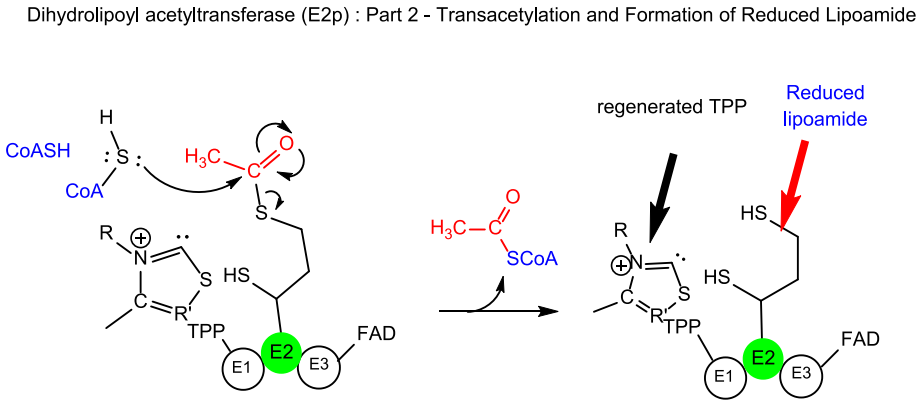

Figure 16.1.10: Transacetylation reaction and formation of reduced lipoamide by pyruvate dehydrogenase E2

The reaction of E3 follows to restore the fully catalytic enzyme, as shown in Figure 16.1.11.

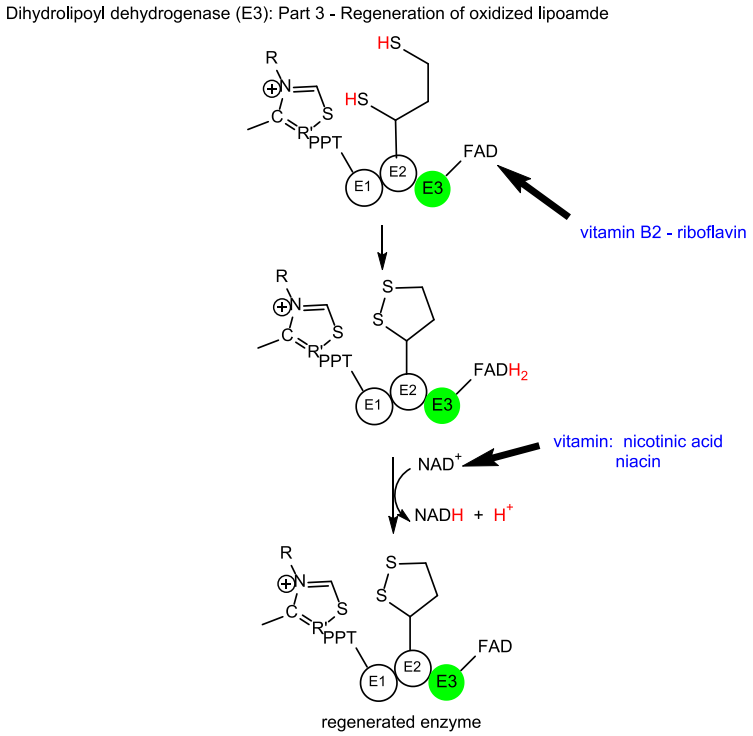

Figure 16.1.11: Regeneration of oxidized lipoamide by pyruvate dehydrogenase E3.

Let's look in greater detail at the structures of both E2 and E3.

16.1.4: E2: DIHYDROLIPOYL ACETYLTRANSFERASE -

In the mammalian complex, 60 E2 subunits arranges into a pentagonal dodecahedron. Most gram-negative bacteria E2 subunits arrange into a cubic of 24 monomers. Figure 16.1.12 shows a simple view of a pentagonal dodecahedron, which has 12 equivalent faces.

Figure 16.1.12: Pentagonal dodecahedron. 1. Rotating dodecahedron: https://commons.wikimedia.org/wiki/F...decahedron.gif. User Cyp on en.Wikipedia, CC BY-SA 3.0 <http://creativecommons.org/licenses/by-sa/3.0/>, via Wikimedia Commons

First let's consider one single E2 monomer. It has a longer disulfide redox domain followed by a smaller dimerization domain which allows the assembly of multiple subunits into the dodecahedron. In greater detail, the monomer has two lipoyl domains, a small domain that allows binding to E1 and a C terminal catalytic domain.

Figure 16.1.12 shows an interactive iCn3D model of E2 inner core 60-mer of human pyruvate dehydrogenase (pdb 6CT0). Symmetry axes are not shown

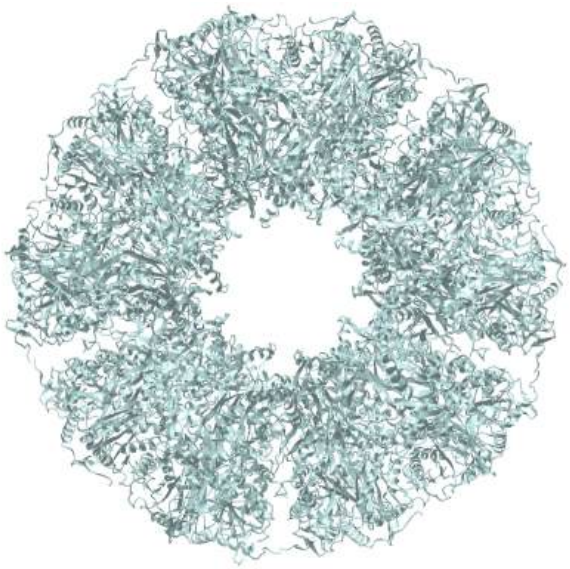

Figure 16.1.12: E2 inner core 60-mer of human pyruvate dehydrogenase (pdb 6CT0). (Copyright; author via source). Click the image for a popup or use this external: https://structure.ncbi.nlm.nih.gov/i...zs6pwfKNuJ2VS6

Each of the 60 subunits is shown in light cyan. To see the C symmetry axes:

- select the menu ☰
- Choose/Check in order: **Analysis, Symmetry, From PDB, 1(global), apply**
- When you see just a single monomeric chain choose **Cl**ear

The symmetry axes will then appear.

16.1.5: E3: DIHYDROLIPOYL DEHYDROGENASE

The sole function of this subunit is reoxidation of the now reduced lipoamide with the free sulfhydryl to the cyclic disulfide form so the enzyme can engage in further catalysis. FAD covalently bound to the E3 subunit is the oxidizing agent. This is our first encounter with FAD. Similarly to NAD^+, this dinucleotide gains a hydride ($:H^-$) but also in contrast to NAD^+ also a proton to form $FADH_2$.

Another way that the $FAD/FADH_2$ differs from $NAD^+/NADH$ is that the $FAD/FADH_2$ or their mononucleotide analog ($FMN/FMNH_2$) pairs are either covalently attached (in about 10% of flavoproteins) or bound with such a low K_D (often in the nanomolar range) that they don't dissociate from the enzyme during catalysis. Hence after oxidizing a bound substrate, the reduced $FADH_2$ must be reoxidized by another oxidizing agent, often NAD^+ which can diffuse into the active site to do its job and then dissociate from the complex in the form of NADH, leaving the enzyme competent for another round of catalysis. (DOI: 10.1002/chem.201704622)

Figure 16.1.13 shows an interactive iCn3D model of E3 bound to both FAD (noncovalently) and NADH (NAI) (1ZMD) in the B chain of E3. Symmetry axes are not shown

Let's put it all together! Figure 16.1.15 shows a video of the pyruvate dehydrogenase complex from the HHMI.

Figure 16.1.15: Video of the pyruvate dehydrogenase complex

16.2: REACTIONS OF THE CITRIC ACID CYCLE

16.2.1: INTRODUCTION

The acetyl-CoA formed by the pyruvate dehydrogenase complex (PDC) now enters a cyclic, non-linear pathway called the citric acid cycle, tricarboxylic acid (TCA) cycle, or the Kreb's cycle after Hans Krebs who discovered it. The cycle is shown in Figure 16.2.1 in wedge/dash form with stereochemistry included to give a more exact representation.

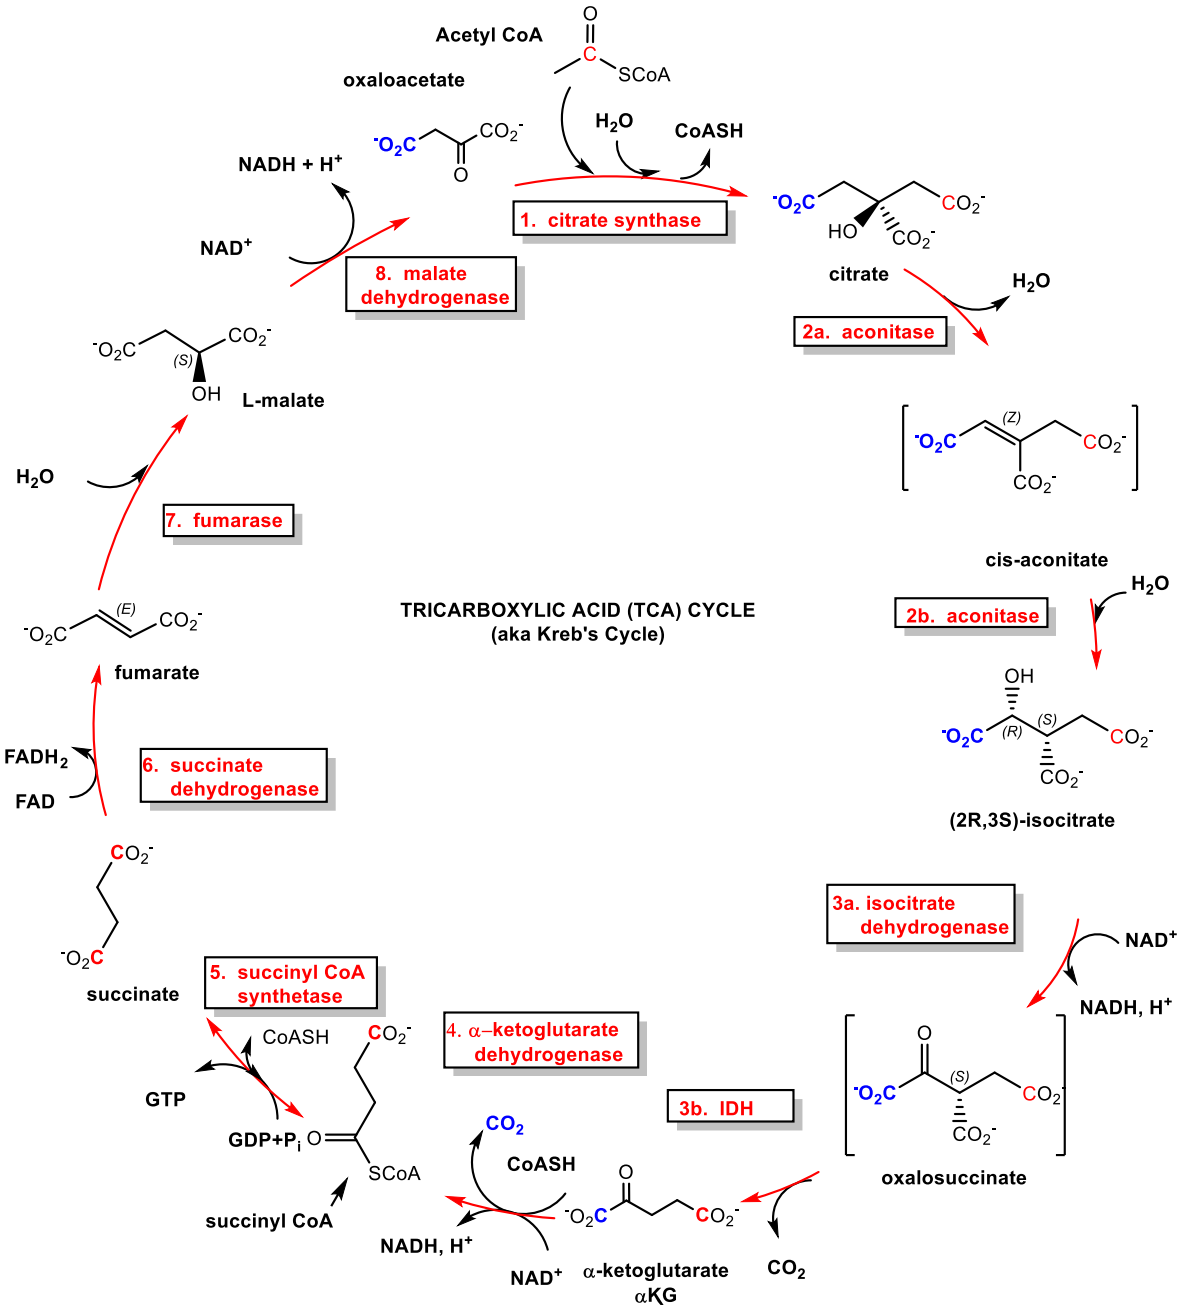

Figure 16.2.1: Citric Acid Cycle

Why is this pathway a cycle and not a linear pathway as we have seen for glycolysis? A simple answer is that it evolved that way, but why would that be advantageous? It turns out that some of the key "intermediates" in the pathway are pulled away for the biosynthesis of other biomolecules. If the citric acid cycle was linear, and intermediates pulled off for other reactions, the linear pathway would taper off, which would not be optimal for a key energy production pathway. Of course, the removal of intermediates from a cyclic pathway would also slow

it down but when this happens, enzymes outside of the cycle are used to produce key reaction intermediates of the cycle to it going. The replenishing reactions are called **anapleurotic reactions.**

Krebs, in his detailed analysis of the enzymes involved in "intermediary" metabolism, used radioisotope-labeled reactants to trace carbon atoms in respiring tissue. He found that when radiolabeled pyruvate and oxaloacetate were added to muscle tissue *in vitro*, radiolabeled citrate was formed.

$$\text{Pyruvate} + \text{Oxaloacetate} \rightarrow \text{citrate} + CO_2$$

This is correct but omits the initial conversion of pyruvate to acetyl-CoA. Hence the "end product" of the pathway (oxaloacetate) reforms the beginning reactant (citrate) so he surmised that the pathway was circular.

The next obvious question is why are eight reactions are required for the oxidation of just 2 Cs in pyruvate. Partly this is a matter of evolution again, as the early evolutionary pathway probably combined an oxidative (clockwise) set of reactions with a reductive (counterclockwise) set. Part of the chemistry in the cycle is devoted to producing either β-keto acids, which are easy to oxidatively decarboxylate, or converting α-ketoacid to molecules with better electron sinks β to the departing CO_2. After the net 2 carbon atoms added to the cycle are released as 2 CO_2s, the rest of the reactions are used to regenerate oxaloacetate, allowing the cycle to continue.

Of course, the ultimate goal of an energy-extractive oxidative pathway is not just to form CO_2 but to form ATP or its equivalent (i.e. GTP). Notice that 3 NAD^+s are used and converted to 3 NADH. In addition, a new, more potent oxidizing agent, FAD, is used and it is converted to $FADH_2$. NAD^+ and FAD are replenished by reoxidation of NADH and $FADH_2$ (reduced forms) back to NAD^+ and FAD, through mitochondrial electron transport (oxidation) reactions, in which electrons are passed to stronger and stronger oxidizing agents, the last being O_2. In this thermodynamically favored process, lots of ATPs are made. We will explore those reactions in the next section.

We will go through each of the steps in the citric acid cycle separately and show how the pathway is regulated (section 16.3). Why such detail? There are only 8 steps. It seems that we should be able to carefully examine each given that the citric acid cycle is a hub that along with glycolysis controls metabolic flow through many interconnected metabolic pathways.

At the same time, we can't explore each reaction in every pathway described in this text in great detail, otherwise, this book would become more of an encyclopedia. In this chapter and beyond, we will focus on mechanistic details only of enzymes that catalyze different types of reactions than those in glycolysis or the citric acid cycle, and those with interesting cofactors and mechanisms.

Other issues add complexity for learners. The PDC and citric acid cycle reaction occur in the mitochondrial matrix. Cytoplasmic pyruvate and NAD^+ must be transported into the matrix from the cytoplasm. In addition, some of the enzymes in the citric acid cycle have both cytoplasmic and mitochondrial variants. Some of these homologous pairs are differentiated by their use of NAD^+ or $NADP^+$ as an oxidizing agent. The ones in the cytoplasm are not part of the cycle. You would expect these enzyme pairs to have similar tertiary structures and active site chemistry. Prokaryotic forms of these enzymes are similar structurally to their eukaryotic forms so the interactive molecular models shown below will show enzymes from a variety of organisms. Finally, there are many variants, shunts, and bypasses of the citric acid pathway in different organisms. We will explore this topic in section 16.4

We will try to pair reaction mechanism diagrams that show the flow of electrons in bond-making and breaking with interactive molecular models of the active site. You should rotate the models to align and identify key amino acids and ligands (substrate, substrate analogs, inhibitors, activators) shown in the static 2D mechanism diagrams. Since the active sites are often conserved across prokaryotic and eukaryotic versions, the choice of PDB structures used depends on which best illustrates a conceptual point.

NOTE

There are many ways to write abbreviated chemical equations showing NAD^+/NADH and FAD/FAD_2 and hydrogen ions in metabolic pathway diagrams. To make sense of them, consider a simplified mechanism for the oxidation of ethanol by alcohol dehydrogenase, as shown in Figure 16.2.2. Note that there are 2 Hs on the oxidized substrate (ethanol) that are involved. One is a hydride and the other is a proton.

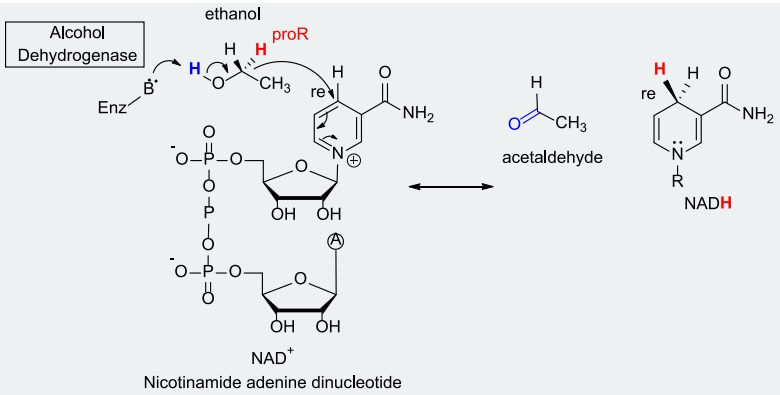

Figure 16.2.2: Oxidation of ethanol using NAD^+

Here is a list of different and seemingly contradictory ways to write a chemical equation to show changes in NAD^+/NADH and H ions:

1. $NAD^+ + :H^- \rightarrow NADH$. This chemical equation is charge balanced and shows just the changes to the NAD^+/NADH pair, but it doesn't show the proton (H^+) lost from the substrate.
2. $NAD^+ + 2e^- + H^+ \rightarrow NADH$. This is the same as equation (1) but with the hydride separated into an electron pair and a proton.
3. $NAD^+ + H^+ \rightarrow NADH$. This is balanced for Hs but not + charge as it doesn't explicitly show the electron pair from the hydride added to NAD^+.
4. $NAD^+ \rightarrow NADH + H^+$. This is balanced for charge but not for Hs. The extra H^+ is the proton from the oxidized substrate.

We will use example 4 above throughout this book. That equation is most useful when trying to account for the change in the number of protons in the individual reactions and entire pathways. We will also write simplified chemical equations involving FAD (in which 2H from the substrate are added) as FAD $\rightarrow$ $FADH_2$.

16.2.2: 1. CITRATE SYNTHASE (CS)

Oxaloacetate + Acetyl-CoASH + $H_2O \rightarrow$ Citrate + CoASH ΔG^o = -7.5 kcal/mol (-31 kJ/mol)

Acetyl CoA is a thioester. Hence it is "high energy" compared to its hydrolysis products. (**Remember, there is no such thing as a "high energy" bond.**) The free energy released in its hydrolysis is used to drive the reaction forward. This is important otherwise citrate would not be formed readily. This reaction feeds the end product of glycolysis into the citric acid cycle. It is summarized in Figure 16.2.3.

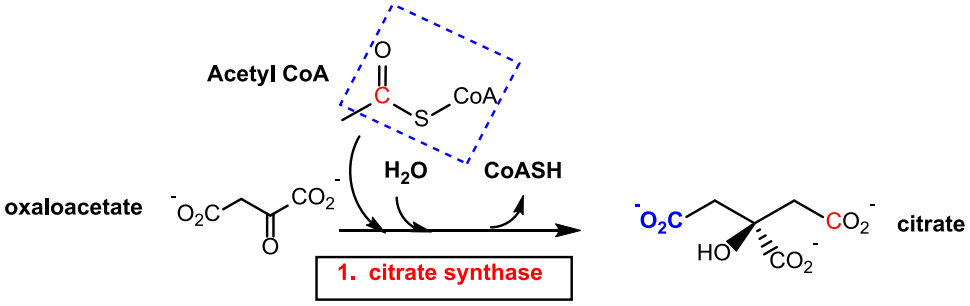

Figure 16.2.3: Summary reaction - Citrate Synthase

The enzyme exists in two major conformations, an open and closed form. When the open form, which has a binding site for oxaloacetate, binds the substrate, a shift to the closed conformation forms on the binding site of acetyl-CoA. These changes sequester the bound substrates and exclude water and prevent spurious hydrolysis of acetyl-CoA. The binding occurs sequentially so the kinetics follow a sequential ordered mechanism.

Figure 16.2.4 left shows an animated gif that shows the conformational changes between the citrate-bound version (open, green) and the citrate and CoASH-bound form (blue). The image below right shows a smoother transition between the open and closed form without bound ligands (1cts, 2cts)

Figure 16.2.4: Conformational changes in citrate synthase on binding substrate

In this reaction, a C-C bond must form between the substrates. One way to do that is to make a nucleophilic carbanion ion from the alpha carbon of acetyl CoA. Remember, this is not a decarboxylation reaction so we don't have to worry about an electron "sink" on the beta carbon. Forming the carbanion would be possible since the negative charge on the carbon can be withdrawn to the carbonyl oxygen to form an enolate. The enolate becomes even more stable if the negative oxygen is protonated. So this is reaction is an aldol condensation, the addition of an enolate to an aldehyde or ketone. The carboxylate group of aspartic acid 375 on citrate synthase removes the acidic alpha proton on acetyl CoA, while histidine 274 donates a proton to form the neutral enol, a much more stable molecule than the enolate anion. His 274 continues to stabilize the enol during the reaction. Bound oxaloacetate is stabilized in part by Arg 329. In the next part of the mechanism, a second histidine (320) protonates the carbonyl oxygen of oxaloacetate, activating the carbonyl carbon for nucleophilic attack by the enol in the next step to form (S)-citryl CoA. The hydrolysis of the CoASH occurs when His 320 deprotonates a water molecule, facilitating nucleophile attack on the carbonyl carbon bonded to -SCoA, forming citrate.

A plausible mechanism is shown in Figure 16.2.5.

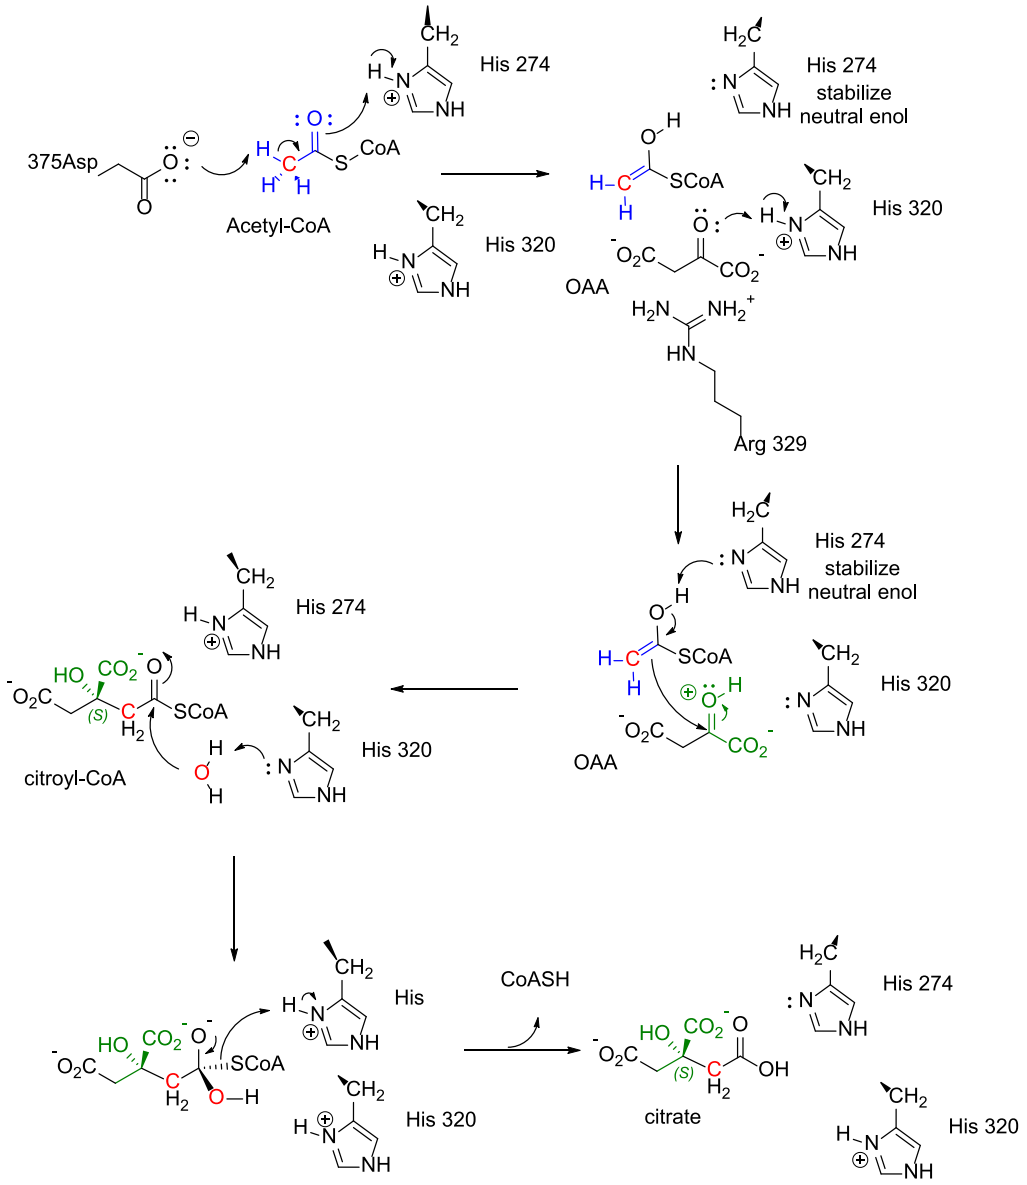

Figure 16.2.5: Citrate synthase mechanism

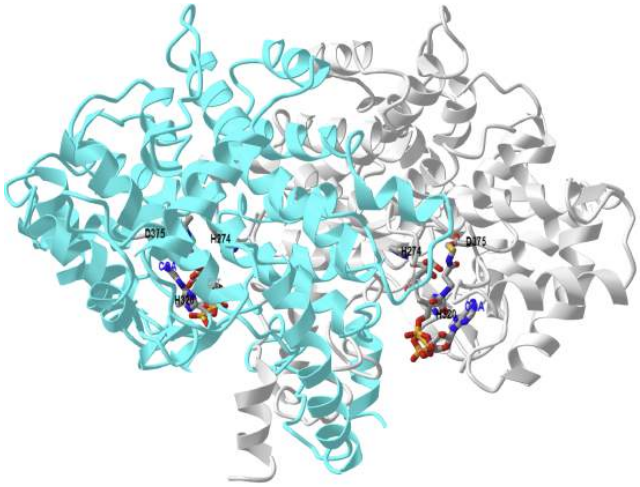
Figure 16.2.6 shows an interactive iCn3D model of the pig citrate synthase bound to CoASH and citrate (2CTS)



NCBI iCn3D Figure 16.2.6: pig citrate synthase bound to CoASH and citrate (2CTS). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...WXqcEsu336tcL7

The enzyme is a dimer with monomers shown in different colors. Citrate and CoASH are shown in sticks and labeled. The active site residues are shown as sticks and labeled in each subunit.

16.2.3: 2. ACONITASE

Citrate ↔ Isocitrate ΔG^o = +2 (rx 2a), -0.5 (rx 2b) kcal/mol; net ΔG^o = + 1.5 kcal/mol (+6.3 kJ/mol)

Thinking like a chess player, who must anticipate future moves, the chemical rationale for this reaction is to move an OH to a beta position, which in a subsequent reaction is converted to a beta C=O, so it can act as an electron sink to facilitate decarboxylation in a following reaction! The reaction is readily reversible (note the low ΔG^o value) since the reactant and product are simple isomers of each other. Figure 16.2.7 shows the summary reaction.

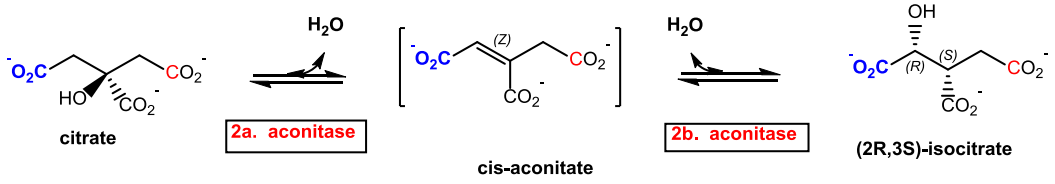


Figure 16.2.7: Summary reaction of aconitase

The enzyme has an inorganic Fe_4S_4 cluster. Each Fe in the cluster coordinates to 4 S^{2-} in a cubane structure, but when either citrate or isocitrate is bound, one of the Fe ions interacts with both the Os of a substrate carboxylate shown. The other two carboxylates of isocitrate are stabilized through ion-ion interactions by Arg 446 and 663.

Figure 16.2.8: below shows a plausible partial mechanism. An active site deprotonated serine abstract a proton at the S carbon. This is followed by the formation of the C-C double bond and a release of the resulting cis-aconitate from one bond to the FeS cluster.

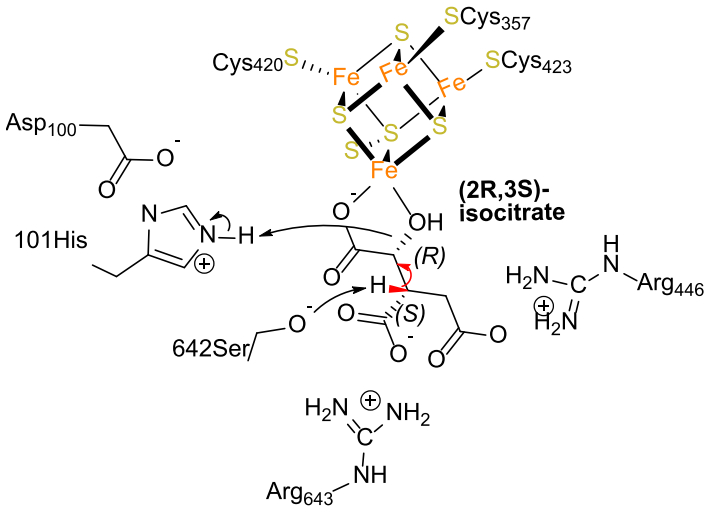

Figure 16.2.8: Mechanism of aconitase

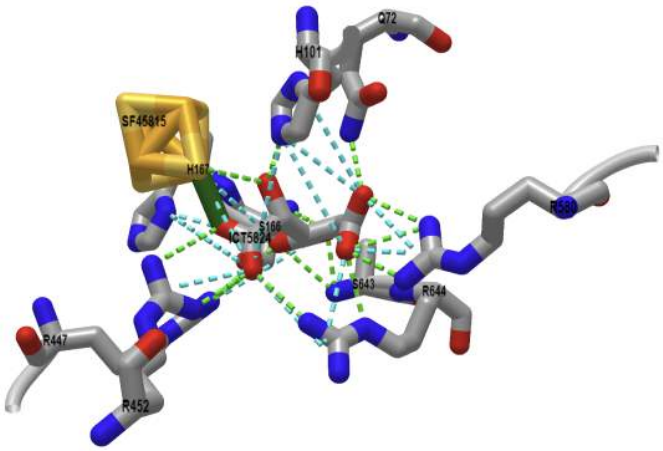
Figure 16.2.9 shows an interactive iCn3D model of the bovine S642A aconitase with bound citrate (1C97).



NCBI iCn3D Figure 16.2.9: Bovine S642A aconitase with bound citrate (1C97). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...iJJRGaFoCDnhf7

This cis-aconitate intermediate in the interconversion of citrate and isocitrate must do an 180^0 flip around the C=C double bond. This is followed by rehydration to form the other isomer. The deprotonated His 101 abstracts a hydrogen from a water-bound to the FeS cluster, with the hydroxide acting as a nucleophile, which along with the redonation of a hydrogen ion on the protonated Ser 642 the alpha-carbon completes the rehydration step in the formation of the other isomer.

Exercise 16.2.1

Why was the S642A mutant used to produce the structure shown in the above iCn3D model?

Answer

It allows the binding of substrate/product, in this case, isocitrate, to an inactive enzyme as the active site serine was mutated to a non-nucleophilic alanine of similar size. Hence no bond-making/breaking occurs in the complex.

References:

https://collab.its.virginia.edu/acce...-_-/index.html

16.2.4: 3. ISOCITRATE DEHYDROGENASE (IDH)

Isocitrate + NAD^+ → α-ketoglutarate + NADH + H^+ ΔG^o = -2.0 kcal/mol (-8.4 kJ/mol)

The chemical rationale should be clear. In this step, through an oxidative decarboxylation, the CO_2 is removed as NADH is produced. The NADH will be reoxidized back to NAD^+ in the electron transport chain, leading to ATP production (see next section). The reaction is summarized in Figure 16.2.10.

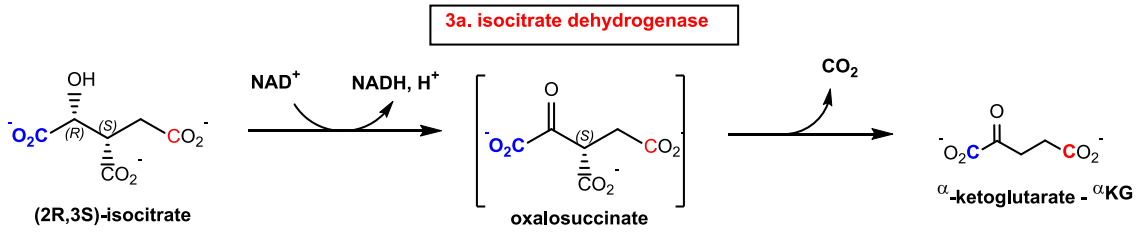


Figure 16.2.10: Summary reaction: isocitrate dehydrogenase

Exercise 16.2.1

Why must the oxidation reaction precede the decarboxylation reaction?.

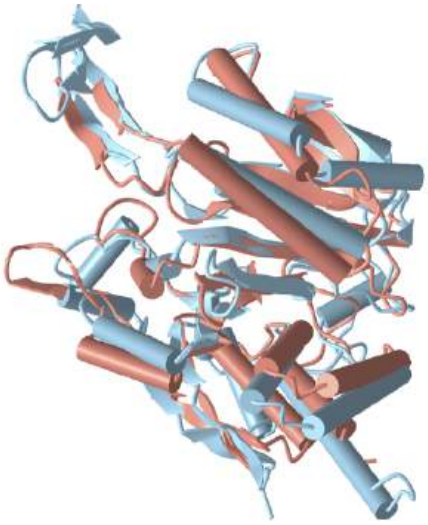
Answer

First, a beta-ketoacid intermediate must form, which allows easy decarboxylation of the intermediate as the beta carbonyl provides an electron "sink" to facilitate the decarboxylation.

There are two forms of this enzyme (IDH), a cytoplasmic ($NADP^+$) form and a mitochondrial (NAD^+) form. The cytoplasmic forms from various organisms are homodimers and have a common mechanism of catalysis. In contrast yeast mitochondrial IDH has two subunits, IDH1 (regulatory, binds the allosteric activator citrate and AMP) and IDH2 (catalytic, binds isocitrate and NAD^+). Mammalian IDHs are tetramers heterodimers ($\alpha\beta + \alpha\gamma$), which can also form a heterooctamer $(\alpha\beta + \alpha\gamma)_2$. The alpha chain is the catalytic subunit.

Mammalian NAD-IDHs are even more complex than yeast NAD-IDH. These enzymes are composed of three types of subunits, α, β, and γ, which share about 40–52% sequence identity. The α and β form an αβ dimer, while α and γ subunits form αγ. These then interact to form the $\alpha_2\beta\gamma$ heterotetramer, which effectively forms the holoenzyme. It can also form an active heterooctamer.e. The αγ heterodimer is regulated by citrate and ADP. On citrate binding to the allosteric site, a conformation change occurs to enhance isocitrate binding. ADP enhances the binding of the allosteric regulator citrate.

Figure 16.2.11 shows an interactive iCn3D model of that shows the superposition of the α chains of cytoplasmic IDH (NADP, sky blue, 4L03) and mitochondrial IDH (NAD) (6KDY, salmon).



NCBI iCn3D Figure 16.2.11: Superposition of the A chains of cytoplasmic IDH (4L03) and mitochondrial IDH (NAD) (6KDY) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...zy9yn4NaF9g1c9

Cytoplasmic IDH is sky blue and mitochondrial IDH is salmon. Click the 3 bar menu icon (top left) in the model in the window, scroll down to Alternate, and toggle back and forth between the two forms. The structures of the alpha chains, although not identical, align well.

Figure 16.2.12 shows a probable mechanism for the reaction based on the conserved catalytic site shown in the model above.

The α subunit is shown in gray and the β in cyan.

16.2.5: 4. A-KETOGLUTARATE DEHYDROGENASE

α-ketoglutarate + NAD^+ + CoASH → succinyl CoA + CO_2 + NADH + H^+ ΔG^o = -7.2 kcal/mol (-30 kJ/mol)

In the last reaction, α-ketoglutarate was formed. Oh no, you might say! It would have been nice to form a β-ketoacid, which could easily decarboxylation. No worries though. We spent all of section 16.1 explaining the biochemistry used to decarboxylate another α-ketoacid, pyruvate. The same chemistry is used to accomplish the oxidative decarboxlation of α-ketoglutarate. Hence we won't expand on the mechanism here. The reaction is shown in Figure 16.2.15.

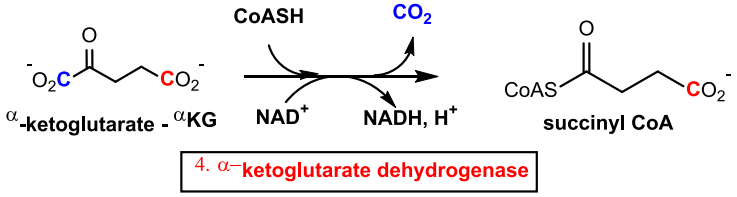

Figure 16.2.15: Summary reaction for α-ketoglutarate dehydrogenase

16.2.6: 5. SUCCINYL-COA SYNTHETASE (SCS)

succinyl CoA + GDP + P_i → succinate + CoASH + GTP ΔG^o = -0.8 kcal/mol (-3.3 kJ/mol)

This is the first step in which the energy change in the cycle is captured specifically in the form of a high energy (with respect to its hydrolysis product) phosphoanhydride bond in the form of GTP (and ATP in some organisms). From a chemical step, the cleavage of the thermodynamically unstable thioester is coupled to the endergonic synthesis of GTP. This can transfer its terminal phosphate to ADP to make ATP in reaction that has a ΔG^o of about 0 kcal/mol. The reaction is shown in Figure 16.2.16.

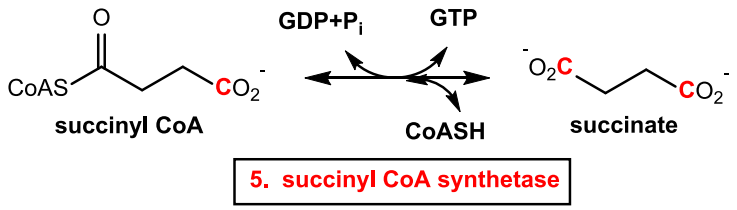

Figure 16.2.16: Summary reaction for succinyl-CoA synthetase

Succinyl-CoA synthases have two subunits, α and β. The enzyme in E. coli is a tetramer ($\alpha_2\beta_2$) with the catalysis occurring at the αβ interface. The alpha-subunits interact only with the beta-subunits, whereas the beta-subunits interact to form the dimer of alpha beta-dimers with CoA bound in each α subunit to a nucleotide-binding loop.

Two histidines, His 246 and His 142 are involved in the reaction, with His 246 becoming phosphorylated to form an intermediate in the reaction. A mutation of His 142 to an asparagine (H142N) essentially abolishes enzyme activity. Different SCSs have different specificities for purine nucleoside triphosphates. Organisms, including mammals, may have two different isoforms, one that binds ADP and

one that uses GDP (as shown in most diagrams of the citric acid cycle). In E. Coli, the α subunit binds CoASH and contains His 246, which gets phosphorylated. The β subunit determines the specificity for either GTP or ATP. In E.Coli the ATP binding site (Site II "in the ATP-grasp fold") is quite distant from the CoASH site (Site II) so phospho-His 246 must move between the sites in the dimer interface.

The three steps in the reaction are shown below, where E is the free enzyme, a · indicates a noncovalent complex, and a - represents a covalent bond (after Biochemistry 2002, 41, 537-546)

1. E + succinyl-CoA + P_i ↔ E · succinyl-PO_3 + CoASH
2. E · succinyl-PO_3 ↔ E-PO_3 + succinate
3. E-PO_3 + NDP ↔ E + NTP

Figure 16.2.17 shows an abbreviated mechanism that shows only the involvement of His 246.

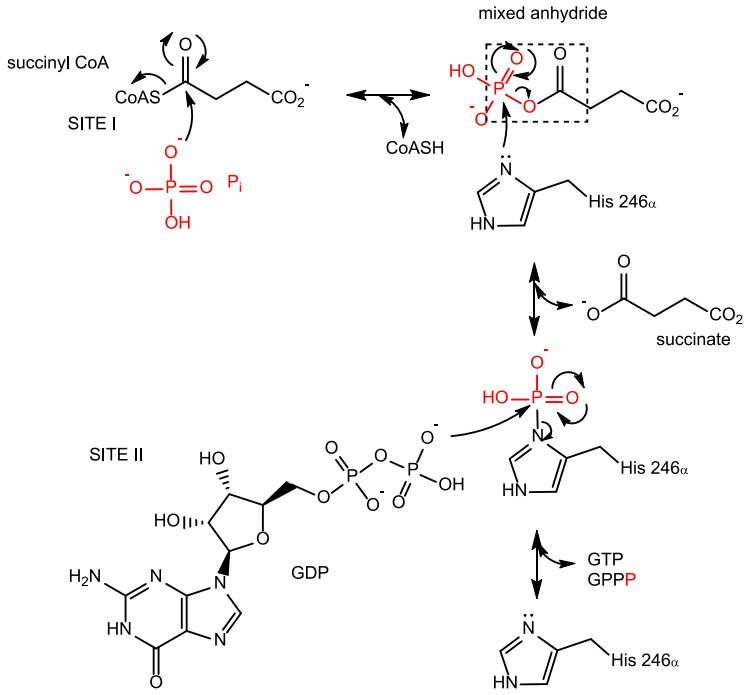

Figure 16.2.17: Abbreviated mechanism for succinyl-CoA synthase

Kinetic analysis suggests that the three substrates bind in a specific order, catalysis occurs, and then the three products leave. This type of reaction is called an ordered ter ter reaction, and is shown in Figure 16.2.18.

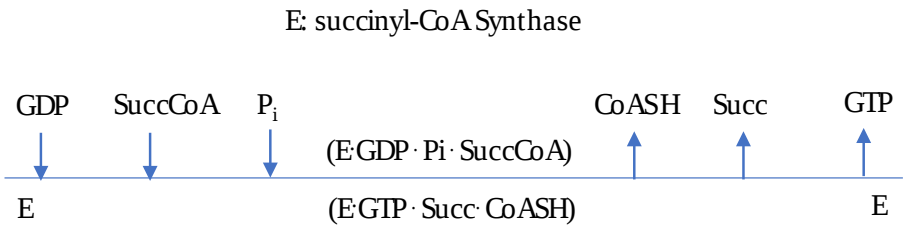

Figure 16.2.18: Ordered ter ter reaction for succinyl-CoA synthase

The iCn3D model below shows key alpha-chain residues in the active site, including the phosphorylated His 246 and bound CoASH. (use iCn3D to visualized 1CQJ, the nonphosphorylated form) I)

Figure 16.2.19 shows an interactive iCn3D model of the complex of ADP and Mg2+ with Dephosphorylated E. Coli Succinyl-CoA Synthetase (1CQI)

16.2.7: 6. SUCCINATE DEHYDROGENASE

succinate + FAD ↔ fumarate + $FADH_2$ ΔG^o = 0 kcal/mol

The enzyme is yet another step in closing the cycle to reform oxaloacetate. It is also our first encounter with FAD as an oxidizing agent. Its reduction product, $FADH_2$, will be reoxidized in the electron transport chain (mitochondrial inner membrane for eukaryotes), producing energy for ATP. Hence it can be considered a proxy ATP-generating reaction. The reaction is shown in Figure 16.2.21.

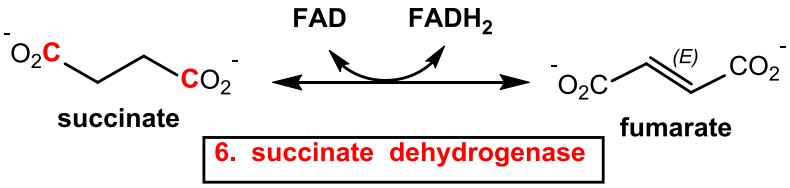

Figure 16.2.21: Summary reactoin for succinate dehydrogenase

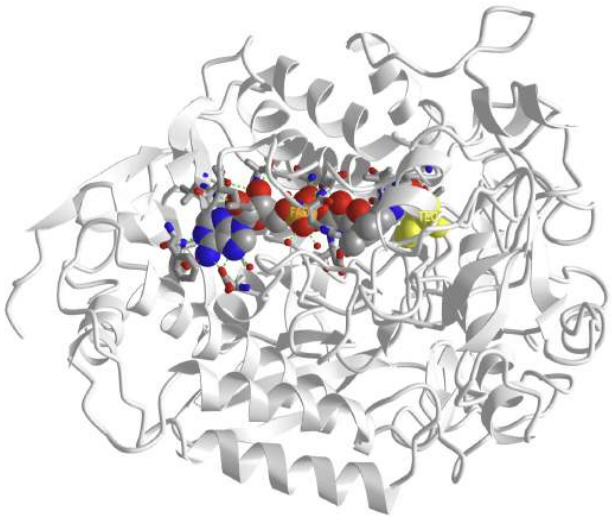
The succinate dehydrogenase enzyme is part of the larger Complex II of the electron transport chain. Complex II has many cofactors involved in its overall activity. It also uses an iron/sulfur cluster cofactor, similar to aconitase, which also produces a C=C doubled bonded intermediate. We will discuss it in greater detail in the chapter on electron transport. For now, let's concentrate on this new cofactor and oxidizing agent, FAD. Many enzymes use FAD/$FADH_2$ in redox chemistry.

In contrast to NAD^+/NADH, the FAD/$FADH_2$ pair stays tightly bound to the enzyme and doesn't readily dissociate. This means that after one cycle of the enzyme (after FAD is converted to $FADH_2$), the enzyme is functionally "dead". Another oxidizing agent must bind to the enzyme and reoxidize $FADH_2$ back to FAD. The dissociation constants for FAD/$FADH_2$ and its protein binder in a flavoprotein are often in the nanomolar range. In around 10% of flavoproteins, FAD/$FADH_2$ are usally covalently bonded to the enzyme.

Figure 16.2.22 shows an interactive iCn3D model of the Avian respiratory complex II FAD binding subunit with FAD and a malate-like intermediate (1YQ3).



NCBI iCn3D Figure 16.2.22: Avian respiratory complex II FAD binding subunit with FAD and a malate-like intermediate (1YQ3). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...SGac3NuN4XBWk7

Note how buried the FAD is in the middle of the dehydrogenase subunit. The malate-like intermediate (TEO) is shown next to the FAD in yellow spacefill.

Exercise 16.2.1

Succinate dehydrogenase is irreversibly inhibited by the toxin 3-nitroproprionic acid (3np) made by some plants and fungi. Eating moldy sugar cane has led to reported deaths.

1. Draw the Lewis structures of succinate and 3-nitroproprionic acid. Compare them and the total number of valence electrons in each.

2. Here is a link to an iCn3D model showing the interaction of 3np with the enzyme. Explain the mode of action of the toxin.

https://structure.ncbi.nlm.nih.gov/i...cja9VKU2ZMCac9

Answer

These molecules are structurally similar and isoelectronic (the same number of electrons in their Lewis structures.

The inhibitor 3np form a covalent adduct through the guanidino group of Arg 297. This is a key catalytic residue that act as a general base that accepts a proton from succinate in the reaction.

Figure 16.2.23 (top) shows a very general and abbreviated mechanism for the enzyme for the immediate reaction of succinate with FAD. The bottom part of the image shows the amino acids surrounding succinate in the avian (bird) version of the enzyme (pdb 1yq4)

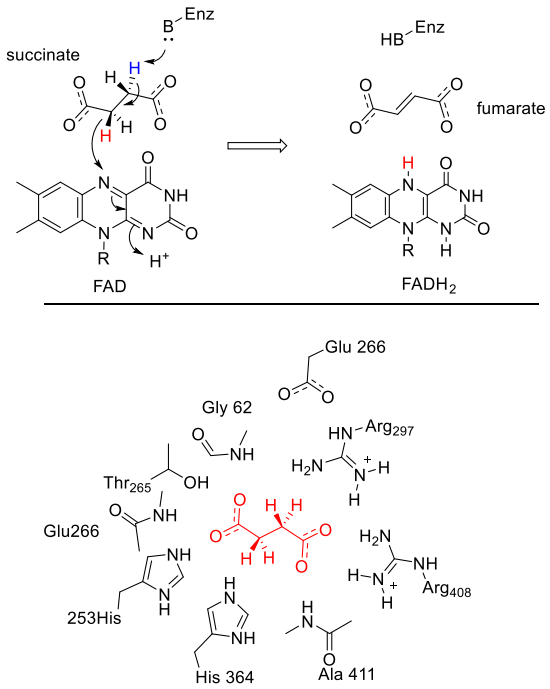


Figure 16.2.23: Top - a very general and abbreviated mechanism for the enzyme for the immediate reaction of succinate with FAD. Bottom - amino acids surrounding succinate in the avian (bird) version of the enzyme (1yq4)

Exercise 16.2.1

One of the amino acids surrounding succinate in the figure above acts as a general base and abstracts a protein from succinate as a hydride is transferred (from a plane above) to FAD. Go to this iCn3D of the active site bound to FAD. Which amino acid is the likely general base? (Note: the figure below shows general protonated states of side chains and not necessarily those involved in the proton abstraction. Go to **Analysis**, **Distance** and **Distance between 2 atoms** to find the likely general base.

Answer

Arg 297

16.2.8: 7. FUMARASE

fumarate + H_2O ↔ L-malate ΔG^o = -0.9 kcal/mol (-3.8 kJ/mol)

The chemical rationale for this reaction is clear - it is the penultimate step in the resynthesis of oxaloacetate, one of the reactants that starts the cycle, allowing the cycle to continue. This reaction introduces an O by hydration which can be oxidized in next step to produce NADH for e- transport/ATP production. The reaction is shown in Figure 16.2.24.

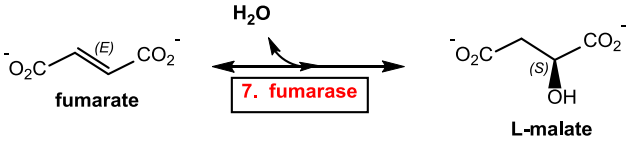

Figure 16.2.24: Summary reaction for fumarase

There are Class I (dimers containing an unstable FeS cluster, examples A and B) and Class II (tetramer, no bound iron, oxygen stable, example C) fumarases. Humans have both cytoplasmic and mitochondrial type II fumarases, resulting from alternative transcription of the fumarase genes. We will consider the type II, fumarase C from *E. Coli* in the following discussion.

The tetramer contains just alpha helices and random coils and has two distinct binding sites. Site A appears to be the active site and contains a buried water molecule. Site A, formed from three of the subunits, binds competitive inhibitors such as citrate and β-(trimethylsilyl)maleate, a cis substrate for fumarase, and is buried. 12 Angstroms away is site B, which is found in only one of the subunits

near a pi-helix (H129 through N135) and is more surface-exposed. Each site has a histidine, but mutation of only one H188N in the A site disrupts enzyme activity. Both sites bind multi-carboxylates. The role of site B is a bit unclear, but it is most likely an allosteric site involved in the transfer of product (malate) from the buried site to the surface for ultimate dissociation.

Figure 16.2.25 shows an interactive iCn3D model of the fumarase with beta-(trimethylsilyl)maleate and citrate (1fuq).

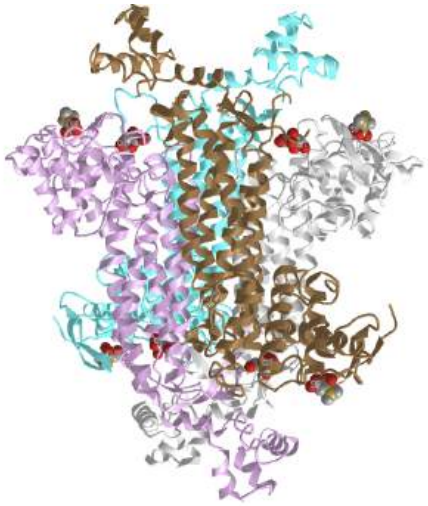

Figure 16.2.25: Fumarase with beta-(trimethylsilyl)maleate and citrate (1fuq). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...MewEQFebi4VL48

The monomers in the tetramer are shown in different colors. Citrate (Cit) and beta-(trimethylsilyl)maleate (SIF) are shown in spacefill.

Figure 16.2.26 shows an interactive iCn3D model of the binding site of citrate, a competitive inhibitor, of fumarase (1FUQ).

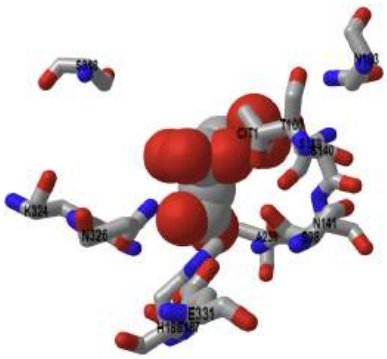

Figure 16.2.26: Binding site of the competitive inhibitor citrate in fumarase (1FUQ). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...yfPc5iPWbExr86

Figure 16.2.27 shows a plausible mechanism for the trans addition of water to fumarate.

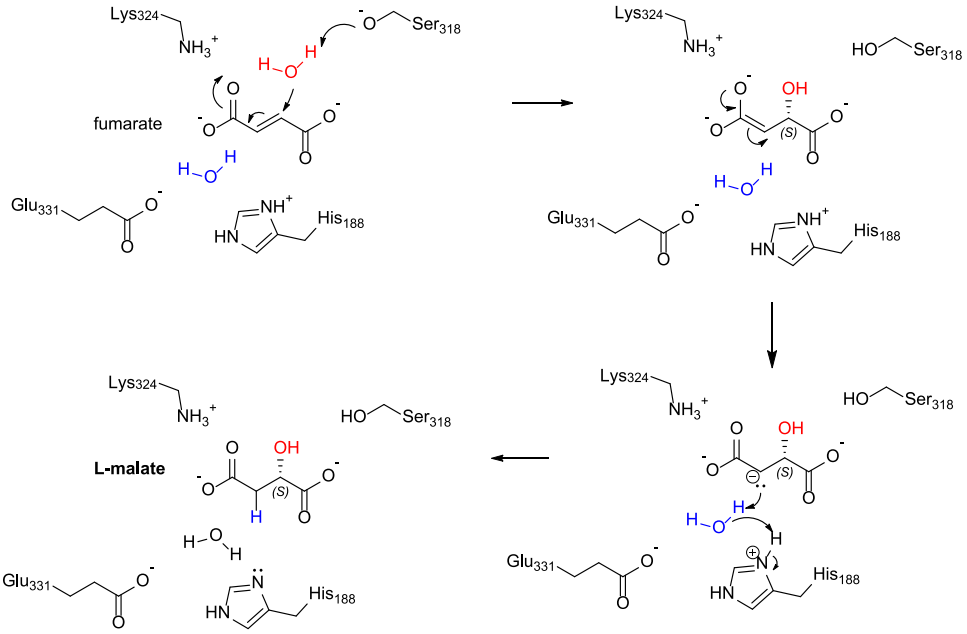

Figure 16.2.27: Mechanism for fumarase

16.2.9: 8. MALATE DEHYDROGENASE (MDH)

L-malate+ NAD^+ ↔ oxaloacetate + NADH + H^+ ΔG^o = +7.1 kcal/mol (30 kJ/mol)

We are finally there! This last reaction of the citric acid cycle produces oxaloacetate, the starting reactant, so the cycle can continue. It also produces NADH for mitochondrial e- transport/ATP production. Notice that is thermodynamically unfavorable (in the standard state) but the reaction is pulled to citrate formation by the first and next step of the cycle, citrate synthase. The reaction is shown in Figure 16.2.28.

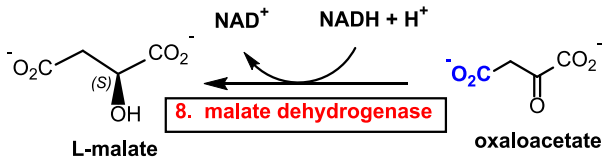

Figure 16.2.28: Summary reaction for malate dehydrogenase

Malate dehydrogenases are found in the cytoplasm, where it is part of the aspartate-malate shuttle that moves cytoplasmic malate (and through MDH indirectly NADH) into the mitochondria. It is also found in the mitochondria, where it is part of the citric acid cycle. There are also NAD^+ and $NADP^+$-dependent forms. Malate can undergo two different types of oxidation reactions, one producing oxaloacetate and using NAD^+, and one, an oxidative decarboxylation producing pyruvate and CO_2, using $NADP^+$. The latter is sometimes called malic enzyme.

Humans have two forms (MDH 1 and MDH 2) that use NAD^+. The enzyme is a homodimer in humans with binding sites on both. It activity is allosterically
regulated by citrate, and it is inhibited by many things, including ATP, ADP, AMP, fumarate, citrate, aspartate, and high concentrations of oxaloacetate.
The enzyme is similar to lactate dehydrogenase, which we encountered in the chapter of glycolysis. Kinetic analyses show that NAD^+ binds first followed by malate.

Figure 16.2.29 shows an interactive iCn3D model of NAD^+ and malate bound to human malate dehydrogenase 2 (4wlu).

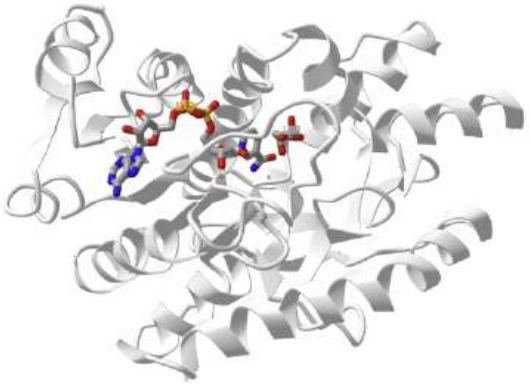

Figure 16.2.29: NAD^+ and malate bound to human malate dehydrogenase 2 (4wlu). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...DrAXBdu64GPzx8

Just one monomer is shown. NAD^+ and malate (LMR) are shown in sticks and labeled.

Figure 16.2.30 shows an abbreviated mechanism for malate dehydrogenase. The numbers refers to the *E. Coli* enzyme.

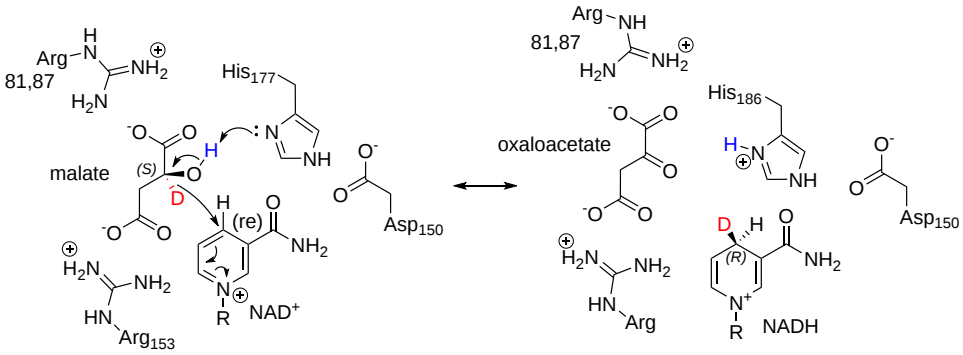

Figure 16.2.30: Abbreviated mechanism for malate dehydrogenase

Note that the hydride transferred from the malate is shown in red as a deuterium (D). It is transferred to the re face of NAD^+ to form NADH. The carbon with the transferred deuterium in NADH is prochiral. Think of that as that carbon being chiral if one of the 2 Hs could be arbitrarily assigned a higher priority in assigning R/S isomers. D has a higher priority than H in the Cahn/Ingold designation system. In the reverse reaction, the D atom, which is above the plane of the ring, occupies the proR position. The proR deuterium is transferred back in this reversible reaction. A D was used simply to indicate the stereochemistry and to assign it in NADH to the proR position.

Figure 16.2.31 shows an interactive iCn3D model of the active site of the E. Coli malate dehydrogenase with bound citrate and NAD^+ (1EMD).

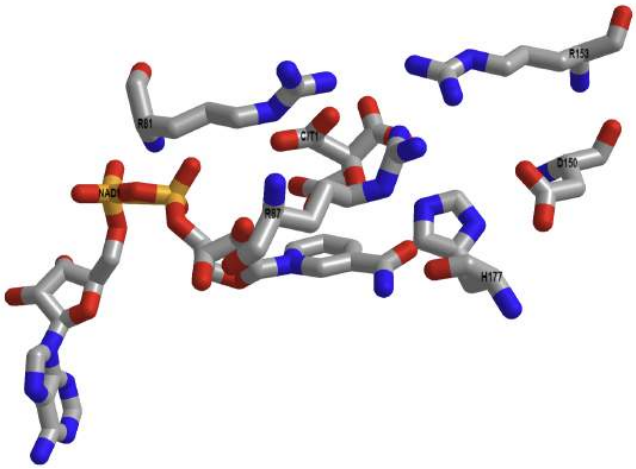

Figure 16.2.31: Active site of the E. Coli malate dehydrogenase with bound citrate and NAD^+ (1EMD). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...mHhmeFQyPpZj18

We have shown many renderings of the enzymes involved in the cycle. Yet another one is shown below. Figure 16.2.32 shows an interactive iCn3D model of the electrostatic surface potential of malate dehydrogenase (4WLU).

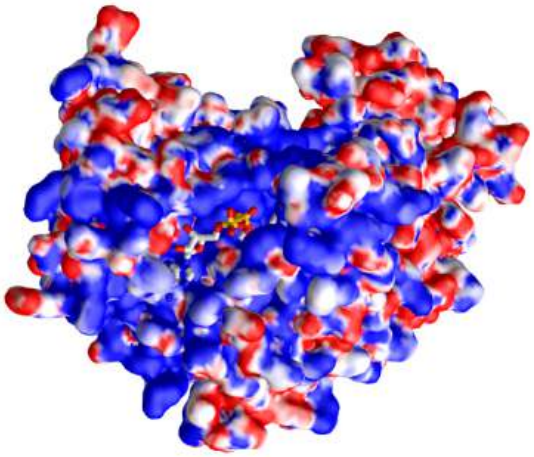

Figure 16.2.32: Electrostatic surface potential of malate dehydrogenase (4WLU)with bound NAD^+ (4WLU). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?izf2dsWXTw2bE8YD7

The display surface is the electrostatic surface potential map of the enzyme. Red shows the surfaces that are more anionic and with a negative electrostatic potential to which cationic molecules would be attracted, while blue represents more cationic surfaces to which the anion would be attracted. Note that the bound NAD^+, which has many oxygens which are slightly or fully negative, is bound in a blue, positive electrostatic potential region.

SUMMARY

Let's do some stoichiometry for the full cycle. Here is the net reaction (assuming that the GTP produced by succinyl-CoA synthetase is equivalent to 1 ATP).

$$\text{Acetyl-CoA} + 3NAD^+ + FAD + ADP + P_i + 2H_2O \rightarrow 2CO_2 + 3NADH + FADH_2 + ATP + 2H^+ + CoASH$$

This must seem like a lot of work to produce just 1 ATP, especially since the partial, anaerobic oxidation of glucose in glycolysis produced in net fashion 2 ATPs. The key, however, is to realize that 3 NADHs and 1 $FADH_2$ are produced, which when they are reoxidized in mitochondrial electron transport/oxidative phosphorylation, will produce multitudes of ATP.

As was true for glycolysis, this main energy-extracting pathway is highly regulated. We will this in the next section.

Figure 16.2.33 shows some key points about each reaction in the citric acid cycle.

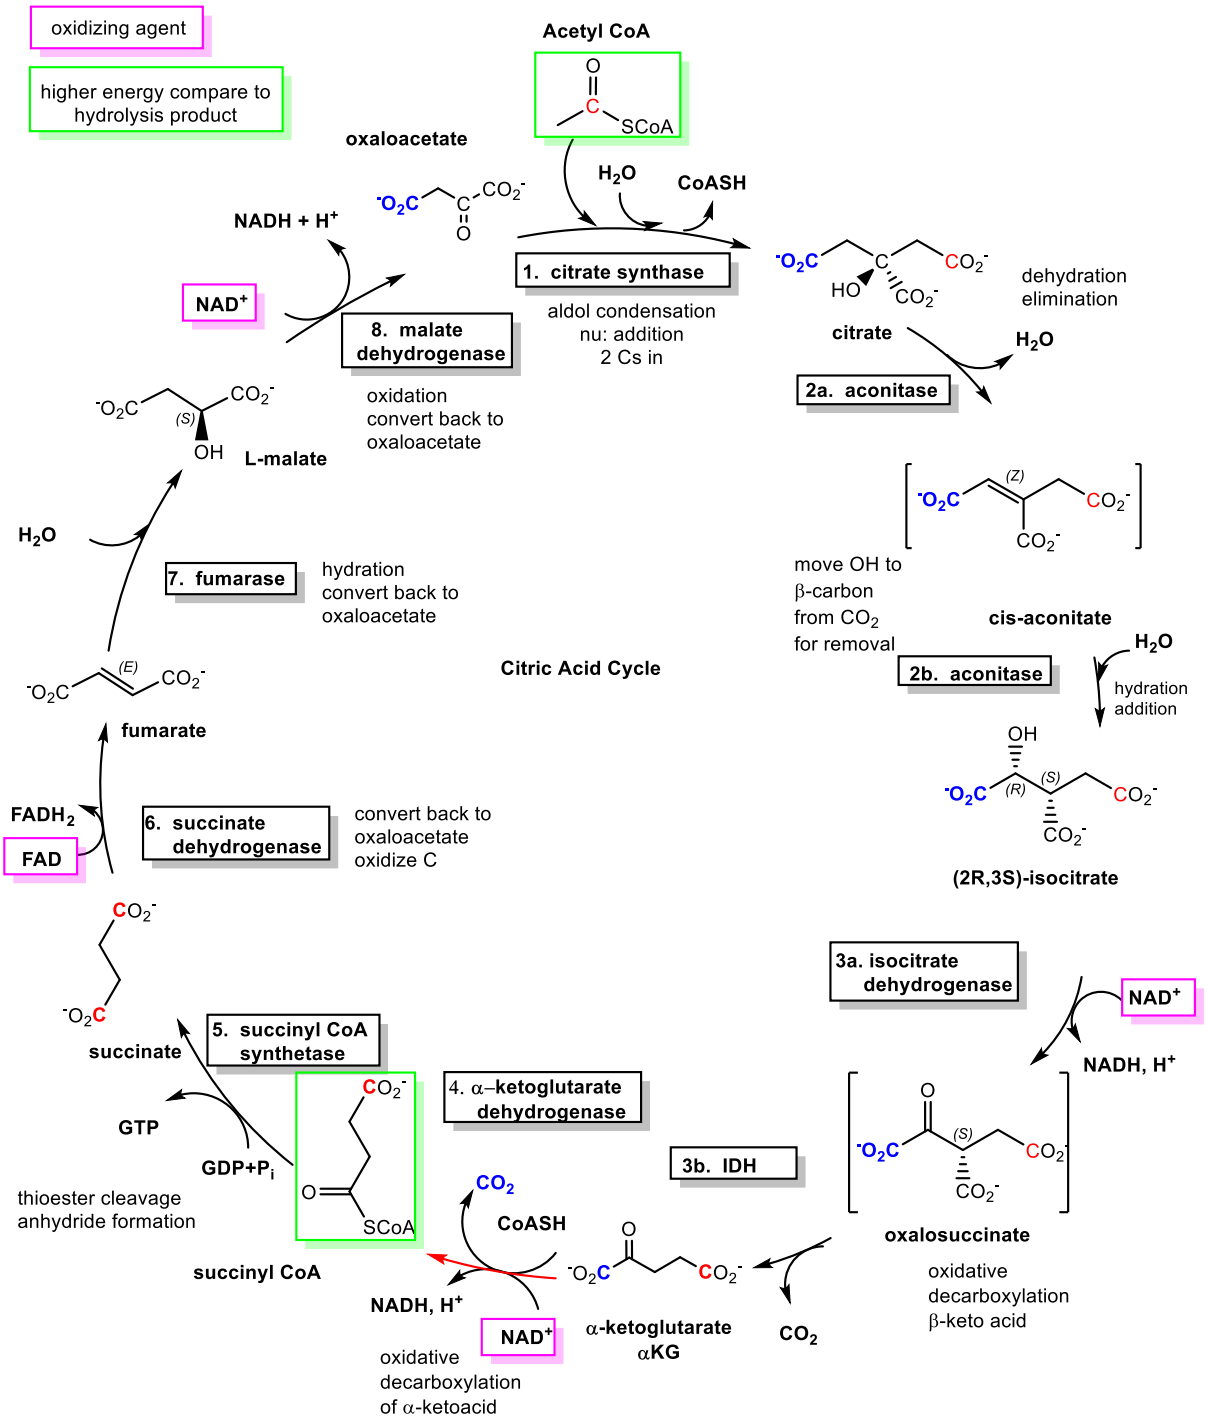

Figure 16.2.33: Summary of the citric acid cycle.

16.3: REGULATION OF THE CITRIC ACID CYCLE

16.3.1: OVERVIEW

Entry of pyruvate into the citric acid cycle leading to the aerobic production of energy and intermediates for biosynthesis is a key metabolic step. Hence both the pyruvate dehydrogenase complex and key enzymes in the cycle are targets for regulation. This occurs through substrate availability, product inhibition, allosteric effectors, and post-translational modifications of key enzymes in the pathway. A summary figure showing key regulators is shown in Figure 16.3.1.

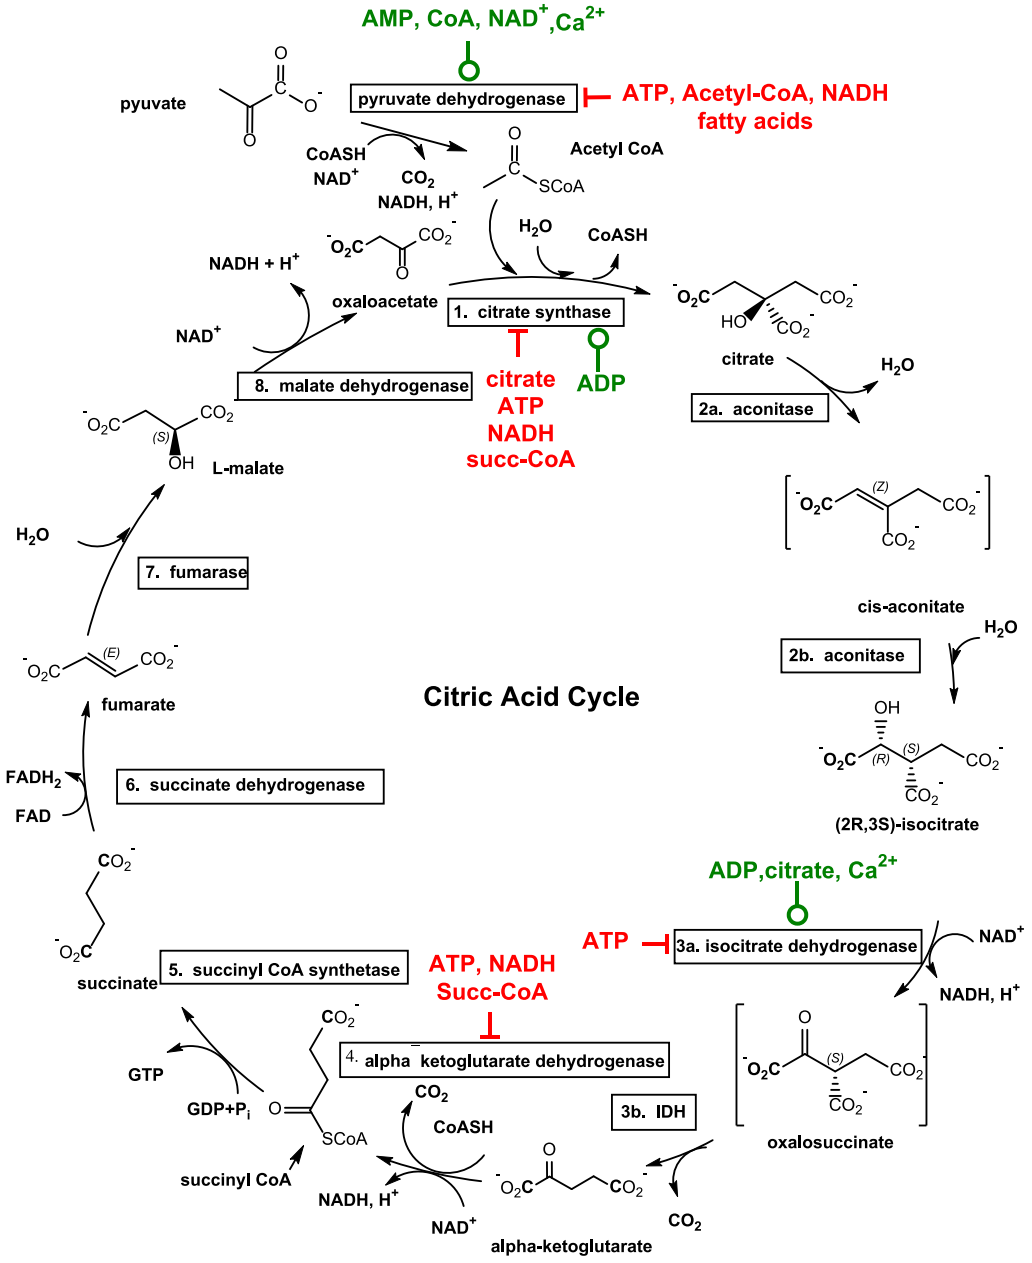

Figure 16.3.1: Regulation of the citric acid cycle

https://www.nature.com/articles/s41598-021-98314-z

Note that the key steps are regulated mainly by the ratio of mitochondrial NAD^+/NADH which is highly influenced by the ratio of ATP/ADP. High NADH inhibits the regulatory enzymes. High levels of acetyl CoA, derived from pyruvate dehydrogenase and also through fatty acids catabolism increases flux through the cycle in part by allosterically activating the first enzyme in the pathway, citrate synthase.

16.3.2: REGULATION OF THE PYRUVATE DEHYDROGENASE COMPLEX (PDC)

Under aerobic conditions, the pyruvate produced by glycolysis will be oxidized to acetyl CoA using the pyruvate dehydrogenase complex (PDC) in the mitochondria (note: its genes are encoded in the nucleus). As this enzyme is a key transition point (the gatekeeper) between cytosolic and mitochondrial metabolism and is highly exergonic ($\Delta G^{0'}$ = -7.9 kcal/mol, -38 kJ/mol), it is highly regulated by both covalent and allosteric regulation. Deficiencies of the PDC are X-linked and present with symptoms of lactic acidosis after consuming a meal high in carbohydrates. This metabolic deficiency can be overcome by delivering a ketogenic diet and bypassing glycolysis altogether.

The PDC is regulated by allosteric and covalent regulations. The complex itself can be allosterically activated by pyruvate and NAD^+. Elevation of the substrate (pyruvate) will enhance flux through this enzyme as will the indication of low energy states as triggered by high NAD^+ levels. The PDC is also inhibited by acetyl CoA and NADH directly. Product inhibition is a very common regulatory mechanism and high NADH would signal sufficient energy levels, therefore decreasing the activity of the PDC. Figure 16.3.2 summarizes the regulation. (Adapted from Marks' Medical Biochemistry)

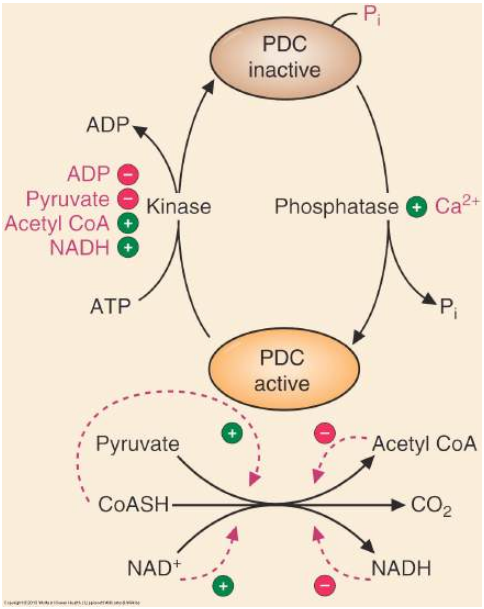

Figure 16.3.2: Regulation of pyruvate dehydrogenase.

The PDC is also regulated through covalent modification. Phosphorylation of the E1 subunits of the complex will decrease the activity of the enzyme.

The enzyme responsible for the phosphorylation of the PDC is **pyruvate dehydrogenase kinase**. The kinase is regulated inversely to the PDC, as shown in Figure 1 above. The kinase is most active when acetyl-CoA, NADH, and ATP are high. These compounds will stimulate the kinase to phosphorylate and inactivate the PDC. PDK is inhibited by dichloroacetate, TPP, Ca^{2+}, and pyruvate. The PDC can be dephosphorylated by a calcium-mediated phosphatase, PDP. Starvation and diabetes result in increased phosphorylation and inhibition of the complex, which impairs glucose oxidation.

Phosphorylation occurs on Serine 264 of the α subunit (site 1), Ser271 (site 2), and Ser203 (site 3) are located on a conserved phosphorylation loop. Sites 1 and 2 (in loop A) are involved in the stabilization of TPP in the active site, while Ser 203 in the adjacent loop B binds Mg^{2+} which stabilizes PP on bound TPP. All it takes for inhibition is the phosphorylation of just one of the Ser side chains. Phosphorylation prevents the ordering of the loop which occurs on TPP binding which hinders the binding of the lipoyl domains of the PDC core to E1p, which inhibits the flow of metabolites in the PDC.

Prevention of PDC phosphorylation by the specific PDK inhibitor dichloroacetate increases levels of reactive oxygen species in mitochondria, which promotes the expression of a mitochondria-K^+ channel axis, leading to cellular apoptosis and the inhibition of tumor growth

A summary of pathway regulation is shown in Figure 16.3.3.

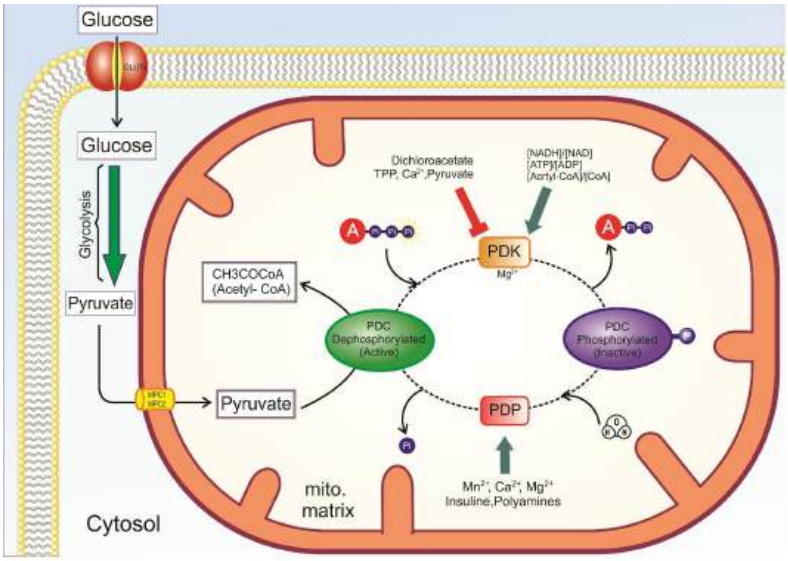

Figure 16.3.3: Summary of the regulation of pyruvate dehydrogenase

In general, PDC is activated through its substrates CoASH and NAD^+, and kinase inhibition or phosphatase activation (PDP) (dichloroacetate, TPP, Ca^{2+}, and pyruvate), is inhibited by its products acetyl CoA and NADH and activation of kinase (PDK). Abbreviations : PDC: pyruvate dehydrogenase complex, PDK: pyruvate dehydrogenase kinase, PDP: pyruvate dehydrogenase phosphatase TPP: thiamine pyrophosphate.

The complex is also acetylated and succinylated.

Table 16.3.1 below shows a summary of the regulation of pyruvate through glycolytic enzymes and pyruvate dehydrogenase

Metabolic Pathway	Major Regulatory Enzyme(s)	Allosteric Effectors	Post-translational modifications	Hormonal Effects
Glycolysis	hexokinase; glucokinase (liver)	Glucose 6P (-)		
	PFK-1	Fructose 2,6BP, AMP (+) Citrate (-)		↑ Insulin/Glucagon leads to dephosphorylation of PFK2 and increases producthe tion of F2,6BP
	Pyruvate Kinase	Fructose 1,6BP (+) ATP, Alanine (-)		↑ Insulin/Glucagon leads to dephosporylation
Pyruvate Dehydrogenase	PDC	Pyruvate, NAD^+ (+) Acetyl CoA, NADH, ATP (-)	dephosphorylation by PDP (+) phosphorylation by PDK (-)	↑ Insulin/Glucagon leads to dephosphorylation

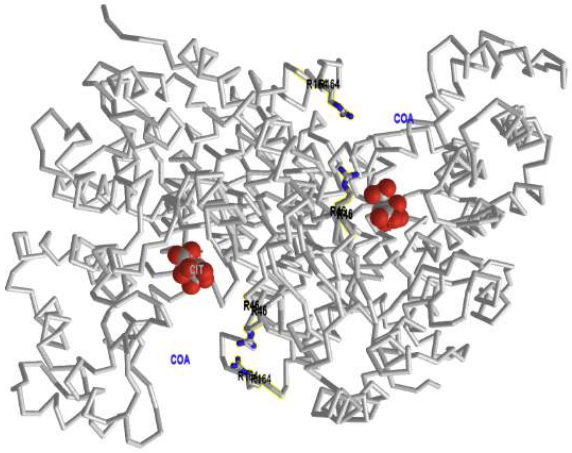
Table 16.3.1: Summary of the regulation of pyruvate through glycolytic enzymes and pyruvate dehydrogenase

16.3.3: REGULATION OF CITRATE SYNTHASE

Citrate synthase (ΔG^o = -7.5 kcal/mol, -31 kJ/mo), Isocitrate dehydrogenase (ΔG^o = -2.0 kcal/mol, -8.4 kJ/mol) and alpha-ketoglutarate dehydrogenase (ΔG^o = -7.2 kcal/mol, -30 kJ/mol) are all exergonic and likely candidates for regulation. Indeed they are. Let's start with citrate synthase.

Citrate synthase is regulated in part by the availability of substrate acetyl-CoA and oxaloacetate. It is inhibited by NADH and also citrate, a competitive inhibitor of oxaloacetate binding. Succinyl-CoA, a downstream product of the citric acid cycle, is a competitive inhibitor of acetyl-CoA binding.

Figure 16.3.4 shows an interactive iCn3D model of a structural comparison of pig citrate synthase with bound citrate (1CTS) and with bound citrate and CoASH (2CTS)



NCBI iCn3D Figure 16.3.4: Structural comparison of pig citrate synthase with bound citrate (1CTS) and with bound citrate and CoASH (2CTS). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...94UeRDsFyGTcdA

Toggle the "a" key back and forth to change from the open structure (gray) with bound citrate (1CTS) to the closed structure (cyan) after CoASH binds (2CTS).

Citrate and CoASH are the products of citrate synthase reaction, but seeing how they interact with the protein gives clues into catalysis. When both are bound, the enzyme is in closed conformation which would prevent spurious hydrolysis of the actual acetyl-CoA when the reaction proceeds to citrate formation. In just the presence of citrate, the enzyme is in open form, allowing the release of citrate as a product. The binding of the reactant oxaloacetate triggers the conversion to the closed form. NADH is reported to be an allosteric inhibitor of bacterial citrate synthases but no entries are available for the binding of NADH to mammalian enzymes.

The effects of binding acetyl-CoA on the structure of citrate synthase are shown in Figure 16.3.5:

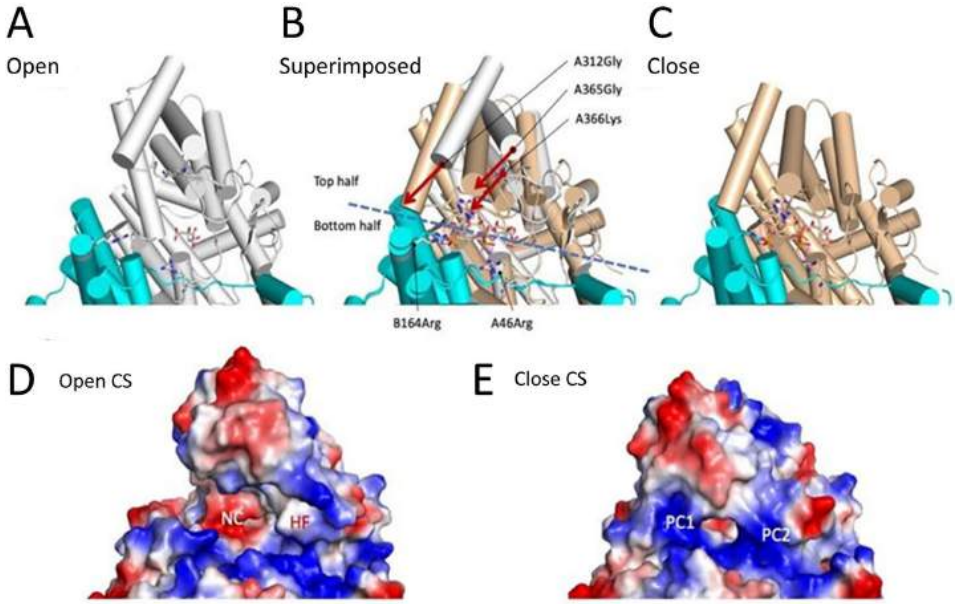


Figure 16.3.5: Effect of acetyl-CoA binding on CS structure. Omini, J., Wojciechowska, I., Skirycz, A. *et al.* The association of the malate dehydrogenase-citrate synthase metabolon is modulated by intermediates of the Krebs tricarboxylic acid cycle. *Sci Rep* **11,** 18770 (2021). https://doi.org/10.1038/s41598-021-98314-z. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

Panel (**A**) shows the open format of CS (PDB ID, 1cts) in a cartoon model, with cylindrical α-helices containing a citrate molecule in a stick model. Subunits A and B are colored white and cyan, respectively. Key residues, A266Lys, A46Arg, and B164Arg, are shown in the sticks' side chains. The residues are shown in the order of the chain name, residue number, and amino acid. the dimer structure was generated using crystallographic symmetry. One active site domain composed mainly of the A-chain is shown.

Panel (**B**) shows the superimposed model between the open (1cts; white) and close (2cts; wheat) formats. The citrate molecule is at the same location with a slight rotation. The CoA molecule is present only in the closed format. The molecular domain shown can be divided into the movable upper half and the rigid bottom half. In the bottom domain, A45Arg and B146Arg are shown in the stick model. The locations of those two Cα in Arg are almost consistent between the open and closed formats. The top half domain is movable. The motion is visible as the rotation of α-helices represented by A312Gly and A365Gly, indicated by arrows. The A366Lys moves inward and forms a hydrogen bond network A366Lys (NZ):: A438COA(O8A):: B164Arg(NH1).

Panel (**C**) shows the closed format of CS (PDB ID, 2cts) with citrate and CoA molecules in stick models.

Panel (**D**) shows the surface electrostatic potential of the open format CS excluding ligands. Calculations were performed in the vacuum environment and ranged between − 71 and + 71. Red and blue represent the negative and positive potentials. The domain shown corresponds to panel A. Patches of negative charge (**NC**) and hydrophobic area (**HF**) are observed.

Panel (**E**) shows the surface electrostatic potential of the closed format CS excluding ligands. The domain shown corresponds to panel D. Patches of positive charge (PC1, PC2) are observed.

We will see how the electrostatic surface potential of citrate synthase allows it to interact with other citric cycle enzymes to form a metabolon at the end of this chapter section.

16.3.4: REGULATION OF ISOCITRATE DEHYDROGENASE

In the previous section, structures of the αγ and αβ heterodimer building blocks of the protein were described. The α subunits contain the catalytic site while the β and γ subunits were the regulatory subunits that bind allosteric effectors. Citrate and ADP allosterically activate both the $\alpha_2\beta\gamma$ heterotetramer and αγ heterodimer. They bind next to each other in the allosteric site, along with Mg^{2+}. Conformational changes in binding citrate lead to a change in and activation of the catalytic subunit α. The binding of ADP just enhances this effect.

The domain and cartoon structure of the αγ heterodimer of human NAD-IDH are shown in Figure 16.3.6.

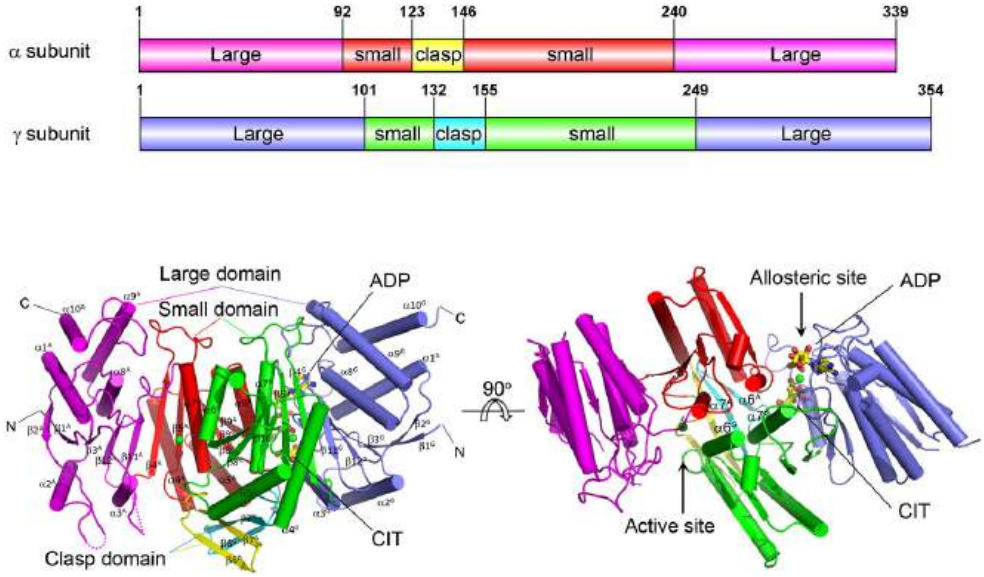

Figure 16.3.6: Domain and cartoon structure of the αγ heterodimer of human NAD-IDH. Ma, T., Peng, Y., Huang, W. *et al.* Molecular mechanism of the allosteric regulation of the αγ heterodimer of human NAD-dependent isocitrate dehydrogenase. *Sci Rep* **7,** 40921 (2017). https://doi.org/10.1038/srep40921. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/

The top panel shows the domain structure of the two monomers. The bottom panel shows two views of the dimer. The color coding is the same as in the top panel.

Figure 16.3.7 shows bound citrate and ADP in the allosteric binding site in the γ subunit of IDH.

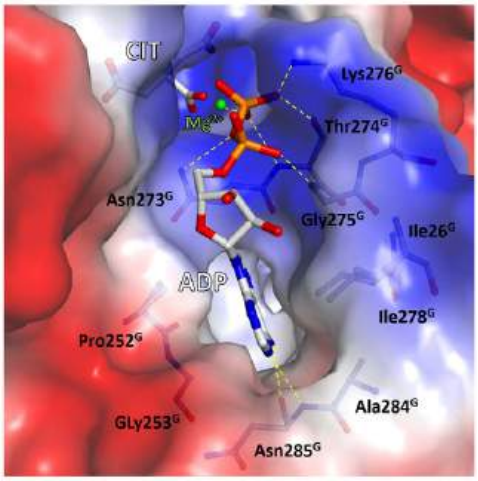

Figure 16.3.7: Bound citrate and ADP in the allosteric binding site in the γ subunit of IDH**.** Ma et al, ibid.

The color represents the electrostatic surface potential of the site with blue indicating more positive and red more negative. Note that both allosteric activators bind adjacent to each other. The binding of ADP does not change the conformation after the citrate is bound.

The proposed molecular mechanism for allosteric regulation of IDH is shown in Figure 16.3.8.

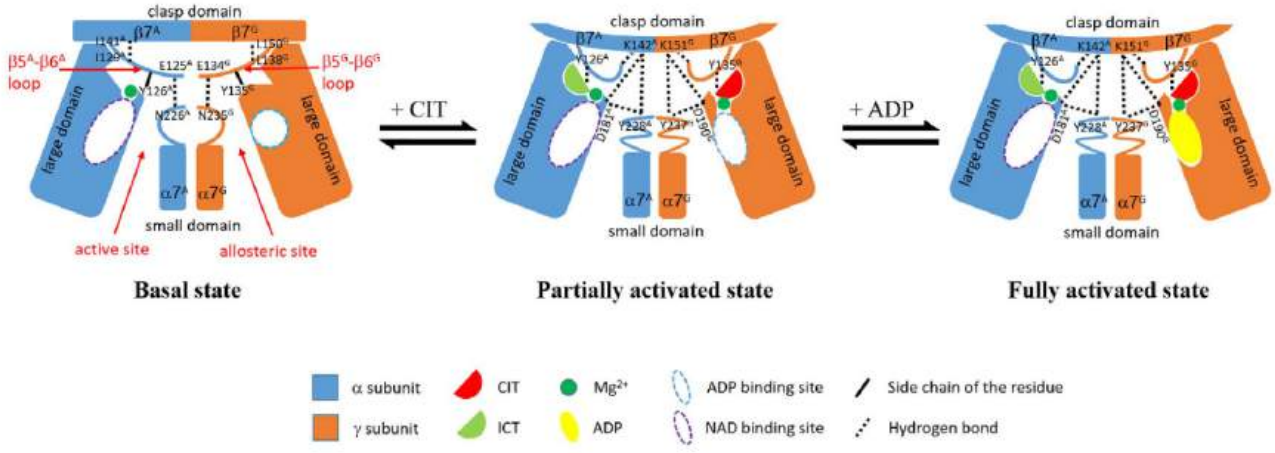

Figure 16.3.8: Mechanism mechanism of allosteric regulation of the αγ heterodimer of IDH. Ma et al, ibid.

Legend: In the absence of any activators, the active site adopts an inactive conformation unfavorable for the ICT binding, and the enzyme is in the basal state which has a high $S_{0.5,\mathrm{ICT}}$ with a low catalytic efficiency. The binding of CIT induces conformational changes at the allosteric site, which are transmitted to the active site through conformational changes of the structural elements at the heterodimer interface, including the β5–β6 loop, the α7 helix, and the β7-strand in both the α and γ subunits, leading to the conversion of the active site from the inactive conformation to the active conformation favorable for the ICT binding. Hence, the enzyme assumes the partially activated state which has a moderately decreased $S_{0.5,\mathrm{ICT}}$ (lower substrate concentration for half-maximal activity) with a moderately increased catalytic efficiency. The binding of ADP in the presence of CIT does not induce further conformational changes at the allosteric site and the active site but establishes a more extensive hydrogen-bonding network among CIT, ADP, and the surrounding residues through the metal ion, which conversely enhances or stabilizes the CIT binding. Hence, the binding of CIT and ADP together has a synergistic activation effect, and the enzyme assumes the fully activated state which has a substantially decreased $S_{0.5,\mathrm{ICT}}$ with a significantly increased catalytic efficiency.

16.3.5: REGULATION OF A-KETOGLUTARATE DEHYDROGENASE

α-ketoglutarate dehydrogenase and pyruvate dehydrogenase complex both catalyzed the oxidative decarboxylation of α-ketoacids. They use a common mechanism involving three enzymes, E1-E3, in a large complex. The regulation of α-ketoglutarate dehydrogenase activity is shown in Figure 16.3.9.

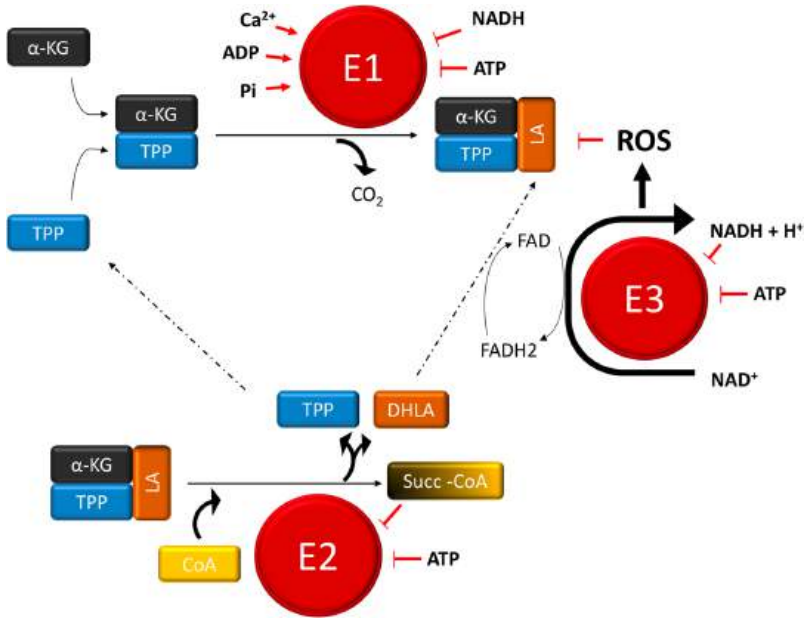

Figure 16.3.9: Regulation mechanisms of α-ketoglutarate dehydrogenase complex (α-KGDC). Vatrinet, R., Leone, G., De Luise, M. *et al.* The α-ketoglutarate dehydrogenase complex in cancer metabolic plasticity. LS and DHLA are lipoamide and dihydrolipoamide, respectively. TPP is thiamine pyrophosphate. *Cancer Metab* **5,** 3 (2017). https://doi.org/10.1186/s40170-017-0165-0. Creative Commons Attribution 4.0 International License (http://creativecommons.org/licenses/by/4.0/),

As with the other key regulatory enzymes, α-KGDC is regulated by ATP/ADP and NADH/NAD^+ ratios. The product, succinyl-CoA inhibits the reaction at E2. The mitochondria are reservoirs for Ca^{2+} ions. These ions increase the activity of pyruvate, isocitrate, and α-ketoglutarate dehydrogenases with α-ketoglutarate dehydrogenases most affected. Calcium effects also depend on ATP/ADP and NADH/NAD^+ ratios.

16.3.6: REGULATION BY METABOLON FORMATION

Several citric acid cycle enzymes interact to form a metabolon, which allows enhance flux through pathways as substrate and products are channeled directly from one enzyme to another in the complex. This "facilitated" diffusion minimizes the dissociation of substrates/products and enhances catalysis. Three enzymes in the citric acid cycle, citrate synthase, malate dehydrogenase, and aconitase form a metabolon, as shown by chemical cross-linking and docking studies. The linkages between malate dehydrogenase, which produces oxaloacetate, and citrate synthase, which uses it, are important since concentrations of oxaloacetate are low and would produce reduced flux in the citric acid cycle if it were not channeled directly into citrate synthase. Malate dehydrogenase is also not favored to produce oxaloacetate based on standard free energy and K_{eq} values so pulling the reaction towards citrate synthase in the metabolon also helps the flux.

$$\text{L-malate} + NAD^+ \leftrightarrow \text{oxaloacetate} + NADH + H^+ \quad \Delta G^o = +7.1 \text{ kcal/mol } (+30 \text{ kJ/mol})$$

Figure 16.3.10 shows models of malate dehydrogenase (MDH) and the open and closed forms of citrate synthase (CS). Electrostatic interactions are key.

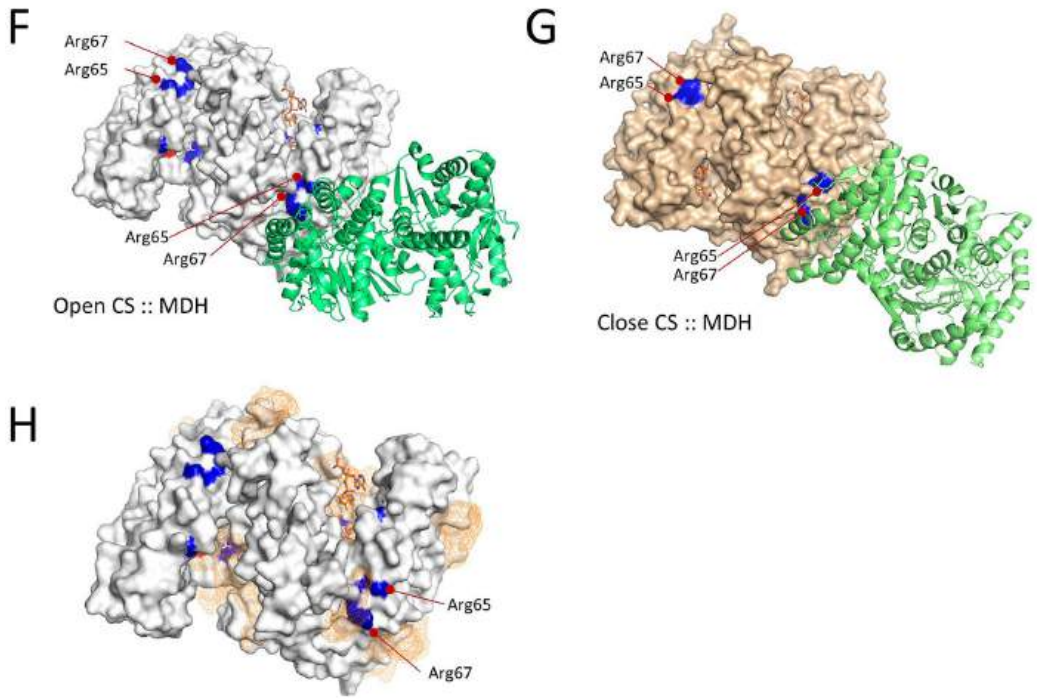

Figure 16.3.10: Models of malate dehydrogenase (MDH) and the open and closed forms of citrate synthase (CS). Omini, J., Wojciechowska, I., Skirycz, A. *et al.* Association of the malate dehydrogenase-citrate synthase metabolon is modulated by intermediates of the Krebs tricarboxylic acid cycle. *Sci Rep* **11,** 18770 (2021). https://doi.org/10.1038/s41598-021-98314-z. http://creativecommons.org/licenses/by/4.0/.Creative Commons Attribution 4.0 International License.

Panels (**F**) and (**G**) show simulated interactions between MDH (green) and CS in its open (white) form (panel F) and between MDH (green) and CS in its closed (wheat) format (panel G). The 65Arg and 67Arg residues that are involved in the MDH-CS interaction are highlighted in blue. Active site residues, His 274, His320 (blue), and Asp375 (red) were shown.

Panel (**H**) Predicted acetyl-CoA binding sites in CS apoenzyme. The white surface model of the CS apoenzyme in the open format is shown. The 274His, 320His, 65Arg, and 67Arg residues are highlighted in blue. The orange mesh indicates the positions of acetyl-CoA at the predicted binding sites. White and orange stick models indicate the citrate and CoA in the reported crystal structure, respectively.

Does the activity of citrate synthase change when it is complexed to malate dehydrogenase in a metabolon? The results of studies probing that question show that it is affected. The results of such studies are shows that it does as illustrated in Figure 16.3.11.

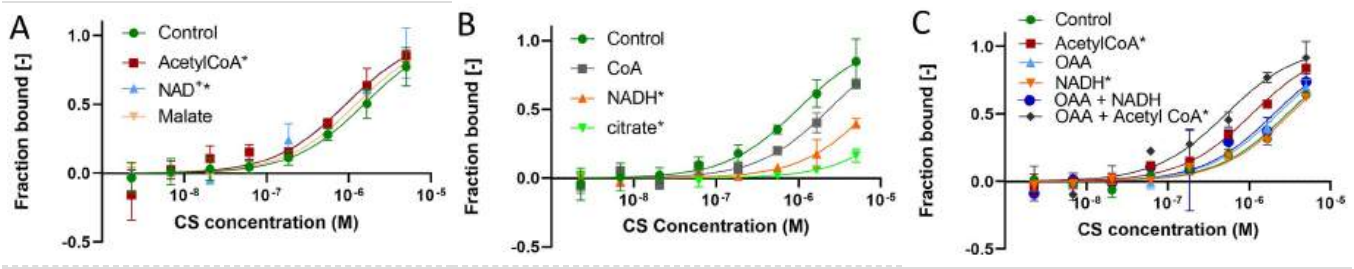

Figure 16.3.11: Effects of metabolites involved in the MDH and CS reactions on the affinity of the MDH-CS multi-enzyme complex. Omini et al, ibid.

Curves represent the response (fraction bound) against CS concentration (M). The interaction was assessed in the MST buffer (control, green) or those with 10 mM of metabolites. Error bars represent the standard deviations of three measurements. Asterisks indicate the conditions that showed significant K_d differences with no K_d confidence overlap with the control.

Panel (**A**) shows the effects of the reaction substrates of MDH and CS. The MDH-CS interaction was assessed in the presence of acetyl-CoA (red), NAD^+ (blue), or malate (brown).

Panel (**B**) shows the effects of the reaction on products of CS and MDH. The MDH-CS interaction was assessed in the presence of CoA (grey), NADH (orange), or citrate (green).

Panel (**C**) shows the effects of oxaloacetate (OAA) in combination with other CS substrates. The effects of sole substrates, acetyl-CoA (red), OAA (blue), and NADH (orange), as well as their combinations, OAA/acetyl-CoA (purple) and OAA/NADH (gray), were analyzed.

These curves clearly show how the ratio of NADH/NAD^+ affects the activity of citrate synthase when it is part of a metabolon. NAD^+ increases activity (Panel A) while NADH decreases it (Panel B).

16.4: VARIANTS OF THE CITRIC ACID CYCLE

16.4.1: CITRIC ACID CYCLE SHUNTS AND BYPASSES

Evolution has allowed variants in the citric acid cycle to produce new functionalities in organisms. Let's consider a few.

16.4.2: GLYOXYLATE SHUNT

What if you were a microorganism that has evolved to use acetate (2C) as a source (if not the sole source) of energy? Remember that the citric acid cycle is also used to generate metabolites for anaplerotic reactions (from the Greek ἀνά= 'up' and πληρόω= 'to fill'). In the full citric acid cycle, activated acetate (2C) reacts with oxaloacetate (4) to produce the 6C molecule citric acid. As the cycle continues back to oxaloacetate, 2 Cs are lost as CO_2, so in sum for 1 turn of the cycle:

oxaloacetate (4C) + acetyl-CoA (2C) → Citrate (6C) → → → succinate (4C) + 2 CO_2 (2C).

In the process, oxidation reactions occur leading to the formation of NADH and $FADH_2$ and the metabolites formed can be withdrawn for biosynthesis (OAA, αKG, and succinyl CoA).

An alternative "cycle" would be to eliminate the two decarboxylation reactions and generate a 4C molecule (succinate) and one 2C metabolite (glyoxylate), which could react with another activated acetate (acetyl-CoA) to form oxaloacetate (or more precisely malate which can be oxidized to it). Hence two acetates are required, but if you are organisms adapted to use this as a metabolic energy source, it's no problem. Here is the next reaction

oxaloacetate (4C) + acetyl-CoA (2C) → Citrate (6C) → → succinate (4C) + glyoxylate (2C);

glyoxylate (2C) + acetyl-CoA (2C) → malate (4C)

This reaction would act as a metabolic shunt, altering the flow of metabolites by bypassing part of the citric acid cycle. The shunt, which is found in many microorganisms and some plants is called the **glyoxylate shunt**, which is shown in Figure 16.4.1.

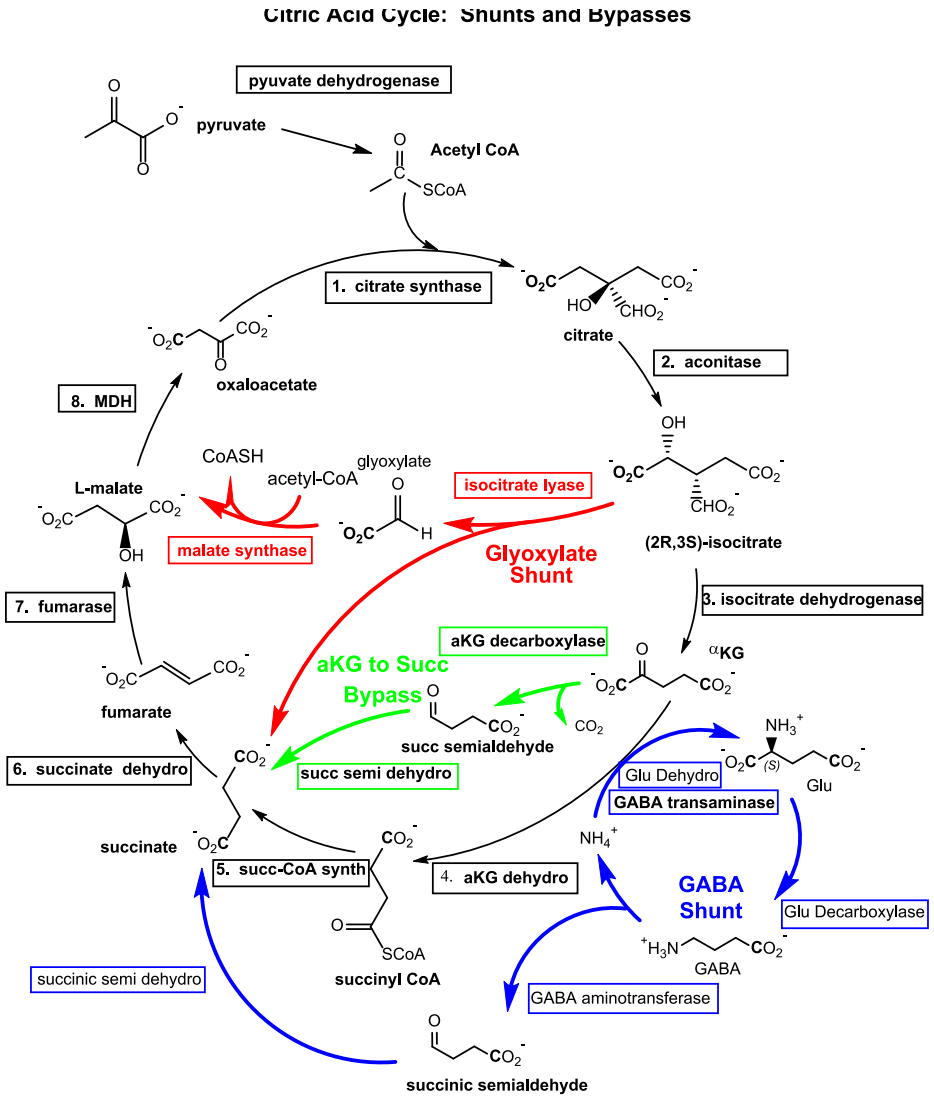

Figure 16.4.1: Citric Acid Cycle Shunts and Bypasses. (Copyright; author via source)

Why is this so cool? First, consider this observation about the citric acid cycle. One acetate, in the form of acetyl-CoA, is needed to form one oxaloacetate in one turn of the cycle, which in turn is needed in the next turn of the cycle. Hence acetyl-CoA cannot, in a net fashion, be used to synthesize oxaloacetate. We saw previously that oxalate is an intermediate in the synthesis of phosphoenolpyruvate from pyruvate in gluconeogenesis. Hence acetate can not be used to form glucose in a net fashion. (Note: pyruvate dehydrogenase is not reversible). Another way to think about this is 2Cs enter the cycle as acetyl-CoA and 2 leave as CO_2 so no net synthesis can occur. And, you are in trouble if you draw off oxaloacetate as well as α-ketoglutarate and succinate for anaplerotic reactions for biosynthesis as they are needed metabolites for a cycle that consumes and produces one of each of these will be depleted if withdrawn

Now if you are an organism (many bacteria and plants) that has the glyoxylate shunt, you have no worries. A mini cycle still occurs with the conversion of isocitrate to glyoxylate to malate and back around to oxaloacetate and citrate (for energy production) with the net production of 1 succinate (for biosynthesis). The only Cs "lost" from the mini cycle are in the form of succinate so they are not lost as they are as 2 CO_2s in the citric acid cycle since they are used for biosynthesis.

The next reaction for the glyoxylate cycle is:

$$2 \text{ Acetyl-CoA} + 2 \text{ NAD}^+ + 2 \text{ H}_2\text{O} \rightarrow 2 \text{ succinate} + 2 \text{ NADH} + 2 \text{ CoASH} + 2 \text{ H}^+ .$$

In plants, this reaction occurs in organelles called Glyoxysomes. The succinate can be converted through its continuation through the citric acid to oxaloacetate which can then form glucose and other carbohydrates through gluconeogenesis. Hence organisms that have the glyoxylate shunt (or cycle) can synthesize carbohydrates in a net fashion from acetate, which can derive from fatty acid degradation as we will see in a subsequent chapter.

Now to operate the glyoxylate cycle efficiently, you do need to activate the carboxyl end of acetate. Plants and other organisms that can grow on acetate can produce acetyl-CoA needed for the above pathways from the following reaction catalyzed by acetyl-CoA synthase (i.e.

not pyruvate dehydrogenase)

$$\text{Acetate} + \text{CoASH} + \text{ATP} \rightarrow \text{Acetyl-CoA} + \text{AMP} + PP_i$$

Note that one phosphoanhydride bond is cleaved and one thioester bond is formed. These molecules are both high energy compared to their hydrolysis products so this reaction alone is not thermodynamically favored in any significant way (remember that there is no such thing as a high energy bond). The hydrolysis of pyrophosphate (PP_i) drives this reaction forward. An analogous reaction drives the creation of peptide bonds in protein as that reaction also uses ATP to create an activated mixed anhydride from the free carboxyl end

16.4.3: GABA SHUNT

Now let's move to the brain where there is lots of chemistry happening as you read this page. Relatively high concentrations of key neurotransmitters are required for neural function and these need to be maintained against metabolic losses. Glutamate is the principal excitatory neurotransmitter and GABA (δ-aminobutryic acid) is the principal inhibitory neurotransmitter. Both are maintained at high concentrations and are principal players in the GABA shunt. Figure 16.4.2 shows a part of the large pathway shown above but in a more expanded form.

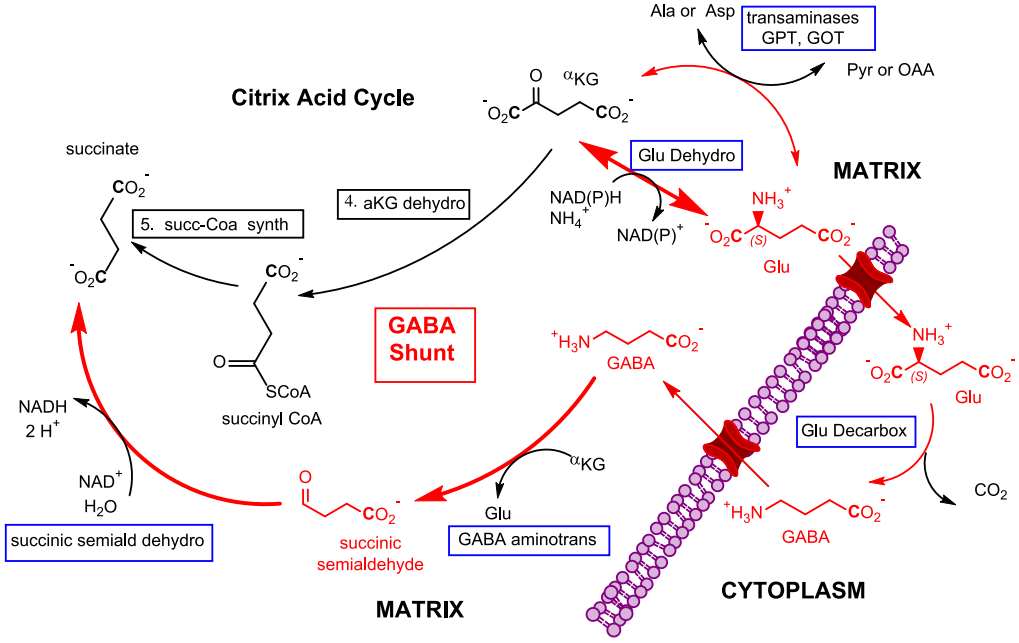

Figure 16.4.2: Expanded view of GABA shunt. (Copyright; author via source)

GABA is formed in the cytoplasm by decarboxylation of Glu by the enzyme glutamate decarboxylase, which appears to be expressed predominantly in neural tissue. It is metabolized by GABA transaminase but only if the compound from which the shunt starts, α-ketoglutarate, is present abundantly. This conserves the supply of GABA in the neuron. Stated in another way, the breakdown product of GABA, succinic semialdehyde, is formed only if GABA's precursor is present. Inhibitors of GABA aminotransferase are used to treat epilepsy. Another function of the shunt is that it effectively allows glutamate to loop into the cycle.

16.4.4: A-KETOGLUTARATE ↔ SUCCINATE BYPASS

In anticipation of the section below, one could ask the following question: What happens when a step in the cycle is impaired or missing? Cyanobacteria, a key player in atmospheric O_2 production and drawn down of natural and anthropogenic atmospheric CO_2, were thought to have an incomplete citric cycle as they lack α-ketoglutarate dehydrogenase. They work around this issue by converting α-ketoglutarate to succinate directly using two enzymes, alpha-ketoglutarate decarboxylase, and succinic semialdehyde dehydrogenase, as shown below. The first enzyme catalyzes a non-oxidative decarboxylation of the substrate to succinic semialdehyde. This bypass is shown in Figure 16.4.3. In addition, cyanobacteria also use the GABA shunt as a bypass for α-ketoglutarate dehydrogenase.

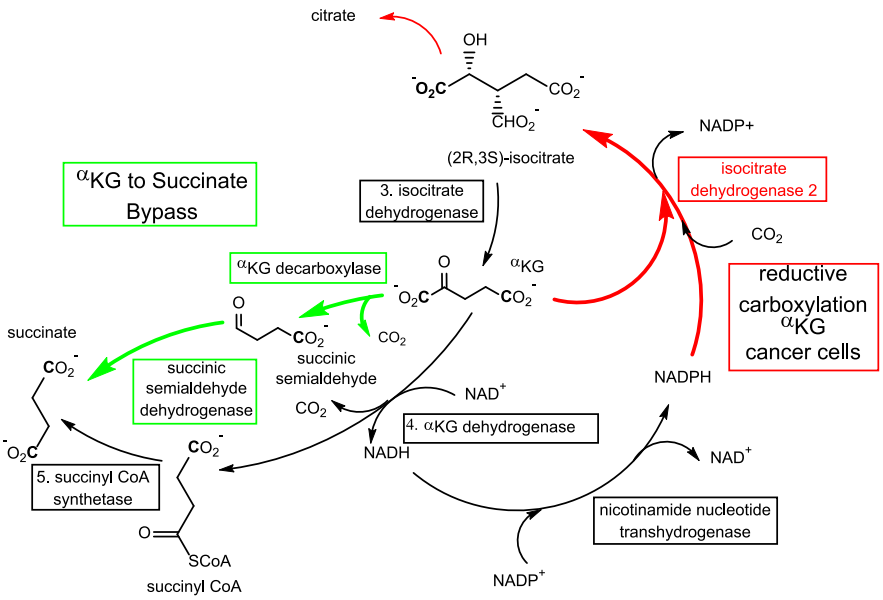

Figure 16.4.3 : α-ketoglutarate to succinate bypass. (Copyright; author via source)

Here is yet another example. Each member of the cycle is an important member. Let's consider the first one, citrate. It is formed in the key step coupling the output of anaerobic metabolism of glucose, pyruvate) with the formation of citrate in the citric acid cycle. What happens if aerobic metabolism is impaired, as it would in hypoxic and anoxic conditions, or if mitochondria function is compromised or in disease states such as cancer? Might there be another way to form citrate? Turns out that there is. and it centers on α-ketoglutarate again. It is illustrated in the above figure.

Lets's consider cancer which is characterized by a state of rapid proliferation of cells. This requires both energy and metabolic precursors for the biosynthesis of carbohydrates, lipids, and proteins. The citric acid cycle offers both. To accommodate this demand for the efflux of citric acid cycle intermediates for reductive biosynthesis, large fluxes of glutamate (derived from abundant glutamine) into the cycle are used in the form of α-ketoglutarate. In another anaplerotic reaction, citrate can be cleaved by citrate lyase to form acetyl-CoA which can be used for fatty acid synthesis needed by rapidly proliferating cells. To replenish the citrate, cancer cells convert α-ketoglutarate by reductive carboxylation to isocitrate by isocitrate dehydrogenase 2, which uses NADPH for the reduction reaction. That NADPH comes from the enzyme nicotinamide nucleotide transhydrogenase, which can interconvert matrix pools of NADH and NADPH using the collapse of a protein gradient across the mitochondria inner membrane (which we will study in a subsequent chapter).

$$H^+_{(in)} + NAD^+ + NADPH \leftrightarrow H^+_{(out)} + NADH + NADP^+$$

Note that both oxidative (α-ketoglutarate to succinyl CoA) and reductive reactions (α-ketoglutarate to isocitrate) occur in this process.

16.4.5: VARIANTS OF THE TCA CYCLE IN MICROORGANISMS

It's very easy to be anthropocentric in constructing a biochemistry text as many who take the course are interested in human medicine. Since a human is an ecosystem of organisms with an expansive microbiome on their skin and in their gut, even from a human health perspective, it is important to compare the same pathway in different organisms. It's also important to understand our role as a small part of a vast biosphere where our survival depends on other organisms, large and small.

In that light, let's consider the citric acid cycle of other organisms. It seems that most organisms have the anaerobic and universal glycolytic pathway. How about the aerobic citric acid cycle? These days of single-cell genomic analysis make it simple in principle to analyze the citric acid cycle genes of any organism. Variants of it are found in generally all aerobic organisms and even some anaerobic one. Some subtle differences exist between eukaryotic and prokaryotic organisms. NAD^+ is used as a substrate in the mammalian form of isocitrate dehydrogenase while prokaryotes use $NADP^+$. An NAD^+-dependent malate dehydrogenase is used in mammals while some prokaryotes use a different enzyme, a $NADP^+$-dependent malate-quinone oxidoreductase. Lastly different enzymes (and unfortunately with varying names) are used to convert succinyl-CoA to succinate. Plants and fungi use ADP as a substrate, mammals have two different enzymes often named different and for the reverse reaction as succinate-CoA ligase (ADP forming) and succinate-CoA ligase (GDP forming).

Analyzes shown that few bacteria have complete cycles. Of those with incomplete cycles, the early steps are least conserved, while the latter are most conserved. The cycle is used not only for the oxidative production of energy but also the generation of metabolites (α-ketoglutarate, oxaloacetate, and succinyl-CoA), which are pulled from the cycle for biosynthesis. Autotrophs that don't have a complete cycle can make those products from pyruvate. Consider α-ketoglutarate. Some make it through the clockwise oxidative reaction from citrate

to α-ketoglutarate while some methanogenic Archaea make it through counterclockwise reduction reactions. Comparative genomic analyses suggest that the citric acid cycle probably arose from a "linear" oxidative pathways leading to α-ketoglutarate and a reductive one leading to succinyl CoA. Knowing the pathways in individual microorganisms can assist in the rational drug design of new antibiotics. Figure 16.4.4 below, adapted from Huynen et al, shows a geometric analysis diagram of the citric acid cycle and variants in other organisms.

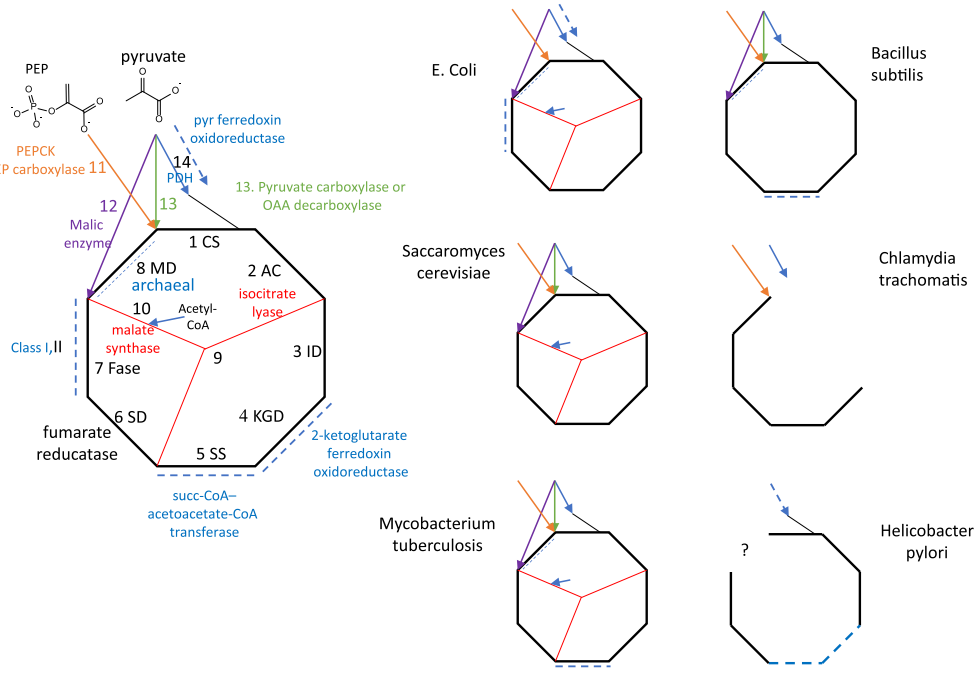

Figure 16.4.4: Geometric analysis diagram of the citric acid cycle and variants in other organism. (Copyright; author via source)

16.4.6: THE A-KETOACID PATHWAY - A PRIMORDIAL, PREBIOTIC ANABOLIC "TCA-LIKE" PATHWAY

You might be wondering after studying the complexity of pyruvate dehydrogenase and the citric acid cycle how the cycle might have originated. As discussed above, clues come from comparative genome analysis of genes encoding the enzymes for the reactions in a multitude of organisms. By looking at evolutionary changes in genes and functions for these reactions, one can obtain some ideas of the first enzymes that evolved in the pathway. But what about an abiotic pathway that might have arisen before the first biological one? Stubbs et al have shown that the very simple molecules glyoxylate and pyruvate can react in mild aqueous conditions (pH 7 in 0.5 M phosphate buffer heated to 50 °C) to form, in a single pot, α-ketoacids similar to present citric acid cycle intermediates. From a kinetic perspective, they were formed in the reverse, counterclockwise reductive direction compared to the citric acid cycle (clockwise, oxidative). No metals or "enzymes" were needed for the transformations. Glyoxylate acts as a reducing agent and is simultaneously the source of carbon atoms. Once these α-ketoacids form, they could be theoretically converted by transamination reactions to amino acids as they should be characterized by a $K_{eq} \approx 1$ and a $\Delta G^0 \approx 0$.

The citric acid cycle is filled are carboxylic acids. Only the α-ketoacids (α-ketoglutarate and oxaloacetate) can readily form carbanions at the alpha carbons as their Hs are slightly acidic due to resonance stabilization of the carbanion through and enolate tautomer. The others are electron-rich so they are less acidic at the alpha carbons, discouraging deprotonation in the absence of harsh catalysts. So perhaps alternative functional groups were present in abiotic precursors. Perhaps they contained α-ketoacids similar to α-ketoglutarate, oxaloacetate, and of course pyruvate. In addition, α-ketoacids have an electrophile in the form of the carbonyl carbon form C-C bond formation.

Figure 16.4.5 shows the reductive, counter-clockwise pathway they determined. Note that in both the glyoxylate "cycle" which has also been proposed as an abiotic pathway and the α-ketoacid reductive pathway, no CO_2 is lost in any step. That suggests that the actual decarboxylation steps, although often favored thermodynamically, required the development of catalysts. The two α-ketoacids substrates in this pathway, glyoxylate (2Cs) and pyruvate (3Cs) are the smallest and most likely formed acids available.

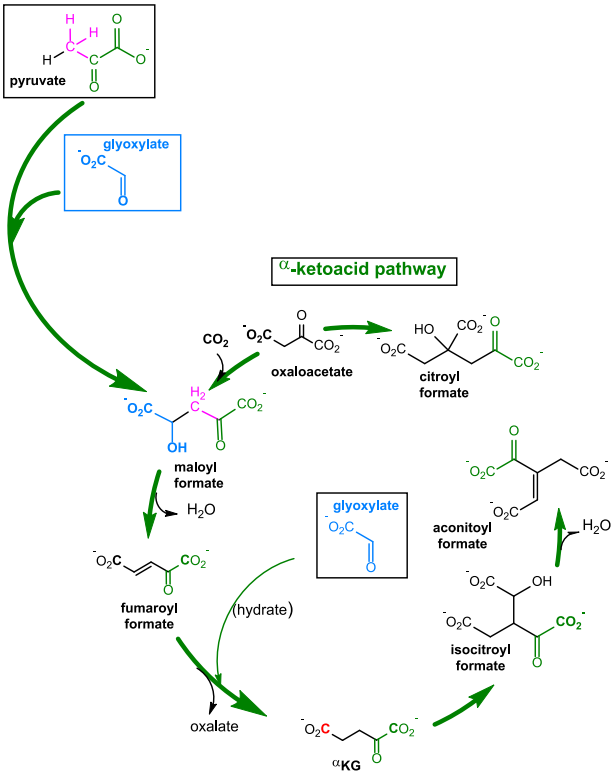

Figure 16.4.5: Proposed prebiotic alpha-keto acids pathway. (Copyright; author via source)

Figure 16.4.6 is an animation that shows the entire citric acid cycle (catabolic, oxidative, running clockwise), the glyoxylate shunt which bypasses many steps in the citric acid cycle, and the proposed prebiotic anabolic alpha-ketoacid pathway (bold green arrows) which essentially runs counterclockwise and is reductive.

Figure 16.4.6: Animation of the citric acid cycle (catabolic, oxidative, clockwise), the glyoxylate shunt (which bypasses many steps in the citric acid cycle), and the proposed prebiotic anabolic alpha-ketoacid pathway (bold green arrows). (Copyright; author via source)

CHAPTER OVERVIEW

17: FATTY ACID CATABOLISM

Fatty acid catabolism is the mechanism by which the body accesses energy stored as triglycerides.

17.1: Digestion, Mobilization, and Transport of Fats

17.2: Oxidation of Fatty Acids

17.3: Ketone Bodies

Thumbnail: Idealized representation of a molecule of a typical triglyceride, the main type of fat. Note the three fatty acid chains attached to the central glycerol portion of the molecule. (Public Domain; Benjah-bmm27 via Wikipedia)

17.1: DIGESTION, MOBILIZATION, AND TRANSPORT OF FATS

17.1.1: INTRODUCTION

In this chapter, we will discuss the breakdown of fats to produce ATP. Most of the available chemical energy stored in fats is in the form of highly reduced fatty acids. One form of fatty acid-containing lipids comes from our diet, which includes triacylglycerols (TAGs) and membrane lipids. Fatty acids, mostly in the form of TAGs, are moved in the circulation in the form of large lipid-carrying vesicles called **lipoproteins**. The lipids can be imported into cells for storage and energy use.

Another source of fatty acids comes from those synthesized within cells from the small molecule acetyl-CoA. Fatty acids are synthesized by an enzyme complex called **fatty acid synthase**. This enzyme is found most prevalently in adipose (fat) tissue and the liver. In addition, it is significantly expressed in the brain, lungs and mammary gland.

TAGs, stored in lipid droplets, are found in most cells. The major tissue used for TAG storage is adipose (fat) tissue, whose volume consists mostly of lipid droplet(s). Given the large mass of muscle tissue, there is also a considerable amount of TAGs stored as small lipid droplets in muscle cells. However, skeletal muscle cells don't synthesize fatty acids. They have the genes for fatty acid synthase but do not transcribe it into RNA so no enzyme is made. They can however import them for catabolism. Muscle TAGs can be oxidized for energy, especially during endurance excercise.

TAGs are also stored in the liver in lipid droplets. The liver also assembles lipoproteins, which are released by the liver. Excess TAGs are stored in the liver in various diseases including alcoholism and also in nonalcoholic fatty liver disease (NAFLD), which can progress into nonalcoholic steatohepatitis (NASH), a much worse disease.

WHITE AND BROWN ADIPOSE TISSUES

There are two major forms of triacylglycerol-storing fat tissues, **white adipose tissue (WAT)** and **brown adipose tissue (BAT)**. The more abundant WAT store triacylglycerols in one large lipid droplet in the cell and release fatty acid in processes controlled by the hormones insulin and epinephrine. This simple role can mask the fact that adipose tissue is a major player in the endocrine system and is involved in cell signaling and systematic control of metabolism. Adipose tissue releases the key hormones **leptin** and **adipisin**, which in analogy to the hormones and signaling agents released by immune cells (cytokines, lymphokines), can be called **adipokines**. They also secrete other adipokines including tumor necrosis factor α (TNF-α), adiponectin, and resistin.

In contrast, BAT is specialized not to store and release fatty acids. but rather to oxidize fatty acids in ways that maximize heat production, preventing hypothermia. They have multiple smaller lipid droplets, displaying a larger surface area for lipolysis, the hydrolytic cleavage of fatty acids from the TAGs. A particular mitochondrial protein, uncoupling protein 1 (UCP1), is expressed in brown but not white adipocytes, allowing a "futile" metabolic cycle leading to dissipation of heat instead of ATP synthesis. The relative abundance of white and brown adipocytes is critical in diseases like obesity and type 2 diabetes. BAT tissue is especially important in small animals (and in newborns) for thermoregulation. For smaller organisms, the surface area to volume ratio is greater than the ratio for larger animals, allowing more heat loss. The ratio of surface area AS per volume V for a sphere is given by:

$$\frac{\mathrm{SA_{sphere}}}{\mathrm{V_{sphere}}} = \frac{4\pi r^2}{\left(\frac{4}{3}\right)\pi r^3}$$

Let's assume an average large adipocyte is a sphere of diameter 100 uM. Compare this to a large sphere with a 100 times greater diameter (10,000 uM). The smaller sphere has a 1/100 of the diameter but a surface area/volume ratio 100 times greater than the large sphere.

An intermediate type of fat tissue consists of "bright" adipocytes. White adipocytes can be coaxed to differentiate into bright and brown cells, which could be an obesity treatment.

In this chapter section, we will follow the fate of fatty acids from dietary lipids which are cleaved from TAGs, loaded into chylomicrons, a lipoprotein assembled in the small intestine, secreted into the circulation, and taken up by the liver. The liver can store the incoming fatty acids in TAGs or release them back into the circulation in the form of another lipoprotein, very low-density lipoproteins (VLDL). Circulating VLDL can exchange lipids with other circulating lipoproteins. Lipoproteins deliver fatty acids to cells after interaction with the cell surface of target cells and either cleavage of TAGs by cell membrane-associated enzyme lipase, followed by fatty acid uptake, or by endocytosis of lipoproteins into the cells.

17.1.2: LIPOPROTEINS

Before we look in more detail at the individual steps in lipids processing, let's look at the different lipoproteins, the large vesicular structures that allow the transport of fats, very insoluble molecules, in the circulation. Unlike normal liposomes or vesicles that have a lipid bilayer

surrounding an interior aqueous compartment, lipoproteins have only a single monolayer of phospholipids encapsulating a nonaqueous interior filled with TAGs, cholesterol, and cholesterol esters. The protein part of the lipoprotein consists of one or several proteins bound on the outside of the particle. The proteins help solubilize the lipoprotein, confine its size, and prevent aggregation of the lipoproteins, which would be a health risk. The structure of a typical lipoprotein is shown in Figure 17.1.1.

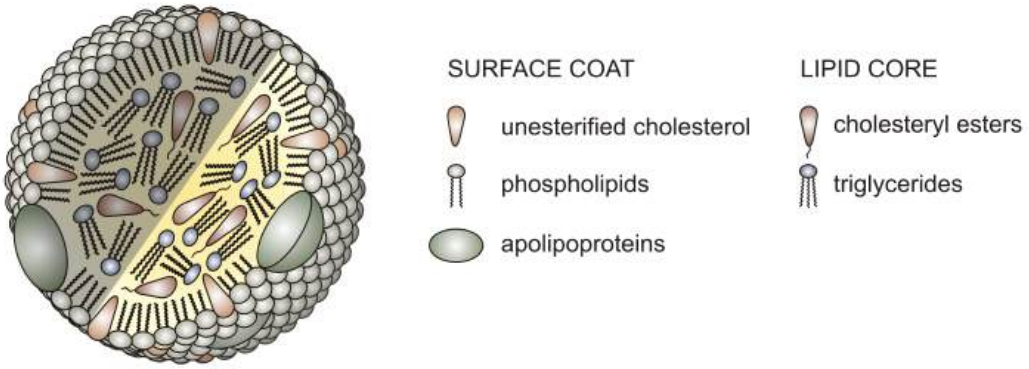

Figure 17.1.1: Lipoprotein particles are composed of a lipid core containing cholesteryl esters and triglycerides, and a surface coat of phospholipids, unesterified cholesterol, and apolipoproteins. (CC BY-SA 3.0 Unported; AntiSense via Wikipedia)

Lipoproteins are classified based on density. The lowest density chylomicrons are the largest with the most lipids (mostly TAGs) in their interior compartment. Very large density lipoproteins (VLDL), intermediate density (IDL), low density (LDL) and high density (HDL) have decreasing size, less encapsulated lipids, and increasing density. The relative sizes are shown in Figure 17.1.2.

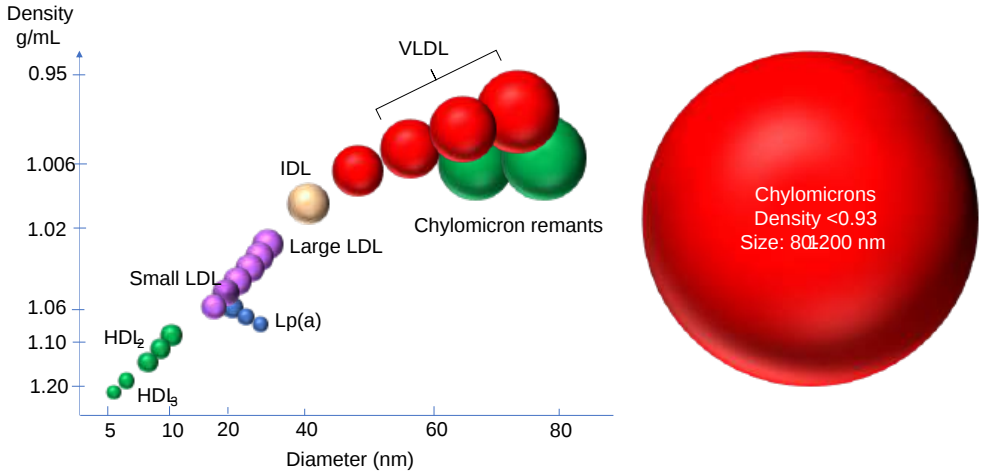

Figure 17.1.2: Modified and used with permission from Endotext.org.

Lipoproteins (except chylomicrons) could be classified as nanoparticles, which typically vary in size from 1-100 nm. Larger lipoproteins as well as chylomicrons form emulsions in the blood, much as milk (also cloudy) is an emulsion of lipid/protein particles. The serum of people with high levels of lipids (hyperlipidemia) can look milky white, especially after eating foods rich in TAGs, when levels of chylomicrons are very high. Figure 17.1.3 shows the blood of a patient with hyperlipidemia after the addition of EDTA (which binds Ca^{2+} and prevents clotting) that has settled (without centrifugation). The milky white plasma on top (lower density) most likely has high concentrations of chylomicrons and/or LDL. The lower layer contains mostly red blood cells.

Figure 17.1.3: This is a standard EDTA (cell count) tube, as may be used to obtain a full blood count or iron studies. The tube was set upright for four hours - it was not centrifuged. (Public Domain; Mark-shea via Wikipedia)

No x-ray structures of lipoproteins are available. However, a structure of a nascent HDL particle (3k2s) has been determined by small-angle neutron scattering. Figure 17.1.4 shows an interactive iCn3D model of it.

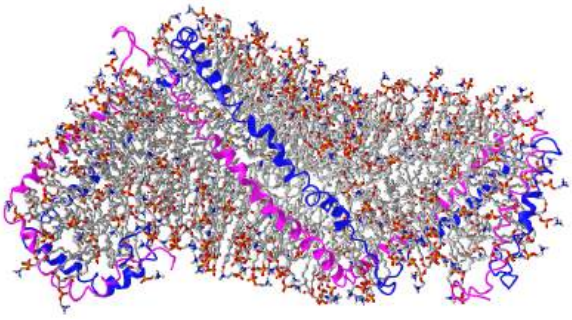

Figure 17.1.4: Nascent HDL (3k2s) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...fF85h11SpeYJg6

The major protein in HDL, a lipoprotein that protects against cardiovascular disease, is apolipoprotein A-I (apoA-I). Figure 17.1.4 shows that it adopts an antiparallel double superhelix as it wraps around the nascent HDL. The more hydrophobic surfaces of apo A-I are oriented inward allowing interactions with hydrophobic lipids in the core. It is probably prototypical for nascent lipoproteins. It will give you an idea of how proteins wrap around the outside of the particle. Mature lipoproteins are most likely spherical. This nascent HDL in the model contains 200 1-palmitoyl-2-oleoyl-sn-glycero-3-phosphocholines (POPC) molecules, 20 cholesterol, and a single copy of apolipoprotein A-I (apoA-I).

Figure 17.1.5 below shows a cartoon image of VLDL, assembled from lipids synthesized/taken up by and released from the liver, and chylomicrons, assembled from dietary fats and released from enterocytes in the small intestine (size of the lipoproteins is not to scale). Note that VLDL has one copy of Apo B-100 while chylomicrons have one copy of Apo B-48.

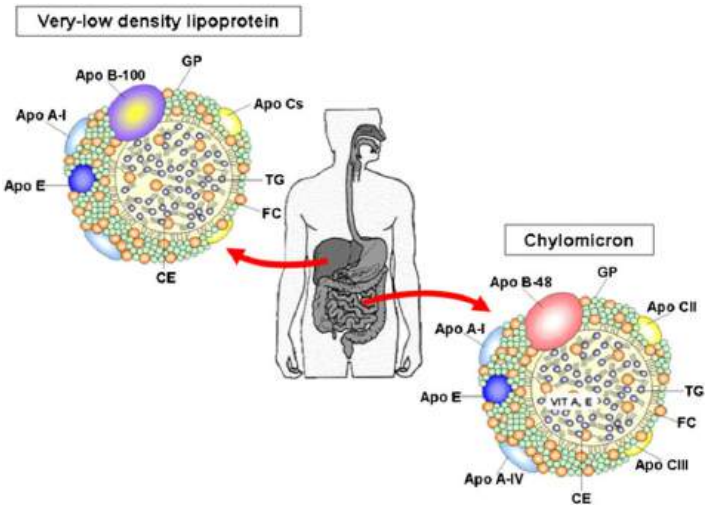

Figure 17.1.5: Emile Levy, Journal of Lipid Research. 56, 945-962, 5/2015. DOI:https://doi.org/10.1194/jlr.R052415. Creative Commons Attribution (CC BY 4.0)

All lipoproteins, except HDL, are members of the **B**eta-lipoprotein family as they contain an apo-**B** protein. The liver synthesizes apo B100, which becomes a permanent part of VLDL (i.e it is not exchangeable with other lipoproteins) and its metabolic derivatives so any lipoprotein containing apo B100 arose from the liver. Other proteins on lipoproteins are exchangeable. In contrast, enterocytes in the small intestine produce apo B-48 (48% the size of apo B100) so this protein marks the lipoproteins (chylomicrons and chylomicron remnants) that were assembled in the small intestine. Apo B100 has over 4500 amino acids and a molecular mass of 555K. The gene for the intestinal apo B48 is the same as for apo B100 except that it has a premature stop codon which leads to the shorter truncated apo B-48.

The apoproteins bind to specific receptors on cells which may allow the uptake of the lipoprotein. For example, the LDL receptors bind to the apo B-100 protein on a region removed from the apo B48 protein of chylomicrons. It also binds ApoE, which is found mostly predominately on HDL and VLDL but some are present in LDL. The LDL receptors have also been called the ApoB/ApoE receptor.

Over 90% of the apoB-containing particles in circulation are LDL. In addition, chylomicrons are present in circulation only after eating. Some apoproteins can act as cofactors and inhibitors for lipoprotein processing.

LIPOPROTEINS AND CARDIOVASCULAR RISK

High concentrations of LDL are associated with increased cardiovascular risk. Chylomicron levels, given their transient and lower concentration levels, do not pose a health risk unless the enzyme required to remove fatty acids from them, lipoprotein lipase, is missing or defective, or if another apoprotein component, apo CII, which mediates the interaction with lipoprotein lipase, is missing. LDL-C (a term used to describe the total cholesterol in LDL particles which is routinely measured in clinical labs) can be lowed by a healthy diet centered around plant food). Drugs like statins, which decrease endogenous cholesterol synthesis, also remarkably lower LDL levels and decrease cardiovascular risk.

However, another protein, lipoprotein, also called Lp(a) or LP little a is an independent cardiovascular risk factor. Its blood concentration is regulated by genetics and not by diet. These particles contain, in addition to apo B100, apo (a), a protein that has a very unique repeating structure (up to 40 times) called a **kringle**, which is also found in some proteins involved in the blood coagulation system. People whose genes encode apo (a) with the fewest number of kringles express lots of that protein and their Lp(a) particles are smaller. This confers a greater cardiovascular risk compared to those expressing proteins with a large number of kringle domains. Figure 17.1.6 (from Amgen) shows models of Lp(a) with different numbers of repeating kringle (kinked) domains.

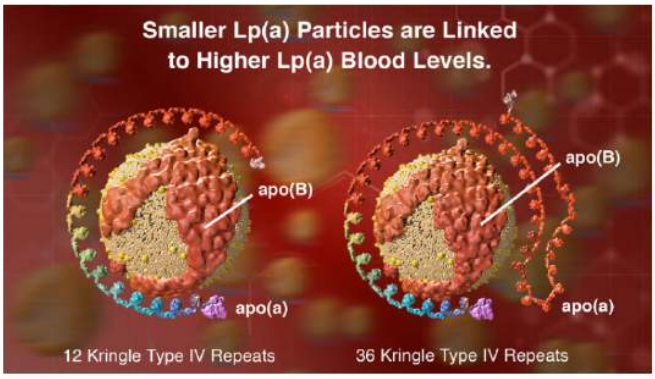

Figure 17.1.6: https://www.amgenscience.com/feature...-lipoproteina/

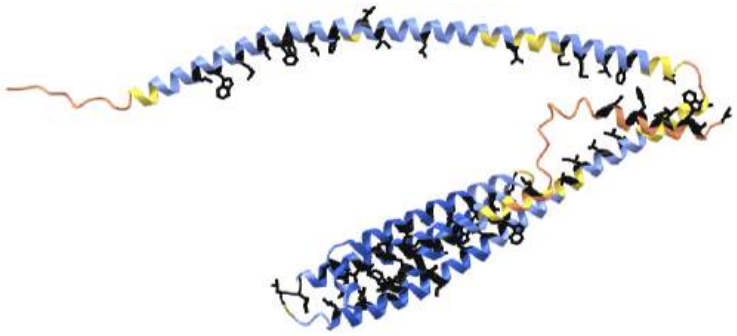
From a biochemical perspective, it is interesting to explore the differences in apolipoprotein binding to a single-leaflet encapsulated lipid nanoparticles compared to the interaction of peripheral and integral membrane proteins with intact bilayers (which we studied in Chapter 12.1). As mentioned above, the more nonpolar surfaces of apo AI in HDL are oriented inward toward the nonpolar lipid core. Presumably, apo B proteins in chylomicrons and LDL also wrap around the entire lipid surface.

The major organizing scaffolding protein of HDL is apoA-I (see iCn3D model above), It presumably plays a role similar to apoB in chylomicrons and LDL, but it is exchangeable. (Note: ApoA-I is also found in chylomicrons.) It is also a cofactor for the enzyme lecithin:cholesterol acyl transferase (LCAT), which effectively converts free cholesterol in the single bilayer into esterified cholesterol esters within HDL. In its apo-form, it also interacts with the cell surface transporter ATP-binding cassette A1 (ABCA1), which plays a role in the assembly of HDL particles. HDL also has apo C and apo E proteins, all of which are exchangeable.

It must be difficult to determine the structure of lipoproteins given their heterogeneity and size. The apoproteins have hydrophobic surfaces that promote self-association and aggregation. Apolipoproteins in the A, C, and E classes have repeating amphiphilic helices which imbed to some degree in the lipid particles. In addition, the proteins have a significant disorder and can adopt many bound conformations.

Figure 17.1.7 shows an interactive iCn3D model of the AlphaFold predicted structure of human ApoA (**P06727**)



NCBI iCn3D Figure 17.1.7: AlphaFold predicted structure of human Apo E (**P02649).** Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...5GtKt3QWaTZ519

The blue cartoon color represents high certainty in the AlphFold predicted structure while yellow to orange represents low certainty. The hydrophobic side chains are shown as sticks and help illustrate the amphiphilic nature of the structure.

Figure 17.1.8 shows an interactive iCn3D model of the AlphaFold predicted structure of human ApoE (**P02649**)

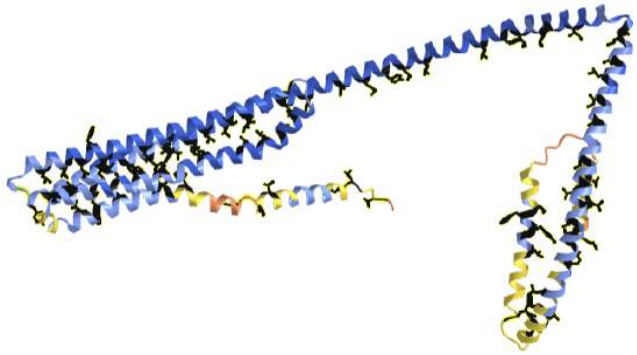


Figure 17.1.8: AlphaFold predicted structure of human Apo A4 (**P02649).** Copyright; author via source). Click the image for a popup or use this external link:https://structure.ncbi.nlm.nih.gov/i...jSw8wSX1MtpcB8

The blue cartoon color represents high certainty in the AlphFold predicted structure while yellow to orange represents low certainty. The hydrophobic side chains are shown as sticks and help illustrate the amphiphilic nature of the structure.

The exchangeable apolipoproteins have similar genetic sequences (four exons and three introns), as well as similar amino acid sequences. They have 11-mer amino acid tandem repeats and some (A-I, A-IV) have 22-mer tandem repeats. These repeats form amphiphilic helices as determined by sequence analysis. The first amino acid in the amphiphilic helix is often positively charged and a negative one is often found in the middle. Proline, a helix breaker, is often, but not always found between the helices.

Figure 17.1.9s shows the primary sequence of apoA-I. An 11-mer repeat is shown in yellow highlight. The other highlighted stretches (different colors) are 22-mer repeats. Note that the repeats are not of identical sequences but rather of sequences that can form amphiphilic helices (i.e. secondary structure repeats).

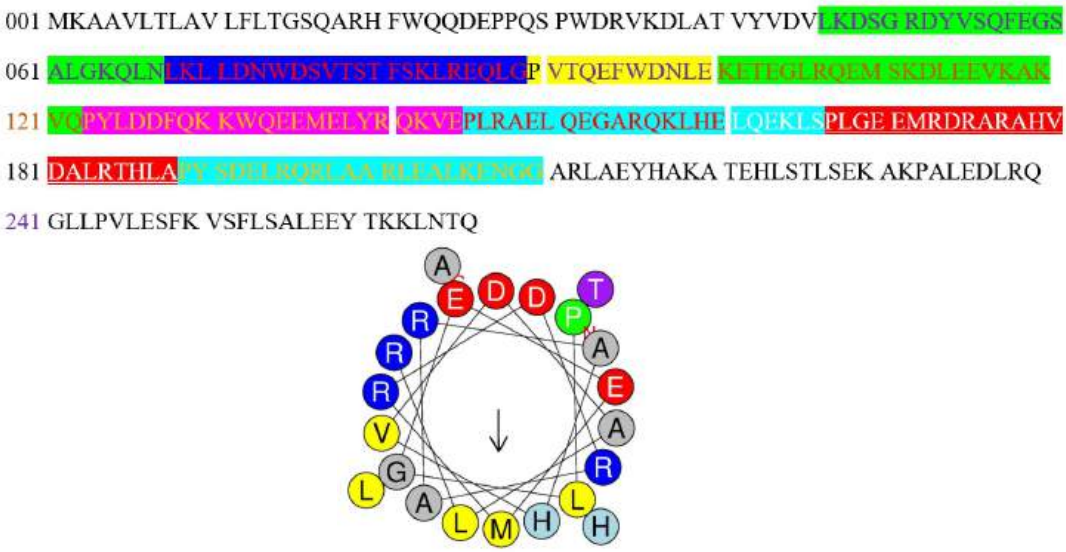

Figure 17.1.9.belows shows the primary sequence of apoA-I. An 11-mer repeat is shown in yellow highlight. The other highlighted stretches (different colors) are 22-mer repeats. Note that the repeats are not of identical sequences but rather of sequences that can form amphiphilic helices (i.e. secondary structure repeats).

The bottom part of Figure 17.1.9 shows a helical wheel projection (using Heliquest) of the red-highlighted 22-mer repeat. The arrow shows the hydrophobic moment with the arrowhead pointing to the more nonpolar face. The particular amphiphilic helix shown may or may not facilitate the binding of the bound conformation of the protein.

It follows that the relative areas of the hydrophilic and hydrophobic faces in the amphipathic helixes influence the lipid-associating properties of the exchangeable apolipoproteins. Another factor that might influence the lipid-binding ability of exchangeable apolipoproteins and which has not been studied in detail so far is the arrangement of tandem repeating amphipathic helixes with respect to one another.

Actual amphiphilic helices would bind to the membrane in a parallel fashion with the nonpolar face anchoring the protein to the lipid surface. Other experimental techniques are used to determine how a peptide or protein that can form amphiphilic helices interact with the

lipid surface. These include site-directed mutagenesis studies coupled with spectroscopic (CD, fluorescence) and binding assay methods (using liposomes).

The properties of a membrane-bound amphiphilic helix are affected by the exact size and distribution of the polar/charged and nonpolar side chains. On binding, they sense or cause membrane curvature, interact with specific lipids, and stabilize specific membrane conformations (such as spherical for lipoproteins). Figure 17.1.10 shows how different proteins with amphiphilic membranes interact with membrane surfaces.

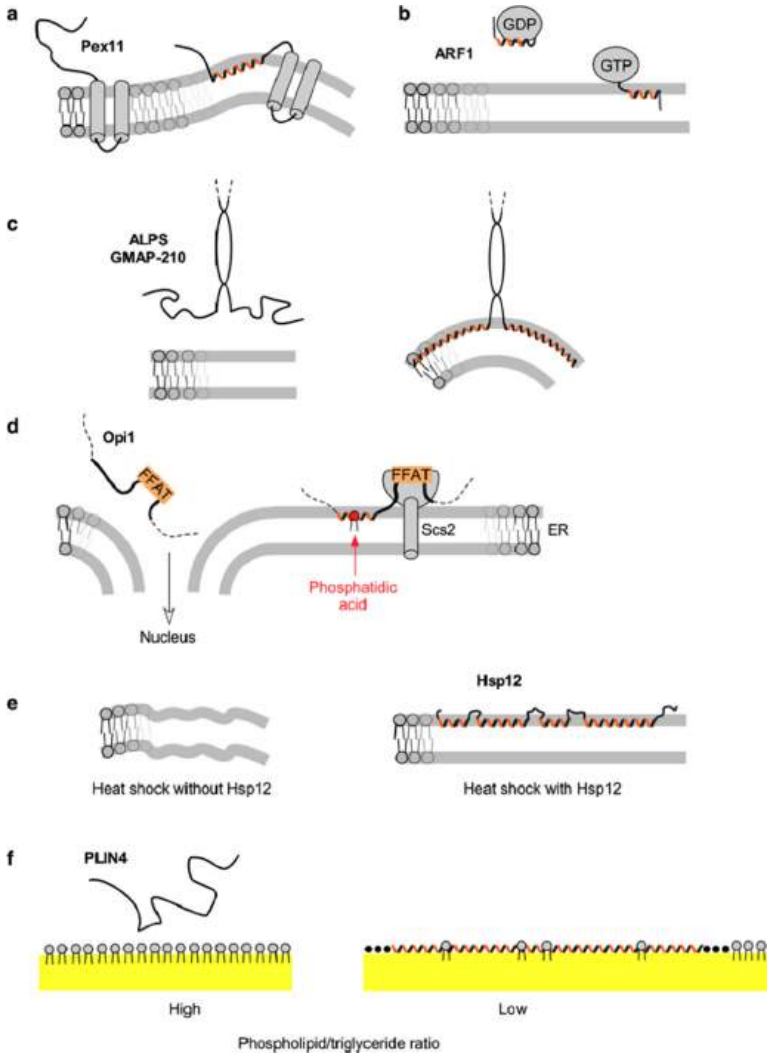

Figure 17.1.10 Interactions of amphiphilic helices with membranes. Manuel Giménez-Andrés et al. Biomolecules. 2018 Sep; 8(3): 45. doi: 10.3390/biom8030045. Creative Commons Attribution (CC BY) license (http://creativecommons.org/licenses/by/4.0/)

A key point to note is the large conformational changes that occur as the protein or parts of it go from the free, more disordered state, to the bound state with lipid-associating amphiphilic helices. The following proteins are depicted in the figure.

a. The peroxisomal membrane protein Pex11 amphiphilic helix distorts the membrane;
b. ARF1 is a small G protein in which only the GTP form localizes and binds through an amphiphilic helix to the membrane;
c. The ALPS motif of the golgin GMAP-210 binds to only highly curved vesicles;
d. The yeast transcriptional repressor Opi1 binds to the endoplasmic reticulum (ER) membrane in part through an amphiphilic helix;
e. The heat shock protein Hsp12 has a long amphiphilic helix which helps stabilize the membrane;
f. The extremely long amphiphilic helix of perilipin 4 coats lipid droplets and stabilizes even if there is a lack of phospholipids.

17.1.3: DIETARY UPTAKE AND RELEASE INTO THE CIRCULATION

Now how are the lipid nanoparticles assembled? We'll start with dietary lipids in the form of TAGs, glycerophospholipids, and cholesterol esters. The figure below shows key steps which are described in Figure 17.1.11

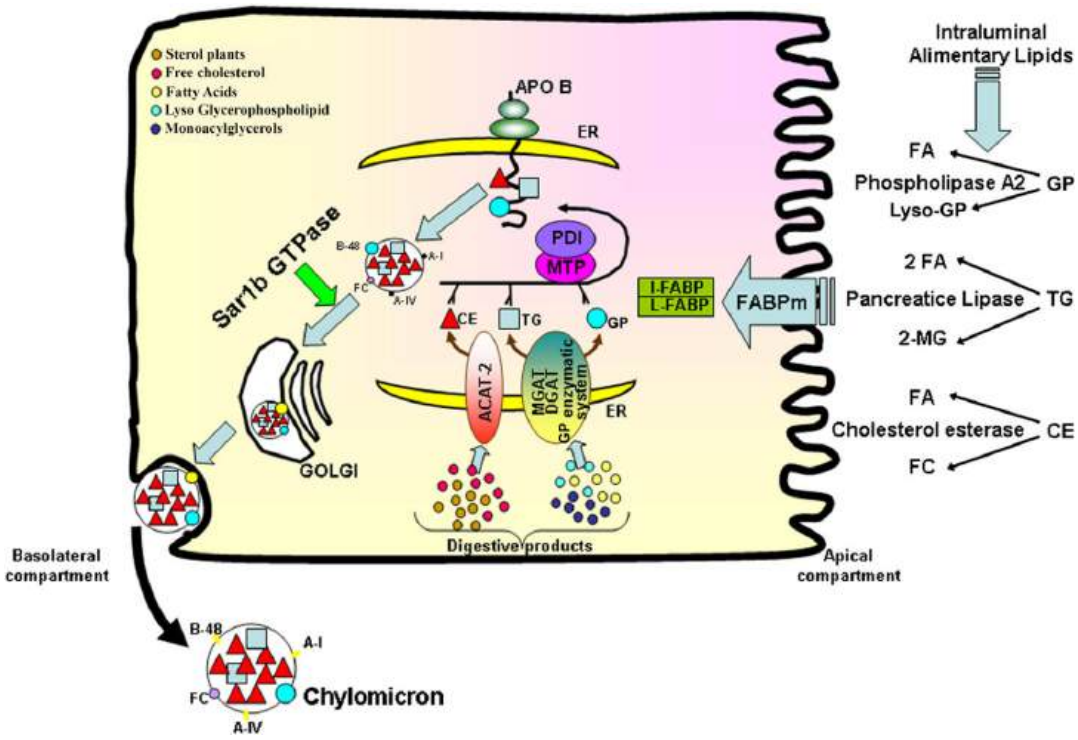

Figure 17.1.11: Emile Levy, Journal of Lipid Research. 56, 945-962, 5/2015. DOI:https://doi.org/10.1194/jlr.R052415. Creative Commons Attribution (CC BY 4.0)

Here are some key steps depicted in the figure:

- hydrolysis (lipolysis) of TAGs by pancreatic lipase, cholesterol esters (CE) by cholesterol esterase, and glycerophospholipids (GP)by phospholipase A2 in the lumen of the intestine. These enzymes interact at the interface of the lipid substrates and aqueous surroundings;
- the resulting products, which include free fatty acids (FA), 2-monoacylglycerol (MG), free cholesterol (FC), and lyso-glycerolphospholipids (lyso-GP), aggregate with the help of bile salts to form emulsions (like oil drops in water), which can be taken up by diffusion or possibly endocytosis when present in high amounts. Alternatively, membrane transporters (like FABPs and other proteins) can move them into the cell by facilitated diffusion;
- cytoplasmic transporters like fatty acid binding proteins move the lipolysis product to the ER where free fatty acids are reesterified. The enzymes involved include mono- and diacylglycerol acyltransferases (MGAT, DGAT) and sterol O-acyltransferase 2, also known as acyl-coenzyme A:cholesterol acyltransferase (ACAT-2). Multiple enzymes are involved in the resynthesis of glycerophospholipids);
- Apo B-48 is synthesized by ribosomes bound to the ER and interacts with a heterodimer of **microsomal triglyceride transfer protein large subunit two (MTP)** and protein disulfide isomerase (PDI). This facilitates the folding of apo B48 and loading of lipids using MTP into pre-chylomicrons;
- pre-chylomicron vesicles move to the Golgi with the help of Sar1b, a small G-protein (and GTPase) where the particle assembles to the full chylomicron, which is released from the cells as the mature large lipid nanoparticle.

An intriguing feature of lipases is that they work at the interface between the aqueous and nonaqueous (in this case lipid nanoparticle) environments. Let's briefly consider the mechanism of hydrolysis of TAGs by equine pancreatic mechanism. This enzyme utilizes the same mechanism we have seen earlier for the hydrolysis of a peptide bond by serine proteases. A catalytic triad of Asp 176, His 263 and Ser 152 as a nucleophilic catalyst is shown in the partial reaction displayed in Figure 17.1.12.

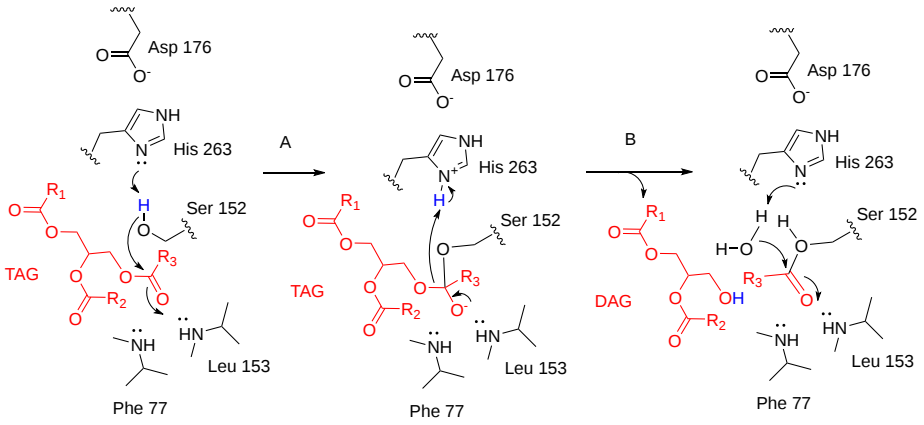

Figure 17.1.12

An acyl-Ser intermediate forms in step B (above), after the collapse of an oxyanion intermediate in step A, to form the product diacylglycerol. In the second half of the reaction (not shown completely), water, in a hydrolysis reaction, cleaves the acyl-Ser intermediate to reform the active enzyme as it releases the free fatty acid, R_3CO_2H. Other lipases also employ the same catalytic triad.

Figure 17.1.13 shows an expanded diagram showing the flow and fate of lipoproteins.

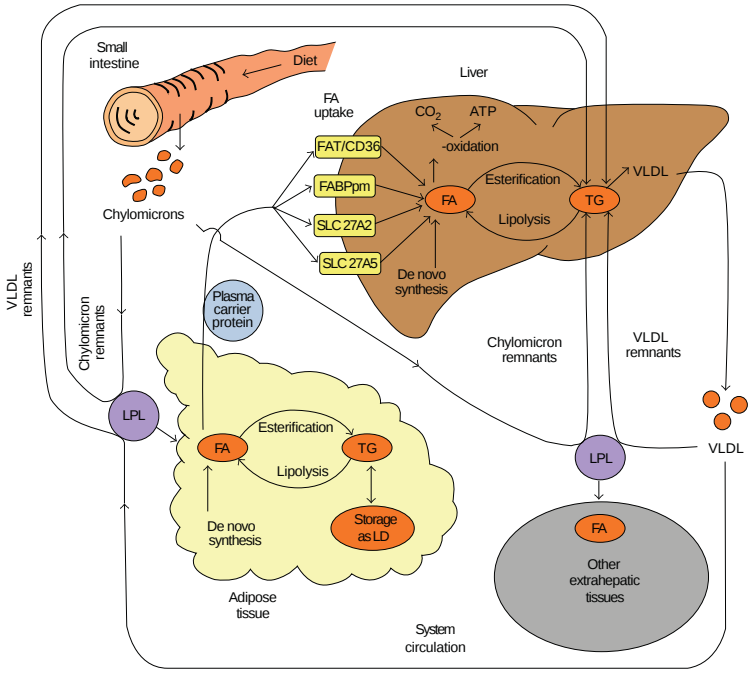

Figure 17.1.13: Merilin Al Sharif et al. PPAR Research. Volume 2014, Article ID 432647, http://dx.doi.org/10.1155/2014/432647. Creative Commons Attribution License.

Chylomicrons interact with lipoprotein lipase (LPL), which also uses an Asp-His-Ser catalytic triad, to cleave fatty acid esters, which allows the delivery of free fatty acids to adipose cells. The adipocytes can also undergo de novo fatty acid synthesis. Fatty acids (FA) can also be produced by lipase-mediated lipolysis of stored TGs. Any of these free fatty acids (FA) in the adipocyte has two fates. They can be reesterified to glycerol to form TAGs (TG in the figure) or be exported from the cell and bind to a plasma carrier protein and transported to the liver, where it can be taken up by a variety of membrane proteins importers shown in the figure in yellow boxes. There, as in adipose cells, they can be reesterified to form TAG stores, which can then be packaged into VLDL particles for export. The fatty acid delivered (or synthesized) could also be used for ATP production through the citric acid cycle and oxidative phosphorylation.

VLDL in circulation can undergo lipolysis by lipoprotein lipase to produce fatty acids for uptake in "extrahepatic" tissue (bottom right of the diagram). As fats are removed from VLDL, their density increases as it forms IDL and LDL, which could be considered VLDL "remnants". VLDL is very enriched in TAGs, but after metabolic processing, the resulting LDL is depleted in TAGs and enriched in cholesterol/cholesterol esters. LDL (not shown in the above figure) can be taken up (endocytosed) by the liver and other cells after binding to LDL receptors, which recognize apo-B100 and other apoproteins. This allows the delivery of predominately cholesterol and cholesterol esters to tissues.

How do adipocytes and hepatocytes determine if free fatty acids should be esterifed for storage or released for energy use by other tissue? We'll discuss that in a subsequent section but the short answer is that in healthy fasting and exercise states, hormones (glucagon, epinephrine) will activate lipolysis in the liver and adipose cells, while in the fed state, insulin will promote storage of fatty acids as triacylglycerols.

Adipose cells don't assemble and release lipoproteins. Instead they release free fatty acids in the circulation which are carried by albumin, the major serum/plasma protein in the blood. The iCn3D Figure 17.1.14 shows an interactive iCn3D model of the complex of human serum albumin (HSA) binding seven 20:4$^{\Delta 5,8,11,14}$ - arachidonic acids (1gnj).

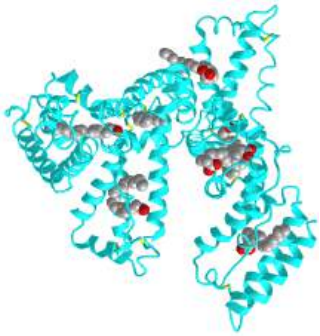

Figure 17.1.14 Human Serum Albumin/Arachidonic Acid complex (1gnj). Click the figure for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?WL7BxK4B23m2p3Z19 (Copyright; author via source)

Given the multiple binding sites for fatty acids in albumin, it should come as no surprise that albumin also binds a host of small drugs, including medicinal drugs and toxins such as warfarin (blood thinner), diazepam, ibuprofen, indomethacin, and amantadine. These appear to bind preferentially at two major drug binding sites. This binding is probably helpful in delivering drugs through the circulation but potentially not useful if they aren't delivered to appropriate target tissue.

We discussed the structure of micelles which are spherical assemblies of single-chain amphiphiles that act as detergents. Oil from your clothes can enter the nonpolar interior of the detergent micelle and effectively solubilize the nonpolar molecule in the micelle, which are effectively nanoparticles with a diameter of 5-15 nm. You should hence not be surprised to discover that lipoproteins can also carry fat-soluble vitamins, steroid-like endocrine-disrupting substances, and drugs.

17.1.4: LIPOPROTEIN LIPASE

The enzyme that breaks now TAGs in circulating chylomicrons and VLDL is **lipoprotein lipase (LPL)**. It is a soluble protein secreted by adipocytes and muscle cells but is made by many cell types. It works at the luminal side of blood vessel endothelial cells and is recruited to that membrane surface by binding to the **glycosylphosphatidylinositol-anchored high-density lipoprotein-binding protein 1 (GPIHBP1)** as well as the proteoglycan heparan sulfate at the cell surface.

What is so interesting is that GPIHBP1 is only synthesized by endothelial cells. When lipoprotein lipase is secreted from cells, it binds to the extracellular matrix heparan sulfate but dissociates on the cleavage of heparan sulfate by heparinases. GPIHBP1 is highly acidic with an intrinsically disordered N-terminal domain containing a sulfated tyrosine and is highly enriched in glutamates and aspartates, which are often sequential in the sequence. Here is the single-letter sequence for amino acids 25-50 of the human version of GPIHBP1: EEEEEDEDHGPDDYDEEDEDEVEEEE. This sequence would have similar electrostatic and binding properties to the highly negatively charged heparan sulfate to which it also binds.

LPL also binds Ca^{2+} which stabilizes the active dimeric form of the protein. Its enzymatic activity is activated by apoC-II. Like pancreatic lipase, it employs a Ser-132, Asp-156, and His-241 triad in its hydrolytic action on TAGs/

Figure 17.1.15l below shows an interactive iCn3D model of LPL in complex with GPIHBP1, shown in brown (6E7K). The calcium ion is shown (grey spacefill) as well as the catalytic triad (labeled, sticks, CPK colors). The highly negatively charged stretch of amino acids in GPIHBP1 was not present in the crystal structure.

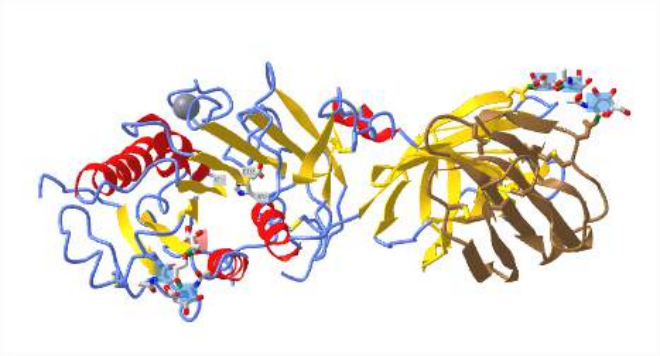

Figure 17.1.15: Lipoprotein Lipase/GPIHBP1 Complex (6E7K)). The calcium ion is shown (grey spacefill) as well as the catalytic triad (labeled, sticks, atom colors). The HPIHBP1 protein is shown in brown. The highly negatively charged stretch of amino acids in GPIHBP1 was not present in the crystal structure. Creative Commons Attribution (CC BY) license (https://creativecommons.org/licenses/by/4.0/).

17.1.5: LDL: RECEPTOR AND UPTAKE

Lipoproteins are taken up into cells through receptor-mediated processes. Let's focus generically on the LDL receptor, the major carrier of cholesterol, given its role in cardiovascular disease. It is found in the cell membranes in most tissues. It is has many domain repeats, as illustrated in the Figure 17.1.16 calculated by SMART.

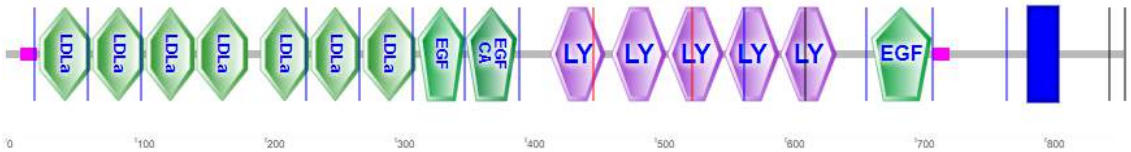

Figure 17.1.16: Domain strucuture of the LDL receptor

They include the N-terminal region cysteine-rich LDLa domains, which bind LDL, epidermal growth factor domains, LY (or LDLb) domains, and a transmembrane domain (blue rectangle).

Figure 17.1.17 shows an interactive iCn3D model of the extracellular domain of the LDL receptor (1n7d).

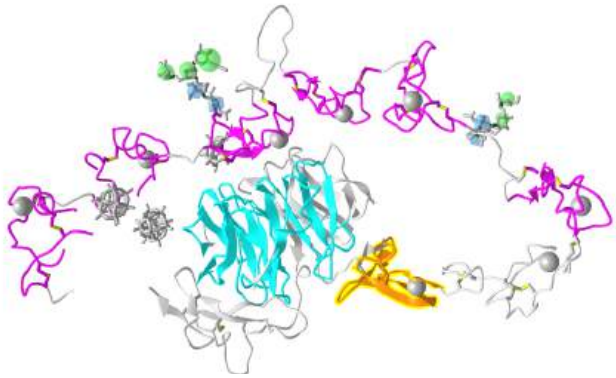

Figure 17.1.17: Click the figure for a popup model or use this external link: https://structure.ncbi.nlm.nih.gov/i...aT7M6ti5iDAbj8 (Copyright; author via source)

Four tandem LY (LDLb) domains are shown in cyan, LDLa domains are shown in magenta and the EGF domain is shown in dark orange. Glycans are shown in symbolic nomenclature for glycans. Zoom into the structure to see the two disulfide bonds in each LDLa domain as well as the Ca^{2+} ions that stabilize the domains.

LDL binds its receptor at a broad binding interface with multiple LDLa domains. This may account for the fact the lipid nanoparticles with apo B100 or apo E can bind to it. The binding triggers a series of signaling events that lead to internalization by endocytosis of the receptor in pits coated with the protein clathrin. These eventually fuse with lysosomes where they are degraded and cholesterol delivered to the cell. The steps are described in Figure 17.1.18.

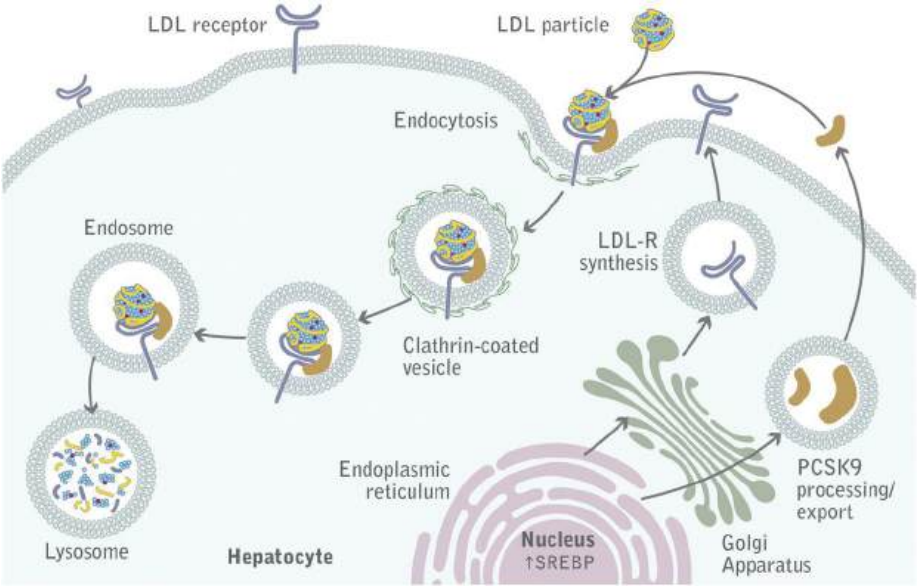

Figure 17.1.18 Gilles Lambert et al. J. Lipid Research, 53, 2515-2524 (2012) DOI:https://doi.org/10.1194/jlr.R026658. Creative Commons Attribution (CC BY 4.0)

The LDL receptor survives lysosomal degradation and along with newly made receptors is delivered to the plasma membrane continually. A key protein, **proprotein convertase subtilisin kexin type 9 (PCSK9)**, a serine protease secreted by the liver, promotes enzymatic degradation of the receptor and prevents its recycling to the membrane. It also binds to VLDLR and apolipoprotein E receptors and promotes their degradation as well. Its action reduces LDL clearance from the blood, increasing cardiovascular risk, so inhibitors of its action might be potent drugs to decrease circulating LDL.

The LDL receptor is just one member of the LDL receptor family. Other members of the family are illustrated in Figure 17.1.19.

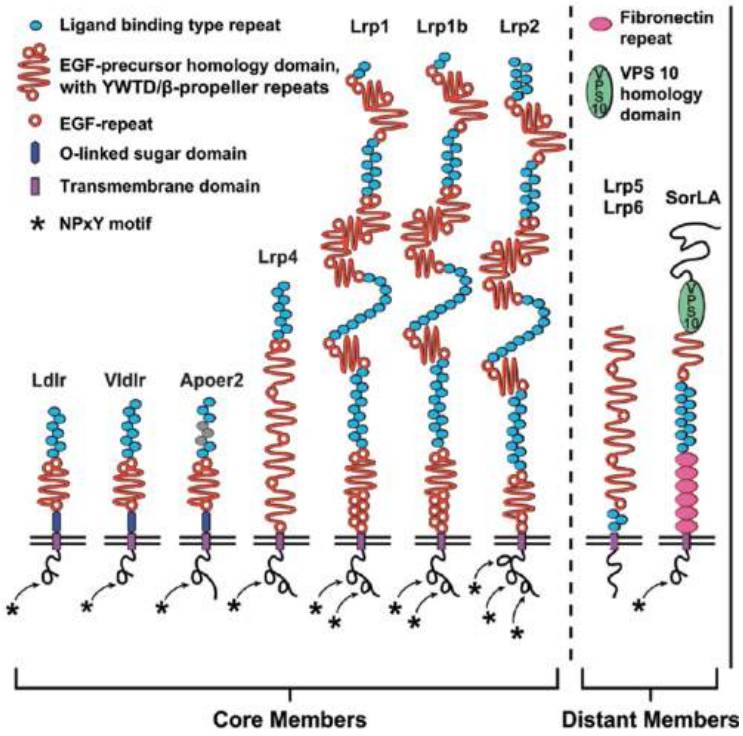

Figure 17.1.19: LDL Receptor Family. Adapted from Theresa Pohlkamp et al. Front. Mol. Neurosci., 01 March 2017 | https://doi.org/10.3389/fnmol.2017.00054. Creative Commons Attribution License (CC BY)

These include the LDL receptor (abbreviated Ldlr in Figure 17.1.17, as well as the VLDL receptor (Vldlr), apolipoprotein E2 receptor (Apoe2), and LDL receptor-related proteins (Lrp)1-4. These also have a NPxY-motif (asterisk in the cytoplasmic domain) and a YWTD/β-propeller domain. Given the similarity in domain structure for the LDL family of receptors, the conformational flexibility of the apolipoproteins (at least free in solution), and similar structures for the exchangeable apolipoproteins, it shouldn't be surprising that the LDL receptor would interact with different classes of lipoproteins, albeit with different affinities.

As mentioned previously, apoE is found most abundantly on HDL and VLDL/chylomicrons and their remnants. It serves as a ligand that binds to members of the LDL receptors family (remember that LDL generally binds the LDL receptor through apo B100).

APO E AND ALZHEIMER

Apolipoprotein E has three major variants (alleles) named ε2, ε3, and ε4 (also called ApoE2, 3, and 4). ApoE3 is the most prevalent. ApoE4 is found in only 15% of people but more than 50% with Alzheimer's Disease (AD), so it's a risk factor for this disease. AD affects the brain, which also contains up to 30% of the cholesterol in the body, so aberrations to cholesterol transport and uptake in the brain are not unexpected in neurodegenerative diseases like AD.

ApoE is secreted by brain microglia (immune) cells and astrocytes (specialized glial cells). It assembles lipids into lipoproteins (HDL-like) and becomes the major vehicle for binding to and importing into neurons in a process initiated by the apoE receptor. The major apoE receptor for clearance of lipoproteins in the brain is sortilin (SorLA in Figure 17.1.17).

AD is characterized by the accumulation of a toxic amyloid prion protein called amyloid beta (Aβ). It is derived from selective but abnormal proteolysis of the neural integral membrane protein amyloid precursor protein (APP). Aβ aggregates to form insoluble neurotoxic extracellular Aβ amyloid plaques. The process in normal and diseased cells is shown in Figure 17.1.20.

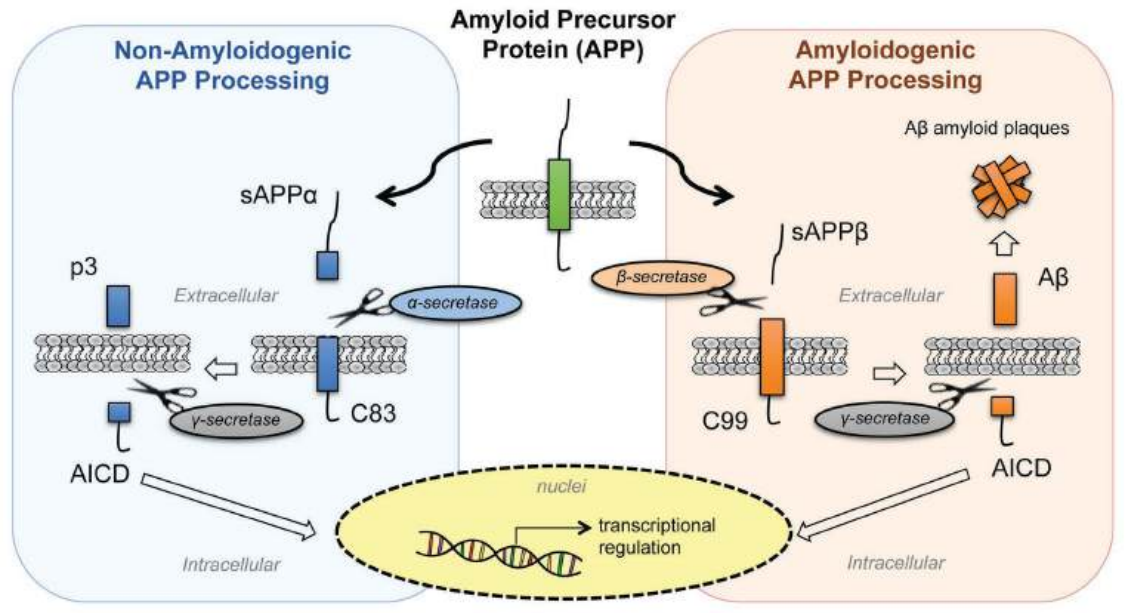

Figure 17.1.20 Processing of amyloid precursor protein (APP). Emma Ristori et al. Front. Physiol., 27 August 2020 | https://doi.org/10.3389/fphys.2020.01056. Creative Commons Attribution License (CC BY).

The figure shows normal (left) and aberrant processing of APP and the family of proteases (secretases) involved. While the LDLR doesn't appear to bind to APP or influence its proteolytic processing, it does bind Aβ. LRP1 is much bigger than LDLR, binds a multitude of ligands, and can be cleaved with the same enzymes as APP. Its expressed in the liver and especially in the brain and can regulate the removal of Aβ.

Immune cells in the brain, called microglial, remove Aβ plaques (which are extracellular) by phagocytosis. ApoE4 increases the inflammatory response (as measured by cytokine release) of the microglia (a good thing if the responses prevents infection or rids Aβ plaques) but also inhibits their ability to phagocytose the Aβ plaques and their metabolic activity.

An additional note: Having one allele ApoE4 allele appears to increase the risk of severe COVID-19 five times while being homozygous for E4 leads to a 17-fold increased risk of severe disease.

17.1.6: SCAVENGER RECEPTORS

Patients with homozygous familial hypercholesterolemia (FH) have very high levels of LDL derived from defects in binding and update. Patients display fatty acids streaks under vessel endothelial cells which morph into calcified plaques and lesions filled with fat. Monocytes/macrophages, which migrate to sites of vascular injury, take up LDL and eventually differentiate into foam cells filled with lipids. Somehow, they have receptors that can bind and internalize LDL when the "normal" LDL receptor can't. Brown and Goldstein found that a specific chemical modification of LDL, acetylation, was necessary for the rapid uptake of "modified" LDL into macrophage receptors. These receptors are now called scavenger receptors (SRs).

There is a large family of scavenger receptors. It consists of classes A-J proteins that share functional but not sequence homology. They are found on macrophages and endothelium. They bind to and help remove "damage" signals including damage-associated molecular patterns (DAMPs) and chemical species chemically modified by reactive oxygen species. The ligands are often polyanions, end-stage glycans, and extracellular matrix proteins. One such example is oxidized-LDL (produced in vivo or by chemical oxidative modification with malondialdehyde), which binds to the same scavenger receptor, **SR-A1**, also called **Macrophage scavenger receptor type I**, as acetylated-LDL. Figure 17.1.21 shows the domain structure of the SR family.

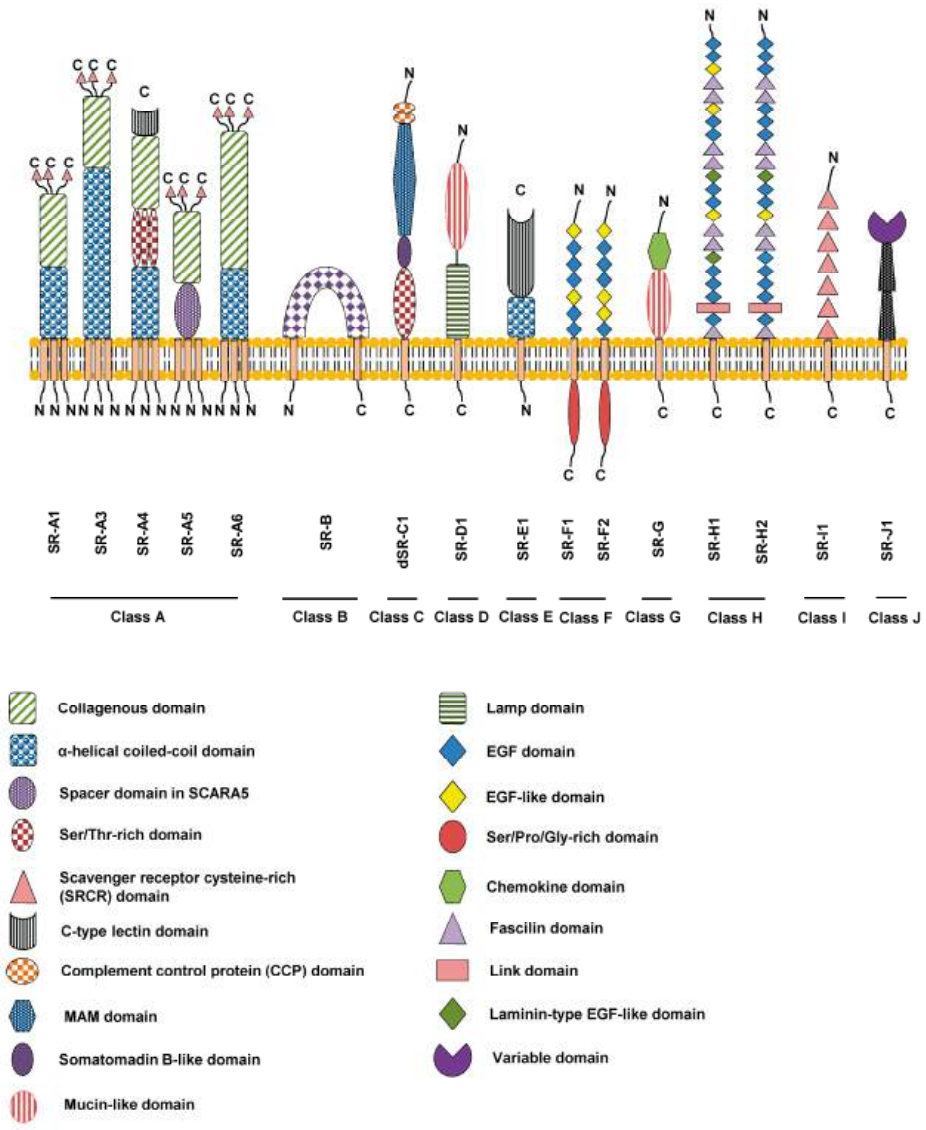

Figure 17.1.21: Domain Structure of the Scavenger Receptor Family. Izma Abdul Zani et al. Cells 2015, 4(2), 178-201; https://doi.org/10.3390/cells4020178. Creative Commons Attribution license (http://creativecommons.org/licenses/by/4.0/)

SR-A1/MSR1 not only binds acetylated and oxidized LDL but also β-amyloid (42), heat shock proteins (43), and PAMPs from some bacteria and viruses.

It's very difficult, given the ever-increasing amount of "omic" data (genomic, proteomic, lipidomics, interactomics, metabolomics), for readers and authors alike, to conceptualize all of the possible combinations of interactions among biological molecules. For visual learners and perhaps everyone else, it's extremely useful to portray information on structures and interactions visually. An example using STRING, a database of known and predicted protein interactions, for the domain structure and protein:protein interactions of SR-A1/MSR1, is shown in Figure 17.1.22.

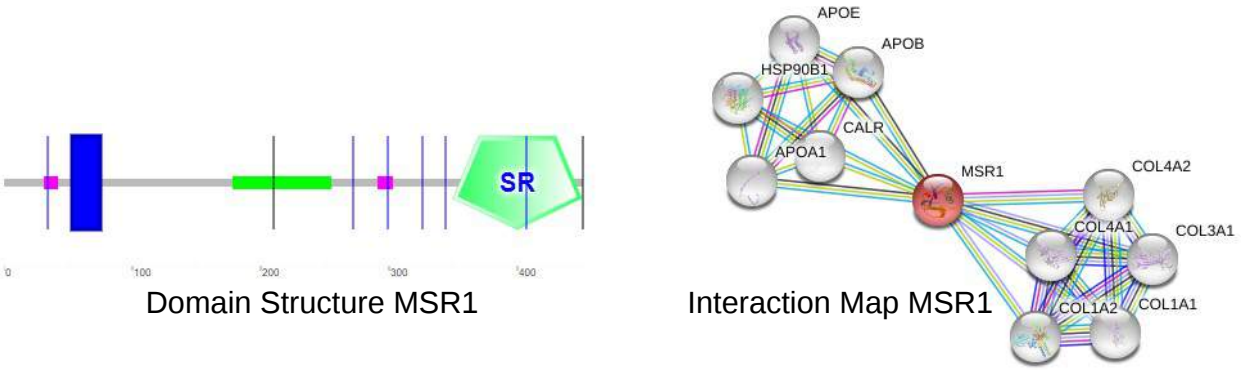

Figure 17.1.22 Visualization of Domain Sructure and Interaction Map of Macrophage Scavenger Receptor 1

Note the interactions with apolipoproteins, apoB, apoE, and apoA1. The right hand side of the figure also shows interactions with **collagen alpha-2(IV) chain** (COL4A2), which is found in the extracellular matrix.

17.1.7: HDL METABOLISM: THE GOOD CHOLESTEROL

High levels of LDL (and Lp(a)) pose a cardiovascular risk. In contrast, high levels of HDL and apo A-I are cardioprotective. HDL is involved in "reverse" cholesterol transport as it is taken up by the liver and sent to the intestines for elimination from the body. We have shown earlier in Figure 2 that HDL exists as many variants, reflecting the assembly and remodeling of HDL by enzymes and lipid transfer proteins. Figure 17.1.23 shows the lifecycle of HDL.

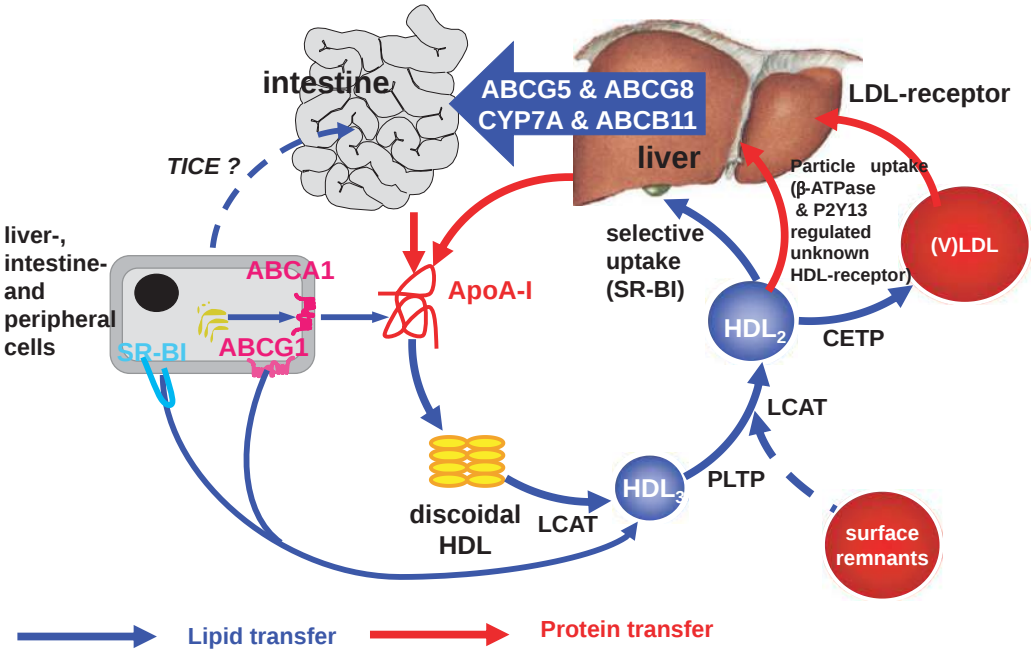

Figure 17.1.23 Arnold von Eckardstein. Tachometer for Reverse Cholesterol Transport? August 2012. Journal of the American Heart Association 1(4):e003723. DOI: 10.1161/JAHA.112.003723. License CC BY 2.5/. Open Access article under the terms of the creative Commons Attribution Noncommercial License

Secreted apo A-1 accretes lipids in the circulation through the transport and delivery of phospholipids and cholesterol from cell membranes by the ATP-binding cassette transporters (ABC) A1 and G1. Another protein, the **scavenger receptor BI (SR-BI)**, a polytopic integral membrane protein, is also involved. It acts as a receptor for a variety of "lipid" ligands including phospholipids, cholesterol esters, and phosphatidylserine (an outer membrane marker for cell apoptosis) as well as lipoproteins such as HDL.

Other proteins are involved as well in both the assembly but especially in the remodeling of HDL. The lipolytic enzyme lecithin-cholesterol acyltransferase (LCAT) removes a fatty acid from phospholipids and adds it to free cholesterol in the HDL to form cholesterol esters. Two major lipid transfer proteins, **phospholipid transfer protein (PLTP)** and **cholesterol ester transfer protein (CETP)**, move lipids between

HDLs and other lipoproteins. Cholesterol ester transport protein is made and secreted from the liver. It appears to exchange cholesterol esters from HDL for the return of TAGs from VLDL. Other enzymes (lipoprotein lipase and hepatic lipase are also involved in forming free fatty acids.

In the final step, HDL can deliver cholesterol ester and cholesterol to the liver through binding to liver scavenger receptor BI (SR-BI) mediated by apo A-I. The protein is expressed by the liver, adrenal gland, endothelial cells, macrophages, and many other tissues. It appears that HDL is **not** primarily taken up by the liver by endocytosis. In contrast, LDL is taken up by endocytosis mediated by the LDL receptor. SR-BI facilitates the transfer of cholesterol esters from bound HDL to the liver cell.

HDL AND CARDIOVASCULAR RISK

Unlike the widespread use of statins, which reduce LDL-C concentrations and clinically reduce cardiovascular disease risk, drugs (fibrates, niacin, inhibitors of cholesterol ester transfer protein - CETP), which raise HDL levels, don't seem to lead to significant decreases in cardiovascular risk. The cholesterol delivered in excess to macrophages can lead to the formation of foam cells under the endothelial layer. Foam cells are proinflammatory and convert in time to cholesterol plaques. In contrast, HDL-C does appear to have this direct atherogenic effect.

17.2: OXIDATION OF FATTY ACIDS

17.2.1: INTRODUCTION

Fatty acids, esterified to glycerol in triacylglycerols, are the major source of stored energy in organisms. As we burn fossil fuels to produce energy to drive our society, so can we "burn" fatty acids to indirectly produce for heat, ATP to drive biosynthetic reactions, and to do work. As discussed in an earlier chapter, fatty acids are highly reduced so their oxidation by dioxygen is highly favored both enthalpically (exothermic reaction) and entropically. Of course, the biological oxidation reactions occur in a stepwise fashion using not O_2 directly, but rather less potent oxidizing agents like NAD^+ and FAD. We'll focus first on fatty acid oxidation in animals (humans).

As we discussed in the previous section, fatty acids released from triglyceride stores on signaling by epinephrine and glucagon in exercise and between meals are used for energy when glycogen stores are low and without breaking down protein in muscles to produce energy. Some fatty acids are broken in the normal process of membrane turnover and removal of xenobiotic lipids.

Most fatty acids are oxidized in the mitochondria, where the oxidation reaction occurs at the beta-carbon of the acyl chain, as shown in Figure 17.2.1.

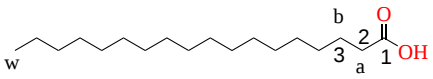

Figure 17.2.1: α and β carbons of fatty acids

This pathway is called **β-oxidation**. Fatty acids are oxidized in a step-wise fashion by this pathway. In each repetitive cycle of this pathway, acetyl-CoA and one CO_2 are released. In addition, oxidation can occur at both the alpha- and beta carbons when oxidized in an organelle called the peroxisome. The **α-oxidation** pathway is used for fatty acid branched at the beta carbon 3 releasing one CO_2 until the beta-oxidation pathway can be used. The peroxisome degrades fatty acids that can't be oxidized in the mitochondria. These include very long-chain fatty acids (VLCFAs) like 24:0 and 26:0, and in addition, branched-chain fatty acids (BRCHAs) including some fatty acids from dietary sources such as pristanic acid (an odd-chain 15:0 fatty acid methylated at carbons 2, 6, 10, and 14). The α-oxidation pathway can't be used to completely oxidized fatty acids in the peroxisome. At some point in the oxidative stepwise pathway, the resulting shorter fatty acids are exported to the mitochondria for β-oxidation. Also, enzymes in the endoplasmic reticulum have the **ω-oxidization** pathway which oxidizes fatty acids at the omega or terminal carbon. The enzyme used is the monooxygenase cytochrome P_{450} which uses one oxygen from O_2 to hydroxylate the ω-carbon.

PEROXISOMES - AN UNDERAPPRECIATED ORGANELLE

These organelles, initially called microbodies, are vital to cellular metabolism and health. In people with Zellweger syndrome spectrum, there is a severe disorder in the formation of peroxisomes, which is often lethal. They are important metabolically in lipid metabolism, synthesis of myelin sheath lipids, and metabolism of reactive oxygen species like peroxides. The enzymes catalase and urate oxidase are found in such high concentrations they often form crystal "bodies" in the matrix of the peroxisome. Additional roles include responses to pathogens and viruses. Effectively they are a protective organelle.

In contrast to mitochondria, peroxisomes, like most other organelles, have a single bilayer and no DNA, from which transcription of RNA and translation of proteins occur. All proteins are hence imported from the cytoplasm after synthesis on free ribosomes. Imported proteins have a peroxisome targeting sequence (PTS) of serine-lysine and leucine (SKL) near their C-terminus which facilitates the binding of the proteins to a PTS receptor in the peroxisome membrane. These organelles oxidize very long-chain fatty acids (VLFA), make and break down hydrogen peroxide (hence the name), and also synthesize plasmalogens. The enzymes involved in the stepwise cycle of reactions in the peroxisome β-oxidation pathway use enzymes different from those used in the mitochondria for β-oxidation.

For those more inclined towards chemistry than biology, yet another organelle with its structures and function may seem like one too many. However, this less-discussed organelle is critically important in its own right. Figure 17.2.2 shows features of peroxisomes and their proteins.

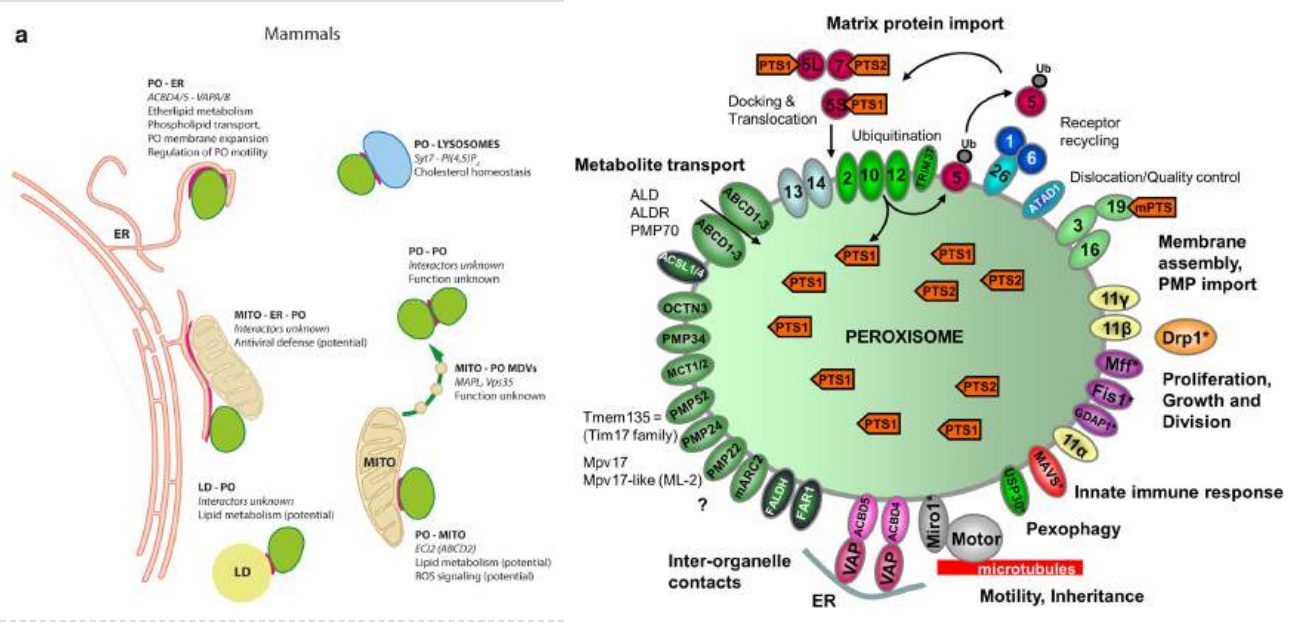

Figure 17.2.2: Features of peroxisomes and their proteins. Islinger, M., Voelkl, A., Fahimi, H.D. *et al.* The peroxisome: an update on mysteries 2.0. *Histochem Cell Biol* **150,** 443–471 (2018). https://doi.org/10.1007/s00418-018-1722-5. Creative Commons Attribution 4.0 International License (http://creativecommons.org/licenses/by/4.0/)

One interesting feature is its relationship with different organelles in cells, as shown in the left panel of Figure 2. Some proteins involved in organelle functions are shown as well (right panel).

The peroxisome (PO, green) has binding interactions (red interfaces) with the endoplasmic reticulum (ER) lysosomes, mitochondria, lipid droplets (a pseudo-organelle), and also itself (left figure). Some of the key membrane proteins (which we have discussed previously) involved in peroxisome function include the ABC transporter proteins ABCD1-3 for fatty acids transport, OCTN3 for organic and cation/carnitine transport, and MCT1/2 for monocarboxylate transport. In addition, peroxisomes have receptors for protein import mediated by PTSs and for peroxisome movement along microtubules in the cell.

17.2.2: MITOCHONDRIAL B-OXIDATION

Mitochondrial β-oxidation in muscle generates acetyl-CoA, which enters the citric acid cycle for subsequent production of ATP through mitochondrial electron transport and oxidative phosphorylation. In the liver, the generated acetyl-CoA is used for ketone body production under fasting states. Figure 17.2.3 shows the β-oxidation pathway for palmitic acid (16:0), a saturated fatty acid, starting with its import from the cytoplasm.

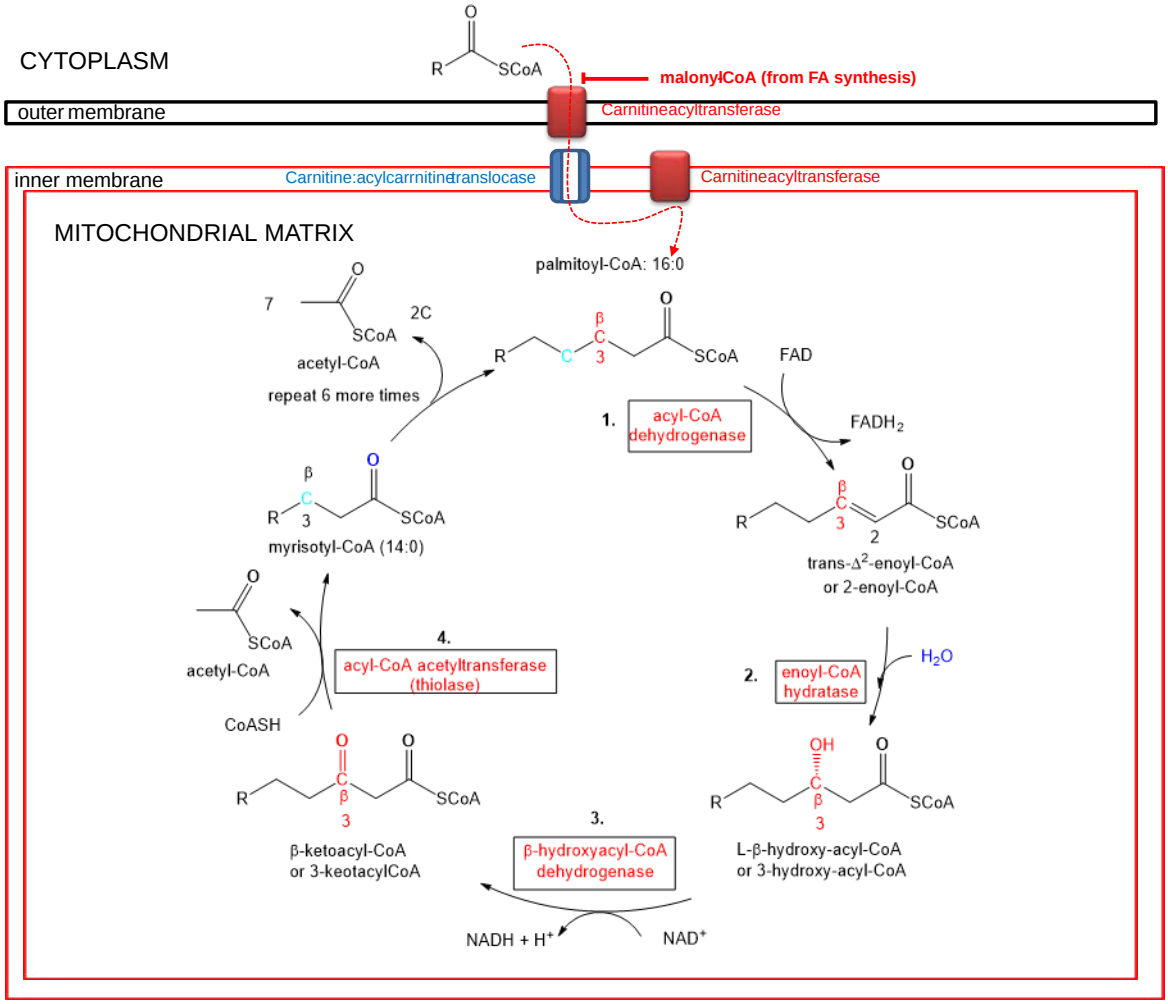

Figure 17.2.3: Mitochondrial β-oxidation of palmitic acid (16:0)

The pathway involved cyclic removal of 2C unit until 16:0 is cleaved 7 times producing 8 2C acetyl-CoAs. The net chemical equation of beta-oxidation of 16:0 is shown in the equation below.

$$C_{16} - CoA + 7NAD^+ + 7FAD + 7CoASH + 7H_2O \rightarrow 8Acetyl - CoA + 7NADH + 7FADH_2 + 7H^+ \quad (17.2.1)$$

Figure 17.2.4 shows an abbreviated comparison of the β-oxidation pathways in the mitochondria and peroxisomes. Peroxisomal beta-oxidation is used to metabolize very-long-chain fatty acids (VLCFAs), which are composed of 24-26 carbon units as well as branched-chain fatty acids (BRCHAs).

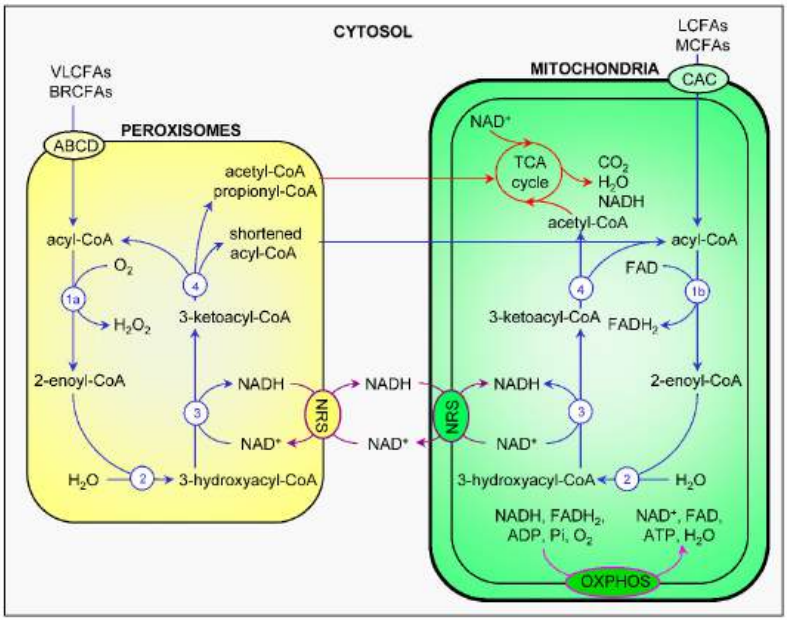

Figure 17.2.4: Comparison and interplay of peroxisomal and mitochondrial fatty acid β-oxidation. Fatty acid β-oxidation, the NAD(H) redox shuttles, the tricarboxylic acid cycle, and the electron transfer chain are respectively depicted in blue, purple, red, and pink. 1a, acyl-CoA oxidase; 1b, acyl-CoA dehydrogenase; 2, enoyl-CoA hydratase; 3, 3-hydroxyacyl-CoA dehydrogenase; 4, 3-ketoacyl-CoA thiolase. ABCD, ATP-binding cassette transporters of subfamily D; ADP, adenine dinucleotide phosphate; BRCFA, branched-chain fatty acid; CAC, carnitine-acylcarnitine carrier; FAD, flavin adenine dinucleotide; FADH2, reduced FAD; LCFA, long-chain fatty acid; MCFA, medium-chain fatty acid; NAD, nicotinamide adenine dinucleotide; NADH, reduced NAD; NRS, NAD(H) redox shuttles; OXPHOS, oxidative phosphorylation; TCA, tricarboxylic acid; VLCFA, very-long-chain fatty acid. Fransen et al. International Journal of Molecular Sciences. 18. 1126. 10.3390/ijms18061126. DOI: 10.3390/ijms18061126. Commons Attribution (CC BY) license (http://creativecommons.org/licenses/by/4.0/).

It should be noted that a likely NAD^+/NADH mitochondria transporter, a multi-pass inner mitochondrial membrane protein has just been identified The transporter, MCART1, is also called SLC25A51,

17.2.3: B-OXIDATION - MECHANISMS

Fatty acids are imported into the matrix from the cytoplasm through their acyl-CoA derivatives. Two different proteins are required for their import. One is **carnitine palmitoyltransferase-1(CPT-1),** which transfers the acyl group from CoASH to a carrier protein carnitine. The acylcarnitine is translocated through the inner membrane by the carrier protein **carnitine-acylcarnitine translocase (CACT)**. Once inside the matrix, the acyl group is transferred back to CoASH by **carnitine palmitoyltransferase-2 (CPT-2)**. This **carnitine cycle** is illustrated in Figure 17.2.5.

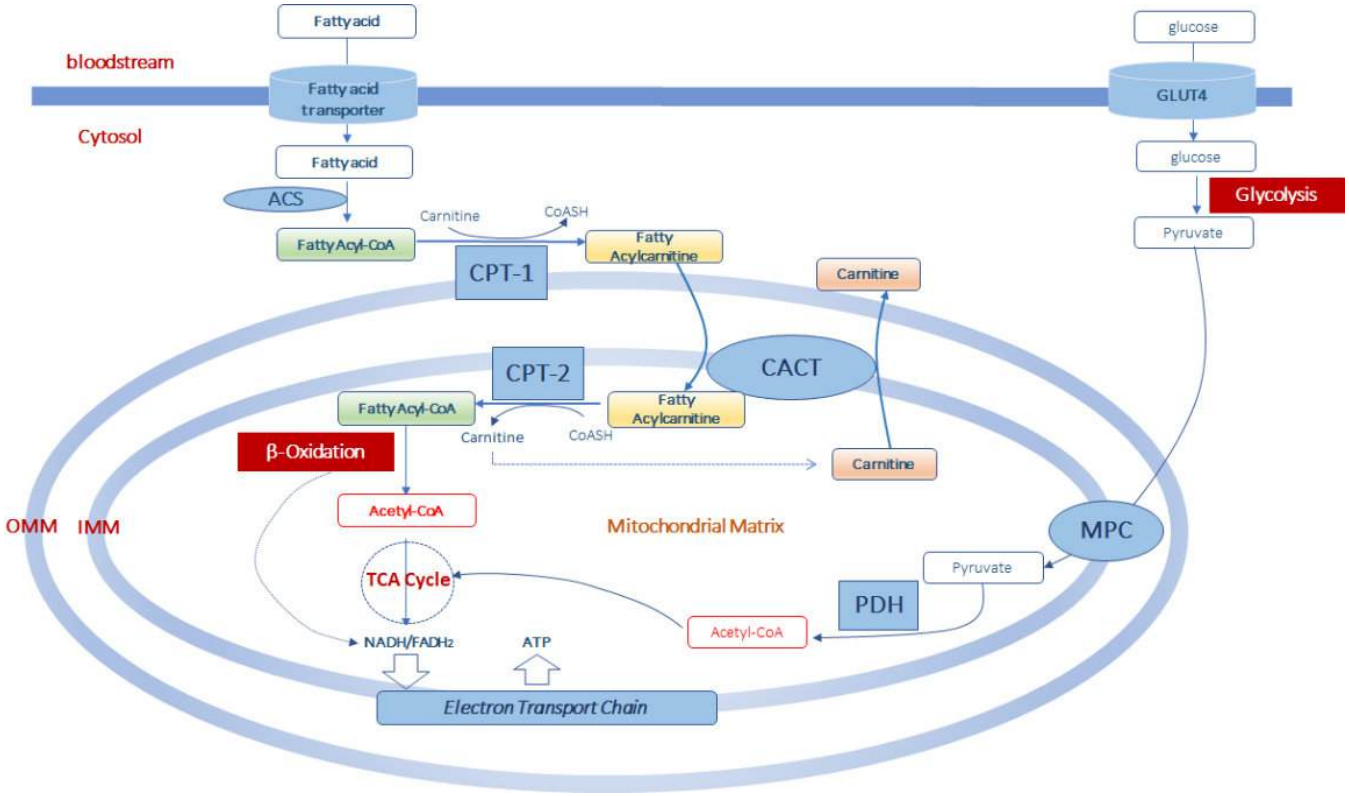

Figure 17.2.5: Carnitine cycle and the connections between major catabolic pathways.

At the outer mitochondrial membrane (OMM), fatty acyl-CoAs become linked to carnitine through carnitine palmitoyltransferase-1 (CPT-1). The complex is translocated across the inner mitochondrial membrane (IMM) via carnitine-acylcarnitine translocase (CACT). In the mitochondrial matrix, CPT-2 converts fatty acylcarnitines back to fatty acyl-CoAs, which enter the β-oxidation pathway. Free carnitine moves back into the cytoplasm through exchange with acyl-carnitines with CACT. β-oxidation in the matrix produces acetyl-CoA, which is also made from glycolytic pyruvate through pyruvate dehydrogenase. Hence acetyl-CoA links both glycolysis and fatty acid oxidation. The resulting acetyl-CoA can enter the TCA cycle when energy is needed.

The mitochondrial carnitine/acylcarnitine carrier protein helps transport acylcarnitines of different lengths across the mitochondrial inner membrane for β-oxidation into the mitochondrial matrix. Figure 17.2.6 shows an interactive iCn3D model of the human mitochondrial carnitine/acylcarnitine carrier protein AlphaFold model (O43772)

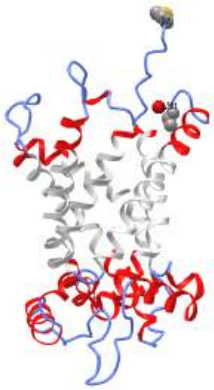

Figure 17.2.6: Mitochondrial carnitine/acylcarnitine carrier protein AlphaFold model (O43772). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...DdDNu9xVJGg2i9

The transmembrane helices are shown in gray. The N- (Met 1) and C-terminal (Leu 301) amino acids are shown in spacefill color CPK.

Malonyl-CoA produced in the first committed step in fatty acids synthesis inhibits CPT1. This should make biological sense since fatty acid oxidation should not occur as fatty acids are synthesized. Palmitoyltransferase II (CPT II), which serves to convert acylcarnitine to fatty acyl

CoA, traps the molecules within the mitochondrial matrix.

In contrast to this regulated transport mechanism, very long chain fatty acids (VLCFAs) and branched-chain fatty acids are transported into peroxisomes by the ABCD1-3 transporters through an ATP-dependent process

Mitochondrial β-oxidation of fatty acids has four steps that occur in the mitochondrial matrix. In those steps, a 16:0 fatty acid (for example) is converted to a (14):0 fatty acid and the 2C molecule acetyl-CoA. The (14):0 fatty acid undergoes 6 more rounds of the β-oxidation cycle until the entire 16:0 fatty acid is fully converted to 8 acetyl-CoAs.

Step 1: Acyl-CoA dehydrogenase

There are long- (LCAD), medium-(MCAD), and short-chain acyl-CoA dehydrogenases (SCAD) which catalyze the first oxidative step in the β-oxidation pathway. These enzymes catalyze the formation of a trans double bond between the α and β carbons (C2 and C3) on the acyl-CoA substrates. A stronger oxidizing agent than NAD^+ is required to form an alkene between the two methylene groups, so FAD is used. Eventually the reduced $FADH_2$ produced will lead to the production of 1.5 equivalents of ATP in the mitochondrial electron transport chain/oxidative phosphorylation.

Figure 17.2.7 shows the key oxidative step in the mechanism of acyl-CoA dehydrogenase to 2-enoyl-CoA by acyl-CoA dehydrogenases

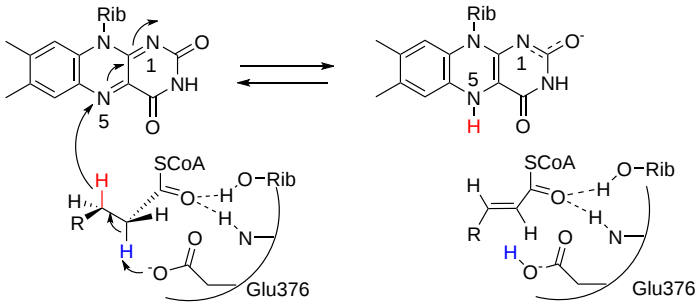

Figure 17.2.7: Mechanism for conversion of acyl-CoA to enoyl-CoA by acyl-CoA dehydrogenase. (after Ghisla and Thorpe. Eur. J. Biochem. 271, 494–508 (2004) doi:10.1046/j.1432-1033.2003.03946.x)

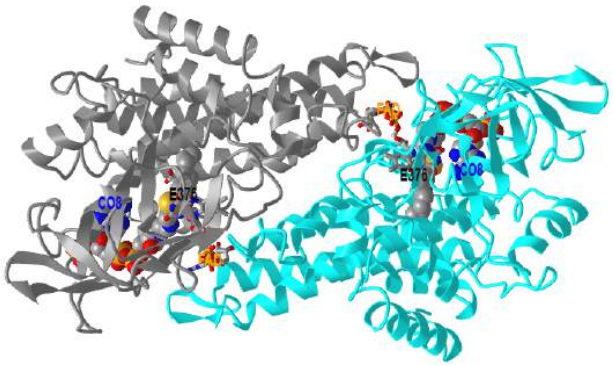
Figure 17.2.8 shows an interactive iCn3D model of the medium-chain acyl-CoA dehydrogenase from pig liver mitochondria with octanoyl-CoA, a substrate (3MDE)



NCBI iCn3D Figure 17.2.8: Medium-chain acyl-CoA dehydrogenase from pig liver mitochondria with octanoyl-CoA substrate (3MDE). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...SiAZExwXVV2TG6

Just two subunits of the biologically active tetramer are shown (dark gray and cyan). FAD is shown in each subunit (sticks, CPK colors, labeled). A bound substrate, octanoyl-CoA (spacefill, CPK colors, labeled CO8) is also shown in each subunit. The catalytic base, Glu 376, is shown in sticks, CPK colors, and labeled.

The structures of the unliganded and acyl-CoA forms of the enzymes are very similar, so there are no large conformational changes on binding octanoyl-CoA. The ligand binds to the enzyme at the rectus (re) face of the FAD with the acyl chain buried. The fatty acyl chain of the thioester substrate is buried inside of the polypeptide and the 3'-AMP moiety is close to the surface of the tetrameric enzyme molecule. The carbonyl oxygen of octanoyl-CoA interacts with the ribityl 2'-hydroxyl group of the FAD and the main-chain carbonyl oxygen of Glu-376. Glu-376 acts as a general base as it removed the alpha proton in the reaction.

Step 2. Enoyl CoA hydratase

This enzyme catalyzes a hydration step of the double bond between the α and β carbons (C2 and C3), adding an OH group to the β carbon, in a reaction that poses little energy barrier. A likely mechanism for enoyl-CoA hydratase is shown in Figure 17.2.9.

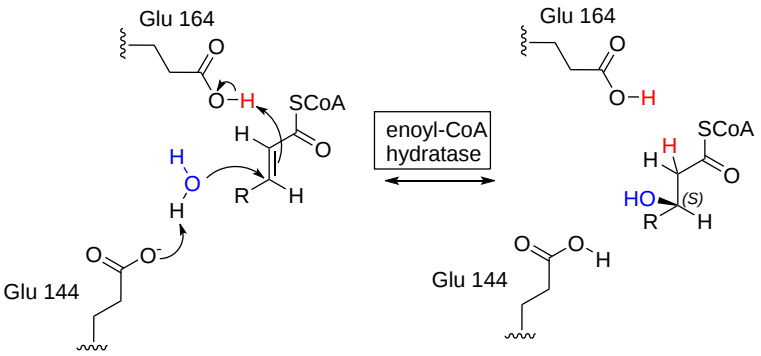


Figure 17.2.9: Mechanism for enoyl-CoA hydratase

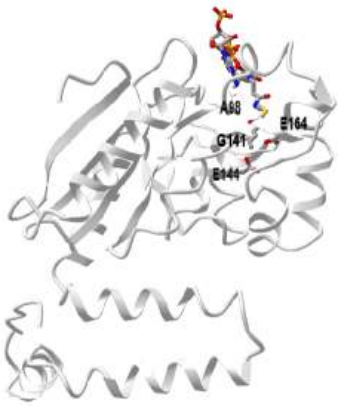
Figure 17.2.10 shows an interactive iCn3D model of the rat enoyl-CoA hydratase in complex with hexadienoyl-CoA (1MJ3)



NCBI iCn3D Figure 17.2.10: Rat enoyl-CoA hydratase in complex with hexadienoyl-CoA (1MJ3). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...byx3eEKewEeEz9

Only one subunit of the biological hexamer is shown for clarity. Two glutamic acids (141 and 164) appear to activate a water molecule for the hydration reaction. Alanine 98 and Gly 141 appear also to be situated in an oxyanion hole which stabilizes the transition state and intermediate.

The addition of the water is syn since the proton and OH group are added to the same size of the double bond. The glycine amide NH provides a strong hydrogen bond to the carbonyl of the substrate, hexadienoyl-CoA, helping to polarize the ene-one. The substrate trans-2-crotonyl-CoA is converted to the 3(S) alcohol instead of the 3(R) alcohol by a huge factor. Both the cis and trans isomers of a substrate analog (hexadienoyl-CoA) can bind to the enzyme, but only the cis isomer is polarized. Since the transition state is polarized as well, it would appear the bound cis isomer is strained and destabilized, suggesting that its binding is an example of transition state binding catalysis.

Step 3. Beta-hydroxyl acyl CoA dehydrogenase

After the addition of the OH on C3 (beta) OH during the hydration reaction, the resulting ROH is oxidized to a ketone, β-ketoacyl-CoA, by the oxidizing agent NAD^+ using the enzyme β-hydroxyl acyl CoA dehydrogenase. The resulting NADH is reoxidized to NAD^+ through the mitochondrial electron transport chain, which leads to the formation of 2.5 molecules of ATP for each NADH. Figure 17.2.11 shows a plausible mechanism for the beta-hydroxyl acyl CoA dehydrogenase-catalyzed reaction.

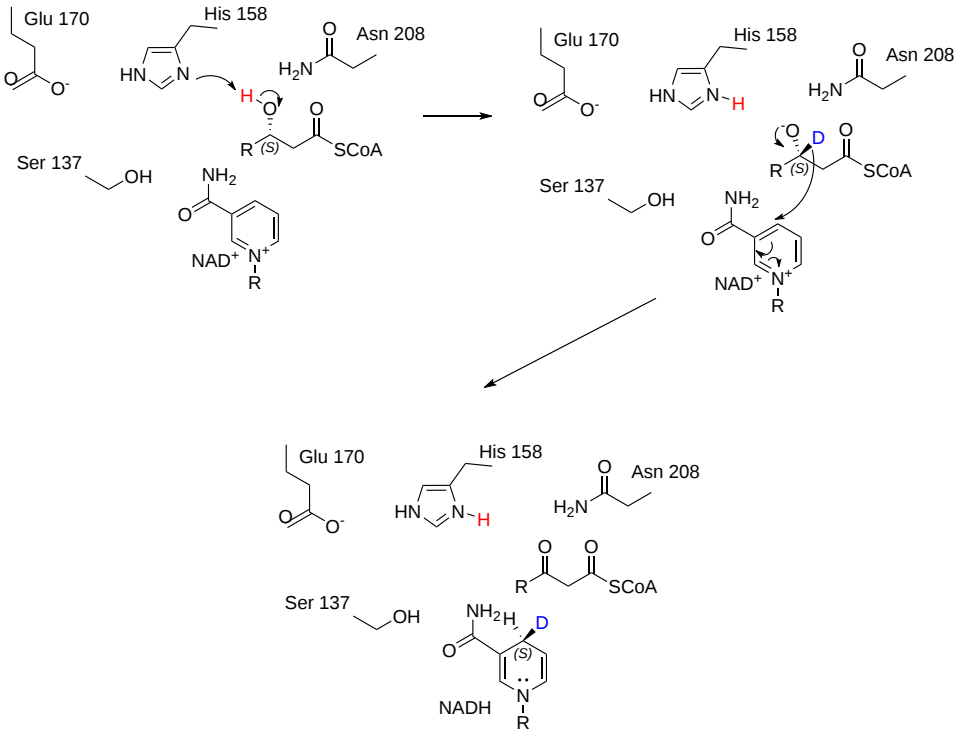


Figure 17.2.11: Mechanism for production of β-ketoacyl-CoASH by b**eta-hydroxyl acyl CoA dehydrogenase**

His 158 acts as a general base. Glu 170 increases the basicity of His 158. The other group is involved in H-bond and electronic stabilization interactions.

Step 4. **Acetyl-CoA acetyltransferase, mitochondrial - ACAT1** (also called 3-ketoacyl-CoA **thiolase**)_

The final step in the beta-oxidation pathway involves cleavage of the bond between the alpha and beta carbon by CoASH. This step is catalyzed by beta-keto thiolase and is a thiolytic (as opposed to cleavage by water - a hydrolysis) reaction. The reaction produces one molecule of acetyl CoA and a fatty acyl CoA that is two carbons shorter. The process repeats until the even chain fatty acid is completely converted into acetyl CoA. The activity of the enzyme is reversible and it can also catalyze the Claisen condensation of two acetyl-CoA molecules into acetoacetyl-CoA, as we will see in the synthesis of ketone bodies in the next chapter section.

The reaction starts with the acylation reaction of the nucleophilic Cys 89 with the carbonyl at the 3-oxoacyl-CoA, with the concomitant release of acetyl-CoA. This forms a Cys 89-acyl covalent intermediate. In the next step, Cys 378 acts as a general base to facilitate the nucleophilic attack of free CoASH on the acyl-intermediate. His 348 acting as a general acid protonates the thiolate leaving group. The amino acids (Cys89, Cys378, and His348) are generally conserved in thiolases (Bhaskar et al. 2020). Kinetically this mechanism is a ping-pong reaction. A reaction mechanism is shown in Figure 17.2.12.

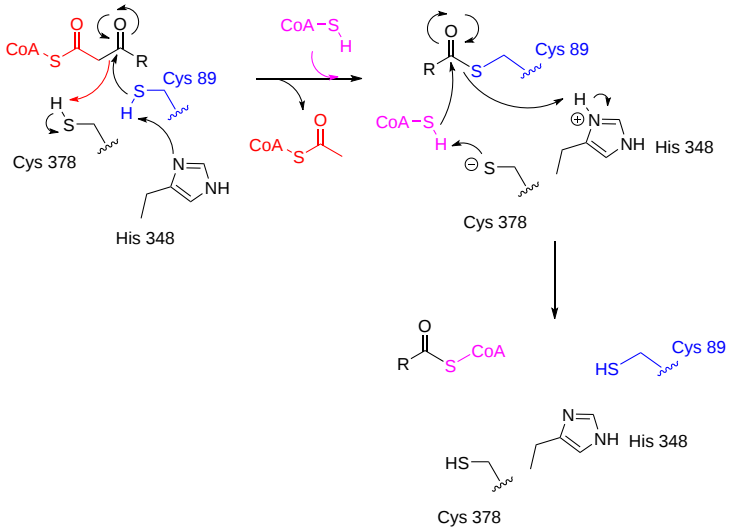

Figure 17.2.12 Reaction mechanism for mitochodrial acetyl-CoA acetyltransferase (ACAT1, thiolase T1)

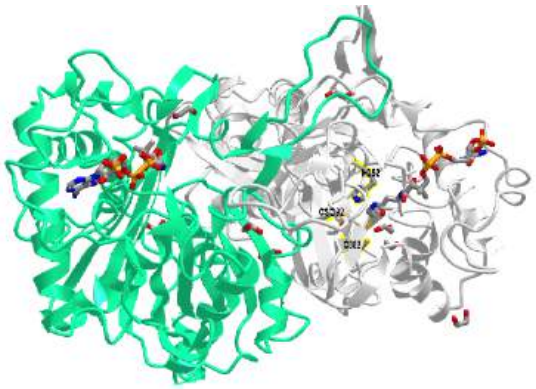
Figure 17.2.13 shows an interactive iCn3D model of Human Mitochondrial 3-Ketoacyl-Coa Thiolase (T1) (4C2J)



NCBI iCn3D Figure 17.2.13: Human Mitochondrial 3-Ketoacyl-Coa Thiolase (T1) (4C2J). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...dzAHKEY77WpNi7

Two subunits in the biological function dimer are shown (cyan and gray). The active site is shown in the gray subunit as CPK-colored stick and labeled. The numbers are a bit different than shown in the mechanistic figure. CoASH is shown in each subunit as sticks. The fatty-acyl tail appears to bind in a tunnel.

17.2.4: A FEW MORE ENZYMES ARE NEEDED

Steps 1 through 4 outlined above apply to the beta-oxidation of a saturated fatty acid with an even-numbered carbon skeleton. Unsaturated fatty acids, such as oleate (18:1) and linoleate (18:2), contain cis double bonds that must be isomerized to the trans configuration by the enzyme **enoyl CoA isomerase** or reduced by the enzyme NADPH (2,4-dienoyl CoA reductase or 24DCR), using NADPH.

Enoyl CoA isomerase

This enzyme catalyzes the isomerization of cis double bounds to the trans form which mimics those formed by acyl-CoA dehydrogenase by FAD in step 1. Figure 17.2.14 shows a plausible mechanism for the conversion of cis double bonds to their trans isomer.

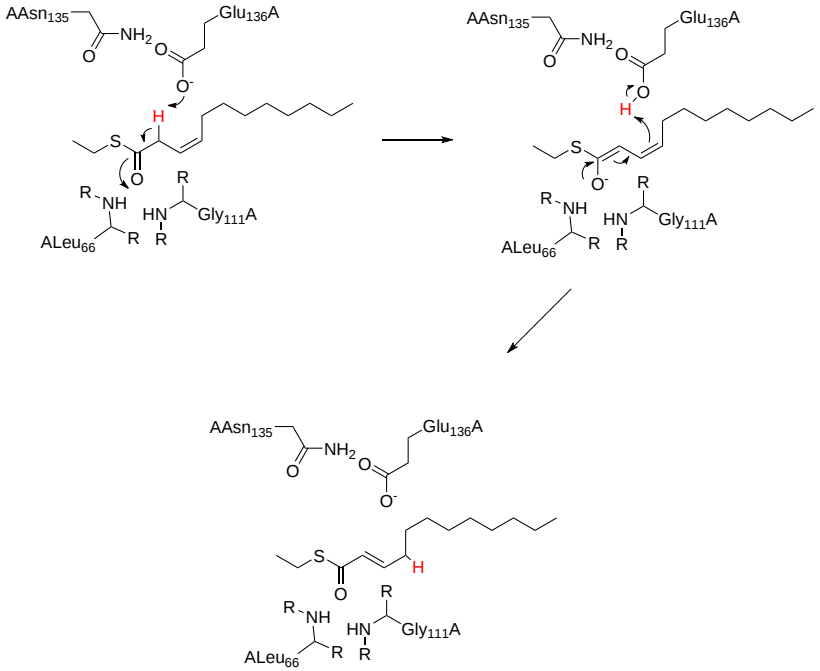


Figure 17.2.14 Cis to trans isomerization by enoyl-CoA isomerase (https://www.ebi.ac.uk/thornton-srv/m-csa/entry/341/)

Glu 136 acts as a general base, while amide Hs of Leu 66 and Gly 111 stabilized the intermediate oxyanion and hence the developing charge in the transition state. They are optimally situated in the oxyanion hole.

Figure 17.2.15 shows an interactive iCn3D model of the Human mitochondrial Δ^3-Δ^2-enoyl-CoA isomerase (1SG4)

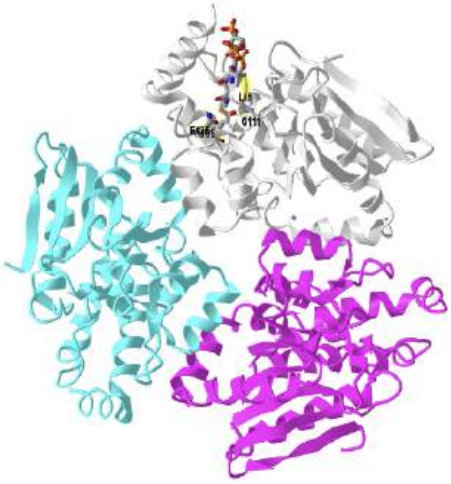

Figure 17.2.15: Human mitochondrial Δ^3-Δ^2-enoyl-CoA isomerase (1SG4) (Copyright; author via source). Click the image for a popup or use this external link:https://structure.ncbi.nlm.nih.gov/i...H6LxEzBKajq8b7

The three subunits are shown in different colors. The substrate analog octanoyl-CoA is shown in spacefill CPK colors bound to the gray subunit. The catalytic residues are shown in sticks with CPK colors and labeled. The distal omega end binds in a hydrophobic tunnel.

2,4-dienoyl CoA reductase or **24DCR**

An alternative way to deal with the cis double bond is simply to reduce it, in this case, NADPH. This enzyme is used on all C=C at the even-number position and more at odd-numbered positions. A mechanism for the reduction is shown in Figure 17.2.16.

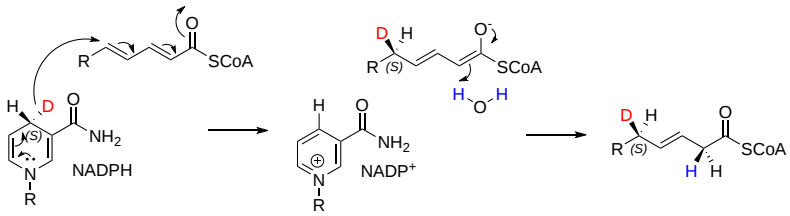

Figure 17.2.16: a mechanism for the reduction of double bonds in unsaturated fatty acids (after Fillgrove and Anderson, B*iochemistry* (2001) https://doi-org.ezproxy.csbsju.edu/10.1021/bi0111606

Figure 17.2.17 shows an interactive iCn3D model of a monomer of the homotetrameric human mitochondrial 2,4-dienoyl-Coa reductase (1W6U)

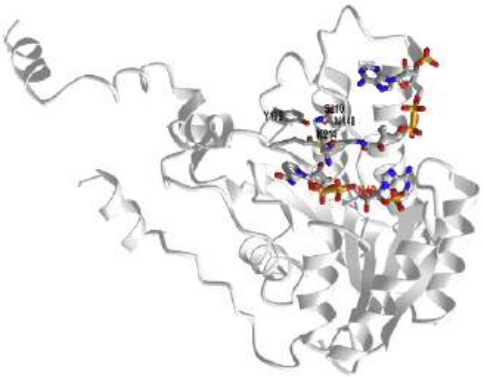

Figure 17.2.17: Monomer of the homotetrameric human Mitochondrial 2,4-Dienoyl-Coa Reductase (1W6U) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...pQueKc84sFqzt7

The model shows bound $NADP^+$ and the substrate trans-2,trans-4-dienoyl-CoA. The active site is open enough to accommodate fatty acids of different lengths. Tyr-199 and Asn-148 stabilize the enolate and the oxidized nicotinamide.

For odd-number chain fatty acids, propionyl-CoA to succinyl-CoA

Although most fatty acids of biological origin have even numbers of carbons, not all of them do. Oxidation of fatty acids with odd numbers of carbons ultimately produces an intermediate with three carbons, propionyl-CoA, which cannot be oxidized further in the beta-oxidation pathway. These additional steps are necessary:

1. carboxylation to make (S)-methylmalonyl-CoA;
2. isomerization to (R)-methylmalonyl-CoA;
3. rearrangement to form succinyl-CoA. The last step of the process utilizes the enzyme methylmalonyl-CoA mutase, which uses the B12 coenzyme in its catalytic cycle. Succinyl-CoA can then be metabolized in the citric acid cycle.

Figure 17.2.18 shows the pathway for the conversion of propionyl-CoA to succinyl-CoA.

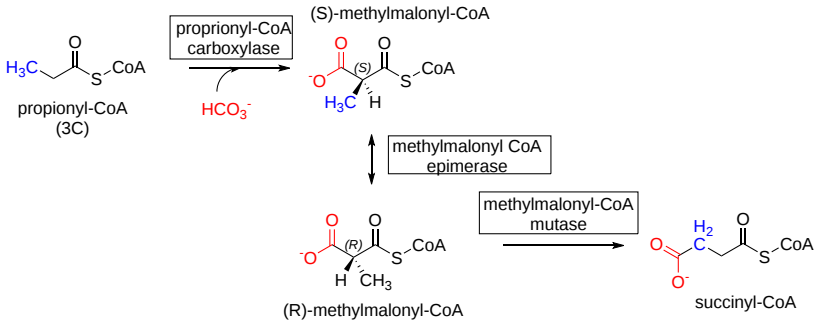

Figure 17.2.18 Conversion of propionyl-CoA to succinyl-CoA

Recent Updates: 7/24/23 Mechanisms for conversion of propionyl-CoA to succinyl-CoA.

We will look at each of the enzymes in turn.

Propionyl-CoA carboxylase

The net reaction for this enzyme is shown in Figure 17.2.19 below.

$$\text{Propionyl-CoA} + \text{ATP} + HCO_3^- \rightarrow \text{(S)-methylmalonyl-CoA} + \text{ADP} + P_i + H^+$$

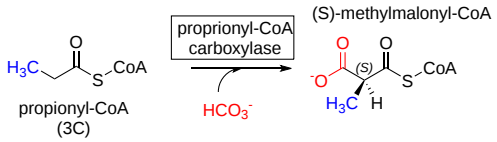

Figure 17.2.19: Propionyl-CoA carboxylase reaction

The enzyme has 3 subunits. The alpha subunits has biotin carboxyl carrier protein and biotin carboxylase domains. The beta subunit has carboxytransferase activity. The mechanism for the *Streptomyces coelicolor* propionyl-CoA carboxylase (PCC) is shown below in two parts.

In Part 1, biotin is carboxylated by HCO_3^- to form an activated bicarbonate derivative (similar to an anhydride) that is high energy in comparison to its hydrolysis product, as shown in Figure 17.2.20 below. This reaction takes place in the alpha subunit.

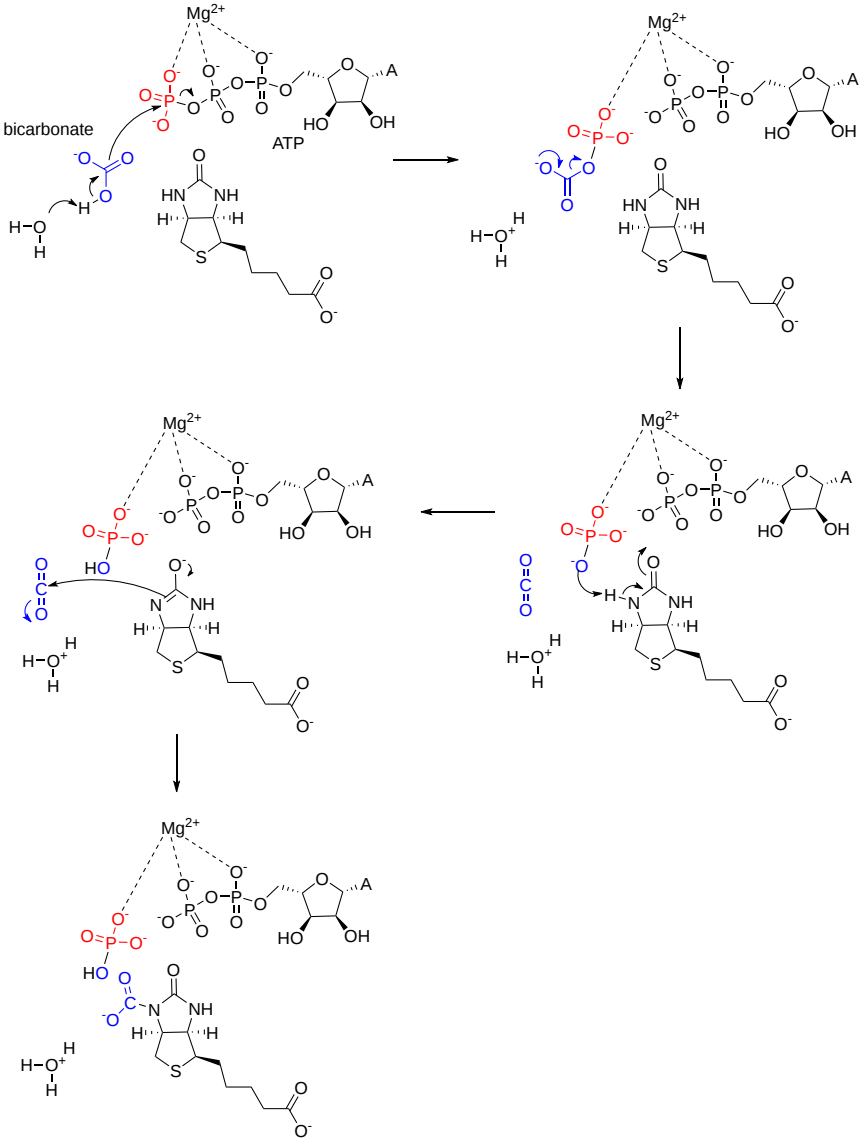

Figure 17.2.20: Formation of carboxylated biotin by propionyl-CoA carboxylase - Part 1. M-CSA. Gemma L. Holliday, Daniel E. Almonacid, Jonathan T. W. Ng. Creative Commons Attribution 4.0 International (CC BY 4.0) License

In Part 2, shown in Figure 17.2.21 below, the carboxyl group on biotin is transferred to propionyl-CoA to form methymalonyl-CoA. This reaction occurs in the beta subunit.

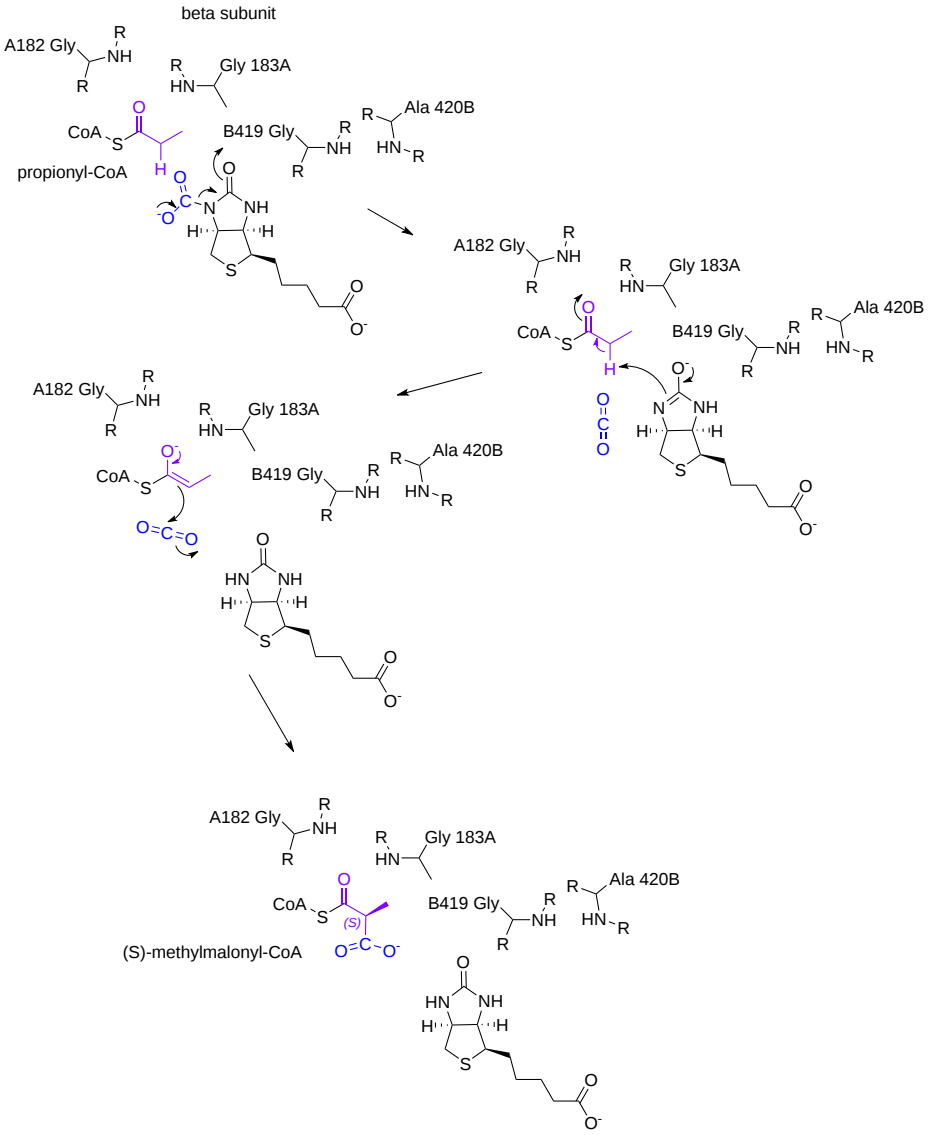

Figure 17.2.21: Part 2 - Formation of (S)-methylmalonyl-CoA by activated CO_2 transfer from carboxybiotin by propionyl-CoA carboxylase. Holliday et al., ibid.

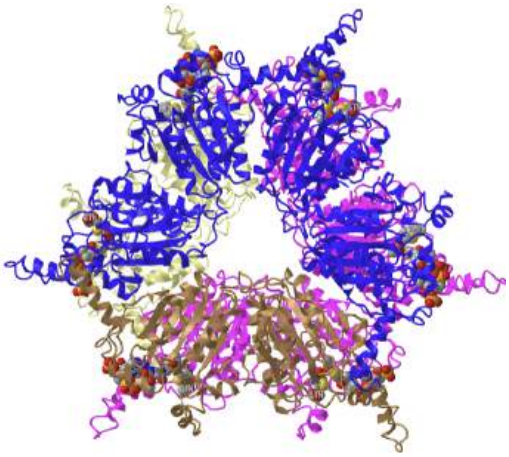
The roles of the main chain atoms of Ala 182 and Gly 183 in the alpha subunit are to stabilize the propionyl-CoA while the backbone atoms of Gly 429 and Ala 430 in the beta subunit are to stabilize the oxyanion of carboxylated biotin.

Figure 17.2.22 shows an interactive iCn3D model of biotin and propionyl-CoA bound to Acyl-CoA Carboxylase Beta Subunit from S. coelicolor (1XNY)



NCBI iCn3D Figure 17.2.22: Monomer of the biotin and propionyl-CoA bound to Acyl-CoA Carboxylase Beta Subunit from S. coelicolor (1XNY). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...K46r5EdZezF4o6

Biotin (labeled BTN) and propionyl-CoA are shown in spacefill in CPK colors.

Methylmalonyl-CoA Epimerase

The net reaction is shown in Figure 17.2.23 below.

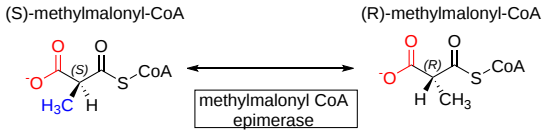


Figure 17.2.23: Methylmalonyl-CoA Epimerase reaction

This reaction proceeds through an enolate intermediate after an abstraction of a proton from the chiral center of the methylmalonyl-CoA, as shown in the reaction mechanism for the enzyme from propionibacterium freudenreichii subsp. shermanii is shown Figure 17.2.24 below. The reaction is readily reversible.

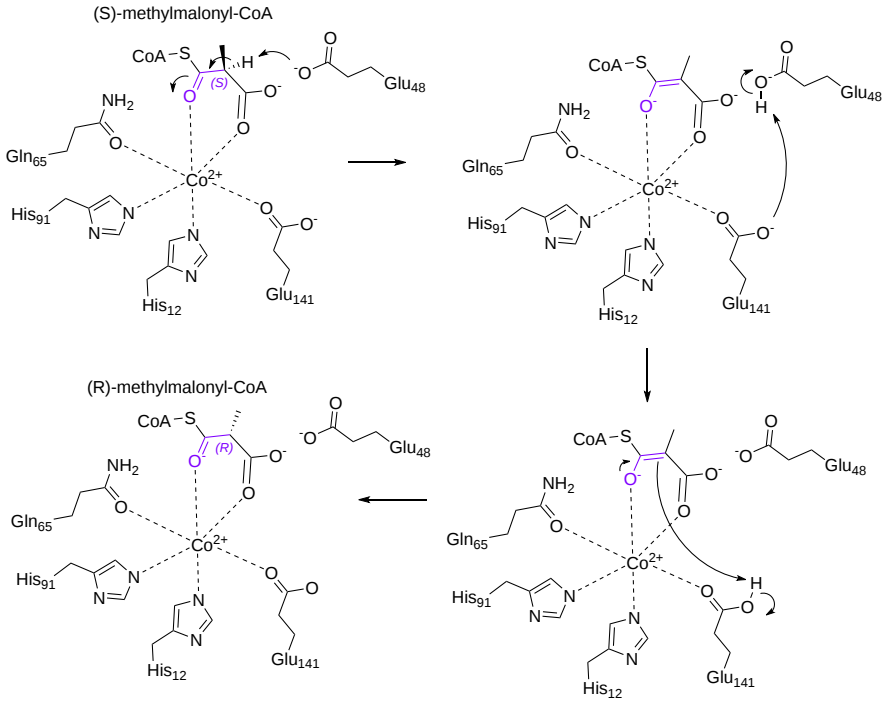

Figure 17.2.24: Mechanism for methylmalonyl-CoA Epimerase. Gemma L. Holliday et al. https://www.ebi.ac.uk/thornton-srv/m-csa/entry/33/. Creative Commons Attribution 4.0 International (CC BY 4.0) License

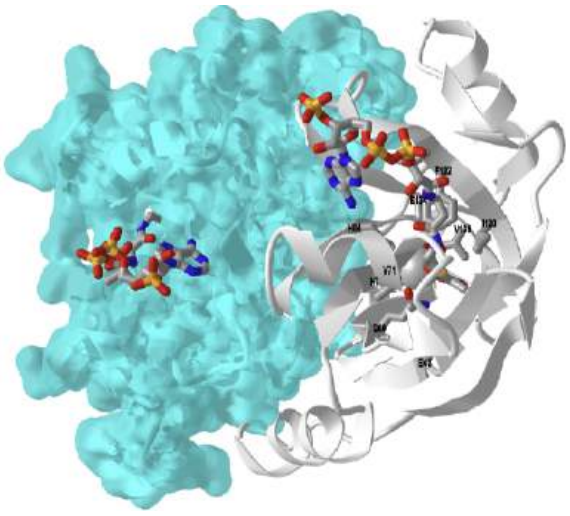
Note the presence of a Co^{2+} ion in the active site.

Figure 17.2.25 shows an interactive iCn3D model of Methylmalonyl-CoA epimerase in complex with 2-nitronate-propionyl-CoA from S. coelicolor (6WFI)



NCBI iCn3D Figure 17.2.25: Methylmalonyl-CoA epimerase in complex with 2-nitronate-propionyl-CoA from S. coelicolor (6WFI). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...Sqc98CCjAvzkp7

The enzyme is a dimer with two identical subunits and catalytic. One of the subunits is shown with a blue transparent surface with the bound 2-nitronate-propionyl-CoA inhibitor. The other is shown in gray cartoon with the key side chains involved in substrate binding and catalysis shown as color sticks and labeled.

Methylmalonyl-CoA Mutase

In this reaction, a methyl group is removed from (R)-methylmalonyl-CoA to form succinyl-CoA, a shown in Figure 17.2.26 below.

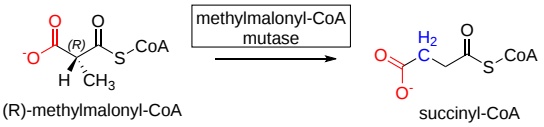


Figure 17.2.26: Methylmalonyl-CoA reaction

This reaction going in the opposite direction is an example of a methyltransferase. Another similar enzyme (which we will see in Chapter 18.4 - Amino Acid Degradation) catalyzes a methyl transfer from homocysteine to a new cofactor, **cobalamin**, which transfers it to cysteine to form methionine in a reaction catalyzed by methionine synthase. Cobalamine and its methylated form are derivatives of Vitamin B12. We will leave details of cobalamin biochemistry to the next chapter and will present a mechanism for methylmalonyl-CoA mutase here.

We present the reaction for the reverse reaction, the conversion of succinyl-CoA to (R)-methylmalonyl-CoA by the enzyme from *Propionibacterium freudenreichii subsp. shermanii* in two parts below. The enzyme is a heterodimer of an alpha and beta subunit and has a cofactor, adenosylcobalamin (coenzyme B12). In contrast, the human mutase, a homodimer, is very similar to the alpha subunit.

First, a free radical is formed from the adenosyl group on the cofactor. This promotes a free-radical rearrangement of succinyl-CoA to (R)-methylmalonyl-CoA (or the reverse for the pathway of interest here). The reaction is shown in two parts for more optimal viewing.

Figure 17.2.27 below the first parts of the reaction for the conversion of succinyl-CoA to (R)-methylmalonyl-CoA by the mutase from *Propionibacterium freudenreichii subsp. shermanii*.

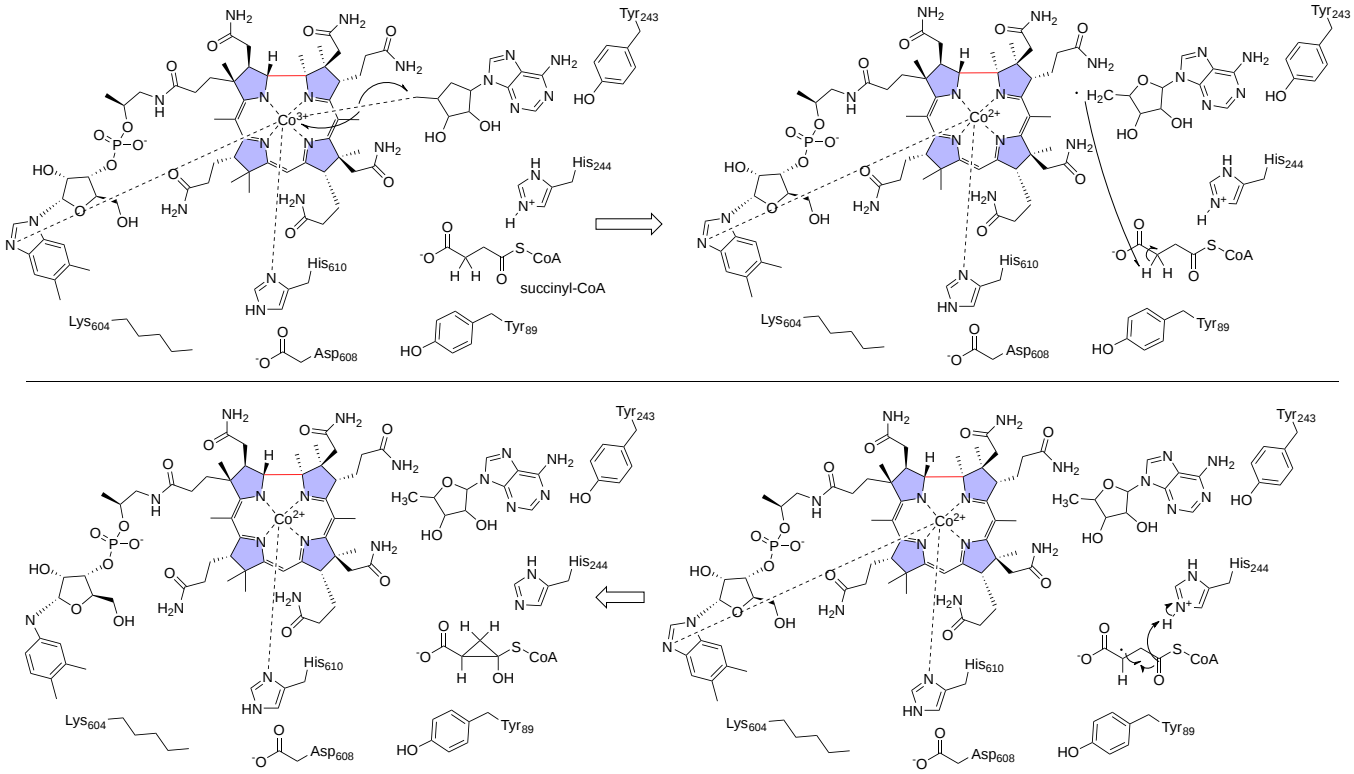

Figure 17.2.27: Part 1 of conversion of succinyl-CoA to (R)-methylmalonyl-CoA by methylmalonyl-CoA mutase. Gemma L. Holliday, Gail J. Bartlett, Daniel E. Almonacid. M-CSA. https://www.ebi.ac.uk/thornton-srv/m-csa/entry/62/. Creative Commons Attribution 4.0 International (CC BY 4.0) License

Figure 17.2.28 below shows the rest of the reaction for the conversion of succinyl-CoA to (R)-methylmalonyl-CoA.

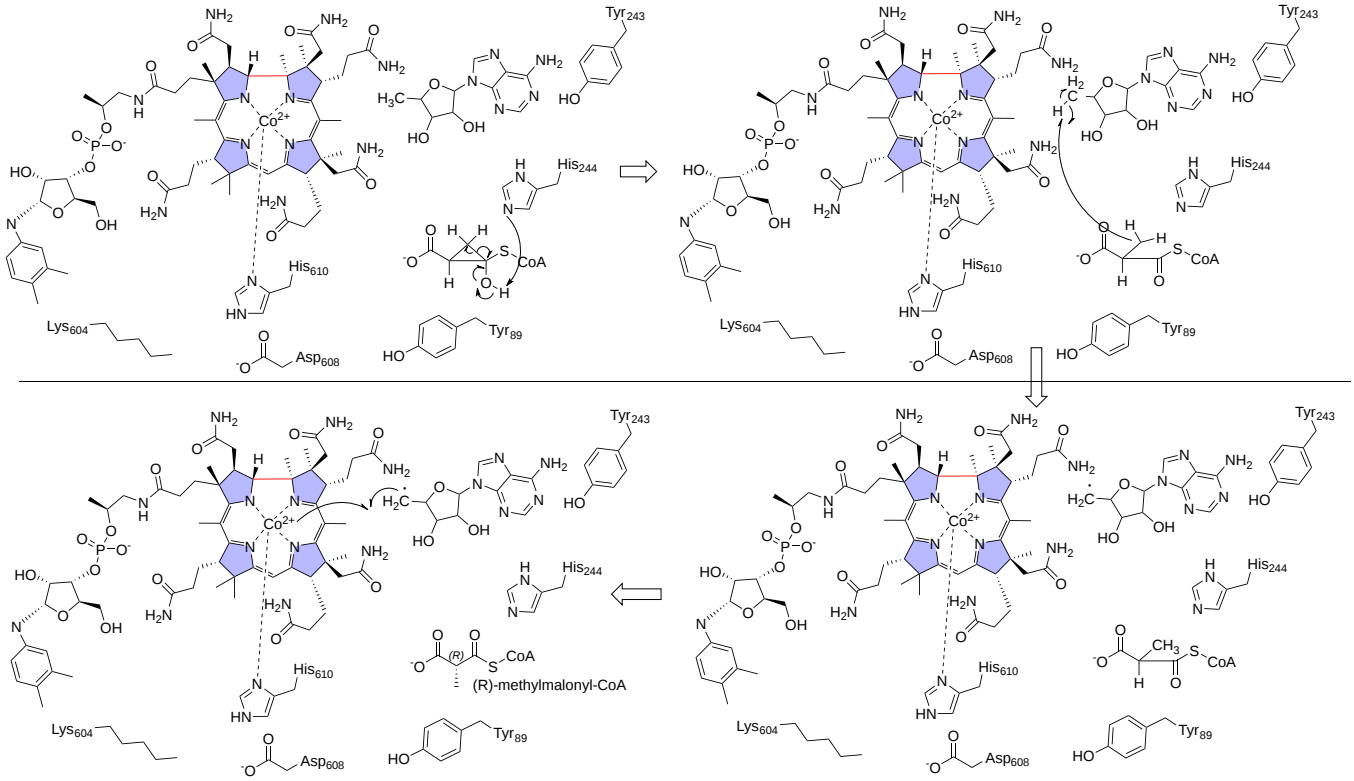

Figure 17.2.28: Part 2 of the conversion of succinyl-CoA to (R)-methylmalonyl-CoA by methylmalonyl-CoA mutase. Gemma L. Holliday et al., ibid.

The very last product from the bottom left reaction, the reformed active adenosylcobalamin cofactor, is not shown. The enzyme facilitates the hemolytic cleavage of the Co-C bond. This is followed by a free-radical rearrangement.

Figure 17.2.29 shows an interactive iCn3D model of the methylmalonyl-coenzyme A mutase from from *Propionibacterium freudenreichii subsp. shermanii* (1REQ)

An analog of CoASH, desulfo-CoA (DCA) , is shown in spacefill, CPK colors and labeled. Adenosylcobalamin is shown in colored sticks and labeled B12. The alpha subunit is shown in gray with the key amino acids from the enzyme mechanism presented above shown as colored sticks and labeled. The beta subunit is shown in blue.

Propionyl-CoA is also produced as a product of the oxidation of methionine, valine, isoleucine, and threonine. (See the amino acid metabolism chapter for more details on mechanisms.)

17.2.5: VERY LONG CHAIN OXIDATION

In contrast to the oxidation of short and medium-chain fatty acids, which under beta-oxidation require four different discrete enzymes, the oxidation of very long-chain fatty acids (VLCFs) is carried out by two proteins with the second protein expressing three enzyme activities. The first step, analogous to step 1 in beta-oxidation described above, is carried out by a very long chain acyl-CoA dehydrogenase (VLCAD). The next three reactions are carried out by a single trifunctional protein (TFP) with two subunits. The α-subunit carries out the hydration (2-enoyl-CoA hydratase, ECH) and next oxidation step (3-hydroxyl-CoA dehydrogenase (HAD), while the β-subunit has 3-ketothiolase (KT) activity. Deficiencies of TFP can cause significant disease and even death.

TFP is a heterotetramer of two α and two β subunits with the beta subunits forming a central homodimer. The two alpha units bind at each end and the whole complex forms an arc. There appears to be a "tunnel" allowing substrate transfer after each step. This minimizes premature intermediate release. Figure 17.2.30 shows an interactive iCn3D model of the human mitochondrial trifunctional protein, a fatty acid beta-oxidation metabolon (6DV2)

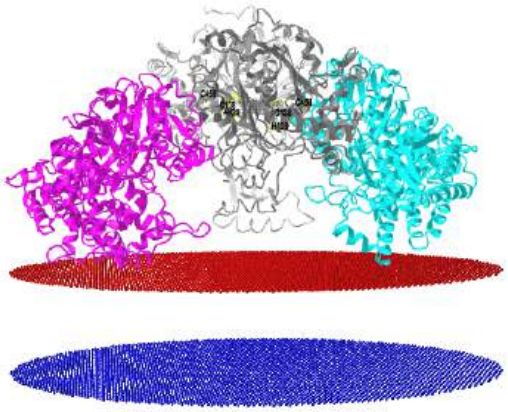

Figure 17.2.30: Human mitochondrial trifunctional protein fatty acid beta-oxidation metabolon (6DV2). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...XiUXru4vkRVh87

- Grays: two thiolase subunits: reversible thiolytic cleavage of 3-ketoacyl-CoA into acyl-CoA and acetyl-CoA, a 2-step reaction involving a covalent intermediate formed with a catalytic cysteine. The catalytic residue (C138, C458, and H428) are shown as sticks with CPK colors.
- Cyan and magenta subunits: enoyl-CoA hydratase (EC 4.2.1.17) and 3-hydroxyacyl-CoA dehydrogenase (EC 1.1.1.35)
- The red dots represent the inner leaflet of the inner membrane so the proteins reside in the mitochondrial matrix.

17.2.6: REGULATION OF BETA-OXIDATION

We saw that the metabolic decision to use carbohydrate energy reserves (glycogen) is a highly regulated event. Glycogen breakdown occurs during fasting and energy need. Fatty acids, our largest stores of energy, are released from triglyceride reserves in adipose cells through extracellular epinephrine and glucagon activation of pathways that activate intracellular hormone-sensitive lipase. Released fatty acids are bound to the serum protein albumin which transports them to tissue. Also as we mentioned above, malonyl-CoA inhibits the movement of fatty acids into the mitochondria. Malonyl-CoA is the first committed product of fatty acid biosynthesis. Each acyl-CoA product of each of the four enzymes engages in product inhibition for the enzyme that produced it. 3-ketoacyl-CoA also inhibits enoyl-CoA hydratase and acyl-CoA dehydrogenase [17]. The NADH/NAD^+ and acetyl-CoA/CoA ratios also influence the beta oxidation pathway through allosteric regulation. For example, the ratio of acetyl-CoA/CoA ratio affects the activity ketoacyl-CoA thiolase.

Fatty acids also bind to the transcription factors called peroxisome proliferator-activated receptors (PPARs) and also coactivator PGC-1α, which regulate the transcription of enzymes in the beta-oxidation pathways. PPARs and the retinoid X receptor form heterodimers that bind to the PPAR response element in key promoters site involved in fatty acid degradation. These include CPT1, long-chain acyl-CoA dehydrogenase (LCAD), medium-chain acyl-CoA dehydrogenase (MCAD), and acyl-CoA synthetase (ACS). The PPARs have tissue specificity. We will discuss PPARs in more detail in the chapter on fatty acid synthesis.

17.2.7: PEROXISOMAL **A**-OXIDATION

Alpha oxidation of fatty acids occurs in the peroxisome. It is used to metabolize phytanic acid (3,7,11,15-tetramethyl hexadecanoic acid), found in dairy products, animal fat, and some fish. Phytanic acid is produced in ruminants on the degradation of plant material and derives from phytol, an isoprenoid alcohol esterified to chlorophyll. Phytol is first converted to phytanic acid.

Fatty acid β-oxidation can also occur in peroxisomes. In animals, peroxisomes are believed to be important in the initial breakdown of very long-chain fatty acids and methyl-branched fatty acids [11]. The enzymes involved in fatty acid oxidation in peroxisomes are different from mitochondria. An important difference is acyl-CoA oxidase, the first enzyme in peroxisome β-oxidation, which transfers the hydrogen to oxygen producing H_2O_2 instead of producing $FADH_2$. The H_2O_2 is broken down to water by catalase. The fatty acyl-CoA intermediates formed during β-oxidation are the same in peroxisomes and mitochondria. Peroxisomes also contain the necessary enzymes for α-oxidation, which are necessary for the oxidation of some fatty acids with methyl branches.

Branched-chain fatty acids also require additional enzymatic modification to enter the alpha-oxidation pathway within peroxisomes. Phytanic acid (3,7,11,14-tetramethylhexadecanoic acid), requires additional peroxisomal enzymes to undergo beta-oxidation. Phytanic acid initially forms phytanyl CoA which is then hydroxylated at the alpha carbon by phytanyl CoA hydroxylase (alpha-hydroxylase), encoded by the PHYH gene. The alpha carbon-hydroxyl bond then undergoes two successive rounds of oxidation to pristanic acid. Pristanic acid undergoes beta-oxidation, which produces acetyl CoA and propionyl CoA in alternative rounds. As with peroxisomal beta-oxidation of VLCFAs, this process generally ends when the carbon chain length reaches 6-8 carbons, at which point the molecule is shuttled to the mitochondria by carnitine for complete oxidation to carbon dioxide and water. Figure 17.2.31 shows the steps in the catabolism of phytanic acid (3,7,11,14-tetramethylhexadecanoic acid).

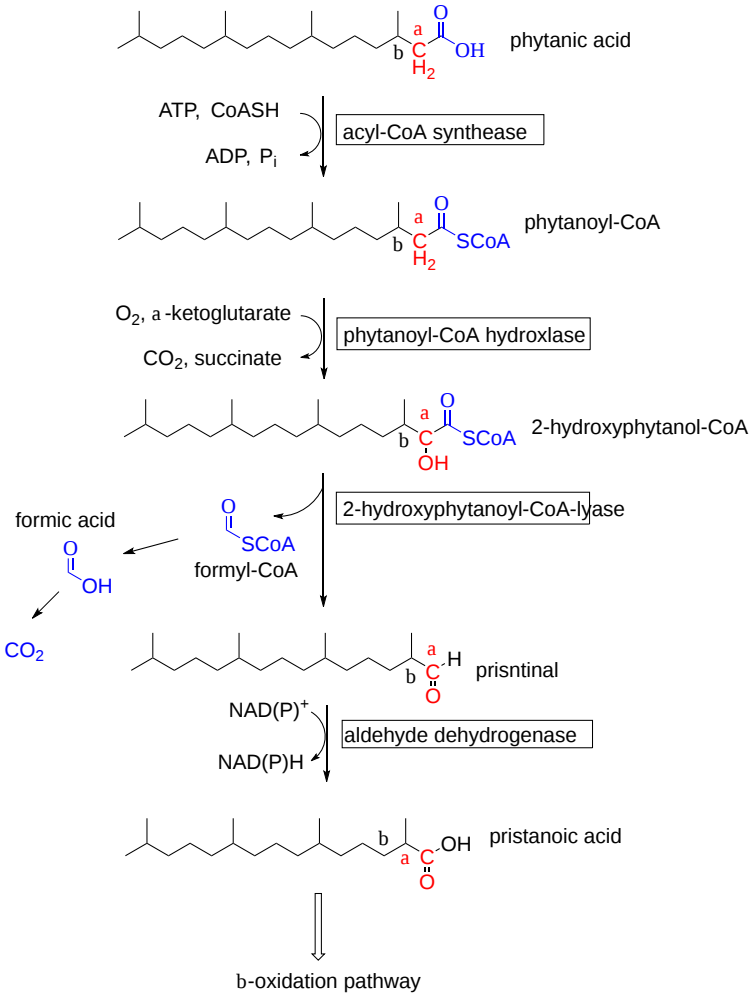

Figure 17.2.31: Alpha oxidation pathway of catabolism of phytanic acid (3,7,11,14-tetramethylhexadecanoic acid)

17.2.8: OMEGA-OXIDATION

The omega-oxidation pathway occurs in the endoplasmic reticulum and is used to metabolize larger fatty acids, which given their hydrophobicity might be damaging to cells in high concentrations. In this pathway the fatty acids are metabolized to dicarboxylic acids which increases their water solubility for excretion in the urine. The first step uses cytochrome P450 enzymes that are also used to modify xenobiotic compounds with dioxygen, making them more soluble as well. The omega oxidation pathway is shown in Figure 17.2.32.

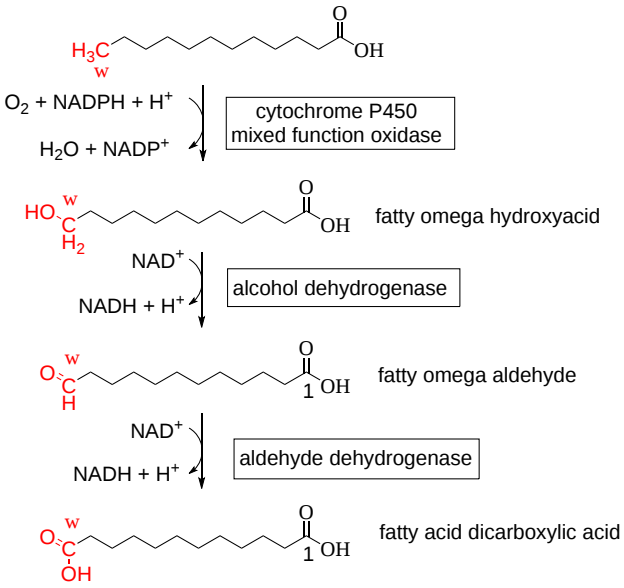

Figure 17.2.32 The ER omega oxidation pathways for catabolism of fatty acids

Three subfamily members of the cytochrome P450s (CYPs) show a preference for hydroxylation of short-chain fatty acids (C7-C10, CYP4B), medium-chain (C10-C16, CYP4A), and long-chain (C16-C26, CYP4F) fatty acids. which can be saturated, unsaturated and branched, fatty acids. Figure 17.2.33 shows a summary of the alpha, beta, and omega oxidation pathway

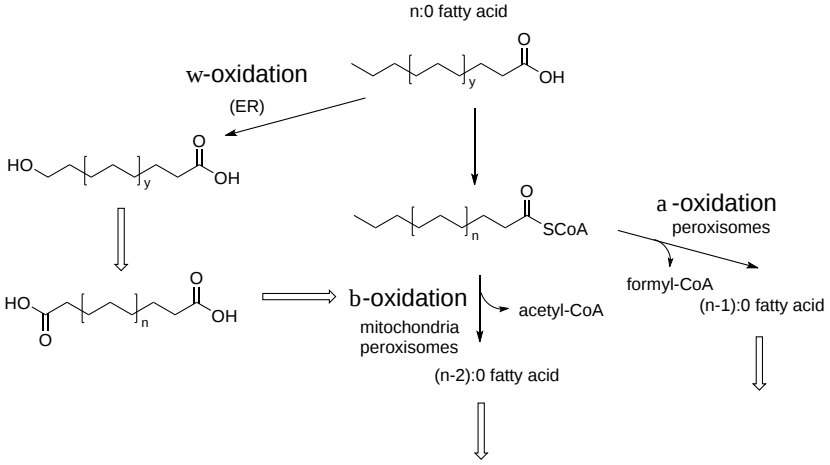

Figure 17.2.33 https://febs.onlinelibrary.wiley.com...8.2010.07947.x

17.2.9: DISEASES OF FATTY ACID METABOLISM

Listed below are a few select diseases that either directly involves defective fatty acid metabolism through intrinsic enzyme deficiencies or indirectly prevent the proper functioning of fatty acid metabolism through extrinsic enzyme deficiencies. Many, but not all, deficiencies of enzymes involved in fatty acid oxidation result in abnormal neurological development and or function early in life; a brief list of signs and symptoms appears under the selected diseases mentioned.

MCAD Deficiency

Medium-chain acyl dehydrogenase is the most common inherited defect of fatty acid oxidation in humans; as one would expect, medium-chain, 6-8 carbon molecules accumulate in this disease. Clinical manifestations of MCAD deficiency primarily present during fasting conditions and include lethargy, weakness, sweating, and hypoglycemia, most commonly in children under the age of 5. Serum measurements of octanoyl carnitine are usually elevated in these patients and can aid in the diagnosis. These abundant molecules then undergo oxidation by the cytochrome P450 system involved in omega-oxidation, resulting in a dicarboxylic acidemia and dicarboxylic aciduria.

Zellweger Syndrome

Zellweger syndrome results from autosomal recessive mutations in the PEX genes, which code for peroxin proteins needed for the assembly of peroxisomes. Almost 70% of all peroxisomal biogenesis disorders (PBDs) result from a PEX1 gene mutation. Many different fatty acid

compounds can accumulate without the oxidative machinery of peroxisomes, including VLCFAs and phytanic acid. Manifestations of this disease generally include the brain, kidneys, and skeleton.

X-Linked Adrenoleukodystrophy (X-ALD)

X-ALD is a genetic deficiency of the ABCD transporters in the membrane of peroxisomes, as mentioned previously, resulting in the pathological accumulation of phytanic acid and VLCFAs within cells and is most clinically significant when the ABCD1 transporter is absent. The disease presents with neurodegenerative and adrenal abnormalities.

Refsum Disease

Refsum disease results from a genetic deficiency of the enzyme phytanyl CoA 2-hydroxylase, which, as previously mentioned, is involved in the alpha-oxidation of phytanic acid, a breakdown product of chlorophyll. Notable clinical manifestations of Refsum disease include cardiac malfunction and defective functioning of the olfactory and auditory nerves due to the accumulation of phytanic acid.

17.3: KETONE BODIES

Much of the material below derives from Kolb et al. BMC Medicine (2021) 19:313 https://doi.org/10.1186/s12916-021-02185-0. Creative Commons Attribution 4.0 International License, http://creativecommons.org/licenses/by/4.0/.

17.3.1: INTRODUCTION

Ketone bodies are the name given to two molecules, acetoacetate (a ketone) and D-β-hydroxybutyrate (its reduction product) that derive from the condensation of acetate in the form of acetyl-CoA. Their structures are shown in Figure 17.3.1.

acetoacetate

R-b-hydroxybutyrate
D-b-hydroxybutyrate

Figure 17.3.1: Structure of ketone bodies

They are synthesized when acetyl-CoA concentrations are high. That would occur under a couple of conditions:

- fatty acids are being mobilized in adipocytes and broken down into acetyl-CoA through β-oxidation in the mitochondria;
- the acetyl-CoA produced can not enter the Kreb cycle leading to the buildup of acetyl-CoA in the matrix.

The latter condition arises when carbohydrate metabolism is compromised so the citric acid cycle has slowed. This occurs if the citric acid cycle intermediate oxaloacetate is pulled away from the cycle for the gluconeogenic synthesis of glucose. Pyruvate, another source of acetyl-CoA (through pyruvate dehydrogenase) is also depleted in gluconeogenesis. Of course, we are describing conditions in the liver, the major site of gluconeogenesis, and also of ketone body synthesis.

These conditions are also met in the underfed or starving state when glycogen supplies are exhausted and fatty acid reserves are being used for energy. Likewise, these conditions are met in diabetes when glucose might be abundant in the circulation but its entry into the cell is compromised by problems with insulin signaling.

Fatty acids released by adipocytes into the blood are bound to serum albumin for transport to tissue. Albumin, with bound fatty acids, does not, however, cross the blood-brain barrier. Ketone bodies are very small and water soluble so they can cross the blood-brain barrier, where they can deliver a soluble equivalent of fatty acids to the brain and other tissues in times of energy need. Ketone bodies can be considered solubilized and easily transportable fatty acid equivalents. They have low pKa values of 3.6 (acetoacetate) and 4.7 (D-β-hydroxybutyrate) so they can lead to "ketoacidosis" in diabetics. Acetone is a nonacidic and sweet-smelling molecule, which can be detected in the breath of diabetics, is produced spontaneously and through catalysis through the decarboxylation of the beta-keto acid acetoacetate. It is also considered a ketone body.

BLOOD-BRAIN BARRIER

The blood–brain barrier (BBB) protects the entire nervous system (CNS). Endothelial cells line the surface of all blood vessels. In the CNS there are additional structures that prevent the entry of many molecules. Tight and adherence junctions form between endothelial cells that prevent the movement of solutes between the cells. Additional protection is provided by the basement membrane, glial cells, and pericytes. In addition, drug efflux transporters (ABC transporters) move xenobiotics (foreign toxic molecules back through the barrier.

Nonpolar molecules like dioxygen molecules and low molecular weight can cross the BBB by simple diffusion. Other molecules like glucose and amino acids are carried across by transporters. Larger substances can move in through receptor-mediated endocytosis. Albumin, the major carrier of free fatty acids, like other proteins, does not readily pass through the barrier, and its drug-macromolecule complex, cannot cross.

Figure 17.3.2 shows a representation of the blood-brain barrier.

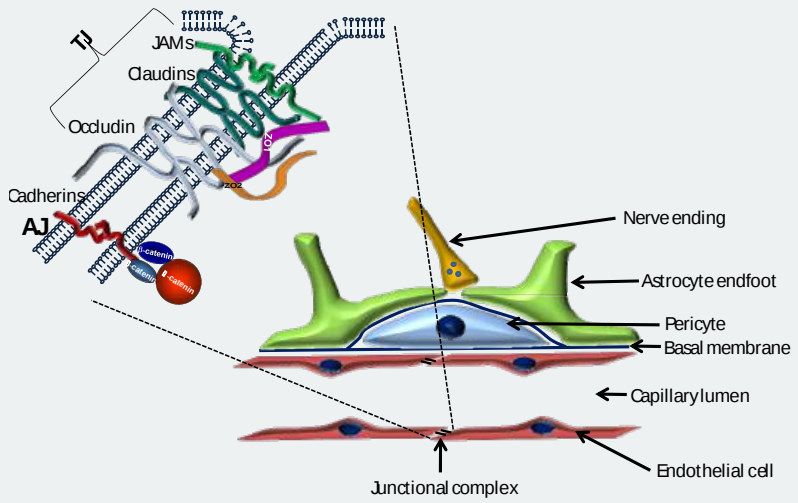

Figure 17.3.2: Structure of the blood-brain barrier. Wilhelm et al. Int. J. Mol. Sci. 2013, 14, 1383-1411; doi:10.3390/ijms14011383. Creative Commons Attribution License (http://creativecommons.org/licenses/by/3.0/).

In this section, we will explore the synthesis and utilization of ketone bodies. The synthesis pathway is called **ketogenesis**, and the degradation pathway is called **ketolysis**. Ketone body production and use are intimately tried to fatty acid metabolism so it is appropriate to discuss them right after fatty acid oxidation. An overview of both ketogenesis and ketolysis is shown in Figure 17.3.3.

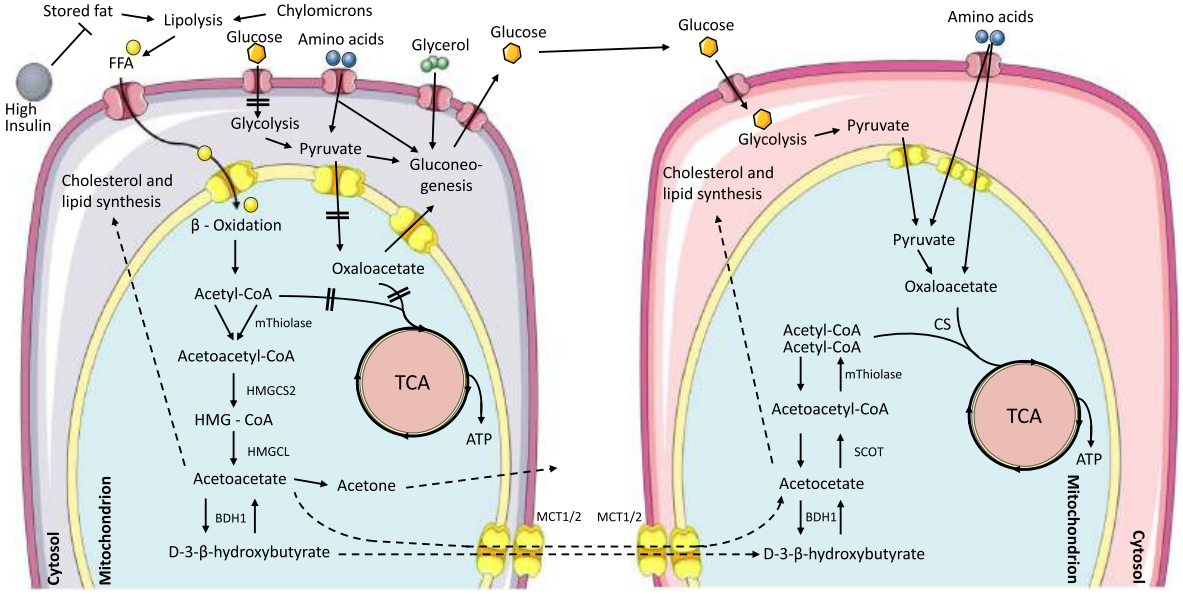

Figure 17.3.3: Overview of the ketogenesis (left) and ketolysis (right) pathways. FFA, free fatty acids; mThiolase, mitochondrial thiolase; HMGCS2, hydroxy methylglutaryl-CoA synthase; HMGCL, HMG-CoA lyase; BDH1, mitochondrial βOHB dehydrogenase; MCT1/2, monocarboxylate transporter 1 and 2; SCOT, succinyl-CoA:3-oxoacid-CoA transferase; CS, citrate synthase. Kolb et al. BMC Medicine (2021) 19:313 https://doi.org/10.1186/s12916-021-02185-0 Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

Most acetoacetate is converted to its reduction product, β-hydroxybutyrate, for blood transport. It can spontaneously or through enzymatic catalysis, can be converted to acetone since it is a β-ketoacid with a built-in electron sink that stabilizes the negative charge in the transition state and intermediate. When ketone bodies enter cells, the β-hydroxybutyrate is converted back to acetoacetate and eventually to acetyl-CoA.

17.3.2: KETOGENESIS: THE DETAILS

Figure 17.3.4 shows the chemical structures of all intermediates in the synthesis of ketone bodies.

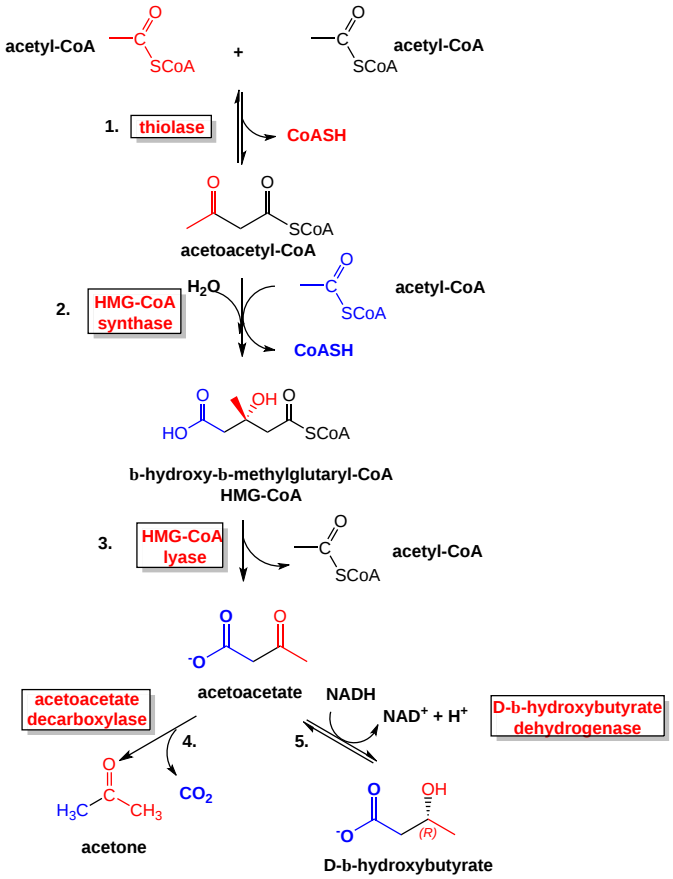

Figure 17.3.4: Ketogenesis

We'll study three of the reactions in ketogenesis in more detail below.

Reaction 1: Thiolase

We have presented the mechanism of thiolase in Step 4 of mitochondrial β-oxidation of fatty acid using the enzyme **acetyl-CoA acetyltransferase (ACAT1)** also called 3-ketoacyl-CoA **thiolase**. The final step in the beta-oxidation pathway involves cleavage of the bond between the alpha and beta carbon by CoASH. This step is catalyzed by beta-keto thiolase and is a thiolytic (as opposed to cleavage by water - a hydrolysis) reaction. The reaction produces one molecule of acetyl CoA and a fatty acyl CoA that is two carbons shorter. The process repeats until the even chain fatty acid is completely converted into acetyl CoA. The activity of the enzyme is reversible and it can also catalyze the Claisen condensation of two acetyl-CoA molecules into acetoacetyl-CoA, which occurs in the first step of ketogenesis. This step makes a C-C bond.

Reaction 2: HMG-CoA Synthase

This enzyme catalyzes the condensation of acetoacetyl–CoA (AcAc–CoA) and acetyl–CoA (Ac-CoA) to form 3-hydroxy-3-methylglutaryl (HMG)–CoA, through the formation of a C-C bond. Forming C-C bonds is critical to all biosynthesis. It's not a simple process. Cofactors are often used such as thiamine pyrophosphate, as we saw with pyruvate dehydrogenase. The reverse process, breaking a C-C bond, is also difficult unless the atoms are activated. One way to activate a carbon atom is to oxidize it through hydroxylation, often using dioxygen in reactions catalyzed by cytochrome P450. Likewise, C-C bond formation often occurs through the reaction of radicals in hemolytic reactions or through the rearrangement of key ionic intermediates. Radical reactions can be between a carbon free radical and heme derivatives. Radical reactions involve heme cofactors (as in P450), non-heme iron proteins (where the iron ion can cycle between different oxidation states), flavoproteins (in which the flavin can undergo both 1 and 2 electron redox steps), radical *S*-adenosylmethionine (SAM) enzymes, and cobalamins.

HMG-CoA synthase is somewhat unique in that it forms a C-C bond by activating the methyl group of acetyl-cysteine. The acetyl group comes from an acyl-CoA "donor". The enzyme catalyzes the first committed step in the formation of complex isoprenoids (like cholesterol) and ketone bodies. The product, 3-hydroxy-3-methylglutaryl HMG–CoA, can either be reduced by HMG-CoA reductase to form mevalonate, which leads to cholesterol synthesis, or cleaved by the enzyme HMG-CoA lyase, to produce acetoacetate, a ketone body.

Since it catalyzes the first step in cholesterol synthesis, the enzyme HMG-CoA reductase has been a primary focus of drug therapy to reduce high levels of serum cholesterol, which is generally associated with cardiovascular disease. Over 200 million people worldwide are on statins, the primary drugs used to block HMG-CoA reductase activity. Luckily, it doesn't affect HMG-CoA lyase. Gram-positive bacteria also require the mevalonate pathway.

HMG-CoA synthase catalyzes a bisubstrate reaction that displays ping-pong kinetics, characteristic of a covalent enzyme intermediate. The first substrate binds to the enzyme and transfers an acetyl group to a nucleophilic Cys 111 in the active site to form an acetyl-Cys 111 intermediae. Free CoA departs. Next the second substrate, acetoacetyl-CoA binds, and condenses with the acetyl group donated by acetyl-Cys 111. This condensation involves an enolate. A plausible reaction mechanism is shown in Figure 17.3.5.

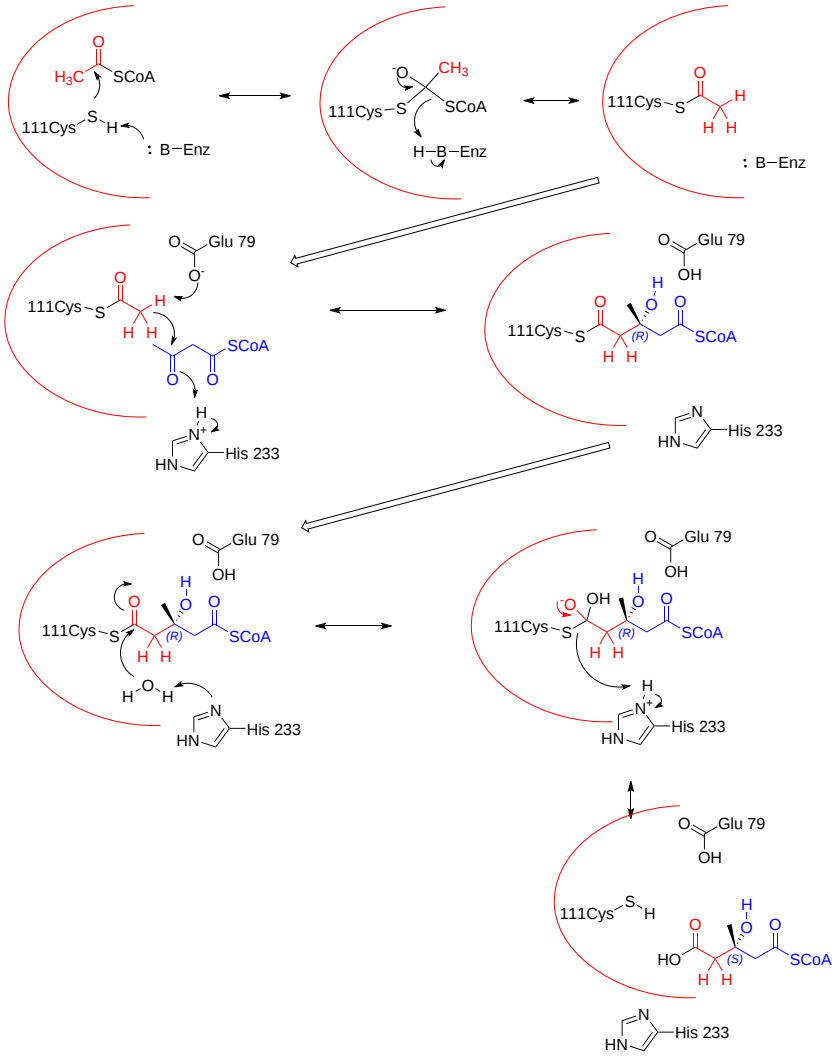

Figure 17.3.5: Reaction mechanism for HMG-CoA synthase

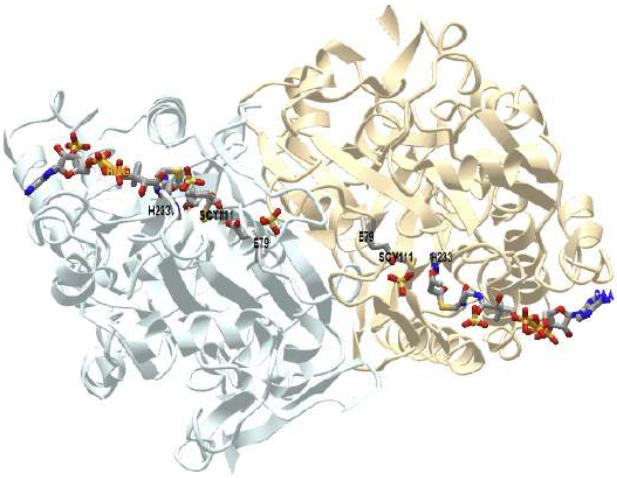
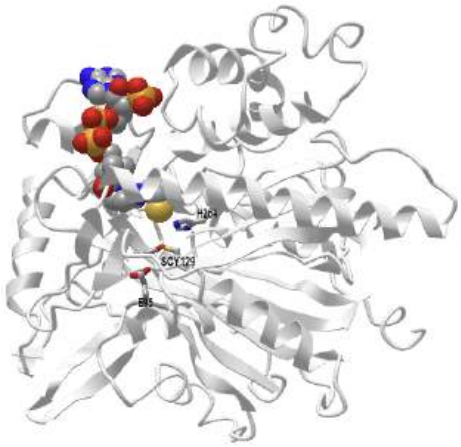
Hence there are three parts of the reaction: acetylation/deacetylation, condensation/cleavage with an enolate intermediate, and C-C formation and hydrolysis/dehydration. Figure 17.3.6 shows an interactive iCn3D model of the Staphylococcus aureus HMG-COA Synthase with bound HMG-CoA and acetoacetyl-CoA (1XPK)



NCBI iCn3D Figure 17.3.6: Staphylococcus aureus HMG-COA Synthase with bound HMG-CoA and acetoacetyl-CoA (1XPK). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...deiFs7JceE5H76

The biologically active unit (homodimer) is shown with each monomer shown in a different color. The A chain (light cyan) has bound HMG-CoA (HMG) while the B chain (light gold) has acetoacetyl-CoA (CAA) bound. The Glu 79, Cys 111, and His 233 in each subunit are shown in CPK sticks and labeled. Note that the Cys 111 is covalently modified in each subunit.

Figure 17.3.7 shows an interactive iCn3D model of the human 3-hydroxy-3-methylglutaryl CoA synthase I with bound CoASH (2P8U)



NCBI iCn3D Figure 17.3.7: Human 3-hydroxy-3-methylglutaryl CoA synthase I (monomer) with bound CoASH (2P8U). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...xxEoUfecTk3eL6

The active site side chains are numbered differently (Glu 95, Cys 129, and His 264) compared to the S. aureus protein. Only the monomer is shown in this model.

Reaction 3: HMG-CoA Lyase

The lyase reaction is a C-C bond cleavage to produce acetyl-CoA and acetoacetate. A gene knockout of this gene in mice is lethal. Figure 17.3.8 shows a plausible mechanism for the reaction.

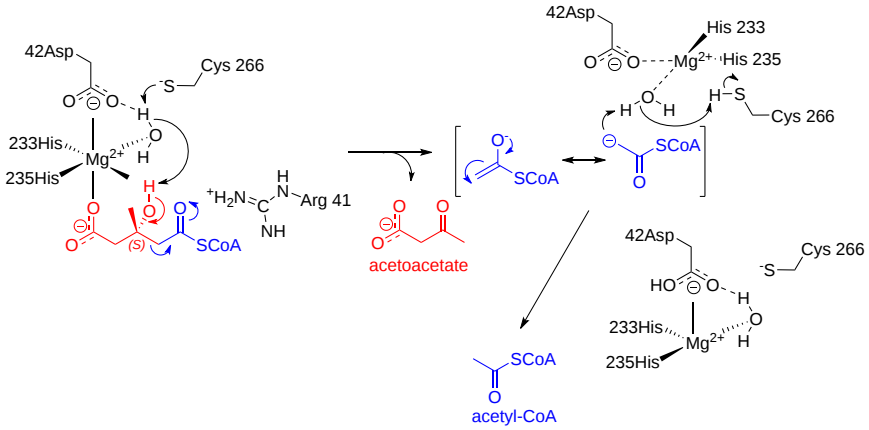


Figure 17.3.8: Mechanism for HMG-CoA lyase of HMG-CoA. (after Fu et al. The Journal of Biological Chemistry, 285, 26341–26349, August 20, 2010)

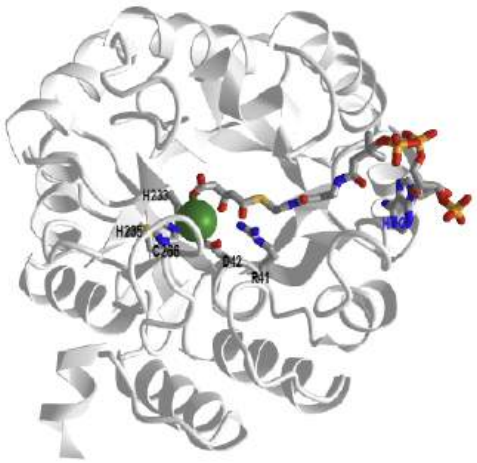
Figure 17.3.9 shows an interactive iCn3D model of the human HMG-CoA lyase with the competitive inhibitor hydroxyglutaryl-CoA (HG-CoA)(3MP3)



NCBI iCn3D Figure 17.3.9: Human HMG-CoA lyase with inhibitor HG-CoA (3MP3). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...VJBWxXpcKQyij8

Only one subunit of the homodimer is shown. The key residues involved in catalysis and binding (Arg 41, Asp 42, His 233, His 235, and Cys 266) are shown in sticks, CPK colors, and labeled. The competitive inhibitor, 3-hydroxyglutaryl-CoA (without the methyl group) is shown in CPK-colored sticks. The S-stereoisomer of HMG-CoA or inhibitor binds, not the R-isomer. Water may shuttle protons between Asp 42 and the C3 hydroxyl of HMG-CoA. Arg 41 facilitates the proper enol/keto tautomer of the product mutation on reaction product enolization. Mutation of Arg 41 have lhas effect on catalysis.

We won't go into detail on the remaining enzymes since we have encountered variants of NAD^+/NADH dehydrogenase reactions before. The acetoacetate decarboxylase just hastens the already spontaneous decarboxylation of the β-keto ester acetoacetate.

Regulation of Ketogenesis

Ketogenesis can be upregulated by hormones such as glucagon, cortisol, thyroid hormones, and catecholamines which lead to fatty acid mobilization. Insulin is the primary hormonal regulator of this process.

Insulin regulates many key enzymes in the ketogenic pathway, and a state of low insulin triggers the process. A low insulin state leads to:

- Increased free fatty acids (FFAs) arising from decreased inhibition of hormone-sensitive lipase
- Increased uptake of FFAs into the mitochondria arising from decreased activation of acetyl-CoA carboxylase, decreasing malonyl CoA, which disinhibits Carnitine Palmitoyltransferase 1 (CPT1)
- Increased production of ketone bodies arising from increased HMG-CoA activity

17.3.3: KETOLYSIS: UTILIZATION OF KETONE BODIES

Figure 17.3.10 shows the chemical structures in the utilization of ketone bodies.

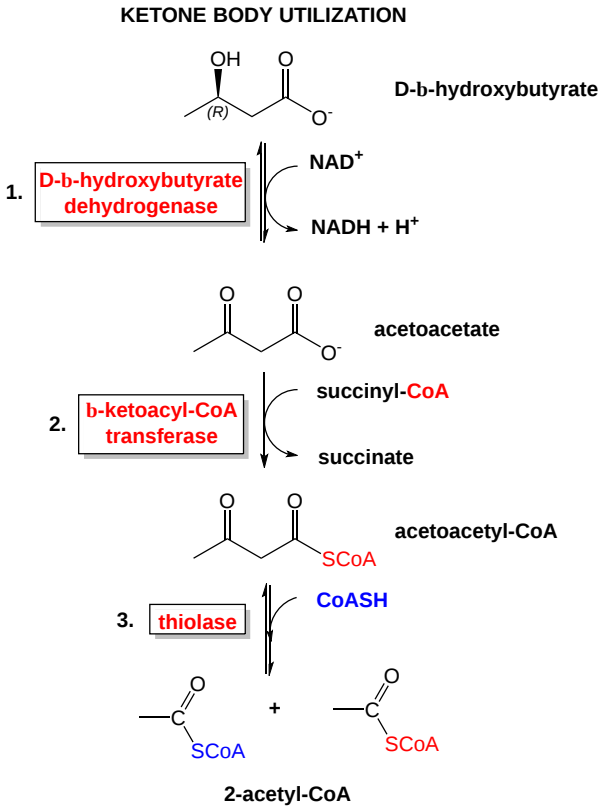


Figure 17.3.10 shows the chemical structures in the utilization of ketone bodies.

Since we have encountered reactions similar to these before, we will not discuss their detailed mechanisms.

Most organs and tissues can use ketone bodies for energy. They are a major source of energy for the brain when glucose is not available. That makes sense given that fatty acids can't cross the blood-brain barrier. The heart prefers fatty acids for energy but can also use ketone bodies. The liver makes but does not use them since the gene for step 2, beta ketoacyl-CoA transferase is not transcribed. D-β-hydroxybutyrate is first converted to the other ketone body, acetoacetate, for the pathway to continue. The net result is the formation of two acetyl-CoAs that can then enter the citric acid cycle for ATP production. Acetone is a dead-end ketone body and is excreted in the urine or eliminated in the breath.

17.3.4: CLINICAL SIGNIFICANCE

An overproduction of ketone bodies through increased ketogenesis can cause ketoacidosis (given the pKas of the ketone bodies). One type is diabetic ketoacidosis (DKA) in Type I and II diabetes which impair glucose use. This leads to liver gluconeogenesis and the resulting depletion of oxaloacetate and pyruvate, impacting the ability of acetyl-CoA to enter the citric acid cycle.

On presentation, patients are usually very dehydrated from being hyperglycemic. High glucose levels in the blood cause higher osmotic pressure in the vessels and decreased water reabsorption in the kidneys. They often have accompanying symptoms like confusion, nausea, vomiting, and abdominal pain. Because of the acidosis, patients often breathe very deeply and rapidly to eliminate carbon dioxide, which can cause and cause respiratory alkalosis. Ketoacidosis also can occur with severe alcoholism and prolonged starvation.

KETOGENIC DIET

The ketogenic diet, characterized by high fat and low carbohydrate consumption, can lead to weight loss. It shifts metabolism to more closely resemble the fasting state. Its long-term effects are not clear but some have suggested the use of ketone-based drugs to mimic the effect of ketone bodies. Fasting can also lead to a ketogenic state and it has been used for the treatment of epilepsy before the drug became available. It is important to differentiate this attempt to induce a ketogenic state from diabetic ketoacidosis.

CHAPTER OVERVIEW

18: NITROGEN - AMINO ACID CATABOLISM

18.1: The Biochemistry of Nitrogen in the Biosphere

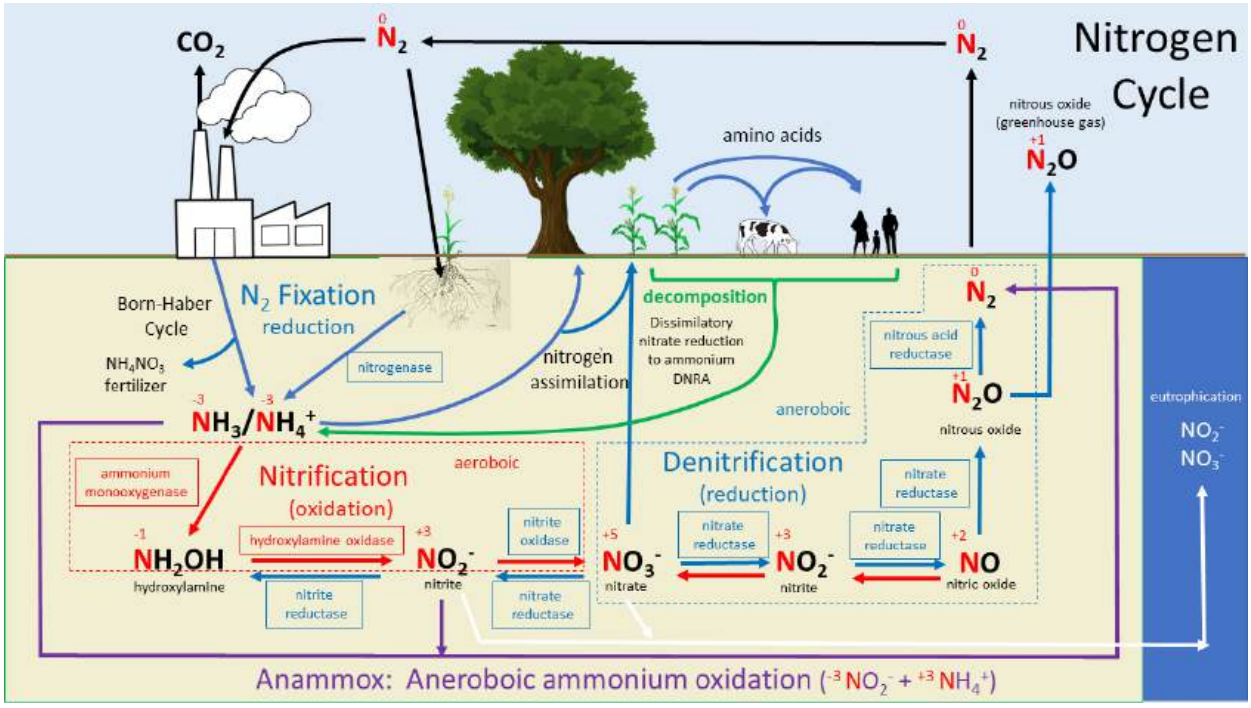
18.1: THE BIOCHEMISTRY OF NITROGEN IN THE BIOSPHERE

18.1.1: INTRODUCTION

Organic chemistry is usually described as the chemistry of carbon-containing molecules. But isn't that definition a bit carbon-centric, especially since the prevalence of oxygen-containing molecules is staggering? What about nitrogen? We live in a dinitrogen-rich atmosphere (80%), and all classes of biomolecules (lipids, carbohydrates, nucleic acids, and proteins) contain nitrogen. Dinitrogen is very stable, given its triple bond and its nonpolar nature. We rely on a few organisms to fix N_2 from the atmosphere to form ammonium (NH_4^+), which through nitrification and denitrification can form nitrite (NO_2^-), nitrate (NO_2^-), nitric oxide (NO), and nitrous oxide (N_2O), the latter being a potent greenhouse gas. We'll concentrate on the metabolic fate of amino groups in amino acids and proteins in the next section. Before exploring their fates, look at the figure below which shows an overall view of the biological nitrogen cycle. The study of biochemistry should encompass more than homo sapiens and expand to the ecosystem in which we are such a small but damaging part.

Let's break down the diagram from a biochemical perspective. There are aerobic and anaerobic processes (conducted by bacteria). Nitrogen-containing substances include both inorganic (ammonium, nitrate, nitrite) and organic (amino acids, nucleotides, etc) molecules. The reactions shown are oxidative and reductive (note: the oxidation number of the nitrogen atoms in the molecules is shown in red). Most of the reactions are carried out underground by bacterial and Archaeal microorganisms.



Here are some of the major reactions:

- N_2 fixation (a reduction): N_2 from the air is converted by bacteria to ammonium (NH_4^+) by the enzyme nitrogenase of soil prokaryotes. The energetically disfavored reaction requires lots of ATPs. Ammonium once made can then be taken up by primary producers like plants and incorporated into biomolecules such as amino acids, which animals consume. For those who may still believe that people have marginal effects on our biosphere, consider this. We may soon fix more N_2 (to NH_3) through the industrial Born-Haber reaction (used for fertilizer and explosive productions) that all the N_2 fixed by the biosphere. Much of the nitrogen in use comes from the Born-Haber reaction. The excess NH_4^+ (upwards of 50%) produced industrially and which enters the soil in fertilizers (mostly as NH_4NO_3) has overwhelmed nature's ability to balance the nitrogen cycle and is not taken up by plants. It is metabolized by microorganisms to nitrite and nitrate.
- Nitrification: Ammonium is converted to nitrite by ammonia-oxidizing aerobic microorganisms and further to nitrate by a separate group of nitrite-oxidizing aerobic bacteria. Here are the reactions (Rx 1 and 2) to produce nitrate through a hydroxylamine intermediate, followed by the formation of nitrate (Rx 3).

$$\mathrm{NH_3 + O_2 + 2\,e^- \longrightarrow NH_2OH + H_2O} \qquad \text{(Rx 1)}$$

$$\mathrm{NH_2OH + H_2O \longrightarrow NO_2^- + 5\,H^+ + 4\,e^-} \qquad \text{(Rx 2)}$$

$$\mathrm{NO_2^- + \tfrac{1}{2}O_2 \longrightarrow NO_3^-} \qquad \text{(Rx 3)}$$

These added ions exceed soil capacity and end up runoff water, polluting our rivers and lakes.

- **Denitrification**: This anaerobic reaction pathway reproduces N_2 from nitrate Here is the net reaction:

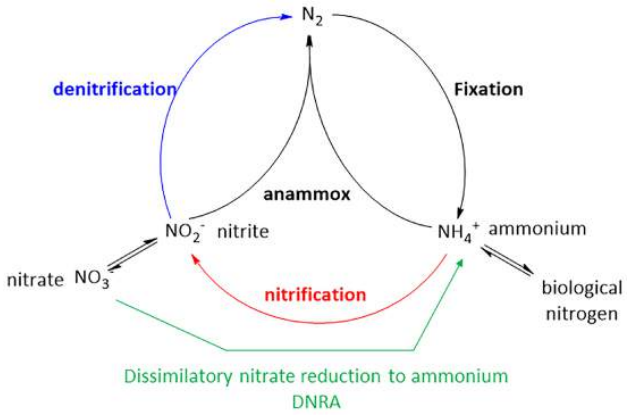
$$2\,NO_3^- + 10\,e^- + 12\,H^+ \longrightarrow 2\,N_2 + 6\,H_2O$$

- **Anammox reaction**: This more recently discovered bacterial anaerobic reaction pathway converts ammonium and nitrate to N_2. Here is the net reaction

$$NO_2^- + NH_3^+ \longrightarrow N_2 + 2\,H_2O$$

- **Ammonification** (not to be confused with mummification) occurs when plants and animals decompose, which returns ammonium to the soil for reuse by plants and microbes.

These reactions are shown in the abbreviated Nitrogen Cycle below.



Nitrogen metabolites are nutrients for plants and perhaps the most important nutrients in the regulation of plant growth (primary productivity) and in regulating life diversity in the biosphere. All living organisms require feedstocks to produce energy and as substrates for biosynthetic reactions. Which ones are used depends on the organism. Plants are primary producers so they use their own synthesized carbohydrates for both energy production and biosynthesis. For carnivores, proteins and their derived amino acids are the source of energy (through oxidation) and serve as biosynthetic precursors. For omnivorous organisms, the source of energy depends on the "fed" state. With abundant food resources, carbohydrates, and lipids are the source of energy. Unlike carbohydrates and lipids, which can be stored as glycogen and triacylglycerols for future use, excess protein, and their associated amino acids can not be stored, so amino acids can be eliminated or used for oxidative energy.

In the fed state, carbohydrates are the main source, while in the unfed state, lipids take a predominant role. Under starving conditions, the organisms' own proteins are broken down and used for oxidative energy production and for any biosynthesis that remains. In diseased states like diabetes, which can be likened to a starving state in the presence of abundant carbohydrates, both lipids and amino acids become the sources of energy.

How are amino acids in animals oxidatively metabolized? Many pathways could be used to do so but it would seem logical that NH_4^+ would be removed and the carbons in the remaining molecule would eventually enter glycolysis or the TCA cycle in the form of ketoacids. NH_4^+ is toxic in high concentrations. Ammonium is not oxidized to nitrite or nitrates in humans as occurs in the soil by microorganisms. It can be recycled back into nucleotides or amino acids, and excess amounts are eliminated from the organism. Both processes must be highly controlled. We will turn out attention to the oxidation of amino acids in the next section.

18.2: METABOLIC FATES OF AMINO GROUPS

From the previous section on the nitrogen cycle, it should be clear that NH_3/NH_4^+ has a central role in metabolism. Nature's fertilizer for plants is ammonium derived from bacterial nitrogenase and human-derived Born-Haber process. Animals get their ammonia mostly from ingested plants (primary producers) and animal protein. In vertebrates, proteins get digested into small proteins and peptides starting in the stomach where pepsin cleaves proteins after aromatic and Leu side chains into smaller fragments. The low pH in the stomach (1-2) facilitates protein unfolding, which allows great access to buried side chains for pepsin cleavage. As the ingested materials move into the small intestine, the protein fragments are further cleaved into small peptides by trypsin, and chymotrypsin and then into individual amino acids by carboxypeptidases (which cleaves C-terminal amino acids) and aminopeptidases (which cleave at the N-terminal end). The individual amino acids are then adsorbed, along with di- and tripeptides into the epithelial cells lining the small intestine. Peptidases cleave short peptides and amino acids are moved into the blood through cell membrane transporters which are coupled to sodium ion intake. Amino acids are taken up by tissues for use in protein synthesis and by the liver of vertebrates for metabolic processing. The gut proteolytic enzymes are secreted into the gut lumen as precursors (proenzymes), where they are activated either autocatalytically or by other proteases into their mature form.

Amino acids are also derived from the degradation of cellular proteins by a supramolecular assembly called the proteasome. Proteins designated for cleavage are covalently modified by ubiquitin, a short ubiquitous protein, which targets them to the proteasome.

18.2.1: DEGRADATION OF AMINO ACIDS TO PRODUCE AMMONIUM

Here is some good advice on giving a seminar: tell what you will tell them, tell them and tell them what you told them. These words imply that repetition is one of the keys to learning. So look at Figure 18.2.1 which shows an overall view of the glycolytic and TCA pathways and see how amino acid catabolism fits into what you already know!

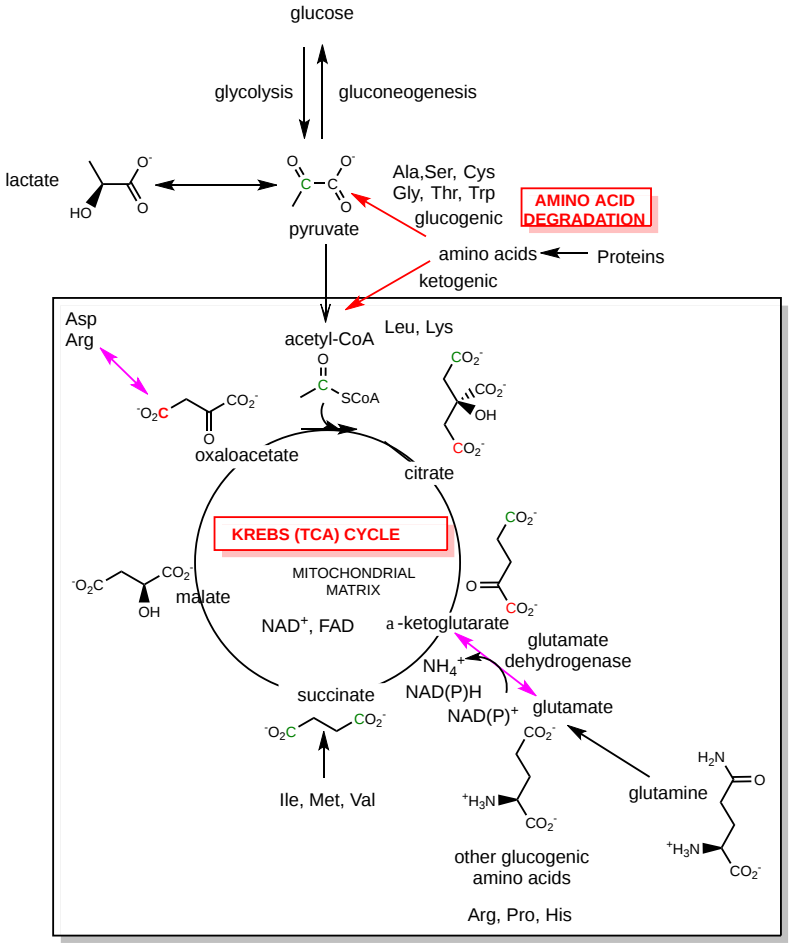


Figure 18.2.1: Amino acids and their involvement with the glycolytic and TCA pathways

A summarizing principle is that amino acids degrade to form intermediates that fit into these two common pathways and can be used for ATP production as well as biosynthesis. Those that form pyruvate are glucogenic amino acids, while those that form acetyl-CoA are ketogenic (form ketones and could form ketone bodies as well). Many form direct intermediates in the TCA cycle.

This chapter will focus on glutamine/glutamic acid, alanine (which forms pyruvate), and aspartic acid. In this section, we will focus on the role of amino acid catabolism in producing ammonium. When new students confront the structures, properties, and reactions of amino acids, they are undoubtedly daunted. Even biochemists would be if amino acid metabolism is outside their active research area. Perhaps some interesting biological properties of **free** amino acids might pique your interest. For example, did you know that ...

- glutamate and glutamine are the most abundant amino acids in red blood cells;
- alanine and glutamine are the most abundant amino acid in the body;
- glutamic acid, glutamine, and alanine are the most abundant amino acids in the cerebrospinal fluid CSF (50-55% of total amino acids);
- glutamine is the most abundant amino acid in blood serum;
- In contrast, leucine is the most abundant amino acid in **proteins**, and free leucine is a prime regulator of protein synthesis through its interaction with the mTOR kinase complex. The other top three amino acids in proteins are serine, lysine, and glutamic acid.

From the above list, it appears that Glu and Gln play special roles in metabolism and signaling. They also play major roles in ammonium metabolism as the pair are major sources of NH_4^+ production in cells. Gln has two Ns (an amine and an amide), so it's not an unexpected source of nitrogen:

- Glutamine can give up its amide nitrogen to form NH_4^+ on conversion to glutamic acid, a reaction catalyzed by **glutaminase**
- Glutamic acid can undergo oxidative deamination to form α-ketoglutarate (a TCA intermediate) and free NH_4^+, a reaction catalyzed by **glutamate dehydrogenase**
- Glutamic acid can also give up its ammonia nitrogen to a ketoacid like pyruvate to form α-ketoglutarate (a TCA intermediate) and another amino acid (alanine if pyruvate was used as the keto acid), a reaction catalyzed by a class of enzymes called **transaminases** (makes sense again), which are also called **aminotransferases**. In this case, free NH_4^+ is not formed but rather is passed to a keto acid to form another amino acid.

In vertebrates, free amino acids are metabolized in the liver. Amino acids that enter the liver transfer their ammonia group to α-ketoglutarate (aka 2-oxoglutarate) to form glutamic acid which enters the mitochondria and can be cleaved by glutamate dehydrogenase to form α-ketoglutarate and free ammonium. The NH_4^+ produced is either recycled or excreted in the form of NH_4^+ in fish, urea, $H_2N(C{=}O)NH_2$ in vertebrates, and uric acid in birds and reptiles. Excess amino acids (which again can't be stored for energy) in other organs pass their ammonia group to glutamic acid to form glutamine, which then heads to the liver for processing. Glutamine then becomes a safe way to transfer 1-2 ammonium equivalents through the blood.

Alanine and aspartic acid also play secondary roles. Ala is one transamination step away, through the removal of its amine group, from pyruvate, a crucial α-ketoacid end product of glycolysis and entry product for the TCA cycle (after pyruvate dehydrogenase). In muscle, excess amino acids pass their ammonia groups to pyruvate to form alanine, another "safe" carrier of ammonium, which heads to the liver for processing. Likewise, aspartic acid is one transamination step way, through the removal of its amino group, to form oxaloacetate, another TCA α-ketoacid.

Figure 18.2.2 shows the key α-keto acids which are also intermediates of the TCA cycle or feed into it (pyruvate) and their respective transamination amino acid products. Their structures immediately show a link between amino acid and carbohydrate metabolism.

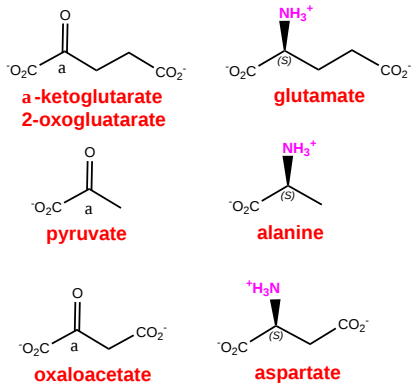

Figure 18.2.2: α-ketoacids and their transamination amino acid products

We will focus most of our attention on glutamine and glutamic acid. Figure 18.2.3 summarizes the important enzymatic steps in the conversion of Gln ↔ Glu ↔ α-KG

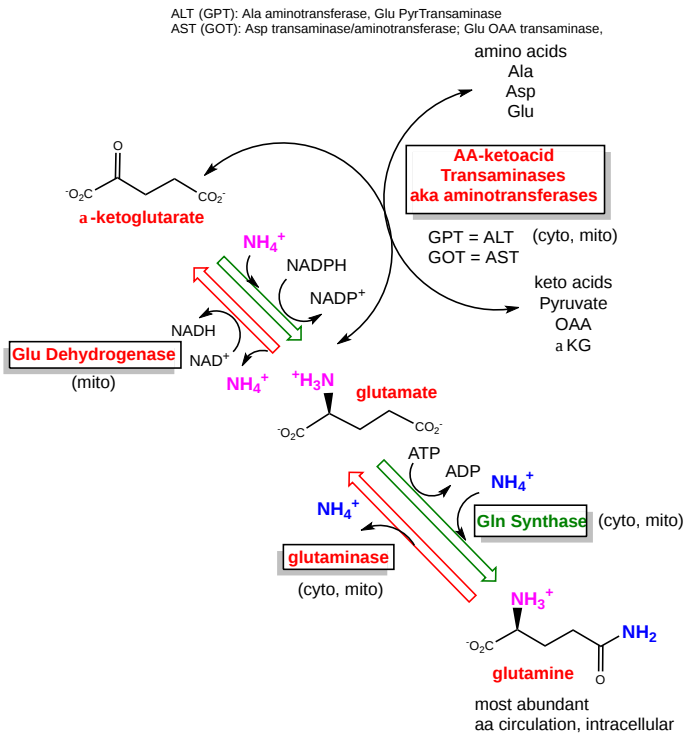

Figure 18.2.3: Important enzymatic steps in the conversion of Glutamine ↔ Glutamic acid ↔ α-ketoglutarate

18.2.2: PYRIDOXAL PHOSPHATE AND TRANSAMINATION REACTIONS

Most free amino acids start their metabolic degradation in the liver with transamination reactions, using PLP as a cofactor. PLP enables other biochemical reactions of amino acids, including racemizations, decarboxylation, and dehydration (of serine). PLP is covalently attached to a Lys through a Schiff base linkage in the enzyme during the reaction cycle so it is not considered a substrate, but rather a cofactor that returns to its original state after the reaction.

Figure 18.2.4 shows the structure of PLP and the imine formed on reaction with an amino acid. The reaction is readily reversible through hydrolysis in the presence of water which would presumably not be present in the active site of PLP-dependent enzymes. A lysine ammonia group in the enzyme forms a covalent adduct with PLP to form an imine. The imine in the figure below is called an **internal aldimine**. Internal implies that the source of the N in the imine link is a Lys internal to the protein. If in your mind you would replace the N in the imine with an O, the functional group with the C=O would be an aldehyde. Hence the imine shown is an aldimine.

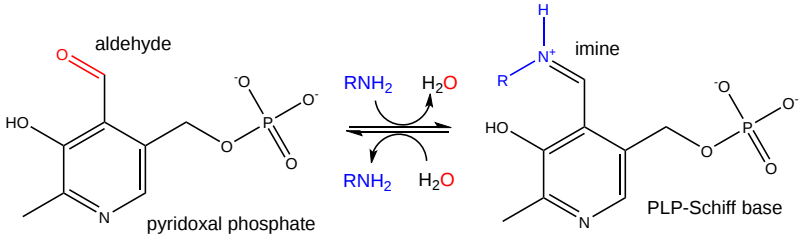

Figure 18.2.4: PLP and its imine-protein conjugate

William Jencks, in his classic text, Catalysis in Chemistry, describes the mechanistic beauty of PLP-dependent enzymes:

> *"It has been said that God created an organism especially adapted to help the biologist find an answer to every question about the physiology of living systems; if this is so, it must be concluded that pyridoxal phosphate was created to provide satisfaction and enlightenment to those enzymologists and chemists who enjoy pushing electrons, for no other coenzyme is involved in such a wide variety of reactions, in both enzyme and model systems, which can be reasonably interpreted in terms of the chemical properties of the coenzyme. Most of these reactions are made possible by a common structural feature. That is, electron withdrawal toward the cationic nitrogen atom of the*

imine and into the electron sink of the pyridoxal ring from the alpha carbon atom of the attached amino acid activates all three of the substituents of this carbon for reactions which require electron withdrawal from this atom."

When PLP-dependent enzymes react with an **external** amino acid acting as a substrate, the amine of the incoming amino acid replaces the amine from the enzyme's active Lys to produce an **external** imine. The figure below shows an external amino acid in imine linkage to PLP, and in the form shown is an aldimine.

Each PLP-dependent reaction involves a protonated and positively charged pyridinium N as an electron sink, which facilitates cleavage of **each bond** around the C_α of the covalently attached amino acid. Bond cleavage would leave a lone pair and negative charge on the α-carbon and no place to stabilize it by resonance. On the formation of a Schiff base with a pKa of around 7.0, the imine nitrogen, especially in its protonated form, is an excellent stabilizer of the negative charge. Continued delocalization of the lone pair and negative charge to the positive pyridinium nitrogen further facilitates the stabilization and hence the reaction. Figure 18.2.5 shows the cleavage of bonds around the C_α of an amino acid-PLP Schiff base.

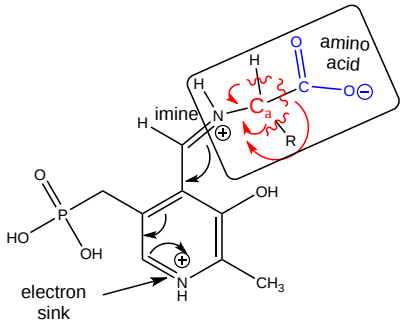

Figure 18.2.5: Cleavage of bonds around the C_α of an amino acid-PLP Schiff base

Figure 18.2.6 shows the mechanism for a transamination reaction using PLP as a cofactor. This is of course the reaction most relevant to this chapter section. The amino acid substrate is first shown in an aldimine linkage to PLP. Also, note the conversion of an aldimine to a ketimine in the next step.

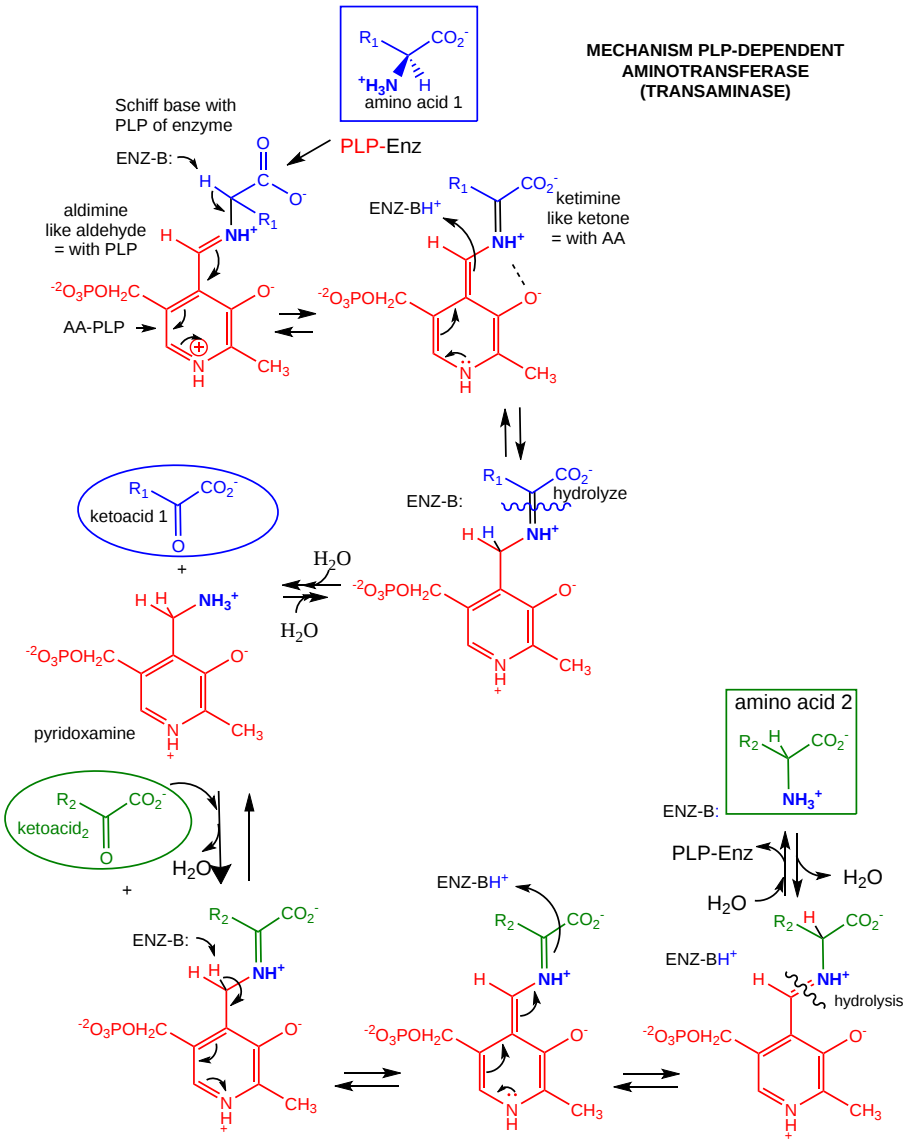

Figure 18.2.6: Mechanism for a transamination reaction using PLP as a cofactor

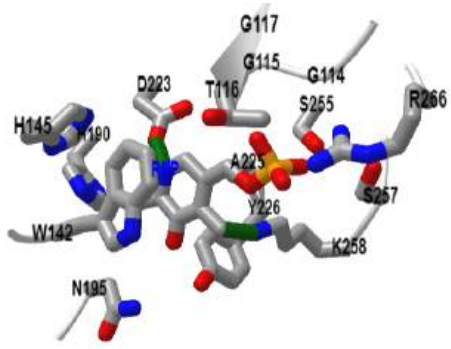
The model below shows the active site of aspartate transaminase from E. Coli (pdb code 1aam) with PLP in Schiff base linkage with lysine 258. Three amino acids critical for enzyme function (Trp 142, Asp 223, and Lys 258) and all side chains within 5 angstroms from the active site defined by those amino acids, are shown. Lys 258 forms the Schiff base with PLP cofactor and also acts as a general acid/base on interconversion between the aldimine and ketamine forms (see figure above). The ring of Trp 142 forms pi-stacking interactions with the aromatic ring of PLP and helps position it. Asp 223 acts as a general acid/base in the catalytic cycle, facilitating the deprotonation of the amine group of the substrate Asp, which makes it a potent nucleophile in the formation of the external aldimine.

Figure 18.2.7 shows an interactive iCn3D model of the active site of aspartate transaminase from E. Coli with PLP (1aam)



NCBI iCn3D Figure 18.2.7: Active site of aspartate transaminase from E. Coli with PLP (1aam). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...YeQ6kah4EuERT9

The various names and abbreviations for transaminases/aminotransferases (which are reversible) can be confusing. Two key ones whose levels are used to assess liver toxicity in clinical tests are AST (GOT) and ALT (GPT).

- **AS**partate Amino **T**ransferase (**AST)** is the same enzyme as **G**lutamate **O**xalacetate **T**ransaminase (**GOT**), named for the reverse reaction:

$$\text{aspartate} + \alpha\text{−ketoglutarate} \leftrightarrow \text{oxalacetate} + \text{glutamate}$$

- **AL**anine Amino **T**ransferase (**ALT**) is the same enzyme as **G**lutamate **P**yruvate **T**ransaminase (**GPT**), named for the reverse reaction:

$$\text{alanine} + \alpha\text{−ketoglutarate} \leftrightarrow \text{pyruvate} + \text{glutamate}$$

We will consider other reactions of PLP-dependent enzymes when needed.

To summarize, different amino acids coming into the liver can donate their amine groups to α-ketoglutarate to form glutamic acid in a reaction catalyzed by a transaminase/aminotransferase to form glutamic acid.

18.2.3: PRODUCTION OF NH_3 - GLUTAMATE DEHYDROGENASE

Now that we made glutamic acid from various amino acids, we can now break it down to make α-ketoglutarate again and ammonium. The overall reversible reaction catalyzed by the enzyme glutamate dehydrogenase in mitochondria is shown in Figure 18.2.8. Mammalian livers can also use $NADP^+$ as an oxidizing agent.

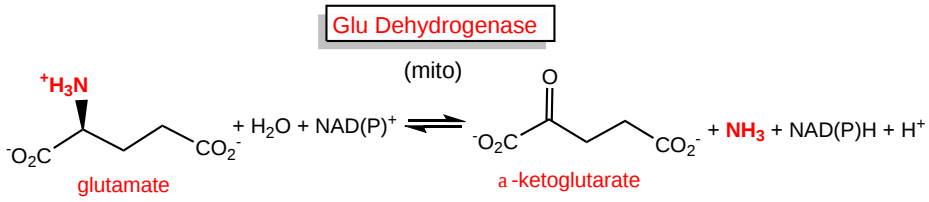


Figure 18.2.8: Overall reversible reaction catalyzed by the enzyme glutamate dehydrogenase in mitochondria

Humans have two isozymes. GluDH1 is expressed at high levels in the liver, brain, pancreas, and kidney, while GluDH2 is found in the retina, testes, and brain. GluDH1 can use both NAD^+ and $NADP^+$ so it can be used in both anabolic and catabolic reactions.

The reaction/product pairs again show this reaction to be a clear link between protein and carbohydrate metabolism. Figure 18.2.9 shows just the first step in the reaction of glutamate dehydrogenase.

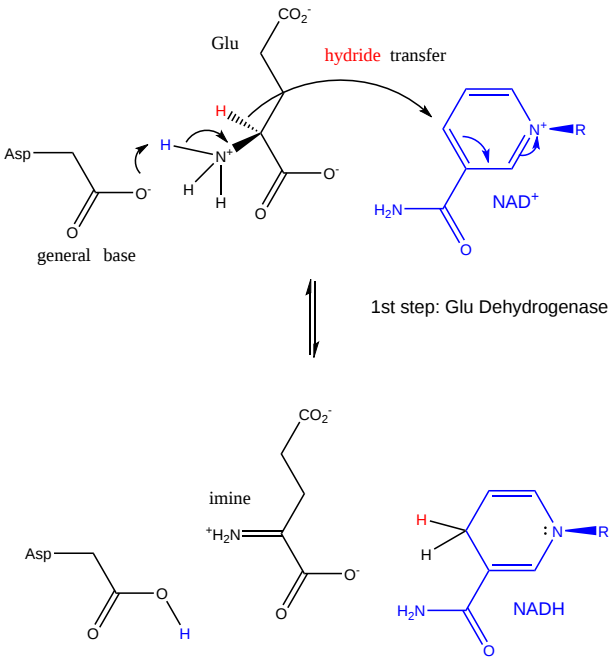

Figure 18.2.9: First step in the reaction of glutamate dehydrogenase

The C-N in Glu becomes C=N in the imine intermediate. You should recognize this as an oxidation step even if the obvious oxidizing agent, $NAD(P)^+$, was not shown. That should also be evident since a hydride (H^-) with a lone pair is removed from glutamic acid and not a H^+ as in an acid/base reaction. Subsequent steps include nucleophilic attack by water (enhanced by a proximal Lys acting as a general base) on the imine C followed by ammonia release on the formation of alpha-ketoglutarate. The overall reaction is an **oxidative deamination**.

NH_3/NH_4^+ are toxic in high concentrations. One possible reason is that the NH_4^+ cation might compete with the transport of other ions across neural membranes, altering transmembrane potentials and hence neural function. Given this toxicity, you expect that glutamate dehydrogenase is highly regulated and it is in mammals. The mammalian enzyme is a hexamer of identical subunits which suggests allosteric regulation of activity (much like tetrameric hemoglobin). ADP and leucine are allosteric activators while GTP, palmitoyl CoA, and ATP act as inhibitors. The GTP/ADP regulation is consistent with the notion that the enzyme is regulated by the need for cellular energy (remember that GTP is formed in the TCA cycle).

Although this reaction is written above in the direction of NH_3 formation, the reaction is reversible, even though the ΔG^0=-6.2 kcal/mol (-26 kJ/mol) and though the human enzymes have a high Km for ammonia (12-62 mM, Brenda Database). As the pH decreases from 8 to 7, the Km for ammonia increases from around 12 to 60 mM. This implies that on glutamate uptake and in acidotic conditions, the reaction runs exclusively in the direction of NH_3 release - as an oxidative deamination reaction.

18.2.4: TRANSPORTING AMMONIUM EQUIVALENTS IN THE BLOOD - GLUTAMINE AND ALANINE

NH_3/NH_4^+ are toxic in high concentration, mechanisms must be in place to transport it in the blood. Ideally, it would be transported in a nontoxic form. Glutamic acid is a key metabolic molecule so glutamine is the preferred molecule for safe "NH_3/NH_4^+" transport from tissue to the liver, while alanine is the choice for muscle tissue. In a way, this less toxic mode of transport is similar in principle to the use of soluble ketone bodies to transport the energy equivalent of the less soluble fatty acids in the blood.

A key enzyme for this process is **glutamine synthetase**, which catalyzes this reaction:

$$NH_4^+ + ATP + Glu \rightarrow Gln + ADP + HPO_4^{2-} + H^+$$

This reaction is important as most ingested glutamine is converted to glutamate on absorption.

NH_3/NH_4^+ made in the intestine and kidney ends up in the circulation where it heads to the liver for the eventual production of urea.

Figure 18.2.10 shows the Glucose-Alanine Cycle in comparison to the Cori cycle we discussed in a previous chapter.

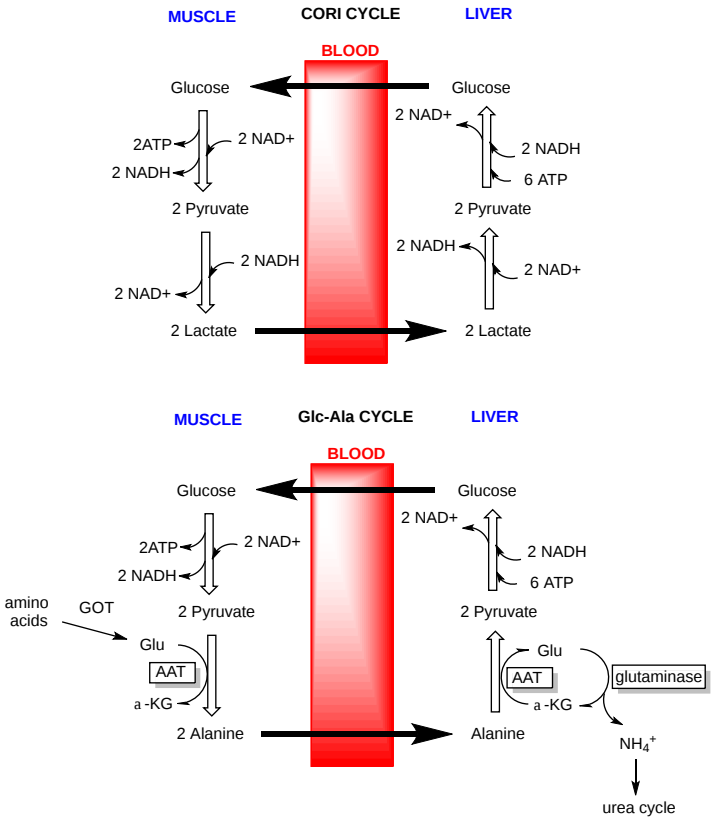

Figure 18.2.10: Glucose-Alanine Cycle in comparison to the Cori cycle

18.2.5: PRODUCTION OF NH_3 - GLUTAMINASE

Most amino acids arriving in the liver for degradation go through two enzymes, transaminases to form glutamic acid followed by glutamate dehydrogenase to form a TCA intermediate (alpha-ketoglutarate) and ammonia. Glutamine is a carrier of excess ammonia in the bloodstream (see below). When it arrives in the liver, it can lose its amide NH_2 as ammonium as it is converted to glutamic acid by the enzyme **glutaminase**, a nonoxidative enzyme that is expressed in the liver, brain, and kidney. Some of the glutamate can lose ammonia by the enzyme glutamate dehydrogenase, but most is reserved for protein synthesis or the creation of anabolic precursors.

As mentioned above, glutamine is the most abundant free amino acid in the body and most cells. It can donate its amide N through reactions catalyzed by **amido**transferase (not to be confused with aminotransferases) leading to the incorporation of nitrogen into many biomolecules.

18.2.6: METABOLIC SUMMARY

- Glutamine is both a carrier of ammonia and a carbon backbone used in metabolism when converted to α-ketoglutarate. It can be metabolized for energy and used in biosynthesis for nucleotides and neurotransmitters. As such its levels are controlled by glutamine synthase and glutaminase. When we get to synthetic pathways, you will find that glutamine is a NH_3/NH_4^+ donor for the synthesis of other amino acids as well as nucleotides, amino sugars, and NAD^+.
- Glutamine that is absorbed in the intestines is mostly converted to glutamic acid in the intestinal epithelial cells and is transported by the blood. The rest heads to the liver for processing. Hence most glutamine must be synthesized by glutamine synthase, a cytosolic enzyme found in most mammalian cells. However, it is most abundant in muscle, liver, and adipose cells which express little glutaminase and from which it can be exported. Glutaminase in the liver and kidney leads to ammonium production
- Glutamine is used as a source of energy and carbon for biosynthesis by tumor cells, which need both energy and intermediates for synthesis by rapidly proliferating cells. Aerobic glycolysis ("Warburg effect") allows that to occur.

18.3: NITROGEN EXCRETION AND THE UREA CYCLE

18.3.1: THE UREA CYCLE

Now we are in a position to see what happens to excess NH_3/NH_4^+ that accumulates in the liver mitochondria. The ammonia that is formed in the liver through oxidative deamination by glutamate dehydrogenase, ends up in urea. Alternatively, it could be added to glutamic acid to form glutamine which can head to the kidney where, after sequential reactions by glutaminase (a deamidation reaction) and glutamate dehydrogenase, it forms ammonia for direct excretion in the urine. If your diet is high in proteins and hence amino acids, since they can't be stored as proteins per se, they are metabolized for energy and the metabolic products can be converted to fat or carbohydrate. That leaves excess nitrogen which ends up mostly as urea for excretion.

Urea is a very water soluble, nontoxic molecule that biochemists use in the lab to chemically denature protein (at concentrations of 3-6 **M**). Clinical blood urea concentrations are expressed as Blood Urea **Nitrogen** (BUN) which range from 7 to 20 mg/dL N, which is equivalent to 2.5 to 7.1 **mM** urea. Serum levels depend predominately on the balance between urea synthesis in the liver and its elimination by the kidney. Normal cellular urea concentrations should be similar.

Urea is produced by a pathway called the urea cycle, as shown in Figure 18.3.1.

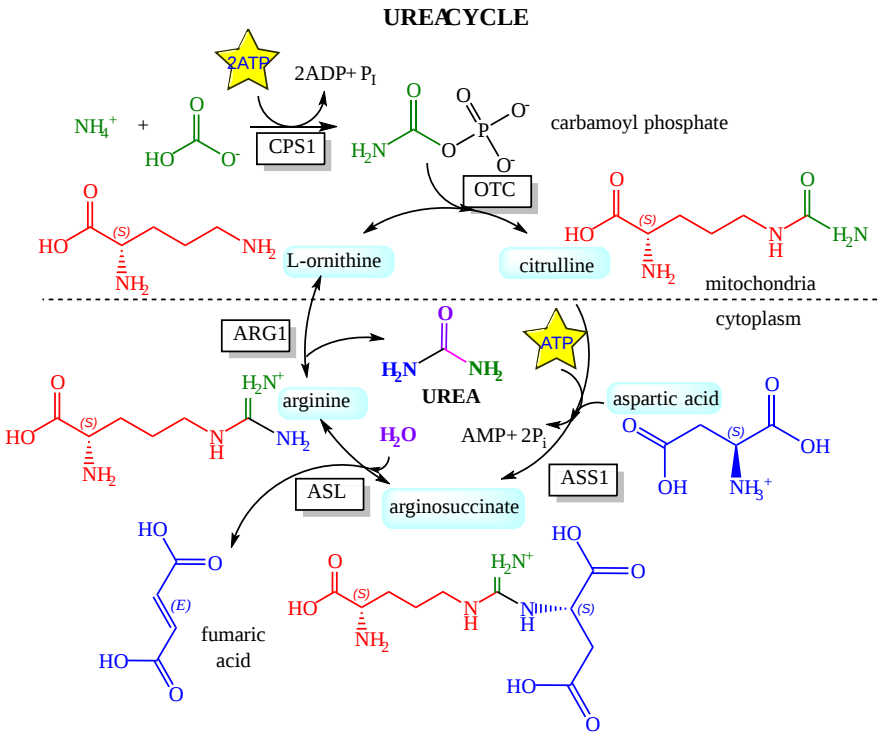

Figure 18.3.1: The Urea Cycle

The enzyme names are:

- CPS1: carbamoyl phosphate synthase I
- OTC: ornithine transcarbamoylase
- ASS1: arginosuccinate synthase 1
- ASL: arginosuccinase lysase (aka arginosuccinase)
- ARG1: arginase

It is color-coded to designate the sources of the C and N atoms. One N comes from ammonia (or indirectly from the amido N of glutamine), while the C atom comes from carbonate. The other comes from the amine of aspartate. Note that 3 ATPs are used to power the cycle. Also note the guanidino group of arginine ($NH(NH_2^+)NH_2$) is the immediate donor of the 2 N atoms in the step that produces urea. Knowing that one amino acid was the immediate donor of the N atoms in urea, you would easily predict that.

Now, let's look at some of the steps, starting with the ones that are powered by ATP, which are also the ones where nitrogen is incorporated into the precursors of urea.

18.3.2: CARBAMOYL PHOSPHATE SYNTHASE I (CPS I)

This enzyme catalyzes the first "committed" path of the pathway and makes the reactant that enters the cycle, carbamoyl phosphate. It requires a specific cofactor, N-acetyl-glutamate (NAG), produced by the acetylation of glutamate by acetyl-CoA using an enzyme NAG synthase which is activated by arginine. The reaction is not part of the cycle but provides the input for it.

A cytosolic version of this enzyme, CPS II, is used to synthesize arginine and pyrimidine nucleotides using glutamine as a donor of NH_4^+which reacts with carboxyphosphate to produce carbamoyl phosphate. It is not regulated by NAG.

CPS I provides a way to form a $(C=O)NH_2$ unit for urea by condensing bicarbonate and ammonia to form a carbamate, which contains a high energy "motif" with respect to its hydrolysis product. (Note: this does not imply that the broken bond is high energy, a misnomer found in many books.) Hence the reaction is powered by 2 ATPs as an energy source. Urea is a molecule that "carries" both NH_3/NH_4^+ and also carbonate.

A reaction mechanism for carbamoyl phosphate synthase is shown in Figure 18.3.2.

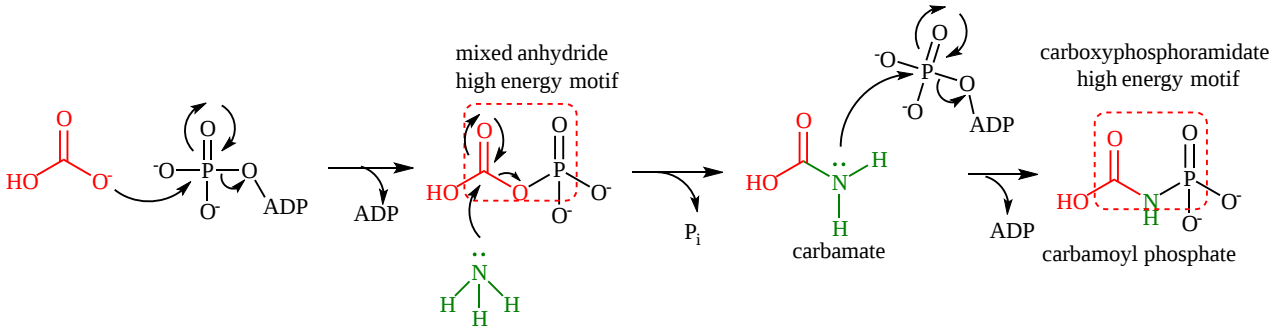

Figure 18.3.2: Reaction mechanism for carbamoyl phosphate synthase

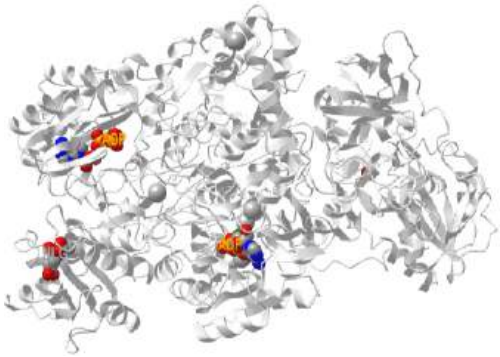
The two high-energy motif molecules (again with respect to their hydrolysis products) are protected from nonspecific hydrolysis as the mixed anhydride pass along a sequestered tunnel to a more distal phosphorylation site in the multimeric enzyme.

Figure 18.3.3 shows an interactive iCn3D model of the human carbamoyl phosphate synthetase I with bound ADP and N-acetyl-glutamate (5DOU).



NCBI iCn3D Figure 18.3.3: Human carbamoyl phosphate synthetase I with bound ADP and N-acetyl-glutamate (5DOU). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...yV8fW3mW9idy6A

The model shows one chain of the multimer. The 2 ADPs and single N-acetylglutamate (NLG) are shown in spacefill and labeled. Additional bound ions are shown (unlabeled).

The protein exists in a monomer-dimer equilibrium mixture. Each monomer has 1 NAG and 2 ADP, which represent the two different binding sites for the two different phosphorylation steps as shown in the reaction above. The two phosphorylation sites are connected by a tunnel allowing passage of the mixed anhydride to the carbamate phosphorylation site. The NAG is an allosteric modifier as it is not bound near the phosphorylation sites. On binding to the apo form of the enzyme, it elicits a large conformation change allowing a competent enzyme conformation with a complete tunnel to predominate.

An image of the tunnel for one monomer of the human carbamoyl phosphate synthetase I is shown in Figure 18.3.4.

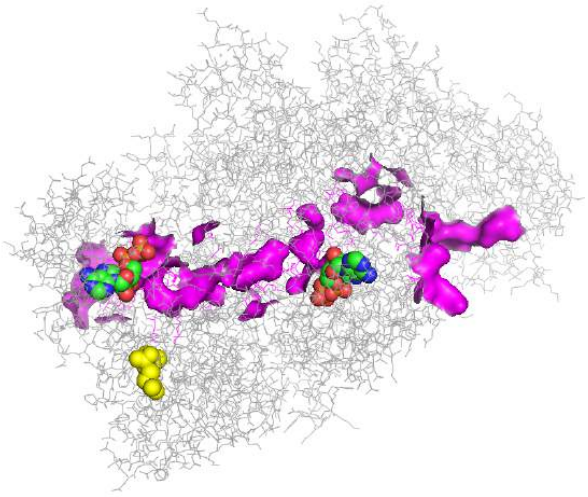


Figure 18.3.4: Tunnel for one monomer of the human carbamoyl phosphate synthetase I enzyme.

Two ADPs are shown below in spacefill with CPK color. The tunnel between the two ADP sites is highlighted in magenta. The yellow molecule is NAG, which again exerts its activation effect by binding to an allosteric site, which effectively opens up the tunnel.

Figure 18.3.5 shows the enzyme monomer in a different orientation with a tunnel made using ChExVis: a tool for molecular channel extraction and visualization. The large red and green spheres show the surface openings.

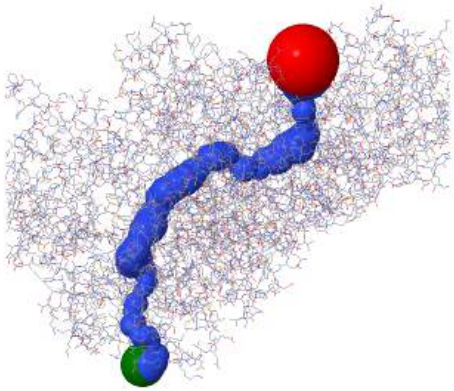

Figure 18.3.5: Second view of the tunnel in human carbamoyl phosphate synthetase I

The top panel in Figure 18.3.6 shows the radius in Angstroms of the tunnel going from the Red sphere to the Green sphere in the image above. The bottom panel shows a measure of the hydrophobicity (red)/hydrophilicity (blue) of the amino acids surrounding the tunnel.

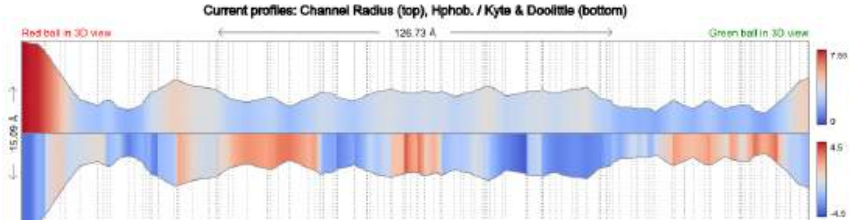

Figure 18.3.6: Tunnel size and polarity profile in human carbamoyl phosphate synthetase I

18.3.3: ASS1: ARGINOSUCCINATE SYNTHASE 1

Another ATP is cleaved to drive the conversion of citrulline to arginosuccinate, as shown in Figure 18.3.7. The product could easily be cleaved in the next step to form the amino acid arginine.

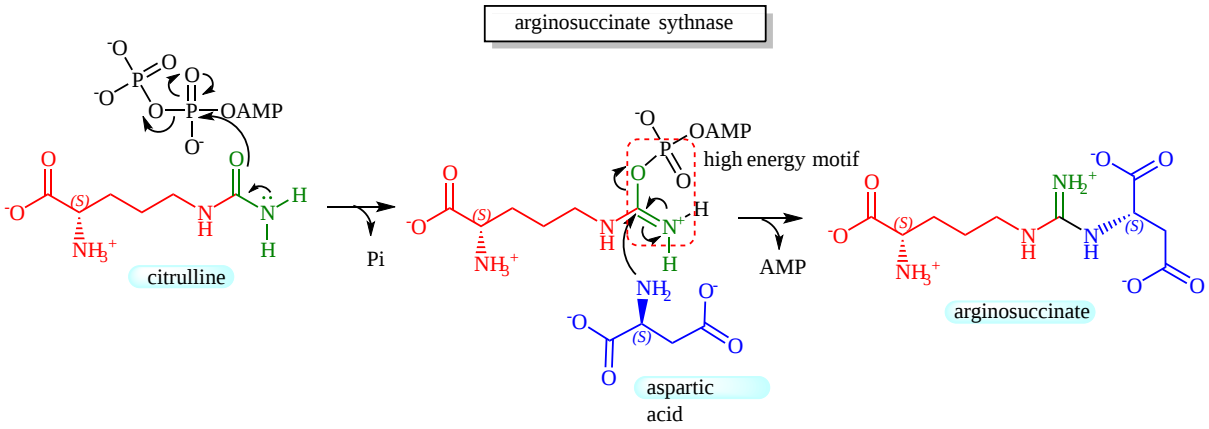

Figure 18.3.7: ATP cleavage drives the conversion of citrulline to arginosuccinate

18.3.4: ASL: ARGINOSUCCINASE LYSASE (AKA ARGINOSUCCINASE)

This enzyme catalyzes a beta-elimination reaction, which may proceed through either an E2 or E1 mechanism. A general but very abbreviated mechanism showing a two-step (E1) elimination proceeding through a carbanion intermediate is shown in Figure 18.3.8: below.

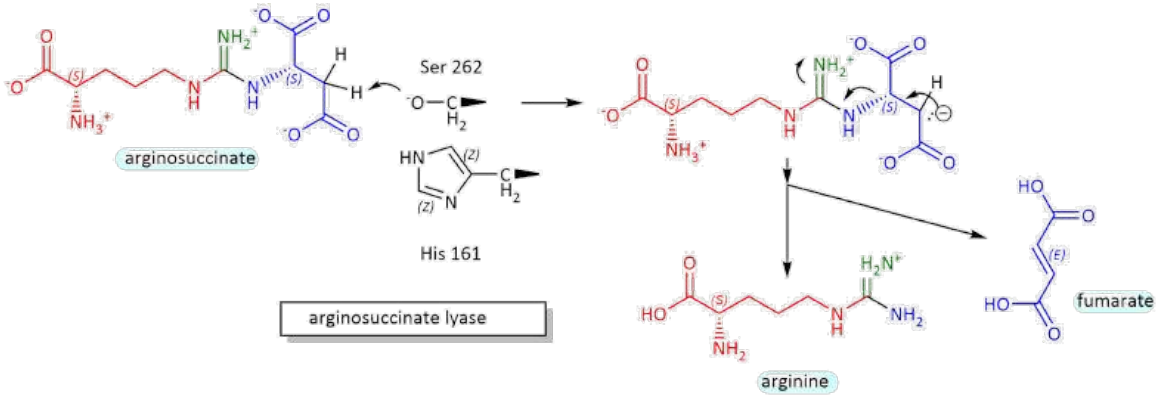

Figure 18.3.8: Mechanism for conversionof arginosuccinate to arginine and fumarate

Figure 18.3.9 shows an interactive iCn3D model of the tetrameric arginosuccinate lyase (ASL) from *Mycobacterium tuberculosis* (6IEN).

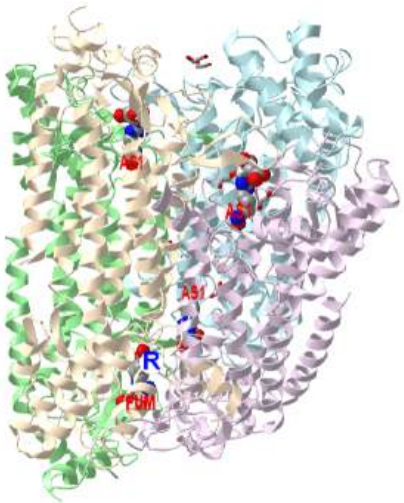

Figure 18.3.9: Tetrameric arginosuccinate lyase (ASL) from *Mycobacterium tuberculosis* (6IEN). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...32EuouGQ6xMVk6

Each monomer of the four monomers is shown in a different color. 3 arginosuccinates (substrate) and 1 fumarate and 1 arginine (products) are shown in spacefill, with CPK colors and labeled. Each monomer has an N-, M-, and a C-domain. The four binding sites consist of

residues from three monomers. The products are in the fourth site. Catalytic residues probably include a serine and histidine act as general acids/bases with a deprotonated lysine making the serine a general base.

18.3.5: ORNITHINE TRANSCARBAMYOLASE

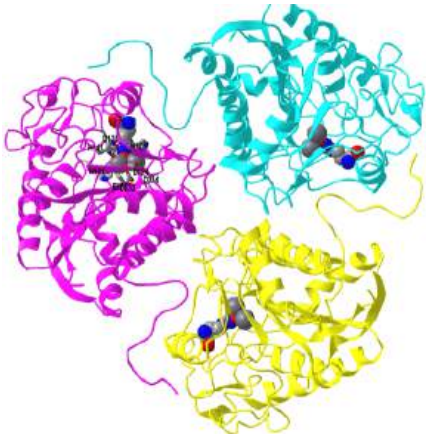
The reaction mechanism here is quite simple. The carbamoyl phosphate is an activated electrophile in which the carbonyl C is attacked by a deprotonated amino of ornithine to produce citrulline. The gene is found on the X chromosome in humans so mutations in males lead to a "hyperammonemic coma" and death. Heterozygous females can be asymptomatic and that generally proves to be fatal. Heterozygous females are either asymptomatic or have problems arising from defects in pyrimidine biosynthesis which a low-protein diet can alleviate with the addition of arginine.

18.3.6: ARGINASE

There are two general variants of this enzyme, Arginase I is a cytosolic enzyme expressed in the liver and is involved in urea synthesis. Arginase II is a mitochondrial enzyme and is involved more generally in arginine metabolism. Arginase I converts arginine to ornithine and urea. The enzyme has 2 Mn ions in the active site. A hydroxide ion bridges the two Mn ions and acts as a nucleophile which attacks the guanidino group of arginine and forms a tetrahedral intermediate. An active site Asp 128 acts as a general acid and protonates the amino leaving group to form ornithine and urea. Water then adds back to the Mn dinuclear cluster and ionizes, donating a proton to solvent through an intermediary His 41 as it reforms the active enzyme.

The model below shows the trimeric human arginase I (3KV2) in complex with the inhibitor N(omega)-hydroxy-nor-L-arginine, in which one of the guanidino Ns is replaced with an OH. The two grey spheres are Mn ions.

Figure 18.3.10 shows an interactive iCn3D model of the trimeric human arginase I in complex with the inhibitor N(omega)-hydroxy-nor-L-arginine (3KV2).



NCBI iCn3D Figure 18.3.10: Trimeric human arginase I in complex with the inhibitor N(omega)-hydroxy-nor-L-arginine (3KV2). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...QaAQpt5t2KKic6

Figure 18.3.11 show an active site water (#480) near the Mn ions.

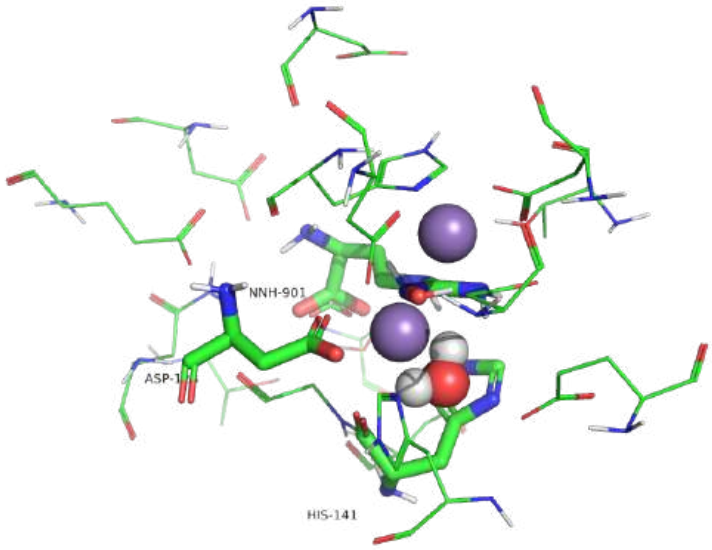


Figure 18.3.11 : Active site of human arginase I with an active site water

Water molecules can act as ligands and bind transition state metal ions through a coordinate covalent bond. The pKa of the bound water shifts to a lower value, making it more likely to deprotonate to form OH^-, which is both a better base and nucleophile. Water 480 in the active site appears to form a coordinate covalent bond to the Mn ion forming an active site hydroxide that attacks the guanidino group of arginine, leading to the formation of urea and ornithine.

18.3.7: REGULATION

If excess amino acids/proteins are consumed, a change in gene expression can increase levels of the enzymes in the urea cycle. In the short term, the activity is regulated by the enzyme that provides access into the cycle, carbamoyl phosphate synthase, whose activity is regulated by N-acetylglutamic acid and which catalyzes the rate-limiting step. As shown above, without the allosteric regulator, NAG, the enzyme is functionally inactive. The levels of NAG are determined by the enzyme NAG synthase, which itself is regulated by free arginine, the immediate precursor of urea in the cycle. Supplemental arginine is given to patients with urea disorder system and its effect probably occurs through the regulation of NAG synthase.

18.3.8: THE LINK BETWEEN THE UREA CYCLE AND THE TCA CYCLE

Two of the major pathways you have explored, the TCA and urea cycles, are not linear but cyclic pathways. What advantages do "circular" offer over linear ones? Perhaps a comparison to economic pathways offers a clue. In a linear economy, raw materials are used to produce a product which is eventually discarded as trash. Unfortunately, linear pathways dominate our world at a great cost to our environment. To reduce the inefficiencies in a linear economy and make it more viable and to decrease environmental damage and associated climate change, the world should move to a circular economy. A circular economy is characterized by what has been referred to as the 3Rs: reduce, reuse, and recycle. This saves resources and energy. These characteristics also apply to circular biochemical pathways as reduced levels of metabolites get reused and recycled.

Given this, it should not come as a surprise that the urea and TCA cycle are linked, especially given that fumaric acid is a product of the urea cycle and a cyclic metabolite of the TCA cycle. In addition, aspartic acid is one transamination step away from oxaloacetate. The interconnections between the urea cycle and the TCA cycle are shown in Figure 18.3.12 along with two additions, the malate aspartate shuttle, and the aspartate arginosuccinate shunt.

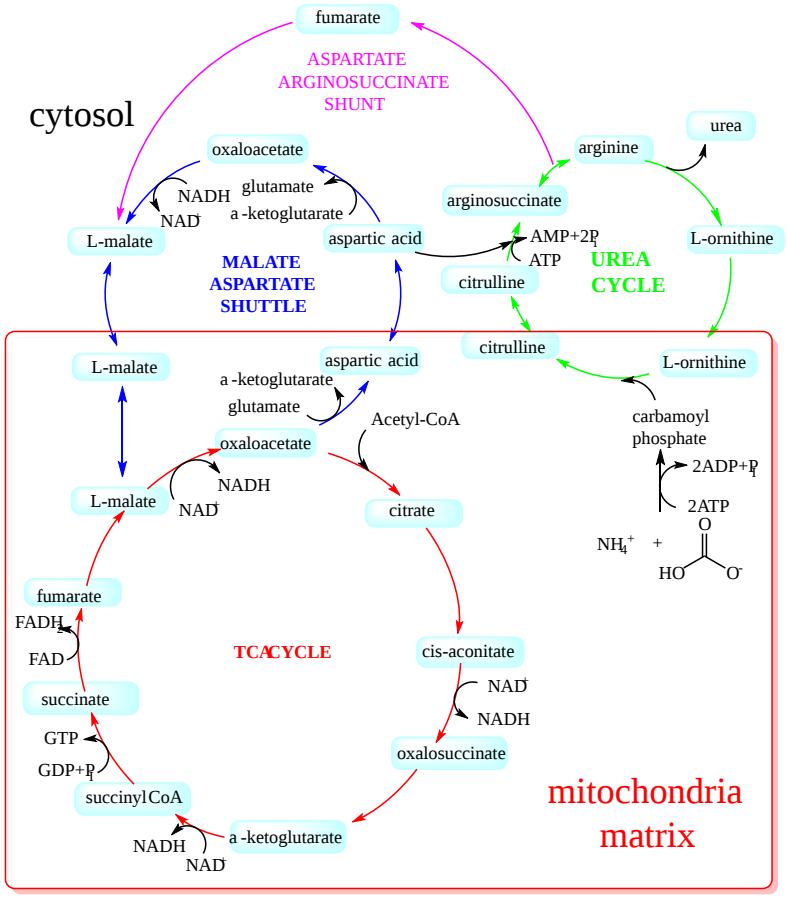

Figure 18.3.12: Urea and TCA cycles linked by the malate aspartate shuttle and the aspartate arginosuccinate shunt.

One of the nitrogens in urea comes from the amine of aspartate, which can be formed through the transamination of oxaloacetate from the TCA cycle to form aspartate. Since the TCA cycle is a cycle, an equivalent of one oxaloacetate must return to the cycle. It does so indirectly from fumarate, a TCA intermediate produced as a by-product of the urea cycle, but the fumarate is produced in the cytoplasm. There, it gets converted to malate, which can get transported into the mitochondria by a transport protein, mitochondrial 2-oxoglutarate/malate transporter, that is part of yet another cycle shown in the figure above, the **aspartate arginosuccinate shunt.** The introduction of fumarate into the shuttle occurs through the **aspartate arginosuccinate shunt** shown in the figure above**.** Once malate enters the mitochondrial matrix, it can be directly converted to oxaloacetate.

Note that these linked cycles require the presence of both mitochondrial and cytoplasmic forms of the several enzymes and balances between two key amino acids across the mitochondrial divide, glutamate, and aspartate. One such key enzyme is **AS**partate Amino **T**ransferase (**AST), aka G**lutamate **O**xaloacetate **T**ransaminase (**GOT**), named for the reverse reaction of aspartate + α−ketoglutarate ↔ oxaloacetate + glutamate. As mentioned in the previous chapter section, this key enzyme can be found in the blood if the liver is damaged, so its levels are routinely used in medical tests for impaired liver function.

Another key function of the malate aspartate shuttle is to bring into the mitochondria reduced "equivalents" of NADH that are produced in the cytoplasm from glycolysis and fatty acid oxidation. There is no membrane transporter for NAD^+ or NADH. Instead, cytoplasmic malate, produced by the cytosolic reduction of oxaloacetate by NADH, can be transported into the matrix which can reform mitochondrial NADH on reconversion to oxaloacetate. The NADH can then be used to power ATP production through mitochondrial electron transport/oxidative phosphorylation pathways.

From an energetic perspective, four phosphoanhydrides bonds in 3 ATP molecules are used to produce one urea molecule. This large energy expenditure is partially compensated for by ATP made from the "fumarate equivalents" that enter the mitochondria through the aspartate arginosuccinate and aspartate arginosuccinate shunts and the passage of NADH through oxidative phosphorylation.

18.4: AN OVERVIEW OF AMINO ACID METABOLISM AND THE ROLE OF COFACTORS

18.4.1: AMINO ACID DEGRADATION

We saw how nitrogen is removed from amino acids to produce urea or NH_4^+ in the previous chapter section. What are the fates of the carbon skeletons that remain? This section is where students might get overwhelmed by the diversity of amino acid degradation pathways, so it helps to realize that carbon skeletons of deaminated amino acids can be used for biosynthesis or energy production and are converted to key glycolytic and TCA intermediates that you have seen many times before. Everything is interconnected which makes the study of metabolism daunting but also fascinating, as organisms try to extract all the energy and molecule-building atoms from a metabolite and minimize waste.

Here are some key features of amino acid catabolism that this chapter section will present.

- some are converted to pyruvate, the end product of glycolysis and the start reactant of gluconeogenesis. Hence, these amino acids are **glucogenic**;
- some are converted to acetoacetate-CoA and or acetyl-CoA. Both of these can be converted to ketone bodies (acetoacetate/β-hydroxybutyrate) so these are considered **ketogenic**. Since the two carbons of the acetyl group of acetyl-CoA are lost as CO_2 in the TCA cycle, and there is no reverse for the pyruvate dehydrogenase reaction (pyr → acetyl-CoA), acetyl-CoA formed by amino acid degradation can not be used to create glucose in net fashion;
- some are metabolized to form TCA intermediates. Since they are added in a **net** fashion to the TCA cycle and don't remove the existing pool of TCA intermediates, they can produce in a **net** fashion directly or indirectly molecules that can be used to produce glucose. These entry reactions to the TCA which replenish or add to TCA intermediates are called anaplerotic (replenishing) reactions. Hence these amino acids are also **glucogenic**.
- some have multiple ways to be degraded and can produce both acetyl-CoA and pyruvate, so they are **both glucogenic and ketogenic.**

Let's get more explicit:

- purely ketogenic: only Leu and Lys (the only amino acids whose name starts with **L** and you have to **L**ove them since there are only 2 amino acids in this category)
- both: 5 including the aromatics - Trp, Tyr, Phe - and Ile/Thr
- purely glucogenic: the rest

General hints as to if an amino acid is glucogenic and/or ketogenic can be derived from their structures.

Fully or Partly Ketogenic Amino Acids: Amino acids except for Arg that have a **continuous chain** of 3 or more carbon atoms in their **side chains** and hence are more "fat-like" are ketogenic or ketogenic/glucogenic. These include Lys, Leu, Ile, and the aromatic amino acids Phe, Trp, and Tyr and exclude Val. (note: Thr, which is both ketogenic and glucogenic, doesn't fit this rule). The fully or partly ketogenic amino acids are shown in Figure 18.4.1.

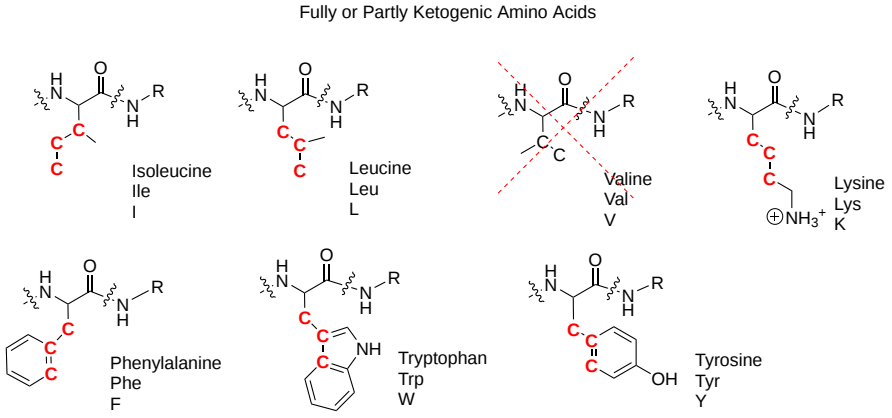

Figure 18.4.1: Fully or Partly Ketogenic Amino Acids

Purely Glucogenic Amino Acids (for Pyr and/or TCA intermediates): Which amino acids produces which intermediate? Except for glycine, it's pretty easy to remember. The number of carbons in the intermediate formed is the same as the number of carbons in the longest chain in the amino acid.

These amino acids form the 5C TCA intermediate alpha-ketoglutarate (2-oxoglutarate) and are shown in Figure 18.4.2.

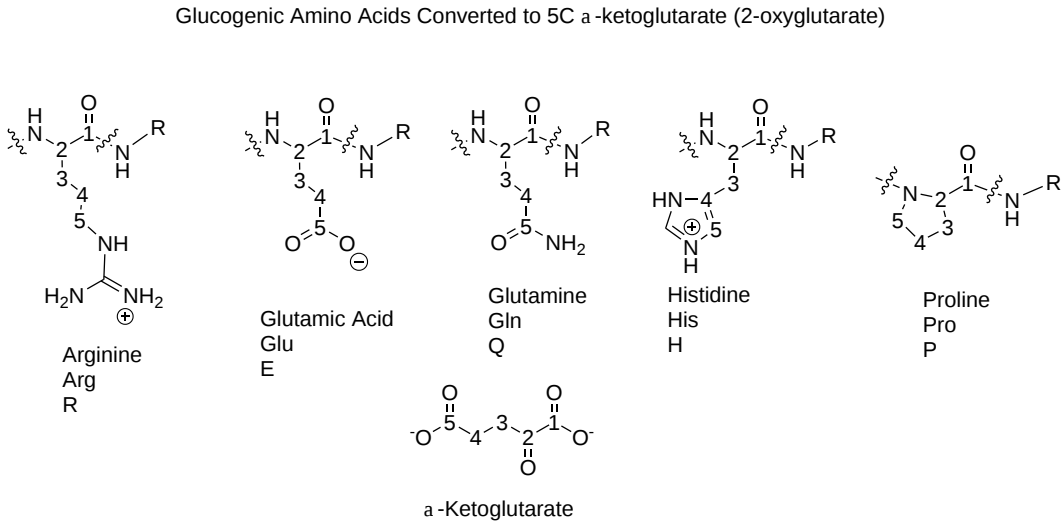

Figure 18.4.2: Glucogenic Amino Acids Converted to 5C α-ketoglutarate (2-oxoglutarate)

These amino acids form either the 4C TCA intermediate succinate or oxaloacetate. Amino acids with more oxidized 4C atoms in the continuous chain produced oxaloacetate (which is more oxidized than succinate), while the least oxidized ones produce succinate acid (which is more reduced than oxaloacetate). These amino acids are shown in Figure 18.4.3.

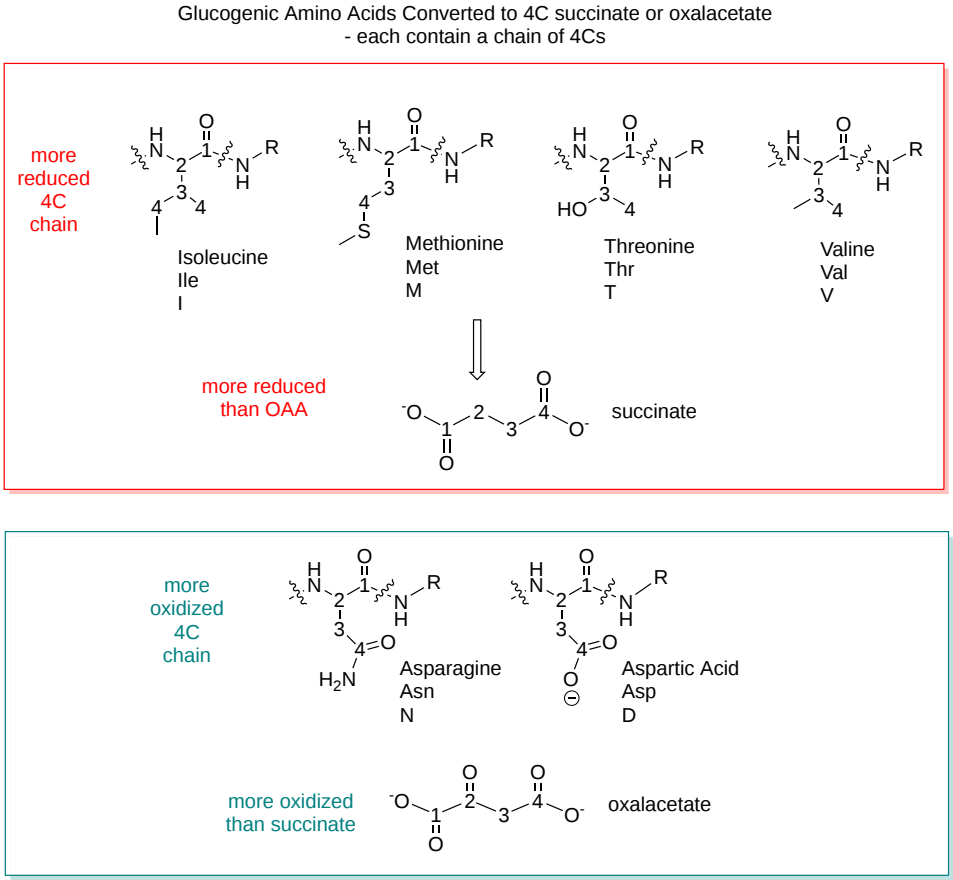

Figure 18.4.3: Glucogenic Amino Acids Converted to 4C oxaloacetate and succinate

The 3C amino acids, Ser, Ala, and Cys, except for glycine, form pyruvate, as shown in Figure 18.4.4.

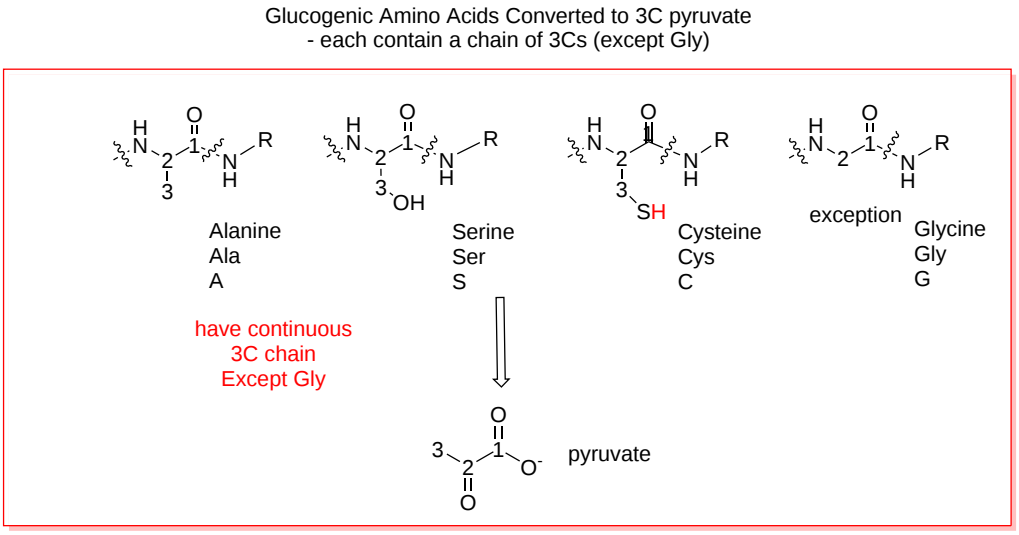

Figure 18.4.4: Glucogenic Amino Acids Converted to 3C pyruvate

A full figure summarizing everything above is shown in Figure 18.4.5!

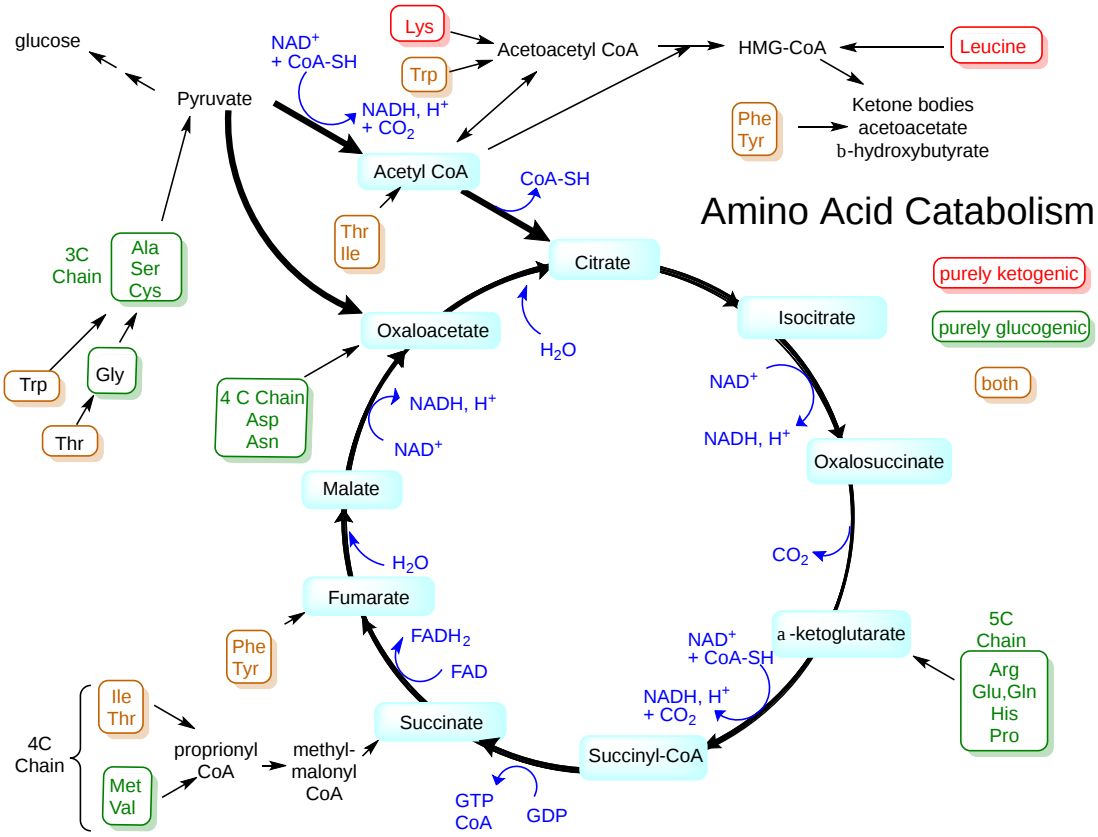

Figure 18.4.5: Summary of amino acid breakdown products

18.4.2: WITH A LITTLE HELP FROM MY FRIENDS: COFACTORS AND AMINO ACID CATABOLISM

The myriad of breaking, making, and rearranging of carbon atoms in amino acid catabolism is daunting. As with all reactions, a pathway for a flow of electrons and stabilization of transition states and intermediates must be in place for the reactions to occur. All methods of catalysis (general acid/base, covalent/nucleophilic catalysis, electrostatic/metal ion catalysis, preferential stabilization of the transition state occur. Yet some reactions need additional "helpers" or "cofactors" to facilitate electron flow and shuttle small motifs (from electrons in

redox reactions to methyl groups in methylases) from one molecule to another. We've seen the important role of pyridoxal phosphate in transaminations/aminotransferases in the previous section. Even the terminology cofactor is a bit confusing since analogous terms are used in different contexts:

- cofactors - nonprotein small molecules or ions (divalent ions, transition metal ions, and Fe/S clusters for example) that must bind to an enzyme, but once bound usually stay put. That is, they don't dissociate during the catalytic cycle. For instance, PLP must initially bind to an enzyme but then becomes covalently attached through a Schiff base through the epsilon amino group of a Lys in the catalytic site. That linkage might swap with an incoming amino acid substrate, for example, but reforms in the catalytic cycle so the enzyme remains functional.
- coenzyme - a vitamin derivative organic cofactor, as compared to inorganic ions, for example. Coenzyme is a poor historical name that persists.
- prosthetic group - this is usually a coenzyme that is either covalently bound (like PLP) or noncovalently bound with such a low K_D (like FAD/$FADH_2$-containing enzymes) that they stay bound
- cosubstrate - these bind as substrate (for example NAD^+), and depart as products (for example NADH).

Here is a table of common nonmetallic cofactors.

Cofactor	Vitamin Derivative	Carrier
biotin	H - biotin	1 C - CO_2 (most oxidized)
tetrahydrofolic acid (FH_4 or THF)	B9 - folic acid	1C - formyl, -(C=O)H, methylene (-CH_2) (more reduced) and methyl -CH_3
cobalamin	B12 - cobalamin	methyl CH_3
thiamine pyrophosphate	B1 - Thiamine	2C group
coenzyme A	B5 - pantothenic acids	acetyl (CH_3-C=O) and acyl (R-C=O)
pyridoxal phosphate	B6 - pyridoxine	amino and carboxyl groups
NAD^+/$NADP^+$	B3 - Niacin	electrons
FAD/FMN	B2 - riboflavin	electrons

Examples of other nonvitamin cofactors include S-adenosylmethionine (SAM or adoMet), a carrier of methyl groups, coenzyme Q, a carrier of electrons, tetrahydrobiopterin, a carrier of oxygen and electrons, and of course heme, a carrier of electrons.

We've already described amino acid deamination reactions using PLP. Now let's consider the biochemistry of two of these cofactors involved in 1 C transfers in amino acid metabolism in more detail, tetrahydrofolate (FH_4) and SAM.

18.4.3: TETRAHYDROFOLATE (FH_4)

Tetrahydrofolate (FH_4) is a key cofactor in the metabolism of amino acids but it is also critical in the biosynthesis of nucleotides. It is also commonly abbreviated as THF, especially in the names of enzymes that use it. To avoid confusion with chemist's use of THF for tetrahydrofuran, it will be referred to mostly here as FH_4 but the enzymes will be named as derivatives of the abbreviation XHF (X = D for dihydro and T for tetrahydro.

FH_4 is a carrier of 1 C units in various oxidation states. It receives 1C units and then transfers them to other species. The structure of FH_4 and derivatives carrying 1 C units with different oxidation numbers (indicating their oxidation state) are shown in Figure 18.4.6.

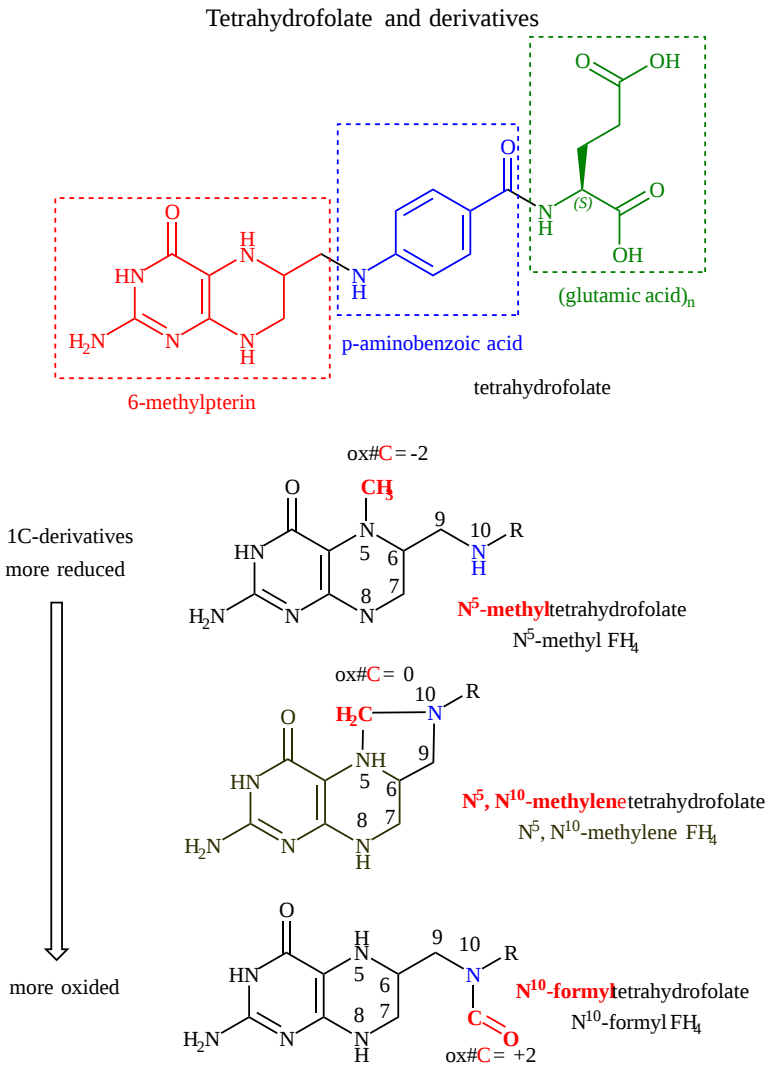

Figure 18.4.6: 1C derivatives in different oxidation states for tetrahydrofolate

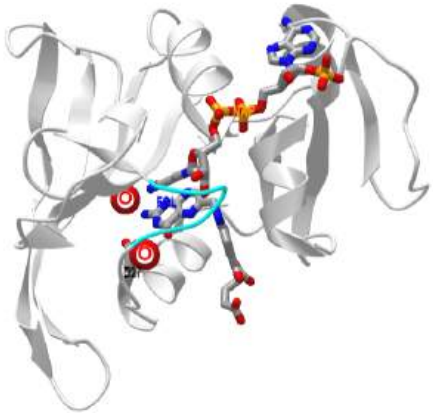
FH_4 is made from the vitamin folate (bacteria, fungi, and most plants can synthesize it), which gets converted first to dihydrofolate (FH2), and then tetrahydrofolate (FH_4), using NADPH as a reducing substrate "cofactor", by the enzyme **dihydrofolate reductase**. The model below shows this small enzyme with NADPH ($NADP^+$) and folate bound to DHFR (7dfr). Folate (FOL) is shown in salmon space fill while NADPH is shown in cyan.

Figure 18.4.7 shows an interactive iCn3D model of dihydrofolate reductase with bound NADPH ($NADP^+$) and folate (7dfr).



NCBI iCn3D Figure 18.4.7: Dihydrofolate reductase with bound $NADP^+$ and folate (7dfr). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...ojdpBZuQH8Lm96

Folate (FOL) and $NADP^+$ (NAP) are shown in spacefill and CPK colors. The side chain of Asp 27 is shown in sticks and CPK colors. The oxygen atoms of two water molecules interacting with folate are shown as red spheres. A disordered and hence mobile loop (residues 16-20) that is involved in binding the nicotinamide is shown in cyan.

As FH_4 is a key substrate in many reactions, including nucleotide synthesis (as we shall see later), this enzyme is a key target for chemotherapy to kill cancer cells which require robust nucleotide synthesis for rapid cell proliferation. One such drug, which inhibits the enzyme, methotrexate, is shown in Figure 18.4.8.

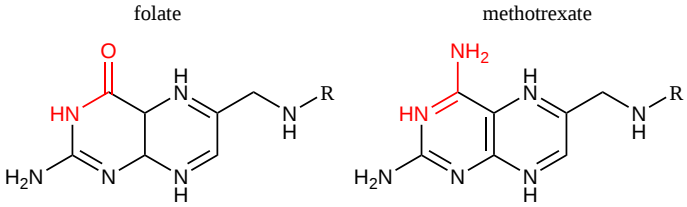


Figure 18.4.8: A structural comparison of the chemotherapeutic drug methotrexate and folate

Before getting into the nitty-gritty of amino acid degradation and tetrahydrofolate chemistry, let's take a look at the mechanism by which dihydrofolate reductase, DHFR, catalyzes the sequential reduction by 2 NADPH molecules of folate to tetrahydrofolate. This is illustrated in Figure 18.4.9.

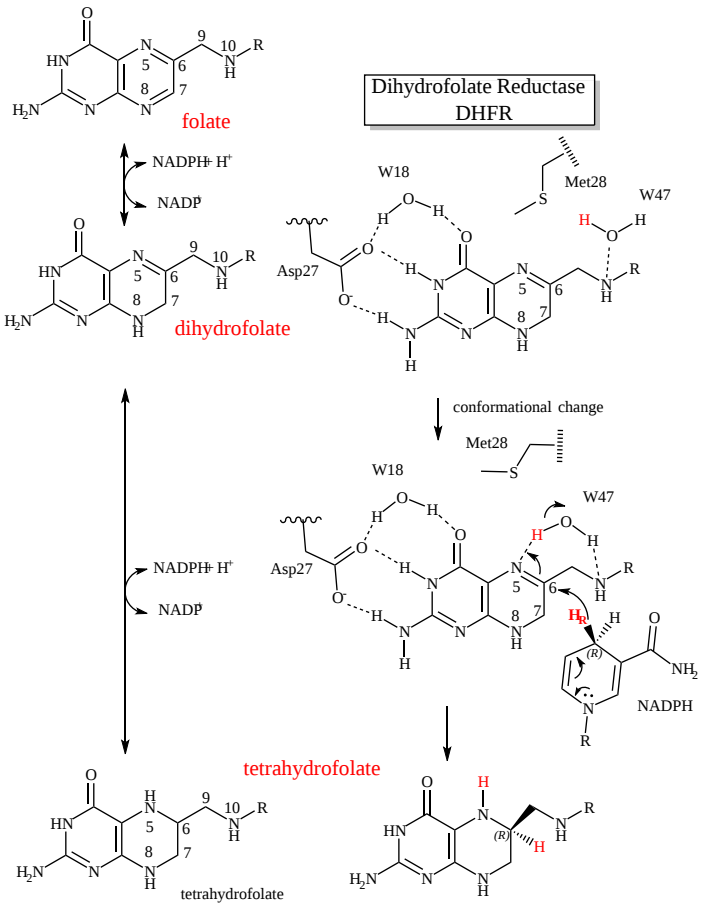

Figure 18.4.9: Conversion of folate to tetrahydrofolate by dihydrofolate reductase

18.4.4: ONE CARBON CHEMISTRY: THE INTERCONVERSION OF FH_4 1C DERIVATIVES

Tetrahydrofolate is a carrier for 1C units in metabolism. As such, is it intimately involved in many anabolic and catabolic reactions. These include thymidine and purine biosynthesis and amino acids metabolism through reactions involving serine, glycine (both with 1C in their side chains), and methionine (with 1C after the sulfur in the side chain). The reactions take place in both the cytoplasm and mitochondria. FH_4 is involved directly or indirectly in epigenetic control of DNA expression as well, as methylation of both DNA and histones is critical to gene expression. The myriad of 1C derivatives of FH_4 make the biochemistry complex, but as the transfer of 1C is a critical job in both the breakdown of the carbon skeleton of amino acids and biosynthesis, we need to explore it. The complexity is simplified by noting that the 1C derivatives have only three different oxidation states (+2, 0, and -2), as noted in Figure 18.4.10.

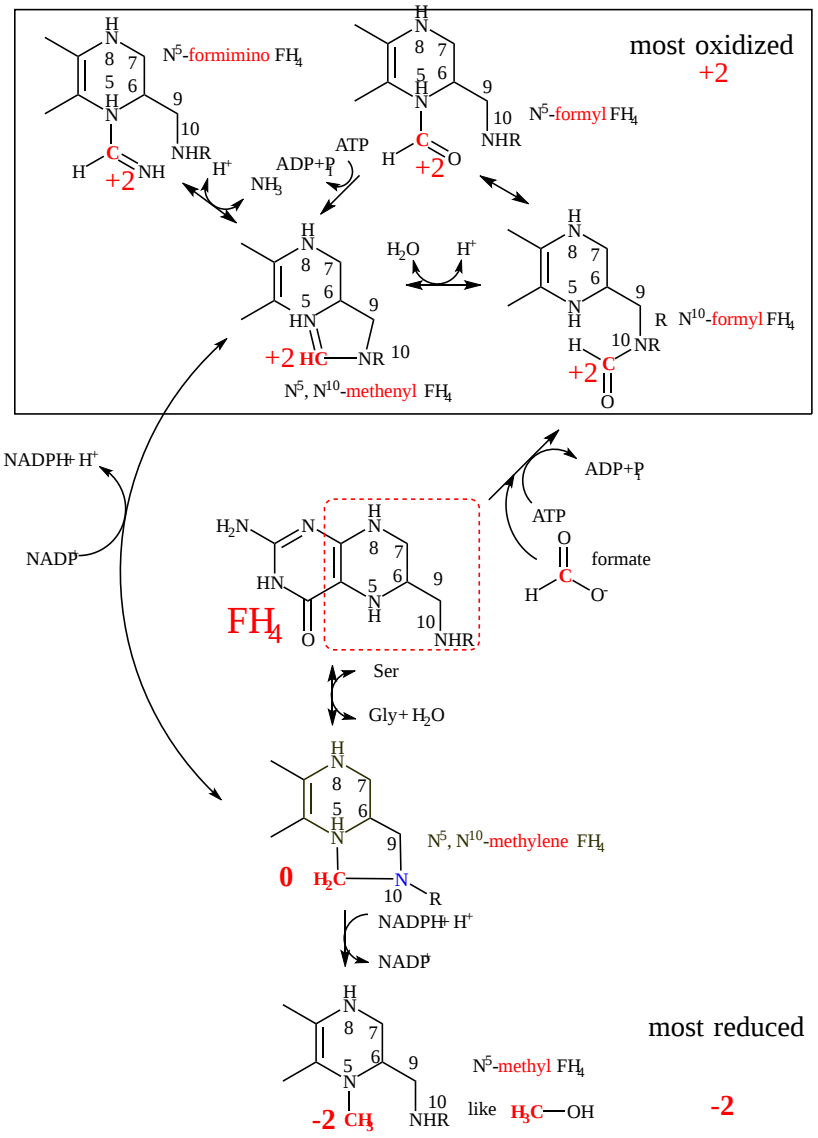

Figure 18.4.10: Interconversion of 1C derivatives of tetrahydrofolate. The oxidation number of the 1C addition is shown in red. (after http://education.med.nyu.edu/mbm/aminoAcids/folate.shtml)

1C units usually enter FH_4 as the N^5,N^{10} methylene unit. This is made in both the cytoplasm and mitochondria since 1C-derivatized FH_4 appears not to cross the mitochondrial membranes. The methylene derivative, with a 1C oxidation # of 0, can be reduced to form methyl (oxidation # -2) or oxidized to methenyl or formyl groups (oxidation # +2).

We will see some of these reactions again in chapters dealing with amino acid and nucleotide biosynthesis. That's not a bad thing - learning occurs best on the repetition of material in different contexts.

18.4.5: SERINE HYDROXYMETHYLTRANSFERASE (SHMT): A COMPLEX REACTION NEEDED TWO COFACTORS - PLP AND FH_4

Let's look in detail at one mechanism that shows how a 1C methylene is added to tetrahydrofolate (FH_4). The mechanism shown is for serine dehydratase, aka serine hydroxymethyltransferase. The enzyme not only uses tetrahydrofolate as a substrate but also PLP, which, as we have seen previously, makes bonds to the alpha-carbon of amino acids labile to cleavage. In this case, the amino acid serine becomes dehydrated through an alpha-elimination reaction. Here is the overall reaction.

$$\text{Serine} + FH_4 \leftrightarrow \text{Glycine} + N^5,N^{10}\text{-}CH_2\text{-}FH_4 + H_2O$$

Figure 18.4.11 shows the dehydration reaction and formation of glycine. using PLP as a cofactor. Figure B shows how the released formaldehyde reacts with FH_4 to form N^5,N^{10}-methylene FH_4. using FH_4 as a cofactor. As this is needed in purine and thymidylate

synthesis, SHMT is a target for malaria treatment as well.

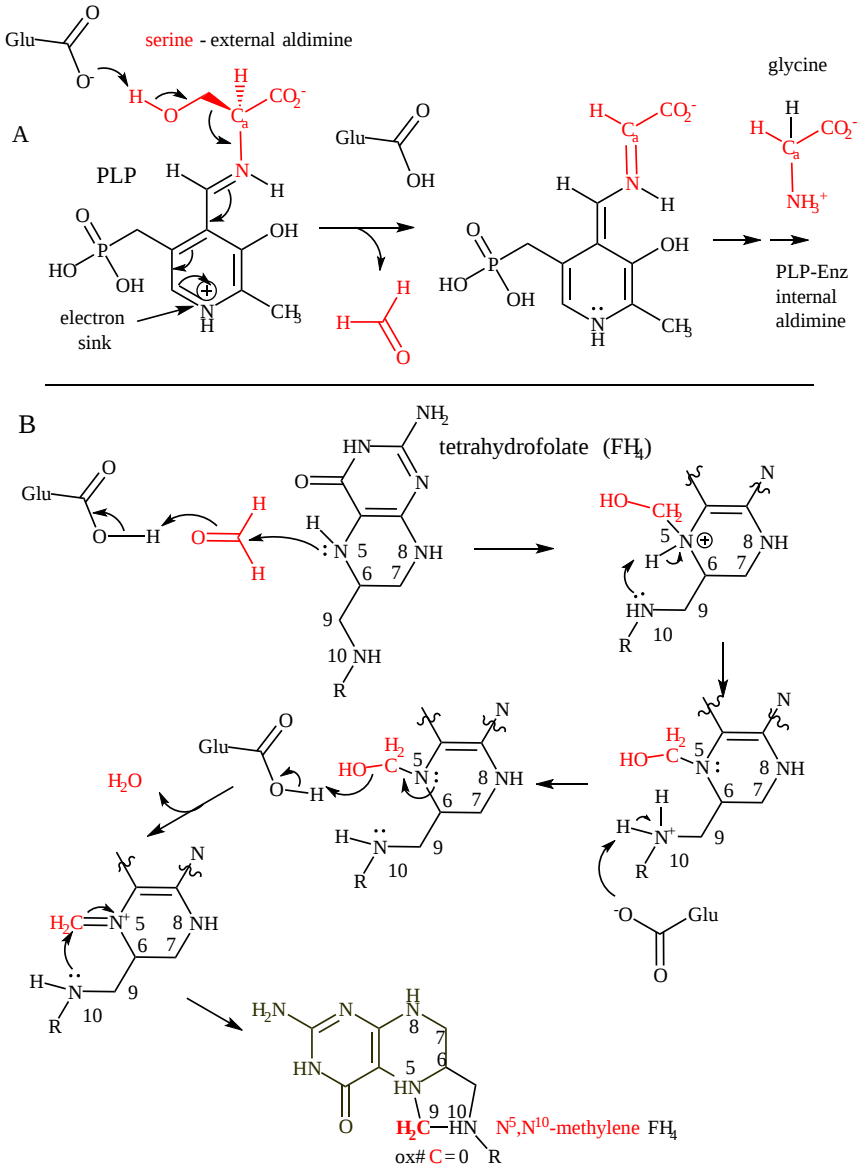

Figure 18.4.11: Serine hydroxymethylltransferase reaction mechanism

Glu 57 plays a key role as a general acid/base throughout the catalytic cycle of the enzyme.

Pathway diagrams showing a myriad of reactants, products, and enzymes can be confusing to students (and to authors as well). It's useful to think about them and see them in different ways. Here is another way to present the conversion of FH_4 and its various 1C intermediates. Figure 18.4.12 concentrates on the **outputs** of 1C FH_4 derivatives (shown in blue eclipses).

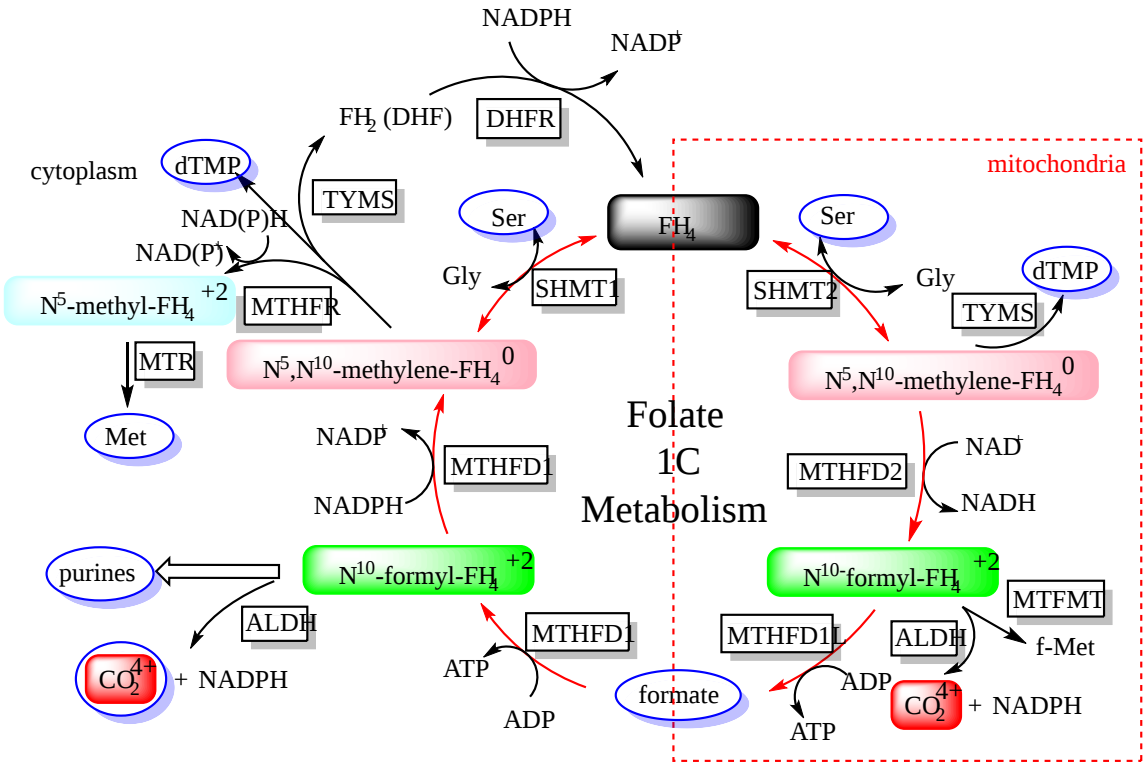

Figure 18.4.12 Folate 1C Metabolism - Cyclic Presentation after Ducker and Rabinowitz, Cell Metab. 2017 January 10; 25(1): 27–42. doi:10.1016/j.cmet.2016.08.009

The enzymes catalyzing these reactions are shown in the table below. This figure applies to both catabolic and anabolic reactions using FH_4 derivatives. Oxidation numbers for the 1C adducts are shown. Any reaction that involves a change in redox state must use $NAD(P)^+$/NAD(P)H as a redox reagent.

- N^5,N^{10}-methylene FH_4 gives thymidine and serine
- N^5-methyl FH_4 gives methionine
- N^{10}-formyl FH_4 gives formate, purines, and CO_2
- N^5-formyl serves more as a passive reservoir of 1C units.

Table 18.4.1: Enzymes catalyzing interconversions of THF derivatives

Abbreviation	Enzyme Name
ALDH	10-formyltetrahydrofolate((aldehyde) dehydrogenase.
DHFR	Dihydrofolate reductase
MTHFD	methylenetetrahydrofolate dehydrogenase
MTHFD1	C-1-tetrahydrofolate synthase, cytoplasmic
MTHFD1L	monofunctional tetrahydrofolate synthase, mitochondrial
MTHFD2/L	methylenetetrahydrofolate dehydrogenase 2/2-like
MTFMT	mitochondrial methionyl-tRNA formyltransferase
MTHFR	methylenetetrahydrofolate reductase
MTR	methionine synthase
TYMS	thymidylate synthetase

A key enzyme in these reactions, methylene-THF reductase (MTHFR), irreversibly removes 1C from the cycle depicted above as it forms N^5-methyl FH_4. As this reaction is a reduction, it requires a reducing agent (NADPH in yeast and animals and NADH in plants). This irreversible removal would deplete the cycle shown so it is allosterically regulated (inhibited) by another methylating agent, S-adenosylmethionine (SAM aka adoMet), as we will see next. Plant versions of the enzyme are reversible so there is no need for regulation by SAM in this feedback loop process.

18.4.6: S-ADENOSYLMETHIONINE (SAM), ALSO KNOWN AS ADOMET

N^5-methyl FH_4 appears to have one function, to methylate a molecule called homocysteine (same as Cys but with an extra -CH_2 in the side chain) to methionine. This is adenosylated (not phosphorylated!) with ATP to produce S-adenosylmethionine (SAM), a more potent methylating agent than N^5-methyl FH_4. SAM is hence part of a cycle involving N^5-methyl-FH_4. The methyl group of N^5-methyl FH_4 reacts with homocysteine to produce methionine, catalyzed by the enzyme methionine synthase, which requires cobalamin (vitamin B12) as a cofactor. The combined Figure 18.4.13 adds the Met and Folate cycles (showing the outputs of the 1C Folate metabolism cycle

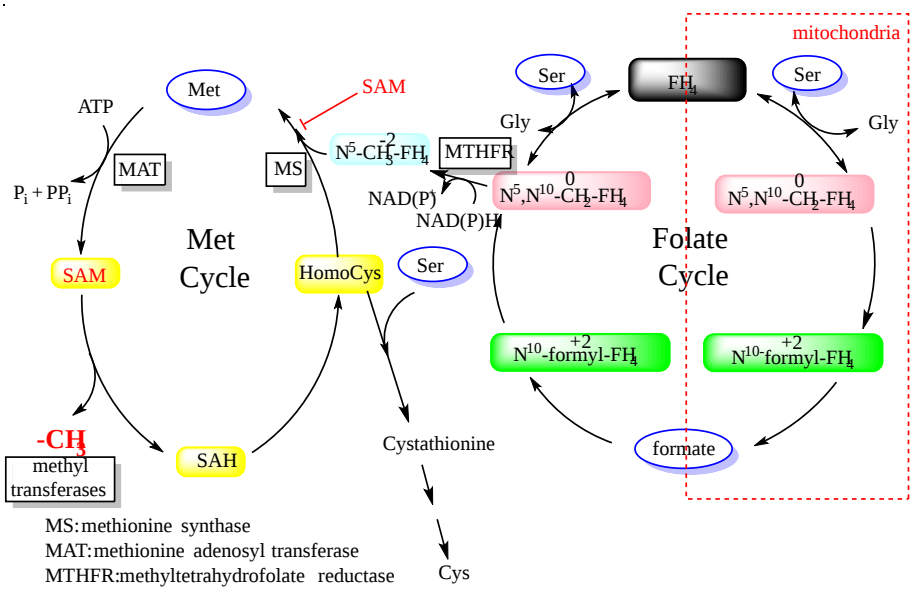

Figure 18.4.13 Folate and Methionine Cycle (after Ducker and Rabinowitz, Cell Metab. 2017 Jan 10; 25(1): 27–42.)

Figure 18.4.14 shows the structures of molecules in the Met Cycle.

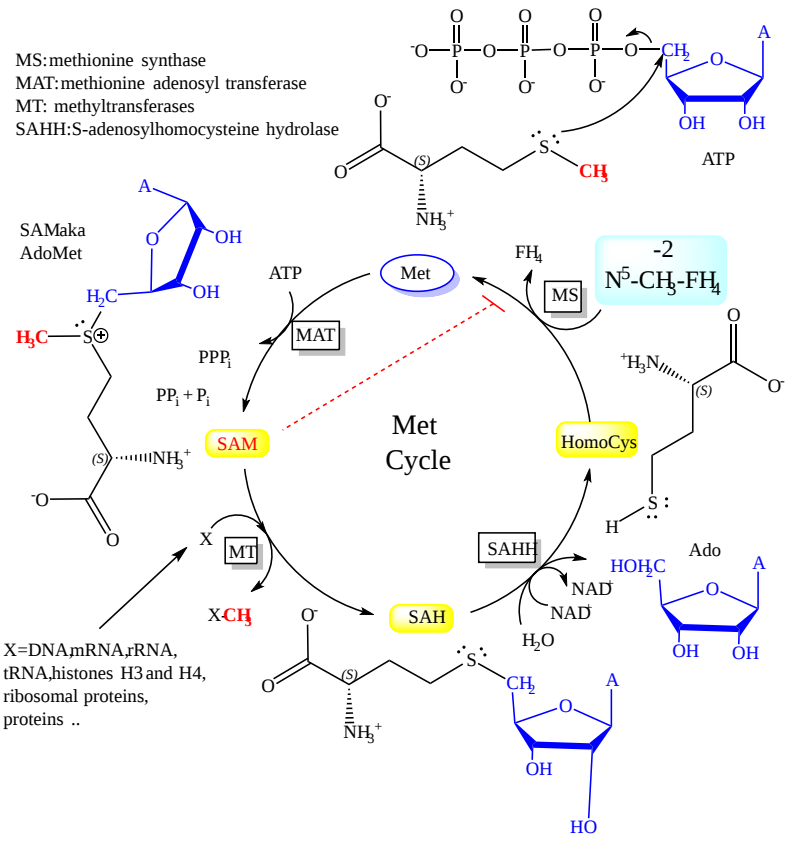

Figure 18.4.14: The Met Cycle and Methylations by SAM

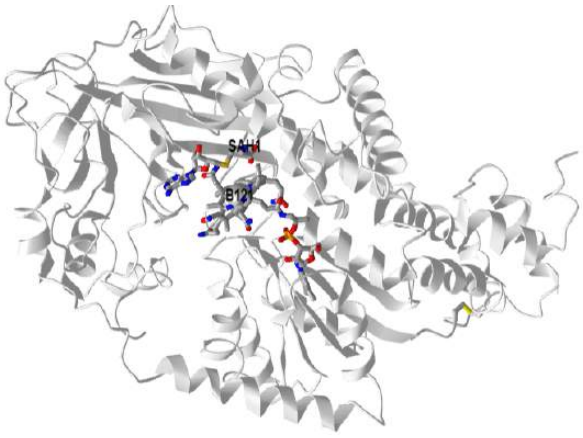
The mechanism of methyl transfers using SAM as the -CH_3 donor involves a SN_2 attack by a nucleophile of the substrate on the CH_3 of SAM, with the electron pair from the C-S bond going to the positively charged sulfonium sulfur, a great "electron sink". An analogous nucleophilic attack on the terminal CH_3 of plain old methionine would not be readily enabled. Hence SAM, with its charged S, has a much high methyl transfer potential than N^5-CH_3-FH_4.

In the actual reaction catalyzed by methionine synthase (MS) in mammals, the methyl CH_3 from N^5-methyl FH_4 is first transferred to cobalamin, a derivative of vitamin B12, to form methylcobalamin, which then transfers it to homocysteine. The structure of the C-terminal half of B_{12}-dependent Methionine Synthase from *E. Coli* with bound adenosylhomocysteine bound (3iva) is shown below and in this link:

Figure 18.4.15 shows an interactive iCn3D model of the C-terminal half of B_{12}-dependent Methionine Synthase from *E. Coli* with bound adenosylhomocysteine bound (3iva)



NCBI iCn3D Figure 18.4.15: C-terminal half of B_{12}-dependent Methionine Synthase from *E. Coli* with bound adenosylhomocysteine bound (3iva). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...E7jTsdvVvx1M1A

In mammals, vitamin B_{12} is a key cofactor in only two enzymes, one being methionine synthase. If vitamin B_{12} is lacking, N^5-methyl FH_4 builds up, and since the enzyme that converts N^5,N^{10}-methylene FH_4 to N^5-methyl FH_4, methylenetetrahydrofolate reductase (MTHFR), is irreversible. This leads to megaloblastic anemia as precursors to red blood cells that can't mature. Folate deficiencies also lead to anemia.

18.4.7: THE SERINE GLYCINE ONE CARBON (SGOC) METABOLIC CYCLE

Figure 12 shows the coupled Folate and Methionine cycles that emphasize the intermediates involved in the 1C -CH_3 transfer reaction, an important part of amino acid metabolism and other anabolic and catabolic reactions as well. Interpreting metabolic figures is complicated. Each is designed to emphasize certain selected features. Another way to present Figure 12 is to emphasize metabolites involved in 1C chemistry in general. Figure 18.4.145 shows what has been called the **Serine Glycine One Carbon (SGOC)** metabolic cycle. It is just a redrawn version of Figure 12 with attention drawn to non-FH4 molecules involved in 1C transfers, namely serine, glycine, and also formate.

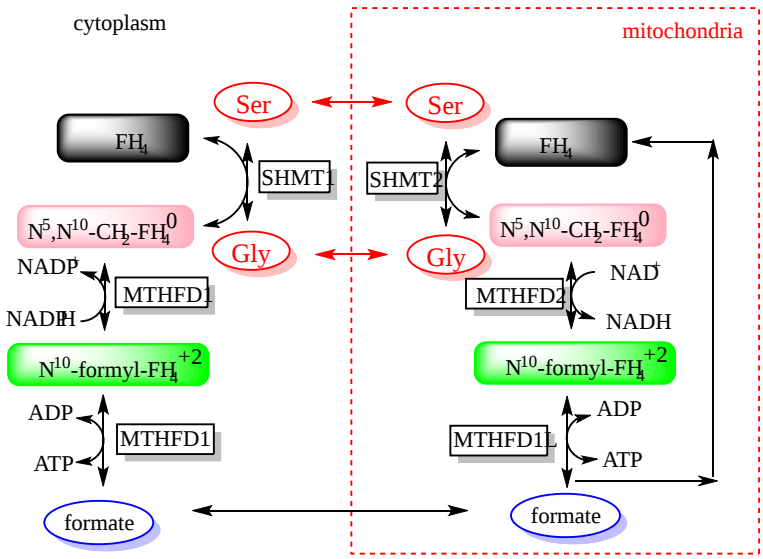


Figure 18.4.15: The Ser-Gly One Carbon (SGOC) Cycle

This cycle and its key substrates, serine, and glycine, integrate many metabolic pathways and controls the conversion of serine and glycine into outputs essential for other pathways. We will see this cycle again in the chapter on the biosynthesis of amino acids. The pathway is especially important in tumor cells, which need precursors for nucleic acid, protein, and lipid synthesis.

18.5: PATHWAYS OF AMINO ACID DEGRADATION

18.5.1: INTRODUCTION

In previous sections, we saw how nitrogen is removed from amino acids to produce urea or NH_4^+, that some amino acids are glucogenic, ketogenic, or both, and the role of tetrahydrofolate derivatives and S-adenosylmethionine in 1C transfer reactions. Now we can focus on how the carbon skeletons of amino acids are processed during degradation.

Here are some key features of amino acid catabolism that were discussed in the previous section.

- some are converted to pyruvate, the end product of glycolysis and the start reactant of gluconeogenesis. Hence, these amino acids are **glucogenic**;
- some are converted to acetoacetate-CoA and or acetyl-CoA. Both of these can be converted to ketone bodies (acetoacetate/β-hydroxybutyrate) so these are considered **ketogenic**. Since the two carbons of the acetyl group of acetyl-CoA are lost as CO_2 in the TCA cycle, and there is no reverse for the pyruvate dehydrogenase reaction (pyr → acetyl-CoA), acetyl-CoA formed by amino acid degradation can not be used to create glucose in net fashion;
- some are metabolized to form TCA intermediates. Since they are added in a **net** fashion to the TCA cycle and don't remove the existing pool of TCA intermediates, they can produce in a **net** fashion directly or indirectly molecules that can be used to produce glucose. These entry reactions to the TCA which replenish or add to TCA intermediates are called **anaplerotic** (replenishing) reactions. Hence these amino acids are also **glucogenic**.
- some have multiple ways to be degraded and can produce both acetyl-CoA and pyruvate, so they are **both glucogenic and ketogenic.**

Let's get more explicit:

- purely ketogenic: only Leu and Lys (the only amino acids whose name starts with **L** and you have to **L**ove them since there are only 2 amino acids in this category)
- both: 5 are, including the aromatics - Trp, Tyr, Phe - along with Ile/Thr
- purely glucogenic: the rest

Figure 18.5.1, also shown in the previous sections, summarizes the fates of the 20 amino acids in their catabolic reactions

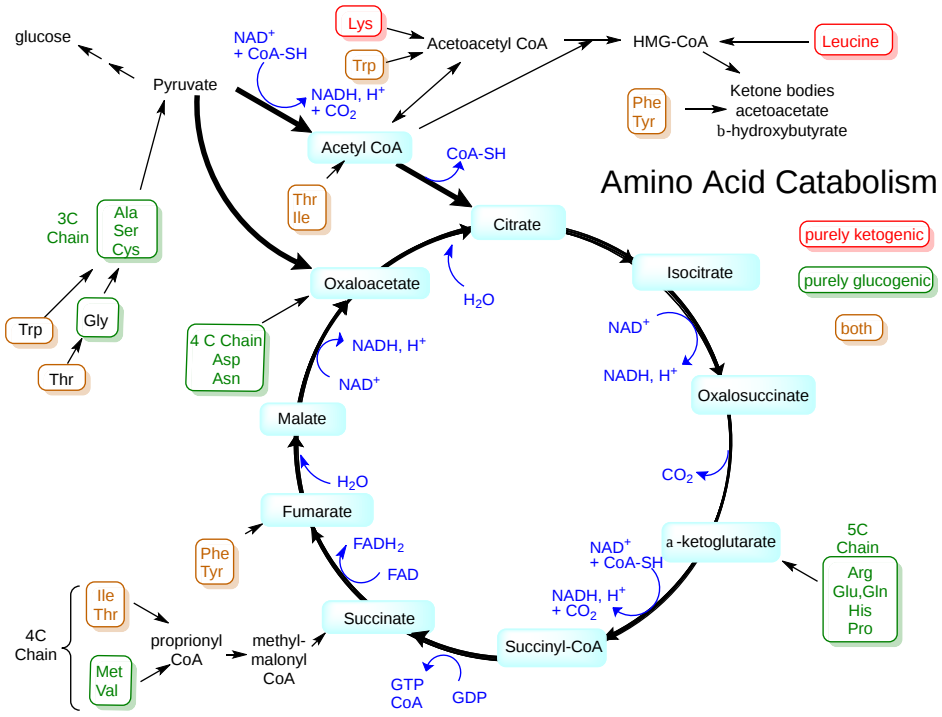

Figure 18.5.1: Fates of the 20 amino acids in their catabolic reactions

Given the myriad of enzymes and pathways involved, we won't delve into the mechanisms for the reactions or the structures of the enzymes, with the exception of one for lysine metabolism.

18.5.2: CONVERSION TO PYRUVATE: ALA, TRP, CYS, SER, GLY, THR

We ended section 18:3 with a discussion of the Ser Gly One Carbon Cycle (SGOC), so some of this will be a bit of a review.

Figure 18.5.2 shows an overview of the conversion of amino acids to pyruvate. More details are provided for each of the steps below.

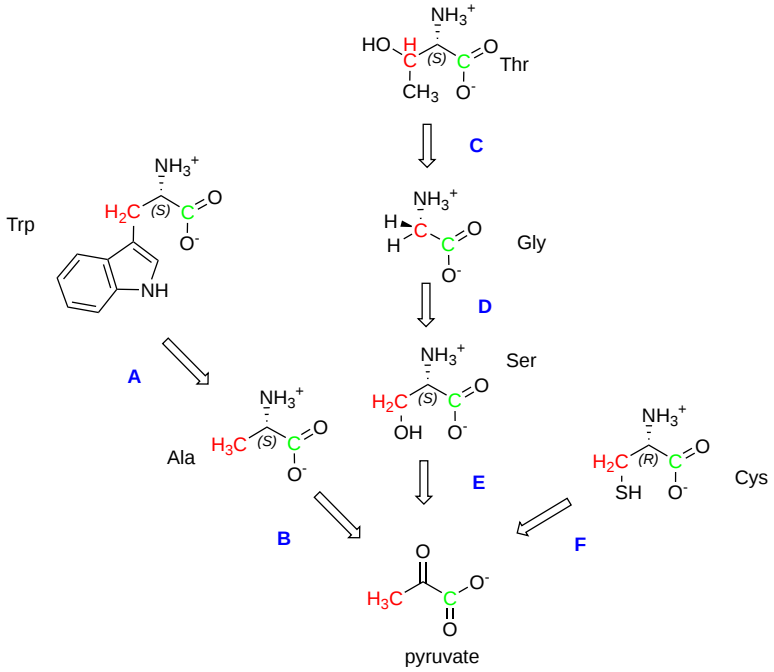

Figure 18.5.2: Overview of conversion of amino acids to pyruvate

The metabolic steps for the chemical transformations shown in A-F are described in more detail below.

18.5.2.1: TRYPTOPHAN TO ALANINE AND ON TO ACETOACETATE

This is a multistep process as shown in Figure 18.5.3.

A. Trp to Ala (and to acetoacetate and NAD+)

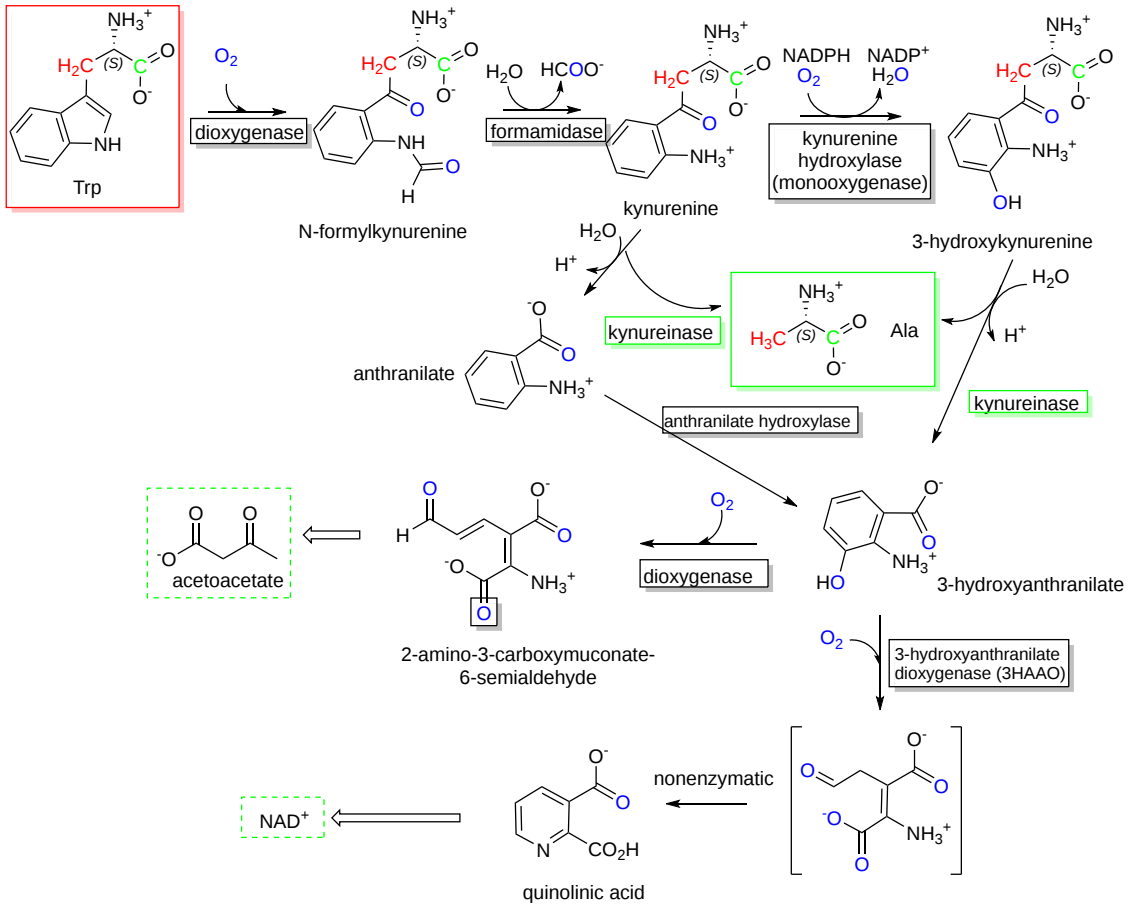

Figure 18.5.3: Conversion of Tryptophan to Alanine and to acetoacetate

The starting material, tryptophan, is highlighted in a red box while the end product of specific interest, Ala, is highlighted in a green box. No reaction occurs in isolation in a cell, but rather as part of a more complex pathway. In the figure below, Ala is presented almost as a side product as the modified aromatic ring found in either anthranilate or 3-hydroxyanthranilate continues on to form either acetoacetate, a ketone body which can breakdown to acetyl-CoA (making tryptophan ketogenic as well as glucogenic) or NAD^+.

18.5.2.2: ALANINE TO PYRUVATE

As described in 18.2, and shown in Figure 18.5.4, the PLP-dependent enzyme **AL**anine Amino **T**ransferase (**ALT**), also known as **G**lutamate **P**yruvate **T**ransaminase (**GPT**), catalyzes this simple transamination reaction:

alanine +α−ketoglutarate ↔ pyruvate + glutamate

B. Alanine to Pyruvate

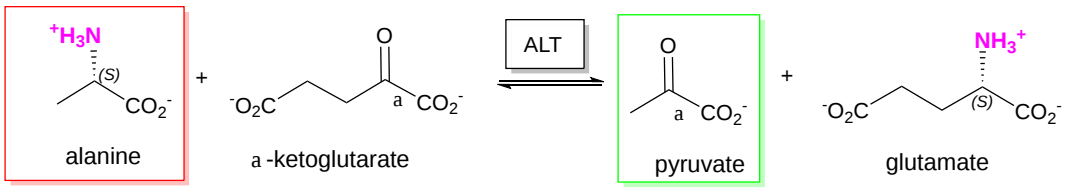

Figure 18.5.4: Alanine to pyruvate

The glutamate produced in this reaction can be oxidatively deaminated to give NH_4^+ and α-ketoglutarate again, giving the net reaction:

18.5.2.3: THREONINE TO GLYCINE

There are several pathways for this conversion.

One involves the conversion of Thr to 2-amino-3-ketobutyrate by **threonine-3-dehydrogenase**.

$$\text{Rx: Thr} + NAD^+ \leftrightarrow \text{2-amino-3-ketobutyrate} + NADH$$

This is followed by the conversion of 2-amino-3-ketobutyrate to glycine by the enzyme **2-amino-3-ketobutyrate coenzyme A ligase.**

$$\text{Rx: 2-amino-3-ketobutyrate} + CoASH \leftrightarrow \text{Gly} + \text{acetyl-CoA}$$

The net of these reactions is

$$\text{Rx: Thr} + NAD^+ + CoASH \leftrightarrow \text{Gly} + \text{acetyl-CoA} + NADH$$

These reactions are illustrated in Figure 18.5.5.

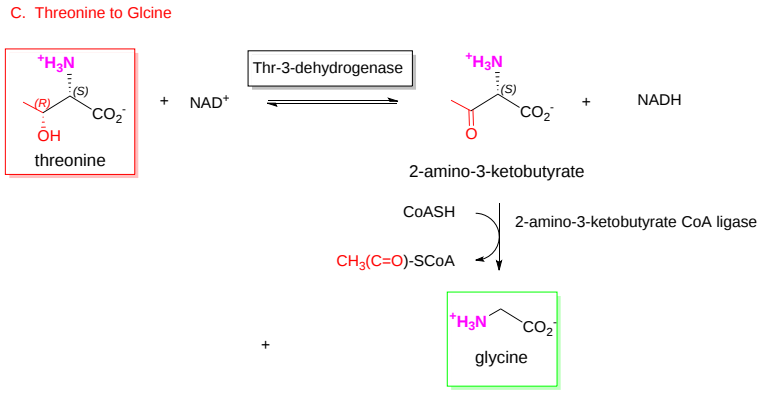

Figure 18.5.5: Threonine to glycine

A second and predominate reaction involves the conversion of Thr to NH_4^+ and α-ketobutyrate by the PLP-dependent enzyme **Ser/Thr dehydratase** (also called threonine ammonia-lyase), an enzyme we have seen in the previous section. Note this reaction does NOT produce glycine but is an intermediate, α-ketobutyrate.

$$\text{Rx: Thr} \leftrightarrow NH_4^+ + \text{α-ketobutyrate}$$

α-ketobutyrate can then be converted to propionyl-CoA.

$$\text{Rx: α-ketobutyrate} + NAD^+ + CoASH \leftrightarrow \text{propionyl-CoA} + NADH + CO_2 + H^+$$

This reaction, catalyzed by the inner mitochondrial membrane branched-chain α-ketoacid dehydrogenase complex (BCKDC or BCKDH complex) is an oxidative decarboxylation reaction. BCKDC is a member of two other enzymes, pyruvate dehydrogenase and alpha-ketoglutarate dehydrogenase, both of which act on short alpha-keto acids to produce key Kreb cycle metabolites.

Propionyl CoA is then converted eventually in several mitochondrial steps to succinyl CoA for entrance into the TCA cycle. Three enzymes are required for this conversion: propionyl CoA carboxylase, methylmalonyl-CoA epimerase, and methylmalonyl-CoA mutase. Propionyl carboxylase, like another alpha-keto acid carboxylase (pyruvate carboxylase), requires **A**TP, **B**iotin, and **C**O_2 (as a substrate) for the carboxylation reaction and hence is often referred to as an **ABC** enzyme.

The three-step conversion pathway of propionyl CoA to succinyl CoA is also used for in the degradation of **V**aline, **O**dd-chain fatty acids (which form multiple 2-carbon acetyl CoA units and 1 3-C propionyl CoA unit), **M**ethionine, and **I**soleucine along with **T**hreonine. This three-step pathway is sometimes referred to as VOMIT pathway.

The third pathway, which we just saw in the previous section, is catalyzed by serine hydroxymethyltransferase (SHMT) (but also called glycine hydroxymethyltransferase or threonine aldolase) and requires the use of both PLP and tetrahydrofolate as cofactors. A 1C methylene is added to tetrahydrofolate (FH_4). PLP makes bonds to the alpha-carbon of amino acids labile to cleavage. In this case, the amino acid threonine becomes dehydrated through an alpha-elimination reaction. However, threonine has an extra CH_3 group which is released as acetaldehyde. Here is the overall reaction.

$$\text{Rx: Thr+ } FH_4 + \leftrightarrow \text{ Glycine} + N^5,N^{10}\text{-}FH_4 + \text{acetaldehyde} + H_2O$$

The enzymes involved in this reaction are a bit unclear in the literature. It appears that SHMT can act on Thr at a lower rate, but that a second enzyme, threonine aldolase, which seems to be afunctional in mammals, acts in other organisms.

18.5.2.4: GLYCINE TO SERINE

As mentioned above, this reversible reaction is catalyzed by serine hydroxymethyltransferase (SHMT) (see the mechanism in section 18.4) and uses tetrahydrofolate and PLP as cofactors. Here is the overall reaction, the reverse of the Gly ↔ Ser we saw in 18.4.

$$\text{Rx: Glycine} + N^5,N^{10}\text{-}CH_2\text{-}FH_4 + H_2O \leftrightarrow \text{Serine} + FH_4$$

Figure 18.5.6 shows the serine dehydratase reaction presented in Chapter 18.4 Figure A below shows the dehydration reaction and formation of glycine. using PLP as a cofactor. Figure B shows how the released formaldehyde reacts with FH_4 to form N^5,N^{10}-methylene FH_4 using FH_4 as a cofactor.

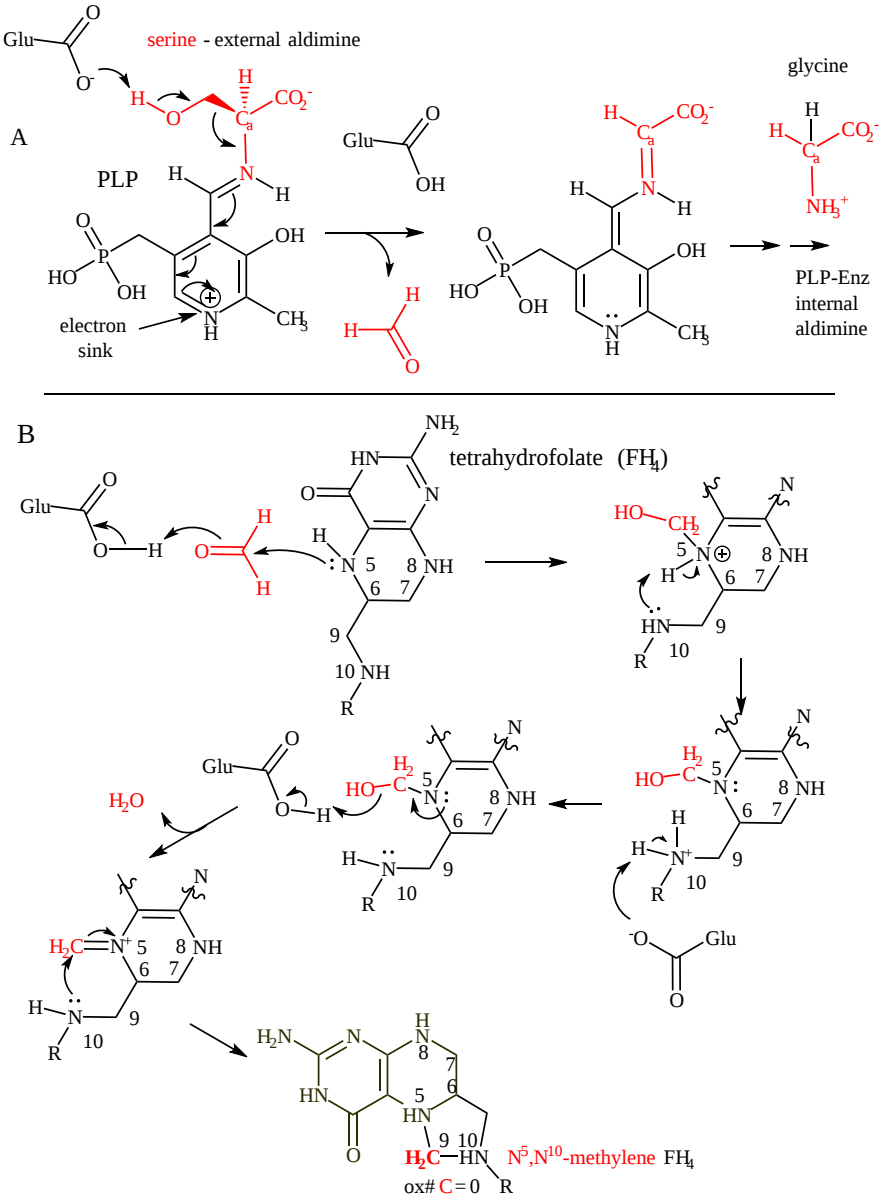

Figure 18.5.6: Reversible reaction of Serine to Glycine

18.5.2.5: SERINE TO PYRUVATE

This reaction is analogous to the Ala → Pyr reaction in Rx B above and is catalyzed by the PLP-dependent enzyme serine/threonine dehydratase/threonine deaminase.

Rx: Serine ↔ Pyr + NH_4^+

The enzyme is found in the cytoplasm and is mainly involved in gluconeogenesis.

18.5.2.6: CYSTEINE TO PYRUVATE

The overall reactions for this conversion are shown in the figure below. The aspartate aminotransferase used in the production of 3 sulfinylpyruvate is cytosolic and not the same as the more abundant version in the mitochondria.

The reaction pathway is shown in Figure 18.5.7.

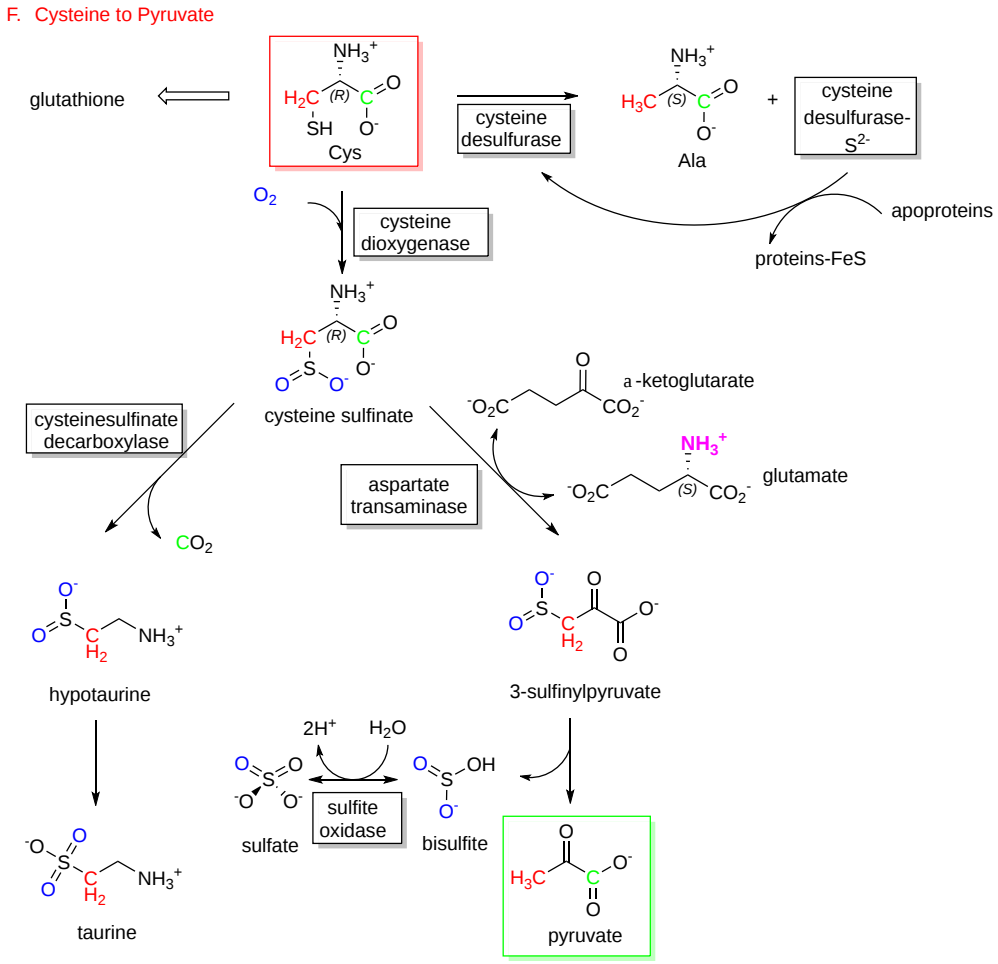

Figure 18.5.7: Cysteine to pyruvate

Other important metabolites are made from cysteine catabolic pathways. One is taurine, which is the most abundant free amino acid in the body and is especially abundant in development and early milk. It is synthesized predominately in the liver. It is unclear if hypotaurine is converted to taurine in a non-enzymatic fashion or by an oxidase/dehydrogenase.

The sulfate produced in the pathways is used to make an interesting derivative of ATP, 3′-phosphoadenosine-5′-phosphosulfate (PAPS), which is used to produce sulfated sugars using in glycolipid and proteoglycan synthesis. This is illustrated in Figure 18.5.8.

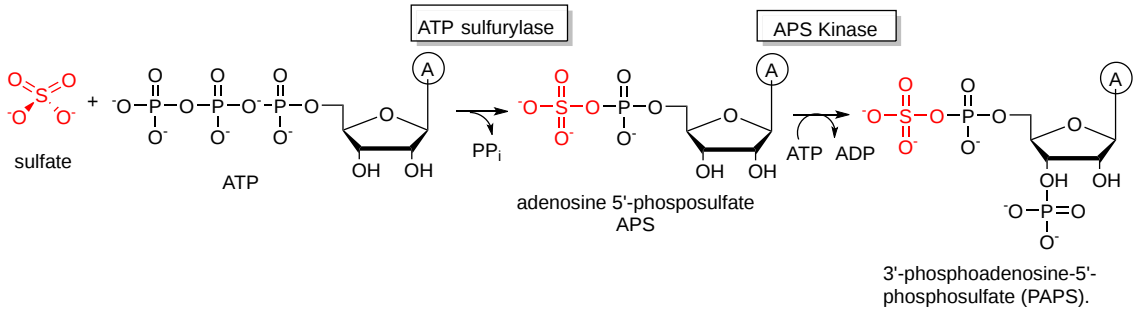

Figure 18.5.8: Sulfate conversion to PAPS

18.5.3: CONVERSION TO ACETYL-COA: TRP, LYS, PHE, TYR, LEU, ILE, THR

An overview of the many reactions in ketogenic amino acid degradation is shown in Figure 18.5.9. The red-boxed amino acids are those that form either acetoacetate (a ketone body) or acetyl-CoA directly (green boxes). Some of the carbons are color-coded red or green to indicate where they end up.

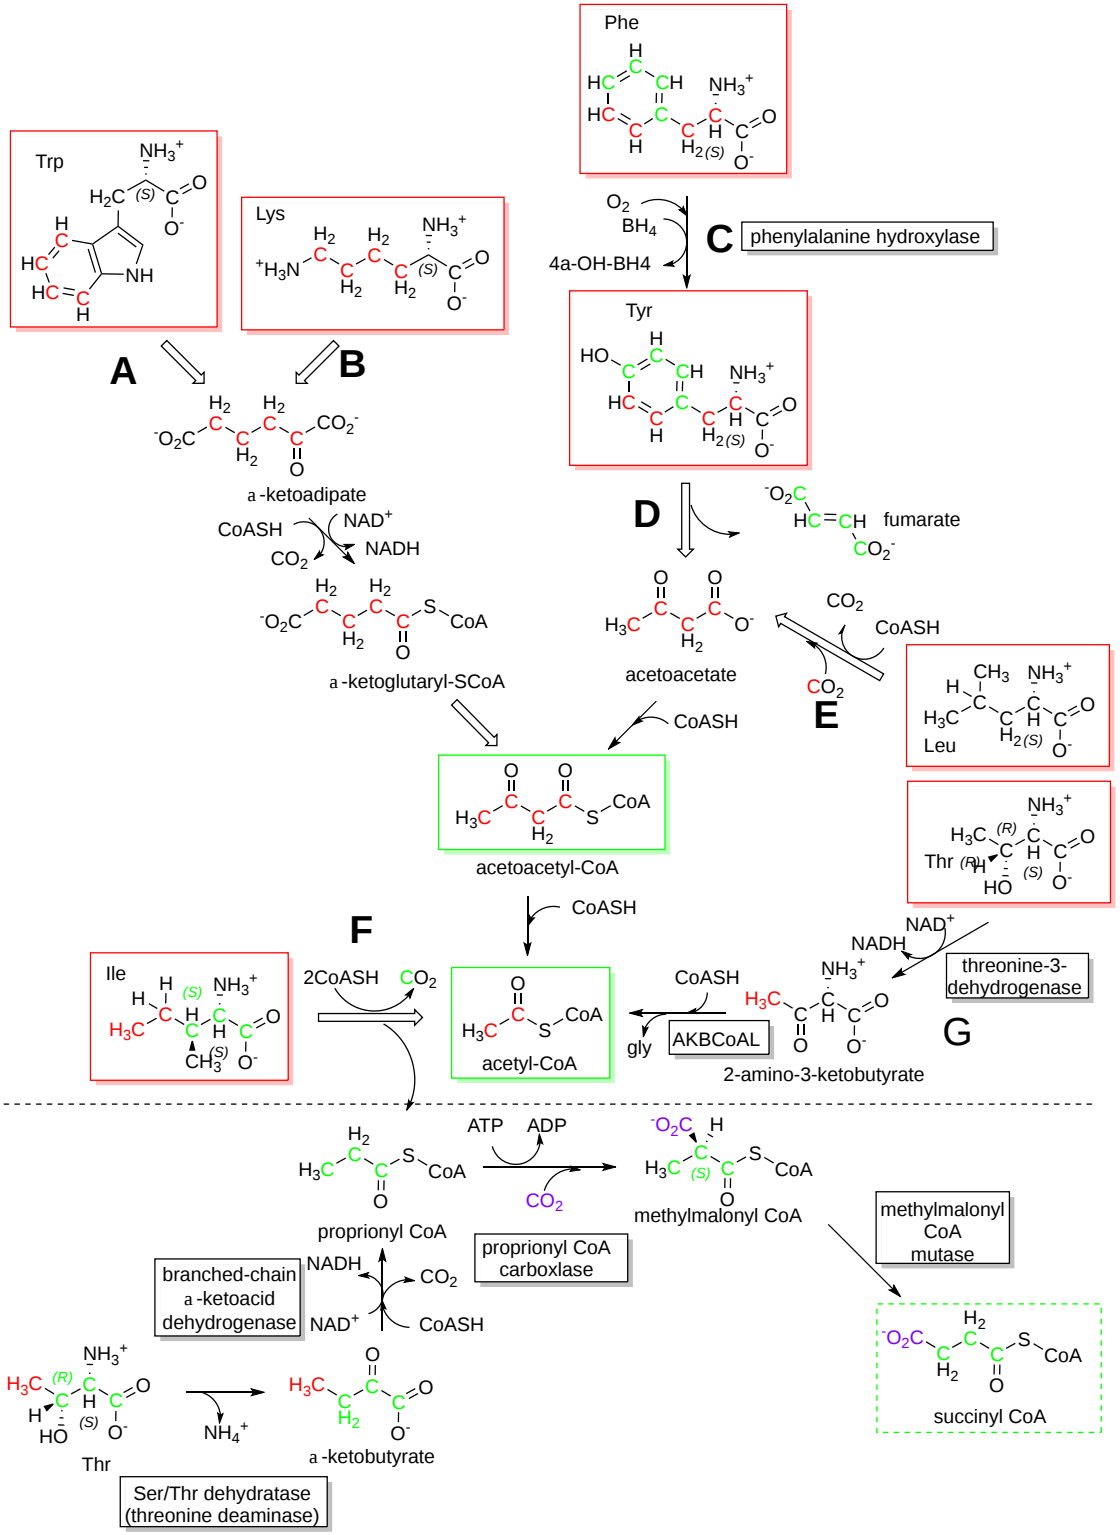

Figure 18.5.9: Ketogenic amino acid pathway

18.5.3.1: TRP TO ACETYL-COA

Fortunately, we have explored the conversion of the non-ring part of tryptophan to alanine and a precursor of acetoacetyl Coa (2-amino-3-carboxymuconate 6-semialdehyde - ACMS) and to NAD^+ (quinolinate). ACMS, through the action of ACMS decarboxylase leads to acetoacetyl CoA and then to acetyl-CoA as shown in Figure 18.5.10. As Trp is a ketogenic amino acid, it seems appropriate to show the steps that lead to acetyl-CoA even at the risk of providing too much detail.

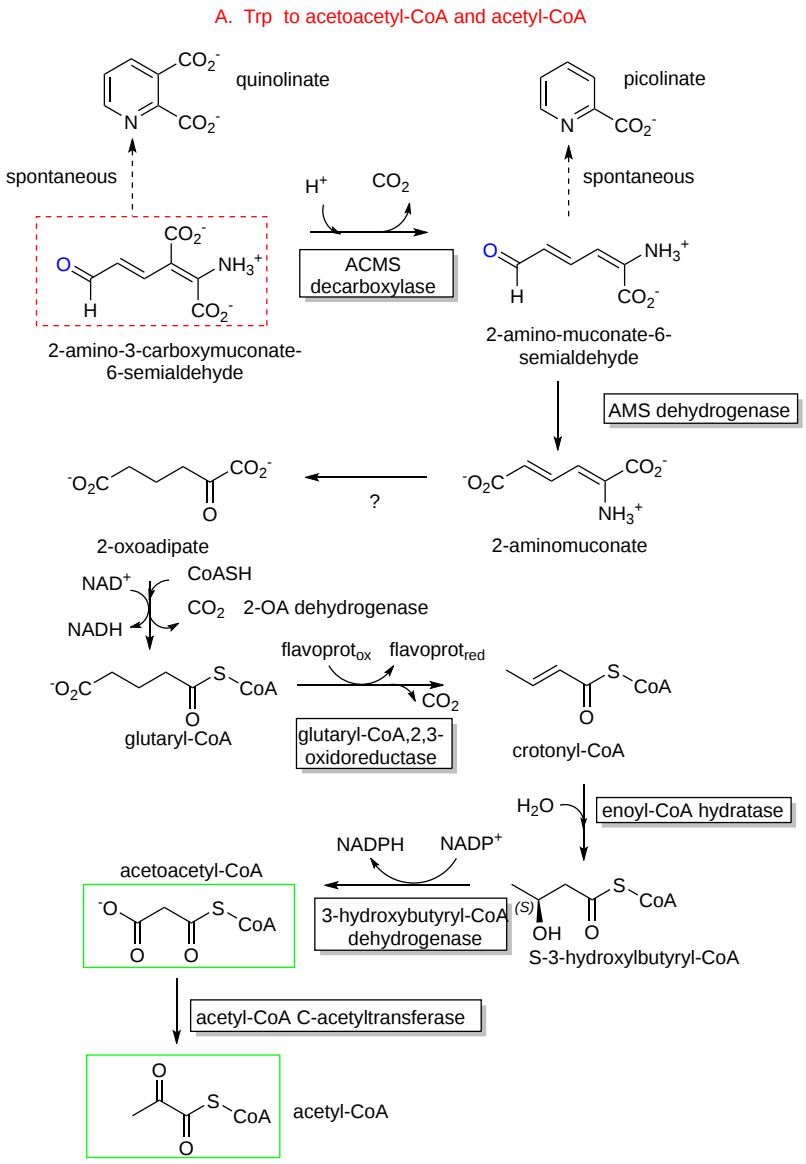

Figure 18.5.10: Part 2 - Tryptophan to acetyl-CoA

18.5.3.2: LYS METABOLISM

In the liver, the main pathway (of several) starts with the formation of saccharopine from the transamination reaction of lysine and α-ketoglutarate, allowing the ε-amino group of lysine to enter the nitrogen metabolic pool. This transamination does not use pyridoxal phosphate (PLP). The first two steps of the reaction are catalyzed by an enzyme, α-aminoadipic semialdehyde synthase, with two activities (condensation/reduction and hydrolysis/oxidation). Lysine is an essential amino acid since the transamination is not reversible. Figure 18.5.11 shows pathways for the conversion of lysine to acetoacetyl-CoA and acetyl-CoA.

B. Lys to acetoacetyl-CoA and acetyl-CoA

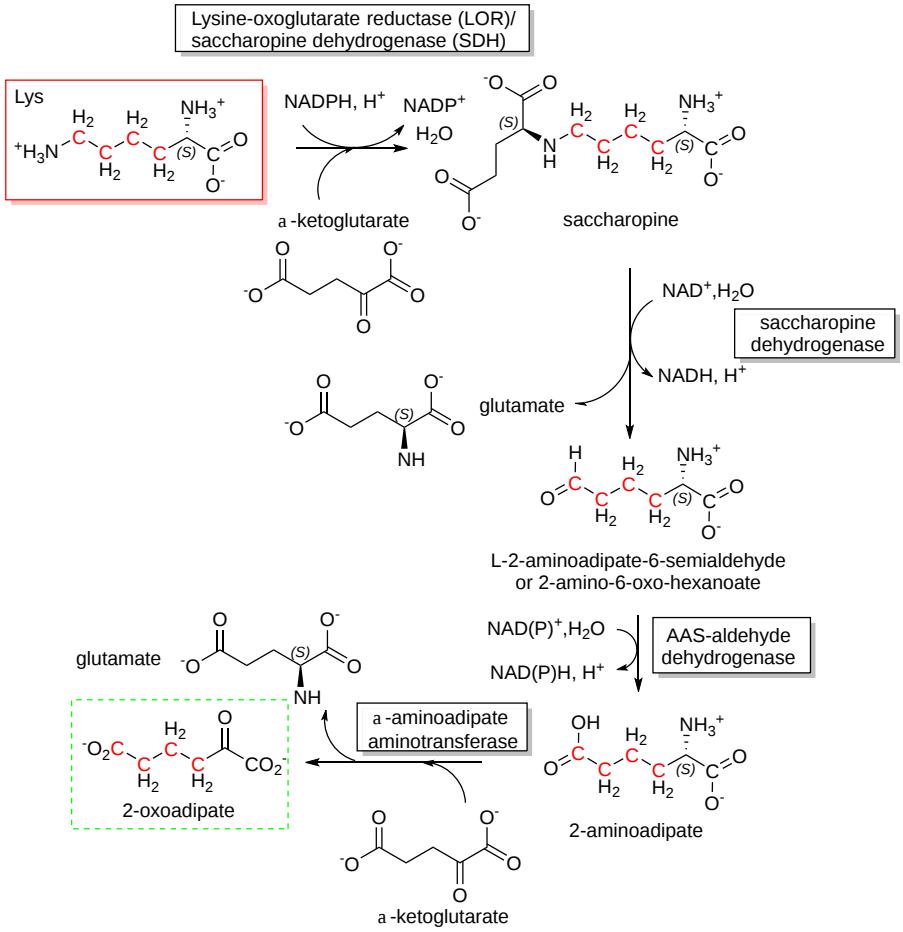

Figure 18.5.11: Pathways for conversion of lysine to acetoacetyl-CoA and acetyl-CoA.

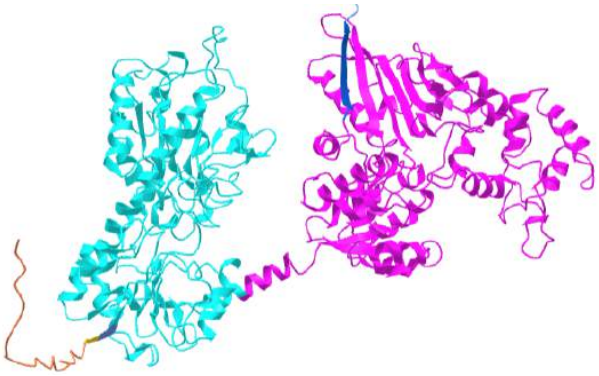
The lysine-oxoglutarate reductase (LOR) and saccharopine dehydrogenase (SDH) are found in one bifunctional enzyme, often called aminoadipic semialdehyde synthase.

Figure 18.5.12 shows an interactive iCn3D model of the AlphaFold predicted structure of aminoadipic semialdehyde synthase (Q9UDR5)



NCBI iCn3D Figure 18.5.12: AlphaFold predicted structure of aminoadipic semialdehyde synthase (Q9UDR5). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...Pi1c7Y5A9DmLa8

The cyan domain represents the lysine-oxoglutarate reductase (LOR) domain. It is connected by a well-predicted alpha helix to the magenta saccharopine dehydrogenase (SDH) domain.

18.5.3.3: PHENYLALANINE CONVERSION TO TYROSINE AND CONTINUES TO ACETOACETATE

We'll follow the conversion of phenylalanine to tyrosine, which continues on to acetoacetate, making Phe and Tyr both ketogenic amino acids, and in subsequent steps that produce fumarate. They can enter the TCA cycle leading to the net production of oxaloacetate, which can be pulled off into gluconeogenesis, making both Phe and Try glucogenic as well.

A new cofactor that facilitates electron flow in the conversion of Phe to Try in the first step, catalyzed by the enzyme tyrosine hydrolase, is required. That cofactor is **tetrahydrobiopterin** (BH_4). The reaction involves the hydroxylation of BH_4 and then its transfer to phenylalanine. Figure 18.5.13 shows a possible mechanism for the conversion of phenylalanine to tyrosine with tetrahydrobiopterin (BH_4).

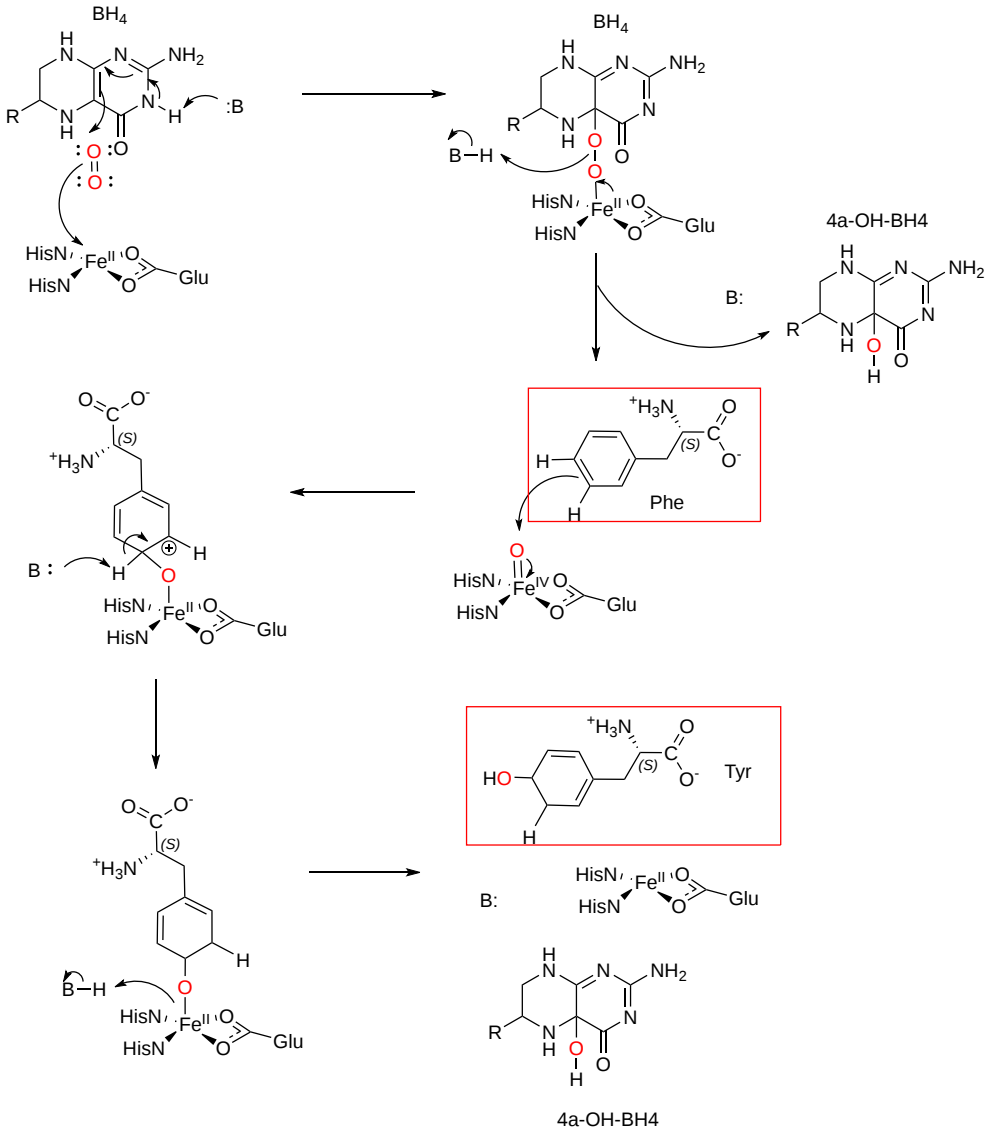


Figure 18.5.13: Conversion of phenylalanine to tyrosine with tetrahydrobiopterin (BH_4)

As in the case with the conversion of dihydrofolate back to tetrahydrofolate (FH_4) by dihydrofolate reductase, the 4a-OH-BH4 is converted to dihydrobiopterin and then to tetrahydrobiopterin by dihydrobiopterin reductase.

Figure 18.5.14 shows the full pathway for the conversion of Phe and Tyr to acetoacetate and fumarate.

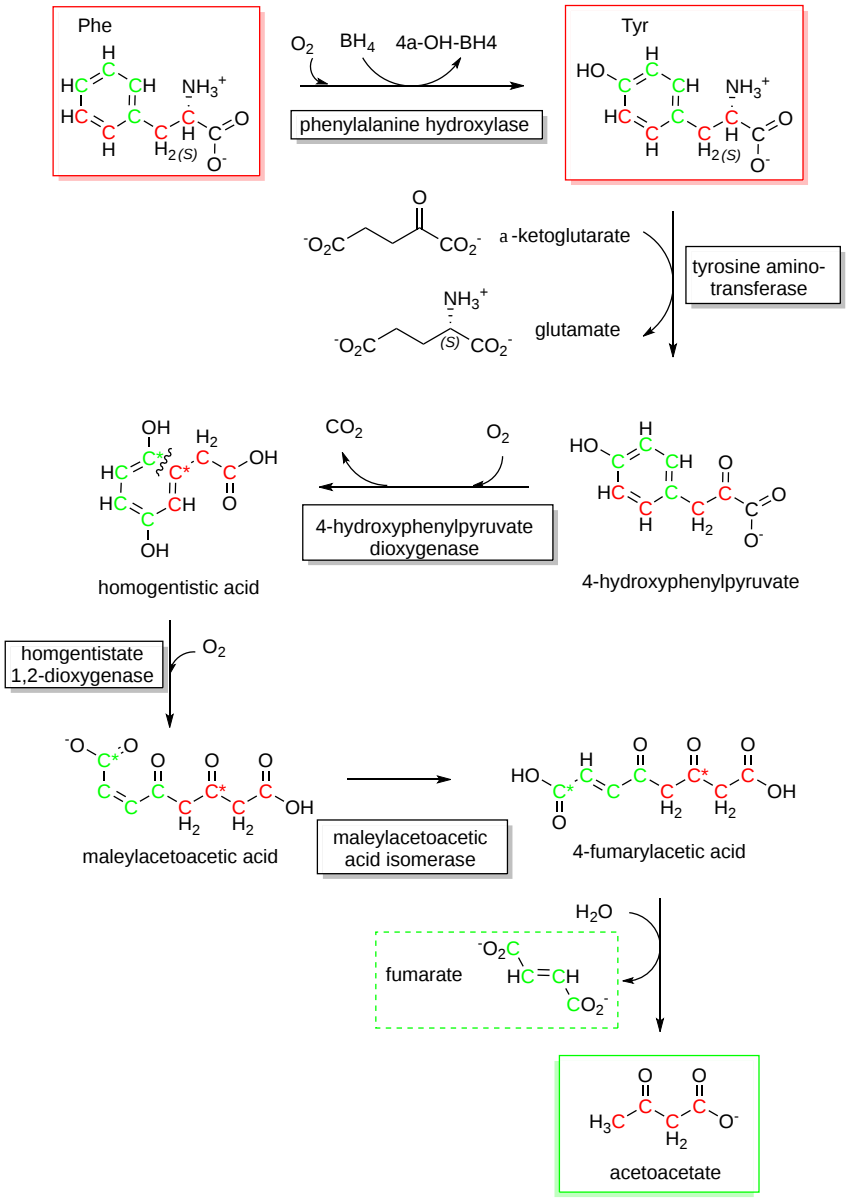

Figure 18.5.14: Conversion of phenylalanine and tyrosine to acetoacetate and fumarate

18.5.3.4: LEU TO ACETOACETATE

The conversion of leucine to acetoacetate is shown in Figure 18.5.15.

E: Leu to Acetoacetate

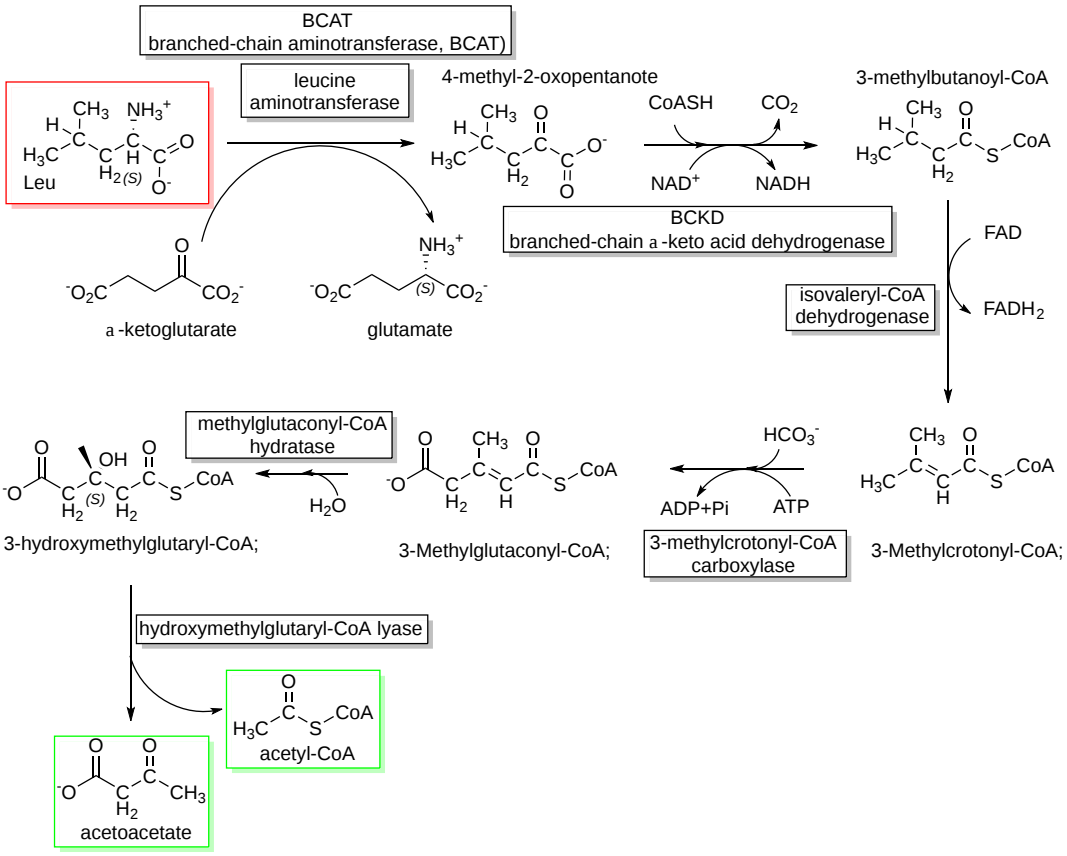

Figure 18.5.15: Conversion of leucine to acetoacetate

The first reaction is a transamination using the PLP-dependent branched-chain aminotransferase (BCAT) with α-ketoglutarate.

18.5.3.5: ISOLEUCINE TO ACETYL-COA

Figure 18.5.16 shows the pathway for the conversion of isoleucine to acetyl-CoA.

E: Ile to Acetyl-CoA

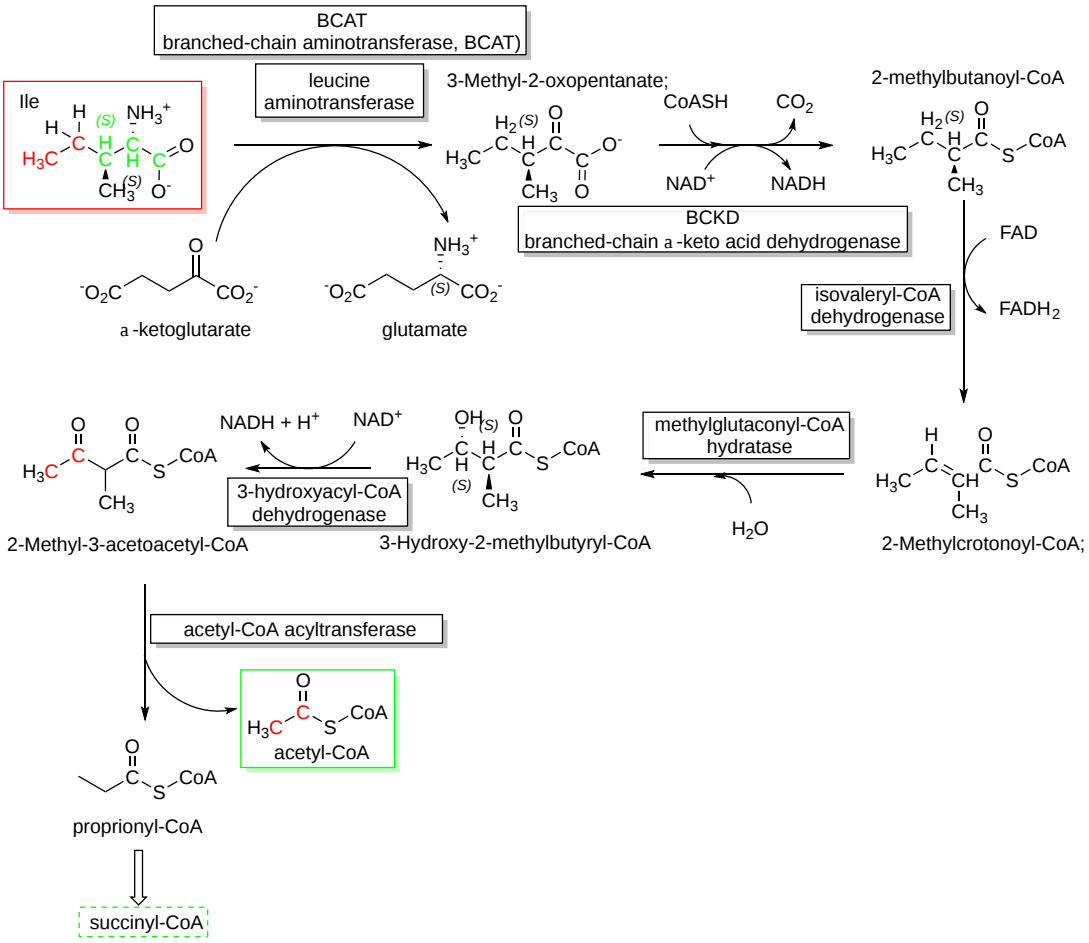

Figure 18.5.16: Pathway for conversion of isoleucine to acetyl-CoA.

18.5.4: CONVERSION TO A-KETOGLUTARATE: PRO, GLU, GLN, ARG,HIS

18.5.4.1: PROLINE AND ARGININE

The conversion of proline (bottom left) to glutamate (top left) is shown in Figure 18.5.17.

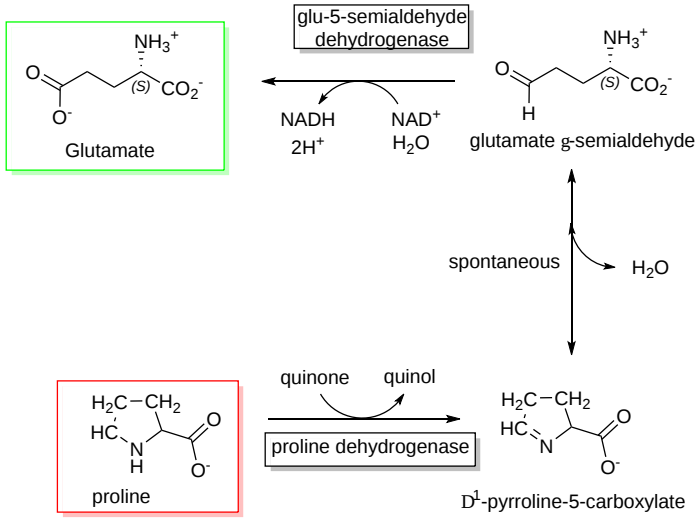

Figure 18.5.17: Conversion of proline (bottom left) to glutamate (top left)

Glutamate can then form α-ketoglutarate so the reaction is glucogenic.

The conversions of arginine (and proline) to α-ketoglutarate are shown in Figure 18.5.18.

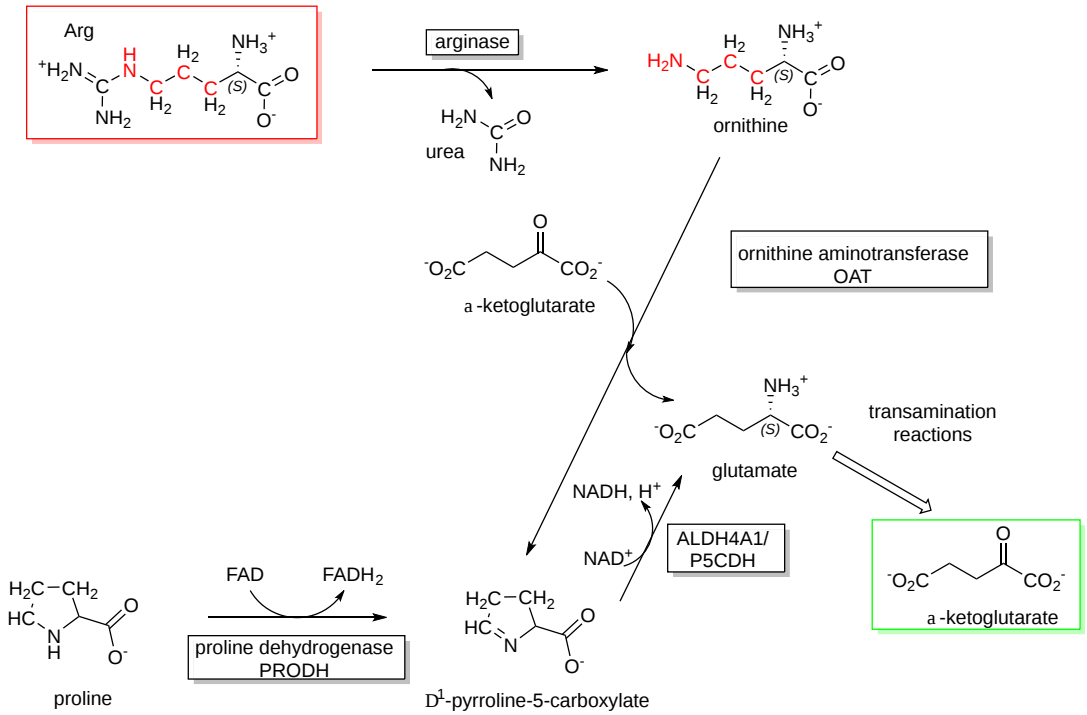

Figure 18.5.18: Conversion of arginine and proline to α-ketoglutarate

18.5.4.2: HISTIDINE

The conversion of histidine to α-ketoglutarate is shown in Figure 18.5.19.

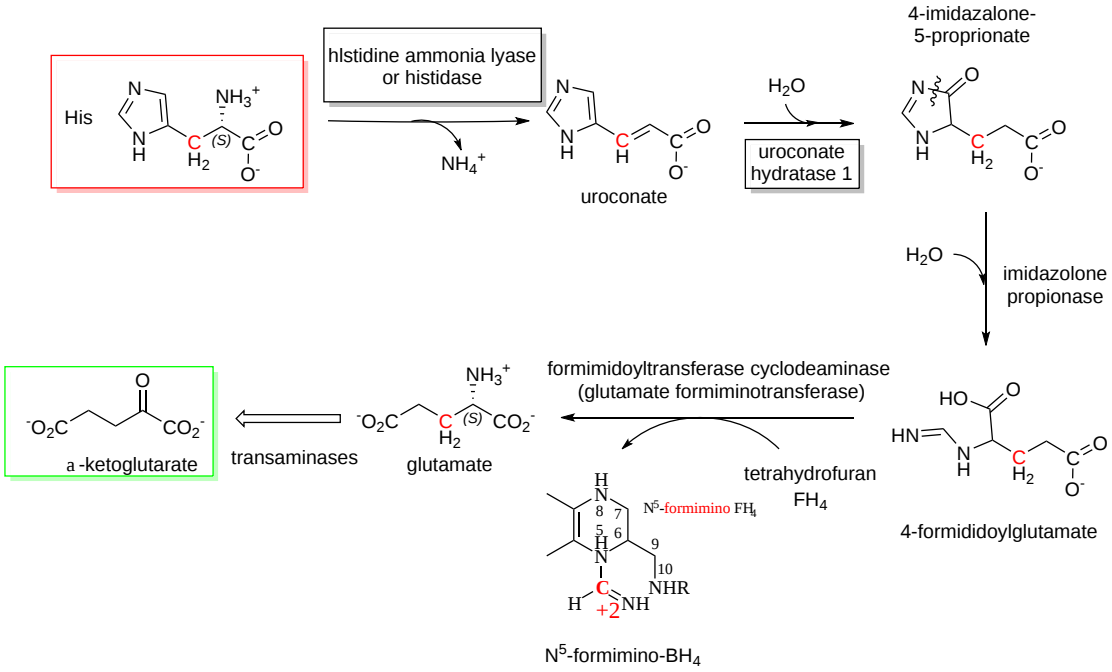

Figure 18.5.19: Conversion of histidine to α-ketoglutarate

As described in the reactions above, can be converted to α-ketoglutarate through transamination reactions. Also, we described in a previous section how glutamine can be deaminated through the action of glutaminase to form glutamine which can likewise form α-ketoglutarate, a gluconeogenic intermediate.

18.5.5: CONVERSION TO SUCCINYL-COA: MET AND THE BRANCHED-CHAIN AMINO ACIDS ILE, THR, VAL

We just saw that two branched-chain amino acids, Leu and Ile, are converted to acetyl-CoA and hence are ketogenic (E and F above). Another branched chain hydrophobic amino acid, Val, and also Leu again, can be converted to succinyl-CoA which can be converted to α-ketoglutarate in the Kreb's cycle in net fashion and hence are glucogenic amino acids. We saw in the introduction to amino acids that produce acetyl-CoA that threonine and isoleucine, two branched-chains amino acids, also form propionyl-CoA which goes on to succinyl CoA. So, let's consider Val, another branched-chain amino acid before we consider Met, both of which have 3 Cs in their side chains.

18.5.5.1: VALINE

The conversion of valine to succinyl-CoA is shown in Figure 18.5.20.

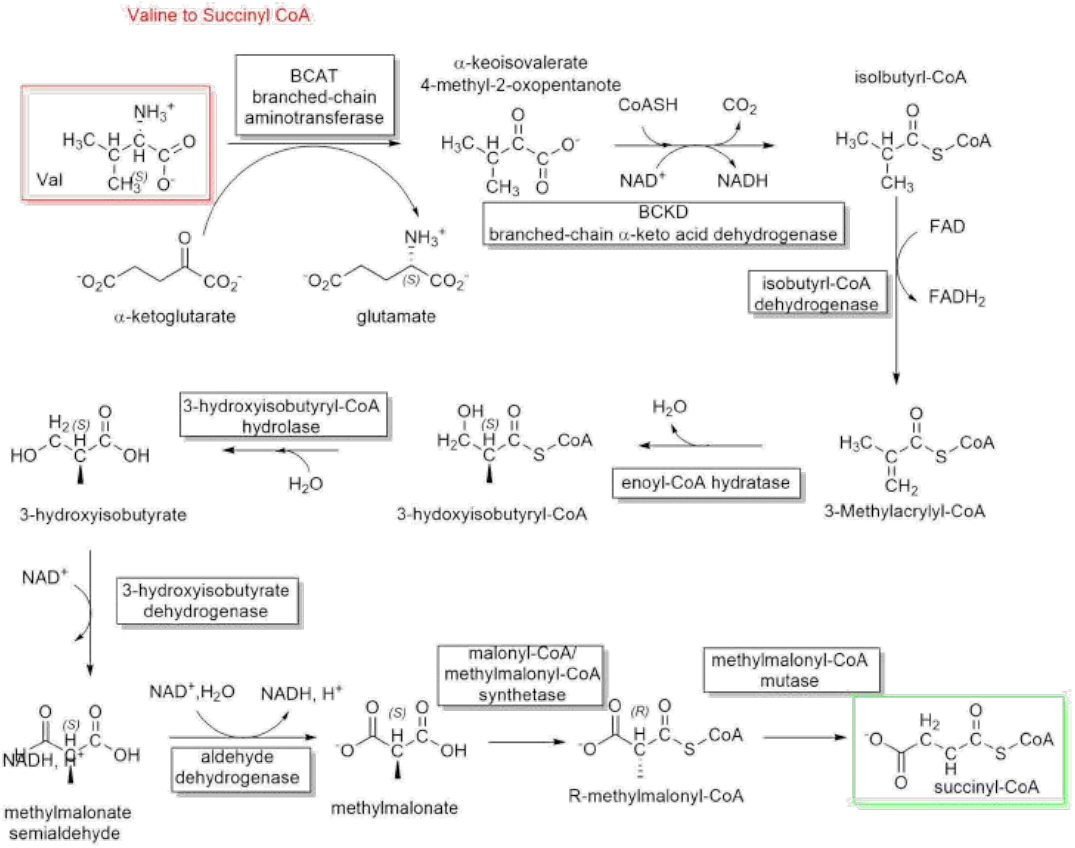

Figure 18.5.20: Conversion of valine to succinyl-CoA

The other two amino acids with branched-chain carbon chains (isoleucine and leucine), use the same enzymes as valine to enter the degradation pathway. They start with branched-chain transaminases (BCATc or BCATm) followed by oxidative decarboxylation reactions catalyzed by branched-chain ketoacid dehydrogenase (BCKD). Three different enzymes are required for the following dehydrogenase reaction. These are short/branched-chain acyl-CoA dehydrogenase (SBCAD) for isoleucine, isovaleryl-CoA dehydrogenase (IVD) for leucine, and isobutyryl-CoA dehydrogenase (IBD) for valine.

18.5.5.2: METHIONINE

Methionine can be metabolized to S-adenosylhomocysteine (SAM) and on to cysteine and α-ketobutyrate, which can also be produced by a transsulfuration reaction, the produces cysteine. That product is metabolized using branched chains dehydrogenases to eventually produce succinyl-CoA, a TCA intermediate. Three enzymes are needed to convert the α-ketobutyrate to succinyl-CoA. Propionyl-CoA carboxylase uses ATP, biotin, and CO_2 while the methylmalonyl-CoA mutase requires vitamin B12. An addition enzyme is an epimerase reaction in which D-methylmalonyl-CoA into L-methylmalonyl-CoA The conversion of propionyl-CoA to succinyl-CoA also occurs for branched-chain amino acids (**V**al, **I**le, **T**hr) as well as **M**et, and in addition **O**dd number fatty acids. This odd assortment of substrates for conversion to succinyl-CoA leads to the name **VOMIT** pathways. These reactions are illustrated in Figure 18.5.21.

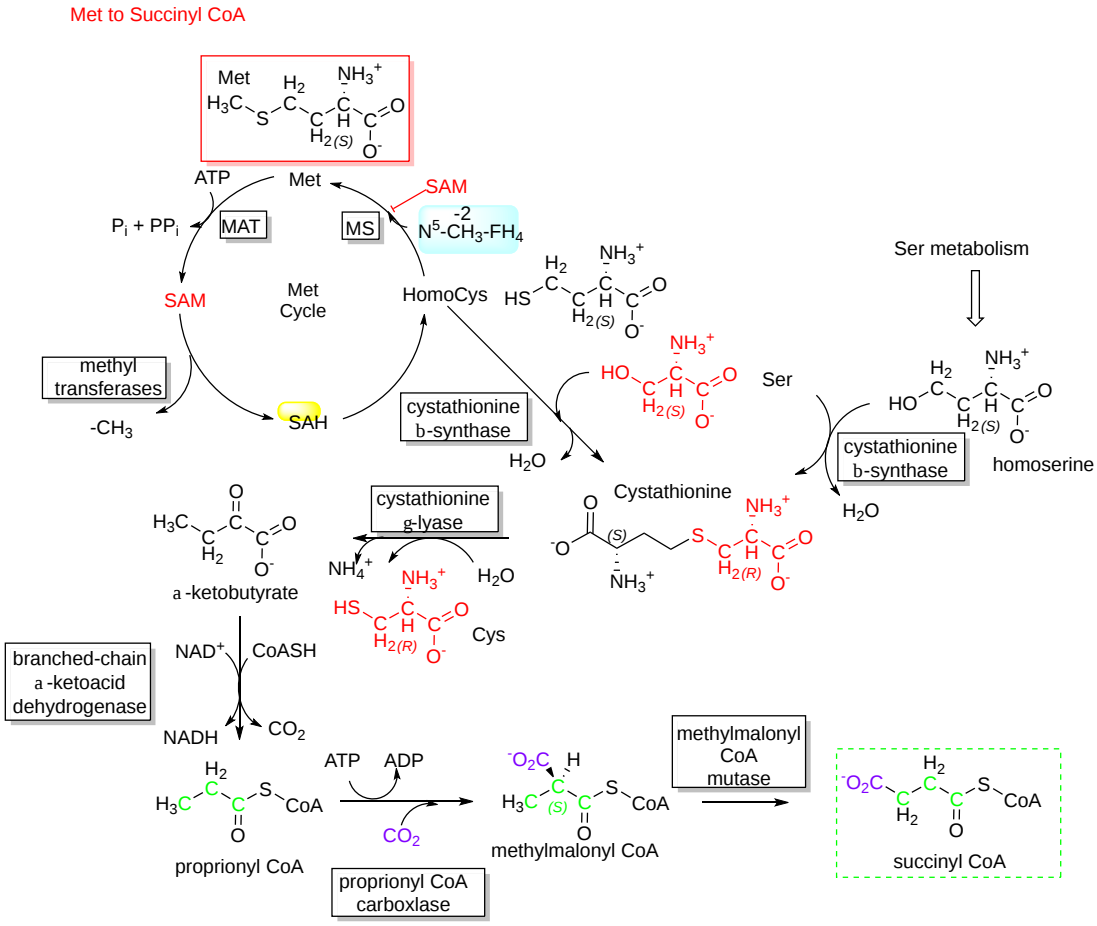

Figure 18.5.21: Methionine conversion to succinyl-CoA

18.5.6: FINALLY, ASPARTATE AND ASPARAGINE

Asparagine is converted to NH_3 and aspartate using the enzyme asparagine. Aspartate is then used in a transamination reaction to form oxaloacetate, a gluconeogenic precursor. Aspartate participates in the urea cycle as a way to eliminate nitrogen. Glutamate also acquires NH_3 through the reaction catalyzed by glutamine synthase.

Both amino acids are substrates for transamination reactions to produce TCA intermediates. Glutamate dehydrogenase can lead to alpha-ketoglutarate.

Glutamate and aspartate are important in collecting and eliminating amino nitrogen via glutamine synthetase and the urea cycle, respectively. The catabolic path of the carbon skeletons involves simple 1-step aminotransferase reactions that directly produce net quantities of a TCA cycle intermediate. The glutamate dehydrogenase reaction operating in the direction of 2-oxoglutarate (α-ketoglutarate) production provides a second avenue leading from glutamate to gluconeogenesis.

CHAPTER OVERVIEW

19: OXIDATIVE PHOSPHORYLATION

19.2: ATP Synthesis

19.3: Regulation of Oxidative Phosphorylation

19.1: ELECTRON-TRANSFER REACTIONS IN MITOCHONDRIA

Search Fundamentals of Biochemistry

19.1.1: AN OVERVIEW OF MITOCHONDRIAL ELECTRON TRANSPORT

The main oxidizing agent used during aerobic metabolism in the citric acid cycle is NAD^+ (although FAD is used in one step). In the process, these oxidizing agents get reduced to form NADH (and $FADH_2$). Unless NAD^+ is regenerated, glycolysis and the citric acid cycle will grind to a halt. This occurs under anaerobic conditions when NADH formed in glycolysis is reoxidized back to NAD^+ by pyruvate which is converted to lactate.

Under aerobic conditions, we are continually breathing one of the best oxidizing agents around, dioxygen. NADH is oxidized back to NAD^+ not directly by dioxygen, but indirectly as electrons flow from NADH through a series of electron carriers to dioxygen, which gets reduced to water. This process is called electron transport. No atoms of oxygen are incorporated into NADH or any intermediary electron carrier. Hence the enzyme involved in the terminal electron transport step, in which electrons pass to dioxygen, is an oxidase. The enzymes of the citric acid cycle and electron transport are localized in mitochondria, which is shown in Figure 19.1.1.

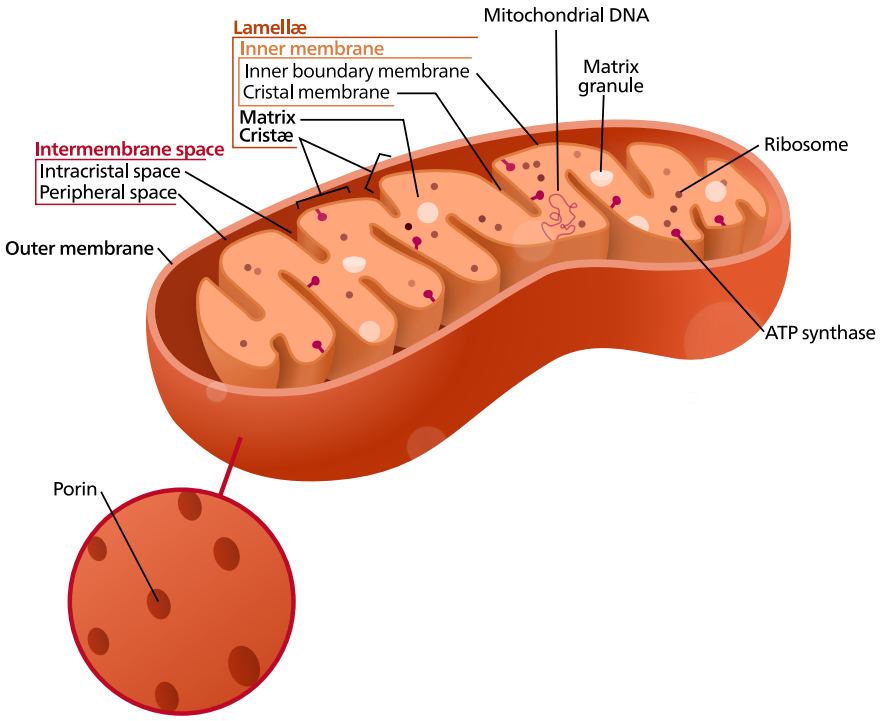

Figure 19.1.1: Mitochondrion. (Public Domain; Kelvinsong via Wikipedia)

By analogy to the coupling mechanism under anaerobic conditions, it would be useful from a biological perspective if this electron transport from NADH to dioxygen, a thermodynamically favorable reaction (ΔG of about -55 kcal/mol, -230 kJ/mol), were coupled to ATP synthesis. It is! For years scientists tried to find a molecule with "high energy" (with respect to its hydrolysis product) phosphorylated intermediate similar to 1,3-bisphosphoglycerate (formed by glyceraldehyde-3-phosphate dehydrogenase in glycolysis), which could drive ATP synthesis in the mitochondria. (**Remember, there is no such thing as a "high energy" bond.**) None could be found. A startling hypothesis was put forward by Peter Mitchell, which was proven correct and for which he was awarded the Nobel Prize in Chemistry in 1978. The immediate source of energy to drive ATP synthesis was shown to come not from a phosphorylated intermediate, but a proton gradient across the mitochondrial inner membrane. All the enzyme complexes in electron transport are localized in the inner membrane of the mitochondria, as opposed to the cytoplasmic enzymes of glycolysis. A pH gradient is formed across the inner membrane in respiring mitochondria. In electron transport, electrons are passed from mobile electron carriers through membrane complexes back to another mobile carrier.

There are four inner mitochondrial membrane complexes involved in the flow of electrons to dioxygen. The first, **Complex I**, passes two electrons from NADH, which engages like NAD^+ in 2 electron redox steps), to a flavin derivative, FMN, covalently attached to Complex I. The oxidation of NADH occurs, as expected, by hydride transfer. The reduced form of FMN then passes electrons in single electron steps (characteristic of FAD-like molecules, which can undergo 1 or 2 electrons transfers) through the complex to the lipophilic electron carrier, **ubiquinone, UQ** as shown in Figure 19.1.2.

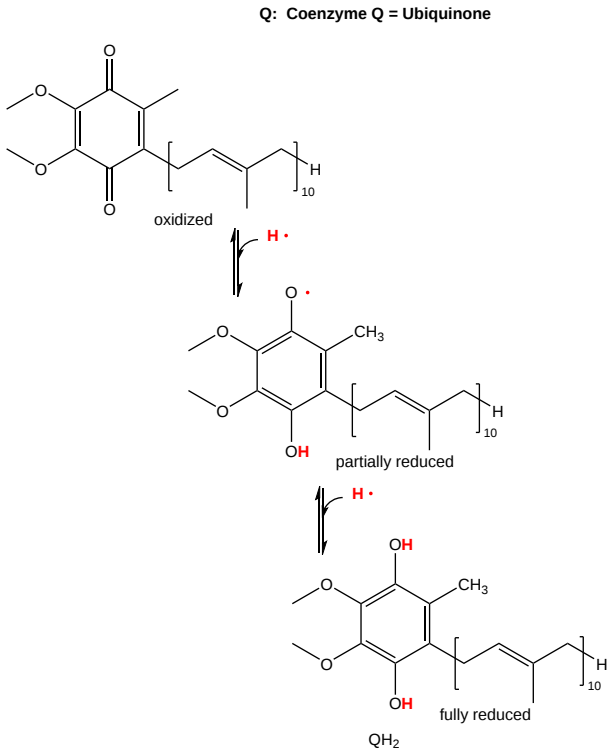

Figure 19.1.2: lipophilic electron carrier, ubiquinone, UQ (Copyright; author via source)

This then passes electrons through **Complex III** to another mobile electron carrier, a small protein, cytochrome C. This protein has a covalently attached heme with a central iron ion that can undergo one-electron redox reactions (Fe^{3+} + $1e^{-}$ ↔ Fe^{2+}). Reduce cytochrome C (Fe^{2+}) passes electrons through **Complex IV**, **cytochrome C oxidase**, to dioxygen to form water. At each step, electrons are passed to better and better oxidizing agents, as reflected in their increasing positive standard reduction potential. Hence the oxidation at each complex is thermodynamically favored. 4 electrons must be added to dioxygen, along with $4H^{+}$ to form water.

$$O_2 + 4\,e^- + 4\,H^+ \rightarrow 2\,H_2O.$$

What happened to Complex II? **Complex II** (also called succinate:quinone oxidoreductase) contains the citric cycle enzyme succinate dehydrogenase, which catalyzes the oxidation of succinate to fumarate by FAD. The bound $FADH_2$ does not dissociate from the enzyme, which is functionally dead for further formation of fumarate until it is oxidized back to FAD by additional components of Complex II. In this process, electrons from $FADH_2$ are passed to the same lipophilic mobile electron carrier from Complex I, ubiquinone. Reduced ubiquinone then can transfer electrons to cytochrome C through Complex III.

For Complex I, III, and IV, the energy released by the oxidative event is used to drive protons from the matrix to the intermembrane space of the mitochondria. The oxidative energy released is NOT used to form a "high-energy" mixed anhydride as we saw in the glyceraldehyde-3-phosphate dehydrogenase reaction from glycolysis. The resulting proton gradient collapses in a thermodynamically favorable process that energetically drives the endergonic synthesis of ATP by the last inner membrane complex, **ATP synthase,** which is sometimes called **Complex V**. This aerobic coupling of electron transfer (from NADH to dioxygen) and ATP synthesis, is shown schematically in Figure 19.1.3. The electron transfer is usually called electron transport, which might suggest to you that it requires energy as in the case of active transport. It does not, however, since it is strongly favored thermodynamically with dioxygen used as the final electron acceptor.

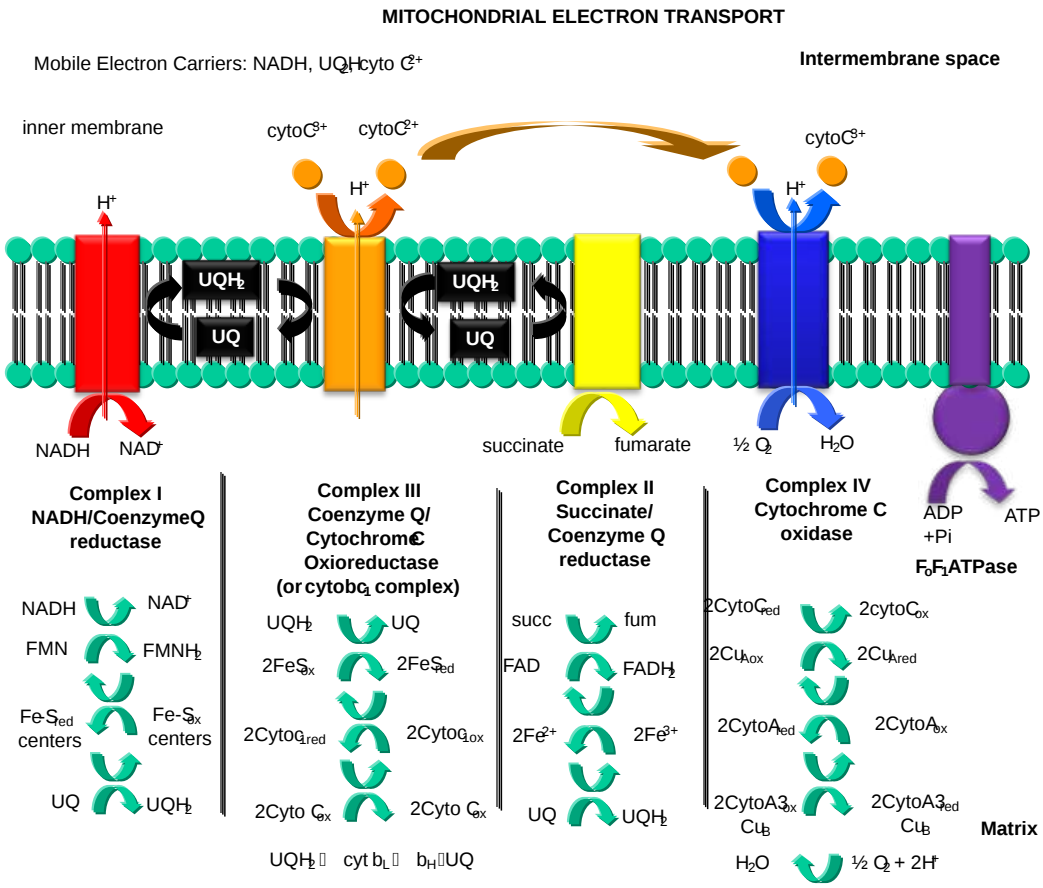

Figure 19.1.3: ELECTRON TRANSPORT AND PROTON GRADIENT FORMATION IN THE MITOCHONDRIA (after Voet and Voet)

You may wish to question the need for such a complicated series of reactions to move the simple electron from one chemical species to another and a simple H^+ from one side of a membrane to another to form a proton gradient that collapses anyway. The movers of these species are aligned in the membrane to optimize the processes and allow the vectorial, nonrandom flow of electrons and protons. This is what evolution has produced. One reason must be to maintain optimal control over the efficiency of the coupled reaction. Another powerful explanation is to reduce dangerous side reactions. In redox chemistry, this involves the formation of highly reactive free radicals that can react quickly and uncontrollably with any species nearby. This is especially true when dioxygen is involved, as we saw in Chapter 13.4 - The Chemistry and Biology of Dioxygen. It takes 4 electrons to fully reduce dioxygen to water. If this process is interrupted, highly reactive oxygen species (ROS) like superoxide and peroxide can form, which can damage membranes, proteins, and nucleic acids.

Before we explore each complex in more detail, let's get a lower resolution view of the entire mitochondrial electron transport and ATP synthesis (often called oxidative phosphorylation or ox-phos) which is shown in cartoon form in Figure 19.1.4.

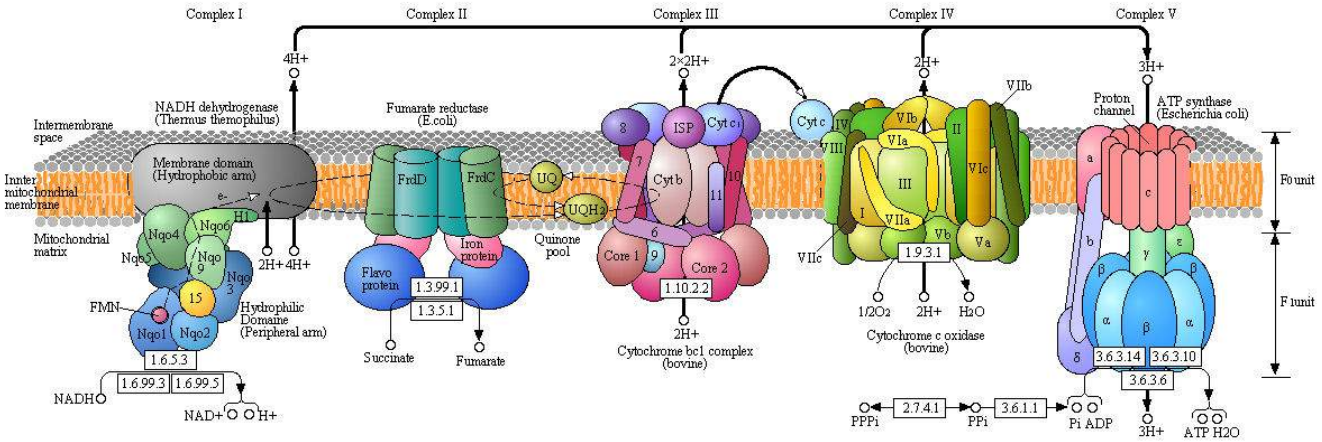

Figure 19.1.4: Overview of coupled electron transport and ATP synthesis (reprinted with permission from Kanehisa Laboratories and the KEGG project: www.kegg.org). Numbers represent Enzyme Commission Numbers. Original KEGG Map with embedded links.

Especially note:

- the subunit complexity of each Complex;
- the location of the subunits (many integral membrane proteins, others more hydrophilic and located in the polar matrix);
- the mobile electron carriers NADH/NAD^+, lipophilic UQH_2/UQ used for both complex I and II, cytochrome C (a protein), and O_2;
- the number of H^+s moved from the matrix to the intermembrane space through Complexes I, III, and IV and back through ATP synthase.

Also note that the prokaryotic structures are displayed, even though they are placed in the mitochondrial membrane! Bacteria do not have organelles like mitochondrial but they have the same complexes inserted into their plasma membranes. For bacteria, protons are ejected into the periplasm space between the plasma membrane and cell wall.

Diagrams like the one shown in Figure 19.1.4 are really useful in simplifying complex biological systems. At the same time, they constrain our ideas about how, in this case, the individual complexes are arranged in the membrane. Much evidence shows that Complex I, III, and IV (those that pump protons) form a very large supercomplex called the **respirasome,** which has some 80 subunits in mammals**.** Clustering the subunits in a supercomplex increases the likelihood that shared mobile electron carriers will not diffuse away, but rather continue passing electrons along the electron transport chain. As mentioned earlier, some reactions generate reactive oxygen species, which need to be kept in the complex to avoid their toxic effects. The stability of the individual complexes is also most likely increased in the larger aggregate.

Using cryoelectron microscopy (cryoEM), the structures of two large super- and mega-complexes have been solved showing the arrangement of all of the respiratory complexes. Two different structures showing the SuperComplex-$I_1III_2IV_1$ ($SCI_1III_2IV_1$) and MegaComplex-$I_2III_2IV_2$ ($MCI_2III_2IV_2$) are shown below in Figure 19.1.5.

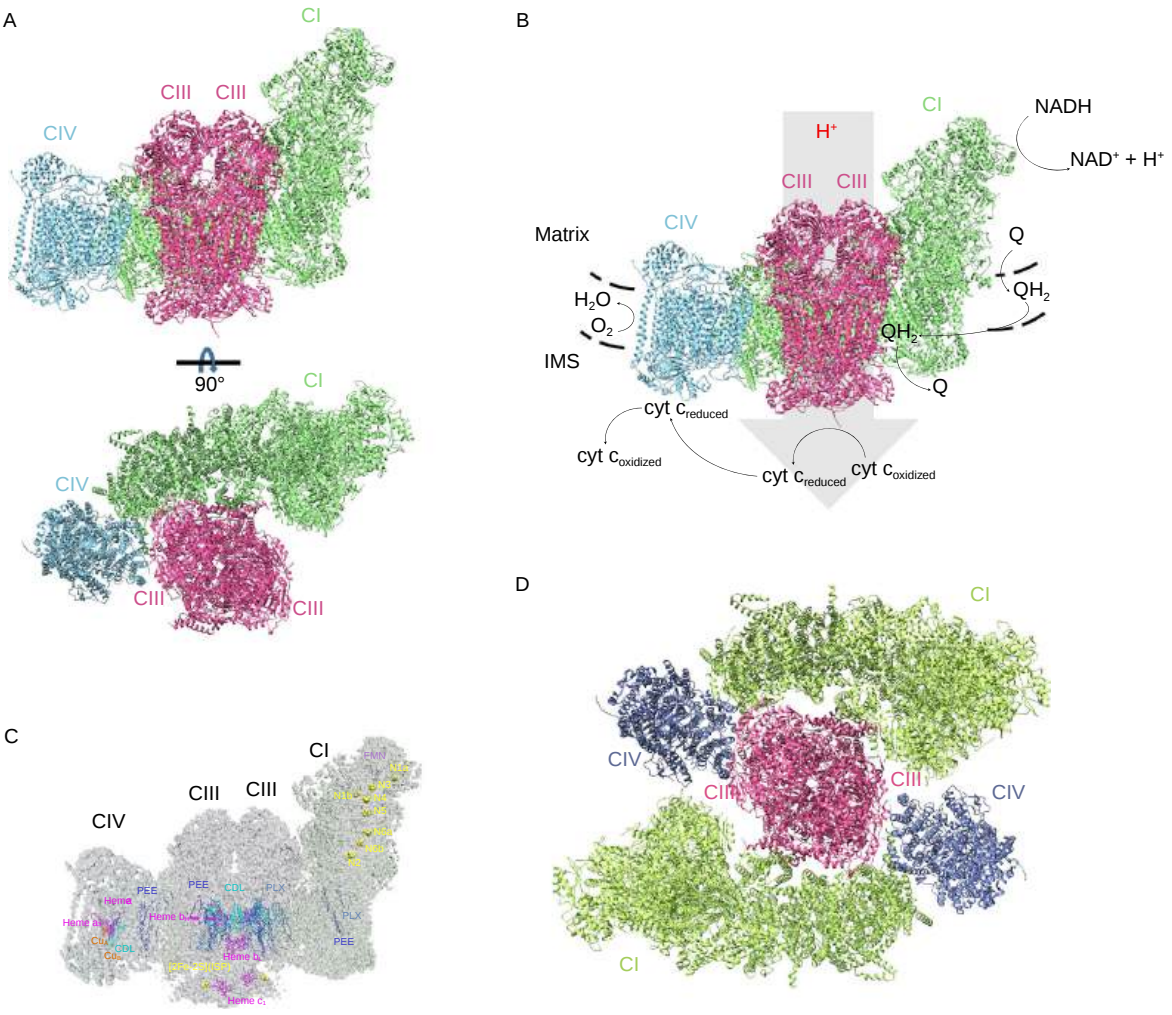

Figure 19.1.5: Structures of Mammalian SCI1III2IV1 and MC I2III2IV2. Meng Wu et al. Protein Cell 2020, 11(5):318–338. https://doi.org/10.1007/s13238-019-00681-x. Creative Commons Attribution 4.0 International License, https://creativecommons.org/licenses/by/4.0/.

Panel (A) shows human SCI1III2IV1 (PDB ID: 5XTH) in side view (along the inner membrane) and a top-down view. Note that CI is adjacent to CIII (located in the center) which is adjacent to CIV. This is the expected orientation given the flow of electrons from NADH to dioxygen. In panel (B) substrates and products are included into the side view, along with the flow of H^+ (from all of the complexes) into the matrix. Panel C shows the added cofactors (FeS clusters, FMN, hemes, etc). Panel (D) shows a very beautiful top-down view of the human megacomplex, which has two copies of each of subunit. Again note the centrality of Complex III.

Figure 19.1.6 shows another model of the megacomplex with Complex II (CII, which does not translocate protons across the membrane) added. It also shows a tetramer of Complex V (ATP synthase)

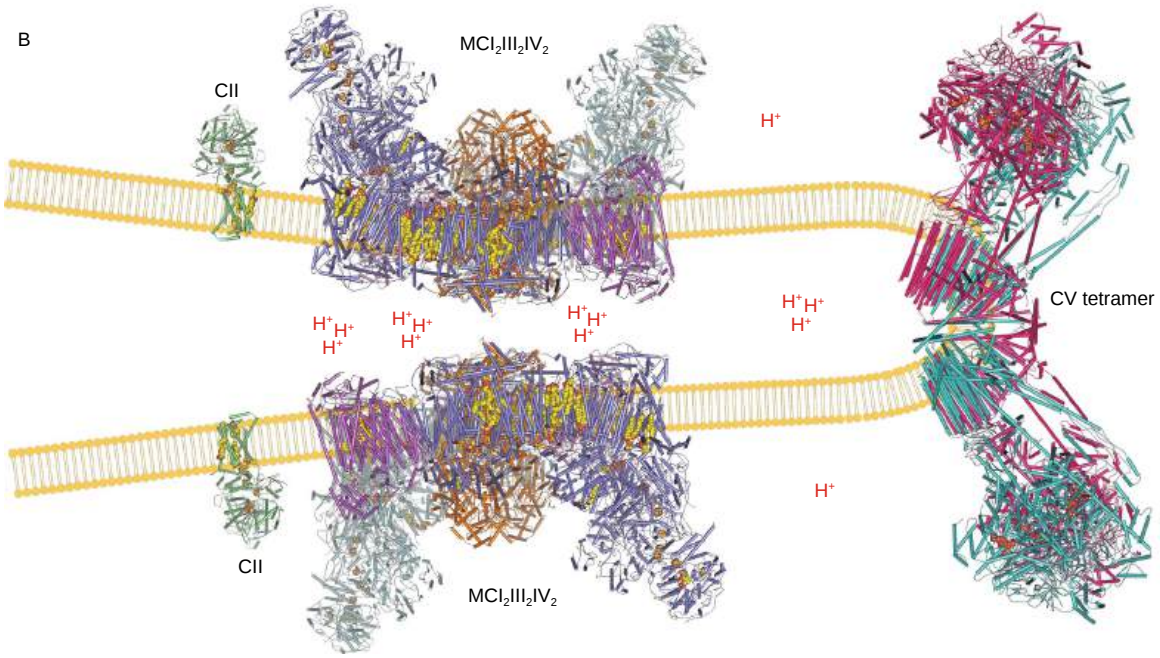

Figure 19.1.6: Arrangement of CII, MCI2III2IV2, and CV tetramer on mitochondrial cristae. (PDB ID of CII: 1ZOY. PDB ID of MCI2III2IV2: 5XTI. PDB ID of SCI1III2IV1: 5XTH. PDB ID of CV: 6J5K. Meng Wu et al. Protein Cell 2020, 11(5):318–338. https://doi.org/10.1007/s13238-019-00681-x. Creative Commons Attribution 4.0 International License, https://creativecommons.org/licenses/by/4.0/.

With this low-resolution background view of the entire mitochondrial oxidative phosphorylation pathway done, now let's explore each pathway in more detail.

19.1.2: COMPLEX I - NADH-QUINONE OXIDOREDUCTASE

Complex I is located in the inner mitochondrial membrane in eukaryotes and in the plasma membrane of bacteria. Bacteria have only 14 subunits while the mammalian Complex I has 45, including the core 14 found in bacteria. Another 31 are term **supernumerary** (in excess of the "normal number") subunits that support the function of the core. The significance of the extra mammalian subunits is still unclear. A cartoon model with the actual crystal structure of the Thermus thermophilus (bacterial) complex is shown in Figure 19.1.7. The hydrophilic or peripheral domain catalyzes electron transfer while the membrane domain (encoded by mitochondrial DNA) is involved in the active transport of protons. It is one of the biggest enzymes around, so it's exciting to try to understand it.

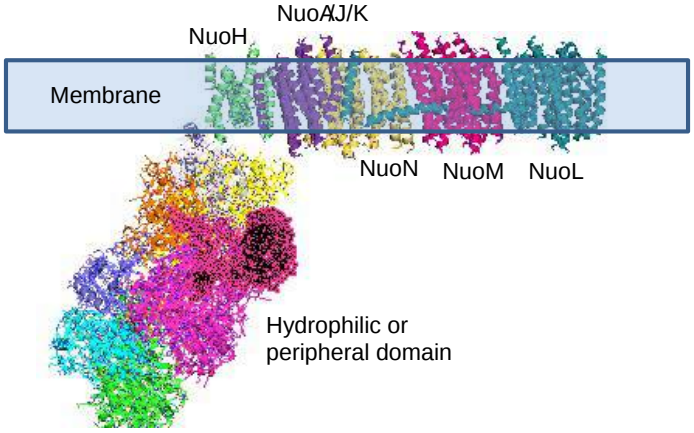

Figure 19.1.7: Detailed view of Complex I from Thermus Thermophilus (Copyright; author via source)

Figure 19.1.8 shows an interactive iCn3D model of the mammalian respiratory complex I (5LDW)

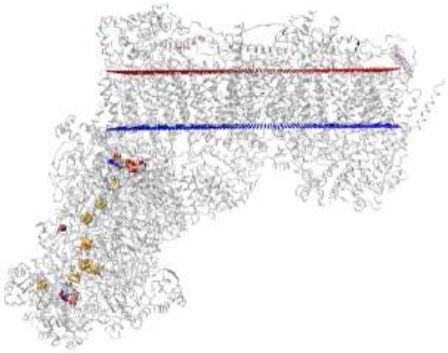

Figure 19.1.8: Mammalian respiratory complex I (5LDW). (Copyright; author via source).
Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...xVjRPLLgaLCi17 (both load slowly given the size of the structures). For the external link, use the mouse scroll to zoom the structure to see the FeS clusters and FMN, all of which are labeled.

The red and blue parallel "dummy" atoms represent the boundary of the mitochondrial inner membrane.

19.1.2.1: ELECTRON TRANSFER IN COMPLEX I

Electron flow occurs from NADH to UQ through a series of one-electron carriers in the hydrophilic or peripheral domain of Complex I. The initial handoff of electrons occurs to a flavin cofactor, FMN, and then through a series of Fe/S clusters, to ubiquinone. These electron acceptors include tetranuclear (Fe_4S_4) and binuclear (Fe_2S_2) iron-sulfur clusters, a FMN flavin mononucleotide, and a Mn (II) ion. These are shown in Figure 19.1.9.

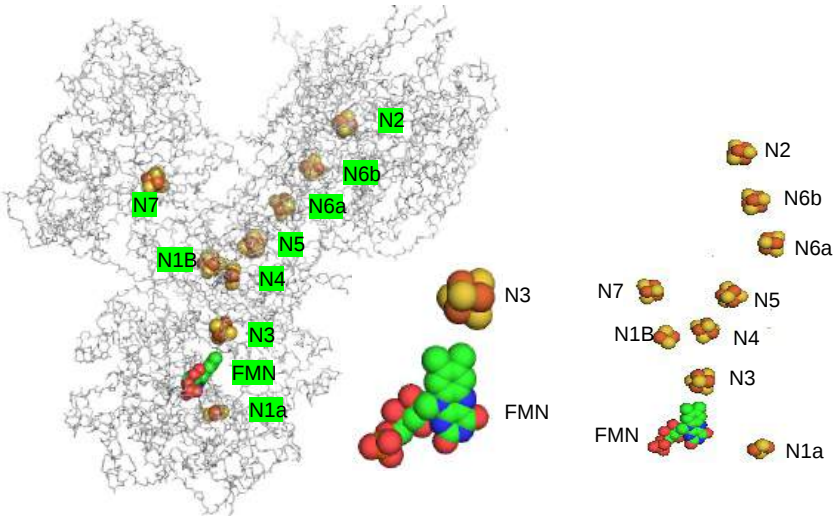

Figure 19.1.9: Electron Flow in Complex I from T. Thermophilus (Copyright; author via source)

The tetranuclear Fe_4S_4 cluster is based on the cubane structure with Fe and S occupying alternating corners of a square in a tetrahedral geometry. Each Fe is also coordinated to thiolate (RS^-) from coordinating cysteines and also sulfide (S^2)-anions. The actual structure is a distorted cube as shown in Figure 19.1.10, along with that of the binuclear Fe_2S_2 cluster, whose bond angles also deviate from those in a perfect tetrahedron.

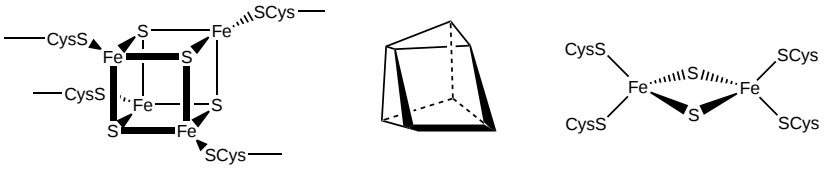

Figure 19.1.10: Fe/S Clusters in Complex I (Copyright; author via source)

Many possible micro-redox states with different standard reduction potentials are possible for tetranuclear Fe_4S_4 clusters, much as polyprotic acids have multiple pKa values. The two relevant to the tetranuclear clusters in Complex I are shown below:

a. $Fe(II)Fe(III)_3/S_2(CysS)_2^{1-} + e^- \leftrightarrow Fe(II)_2Fe(III)_2/S_2(CysS)_2^{2-}$ (less positive standard reduction potential)

b. $Fe(II)_2Fe(III)_2/S_2(CysS)_2^{2-} + e^- \leftrightarrow Fe(II)_3Fe(III)/S_2(CysS)_2^{3-}$ (more positive standard reduction potential)

PK$_A$S AND E^0 VALUES

You have studied Bronsted acids in many courses and know the factors that affect the pK_a of different acids that are **structurally similar**. These include the initial charge on a potential proton donor. The relative strength of a series of structurally similar acids can be predicted by examining the factors that stabilize the negative charge on the resulting conjugate base. The more stable the conjugate base, the more acidic the parent acid. Factors that stabilize a negative conjugate base are electronegativity of the atom holding the negative charge, resonance which might delocalize the charge, inductive/electron release effect of substituents, and the hybridization of the atom holding the charge (sp anions are more stable due to more s character with electrons pulled more closely to the nucleus).

What about a single acid? The pKa of given acid is a constant for a given set of conditions (temperature, solvent polarity, etc) but it can be altered by changing conditions. The diagram below in Figure 19.1.11 shows ways to "tip" the pKa of a given acid (in this case a simple carboxylic acid) to a lower value, making the acid stronger in the new set of conditions.

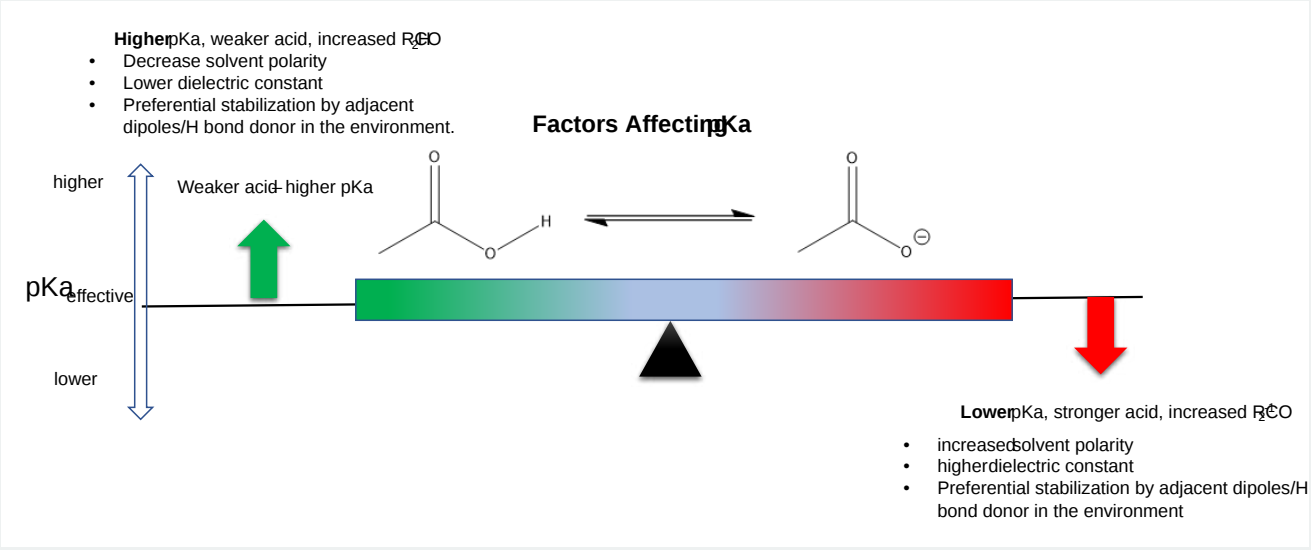

Figure 19.1.11: Factors affecting pKa of a given acid

The same ideas apply to the strength of a potential oxidizing agent (electron acceptor) as described by the E^0 value (higher for stronger oxidizing agents/electron acceptors). Figure 19.1.12 shows the factors that could alter the E^0 value for a binuclear FeS cluster. In this case, changes in coordinating ligands, analogous to changes in substituents for an acid) are included since most students have probably spent more time thinking about pKa values than E^0 values.

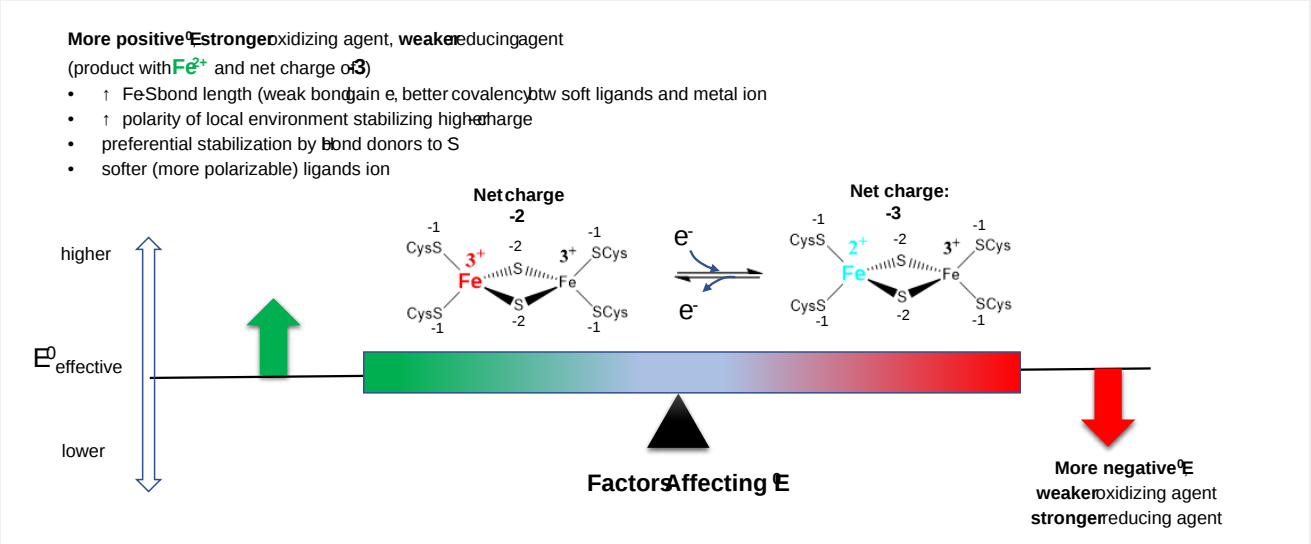

Figure 19.1.12: Factors affecting E^0.

In either case, it can be understood through Le Chatelier's principle. The equilibrium can be shifted to the right (stronger acids with lower pKa or stronger oxidizing agent/electron acceptor with a higher E^0) by preferentially stabilizing products compared to the initial

reactants.

Electrons are passed singly to oxidized UQ in one electron steps to form UQH_2.

Fe-S clusters are synthesized predominately in the mitochondria where they serve as redox cofactors in electron transport as described above. They are ubiquitous in all life forms and serve other roles in addition to redox cofactors per se as they serve structural roles in proteins and are used in redox signaling within the cell as they change oxidation states. Many proteins that interact with DNA (repair enzymes, polymerases, and helicases) contain an FeS cluster.

Evidence suggests that they placed critical roles in the abiotic evolution of life in the absence of oxygen as a terminal electron acceptor in exergonic oxidation reactions. When oxidation became available, they became potentially became toxic to the cell as the Fe^{2+} could participate in reactions (such as the Fenton reaction) leading to the generation of deleterious reactive oxygen species (such as superoxide). To prevent toxicity, when delivered to the cytoplasm and nucleus they are carried and delivered by cytoplasmic iron-sulfur assembly (CIA) proteins.

Figure 19.1.13 shows models of the complex and paths for electron flow.

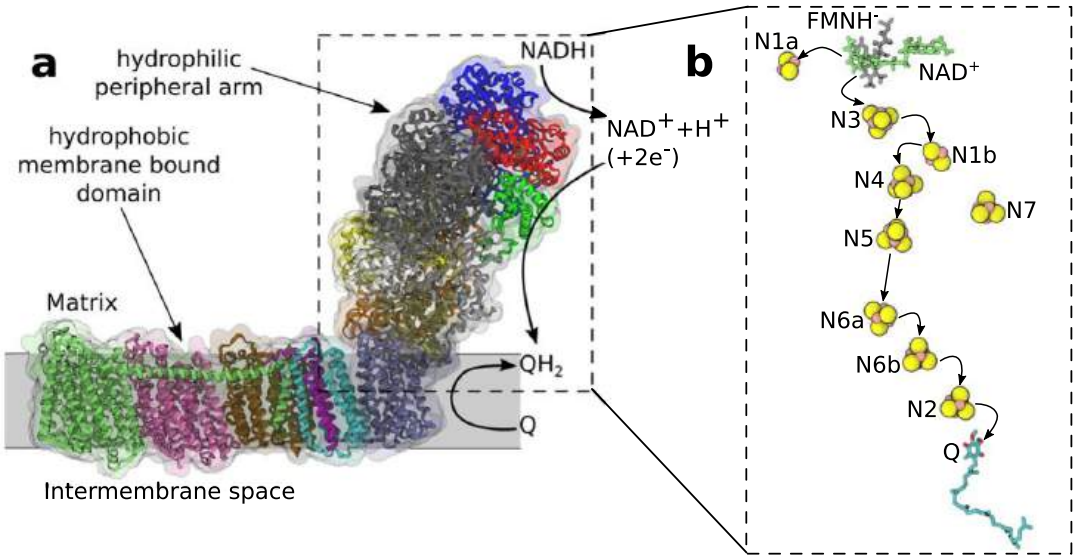

Figure 19.1.13: Complex I and electron transfer. Martin, D.R., Matyushov, D.V. Electron-transfer chain in respiratory complex I. *Sci Rep* **7,** 5495 (2017). https://doi.org/10.1038/s41598-017-05779-y. Creative Commons Attribution 4.0 International License, http://creativecommons.org/licenses/by/4.0/.

Electrons "tunnel" from one cofactor to another in Complex I through quantum mechanical "hops". Since all of the redox cofactors after the favored hand-off of electrons from NADH to FMN are FeS clusters, which would have similar E^0 values (modulated only by local environments), there is no significant thermodynamic barrier to electron flow. The final N2 FeS cluster has a E^0 value about 100 mV higher than the started ones so it most readily accepts an electron.

The separation of the hydrophilic mitochondrial matrix domains, where electron transfer occurs, from the transmembrane domains, where proton transfer occurs, is an elegant design that keeps the key and reactive particles, e^- and H^+, from reacting with each other. The electrons stay on one side of the membrane, as the protons move to the other side (until the return in the last step when Complex V produces ATP).

19.1.2.2: PROTON TRANSFER IN COMPLEX I

Proton transport occurs in the membrane domain. Available evidence suggests that 4 protons move from the cytoplasm to the periplasmic space against a concentration gradient during a catalytic cycle of Complex I in bacteria and other organisms.

Figure 19.1.14 shows multiple views of both the key electron transfer step and H^+ ejection from the matrix into the intermembrane space. The key to proton transports is the discrete membrane domains shown in the bottom left part of Panel (a). There are 4 such domains involved from left to right, each one associated with the transport of $1H^+$. The individual membrane domains have different names and abbreviations depending on the organism. They are from left to right:

- Nqo12, NuoL or ND5
- Nqo13, NuoM, or ND4
- Nquo14, NuoN or ND2
- Nqo8, NuoH, or ND1.

The Nqo8, NuoH, or ND1 domain is proximal and closely linked to the site for the reduction of UQ to UQH_2.

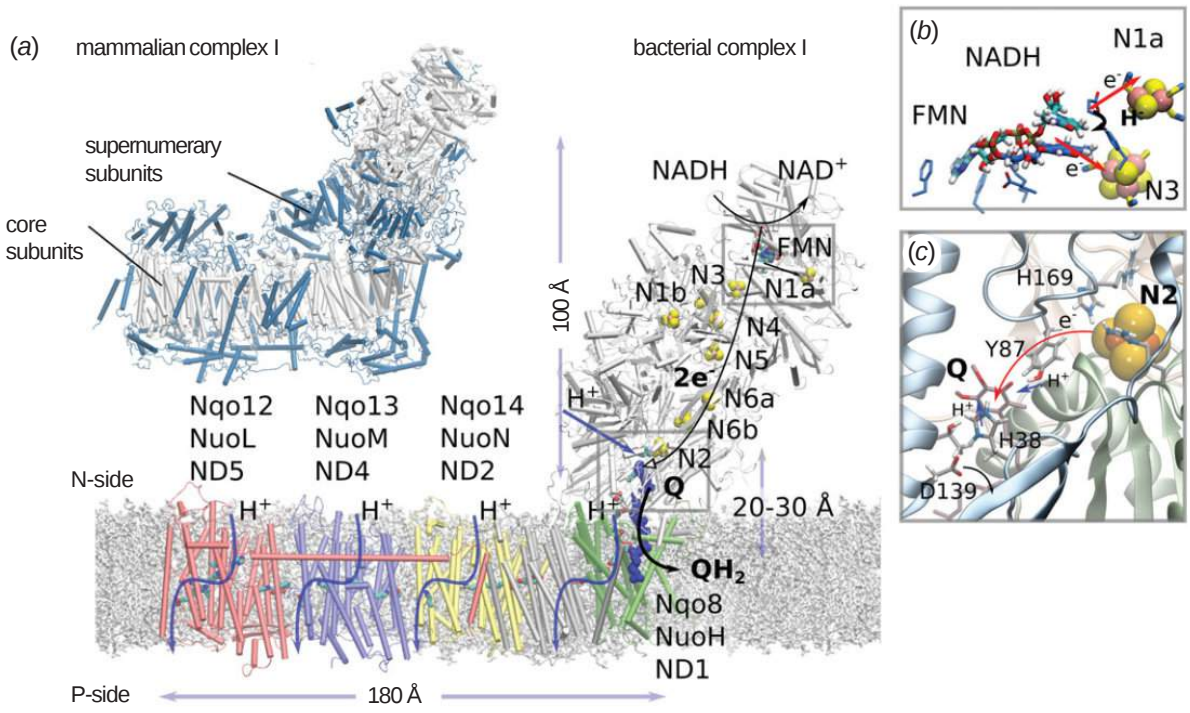

Figure 19.1.14: Structure and function of complex I. Panel (a) shows a large structural model of complex I from Thermus thermophilus (4HEA) showing the flow of electrons in the hydrophilic domain, while the mammalian complex (5LC5), with its supernumerary subunits in blue, is shown at the top left. Panel (b) shows the NADH/FMN site (3IAM) and its close proximity to the N3 tetranuclear cluster. Panel (c) shows the N2/Q reduction site with pi-stacking interactions of the ubiquinone ring with the aromatic His 38 ring. The P (positive side) accumulated H^+s while the N (negative side) becomes depleted in them. Kaila VRI. 2018 Long-range proton-coupled electron transfer in biological energy conversion: towards mechanistic understanding of respiratory complex I. J. R. Soc. Interface 15: 20170916. http://dx.doi.org/10.1098/rsif.2017.0916. Creative Commons Attribution License http://creativecommons.org/licenses/by/4.0/,""

The NuoN/Nqo14/ND2, NuoM/Nqo13/ND4 and NuoL/Nqo12/ND5 domains act as and are structurally similar to antiporters. Note also a very long helix that crosses the left three-most antiporter domains. This helix runs parallel to the membrane and probably acts as a lever allowing coupled conformational changes of the three H^+ transporters. We looked in a previous chapter at transporters and showed in both cartoon and structural models that they alternated between inward and outward-open conformations.

Figure 19.1.15 shows more details of the antiporter domains and the unique structural features allowing proton transport. Each antiporter domain has two 5-helix bundles that display pseudo-symmetry with transmembranes helices number TM4-8 and TM9-13. The next to last helix in each bundle (7 and 9) is interpreted, with unbroken parts of the helices number TM7a/b and TM12a/b. Running along the middle of each of the antiporter-like domains of the membrane domain is a series of conserved charged amino acids (aspartate, glutamate, lysine, and histidine) that participate in a hydrogen bonding network. Molecular dynamics simulations show water molecules (panel b), represented by red dots (for the oxygen atoms), transiently occupying a hydrogen-bonded network of waters that serve as a conduit for H^+ flow. An unbound "naked" proton (H^+) would not persist long in any aqueous biological system. Panel C shows the conformational flexibility in broken interrupted helices that presumably gates the proton pore open and closed.

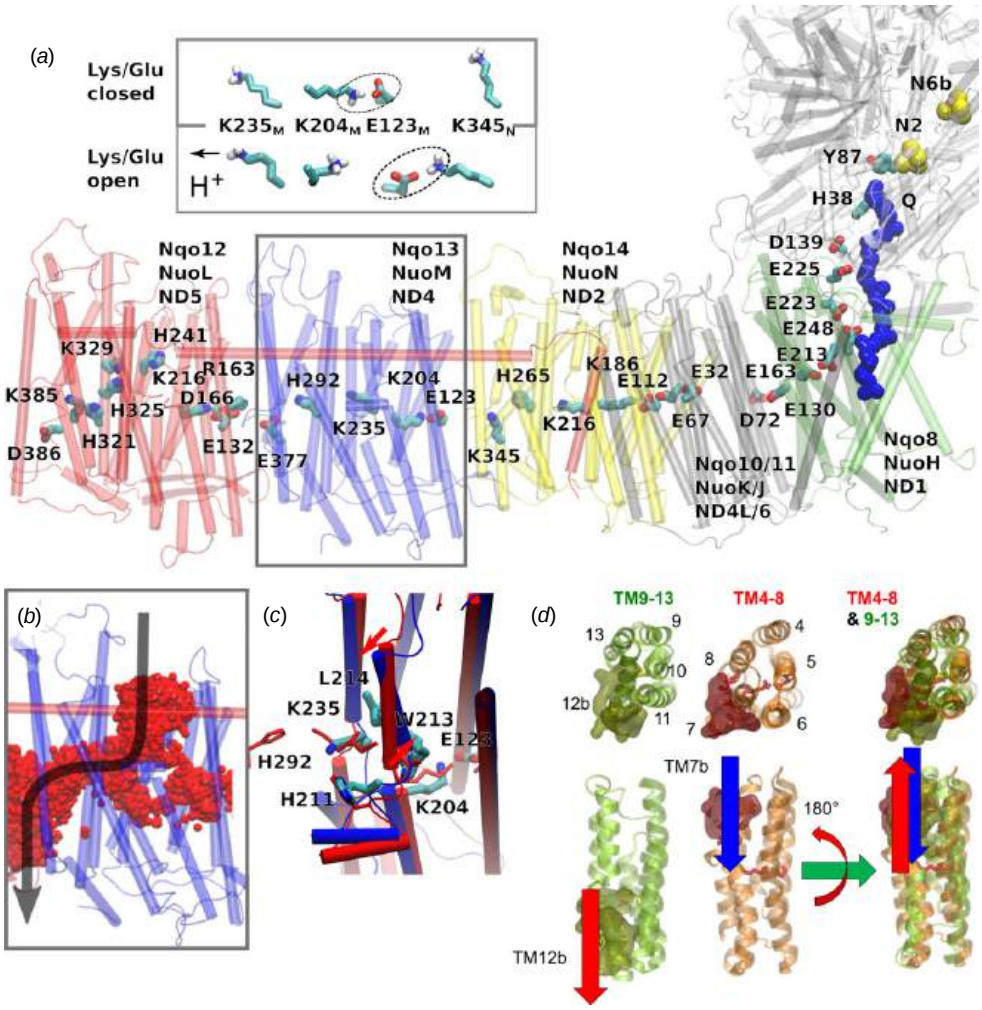

Figure 19.1.15: Structure of the proton-pumping membrane domain in complex I.

(a) The membrane domain of complex I have conserved buried charged/hydrophilic residues. NuoL (red); NuoM (blue); NuoN (yellow); NuoH (green); Ubiquone - Q (blue van der Waals representation). Inset: The conformation of the Lys/Glu ion pair (here Lys-204M/Glu-123M) can modulate the pKa of the middle Lys (Lys-235M).

(b) The NuoM antiporter-like subunit with water molecules (red dots). The arrow shows the flow of protons through a hydrogen bond-linked network of waters that "visit" the structure during μs molecular dynamics simulation.

(c) Snapshot of structures obtained from molecular dynamic simulations of open (in blue) and closed (in red) proton channels from the N-side in Nqo13 (NuoM/ND4), showing conformational changes in the broken helix element.

(d) The structural symmetry of the antiporter-like subunits with an N-side input channel near broken helix TM7b and output channel near broken helix TM12b.

How is the reduction of ubiquinone and proton transport coupled? The mechanism likely involves conformational changes in flexible regions in the interface of the hydrophilic and membrane domains of the complex.

19.1.2.3: INHIBITION OF COMPLEX I

Complex I is inhibited by more than 60 different families of compounds. They include the classic Complex I inhibitor rotenone and many other synthetic insecticides/acaricides. The classes include Class I/A (the prototype of which is Piericidin A), Class II/B (the prototype of which is Rotenone), and Class C (the prototype of which is Capsaicin). They appear to bind at the same site. Figure 19.1.16 shows their structures. From the structure of the 3 prototypes, what are the characteristics of the pharmacophore, the “ideal binding ligand”? Where do they likely bind? How “promiscuous” is the binding site?

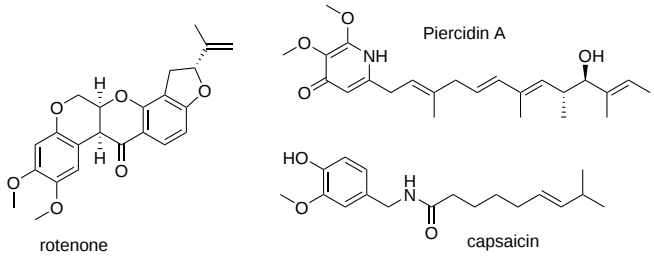

Figure 19.1.16: Inhibitors of Complex I (Copyright; author via source)

Many devastating neurological diseases are associated with defects in Complex I. In addition to major problems with oxidative ATP production, reactive oxygen species (ROS) increase. The major sites for the generation of ROS are Complex I and Complex III. Given the locations of the electron carriers at the periphery and internal within the protein complex, which electron carriers might most readily leak electrons to dioxygen? What ROS is likely to form in the process?

Inhibitors might block access to UQ or conformational changes necessary for the final reduction of the ubiquinone free radical. Class A inhibitors dramatically increase ROS production. The actual site of ROS production in Complex I is a bit controversial. One possible electron donor to dioxygen is FMN since both can engage in 1 e^- transfers. Mutants that lack N2 iron-sulfur cluster showed ROS production.

In submitochondrial preparations, normal Complex I activity occurs (which leads to the formation of a sustained proton gradient). Also reverse electron transport, powered by an artificial proton gradient can occur, which leads to the reduction of NAD^+, as shown in Figure 19.1.17.

Figure: Normal and Reverse Electron Transport Complex I

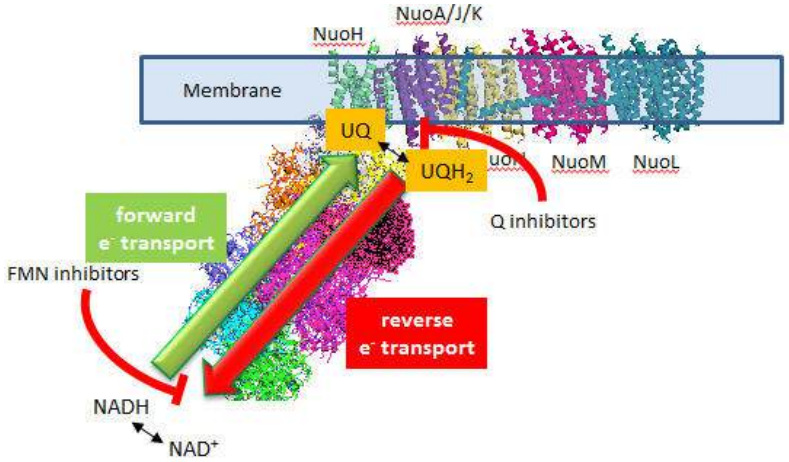

Figure 19.1.17: Overview of forward and reverse electron transport in Complex I.

A summary of the finding on superoxide production by Complex I show that:

- superoxide production is inhibited by flavin site inhibitors but not Q site inhibitors.
- reverse electron transport leads to NAD^+ and O_2 reduction
- Reverse electron transport superoxide production is inhibited by both flavin and Q site inhibitors

Figure 19.1.18 shows an expanded view of electron transport and sites where ROS production are enhanced. Refer to the legend for details.

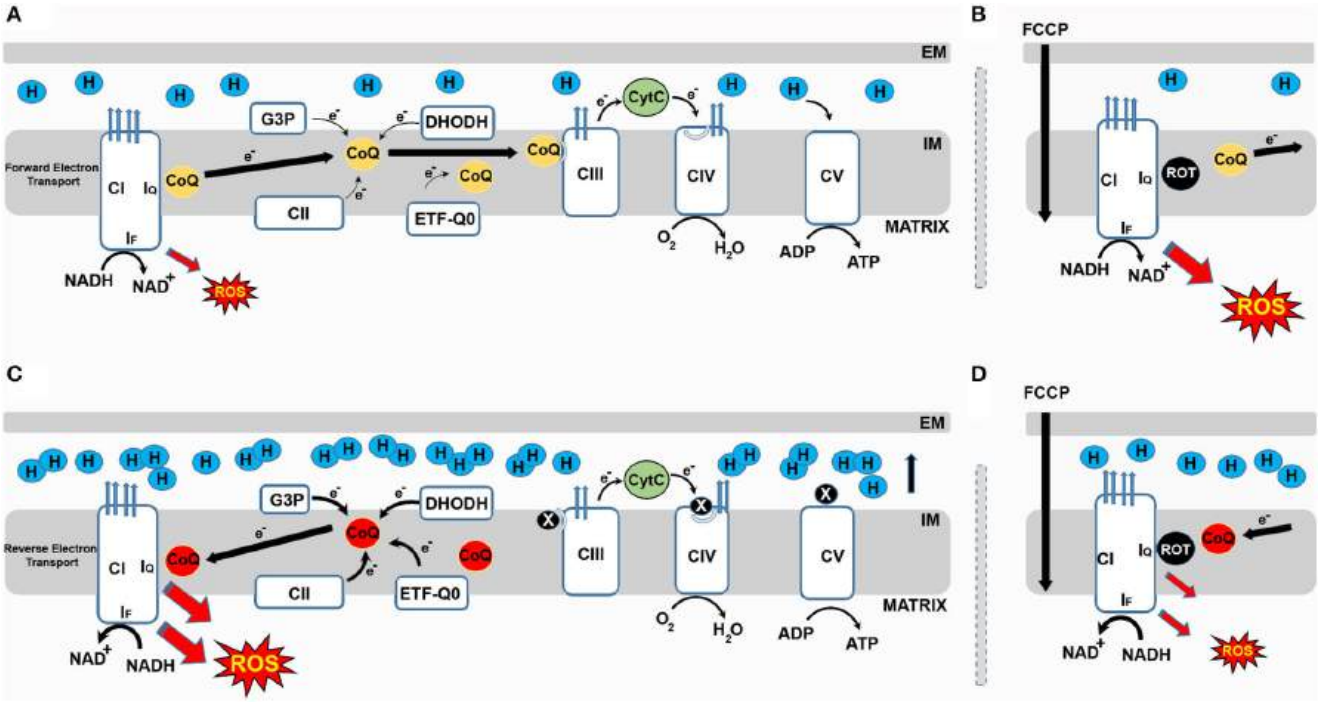

Figure 19.1.18: Complex I (CI) produces ROS in both the forward and reverse directions. Scialò Filippo et al. Frontiers in Physiology (8), 2017. https://www.frontiersin.org/article/...hys.2017.00428. DOI=10.3389/fphys.2017.00428. **Creative Commons Attribution License (CC BY)**.

(A) During **forward electron transfer (FET)**, ubiquinone, also called Coenzyme Q (CoQ) receives electrons from complexes I and II, glycerol-3-phosphate dehydrogenase (G3P), electron-transferring flavoprotein (ETF-QO) or dihydroorotate dehydrogenase (DHODH). During this process electrons mainly leak to produce superoxide from the FMN binding site (I_F) of CI during the oxidation of NADH to NAD^+.

(B) In these conditions, if rotenone blocks the ubiquinone binding site (I_Q) site, electrons cannot be transferred to CoQ, so they leak and generate ROS. FCCP, a molecule that collapses the H^+ gradient by simple diffusion across the membrane, bypassing Complex V - ATP synthase) also increases mitochondrial ROS generation during FET.

(C) When the CoQ pool becomes over-reduced, a high membrane potential favors the reverse transfer of electrons from ubiquinol to CI in a process called **reverse electron transport (RET)**. During RET electrons leak at either I_F or I_Q generating a significant amount of superoxide.

(D) Blocking the I_Q site with rotenone during RET prevents CoQ from transferring electrons back to CI and reduces ROS production. Similarly, FCCP reduces ROS by dissipating membrane potential.

19.1.3: COMPLEX III

Complex III is a complicated, multisubunit protein that is at the heart of the respirasome. The subunits involved in electron transfer are cytochrome b, cytochrome c_1, and the Rieske iron-sulfur protein (ISP). Cytochrome b has two hemes. One is cyto b_{562} which is also called the low potential heme or cyto b_L. The other is cyto b_{566} which is called the high-potential heme or cyto b_H. The cytochrome c_1 subunit has one heme. The Rieske iron-sulfur protein contains a Fe_2S_2 cluster. Figure 19.1.19 shows the relative position of the bound mobile electron carrier, cytochrome C, and the internal ones, the Rieske Fe/S cluster and cytochrome b_L and b_H. Note also the molecule stigmatellin A, which binds to the site where UQ becomes reduced (called the Qo site) and inhibits the complex. This shows that UQ/UQH_2 are in a position to react readily with the Rieske center and cytochrome b_L heme.

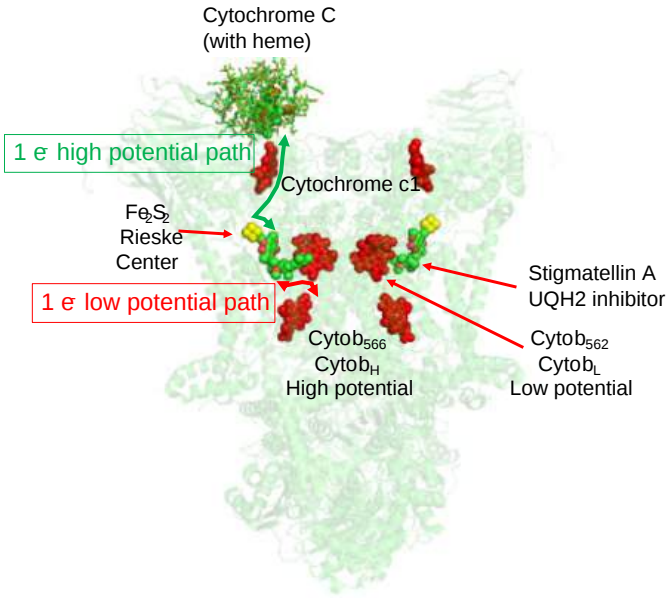

Figure 19.1.19:

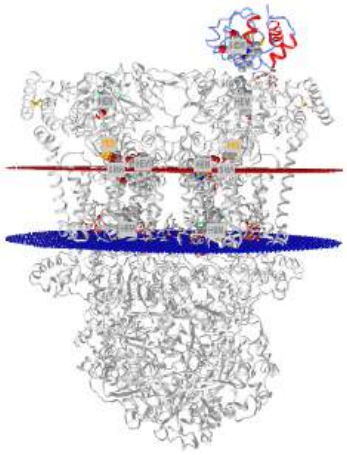
Figure 19.1.20 shows an interactive iCn3D model of a eukaryotic respiratory complex III (3CX5)



NCBI iCn3D Figure 19.1.20: eukaryotic respiratory complex III (3CX5). (Copyright; author via source).
Click the image for a popup or use this external link:https://structure.ncbi.nlm.nih.gov/i...5riT4GSSGhCHfA. (loads slowly given the size of the structures).

The Rieske iron-sulfur protein has a Fe_2S_2 iron-sulfur cluster which differs from other such clusters in that each Fe is also coordinated to two His side changes, as shown in Figure 19.1.21. Alterations in H bonds to the histidines and to the sulfurs in the complex can dramatically affect the standard reduction potential of the cluster.

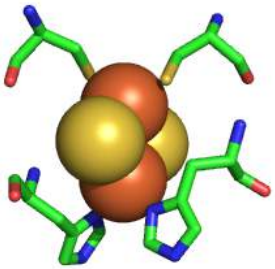


Figure 19.1.21: The Rieske Fe_2S_2 cluster

As with Complexes I and IV, proton and electron transfer are coupled processes. However, in contrast to Complex I, in which protons pass through protein domains that have homology to K^+/H^+ antiporters, and Complex IV, in which they pass through a combination of a water channel and the H-bond network, the protons in Complex III are carried across the intermembrane space by ubiquinone itself. Two reduced ubiquinones (UQH_2) from complex I pass their four matrix-derived protons into the intermembrane space. In the process, four electrons are removed in a multiple-step process called the Q cycle.

The two electrons from each UQH_2 take different paths. One electron moves to a Fe/S Rieske cluster and the other to cytochrome b_L. The electrons moved to the Rieske center then move to cytochrome c_1 and then to the mobile electron carrier cytochrome C which is bound to the complex in the intermembrane space. The electrons moved to cyto b_L are transferred to cytochrome b_H in the complex. Through this latter path, two electrons (from two UQH_2) are then moved to oxidized UQ, and two matrix protons are added to reform one UQH_2. Hence, only one UQH_2 participates in the net reaction shown below.

$$QH_2 + 2 \text{ cyto } c^{3+} + 2H^+_{matrix} \rightarrow Q + 2 \text{ cyto } c^{2+} + 4H^+_{IMS}$$

This net overall reaction, the Q cycle, is illustrated below. This net overall reaction, the Q cycle, is illustrated in Figure 19.1.22.

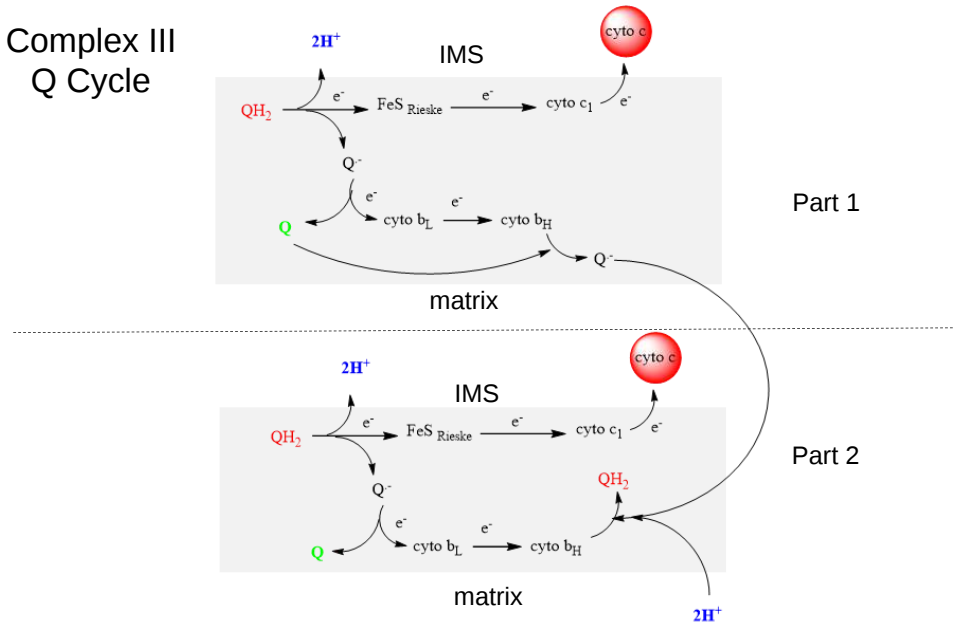

Figure 19.1.22 Q cycle of Complex III

Once again, there are no “proton” channels or hydrogen-bonded networks in the protein for proton transfer across the inner membrane.

Another way to think about the electron transfer process from UQH_2 to cytochrome C is that the 2 electrons from UQH2 take two different paths, one a high potential path to the Rieske center and on to cytochrome C, and another low potential path to the b_L heme and on to the b_H heme and then to UQ to reform UQH2 (see figure above).

Complex III, along with Complex I, can also produce unwanted reactive oxygen species (ROS). Only three of the protein subunits, cytochrome b (with the b_L and b_H hemes), cytochrome c_1, and the Rieske iron-sulfur protein (ISP) are involved in electron transfer, so one of those is most likely involved in ROS production. Experiments and mathematical models support a mechanism that involves a reduction of UQ by the addition of one electron from cytochrome b_L to form $UQ^{\cdot}$ which then passes its electron to dioxygen to form superoxide ($O_2^{-\cdot}$).

As two ubiquinones must bind to the complex, there must be two proximal sites. One is the Qi site where oxidized UQ binds and receives an electron. The other is the Qo site where UQH_2 binds.

From a kinetic perspective, the first UQH_2 binds and transfers two electrons, one to the Rieske cluster (and on to cytochrome c_1 and then to cytochrome C) and one to cytochrome b_L (and on to heme b_H) and then to an oxidized UQ bound at the Qi site. The $UQ^{\cdot}$ radical is stabilized by the adjacent b_H heme which has a lower affinity for electrons. Now a second UQH_2 binds to the Qo site, and transfers two electrons, again one via the Rieske cluster and the second through cytochrome b_L and b_H to the $UQ^{\cdot}$ radical present at the Qi site to form UQH_2 after two protons are transferred to it from the matrix.

Now a second UQH_2 binds to the Qo site, and transfers two electrons, again one via the Rieske cluster and the second through cytochrome b_L and b_H to the $UQ^{\cdot}$ radical present at the Qi site to form UQH_2 after two protons are transferred to it from the matrix.

Antimycin A, an extremely toxic drug, binds to the UQ Qi site and hence blocks electron transfer from cytochrome b_L to b_H at the Qi site. Heme b_L can then pass its electron to dioxygen to produce superoxide.

Before we leave Complex III, just a quick observation. The complex has two identical cytochrome b subunits, each with a b_L and b_H heme. The standard reduction potential of the b_L and b_H hemes in a subunit differ. This is another example that shows that the standard reduction potential, E^0, depends on the environment of the electron acceptor/donor, just as the pKa of an acid depends on its environment.

Figure 19.1.23 shows an interactive iCn3D model of just the cytochrome b subunits and all the hemes in the eukaryotic respiratory complex III (3CX5) tp give more clarity to the differing environments of the hemes in the two identical cytochrome b subunits.

19.1.4: COMPLEX IV - CYTOCHROME C OXIDASE (CCOX)

This is the final complex in the electron transport chains and is the one that passes 4 electrons and 4 "substrate" protons to dioxygen to produce water. In addition, it moves as many as 4 H^+s from the matrix to the intermembrane space, for a net change of 8 H^+s. Here is a modified version of Equation 1 that represents the transported Hs.

$$O_2 + 4\,e^- + 4\,H^+ + 4\,H^+(in) \rightarrow 2\,H_2O + 4\,H^+(out).$$

The structure of complex IV is shown in Figure 19.1.24. KEGG pathways (with permission).

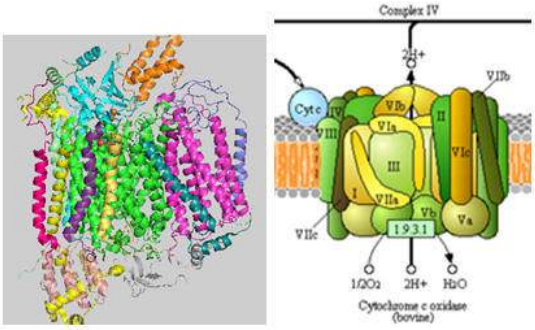

Figure 19.1.24 Cytochrome C Oxidase structure (left) and cartoon model (right) showing subunits (taken KEGG pathways with permission). (Copyright; author via source)

The 4 H^+s that are moved across the membrane are not transported by protein domains that are structural equivalents of antiporters, as in Complex I. Rather elaborate H-bonded water channels with contribution from a space of polar backbone and side chain H-bond donors and acceptors are involved in proton transport. Hence a key question to understand is how electron transfer is coupled to H^+ transfer through this hydrogen-bonded network. Since it's quite complicated we will present multiple different but somewhat redundant figures of low to high resolution to help explain this coupled process.

Figure 19.1.25 shows an interactive iCn3D model of the 14-subunit human cytochrome c oxidase (5z62) with bound cofactors required for electron transfer. Note that it does not show cytochrome C.

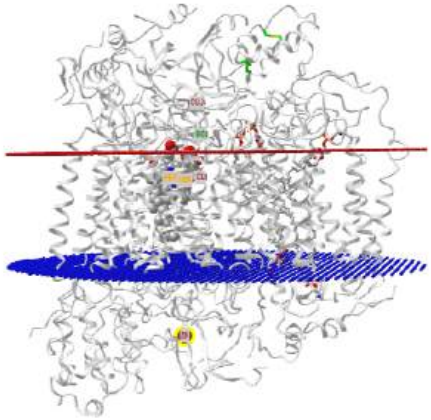

Figure 19.1.25: 14-subunit human cytochrome c oxidase (5z62). (Copyright; author via source).
Click the image for a popup or use this external link:https://structure.ncbi.nlm.nih.gov/i...XoHRyCkpeRN917. (loads slowly given the size of the structure).

Reduced cytochrome C, a mobile electron carrier protein, binds to Complex IV in the intermembrane spaces and singly passes 4 electrons to a series of electron carriers (oxidizing agents) in the protein, eventually to dioxygen as the terminal electron acceptor. Figure 19.1.26 shows the arrangement of the electron acceptor cofactors in Complex IV. Electron transfer presumably occurs through quantum mechanical tunneling.

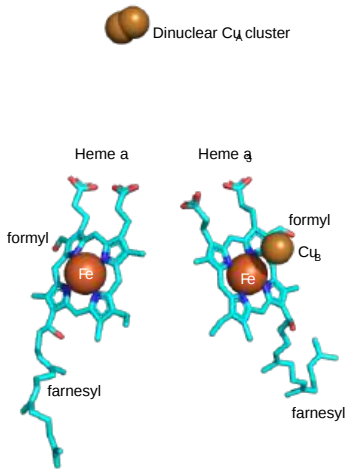

Figure 19.1.26: Electron acceptor cofactors in Complex IV.

Cytochrome C, the initial “substrate” of this complex, delivers electrons from its heme cofactor to a dinuclear copper cluster, Cu A, where the copper ions are collectively coordinated to two histidines and two cysteines, and a methionine. Figure 19.1.27 shows an interactive iCn3D model of the coordinating ligands for Cu A cluster in Complex IV (5z62)

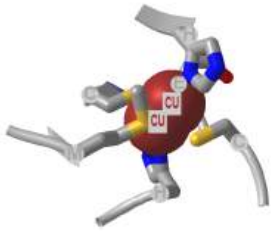

Figure 19.1.27: coordinating ligands for Cu A cluster in Complex IV (5z62). (Copyright; author via source).
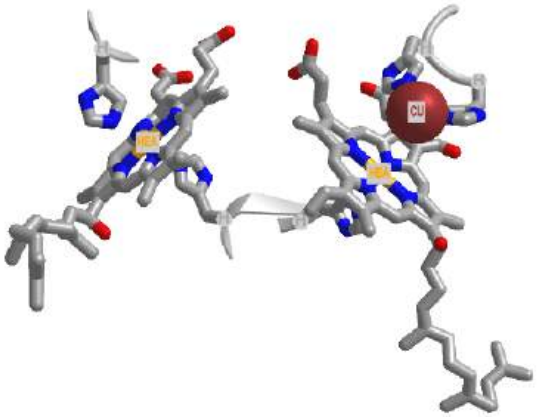
Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...7ARphDU4oyDS4A

From there, electrons flow to an adjacent **heme a** (low spin), which has two coordinating histidine ligands. This heme hence does not bind dioxygen. From there, electrons move to another heme, **heme a_3** (high spin), and then finally to dioxygen which is coordinated to the Fe in heme a_3 and to an adjacent Cu B. Heme a_3 has only one coordinating histidine ligand, which allows dioxygen binding to the unligated site.

The heme a_3 Fe:Cu dinuclear cluster is unique among all hemes. Figure 19.1.28 shows an interactive iCn3D model of the coordinating ligands for the hemes and Cu B in Complex IV (5z62)



NCBI iCn3D Figure 19.1.28: coordinating ligands for CuB, heme a and heme a_3 in Complex IV (5z62). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...4EUooXkwh13Fm8

First, let's consider the transfer of electrons from heme a to heme a_3 and then on to dioxygen (we will consider the entry of electrons into the complex later). If dioxygen, a substrate for the reaction, dissociated from the heme a_3 Fe before it was completely reduced, toxic ROS would result. This suggests a reason for the evolution of this key enzyme to have produced the unique heme a_3 Fe:Cu dinuclear cluster

Heme a and a_3 vary from the heme in hemoglobin as they both have a formyl group replacing a methyl and a hydroxyethylfarnesyl group added to a vinyl substituent. Its structure is shown in Figure 19.1.29. What is its overall charge of the heme in its reduced state? In its oxidized state?

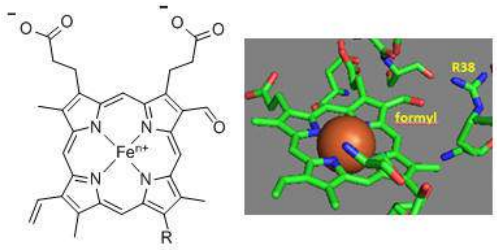


Figure 19.1.29: Heme-Formyl group of Cytochrome C Oxidase

As hemes are prosthetic groups, they must bind to the apoprotein. The hydroxyethylfarnesyl group, with its nonpolar tail, facilitates the binding of the heme to both the Fe^{+2} and Fe^{+3} forms by about 6.3 kcal/mol (26 kJ/mol). The formyl group in heme a increases the E^0 value (i.e. make the heme a better oxidizing agent) by about 179 mV (4.1 kcal/mol, 17 kJ/mol). The effect appears to be mediated by the binding of the heme group to the protein again, only in this case there is a differential effect. The formyl group preferentially stabilizes the binding of the Fe^{+2} heme compared to the Fe^{+3} heme, which in a thermodynamic cycle, would promote the binding of an electron to Fe^{+3}-heme (increasing its E^0 value) to form the more stably bound Fe^{+2} heme.

The key challenge has been to understand the redox coupling to H^+ transport. How is this done? The electrostatic environment of the hemes must be considered. In heme a, the two axial ligands are uncharged imidazole side chains of histidines. The overall charge on Fe^{2+}-heme is zero as the two propionates cancel the charges on Fe^{2+}. However, there is a net +1 charge in the Fe^{3+}-heme. This charge could be delocalized within the conjugated pi electrons of the planar heme, which could contribute to the deprotonation of a side chain near heme a in a process that would couple redox and H^+ movement. The formyl group of heme a is coplanar with the heme ring in both Fe^{3+}-heme and Fe^{2+}-heme, which allows it to participate in the pi-conjugated electron system of the ring. As the formyl group forms an H bond with Arg 38, changes in oxidation might affect Arg 38 as well.

Many other amino acids are involved as well. One is Asp-51 of subunit I which contains heme a. This undergoes a conformational change which moves it to the surface of the inner membrane on reduction. It is near the matrix in the oxidized state. Hence it is likely involved in a proton transport pathway. In fact, crystal structures of oxidized and reduced Complex IV show water channels and small "cavities" which calculations show can hold 1-3 water molecules. Hence groups around the heme, including R38 are assessable to water. Water would be involved in H^+ transport through "handshaking" transfer of protons through a hydrogen-bonded network of waters and selective side chains. Some of the amino acid residues associated with the water channels are shown in Figure 19.1.30: and include R38 (the one hydrogen bonded to the formyl group of the heme), S34, T 424, S461, S382, and H413.

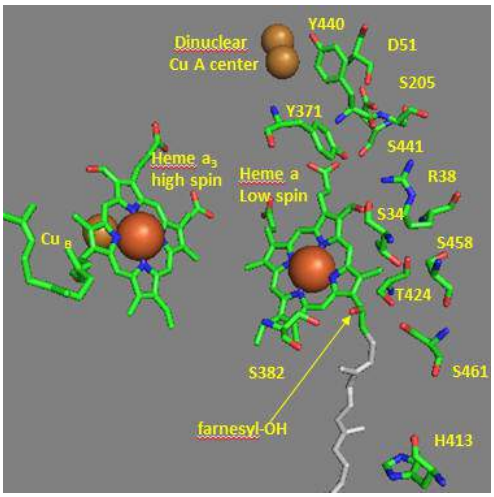

Figure 19.1.30: Possible amino acids involved in H^+ transport through a hydrogen-bonded network in Complex IV

Another consequence of electron transfer to heme a involves the interaction of S382 and the farnesyl OH group, which are close in space and proximal to a water cavity. On reduction of the heme, a conformation change occurs which increases the standard reduction potential of the S382-farnesyl OH group. What effect would this have on the interaction of the two and the S382-L381-Val380 localized conformation? A new water cavity appears to emerge on reduction in this region. How might this impact proton transfer from the matrix?

Now let's consider the entry site of electrons into the complex and how they might influence proton transport. As mentioned above, Asp 51 (D51) appears to play a key role. It is shown in Figure 19.1.29 above and also in Figure 19.1.30 below. In the oxidized state, D51 interacts with two OH side chains (S205 and S441) and amide NH backbone groups but is not exposed to water. On reduction, D51 lies on the surface in an aqueous environment. Near D51 is Y440-S441. The backbone carbonyl group between 440 and 441 forms an "indirect" interaction with R38 (right panel in Figure 19.1.31), which we showed earlier is affected by the redox state of heme a. They are too far apart to form H bonds. Add two water molecules and envision a bridging interaction between the carbonyl O and the side chain R38 via Y371. Likewise in your mind add a water to allow a bridged hydrogen bond interaction between Y371 also forms a H bond and the heme a propionate.

Figure: Role of Amino Acids near D51 in Cytochrome C Oxidase

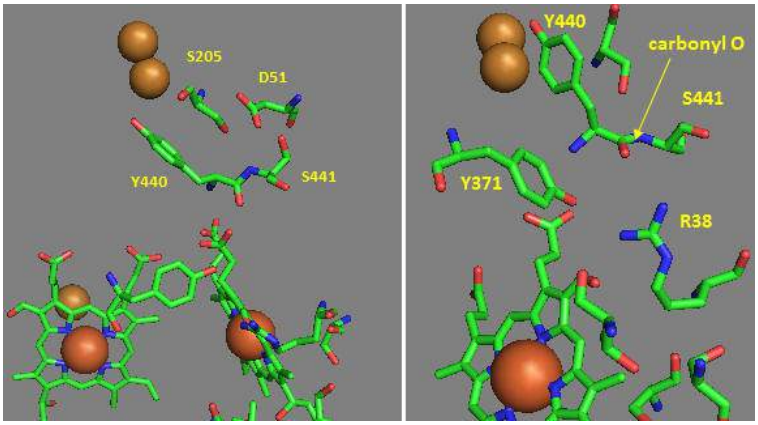

Figure 19.1.31: Local environment of D51, R38 in hemes in Complex IV

A more nuanced understanding of the mechanism and linkage between H^+ and e^- movement derives from high-resolution structures determined by Yano et al (2016). In their model (shown in the figures below based on the oxidized form of the protein, pdb 5b1a), protons from the negative (matrix) N side of the complex enter through a water channel and proceed to the positive (intermembrane side) through a H bond network (as described above and depicted below). These comprise the **H-Pathway** for H^+ transfer across the membrane. Two other H^+ transfer pathways, the **D- and K-pathways,** are used as a source of substrate H^+ for the 4 H^+s added to dioxygen to form $2H_2Os$.

Directional movement is mediated by proton:proton repulsion aided by an increase in + charge on heme a when it transfers an electron to heme a_3. Of course, proton:proton repulsion would move protons in both directions. Reverse flow back through the water channel is prevented by a conformational change on oxygen binding that closes the channel.

Ultimately 4 electrons are transferred from cytochrome Cs (in single electron steps) to the dicopper cluster, CuA, and then sequentially to heme a to heme a_3 (near the copper B ion) to dioxygen to form water. The motion of electrons and protons is coupled electrostatically.

Figure 19.1.32 gives an overview of these movements. The small red dots are the oxygen atoms of internal water molecules (the rest have been removed using Pymol). It should be apparent, given the number and location of the internal water molecules, that many would be involved in the proton translocation pathways.

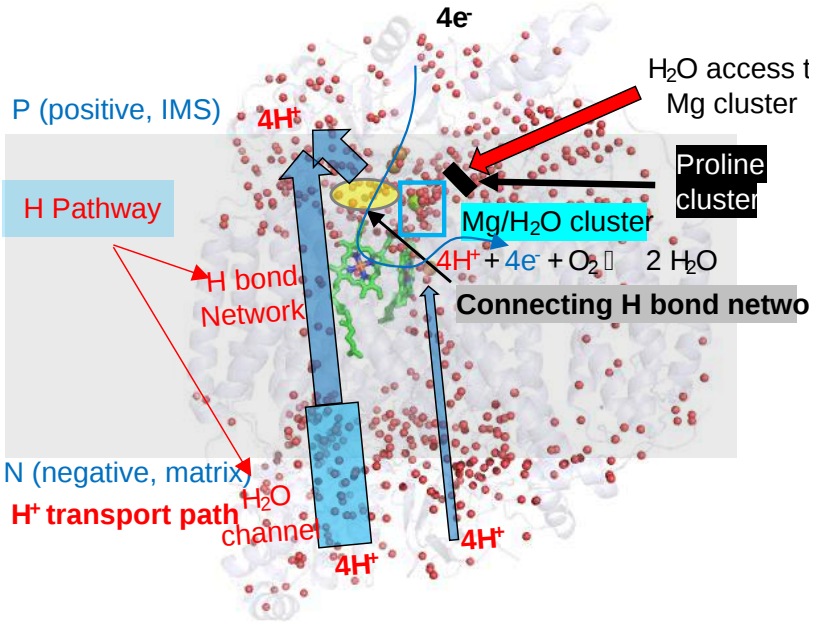

Figure 19.1.32 Cartoon showing movement of H^+s and e^-s in Complex II

What's so interesting about this model is the detailed description of two types of protons, the ones that add to dioxygen and end up in water (substrate protons), and those that are vectorially (directionally) transported to the IMS. In their model, the H^+s that end up being transported move through the water and H bond network through a connecting H bond link region to a Mg^{2+}/water cluster. Since the binding of oxygen leads to structural changes that close off the water channel, all protons to be transported to the IMS must be bound in the cluster before dioxygen binding.

Figure 19.1.33 shows that initially, 4 H^+s move through the H system to the Mg^{2+}/H_2O cluster. Oxygen binding then closes the water channels. This buildup of positive charges would certainly lead to enhanced electrostatic attractions for the next phase of the reaction, the movement of electrons into the heme cofactors. Additionally, the 4 H^+s in the cluster are probably prevented from leaking to the P side through waters that are proximal (see above figure) by a proline cluster, which presumably restricts the dynamical motion of the protein in that region necessary for proton movement. The figure does not show charge changes in the electron carriers.

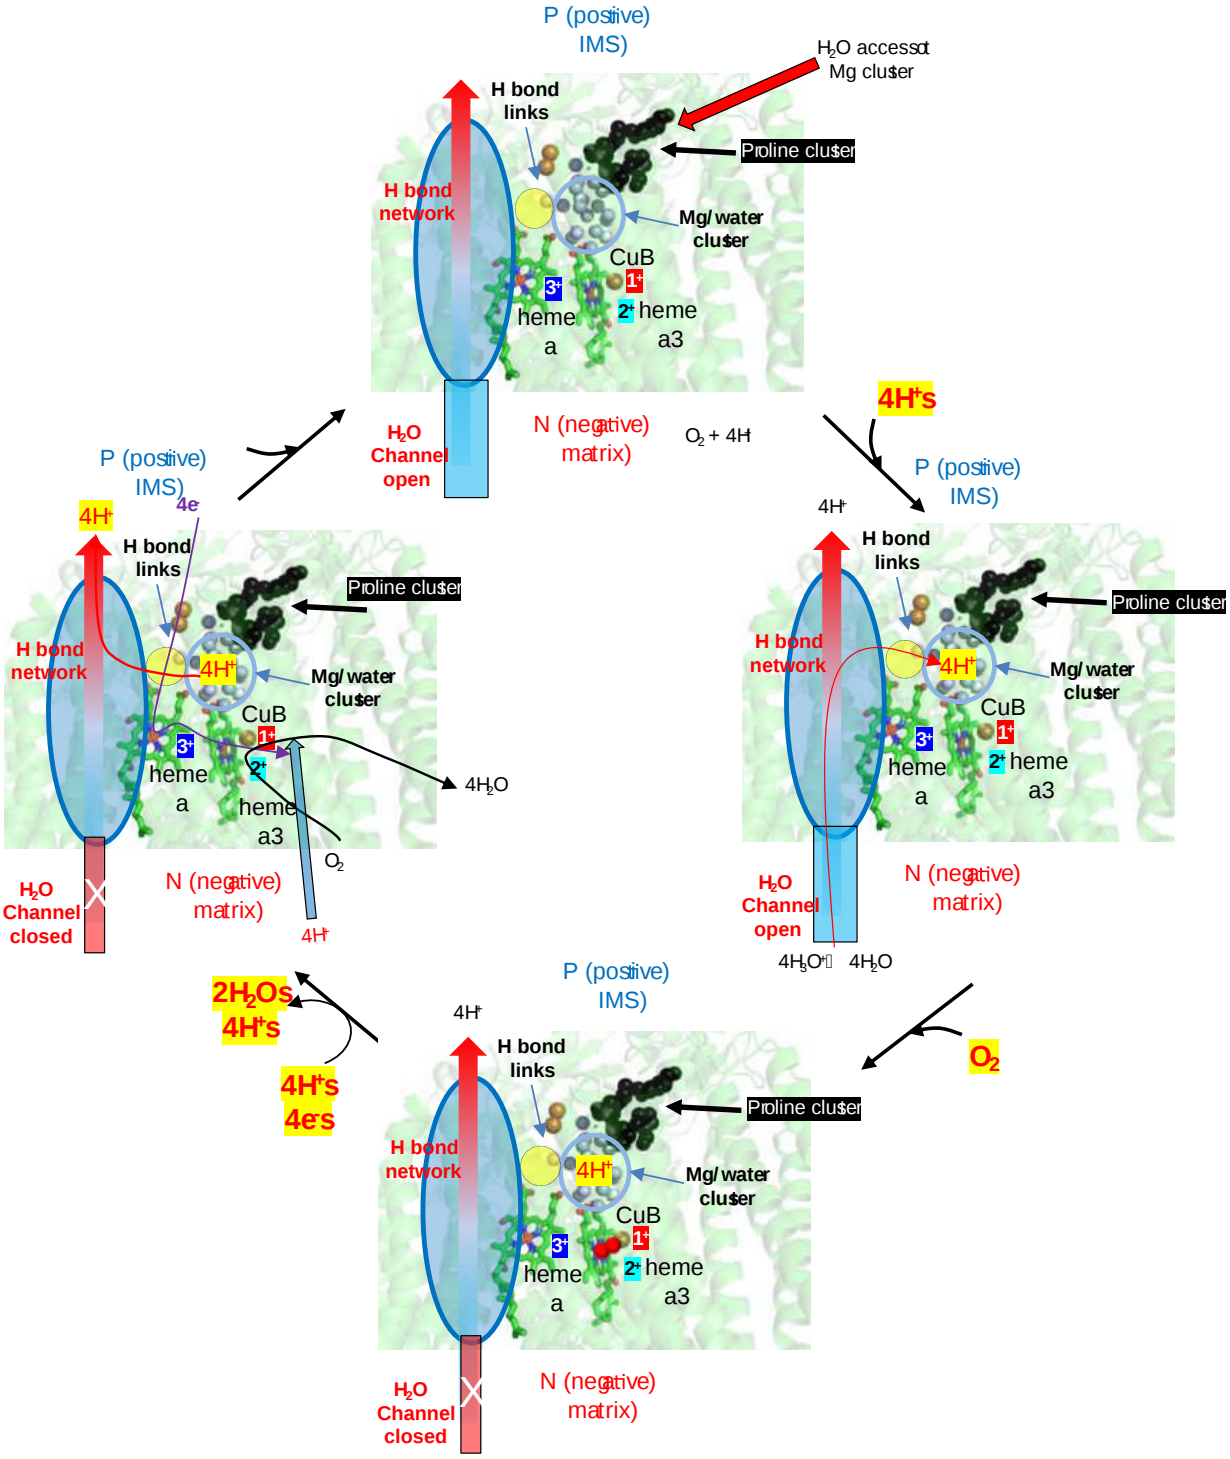

Figure 19.1.33: Proton movement in Complex IV

The figure below breaks downs the mechanism to show the addition of the first electron to the CuA (dicopper cluster), delivered from cytochrome C, and the subsequent transport of one proton from the fully proton-loaded Mg^{2+}/water cluster after dioxygen binding. This figure does show the stepwise redox changes in the electron carriers.

After CuA receives an electron from cytochrome C, it donates it to heme a and not to heme a_3, even though both are close. The extra negative on heme a facilitates proton pumping though the H pathways shown.

Figure 19.1.34s shows a cartoon description of the movement of protons and electrons through Complex IV.

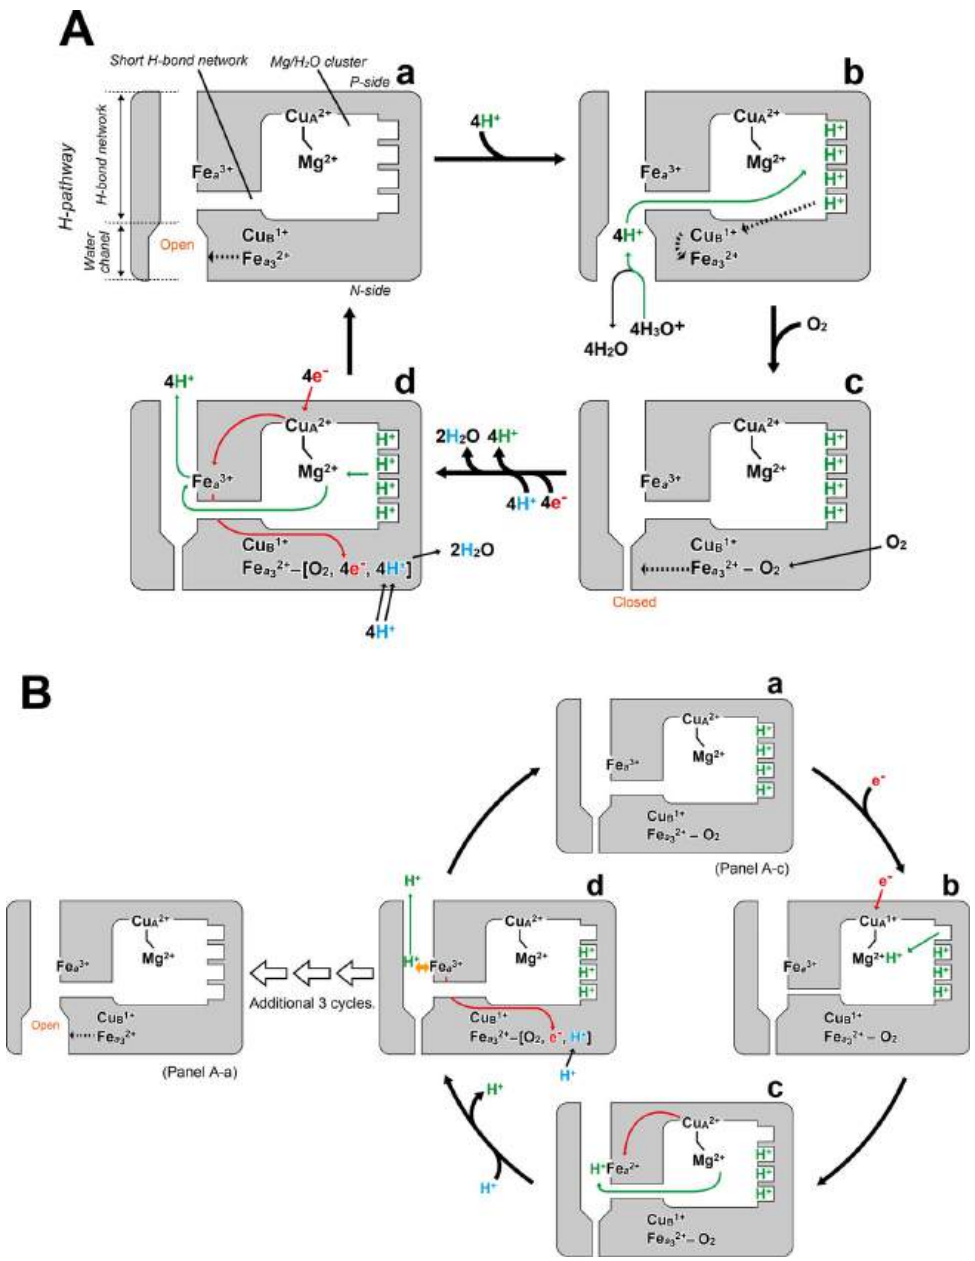

Figure 19.1.34: **A schematic representation of the role of the Mg/H_2O cluster in the proton-pumping mechanism of bovine heart CcO.** Yano N et al. J Biol Chem. 2016 Nov 11;291(46):23882-23894. doi: 10.1074/jbc.M115.711770. Epub 2016 Sep 7. PMID: 27605664; PMCID: PMC5104913. Creative Commons Attribution (CC BY 4.0)

The Mg/H_2O cluster and the H-pathway are connected with the short hydrogen bond network, as *labeled* in *A* (*a*). The location of heme a is shown by Fe_a^{3+} or Fe_a^{2+} attached to the hydrogen bond network of the H-pathway. The Cu_A site is on the water-accessible surface of the Mg/H_2O cluster. The conformation of the Cu_A-Mg^{2+} complex is shown by the *shape* of a *line* connecting the two metal ions. The proton-accepting sites are shown by the *four hollows* on the water-accessible surface of the Mg/H_2O cluster. The O_2 reduction site is shown by Cu_B^{1+} and Fe_{a3}^{2+}. The pumping and chemical (water-forming) protons are *labeled* in *green* and *blue*, respectively. Electron transfers are shown by *red curves*. *A*, overall catalytic cycle of CcO. *B*, a typical single electron transfer from Cu_A to the O_2 reduction site, coupled with the uptake and release of protons. For the sake of simplicity, the uptake of one chemical proton equivalent (the average number) is given in *B*. Various oxidation and ligand binding states in both Cu_B and Fe_{a3} in the intermediate states shown by *A* (*d*) and *B* (*d*) are not included for the sake of simplicity.

Figure 19.1.35 converts the schematic representation into a "structural cartoon" representation showing one cycle of coupled electron and proton transfer into Complex IV.

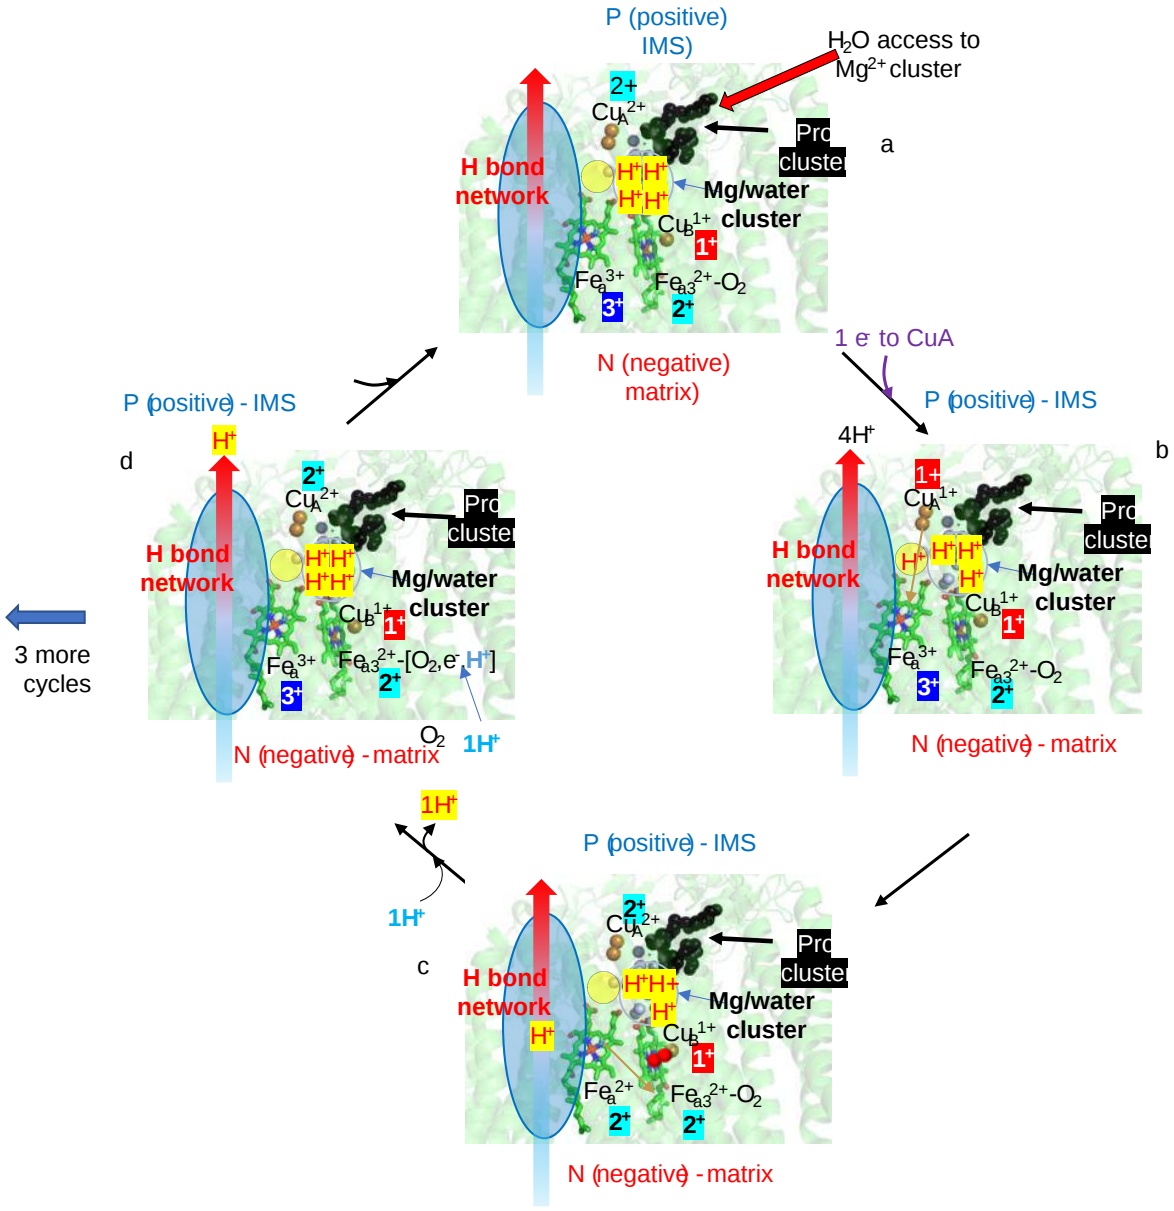

Figure 19.1.35: Structural cartoon representation showing one cycle of coupled electron and proton transfer into Complex IV.

The H- (for transport of $4H^+$s across the membrane) and the D- and K-pathways (sources of substrate $4H^+$s for water synthesis from O_2 are shown in Figure 19.1.36.

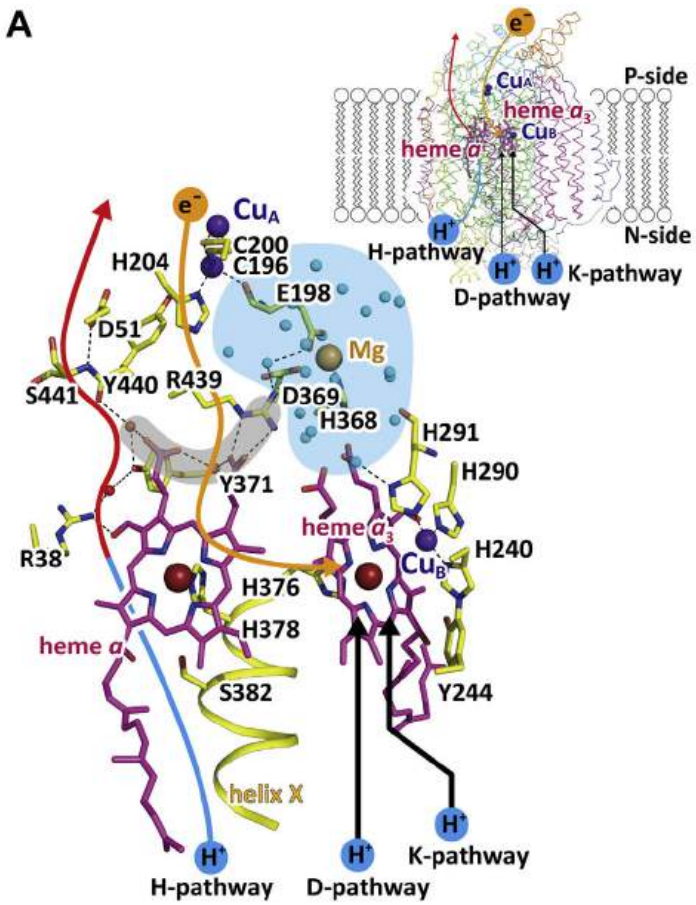

Figure 19.1.36: The H-, D- and K-pathways in bovine heart Complex IV (5B1A). Atsuhiro Shimada et al. J. Biol. Chem.(2021) 297(3) 100967. Creative Commons. https://creativecommons.org/licenses/by/4.0/

Two black arrows show the D- and K- for substrate H^+s that form water, while the blue arrow shows the H-pathway for the hydrogen bonding network of water in the water channel. The Mg/H_2O cluster (blue area) is attached to the hydrogen-bond network of the H-pathway by a short hydrogen-bond network (gray area with water shown as blue sphere). The formyl group and one of the propionate groups of heme a are hydrogen-bonded with Arg38 and a fixed water molecule in the hydrogen-bond network of the H-pathway. Compare this diagram to the ones presented in the figures above it. Again we show multiple representations to give readers many opportunities to conceptualize this complicated complex.

19.1.5: COMPLEX II - SUCCINATE:UBIQUINONE OXIDOREDUCTASE (SQR) - SUCCINATE DEHYDROGENASE

You've seen complex II before with another name, succinate dehydrogenase from step 6 of the citric acid cycle, which catalyzes the following reaction.

$$\text{succinate} + \text{FAD} \leftrightarrow \text{fumarate} + \text{FADH}_2 \quad \Delta G^o = 0 \text{ kcal/mol}$$

The ΔG^o for this reaction is about 0 kcal/mol so it is readily reversible.

However, something vital is left out of this description. The above reaction appears to suggest that the FAD/$FADH_2$ are readily diffusable and bind and unbind after catalysis. That's not true. Instead, FAD/$FADH_2$ are covalently attached to the enzyme so after one cycle of enzyme catalysis, the enzyme is dead. Another substrate/product pair must interact with enzymes to reconvert the covalently attached $FADH_2$ back to FAD so catalysis can continue. The other pair is ubiquinone (UQ/UQH_2). A better description of the reaction equation is shown in Figure 19.1.37. Complex II clearly links the tricarboxylic acid cycle to electron transport!

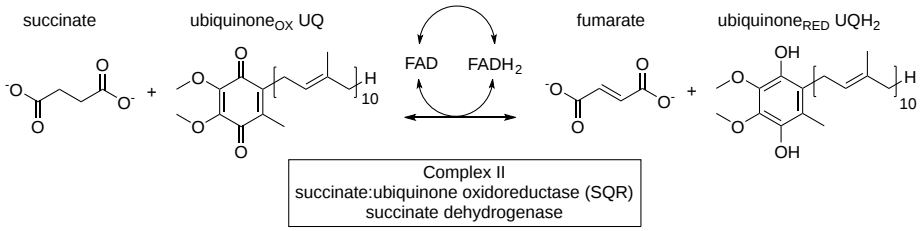

Figure 19.1.37: Complex II - Succinate Dehydrogenase Reaction

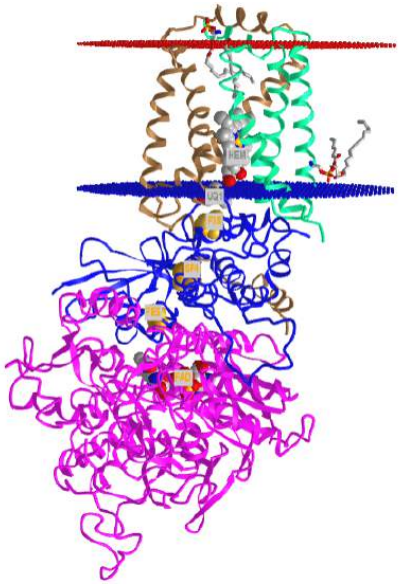
As with the other mitochondrial electron transport complexes, Complex II is a multisubunit integral membrane protein. The hydrophilic section protruding into the matrix contains two proteins, a flavin-binding protein (Fp) and an iron/sulfur protein (Ip). The transmembrane domain has two "cytochrome binding proteins", a lighter one (CybL) and a heavier one (CybS). The complex has binding sites for dicarboxylic acids (succinate/fumarate) and two binding sites for ubiquinone, a proximal higher affinity site (Qp) on the matrix side closer to the succinate binding site, and a distal lower affinity site (Qd) near. The ubiquinone sites bind 2-thenoyltrifluoroacetone (TTFA) which acts as an inhibitor of ubiquinone reduction. 3-nitropropionate - $(NO_2)(CH_2)_2CO_2^-$ is structural similar to succinate - $(CO_2^-)(CH_2)_2CO_2^-$ and is an inhibitor of succinate oxidation.

Figure 19.1.38 shows an interactive iCn3D model of the Mitochondrial Respiratory Complex II from porcine (pig) heart (1ZOY). The chains are:

- hydrophilic FAD-binding protein (lavender)
- hydrophilic FeS protein (blue)
- integral membrane large cytochrome binding protein (brown)
- integral membrane small cytochrome binding protein (green)



NCBI iCn3D Figure 19.1.38: Mitochondrial Respiratory Complex II from porcine heart (1ZOY) . (Copyright; author via source).
Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?KKPWG9dW1ARq3wQf9. (loads slowly given the size of the structure).

Given the role of the enzyme in both the mitochondrial citric acid and electron transfer pathways, you would expect high electron transfer rates between the dicarboxylic acid and the ubiquinone binding sites. Any disruptions in electron transfer (by inhibitors or mutations) could lead to the production of toxic reactive oxygen species (ROS). Binding an inhibitor to the proximal Qp site would lead to a buildup of $FADH_2$ which could transfer electrons in single-electron steps to dioxygen to produce ROS. This would occur if the dicarboxylic site were empty.

As there is no H^+ transfer from the matrix to the intermembrane space for Complex II, we'll only focus on electron transfer from succinate to FAD and on to ubiquinone.

The transfer of electrons from succinate to ubiquinone hence takes place in two steps.

Step 1: Succinate + FAD ↔ Fumarate + $FADH_2$. Figure 19.1.39 shows a plausible mechanism using a histidine in the active site as a general base. This is a simple hydride ($2e^-$) transfer reaction to FAD. Note that no FeS cofactors are required.

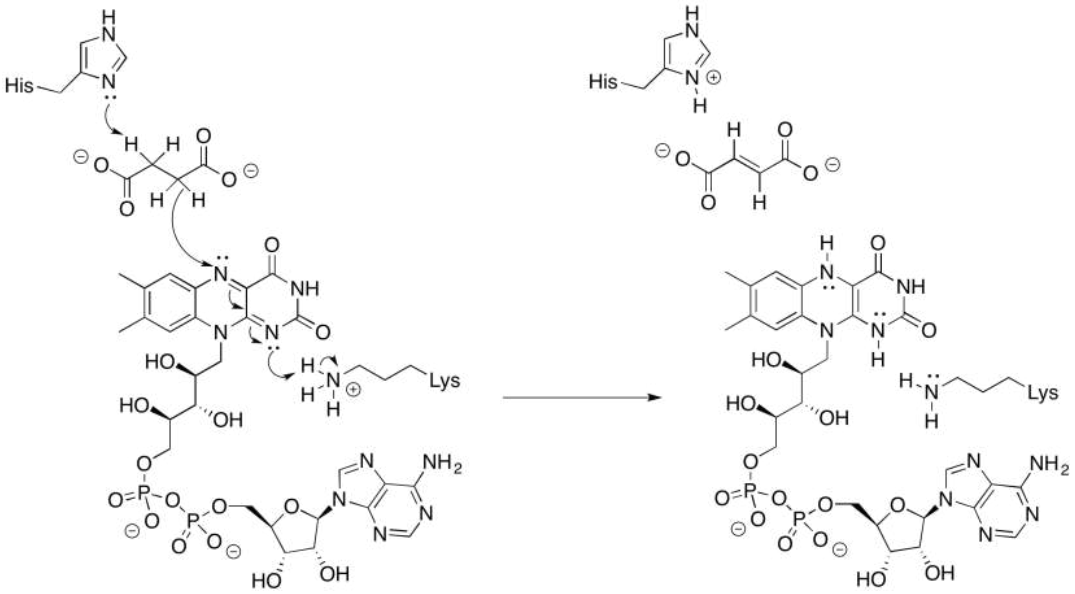


Figure 19.1.39: A mechanism for Succinate oxidation by FAD to Fumarate and $FADH^2$ (after Schaller, LibreText)

Step 2: $FADH_2$ + UQ ↔ FAD + UQH_2. This does not proceed by transfer of 2 e^- from $FADH_2$ directly to UQ. Rather it occurs through a series of the FeS cofactors (Fe_2S_2, Fe_4S_4, and Fe_3S_4 clusters) and heme. First, let's consider the path of electron transfer which will occur in single electron steps through the intermediary FeS clusters to ubiquinone as shown in Figure 19.1.40. The standard reduction potential E^0 is shown for each step. Note that FAD is shown instead of the actual electron donor, $FADH_2$, to correspond to the standard reduction E^0 values shown in tables.

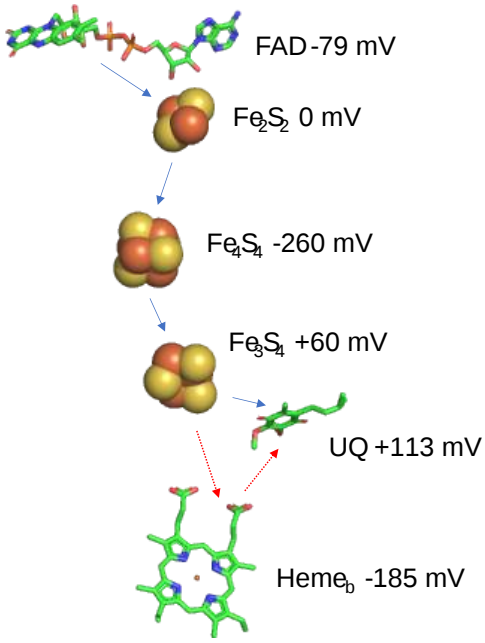

Figure 19.1.40: Pathway for electron transfer in Complex II

Electrons flow from $FADH_2$ (lowest, most negative E^0 value, -79 mV) to UQ (highest, most positive value E^0 value, +113 mV) or from weakest to strongest oxidizing agent. Electron transfer depends on distance as well. It appears that the transfer of electrons to heme $_b$ is not likely, given the presence of the closer UQ with the most positive E^0 value. Hence the function of heme $_b$ is unclear. However, if electrons are transferred to it, it would quickly and favorably send them on to UQ. Note that the FeS clusters have progressively more positive E^0 values except for Fe_4S_4 whose E^0 = -260 mV. Its E^0 is depressed by the presence of charged/polar groups which would make the transfer of a negative electron less likely. The net transfer standard potential is clearly favored thermodynamically. As the E^0 and corresponding G^0 values are state functions, the final ΔG^0 doesn't depend on the path. The high value of E^0 for Fe_4S_4 presents an activation energy barrier for transfer in both directions and probably prevents reverse electron transport in this complex.

The membrane domains have two polar (Asn, Ser) and 5 polar-charged (Asp, Glu, and Lys) side chains.

Now let's look at the terminal step in the transfer of electrons from Fe_3S_4 to ubiquinone. Figure 19.1.41 shows a plausible mechanism. Ubiquinone is shown in black. TTFA, which binds to the ubiquinone site and inhibits electron transfer, is shown in brackets. Tyrosine 91, Serine 41, and Histidine 216 are likely candidates for involvement in catalysis as shown below. Arginine 46 and aspartate 90 might be involved in the protonation steps of UQH_2.

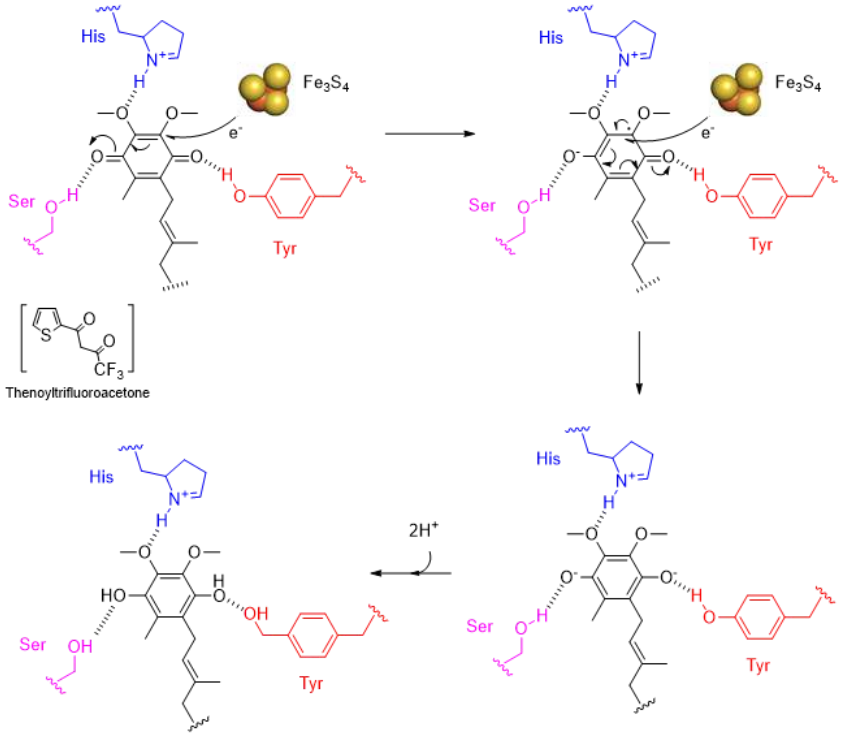

Figure 19.1.41: Terminal step in the transfer of electrons from Fe_3S_4 to ubiquinone

Figure 19.1.42 shows an interactive iCn3D model of the iCn3D TTFA1 binding site (where ubiquinone binds).

19.2: ATP SYNTHESIS

Search Fundamentals of Biochemistry

19.2.1: INTRODUCTION

ATP synthase, also called F_1F_oATPase, is a rotary motor enzyme. This enzyme is found in the inner membrane of mitochondria, the analogous thylakoid membranes of chloroplasts, and the cell membrane of bacteria. The enzyme consists of two parts, the membrane-bound F_o which is a proton translocator, and the F1 part which has catalytic (ATP synthesis or hydrolysis activity. The F_o part can be considered to be a rotary electrical motor powered by proton flow, while the F_1 part acts as a rotary chemical motor powered (in reverse) by ATP hydrolysis. The F_o part is named since it is sensitive to **o**ligomycin (note that it should theoretically be read as F_o and not F_{zero}). The F_1 part is named since it was eluted from a column chromatography column in **F**raction **1**.

The elucidation of its structure and mechanism by many but especially by Paul D. Boyer and John E. Walker, was a major feat of scientific study. They, along with Jen Skou, who studied the mechanism of the analogous Na/K ATPase, were awarded the Nobel prize for their work.

Let's start with the known structure of this complicated membrane-bound rotary enzyme and then work towards an understanding of how it works. The structure of the bovine F_1F_oATPase is shown in Figure 19.2.1 .

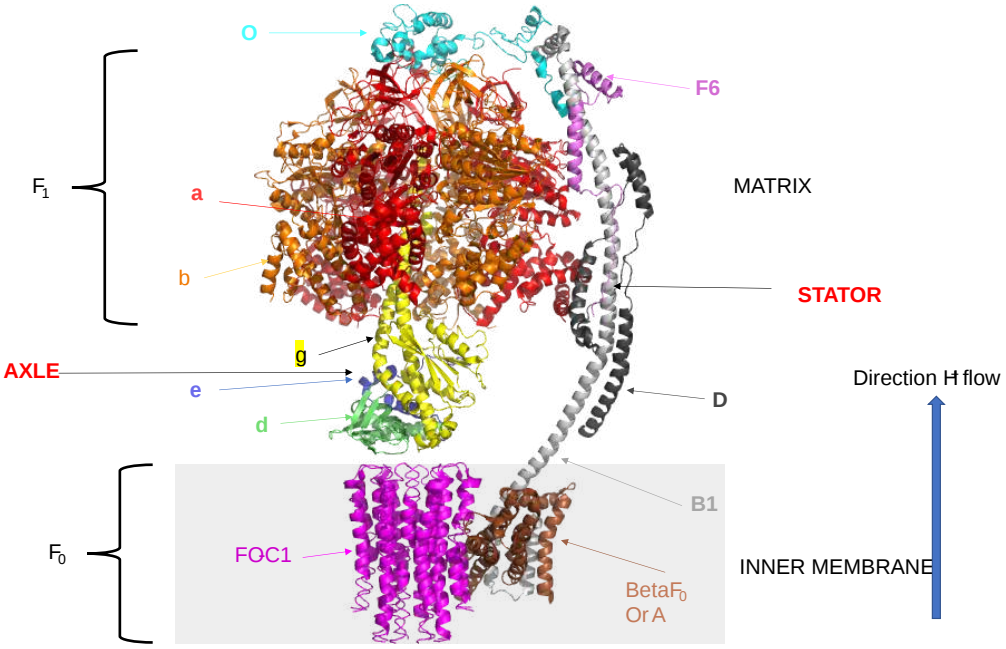

Figure 19.2.1 : Bovine F_1F_oATPase.

In the previous section, we discussed how oxidative electron transport in the mitochondria is accompanied by proton transport against a concentration gradient from the matrix through the inner member to the intermembrane space. The synthesis of ATP from ADP and P_1 is endergonic and requires an energy source. That energy source is provided by the thermodynamically favored collapse of the pH gradient across the mitochondrial inner membrane. Protons flow through the F_o membrane spanning C helices from the intermembrane space (not shown in Figure 1) to the matrix. This powers the synthesis of ATP from ADP and P_i by the F_1 part of the enzyme in the matrix lumen.

Figure 19.2.2 shows an interactive iCn3D model of the entire bovine mitochondrial ATP synthase (5ARA). The subunits are shown in the same color as Figure 1 above.

Figure 19.2.2: Bovine mitochondrial ATP synthase (5ARA). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...3YUBWrX91nnua9

The enzyme is reversible. If protons flow down a concentration gradient through F_o, ATP is synthesized by F_1. Alternatively, ATP hydrolysis by F_1 leads to the transport of protons through F_o and against a concentration gradient. Isolated F_1 can only break down ATP, and not synthesize it.

We called this structure a rotary enzyme, so what rotates? A rotary "axle" protein complex comprised of the γ, ε, and δ subunits (some also describe the γ, ε, and δ subunits as part of F_1) rotates. Its interactions with the multimeric complex of c alpha helices (shown in purple in the figures above) in the main F_o complex causes the "c-ring complex" complex in F_o to rotate as well. The F_1 part does not rotate because of the conformational stability of the β subunit and the connection to the long alpha helices of the D and B1 proteins, which comprise the "stator (the stationary) part of an electric motor", which keeps F_1 stationary.

Hence the enzyme does truly act like an electric motor, whose components are shown in Figure 19.2.3.

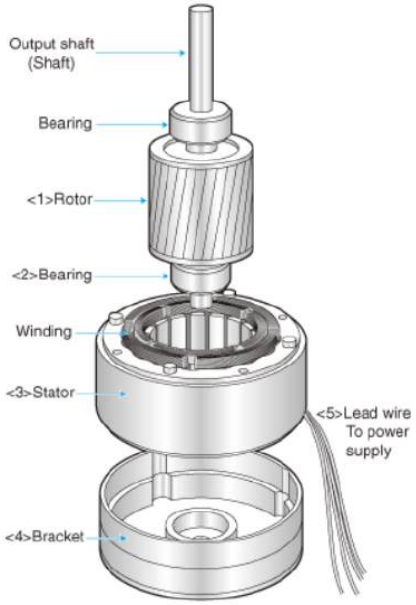

Figure 19.2.3: Electric motor with rotor, shaft, and stator. http://www.cdmmotor.com/en/article-22982-28485.html

Now let's look at the mechanisms and the evidence for them for each part of this remarkable enzyme.

19.2.2: F_1

The F_1 unit (with a quaternary structure of $a_3\beta_3$ forming a hexagonal ringed structure with a central cavity, occupied by a gamma subunit)is about 80 angstroms from the Fo subunit and both are connected to the rod-shaped γ subunit which spans the center of the $a_3\beta_3$ ring. Energy transduction (necessary to capture the negative free energy change associated with the collapse of the proton gradient to drive the positive free energy change for ATP synthesis) occurs between the two subunits.

Figure 19.2.4 shows a top view of the α (red) and β (green) subunits in the $a_3\beta_3$ F_1 complex

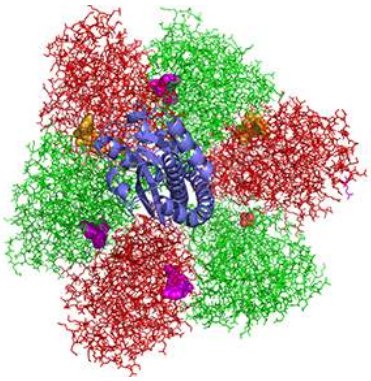

Figure 19.2.4: Top view of the α (red) and β (green) subunits in the $a_3\beta_3$

The γ subunit is shown coming out of the plane of the ring. ATP is shown in gold spheres, ADP in purple, and the smaller SO_4^{2-} (from a crystallizing agent) is shown in CPK spheres. They are sandwiched between the a and β subunits.

Boyer, in the absence of the complete structure of the F_1F_o ATP synthase, was able to deduce from experimental evidence that the $a_3\beta_3$ complex, which can be viewed as three aβ dimers (with catalysis occurring between subunits of individual dimers where ATP and ADP bind), have three different, interconvertible conformation defined as a Loose (L), Open (O) and Tight (T) states, with names describing the strength of substrate binding in each dimer.

- O - open state with very low affinity for substrates and has no catalytic activity;
- L - loose state with low affinity for substrates and also no catalytic activity;
- T - tight state with high affinity for substrates and with catalytic activity.

The three states rotate not physically with respect to some central axis but conformationally, depending on their interaction with the γ subunit which binds perpendicularly in the central junction of the $a_3\beta_3$ ring. Changes in the orientation of the central γ subunit due to its rotation with respect to the $a_3\beta_3$ ring cause the conformation of the O, L, and T states to change in situ with the orientation of the rotating γ subunit

The conversion of the LOT conformations, their binding of substrates (ADP and P_i), the conversion of bound ADP and P_i, and the release of the product (ATP) proposed by Boyer are shown in Figure 19.2.5.

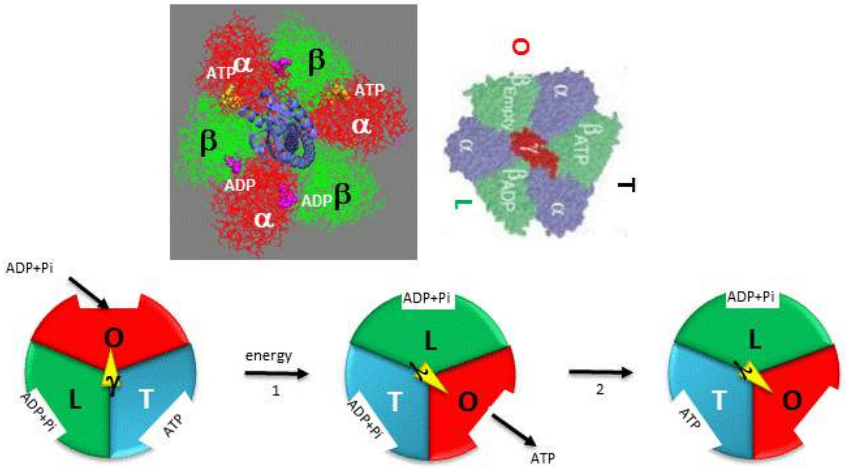

Figure 19.2.5: Boyer's three-state conformational model (L-O-T) for ATP synthesis

The collapse of the proton gradient (i.e. the proton-motive force) causes the γ subunit to rotate like a crankshaft relative to the F1 subunit, forcing the β subunit to change conformation from the T to the O (releasing ATP) and then to the L (binding ADP and Pi) states. The γ subunit does not appear to undergo any significant conformational change on ATP hydrolysis as evidenced by tritium exchange studies of amide protons.

To prove that the γ subunit rotates, you'd have to observe a single molecule. Since the γ subunit was too small to visually discern its rotation, Noji et al covalently attached a fluorescein-labeled actin filament to the γ subunit (near where F_o would bind). The whole F1 molecule was fixed to a glass slip through a His-tag such that the $a_3\beta_3$ ring was effectively immobilized. The γ subunit was free to rotate, which could be

detected by observing the fluorescence under a fluorescent microscope from the attached actin filament. This experiment and the outcomes are described in Figure 19.2.6.

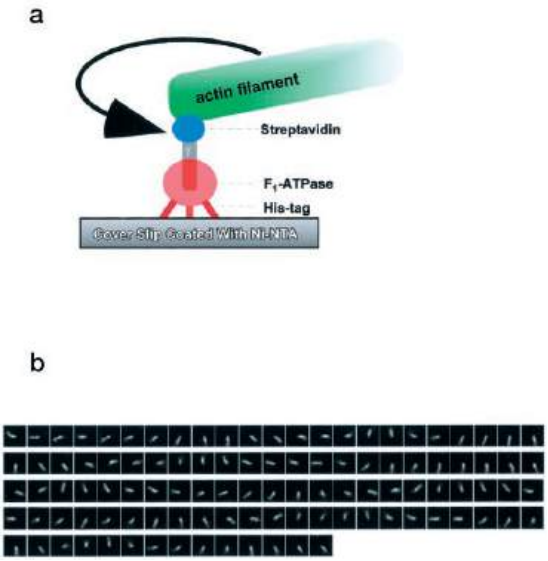

Figure 19.2.6: The direct observation of the γ rotation in the F_1 motor. Noji and Yoshida. JBC (2001) DOI:https://doi.org/10.1074/jbc.R000021200. Creative Commons Attribution (CC BY 4.0)

Panel **A** shows the experimental system for the observation of the γ rotation using an optical microscope. The F_1 motor tagged with 10 His residues at the N terminus of the β subunit was immobilized upside down on a coverslip coated with nickel-nitrilotriacetic acid (*Ni-NTA*). An actin filament (*green*) labeled with fluorescent dyes and biotins was attached to the biotinylated γ subunit (*gray*) through streptavidin (*blue*).

Panel **B** shows the rotary movement of an actin filament observed from the bottom, the membrane side, with an epifluorescent microscope. Length from the axis to tip, 2.6 μm; rotary rate, 0.5 revolutions per s; the time interval between images, 133 ms.

The actin filament rotated only in the presence of ATP. It rotated only counterclockwise, indicating that the motion was not random, but a specific motion of the γ subunit. At extremely low concentrations of ATP, rotation occurred only in 120^o increments, implying one step per molecule of ATP hydrolyzed. (Remember the β subunits are separated by 120^o). As the rotation occurs, there is viscous resistance to the movement of the actin filament. He calculated that for a single 120^o step caused by hydrolysis of a single ATP molecule, the amount of work was 80 piconewton which is about the free energy of hydrolysis of a single ATP molecule.

Later experiments in which a colloidal gold nanoparticle (40 nm diameter, with less frictional resistance to movement) was used instead of an actin filament showed the same result. At low [ATP], the motor rotates in 120^o steps. At high [ATP], the rotation rate becomes continuous and saturates (with Michaelis/Menten kinetics) at 130 revolutions per second.

Other experiments using immobilized ATPase and magnetic tweezers have addressed the timing of substrate binding and product release when the enzyme is run in reverse (ATP hydrolysis). On rotation of the γ subunit, the three binding sites change properties. In hydrolysis, ATP binds to the open site and helps promote the 120-degree rotation. In the next step, ATP is hydrolyzed. In the final step, products dissociate. Pi dissociation occurs last from the third site. Hence each of the 3 beta-binding sites has different roles. One binds the substrate, one performs catalysis and third releases products. Assuming the synthesis pathway is the reverse of the ATPase reaction, the final release of Pi in ATP cleavage predicts that Pi binds first in the synthetic direction. This would preclude the binding of ATP next which is critical since its concentration during synthesis can be 10x higher than that of ADP. As Pi is bound first, only ADP, not ATP can bind next.

The γ subunit rotation plays a "catalytic" role as its rotation induces cyclic conformational changes in the beta subunit of the synthase. Can ATP synthesis occur without the gamma subunit by a mechanism that involves a less proficient, but a concerted set of cyclic changes in beta subunit conformation? It can. Uchihashi et al have used high-speed atomic force microscopy (AFM) to study the $a_3\beta_3$ ring from the F1 subunit without the gamma subunit. They found that upon ATP hydrolysis, the beta subunits underwent conformational changes in the same counterclockwise rotary direction as when the gamma subunit was present. This is illustrated in Figure 19.2.7.

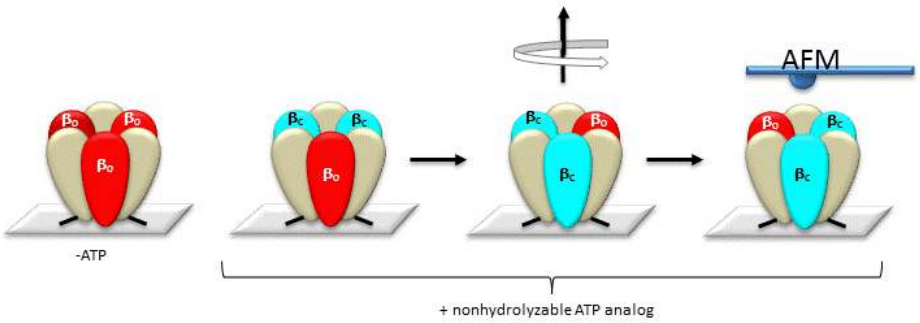

Figure 19.2.7: AFM Study of Conformational Changes in F1 "gammaless" subunit

These experiments conclusively show that the F1 subunit is effectively a rotary motor with the gamma subunit acting as a rotor in the stationary hexagon ring composed of the 3 pairs of alpha/beta subunits which acts as the stator (stationary part of an electric rotary motor).

The actual amino acids involved in the mechanism of ATP synthesis/hydrolysis are still not clearly defined but Glu 190 on the beta subunit acts as a general base. Figure 19.2.8 shows bound ADP and the proximity of Glu 188. Ala 158 is thought to move towards the active site after a conformational change, with the nonpolar methyl side chain displacing an adjacent water molecule which could leave as a product of ATP synthesis.

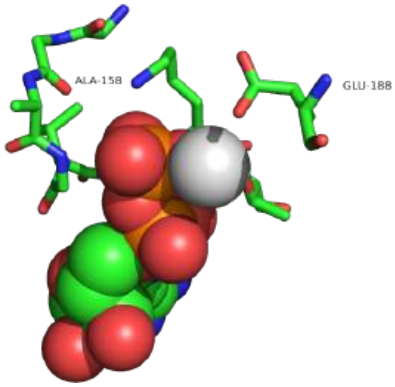

Figure 19.2.8: Active site residues for the synthesis of ATP. ADP is shown in spacefill, and CPK colors. Mg^{2+} is shown as a gray sphere (1E79).

19.2.3: F_O AND PROTON TRANSFER

The mechanism by which the proton gradient drives ATP synthesis involves a complex coupling of the F_o and F_1 subunits. Proton translocation occurs through the interface of the inner mitochondrial (or cell membrane of bacteria) membrane proteins C1 and A (or beta), whose structures from the bovine enzyme are shown again in Figure 19.2.8.

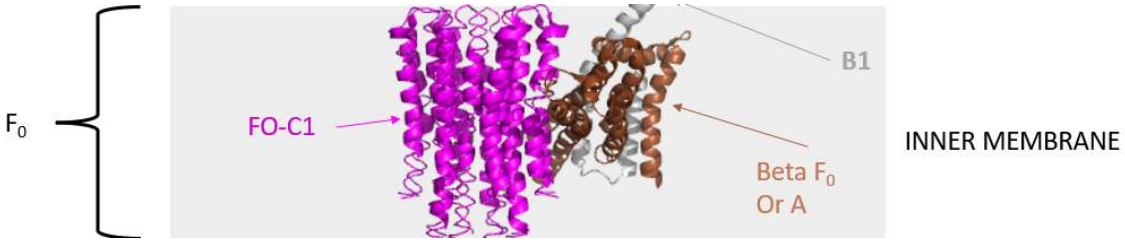

Figure 19.2.8: Inner membrane proteins C1 and A (or beta)

For protons to translocate through the membrane, there must be an aqueous channel on the matrix side and the lumenal side (bounded by the inner and outer mitochondrial membranes). So we have two understand two features:

- how the rotary axle part of the complex interacts with the C1 hexameric ring, causing the ring to rotate in the membrane.
- The nature of the water channels and the pathway for proton translocation.

The number of c monomers in the c-ring can vary between 8-17. For example, the bovine ATP synthase shown in Figures 1 and 2 has 8 c-monomers. Each has a critical proton donor and acceptor located near the a or beta-F_o chain. In the bovine case, it is glutamate 58. (The side chains in the bovine structure presented in Figure 2 do not show since they were not resolved in the cryoEM structure.) In E. Coli, which we will explore further below, it is aspartate 61. In yeast, it is at position 59. They are positioned near the center of the membrane helices. Mutations in these residues cause significant decreases in enzyme activity. An E56Q mutation in some bacilli species prevents proton pumping and ATP synthesis. Another key charged group, arginine, in the a or beta F_o protein is also key.

Figure 19.2.9 shows an interactive iCn3D model of the E. Coli A_1-C_{12} subcomplex of F_1F_O ATP Synthase (1C17).

Figure 19.2.9: E. Coli A_1-C_{12} Subcomplex OF F_1F_O ATP Synthase (1C17). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...sfRJBHEBiC5sy9

The key aspartate 61 (sticks and labeled) in each C ring subunit (red) and the proximity of two of the aspartate 61s to arginine 210 in the A subunit (brown) are evident.

Two classic inhibitors (structures shown below) of ATP synthase interact with the F_o subunit. One, oligomycin A, binds between the a and c subunits and blocks proton transport activity of the F_o subunit. The O protein at the top of the F_1 complex is also called the Oligomycin-sensitivity-conferring protein (OSCP), even though oligomycin does not bind there. The soluble F_1 by itself is not sensitive to oligomycin, but when it's linked to F_o in part through the O or OSCP peripheral stalk protein, it becomes sensitive to oligomycin.

Another inhibitor, dicyclohexylcarbodiimide reacts with a protonated Asp 61 in c subunits of F_o. It does so even at pH 8.0 which indicates that the pKa of the Asp 61 is much higher than usual. This might occur if the Asp is in a very hydrophobic environment. The modification of one Asp 61 in only one c subunit is necessary to stop Fo activity. The protonated carboxyl group donates a proton to a nitrogen atom in DCCD, which then reacts with the deprotonated Asp to form an O-acyl isourea derivative. Figure 19.2.10 shows the structures of oligomycin A and DCCD, inhibitors of proton transport by F_o.

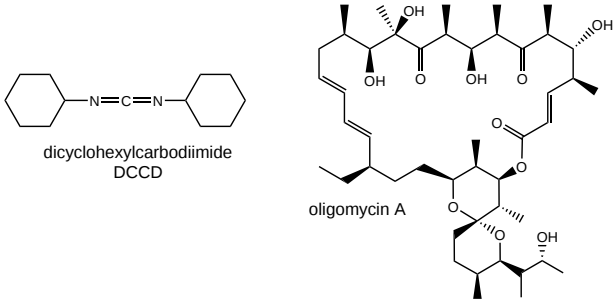

Figure 19.2.10: structures of oligomycin A and DCCD

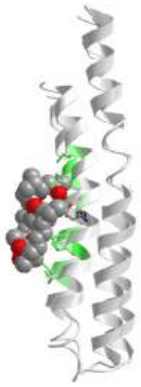
Figure 19.2.11 shows an interactive iCn3D model of the F_1F_oATPase c10 ring with bound oligomycin (4F4S)



NCBI iCn3D Figure 19.2.11: E. Coli A_1-C_{12} Subcomplex OF F_1F_O ATP Synthase (1C17). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...pJw1pFr8jTPmK8

Only two of the c-subunits are shown interacting with one oligomycin. The actual complex has 10 c-subunits and 8 oligomycins bound. The oligomycin is shown in spacefill with CPK colors. The two c-subunits are shown in gray. The side chains from the two c-subunits interacting with oligomycin are shown as CPK-colored sticks. They are conserved between humans and yeast. Note the single H bond between the critical Glu 59 and oligomycin. The green colors indicate hydrophobic parts of the c-subunits which interact with the mostly nonpolar parts of the antibiotic.

How do these key Asp or Glu side chains participate in proton translocation across the membrane and c-ring rotation and how do they access the matrix and lumenal water channels?

We can start to understand the answer to these question by examining the structure of the c-ring and its interaction with the a-chain from *Bacillus* PS3 ATP synthase, as shown in Figure 19.2.12, which show the key Glu59 residues in each of the c subunits of the 10-mer ring along with Arg 176 and two other glutamates (Glu 223 and Glu 162) in the A ring.

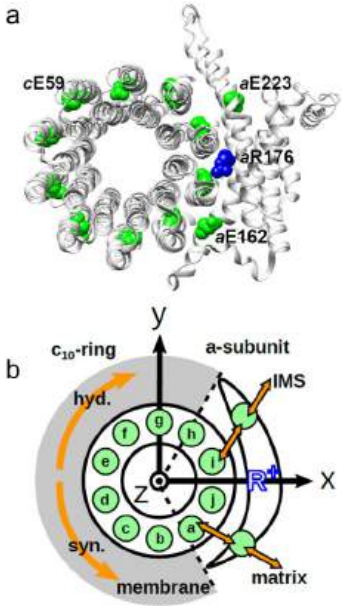


Figure 19.2.12: Schematic picture of the *a*-subunit and *c*-ring of F_o. Mitome et al. (2022). *eLife* **11**:e69096. https://doi.org/10.7554/eLife.69096. Creative Commons Attribution License

Panel (**a**) shows the ac_{10} part of the F_o region with the key amino acids shown as colored spheres (and numbered based on the yeast protein).

Panel (**b**) shows a cartoon of a simulation model developed by Mitome et al (ibid). The Glu 59s are shown as green circles and labeled a-j. The gray represents the membrane.

Protons move between the protonated Glu 59 in c subunits that are proximal to the deprotonated Glu 223 and Glu 162 in a hydrogen bond "handshake". The Glu 59s in the c chains in the 10-mer ring are likely to be protonated given their position in the center of the membrane, whereas the proximal Glu 223 and 162 are more likely to be initially deprotonated given their proximity to aqueous channels, where they

"hand off" their protons to complete the translocation from the intermembrane luminal space to the matrix. Now of course, once a c-ring Glu 59 is deprotonated, it has a negative charge.

Simulations suggest that there are 2-3 deprotonated Glu 59 with a negative charge proximal to the a-subunit. One is likely to take up a proton in a process leading to ATP synthesis. The orange arrows show the direction of proton flow. If the c-ring rotates in the clockwise direction, ATP is hydrolyzed while counter-clockwise rotation leads to ATP synthesis.

Now let's look at the water channel forming at the interface between the c-ring and a-subunit and an additional protein ASA6 from the unicellular green alga *Polytomella sp*. The interactions and nature of the water channels are shown in Figure 19.2.13.

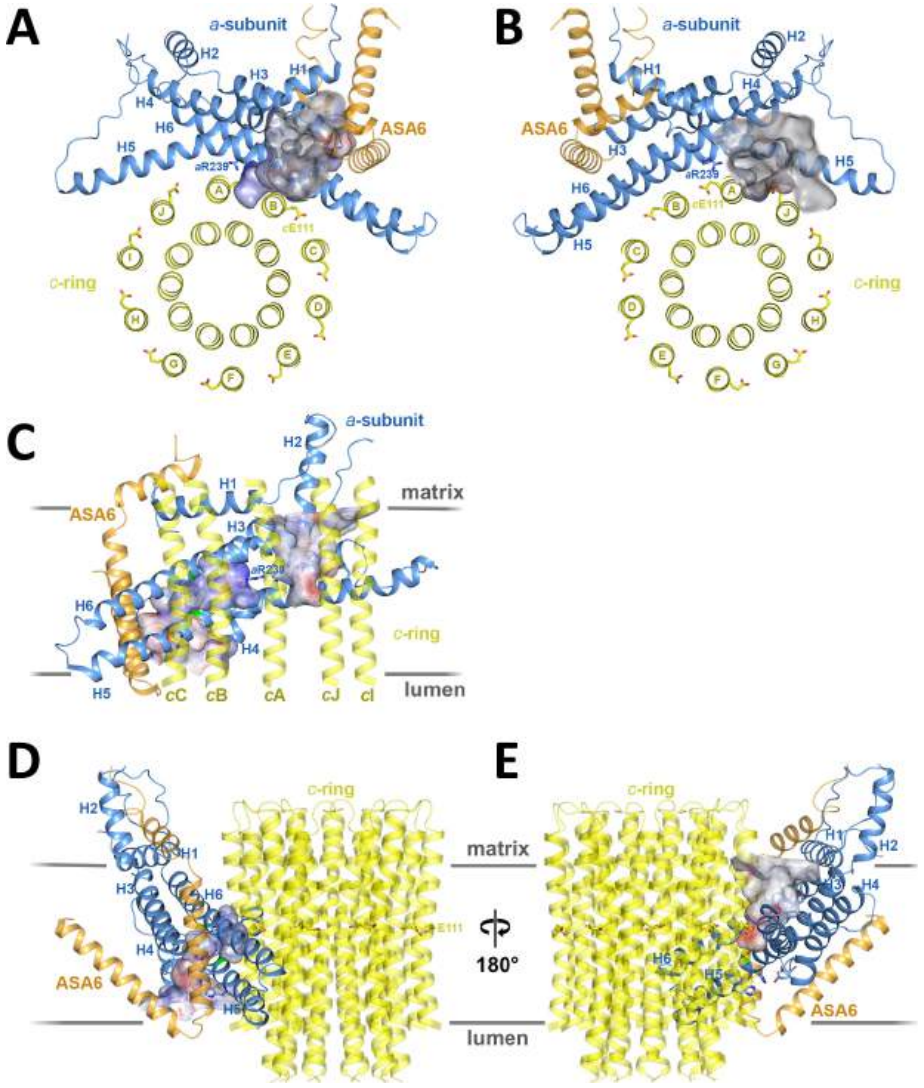

Figure 19.2.13: Two aqueous channels in F_o. Niklas Klusch, Bonnie J Murphy, Deryck J Mills, Özkan Yildiz, Werner Kühlbrandt (2017) Structural basis of proton translocation and force generation in mitochondrial ATP synthase eLife 6:e33274. https://doi.org/10.7554/eLife.33274. Creative Commons Attribution License

Subunit-a is shown in blue, the c_{10}-ring in yellow, and the associated ASA 6 protein in brick. The channels are shown as potential surfaces (red, negative; blue, positive; grey, neutral). (**A**) and (**B**) display a 5 Å slice of the c_{10}-ring at the level of the protonated *c*Glu111.

Panel(**A**) shows a 5 Å slice of the c_{10}-ring at the level of the protonated c-chain Glu111, with the lumenal channel seen from the crista lumen.

Panel (**B**) shows a 5 Å slice of the c_{10}-ring at the level of the protonated c-chain Glu111, with the matrix channel seen from the matrix.

Panel (**C**) shows a side view of both channels seen from the *c*-ring, with outer *c*-ring helices in transparent yellow. Lumenal channel, left; matrix channel, right. The strictly conserved a-chain Arg239 in helix 5 (H5) separates the lumenal and matrix channels.

Panel (**D**) shows that the lumenal channel passes through the H5/H6 hairpin at the small sidechains *a*Ala246, *a*Gly247 (H5), and *a*Ala292 (H6) (green).

Panel (**E**) shows H4, the N-terminal half of H5, and the connecting H4/H5 loop at the matrix channel.

Figure 19.2.14 a probable proton pathway through the F_o subcomple

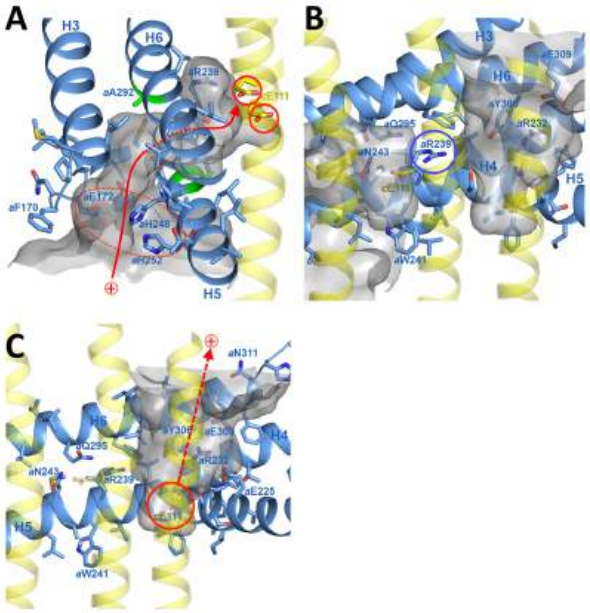

Figure 19.2.14: Proton pathway through the F_o subcomplex. Klusch et al, ibid.

The a-subunit is shown in blue, the adjacent *c*-ring helices in transparent yellow, and the aqueous channels in translucent grey.

Panel (**A**) shows the movement of protons (red arrow) in the lumenal channel. They likely move between Glu172, His248, His252, and Glu288 in the a-chain (dashed red ellipse) through the H5/H6 helix hairpin at the small sidechains of a-chain Ala246 and Gly247 (H5) and Ala292 (H6) (green) to c-chain Glu111 in the rotor ring *c*-subunits (red circles).

Panel (**B**) shows that a-chain Arg239 (blue circle) is located halfway between the lumenal channel on the left and the matrix channel on the right, forming a seal to prevent proton leakage. *c*-ring helices (transparent yellow) with *c*Glu111 are seen in the foreground.

Panel (**C**) shows the movement of protons (dashed red arrow) in the matrix channel as they pass directly from the deprotonated c-chain Glu111 to the pH 8 matrix.

A final summary view showing c-ring rotation powered by the collapse of the pH between the lumenal (intermembrane space) channel (pink) and matrix channel (light blue) is shown in Figure 19.2.15.

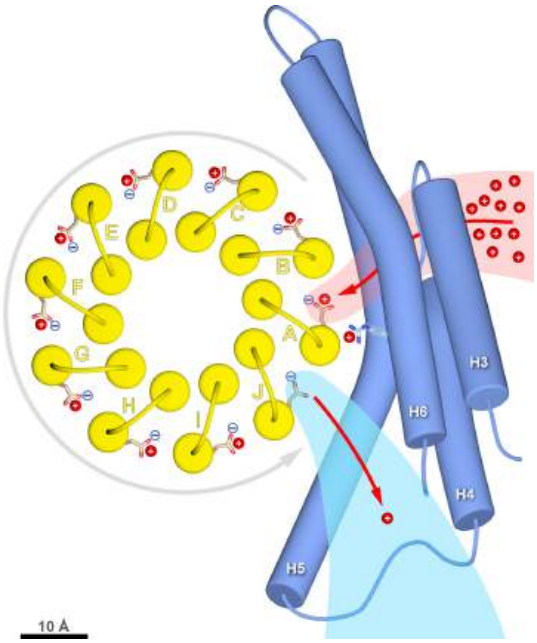

Figure 19.2.15: c-ring rotation is powered by the potential gradient between the lumenal channel (pink) and matrix channel (light blue). Klusch et al, ibid

The *c*-ring (yellow) and the membrane-intrinsic four-helix bundle of subunit *a* (blue) are drawn to scale as seen from the matrix. Protons (red) pass from the crista lumen below the projection plane through the lumenal channel between H5 and H6 to protonate Glu111 of *c*-subunit *A*, while subunit *J* is deprotonated by the higher pH of the matrix channel. The positively charged a-chain Arg239 is likely to interact with the deprotonated c-chain Glu111 during its short passage to the lumenal channel. The lumenal and matrix channels approach one another to within 5–7 Å. A protonmotive force of 200 mV between the closely spaced channels creates a local electrostatic field in the range of 40 million to 100 million V/m, depending on the protein dielectric. The field exerts a force on the deprotonated c-chain Glu111 that results in a net counter-clockwise rotation of the *c*-ring (grey arrow). Scale bar, 10 Å.

In summary, F_1F_oATP synthase is a rotary enzyme that ultimately couples the collapse of a proton gradient (a chemical potential gradient that contributes to the transmembrane electrical potential) to a chemical (phosphorylation) step. The rotor, which is in contact with both the F_o proton pore and the F_1 synthase, moves with respect to both subunits, which couples them. Both the axle and c-ring of F_o rotate. The interaction of the delta protein with the F_1 $a_3\beta_3$ hexamer does not cause $a_3\beta_3$ to physically rotate as a whole, as does the c-ring. Rather it causes a sequential rotation in the conformation of the three aβ dimers from the Loose to Open to Tight (LOT) conformations. The F_o pore can hence be considered an electrical motor and the F_1 synthase a chemical motor. Carrying the analogy of a motor even further, the F_o electrical motor turns the F_1 chemical motor into a generator, not of electricity but of ATP. The figure and link below, taken from the Protein Data Bank, go into more depth about this nanomotor.

The concerted movement of the c-ring and axle protein with respect to the not physically rotating $a_3\beta_3$ F_1 part can be seen in Figure 19.2.16, which is derived from cryoEM structure of different rotated states of bovine ATP synthase.

This amazing enzyme can be purified and reconstituted in a lipid vesicle along with bacteriorhodopsin. If these proteins are oriented in the correct fashion, light can cause proton translocation into the lumen of the vesicle creating a transmembrane potential. The proton gradient can collapse as protons move from the lumen through the F_o part of F_1F_o ATP synthase, causing ATP synthesis from ADP and Pi in the outside solution. This is shown in Figure 19.2.18.

19.2.4: PROTON GRADIENT COLLAPSE AND ATP SYNTHESIS - THERMODYNAMICS

Mathematical analyses show that the free energy change on proton gradient collapse can easily power the endergonic synthesis of ATP. Consider a typical pH gradient (-1.4 pH units) across the inner membrane of respiring mitochondria (with the outside having a lower pH than the inside making the inside more depleted in protons). There is a chemical potential difference in protons across the membrane. However, another factor determines the thermodynamic driving force for proton translocation across the membrane. A transmembrane potential exists across the inner membrane of the mitochondria, as it does across most membranes. The source of the membrane potential will be discussed in the signal transduction chapter (Chapter 28). The inside is more negative than the outside, giving the membrane a transmembrane electrical potential. of about -0.14 V. Clearly, protons would be attracted to the other side of the membrane (into the matrix) by this potential difference, which then augments the chemical potential difference as well. A simple mathematical derivation shows that indeed, a proton gradient can supply enough energy for ATP synthesis, especially when coupled to a transmembrane electrical potential. We reshow a small image of the complex and its activities in Figure 19.2.19 to help you through this section

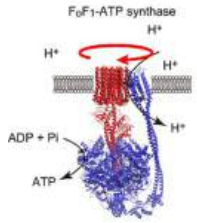

Figure 19.2.19: ATP synthase and its activities. Noji, H., Ueno, H. & Kobayashi, R. Correlation between the numbers of rotation steps in the ATPase and proton-conducting domains of F- and V-ATPases. *Biophys Rev* **12,** 303–307 (2020). https://doi.org/10.1007/s12551-020-00668-7. Chemical Potential (use G instead of μ)

Since most students use free energy and not chemical potential (which is just free energy /mole at constant T and P, we will derive these equations using free energy G.

Let's consider the free energy of the protons on the outside (low pH, higher concentration) and in the inside (matrix, higher pH, low concentration):

$$\mathrm{H^+}_{\mathrm{out}} \longrightarrow \mathrm{H^+}_{\mathrm{in}}\ \mathrm{G} = \mu = \text{ chemical potential (kcal/mol)} \tag{19.2.1}$$

Now express this as the change in free energy, ΔG

$$\Delta G_{\mathrm{chem}} = G_{\mathrm{in}} - G_{\mathrm{out}} = G^0 + RT \ln \left[H^+\right]_{\mathrm{in}} - \left(G^0 + RT \ln \left[H^+\right]_{\mathrm{out}}\right) \tag{19.2.2}$$

This can be rewritten as:

$$\Delta G_{\mathrm{ohem}} = \mathrm{RT} \ln \frac{[H^+]_{\mathrm{in}}}{[H^+]_{\mathrm{out}}} = 2.303RT \left[-\log \left[H^+\right]_{\mathrm{out}} - \left(-\log \left[H^+\right]_{\mathrm{in}}\right)\right] \tag{19.2.3}$$

Hence

$$\Delta \mathrm{G}_{\mathrm{chem}} = 2.303 \mathrm{RT}\left(\mathrm{pH}_{\mathrm{out}} - \mathrm{pH}_{\mathrm{in}}\right) = 2.303 \mathrm{RT} \Delta \mathrm{pH} \tag{19.2.4}$$

In respiring mitochondria, ΔpH = -1.4, so

$$\Delta \mathrm{G}_{\mathrm{chem}} = 2.303 \mathrm{RT} \Delta \mathrm{pH} = 2.303 (1.99 \mathrm{cal/mol \cdot K})(298\ \mathrm{K})(-1.4) = -1.91 \mathrm{kcal/mol H^+} \tag{19.2.5}$$

Electrical Potential

Consider the relationship between ΔG and the transmembrane electrical potential

$$\Delta G_{\mathrm{elect}} = +ZF\Delta\psi \tag{19.2.6}$$

where Δψ is the transmembrane potential, Z=+1 (charge on a proton) and F is the Faraday constant

This equation is similar to

$$\Delta G \text{ elect } = -nF\Delta E \tag{19.2.7}$$

where ΔE is the cell potential or EMF. If ΔE is + and Δψ is -, then ΔG is -.

In respiring mitochondria, Δψ = -0.140 V (remember that 1 V = 1 J/C). Hence

$$\Delta G_{\text{elect}} = +ZF\Delta\Psi = 1(96.485\text{C/mol})(-0.140\text{ J/C}) \times (1\text{cal}/4.18\text{ J}) = -3.23\text{kcal/molH}^{+} \tag{19.2.8}$$

Electrochemical potential

Now let's add the equations to get the full driving force, the electrochemical potential:

$$\Delta G_{\text{tot}} = 2.303\text{RT}\Delta\text{pH} + \text{ZF}\Delta\psi = -5.15\text{kcal/molH}^{+} \tag{19.2.9}$$

This gives

$$\frac{\Delta G_{\text{tot}}}{F} = \frac{2.303RT\Delta pH + +zF\Delta\psi}{F} \tag{19.2.10}$$

Hence

$$\Delta p = \Delta\psi + \frac{2.303RT\Delta pH}{F} = \Delta\psi + 0.059\Delta pH = 0.224\text{ V} \tag{19.2.11}$$

where Δp is the protonmotive force.

19.3: REGULATION OF OXIDATIVE PHOSPHORYLATION

19.3.1: INTRODUCTION

The main function of oxidative phosphorylation (oxphos) is to produce, under aerobic conditions, lots of ATP. It should make sense that to a first approximation, the regulation of oxphos depends primarily on the energy state of the cell, which is reflected by the ADP/ATP ratio. In contrast to glycolysis and the citric acid cycle, which produce NADH, the primary and first electron carrier in oxphos, the regulation does not depend on the binding of allosteric effectors to key enzymes in the pathway. Likewise, hormonal regulation is not involved. Perhaps this occurs since the oxphos pathway is downstream from the glycolytic and citric acid pathways, where allosteric and hormonal regulation robustly affects their outputs.

If you consider the primary reactants in electron transport to be NADH, $FADH_2$, O_2, ADP, and P_i and if you assume that O_2 levels are constant, ADP appears to be the main molecule that determines the rate of the oxphos reactions. This is in accordance with what we have previously described: AMP, ADP, and ATP levels regulate many of the key enzymes in the glycolytic and citric acid pathways, as reviewed in Figure 19.3.1.

Coordinate regulation of ATP production:

Regulation by:

- [ATP]
- [ADP]- the "PO_4" acceptor
- Mass action ratio, [ATP]/[ADP][P

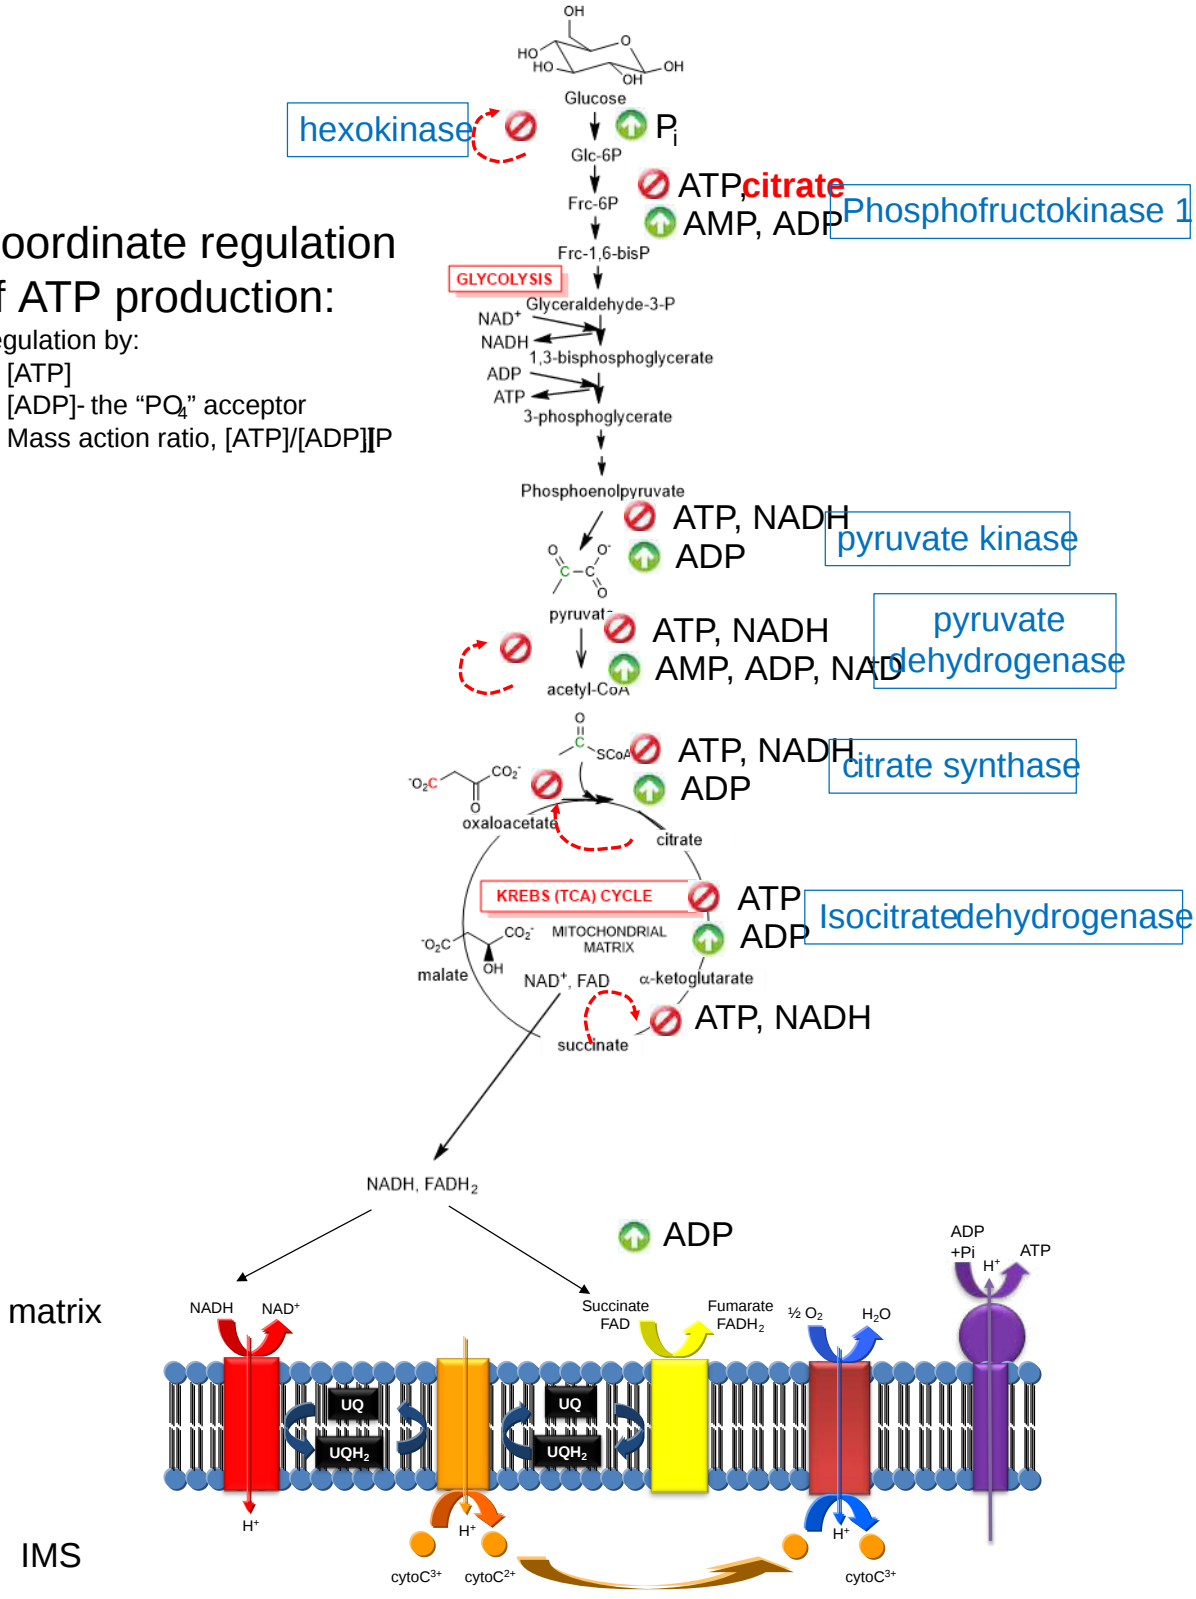

Figure 19.3.1: Regulation of glycolysis, the citric acid cycle, and oxphos by ATP, ADP, and AMP.

Overall there are several levels of oxphos regulation, which occurs at the level of the kinetics of the electron transport chain complexes, the efficiency of electron and proton transfer, the structure of the mitochondria, and mitochondria formation and their degradation.

19.3.2: COUPLING AND UNCOUPLING OF ELECTRON AND PROTON TRANSPORT

What is key is that the regulation of oxidation (electron transport) is coupled to the regulation of ATP synthesis (phosphorylation). These processes can also be uncoupled if electrons "leak" away from their transfer from NADH to O_2, which leads to the production of harmful reactive oxygen species (ROS) such as superoxide. Proton can also "leak" away from the proton gradient if they bypass the ATP synthase complex and pass through the inner membrane with the help of specific carriers and protein uncouplers, as shown in Figure 19.3.2.

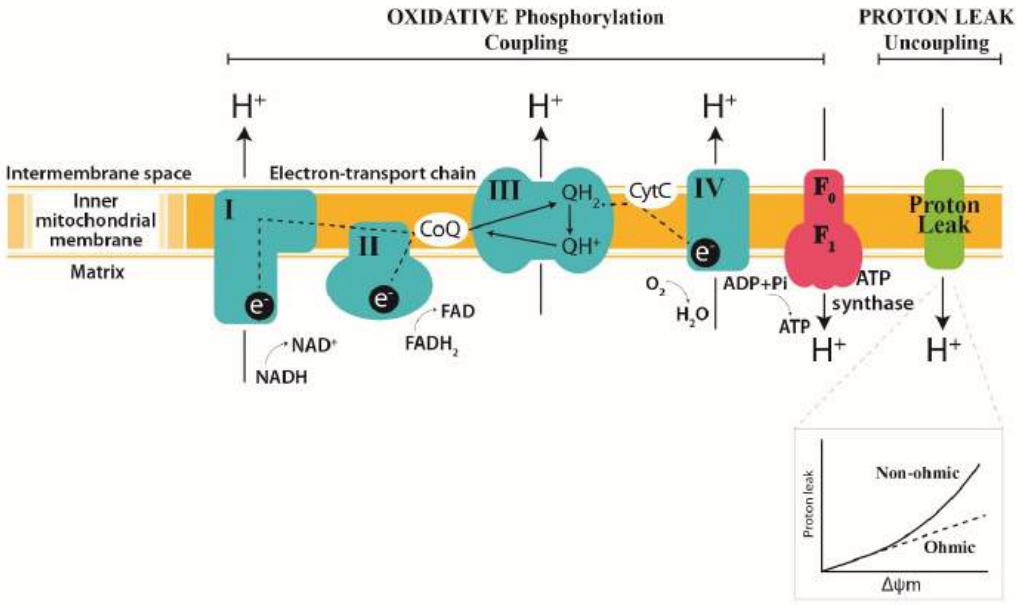

Figure 19.3.2: Coupling and uncoupling of oxidative phosphorylation. Eyenga, P.; Rey, B.; Eyenga, L.; Sheu, S.-S. Regulation of Oxidative Phosphorylation of Liver Mitochondria in Sepsis. *Cells* **2022**, *11*, 1598. https://doi.org/10.3390/cells11101598. **Creative Commons Attribution License**

The far right light green proton and the insert show the proton leak's kinetics. The dotted line indicates the electron pathways.

There are two types of proton leaks:

- a basal leak through mitochondrial anion carriers in a non-regulated and minor process.
- an inducible leak through specific proteins, adenine nucleotide translocase (ANT), and uncoupling proteins (UCPs), which leads to loss of energy as heat. They can be activated by fatty acids as well as ROS. A particular UCP, UCP1, is found most abundantly in brown fat in mammals.

The basal leak occurs in the presence of inhibitors of ANT (carboxyatractylate) and UCP1 (GDP). It can be significant (about 25% of the resting metabolic rate of liver cells and up to 50% in respiring skeletal muscle cells). It is less understood than inducible leaks and does appear to be attributed to ANT in some fashion.

When oligomycin, which inhibits the collapse of the proton gradient through ATP synthase, is added to mitochondria, the proton gradient (protonmotive force, Δp) decreases. The rate of leakage increases exponentially with increasing Δp, so it represents **non-Ohmic leakage**. Ohmic leakage would give a linear dependence on Δp. This can be seen from a rearrangement of Ohm's Law (V=IR) to give I = V/R = conductance(V), where V is voltage, I is the current (analogous to the leak), R is resistance and 1/R is conductance. The exponentially increasing non-Ohmic leakage (usually measured by O_2 uptake in the presence of oligomycin) shown in the inserted graph in Figure 2, is not associated with non-specific membrane damage.

A particular uncoupling membrane protein, UCP1, is especially prevalent in hibernators, small mammals, and human infants, which allows them to stay warm. The UCP family is activated by fatty acids, which may act as required cofactors for the protein or as antagonists of the inhibition of UCPs by nucleotide diphosphates.

Two methods are used to determine the efficiency of coupling of oxidation and phosphorylation.

- One is to determine the ADP/O ratio as both are substrates for oxphos, where O represents the amount of O_2 consumed in the conversion of a defined amount of ADP to ATP when ADP is at high levels (which might not be physiologically relevant). This would give the maximum phosphorylation rate (defined as state 3).

- A second is to measure ATP (or ADP)/O ratio directly through methods that give spectrophotometric signals such as the production of NADH by a coupled hexokinase/glucose-6-phosphate dehydrogenase assay in which ATP is used in the following reactions to make NADH, as shown in Figure 19.3.3.

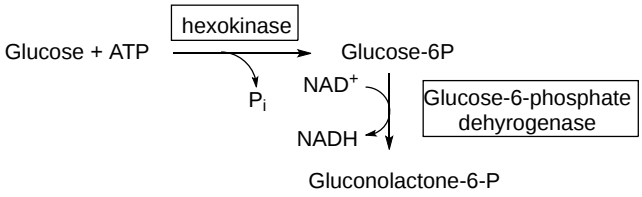

Figure 19.3.3: Generation of NADH on the combined reaction of hexokinase and glucose-6-phosphate dehydrogenase.

In this coupled assay, one ATP used produces one NADH, which absorbs at 340 nm. Also, the ATP used as a substrate in the coupled reaction has left the mitochondria for it to have access to hexokinase, so the internal ratios of ADP/ATP in the respiring mitochondria are unchanged during the time course of the reaction. This method also allows the measurement to be made under nonsaturating ADP concentrations.

Uncoupling of electron transport and ATP synthesis can occur through a combination of mechanisms, including proton loss at ANT and UCPs, at the complexes in electron transport that transport electrons and protons, and through ATP synthase itself.

Other mechanisms would include substrate depletion or effects on the **mitochondrial permeability transition pore (mPTP)**, which is an inner membrane transmembrane protein, which is gated open by increases in matrix Ca^{2+}, adenine nucleotide decreases and increases in Pi. It is also a voltage-gated channel. When open the mitochondrial membrane depolarizes, ATP is depleted and cell death can be triggered. We'll discuss this complex later.

Figure 19.3.4 shows the chemistry used to analyze the efficiency of oxphos and their graphical results.

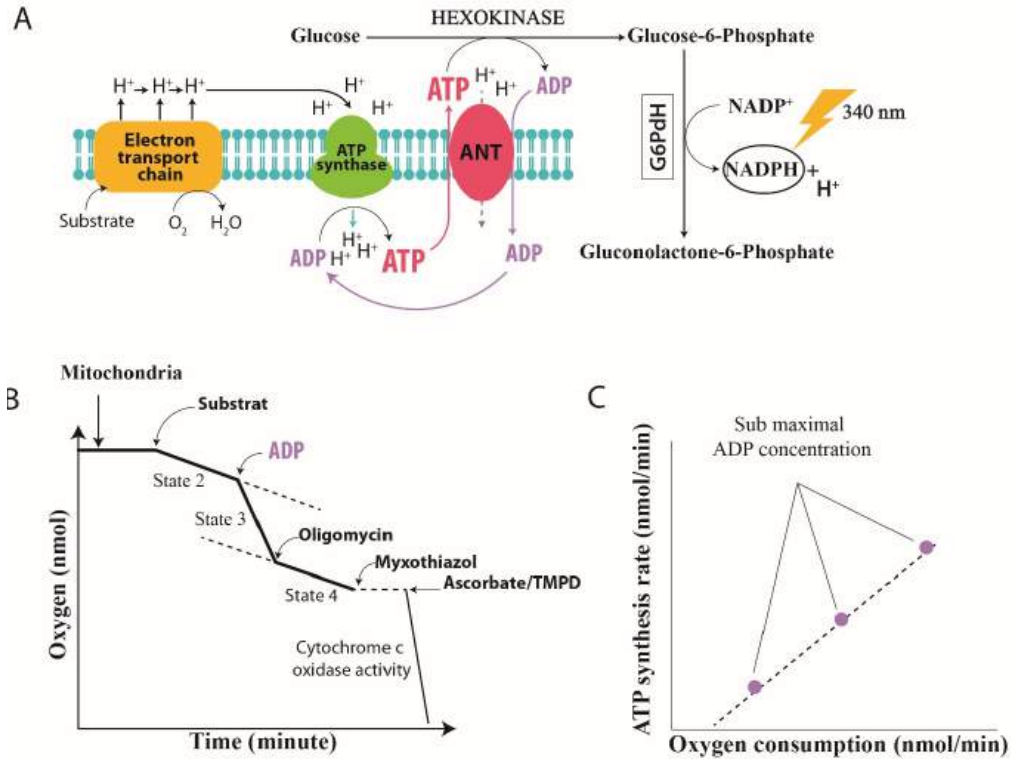

Figure 19.3.4: Measurement of coupling efficiency in respiring mitochondria. Eyenga et al. Ibid.

Panel (**A**) shows the chemistry involved in the determination of the ATP/O ratio to measure coupling efficiency. Note that this step allows the regeneration of ADP and efficiency can be measured at any ADP concentration.

Panel (**B**) shows changes in O_2 with time. The respiration rate is given by the slope of the curve. Until substrate is added, O_2 levels are constant. On the addition of substrate, O_2 is consumed in electron transport so levels O_2 levels fall linearly. When ADP is added, the rate of O_2 consumption increases which is reflected in a steady linear decline in O_2 levels. This state which is at fixed ADP levels (as illustrated in Panel (A)), is called state 3 (maximum ATP synthesis at a given ADP level). When oligomycin, an inhibitor of proton flow across ATP

synthase which inhibits ATP synthesis (and ADP use) is added, state 4 ensues with shows decreased O_2 consumption when ATP synthesis is stopped. Note the parallel lines for stages 2 and 4. The Cytochrome c oxidase activity at the end of the curve is the maximal respiration with ascorbate (as an oxidizing agent) and N,N,N′N′-tetra methyl-p-phenylenediamine (TMPD) as a substrate.

Panel (**C**) shows a graph of the rate of ATP synthesis vs the rate of O_2 consumption. The slope gives the rate of ATP generation to that of O_2 consumption (ie. the ATP/O ratio). Note that the graph is linear:O is linear over a range of fixed, non-saturating ADP concentrations.

19.3.3: CHANGES IN PROTON GRADIENT FROM "SLIPPAGE"

Slippage in the electron transport chains: Redox Slipping

Proton translocation from the matrix to the inner membrane space is an integral part of the function and activity of the electron transport chains that establish the pH gradient and hence the Δp. These components are Complexes I, III, and IV. Complex IV (cytochrome C oxidase - CCO) appears to be especially important. Protons are removed by CCO from the matrix on the reduction of O_2 to H_2O. This requires exactly 4 electrons and 4 protons so the stoichiometry is fixed. Also, CCO moves protons into the inner membrane space in the formation of the pH gradient. This is where the electron-to-proton ratio may vary depending on redox and coupling conditions. Alterations in CCO or even decreases in its concentration would impact the movement of protons as well. Instead of calling these alterations in nominal proton translocation leakages, they are called slippage since an ordinary function of CCO is proton translocation. Slippages through CCO would decrease proton transport and decrease ATP/O. Reactive nitrogen species (NO and peroxynitrite) can also decrease ATP/O.

Slippage at ATP synthase

Proton leakage at ATP synthase would also result in a decreased ATP/O ratio. This occurs especially if nucleotides are low or if the holoenzyme is compromised by low subunit availability. ATP synthase forms dimers and other multimers to form supercomplexes, and this affects (or is determined by) the formation of invaginations in the inner membrane which form cristae.

Given that the multimeric c-ring of F_0 effectively moves protons across the inner membrane, it is a likely source of slippage. It most likely occurs through a modified version of the F_0 ATP synthase unit called the **ATP synthase c-subunit leak channel (ACLC).** This is different from the mitochondrial permeability transition pore (mPTP) mentioned above. Alternatively, it may be that the ACLC might be part of the leak channel of the mitochondrial permeability transition (MPT) pore discussed above. Studies show that the c-ring can form large conductance channels that are voltage-gated without regulatory subunits. In addition, added F_1 subunit inhibits it. In neurons stimulated by the excitatory neurotransmitter glutamate, F_1 dissociates from the F_1F_0 complex, allowing the c-ring to slip protons through the membrane. Finally knockdown of the c-subunit eliminates high conductance. Hence the c-ring is part of a type of mPT that is regulated by cyclophilin D (CypD), which is a mitochondrial peptidyl-prolyl cis-trans isomerase, that regulates the mitochondrial permeability transition pore (PTP).

In vitro, c-rings incorporated into vesicles form a large voltage-gated channel that is inactivated by the addition of F_1. Also in neurons stimulated with the excitatory neurotransmitter glutamate, which leads to increases in cytoplasmic Ca^{2+}, binding and ensuring conformational changes in the complex leads to dissociation of F_1 from the complex, freeing F_0 for proton "slippage" and transport uncoupled from ATP synthesis.

A Proposed “bent-pull-twist” model of ACLC gating in physiological and pathological conditions is shown in Figure 19.3.5.

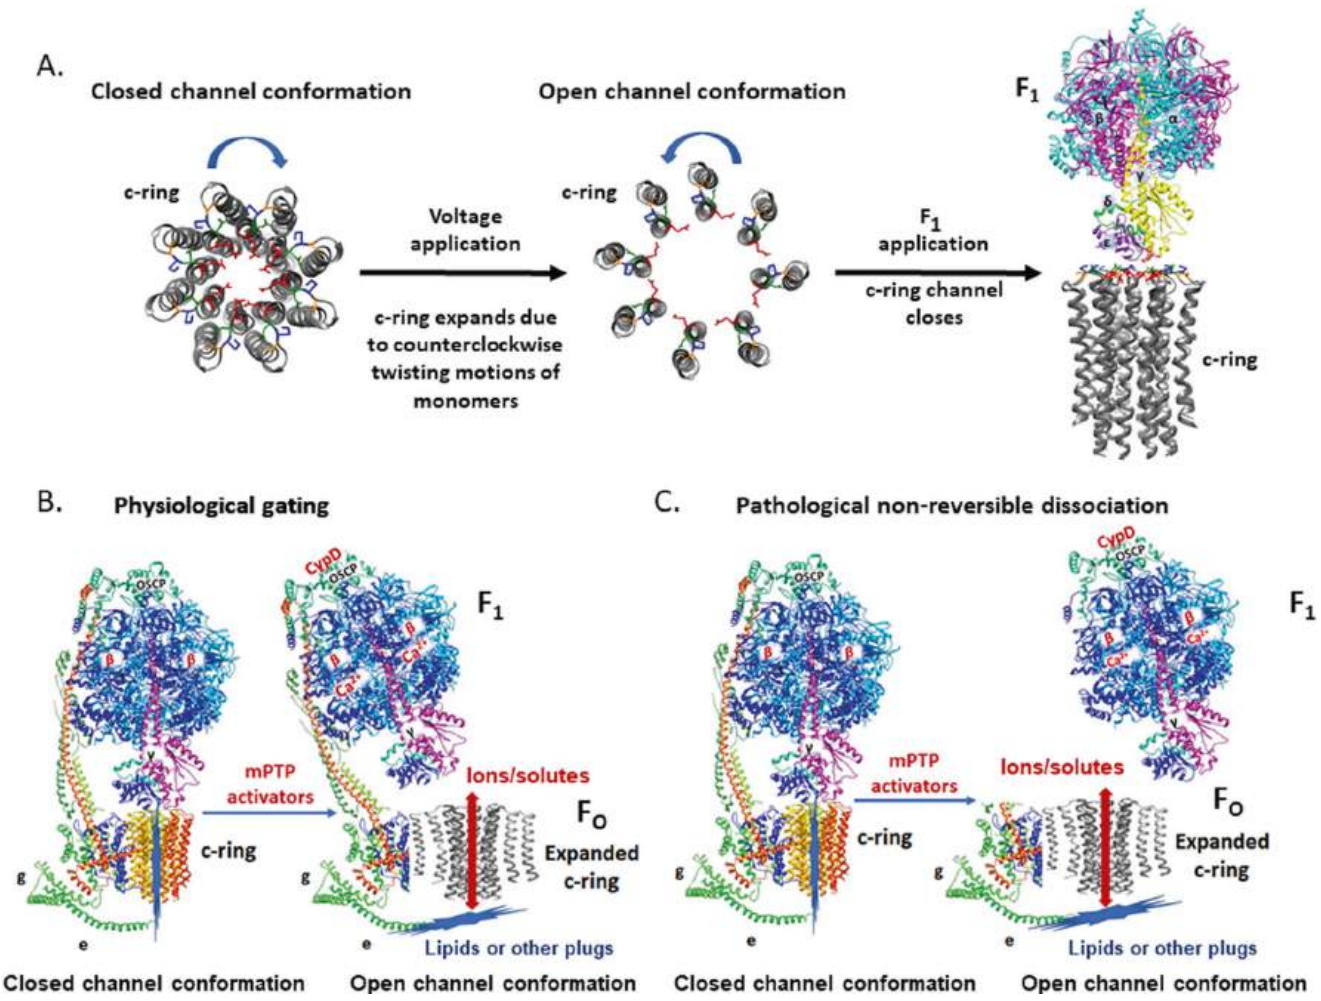

Figure 19.3.5: B**ent-pull-twist model of ACLC gating in physiological and pathological conditions.** Mnatsakanyan, N., Park, HA., Wu, J. *et al.* Mitochondrial ATP synthase c-subunit leak channel triggers cell death upon loss of its F_1 subcomplex. *Cell Death Differ* (2022). https://doi.org/10.1038/s41418-022-00972-7. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

Panel A shows c-ring diameter changes during the electrophysiology recordings, upon the application of voltage and F_1. F_1 added during c-ring recordings probably inactivates the channel due to the specific interactions between F_1 and c-ring that induce twisting motions in c-subunit monomers in a clockwise direction, to stabilize the ring, reduce the pore diameter and close the channel.

Panel B shows reversible brief openings of ACLC in physiological conditions.

Panel C shows that non-reversible dissociation of F_1 from F_O occurs during long-lasting openings of the c-ring channel in severe pathology. For simplicity, only ATP synthase monomer is shown. ATP synthase subunits are drawn as ribbon representations (modified PDB ID code: 6J5I) [14]. In **B** and **C**, red arrows indicate the path of ion flow through the channel. Closed and open conformations of the channel are noted.

19.3.4: A CLOSER LOOK AT UNCOUPLER PROTEIN 1 (UCP1)

UCP1 is an inner membrane protein in the mitochondria that bypasses the movement of protons through the c-ring of F_1. UCP1 is activated by fatty acids and inhibited by purine nucleotides. The mechanism of proton translocation is unclear. It could arise from a "handshake" of protons through a series of linked hydrogen bond donors and acceptors in the membrane protons. Evidence suggests that what moves are bound and protonated fatty acids which flip across the inner membrane where the carboxyl group deprotonates in the high pH matrix side of the membrane.

The role of UCP1 in this process could be to flip the deprotonated fatty acid back across the membrane. This model is called the protonophoretic model in which the fatty acid acts as a "protonophore" much like valinomycin, which transports K^+ across the membrane and is called an ionophore. UCP1 doesn't interact with the H^+ directly but just flips the deprotonated fatty acid back to continue the cycle. This model would give a stoichiometry of one flipped negatively charged fatty acid per proton transferred.

In the second "H^+-shuttling" model, UCP1 is considered a fatty acid/H^+ symporter (carries both species in the same direction). In this model, a fatty acid is strongly bound to UCP1 with the head group inside a cavity in the protein. Both models required UCP1 to carry deprotonated fatty acids back across the membrane.

The NMR structure of a similar protein, UCP2, is known. It can bind fatty acids with the acyl tail near the matrix side. However, UCP2 does not seem to be involved in thermogenesis and doesn't uncouple oxphos. It binds and catalyzes the exchange of malate, oxaloacetate, and aspartate for phosphate and H and hence has other metabolic roles. UCP 1 and 2 are about 60% homologous but have similar alpha-helical structures based on modeling.

Perturbation of NMR signals from assigned side chains was used to show the fatty acids bind to UCP1 and it's closer to the matrix than the inner membrane space. Two key lysines (K56 on helix 1 and K269 at the matrix side of helix 6) probably bind with the carboxylate end of the fatty acid. UCP1also has a hydrophobic grove (T31, F32, L34, D35, L278, G279, S280, W281, and V283) to accommodate the fatty acid. In addition, both UCP1 and UCP2 transport/flip alkyl sulfonates, analogs of fatty acids. This is consistent and required with both models.

Figure 19.3.6 shows an interactive iCn3D model of the predicted AlphaFold model of human UCP1 (P25874). The subunits are shown in the same color as Figure 1 above.

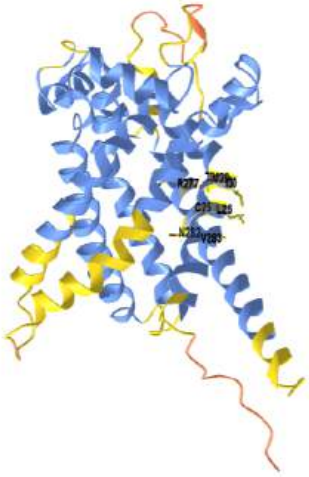

Figure 19.3.6: Predicted AlphaFold model of human UCP1 (P25874). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...Qf8W1MgVH6u546

The blue colors represent assigned structures with the highest predicted confidence, and the red the lowest. The amino acid side chains that are implicated in binding to fatty acids based on perturbation of NMR signals on fatty acid binding (http://dx.doi.org/10.1016/j.str.2017.07.005) are shown in sticks, with CPK colors and labeled. The membrane would be positioned perpendicular to the average vertical orientation of the helices in the above orientation.

19.3.5: ADDITIONAL CONTROLS

From the perspective of moving electrons into the electron transport pathway, the key deliverers of electrons are NADH derived from integrated multiple pathways at Complex I (as illustrated in Figure 1) and $FADH_2$ from the citric acid cycle at Complex II. Hence if intermediates in the citric acid cycle are low, the flux through electron transport is compromised. Flux through Complex I seems to determine the rate-limiting steps for oxygen use.

In the previous chapter section, we calculated the total chemical potential driving force across the membrane. A pH difference of 1.4 across the membrane provides a -1.9 kcal/mol (-8 kJ/mol) H^+ chemical potential compared to the -3.23 kcal/mol (13.5 kJ/mol) from the transmembrane potential, $\Delta\psi_m$. Both contribute to the thermodynamically favorable movement of H^+ across the inner membrane in respiring mitochondria, but $\Delta\psi_m$ is a large contributor. Hence $\Delta\psi_m$ and ATP synthesis are also coupled with maximal synthesis occurring between -100 to -150 mV. At values around -200 mV, give rise to increased permeability for protons (which decreases Δp) but also the production of superoxide and peroxides. Hence $\Delta\psi_m$ is also regulated.

ADP levels control ATP synthesis as well, with higher concentrations leading to increased ATP synthesis and a decrease in Δp. Decreased ATP synthesis from increased Δp affects coupling, slippage in cytochrome C oxidase, and heat generation.

Reduction of O_2 to water by stepwise addition of electrons involves the generation of superoxide, O_2^-. As shown in an earlier section, superoxide formed by Complex I would move to the matrix, while those formed by Complex III to both sides of the membrane. Hydrogen peroxide can also form from monoamine oxidase and α-ketoglutarate dehydrogenase, which produces increased peroxides with increasing

NADH concentrations. Respiratory state 4 (when proton transport is blocked by oligomycin) leads to higher levels of ROS. Hence ROS levels are also determined by not only the respiratory state but also Δp.

Other control mechanisms are potentially derived from other protein subunits that bind to the complex within a lipid bilayer. These include A6L, DAPIT (diabetes-associated protein in insulin-sensitive tissues), and the proteolipid 6.8PL. Another is the ATPase inhibitory factor 1 (IF1), which turns out to be a significant regulator. When the $\Delta\psi_m$ falls too low, IF1 inhibits ATP depletion which leads to ATP hydrolysis by the complex to move protons from the matrix to the inner membrane space. The interaction of IF1 with ATP synthase is shown in Figure 19.3.7.

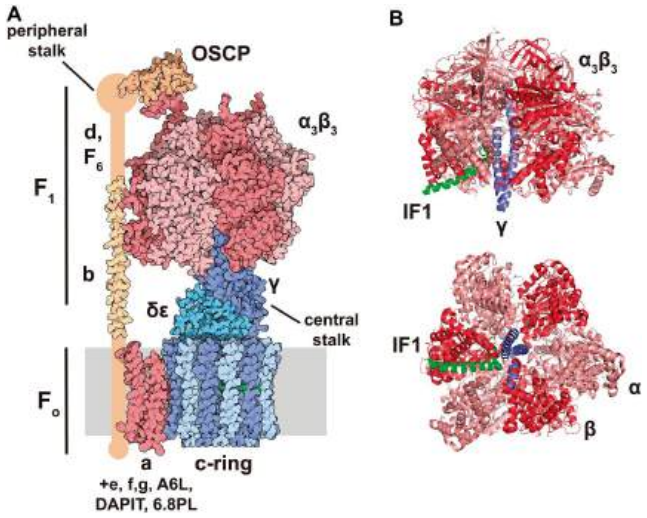

Figure 19.3.7: Structure of the bovine H^+-ATP synthase and binding site of IF1. Esparza-Moltó, P.B., Nuevo-Tapioles, C. & Cuezva, J.M. Regulation of the H^+-ATP synthase by IF1: a role in mitohormesis. *Cell. Mol. Life Sci.* **74,** 2151–2166 (2017). https://doi.org/10.1007/s00018-017-2462-8. Creative Commons Attribution 4.0 International License (http://creativecommons.org/licenses/by/4.0/)

Panel **(a)** shows the soluble F_1-ATPase domain composed by the 3α3β subassembly (*salmon*/*red*) and γ (*dark blue*), δ and ε (*light blue*) subunits, while the membrane-embedded F_o domain is formed by subunit a (*red*) and a ring of 8c subunits (*light*/*dark blue*). Both domains are linked together by a central stalk (γ, δ, ε subunits of the F_1 domain) and a peripheral stalk (b, d F6, A6L, OSCP subunits, in *orange*). The 3D structure of the peripheral stalk is not fully resolved. Except for a and A6L subunits, the remainder is encoded in the nucleus. (model comprised of multiple PDB structures)

Panel **(b)** shows the lateral and basal view of the bovine F_1 domain (α subunit is shown in salmon, β in *red*, and γ in *blue*) complexed with a fragment of IF1 (*green*). IF1 binds to the αβ interface through residues 1–37 and also contacts the γ subunit. (PDB: 1OHH)

IF1 has an intrinsically disordered N-terminal domain that binds to ATP synthase between the α and β subunits of the F_1, where it adopts an alpha-helical conformation. It can dimerize through self-interactions with the C-terminal domain. Interestingly, bound IF1 inhibits both ATP synthesis and hydrolysis as well as H^+ translocation through the complex. These activities are illustrated in Figure 19.3.8.

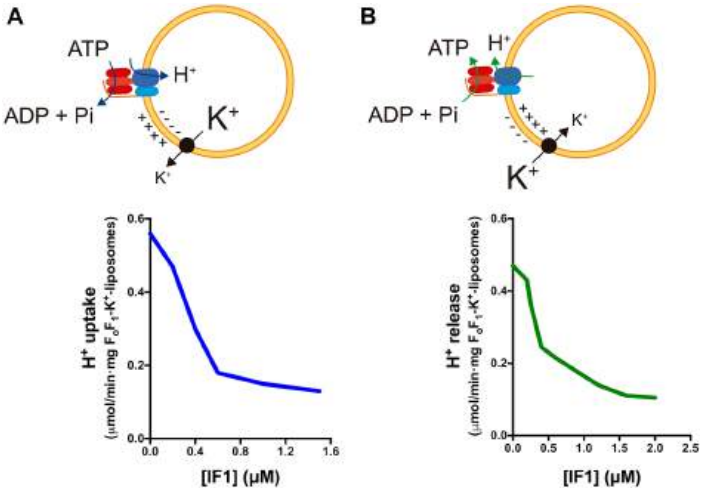

Figure 19.3.8: IF1 inhibits H^+ translocation through the H^+-ATP synthase in both synthetic and hydrolytic modes. Esparza-Moltó, ibid.

Panel **(a)** shows H^+ uptake is induced by valinomycin-mediated K^+ release from F_oF_1-K^+ liposomes with the H^+-ATP synthase functioning in the hydrolytic mode.

Panel **(b)** shows H^+ release is induced by valinomycin-mediated K^+ uptake in F_oF_1-K^+ liposomes with the H^+-ATP synthase functioning in the synthetic mode. The rates of H^+ uptake **(a)** and H^+ release **(b)** are reduced when the liposomes are incubated with increasing concentrations of isolated IF1. *Black circle* valinomycin.

Five key histidines in IF1 play a role in the inhibition of the ATPase activity and the oligomerization of IF1. When the pH gradient collapses, and the matrix becomes more acidic (as seen in hypoxia and ischemia), IF1 form dimers that inhibit ATP hydrolysis. At higher pHs, IF1 forms a dimer of IF1 dimers, or effectively a tetramer, which prevents its binding to ATP synthase and hence prevents the inhibition of ATP synthesis. An IF1-H49K mutant is an active inhibitor even at higher pHs. These properties are illustrated in Figure 19.3.9.

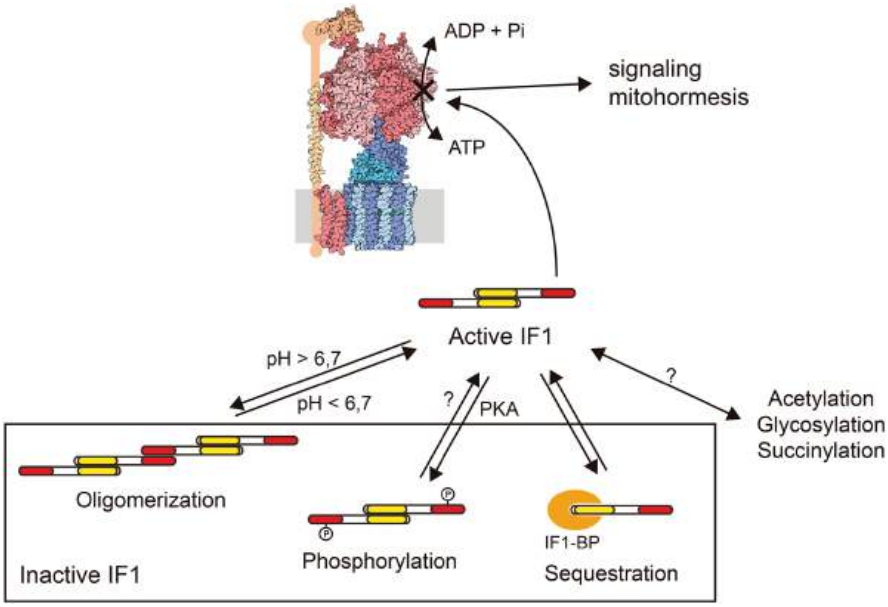

Figure 19.3.9: Post-translational regulation of IF1 activity. Esparza-Moltó, ibid.

IF1 inhibition of ATP hydrolysis is not only relieved by pH-dependent oligomerization as illustrated above, but also by phosphorylation by a mitochondrial Protein kinase A-like molecule, or by its interaction with yet another protein, BP. A conserved serine 39 is important in its inhibitory action. When dephosphorylated, IF1 binds to ATP synthase and inhibits both ATP synthesis and hydrolysis. When phosphorylated it can't bind and hence can't inhibit ATP synthase.

19.3.6: MITOCHONDRIA - NUCLEAR SIGNALING

We would be remiss to not include the role of the mitochondrial genome and its relationship to the nuclear genome in the control of mitochondrial function, including oxidative phosphorylation. Mitochondrial arose from the internalization of a distant bacteria into a eukaryotic cell. They developed an endosymbiotic relationship in which some of the genes from the original bacterial species remain in mitochondria today. The mitochondrial genome is shown in Figure 19.3.10.

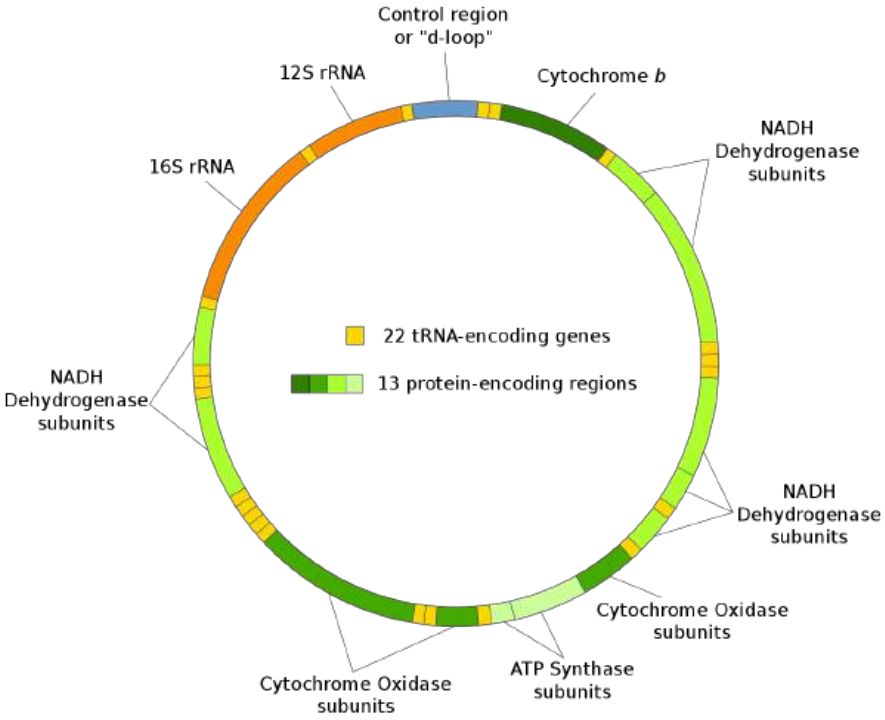

Figure 19.3.10: Mitochondrial genome. https://commons.wikimedia.org/wiki/C...ial_DNA_en.svg

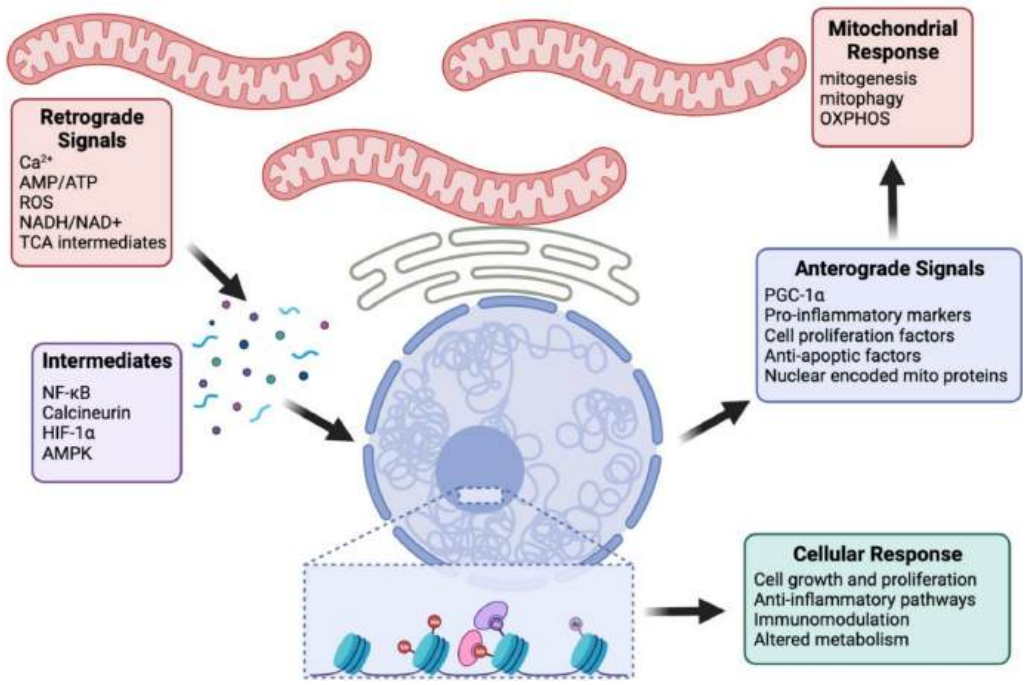
Mitochondrial DNA is a double-stranded molecule of 16.5 kilobases. It encodes some proteins, as well as its own tRNA and ribosomal RNAs. There are many copies (100s to 1000s) of the circular genome in each cell.

Some (actually 13), but not all of the genes for proteins required for oxidative phosphorylation are found in the mitochondrial genome. The rest reside in the nuclear genome, and after transcription and translation, the resulting protein must be imported into mitochondria. In fact, over 95% of mitochondrial proteins are encoded by nuclear genes. Mitochondria move in the cells guided by the internal cytoskeleton to sites where energy (ATP) is needed. They also participate in buffering intracellular Ca^{2+} ions in the cell, much like the ER with which mitochondria form intimate membrane contacts. The ER also makes contact with the outer nuclear membrane, so, likely, the mitochondria can closely associate with the nucleus as well.

Hence there must be regulation of the respective genomes to produce the correct type and amounts of proteins required for oxidative phosphorylation. To accomplish this, there is a bidirectional regulated signaling between the two organelles. There is direct signaling between the nucleus and mitochondria and retrograde signaling in the other direction. Signals and processes affected in these signaling pathways are shown in Figure 19.3.10.



jdjkfj

Figure 19.3.11: Signaling from the mitochondria to the nucleus. Brittni R. Walker and Carlos T. Moraes. *Biomolecules* **2022**, *12*(3), 427; https://doi.org/10.3390/biom12030427. Creative Commons Attribution (CC BY) license (https://creativecommons.org/licenses/by/4.0/)

Signals originating from the mitochondria, including calcium, reactive oxygen species (ROS), and AMP/ATP, often stimulate pathways, leading to transcriptional changes in the nucleus. Nuclear responses can involve upregulating cell proliferation and anti-apoptotic factors, as well as proteins involved in mitogenesis, such as PGC-1α and nuclear-encoded mitochondrial proteins. The levels of other molecules, such as TCA intermediates Acetyl CoA and α-ketoglutarate, can influence the epigenome by modifying methylation and acetylation, and consequently, the cell physiology.

We've encountered several key enzymes involved in the regulation of metabolism, including:

- AMP-activated protein kinase (AMPK) senses the energy state (AMP/ATP ratio) of the cell. When ATP is low (AMP is high), it activates pathways to produce ATP and inhibits pathways that require ATP. AMPK has been found at or near the mitochondrial membrane and may also be found in it. AMPK also promotes mitochondrial biogenesis (mitogenesis)
- mTOR (mammalian target of rapamycin) which is a serine/threonine kinase that regulates protein synthesis and other anabolic pathways based on the energy status of the cell. processes in response to growth factors, energy status, and oxygen levels. It also simulated mitogenesis.

CHAPTER OVERVIEW

20.1: LIGHT ABSORPTION IN PHOTOSYNTHESIS - AN OVERVIEW

20.1.1: INTRODUCTION

We have seen how we can transduce the chemical potential energy stored in carbohydrates, into the chemical potential energy of ATP. This occurs namely through coupling the energy released during the thermodynamically favored oxidation of carbon molecules through intermediaries (high energy mixed anhydride in glycolysis or a proton gradient in aerobic metabolism) to the thermodynamically uphill synthesis of ATP. There is a situation that occurs when we wish to reverse the entire process:

$$CO_2 + H_2O \rightarrow \text{carbohydrate} + O_2$$

This process is, of course, photosynthesis, which occurs in plants and certain photosynthetic bacteria and algae. Given that this process must by nature be an uphill thermodynamic battle, let us consider the major requirements that must be in place for it to occur:

- A **strong oxidizing agent** must be formed which can oxidize water to dioxygen. We know that redox reactions occur in the direction of a stronger to a weaker oxidizing agent (just as acid/base reactions are thermodynamically favored in the direction of strong to weak acid). Somehow we must generate a stronger oxidizing agent than product dioxygen, which often has the most positive standard reduction potential in common tables.
- Plants must have high concentrations of a **reducing agent** for the reductive biosynthesis of glucose from CO_2. The reducing agent used for most biosynthetic reactions in nature is NADPH, which differs from NADH only by the addition of a phosphate to the ribose ring. This phosphate differentiates the pool of nucleotides in the cells used for reductive biosynthesis ($NADPH/NADP^+$) from those used for oxidative catabolism ($NADH/NAD^+$)
- Finally, plants need an abundant source of **ATP** which will be required for reductive biosynthesis.

The *light reaction* of photosynthesis produces these three molecules, O_2, NADPH, and ATP. We will explore the light reaction in the next few sections of this chapter. The **dark reaction**, which as the name implies can occur in the dark, involves the actual fixation of carbon dioxide into carbohydrates using the ATP and NADPH produced in the light reaction.

The energy to power the light reactions comes directly from sunlight. Clue two is that plants have an organelle that animal cells don't - the chloroplast. Its structure is in many ways similar to mitochondria in that it has an outer membrane, an intermembrane space, and an inner membrane. In addition, it has a series of stacked, interconnected compartments called thylakoids bounded by a thylakoid membrane surrounding a lumen. A schematic is shown in Figure 20.1.1 below.

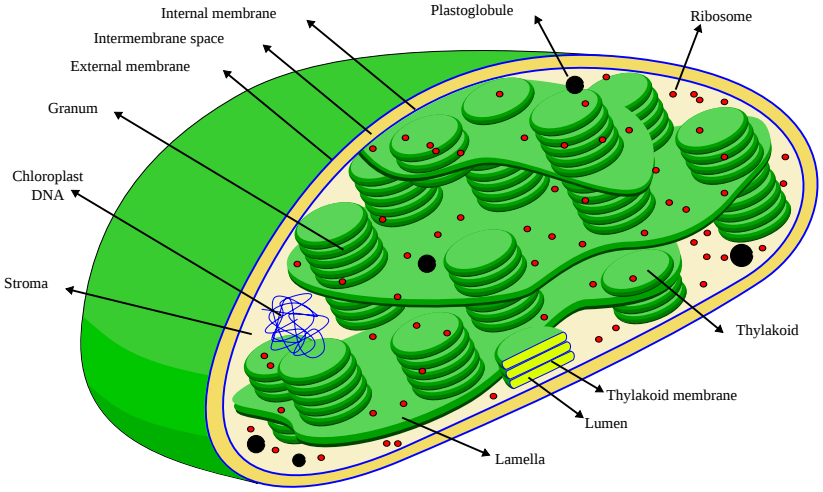

Figure 20.1.1: The chloroplast. chloroplast: https://commons.wikimedia.org/wiki/F...roplast-en.svg. Creative Commons Attribution-Share Alike 4.0

Stacks of thylakoids are called grana. Each thylakoid represents one granum. The thylakoids are where the **light reactions** occur. In contrast, the stroma contains the enzymes for the **dark reactions** of photosynthesis.

The enzyme complexes involved in the light reaction are aligned in the thylakoid membrane just as the membrane complexs involved in mitochondrial electron transport/oxidative phosphorylation were aligned in the mitochondrial inner membrane. That process used Complex I, Complex III, Complex II (succinate dehydrogenase), and Complex IV to transfer electrons from NADH and $FADH_2$ to increasingly potent oxidizing agents (ubiquinone, cytochrome C) ending with dioxygen. The energy released during that thermodynamically favored process was captured in the formation of a proton gradient, which collapsed through the F_0F_1ATPase to drive ATP synthesis.

For the light reaction, three complexes, the **Light Harvesting ComplexII -Photosystem II** (also called the **LHC-PSII supercomplex**), **cytochrome b_6f,** and the **light-harvesting complex Photosystem I** (called the LHC-PSII supercomplex) are used to carry out the light reactions of photosynthesis. These include the photooxidation of water to produce O_2 and the transfer of the lost electrons through a series of mobile electron carriers (plastoquinone and plastocyanin) to a terminal acceptor, $NADP^+$ to form the reducing agent NADPH needed for carbohydrate synthesis in the dark reaction. The energy released during the electron transfer process is likewise captured in the form of a proton gradient as protons are moved from the chloroplast stroma to the lumen of the thylakoid. The collapse of the resulting proton gradient powers ATP synthesis. These reactions are shown in Figure 20.1.2.

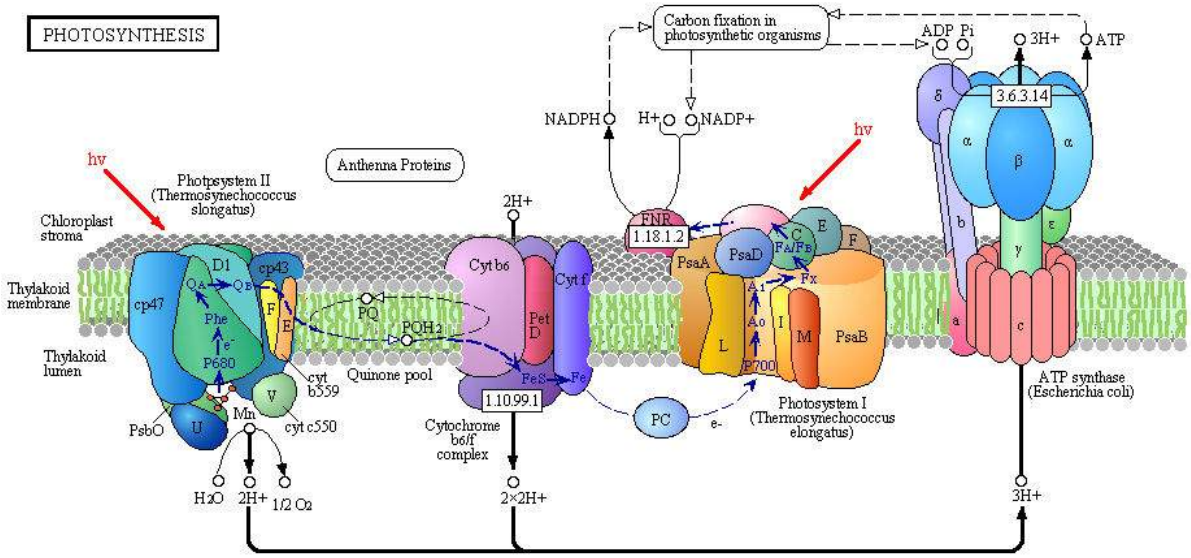

Figure 20.1.2: Light reaction of photosynthesis. The boxed numbers represent Enzyme Commission Number. Original KEGG Map with embedded links. (reprinted with permission from Kanehisa Laboratories and the KEGG project: **www.kegg.org**)

In this section, we will explore the absorption of light by the light-harvesting complex (LHCII) of the LHC-PSII supercomplex. Before we get into too much detail, let's start with a simplified review of light absorption in the LHCII.

20.1.2: ABSORPTION OF LIGHT

Plants have many pigments (chlorophylls, phycoerthryins, carotenoids, etc.) whose absorption spectra overlap that of the solar spectra. The main pigment, chlorophyll, has a protoporphyrin IX ring (same as in heme groups) with Mg^{2+} at its center instead of Fe^{2+}. When the chlorophyll absorbs light, the excited electrons must eventually relax to their ground state. It can do this by either radiative or nonradiative processes. In radiative decay, a photon of lower energy is emitted (after some energy has already been lost by vibrational transitions) in a process of either fluorescence or phosphorescence. In nonradiative decay, the energy of an excited electron can be transferred to another similar molecule (in this case other chlorophyll molecules) in a process that excites the electron in the second molecule to the same excited state. It is as if a photon is released by the first excited molecule, which then is absorbed by an electron in a second molecule to excite it to the same excited state. However, no photon is involved in the energy transfer. In this fashion, energy is transferred from one chlorophyll to another. This type of energy transfer is called resonance energy transfer or **exciton** transfer, as shown in Figure 20.1.3.

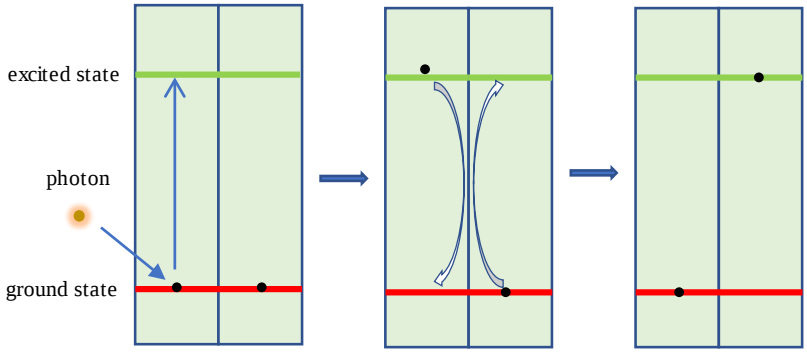

Figure 20.1.3: Resonance Energy (Exciton) Transfer

Because of its unique environment, one type of chlorophyll has slightly different characteristics. The energy level of the first excited state in the chlorophyll reaction center is lower than in the rest of the chlorophyll molecules, in much the same way that pKa values of amino acid side chains differ with the local and solvent environment, and the standard reduction potential of FAD molecules that are tightly bound to enzymes differ due to the different environment of bound FAD/$FADH_2$.

Instead of a radiationless transfer of energy to this special chlorophyll, an actual electron from the excited state chlorophyll is transferred, which by definition is a redox reaction. The electron donor (the excited chlorophyll) loses an electron (an oxidation reaction) as the recipient molecule gains one (a reduction). This charge (electron) transfer reaction produces charge separation in the formation of a positively charged chlorophyll (now an oxidizing agent) and a negatively charged chlorophyll (now a reducing agent). The chlorophylls directly involved in this final process are collectively called the **reaction center.** This process is shown in Figure 20.1.4 below.

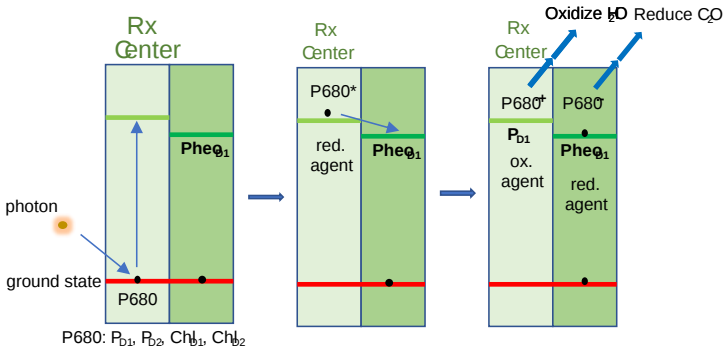

Figure 20.1.4: Reaction Center

The reaction center chlorophylls absorb light at 680 nm so sometimes these chlorophylls are labeled P680. There are 4 unique chlorophylls (P_{D1}, P_{D2}, Chl_{D1}, and Chl_D) that are the main players in the reaction center. Both sets of labels are shown in the figure above.

Figure 20.1.5 shows a cartoon of the absorption of photons and subsequent handoff of energy to "antennae" chlorophylls leading to photoexcitation of the reaction center and subsequent transfer of an electron to the special chlorophyll which has a lower first excited state energy. This molecule is named pheophytin A. It is identical to chlorophyll A but lacks the central Mg^{2+} ion.

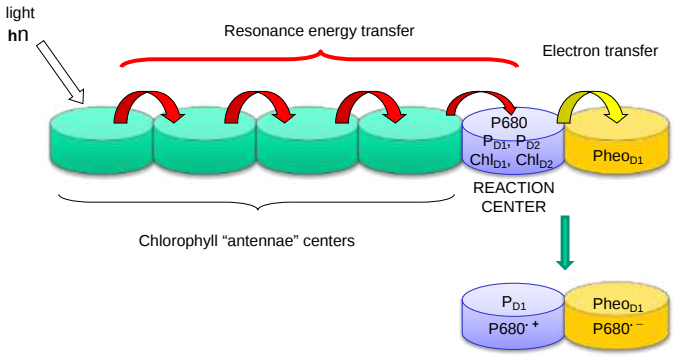

Figure 20.1.5: Photoexcitation and electron transfer of chlorophylls

Photosystems I and II contain many chlorophyll molecules that act as antennas that transfer energy to the reaction centers. The "antenna" proteins involved in photon adsorption and energy transfer in Photosystems I and II are shown in Figure 20.1.6 below. Note the D1, D2, cp47, and cp43 protein subunits in the figure below are also shown in the figure above. The D1 and D2 subunits contain the reaction center chlorophylls.

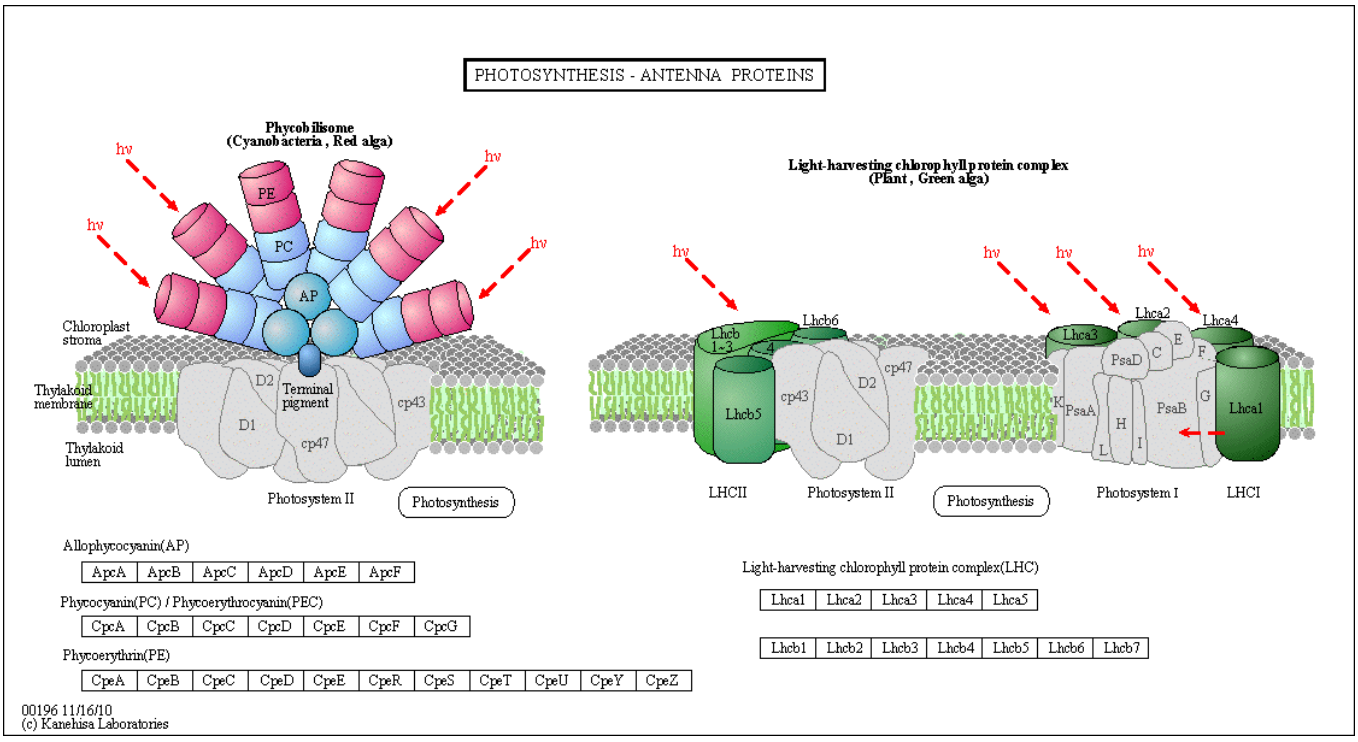

Figure 20.1.6: Antennae Proteins (reprinted with permission from Kanehisa Laboratories and the KEGG project: www.kegg.org)

The different chlorophylls have absorption spectra that overlap reasonably well with the solar spectrum, as illustrated in Figure 20.1.7.

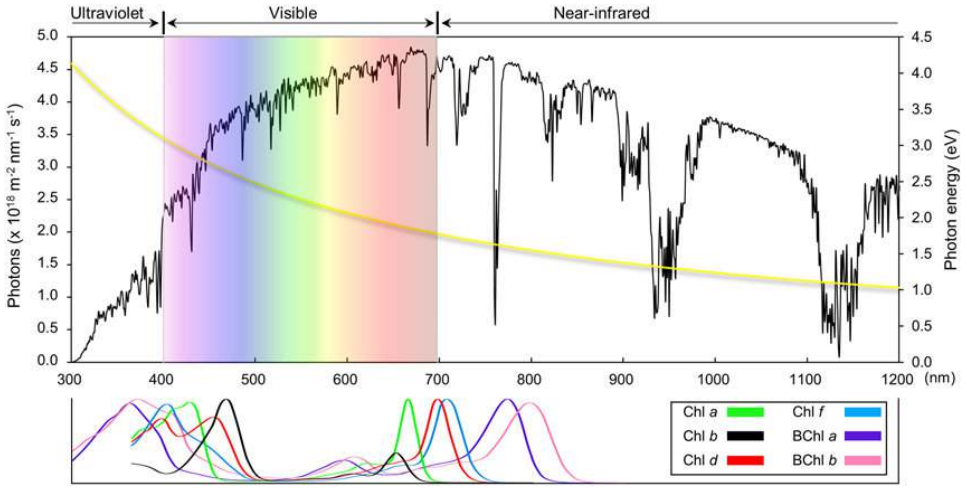

Figure 20.1.7: Solar spectrum and absorption profiles of chlorophyll and bacteriochlorophyll pigments. Cardona T, Shao S, Nixon PJ. Enhancing photosynthesis in plants: the light reactions. *Essays Biochem*. 2018;62(1):85-94. Published 2018 Apr 13. doi:10.1042/EBC20170015Creative Commons Attribution License 4.0 (CC BY).

The black lines show the solar flux spectrum (photons per meter square per wavelength) from 300 to 1200 nm. The yellow line is the photon energy (E=hc/λ) at each wavelength. The absorbance spectra of the chlorophyll species are normalized to the same maximal value.

If you use the energy required to make glucose from CO_2 and H_2O as a standard, about 95% of the incoming solar energy is wasted since not all of the incident light photons have the right wavelength. Waste also occurs due to reflectance and heat generation.

20.1.3: THE LIGHT HARVESTING COMPLEX (LHCII) - PHOTOSYSTEM II (PS II) SUPERCOMPLEX

Now let's look in more detail at the chloroplast thylakoid membrane complex that interacts with light and results in the oxidation of water to form O_2. This first structure is called the **Light Harvesting Complex II (LHCII) - Photosystem II (PS II) Supercomplex**. It is a super complex (a pun) to understand. The supercomplex has a **PSII core complex** interacting with a variable number of light-harvesting complex IIs (**LHCIIs)** complexes. Sometimes the entire super complex is more simply called Photosystem II. The supercomplex consists of

- a PSII core **C** with a Mn_4CaO_5 cluster called the oxygen-evolving complex (OEC or OEX) that oxidizes water to O_2;

- peripheral antennae complexes **M** and **S**, also called light-harvesting complexes II (LCHIIs)

The core part of the Photosystem II supercomplex contains the key to the existence of aerobic organisms as it produces the dioxygen in our atmosphere. Its chemistry is phenomenal. Many are seeking to modify it to produce, in addition to O_2, a green energy source, H_2. We will explore the mechanisms for the oxidation of water to O_2 by a PSII-bound inorganic Mn_4CaO_5 cluster, the oxygen-evolving complex (OEC) in the next section. Let's first look at PSII in light of the discussion above. Where are all the chlorophylls? The mystical "reaction center"?

The PSII Core Complex (within the supercomplex) has over 20 subunits. These include:

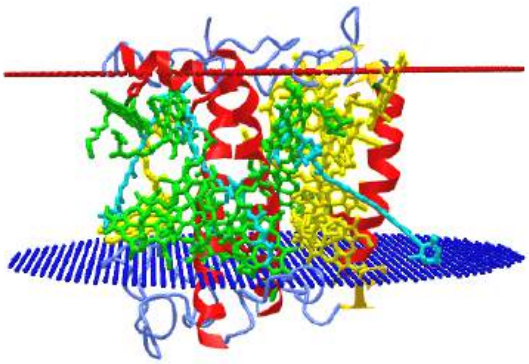
- reaction center subunits D1 and D2
- inner antennae subunits CP43, CP47
- many other small protein subunits
- peripheral subunits that project into the lumen that interact with the OEC

The peripheral antennae complexes (light-harvesting complexes - LHCIIs M and S - consist of proteins encoded by 6 different Lhcb genes (1-6).

- Lhcb1-3 monomers form trimeric (homo- or hetero) LHCIIs (Lhcb1-3). An example is $(Lhcb3)_3$. That trimer is often called the M-LHCII. There is also an S-form trimer as well as L- and N-forms. S represents a strong association with the reaction center, M for moderate and L for loose.
- Lhcb4-6 are called the minor components and consist of the monomeric proteins named **CP29, CP26, and CP24**, respectively.

20.1.4: LIGHT-HARVESTING COMPLEX PROTEINS

Each Lhc apoprotein consists of 3 alpha-helices and binds 8 chlorophylls a, 6 chlorophyll b, and 4 carotenoid molecules. Figure 20.1.8 shows an interactive iCn3D model of the monomeric pea chlorophyll a-b binding protein AB80 (LHCII type I CAB-AB80) (2BHW)



NCBI iCn3D Figure 20.1.8: Monomeric pea chlorophyll a-b binding protein AB80 (LHCII type I CAB-AB80) (2BHW). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...QtEEWeQ5Y9n2i8

The color scheme is as follows:

- protein - secondary structure colors
- Chlorophyll a - Green
- Chlorophyll b - yellow
- carotenoids - cyan

Now let's look at a trimeric form of the same protein. of LHCII, the chlorophyll-binding protein, from PSII. It's also called LHCII type I CAB-AB80. We showed the role of the LHCII trimer in the figures above. The subunits function to absorb light for the light reaction and through resonance transfer energy to the reaction centers in PSII and in addition PSI. Figure 20.1.9 shows an interactive iCn3D model of the trimeric Light Harvesting Complex (LHC_II) from pea photosystem II (2bhw).

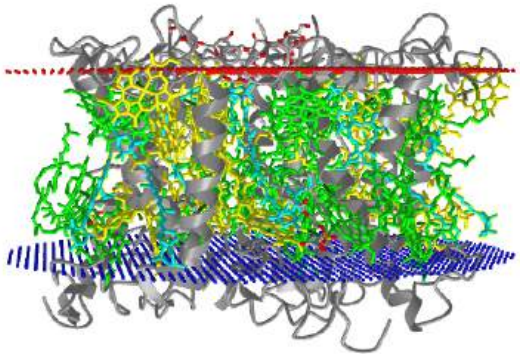


Figure 20.1.9: Light Harvesting Complex (LHC_II) from pea photosystem II (2bhw). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...BK6WvzrxABPDh6

The protein is shown in grey. To simplify the model, chlorophyll A molecules are shown in magenta, and chlorophyll B isomeric variants are in green. Note a large number of chlorophylls (42) in the LHCII complex, which differentiates it from most protein complexes which might have just a few ligands bound.

Photosynthetic bacteria and plants have an abundance of molecules that interact with visible light. The main one found in PS II is chlorophyll a whose structure is shown in Figure \(\PageIndex{10}\) below, along with the variant, chlorophyll b. Remember the pheophytin A is identical to chlorophyll A but lacks the central Mg^{2+} ion.

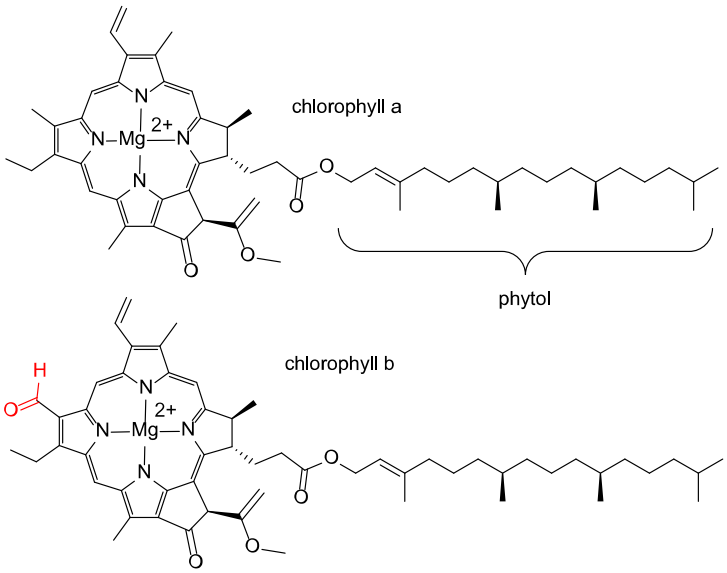

Figure 20.1.10: Chlorophyll a and b

20.1.5: PHOTOSYSTEM II (PS II) SUPERCOMPLEX STRUCTURES

The most common version of the supercomplex is a dimer. A simplified cartoon of the monomeric version of the **PSII-LHCII supercomplex** is shown in Figure 20.1.11. The PSII core is shown in the blue rectangle. The CP29, CP26, and CP24 in the peripheral antennae complexes (light-harvesting complexes - LCHIIs) are shown outside of the blue-outlined rectangle. They surround the PSII core.

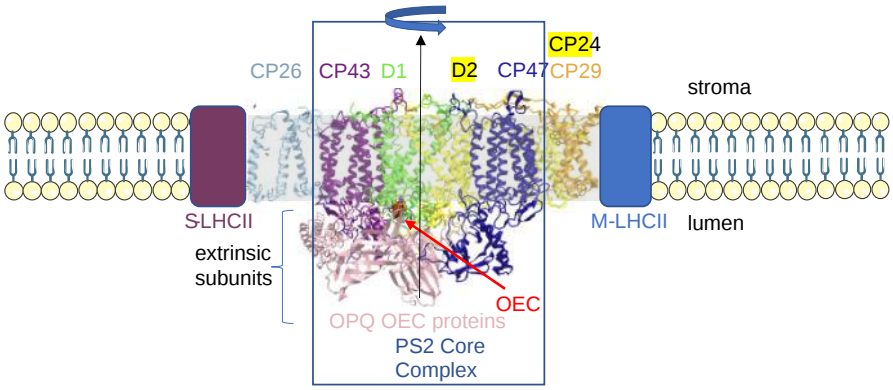

Figure 20.1.11: Cartoon of the monomeric PSII-LHCII supercomplex structure of the PSII-LHCII supercomplex from Pisumsativum

- The PSII core **C** (outlined in the blue box) contains two 2 reaction center subunits D1 and D2, as well as two inner antennae subunits CP43 and CP47. The core also contains extrinsic subunits (pink) surrounding the OEC (red spacefill)
- A **S**trongly bound LHCIIs protein, **S -LHCII**, left (maroon rectangle) interacting with CP26. The S-LHCii complex is a trimer of individual Lhcb monomers.
- A **M**oderately bound LHCIIs protein complex, **M-LHCII,** right (lighter blue rectangle) interacting with the CP24/CP29 dimer. The M-LHCII complex is a trimer of 3 lcbh-3 subunits $(Lcbh3)_3$.

There can be a variable number of LHCIIs in the complex. The predominant form of the supercomplex is the $\mathbf{C_2S_2M_2}$ complex. There are also many other proteins in the supercomplex that are not shown in Figure 11. A cartoon showing the top-down view of the actual supercomplex dimer, $C_2S_2M_2$, is shown in Figure 20.1.12.

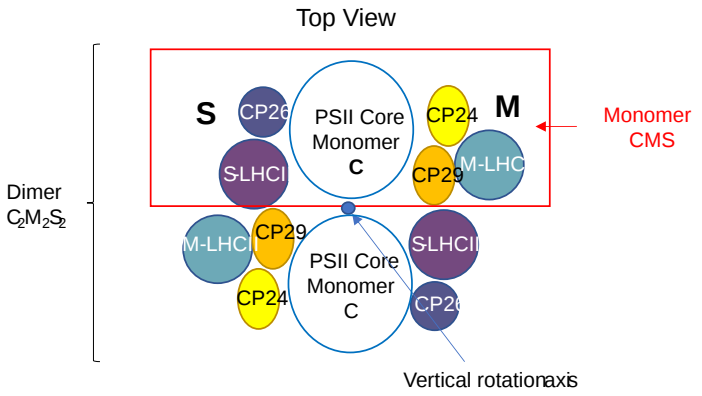

Figure 20.1.12: Top town view of the **PSII-LHCII supercomplex dimeric complex.**

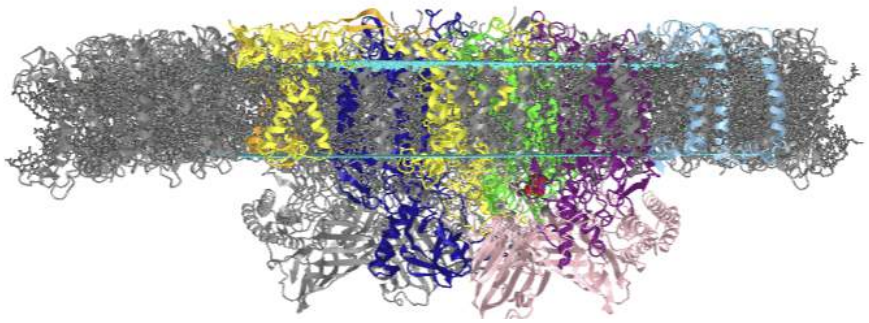
You could imagine forming the dimer by spinning the monomer CSM 180^0 and reproducing the monomer there.

Figure 20.1.13 shows an interactive iCn3D model of the full C2S2M2-type PSII-LHCII supercomplex from Pisum sativum (5XNL). (long load time)



NCBI iCn3D Figure 20.1.13: C2S2M2-type PSII-LHCII supercomplex from Pisum sativum (**5XNL)**. (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...F4WFfHoevxaVV8 (long load time)

Only a single CSM monomer of the C2S2M2 dimeric supercomplex is colored. The colors match those in Figures 8 and 9. The molecules shown in gray sticks that outline a bilayer include chlorophyll Bs (98 of them), chlorophyll As (216), and carotene or its derivatives (88) as well. The different proteins in the supper complex are colored as shown below.

- CP47 Rx Center (inner antenna protein) Dark Blue
- CP43 Rx Center (inner antenna protein) - Purple
- D1: green
- D2: yellow
- OEC: spacefill Red
- O, P, Q - OEC peripheral: Light pink
- CP24 (peripheral antenna protein): yellow
- CP29 (peripheral antenna protein): orange
- CP26: Light blue
- LHCIIs (S and M) - not shown
- membrane bilayers - cyan spheres

(A quick load version of the C2S2M2-type PSII-LHCII supercomplex with different coloring than above)

20.1.6: PSII SUPERCOMPLEX REGULATION

Plants have evolved a great ability to absorb light over the entire visible range of the spectra. Can they absorb too much energy? The answer is yes, so plants have developed many ways to protect themselves. IF too much light is absorbed, the pH gradient developed across the thylakoid membranes becomes greater. This is sensed by a protein, PsbS, and through subsequent conformational changes transmitted through the light-harvesting antennae, the excess light energy is dissipated as thermal energy. Mutants lacking PsbS showed decreased seed yield, a sign that it became less adaptable under conditions of stress (such as exposure to rapidly fluctuating light levels). Molecules called xanthophylls and other carotenoids such as zeaxanthin are also important in excess energy dissipation. These molecules appear to cause excited state chlorophyll (a singlet-like excited state dioxygen) to become deexcited. Without the xanthophylls, the excited state chlorophyll could deexcite by transfer of energy to ground state triplet dioxygen, promoting it to the singlet, reactive state, which through electron acquisition, could also be converted to superoxide. These reactive oxygen species (ROS) can lead to oxidative damage to proteins, lipids, and nucleic acids, alteration in gene transcription, and even programmed cell death. Carotenoids can also act as ROS scavengers. Hence both heat dissipation and inhibition of the formation of ROS (by such molecules as vitamin E) are both mechanisms of defense against excessive solar energy

Given that both plants and animals must be protected from ROS, antioxidant molecules made by plants may prove to protect humans from diseases such as cancer, cardiovascular disease, and general inflammatory diseases, all of which have been shown to involve oxidative damage to biological molecules. Humans, who can't synthesize the variety and amounts of antioxidants that are found in plants, are healthier when they consume large amounts of plant products. These phytomolecules also have other properties, including regulation of gene transcription which can also have a significant effect on disease propensity.

Plants have to respond to different qualities and quantities of light. When light is low, they seek to maximize light capture. Too much light could damage a plant so molecular adaptions are made to prevent it. Part of the regulation occurs in the stoichiometry of the supercomplex by altering the antenna protein (the LHCs) composition. The most abundant component of the complex is $C_2S_2M_2$ and C_2S_2M. C_2S and C_2S_2 increase as an adaption to increasing levels of light.

Light levels can also promote grana membrane association mediated by interactions of a PSII-LHCII supercomplex (PSII-LHCIIsc) on one thylakoid membrane interacting with a PSII-LHCIIsc on an adjacent thylakoid membrane to form a large PSII-LHCIIsc dimer. The structure and properties of paired PSII-LHCIIsc are illustrated in Figure 20.1.14.

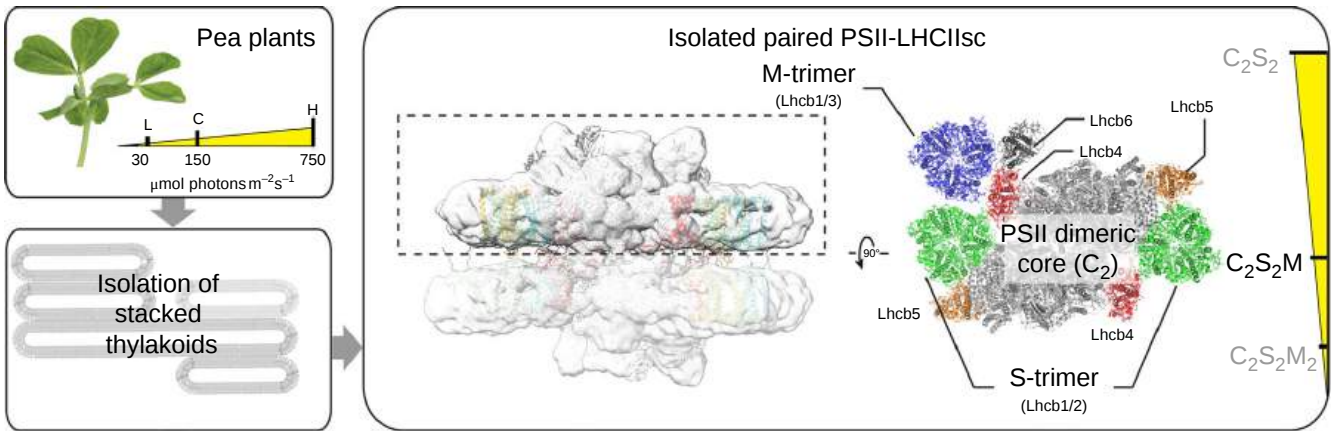


Figure 20.1.14: Light-driven modulation of paired PSII–LHCIIsc. Heterogeneous mixtures of PSII–LHCIIsc from pea plants grown at different light intensities (L, low; C, moderate used as control; H, high) were isolated and analyzed. Albanese et al. Nature Communications | (2020) 11:1361 | https://doi.org/10.1038/s41467-020-15184-1. Creative Commons Attribution 4.0 International License. http://creativecommons.org/ licenses/by/4.0/.

The figure also shows the variation in the PSII–LHCIIsc with light intensity. At low light $C_2M_2S_2$ prevails while at high light intensity C_2S_2 is most abundant. The system moves to regulate activity by increasing the abundance of LHCIIs in low light and decreasing them in high light intensities!

Figure 1 shows the stacking of individual granum in the chloroplasts. The stacking is maintained at various light levels and is mediated by loops of the LHCII trimers that are exposed in the stroma and Lhcb4 subunits on adjacent membranes. The stromal surfaces are flat and tightly stacked in grana. Stacking is a dynamic process and depends on cross-membrane interactions between and reorganization of the PSII -LHCIIsc.

The PSII–LHCIIsc is regulated through light-dependent post-translational phosphorylation, particularly on LHCII, and acetylation. which further regulates energy distribution. In plants, the core proteins CP43, D1 and D2, and PsbH are phosphorylated by the kinase Stn8. The peripheral antenna LHCII proteins are phosphorylated by Stn7. Phosphorylation of PSII is not seen in cyanobacteria and red algae. Higher light levels promote higher levels of core protein phosphorylation. Stn7 appears to be inhibited at high light levels. Figure 20.1.15 shows putative Stn8 phosphorylation sites in the PSII -LHCIIsc

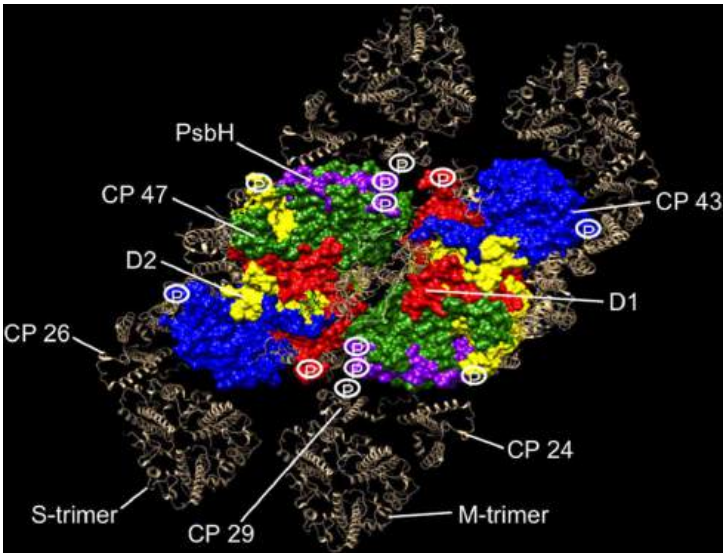

Figure 20.1.15: **Phosphorylation map of the C2S2M2 supercomplex as catalyzed by the Stn8 kinase**. Puthiyaveetil Sujith and Kirchhoff Helmut, Frontiers in Plant Science, 4 ,2013. https://www.frontiersin.org/article/...pls.2013.00459. DOI=10.3389/fpls.2013.00459. **Creative Commons Attribution License (CC BY)**

The structure is a model pieced together from multiple pdb files. The approximate positions of phosphorylation sites of D1, D2, CP43, PsbH, and CP29 are shown.

Most free N-terminal loops in LHCII can be phosphorylated. Both phosphorylation and lysine acetylation on Lhcb2 N-terminal loops help regulate the redistribution of LHCII from PSII (in grana stacks) to PSI (in single-layered thylakoid regions). Grana stacking by N-terminal loop association between facing PSII–LHCIIsc and their N-terminal acetylation appear to strengthen grana stacking.

How does PSII respond when not the intensity but the wavelength of light is changed? For this, we have to briefly discuss photosystem I (**PSI**), which we will explore in more detail in Chapter 20.3. Both PSII and **PSI** work together to transduce light into chemical energy so you would expect that their activities are regulated in a linked fashion. They have different absorbance spectra characteristics as well, with PSI absorbing more in the red region. If the effective absorbance (normalized for concentrations and LHCIIs) were the same, you would predict that the effective absorbance ratio over a broad wavelength range for the two photosystems, **PSI**/(**PSI**+PSII) would be 0.5. This is approximately the case over the entire spectral wavelength except for between 670-730 nm, where the ratio is close to 1, showing that PSI absorbance and hence activity is tilted toward the red end of the absorbance spectra. Changes in light characteristics (i.e. wavelength) would then affect each photosystem differently and can cause imbalances in their activities and their states, which should lead to a restorative balance. When exposed to far-red light, the systems move to state I. In this state, the major mobile antenna proteins (LHCIIs) move to PSII to restore a "photoabsorption" balance. When exposed to light depleted in the high end of visual spectra, the system moves to state II, in which mobile LHCIIs move to PSI. What an interesting reciprocal way to balance activity, even if it is hard to conceptualize regulation involving the movement of membrane proteins. Of course, such movement is seen often in the clustering of ligand-bound membrane receptors.

As mentioned above, the location and hence movement of the LHCII is regulated by phosphorylation by LHCII kinase. We'll explore that more in Chapter 20.3 when we discuss PSI in more detail.

20.1.7: A CLOSER VIEW OF THE REACTION CENTER AND ITS LOCAL ENVIRONMENT

Let's look at the structure of a simpler PSII complex from Thermostichus vulcanus (3WU2). It has 70 chlorophyll a molecules, 4 special chlorophylls, 4 pheophytin As (PHOs), 20 beta-carotenes, 4 plastoquinol-9s (PL9s), 4 hemes, and 2 caroten-3-ols. Figure 20.1.16 shows the arrangement of chlorophyll molecules in the CP47 and CP44 (not CP43 as shown in several of the above diagrams) antennae subunits of PSII from T. vulcanus (3WU2).

.

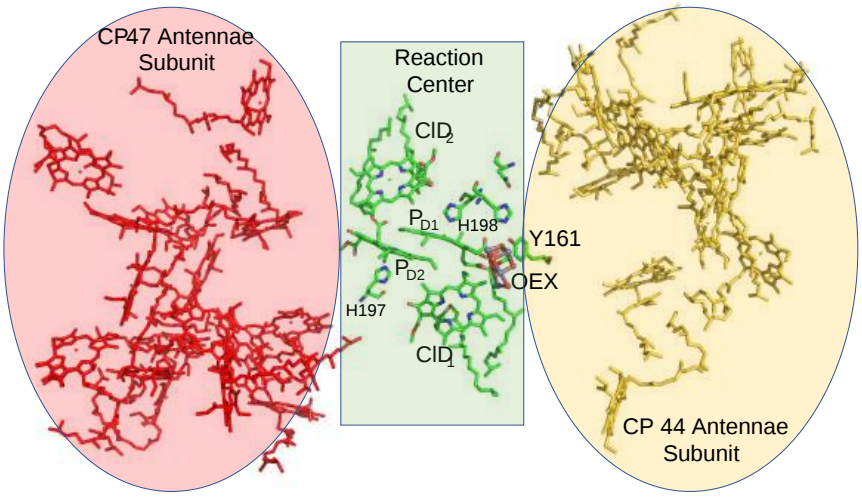

Figure 20.1.16: Reaction Center with special chlorophylls sandwiched between antennae subunits

- CP44 is the **Photosystem II CP44 reaction center protein, psbC gene,** Photosystem II 44 kDa reaction center protein;
- CP47 is the **Photosystem II CP47 reaction center protein, psbB gene;** Photosystem II CP47 chlorophyll apoprotein

Sandwiched in between them is the reaction center containing the 4 special chlorophylls, the inorganic metal cluster called the oxygen-evolving complex (OEC or OEX), and a key amino acid near the OEC, Tyr 161 (pdb 3ARC).

Two special chlorophylls, $ChlD_1$ and $ChlD_2$, accompanied by partner chlorophylls, P_{D1} and P_{D2}, that are coplanar to each, are found near the OEC and are the key chlorophylls in the reaction center that turn OEC into a powerful enough oxidant to oxidize H_2O

A special reaction center chlorophyll/pheophytin absorbs a photon of light at 680 nm so the species that absorbs the photon is given the label P680. On absorption, it forms the excited state, P680*. This transfers the excited state electron to pheophytin which forms a pheophytin radical anion, while the electron donor P680* becomes $P680^{\cdot+}$, a radical cation. The radical cation, an unstable species, can oxidize another molecule to regain stability, and in a series of addition linked oxidation stems, water is oxidized (O in water has an oxidation state of 2-) to O_2 (in which each oxygen has an oxidation state of 0). This happens through the oxygen-evolving complex, which we will explore in the next section.

Which of the chlorophyll molecules absorbs the light (ie. which is P680)? The answer is probably all four chlorophylls in the reaction center, P_{D1}, P_{D2}, Chl_{D1}, and Chl_{D2} through a delocalization of the excited electron, which would be described by a wave function for the combined chlorophylls. On donation of the electron from the P680*, the positive charge, which can be also described as a "hole" (similar to

transistors) delocalizes as well. Quantum mechanical calculations show a coupling between P_{D1} and P_{D2}, such that 80% of the positive charge and radical character is situated on P_{D1} and 20% is on P_{D2}.)

Figure 20.1.17 shows the four chlorophylls in the reaction center of T. Vulcanus. P_{D1} appears closest to the OC.

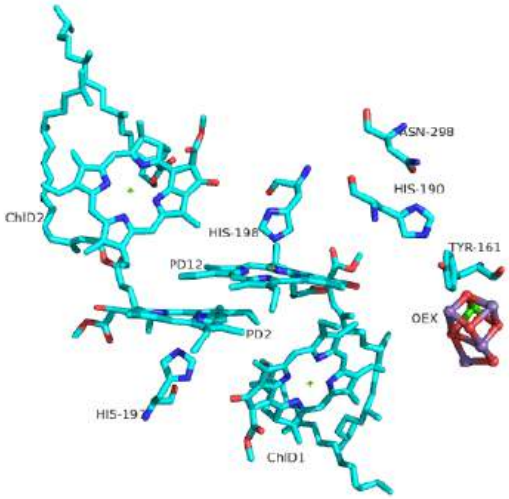

Figure 20.1.17: Closeup of the reaction center chlorophylls and OEC

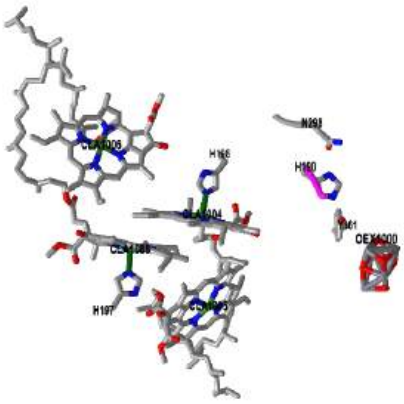
Figure 20.1.18 shows an interactive iCn3D model of the key chlorophylls and OEC of photosystem II from Thermostichus vulcanus (3WU2)



NCBI iCn3D Figure 20.1.18: Key chlorophylls and OEC of photosystem II from Thermostichus vulcanus (3WU2). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...qYxWN5sKcquGK7

Now in any enzymatically catalyzed reaction mechanism, the enzyme must return to the beginning state and a path for electron flow must be apparent. How does the radical cation $P680^{\cdot+}$ return to the ground state? As we will see in the next section, it "grabs" an electron from the nearby Y161 (also called **YZ**), which then forms a radical cation, $Y^{\cdot+}$. This likewise returns to the ground state by grabbing an electron from the OEC which ultimately grabs one from water. This process repeats four times to remove the four electrons from two waters needed to form dioxygen.

Figure 20.1.19 shows the first step in process of reforming P680 and the formation of the Y161 radical cation.

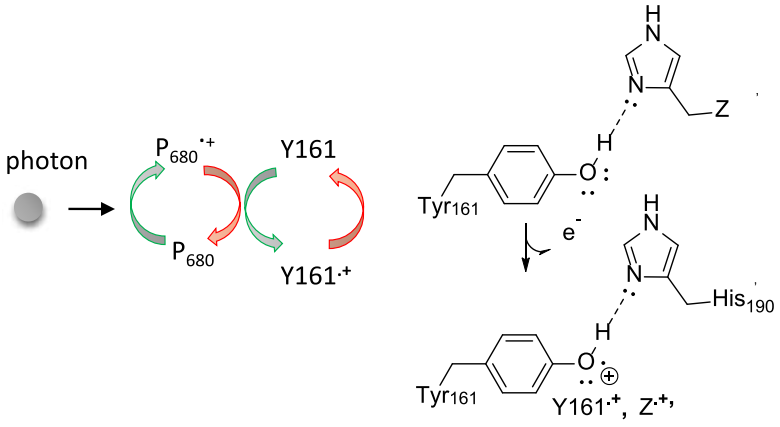


Figure 20.1.19: First step in process of reforming P680 and formation of the Y161 radical cation.

A different process occurs to remove electrons from the radical anion, $P680^{-}$. This is passed on to a series of other electron acceptors/carriers as part of the Z scheme for the light reaction of photosynthesis. The electron is ultimately passed on to $NADP^{+}$ to form NADPH for the reductive biosynthesis of carbohydrates.

Light is also absorbed in photosystem I, which does not form O_2. Rather it receives electrons from a mobile electron carrier and passes them on $NADP^{+}$ to form NADPH, a reducing agent needed for the reductive biosynthesis of carbohydrates. It also helps produce a proton gradient which helps drive ATP synthesis.

With this background, we can now explore in greater detail the key reactions that enable the evolution of aerobic organisms.

20.2: THE KOK CYCLE AND OXYGEN EVOLVING COMPLEX OF PHOTOSYSTEM II

20.2.1: INTRODUCTION

We have just seen how photoexcitation of the non-reaction center chlorophyll turns that molecule into a good reducing agent, which transfers its electron to the nearest excited state level of the reaction center chlorophyll. If you count both steps together, the non-reaction center chlorophyll gets "photooxidized", in the process producing the "strong" oxidizing agent which is the positively charged chlorophyll derivative. The extra electron passed onto the second molecule will eventually be passed on to $NADP^+$ to produce NADPH.

These reactions occur in the presence of light and hence are called the **light reactions**. The light reactions of photosynthesis in green plants are shown in Figure 20.2.1, along with the standard reduction potentials of the participants, the Z scheme.

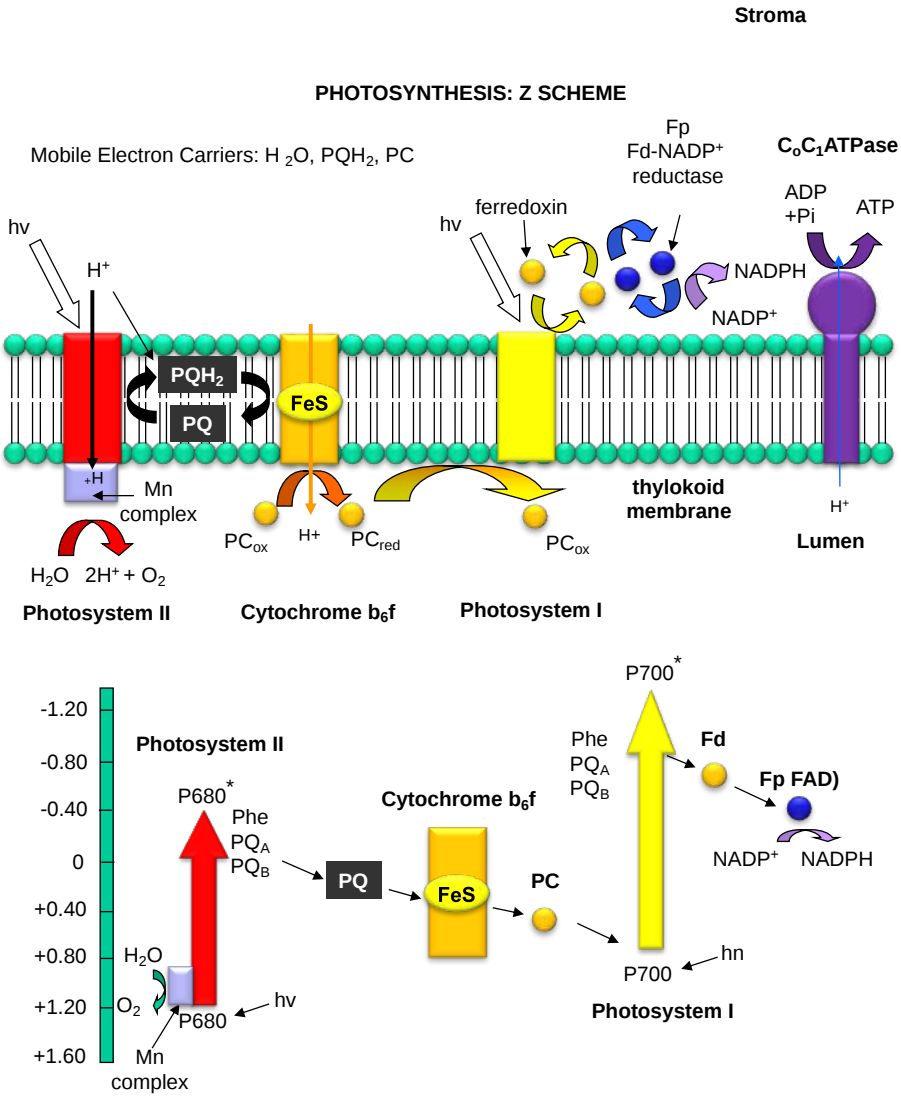

Figure 20.2.1: Light reaction of photosynthesis and associated standard reduction potentials

The combined processes of PSII and PSI resemble a "Z" scheme (rotate in your mind the standard reduction potential figure 90 degrees clockwise). In an organization reminiscent of electron transport in mitochondria, water is oxidized by **photosystem II (PSII)**. Electrons from water are moved through PSII to a mobile, hydrophobic molecule, plastoquinone (PQ) to form its

reduced form, PQH_2. Another photosystem, **photosystem I (PS1)**, is next in the electron transport pathway. It takes electrons from another reduced mobile carrier of electrons, plastocyanin (PC_{red}) to ferredoxin, which becomes a strong reducing agent. Ferredoxin is a protein with an Fe-S cluster (Fe-S-Fe-S in a 4-membered ring, with 2 additional cysteine residues coordinating each Fe). It ultimately passes its electrons along to $NADP^+$ to form NADPH. Note the complexes that produce a transmembrane proton gradient. In contrast to mitochondria, the lumen (as compared to the mitochondrial matrix) becomes more acidic than the stroma. Protons then can move down a concentration gradient through the C_0C_1ATPase to produce ATP required for the reductive biosynthesis of glucose.

Figure 20.2.2 a more detailed view of the molecular players in the light reaction.

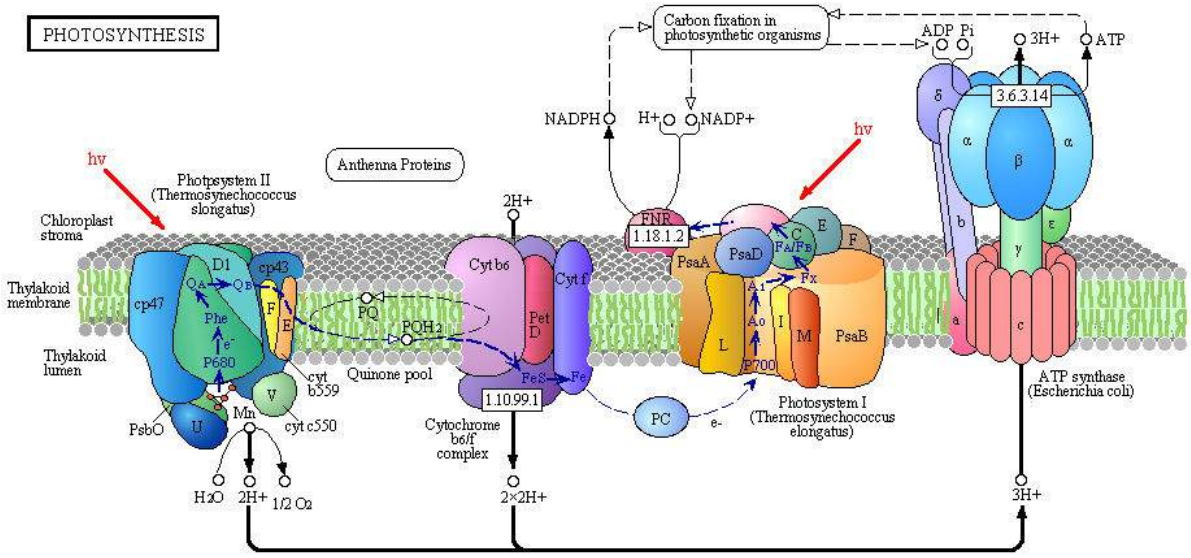

Figure 20.2.2: Detailed View of Light Reaction of Photosynthesis (reprinted with permission from Kanehisa Laboratories and the KEGG project. The boxed numbers represent Enzyme Commission Number. Original KEGG Map with embedded links.

20.2.2: PHOTOSYSTEM II

PSII has a complicated structure with many polypeptide chains, lots of chlorophylls, and Mn, Ca, and Fe ions. A Mn cluster, called the **oxygen-evolving complex, OEC** (also called the OEX) is directly involved in the oxidation of water. Two key homologous 32 KD protein subunits, D1 and D2, in PSII are transmembrane proteins and are at the heart of the PSII complex. It has been said of PSII that "Of all the biochemical inventions in the history of life, the machinery to oxidize water — photosystem II — using sunlight is surely one of the grandest." (Sessions, A. et al, Current Biology 19 (2009)

The net reaction carried out by PSII is the oxidation of water and reduction of plastoquinone.

$$2PQ + 2H_2O \rightarrow 2PQH_2 + O_2\,(g)$$

The oxidation number of oxygen in water is -2 and 0 in O_2, so this is a loss of electrons or oxidation of the water. Note that water is not converted to $2H_2 + O_2$, as in the electrolysis of water. Rather the Hs are removed from the water as protons in the lumen of the chloroplast, since the part of PSII that oxides water is near the lumenal end of the transmembrane complex. Protons are required to protonate the reduced (anionic) form of plastoquinone to form PQH_2, an activity of PSII found closer to the stroma, derive from the stroma. That being said, researchers actively trying to develop a photosynthetic scheme or mimic that does produce H_2 for use as a clean and essentially boundless fuel source to replace climate-warming fossil fuels.

A quick look at standard reduction potentials (SRP) shows that the passing of electrons from water (dioxygen SRP = +0.816 V) to plastoquinone (approx SRP of 0.11) is **not** thermodynamically favored. The process is driven thermodynamically by the energy of the absorbed photons.

The crystal structure of PSII from a photosynthetic cyanobacterium consists of 17 polypeptide subunits with metal and pigment cofactors and over 45,000 atoms. Of particular interest is the **P680 chlorophyll reaction center**, which consists of four monomeric chlorophylls adjacent to a key Tyr 161 side chain. When H_2O gets oxidized to form dioxygen, 4 electrons must be removed by photoactivated P680. In PSII, this process occurs in 4, single electron steps, with the electrons first being transferred to the oxygen-evolving complex. The electrons passed through the Mn complex are delivered to P680 by a photoactive **Tyr 161 (Tyr Z or YZ)** free radical.

Five discrete intermediates of the OEC, S_0-S_4, are suggested from the experimental data and are consistent with the Kok cycle, which we will discuss below. These were postulated from experiments in which spinach chloroplasts were illuminated with short light pulses. A pattern of dioxygen release was noted that repeated after 4 flashes. Ultimately, light absorption by P680 forms excited state P680*, which donates an electron to **pheophytin**, which passes them to quinones. Hence P680 gets photooxidized as it forms the cationic $P680^+$. This then removes an electron from Tyr 161 (YZ) producing the tyrosine radical cation, **Tyr 161$^{\cdot+}$**. Given its positive charge, its reactive nature as a free radical, and its proximity to Mn ions in the OEC, it pulls an electron from a Mn ion in the OEC. This process repeats itself 4 times for the oxidation of two H_2Os, which injects 4 electrons back into the OEC to return to the basal state.

The mechanism is very complicated and still not fully understood. It is perhaps easiest to think about the mechanism involving a series of sequential electron and proton transfer and their accompanying change in charge and redox states. Most biochemistry students have a limited understanding of transition state complexes and chemistry but even the experts struggle with the mechanism.

In summary, for PSII in plants:

1. a pair of chlorophylls (P680) in the D subunits absorb light (maximum absorbance around 680 nm) and reach an excited state
2. electron transfer from P680 to a nearby chlorophyll with a lower energy level for the excited state electron occurs, which produces an anionic chlorophyll. This chlorophyll has 2 H^+ ions in the chlorophyll instead of Mg^{2+} (again note the charge balance). After electron transfer, P680 now becomes the cation $P680^+$.
3. This "anionic" chlorophyll transfers an electron to oxidized plastoquinone.
4. The $P680^+$, a strong oxidizing agent, removes one electron from an adjacent Tyr 161 to reform P680 and the radical cation **Tyr 161$^{\cdot+}$**. Its proximity to the OEC complex leads to it removing an electron from the OEC, making it a more potent oxidizing agent
5. This process repeats a total of 4 times to fully oxidize two water molecules to produce 1 O_2 with the 4 electrons removed from 2 glasses of water added back to the metal centers of the OEC.

This suggests that there are 5 states of the OEC, an initial state, which we will call S_0, and four other states (S_1, S_2, S_3, and S_4). S_1 forms after the removal of one electron from the OEC by the adjacent radical cation **Tyr 161$^{\cdot+}$** (formed after absorption of one photon). S_2, S_3, and S_4 are sequentially formed after the removal of one electron by a newly regenerated **Tyr 161$^{\cdot+}$** after another round of photoexcitation. S_4 then returns to its original state, S_0. This series of reactions is called the Kok cycle, which is shown in Figure 20.2.3.

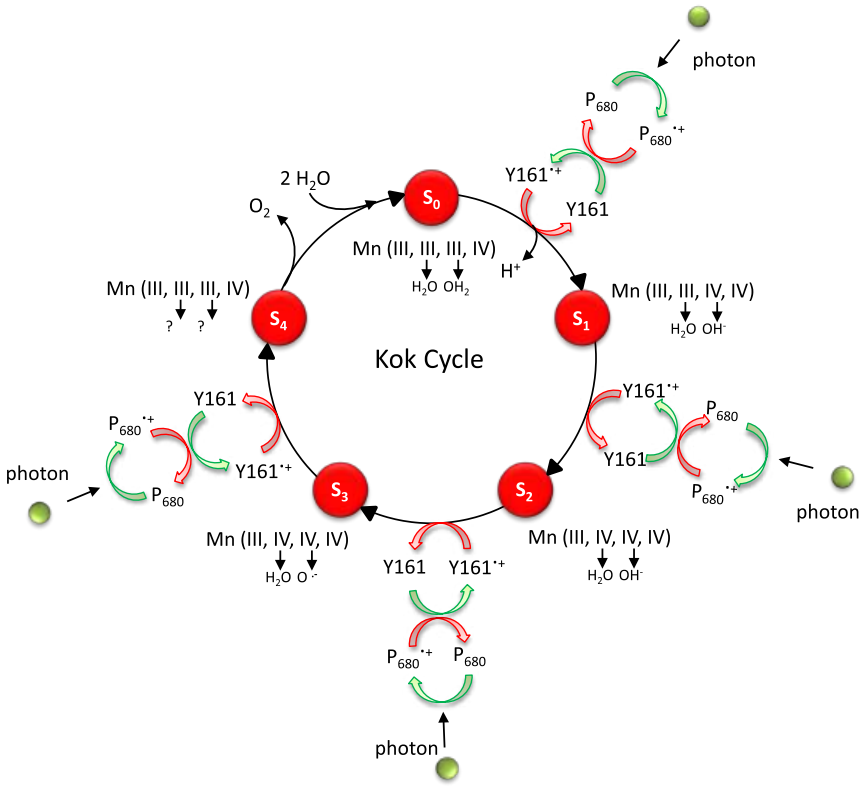

Figure 20.2.3: The Kok cycle

There is no structural information given in the above figure. What is shown instead are possible and consistent oxidation numbers of the four Mn^{n+} ions in the OEC that are consistent with charge balance and the changes in the oxidation number (-2) of the oxygen atom in water as it progresses to O_2 with an oxidation number of 0. The Mn ion states in the Kok diagram denote different discrete oxidation states where n is the number of oxidative “equivalents” stored in the OEC during cycle progression. Think of the OEC as the key catalyst, which will interact with substrate H_2O molecules. We start with the S_0 state and must return to it in the full cycle.

Remember that when O_2 acts as an oxidizing agent in combustion reactions, it forms $2H_2O$. That requires the addition of four electrons. If done sequentially, the oxygen intermediates include superoxide, peroxide, and oxide, the latter of which when protonated is water. Hence two waters and four cycles are required to remove the four electrons required to produce dioxygen. Intermediate but transient oxygen states are also presumably important in this mechanism.

A similar mechanism is found in PSI, except plastocyanin, not dioxygen is oxidized, with electrons moved to ferredoxin. This is likewise a difficult process since the reduction potential for oxidized plastocyanin (the form that can act as a reducing agent) is +0.37 while for ferredoxin it is -0.75. This transfer of electrons is an uphill thermodynamic battle since the more positive the standard reduction potential, the better the oxidizing agent and the more likely the agent becomes reduced. What drives this uphill flow of electrons. Of course, it is the energy input from photon. We won't go into any more detail about PSI since it is very similar to PSII but of course, does not have the OEC.

20.2.3: THE OXYGEN EVOLVING COMPLEX - OEC

Even though this is not a bioinorganic textbook, we must move past the "simple" Kok cycle diagram and look at the actual structure of the minicatalyst, the OEC, and the protein and water (substrate) environment around it to understand the mechanism. The mechanism of the OEC is still not fully understood. It's experimentally difficult to unravel given its complexity as the intermediates are very labile and the x-ray-induced transient alterations in the structure of OEC complicate matters more. Paradoxically it is quite simple in overall terms. Here is the essential reaction:

$$2H_2O + 4 \text{ photons} \rightarrow 4\ H^+(\text{lumen}) + 4\ e^- + O_2.$$

The crystal structure of PS2 from T. vulcanus has significantly improved our understanding of the OEC and electron flow on water oxidation. We will concentrate on developing an understanding of the amazing Photosystem II from Thermosynechococcus vulcanus, a cyanobacterium (19 subunits with 35 chlorophylls, two pheophytins, 11 beta carotenes, 2 plastoquinones, 2 heme irons, 1 non-heme iron, 4 Mn ions, 3-4 Ca ions, 3 Cl ions, 1 carbonate ion, and around 2800 water molecules).

Nature has appeared to evolve a single gene for the central protein in PSII that binds the OEC. The cluster, Mn_4CaO_5, appears identical in all photosynthetic organisms and is shown below. Researchers were surprised to find that the Ca ion was an integral part of the basic geometric “framework” of the OEC instead of a Mn which was found to be “dangling” from the basic geometric framework. A detailed structure of the OEC from T. vulcanus is shown in Figure 20.2.4.

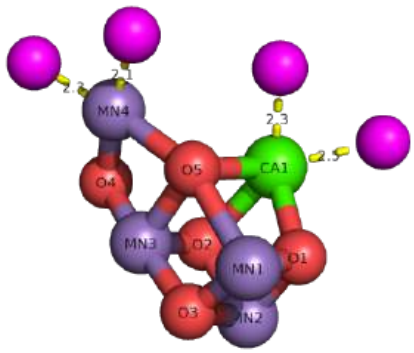

Figure 20.2.4: Structure of the OEC

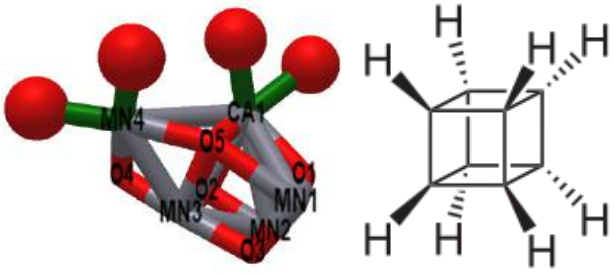
Note the basic structure is a distorted cube the metal ions at every other corner separated by oxides. Again, it was a surprise that not all of the 4 Mn^{2+} ions were in the cubic structure. Note one "dangling" Mn^{2+} with the other last metal site in the distorted cube occupied by Ca^{2+}. Four oxygens (presumably from waters) are shown interacting with MN4 and CA1.

It is very difficult to visualize this structure correctly from a 2D figure. Figure 20.2.5 shows an interactive iCn3D model of the OEC with bound water of photosystem II from Thermostichus vulcanus (3WU2) which should help in visualizing this structure. (very long load time!)



NCBI iCn3D Figure 20.2.5: OEX with bound water of photosystem II from Thermostichus vulcanus (3WU2). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...F8vwgkDXV6C1S6. (very long load time)

The shape outlined by O5-CA-O1-MN1 and MN3-O2-MN2-O3 is similar to cubane (shown above right)

Now let's zoom out and view some of the amino acid side chains that interact with the OEC from T. vulcanus. These are shown in Figure 20.2.6.

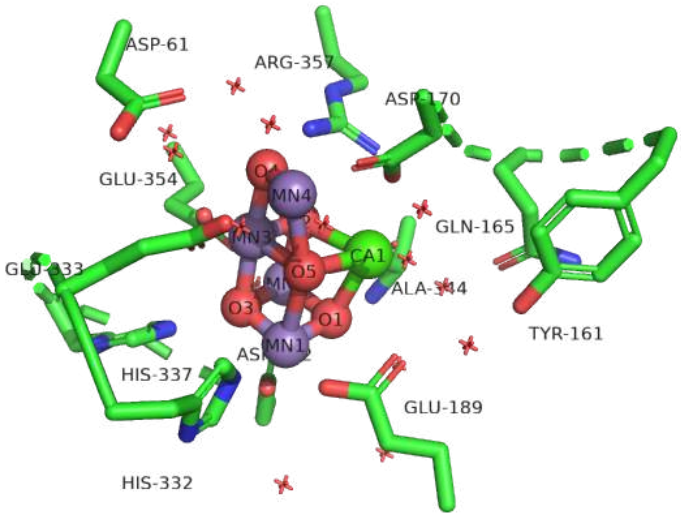


Figure 20.2.6: OEC and surrounding amino acids from T. vulcanus

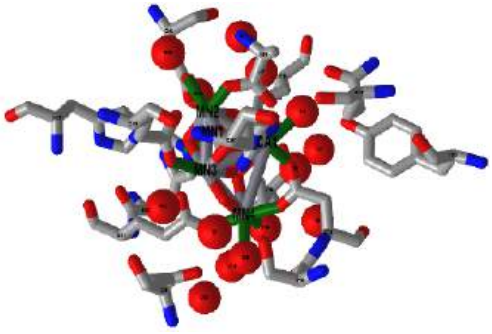
The coordination number for all the Mn ions (including those interacting with water) is identical. Note the proximity of Tyr 161 which is involved in electron removal from the OEC after it becomes the radical cation **Tyr 161**$^{\cdot+}$ in the primary photooxidation event.

Figure 20.2.7 shows an interactive iCn3D model of the OEX with surrounding amino acids and water in photosystem II from Thermostichus vulcanus (3WU2). (long load time) presented to once again help you better understand the 2D structure shown above.



NCBI iCn3D Figure 20.2.7: OEX with surrounding amino acids and water in photosystem II from Thermostichus vulcanus (3WU2). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...bP6ttbaWUmQAg7

The OEC can be thought of as a distorted cubane with a MN3-O4-MN4-O5 back. Bonds to O5 are longer than the other bonds which suggest they are weaker than the other metal-oxygen bonds. This could suggest that it may not be an oxo (O^{2-}) ligand but another variant

such as OH^- (lower charge), which may imply involvement in the splitting of dioxygen in the reaction mechanism. From a mechanistic perspective, an **O-O bond must form between two waters**. Both sets of bound "waters" (purple spheres in Figure 4 and red spheres in Figure 5 shown without Hs attached if they are present) are close to O5.

It is important to remember that electrons removed from the metal ions in the OEC by **Tyr 161$^{\cdot+}$** must be restored to the OEC to allow the catalytic cycle to continue. These electrons come from the waters that get oxidized. Such a reversible loss and gain of electrons most readily occur from the transition state Mn ions, which you all remember from introductory chemistry have multiple oxidation states. To bring back introductory chemistry again, we present the standard reduction potentials of different Mn ions in Table 20.2.1 below.

Reduction reaction	Standard Reduction Potential
Mn^{2+} (aq) + 2 e^- → Mn (s)	-1.185
MnO_4^- (aq) + 2 H_2O (l) + 3 e^- → MnO_2 (s) + 4 OH^-	+0.595
MnO_2(s) + 4H^+ + e^- → Mn^{3+} + 2H_2O	+0.95
MnO_2(s) + 4H^+ + 2e- → Mn^{2+} + 2H_2O	+1.23
MnO_4- (aq) + 8 H^+ (aq) + 5 e^- → Mn^{2+} (aq) + 4 H_2O (l)	1.507
MnO_4^- (aq) + 4 H^+ (aq) + 3 e^- → MnO_2 (s) + 2 H_2O (l)	1.679
$HMnO_4^-$ + 3H^+ + 2^{e-} → MnO_2(s) + 2H_2O	+2.09
O_2(g) + 4H^+ + 4e^- → 2H_2O +1.229	+1.229

Table 20.2.1: Standard reduction potentials for Mn ions compared to O_2.

You should be able to determine the oxidation number of the Mn ion in each compound. Based on standard reduction potentials, which oxidation states might be sufficient for the oxidation of H_2O in the OEC?

How does this translate into structural/chemical changes in the OEC? Figure 20.2.8 provides a recent mechanism consistent with each of the Kok states (S_0-S_4).

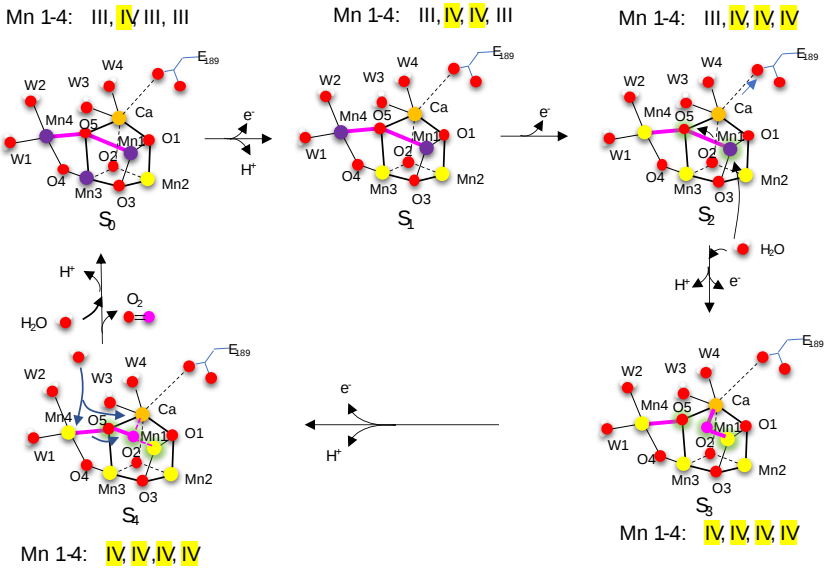


Figure 20.2.8: Mechanism for water oxidation and O_2 formation through the OEC consistent with the Kok cycle (adapter from Britt & Marchiori, 10.1126/science.aaz4522)

The proposed change in redox state for each Mn ion is illustrated with Mn (III) ions in purple and Mn (IV) ions in yellow. Note the change in the oxidation state of the 4 Mn ions from (III, IV, III, and III) in S_0 to (IV, IV, IV, and IV) for all of them in S_3 and S_4. A flip in the side chain of E180 in S_2 allows the binding of Mn1 through an oxy link to Ca. There are many possible different forms of oxygens in the structure including waters, oxides (bridging oxos and possibly terminal oxides), and hydroxides, and the exact form at some sites are still a bit uncertain. Note also the elegance of having a Mn_4 cluster to catalyze the 4 electron oxidation of 2 water through the loss of 4 electrons. Also, the redox state change in the Mn ions is different than the one shown in the Kok diagram in Figure 3. In addition, the final O2-producing step going from S_4 → S_0 is still uncertain. The above mechanism is based on x-ray structures of intermediates and quantum calculations. In it, S_4 has an Mn(IV)O· that bonds with the bridging O5 to form O_2.

20.2.4: WATERS

As water is a reactant in PSII, there must be water channels leading to the OEC that provide a way for water to enter and for protons to be removed and directed to the lumen to develop a proton gradient. Another rendering of the Kok cycle, the position of the OEC in PSII on the luminal side of the membrane, and the presence of water channels (Cl1, O4, O1) and the Yz network, which connect Tyr 161 (Yz) to the lumen, are shown in Figure 20.2.9.

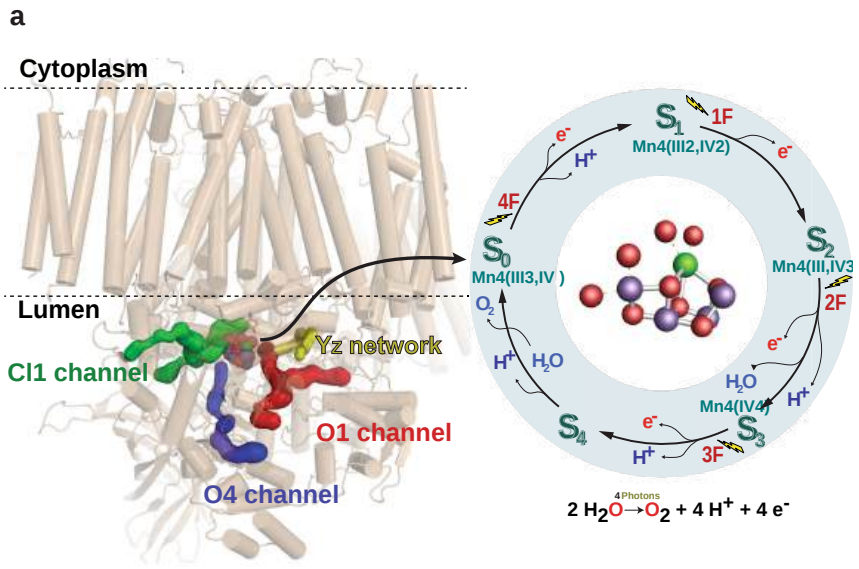

Figure 20.2.9: An overview of Photosystem II and the main water channels and networks from the OEC to the lumenal side. Hussein, R., Ibrahim, M., Bhowmick, A., *et al*. Structural dynamics in the water and proton channels of photosystem II during the S_2 to S_3 transition. *Nat Commun* **12,** 6531 (2021). https://doi.org/10.1038/s41467-021-26781-z. Creative Commons Attribution 4.0 International License. http://creativecommons.org/ licenses/by/4.0/.

The left part of the figure illustrates the structure of PS II showing the membrane-embedded helices and the extrinsic subunits in beige. The OEC and the water channels, in addition to the Yz network, are shown in color. The Kok cycle of the water oxidation reaction that is triggered by the absorption of photons is shown on the right and highlighted with a blue circle. F represents a photon.

A more detailed representation of water channels and the Yz networks is shown in Figure 20.2.10.

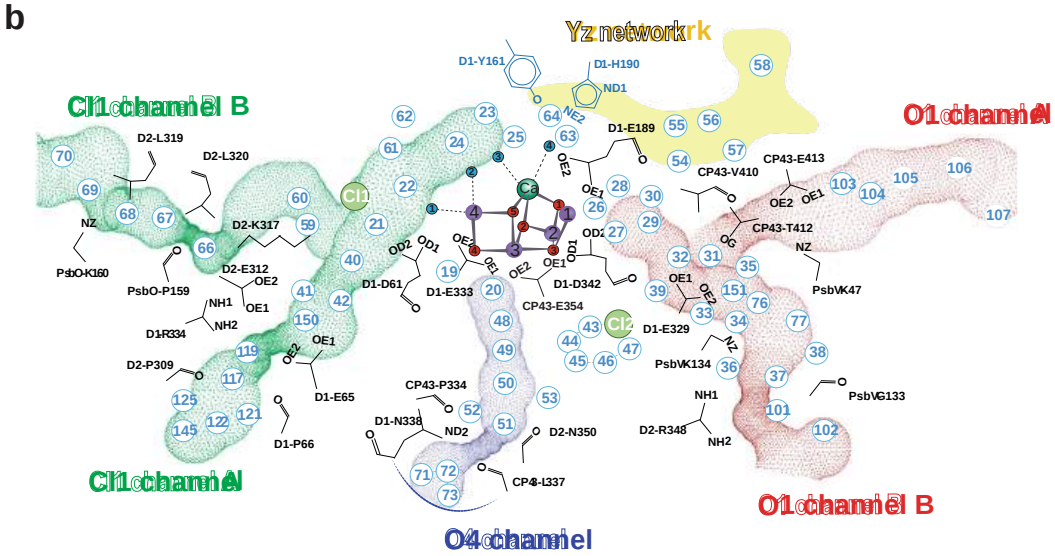

Figure 20.2.10: A detailed view of the water channels showing the waters within each channel (O1 Channel red dotted, O4 Channel blue dotted, and Cl1 Channel green dotted). The region highlighted with solid yellow represents the Yz network. Residues involved in forming bottlenecks in the channels are shown in black. Water molecules found in the crystal structures are labeled with blue numbers with the channel. Hussein, R., Ibrahim, M., Bhowmick, A., *et al.*, ibid.

These structures show that there is no direct water pathway from across the OEC and that all channels restrict water movement to some degree. The O4 and Cl1 channels are narrower than the O1 channel so water in those is less mobile. In the O4 channels, waters 50-53 are

near charged groups and are close to a major bottleneck (residues D1-N338, D2-N350, and CP43-P334, -L334).

Based on the x-ray structures and molecular dynamic simulations, it appears that the O1 channels allow access of water to the OEC. The Cl1 channel A, which is more rigid, may be involved in H^+ transfer during $S_2 \rightarrow S_3$.

20.2.5: THE LAST STEP: ELECTRON TRANSFER TO PLASTOQUINONE

We are almost ready for the next section in which we will present the flow of electrons away from PSII through mobile electron carriers, leading to the synthesis of NADPH for the reductive biosynthesis of carbohydrates. Before we leave PSII, let's look at what happens to the radical anion $P680^-$, also known as $PheA^-$ (**pheophytin A**) or $PheA_{D1}$, the reaction center chlorophyll without a central Mg^{2+} ion) which received an electron from photooxidation of the reaction center P680, as summarized again in Figure 20.2.11.

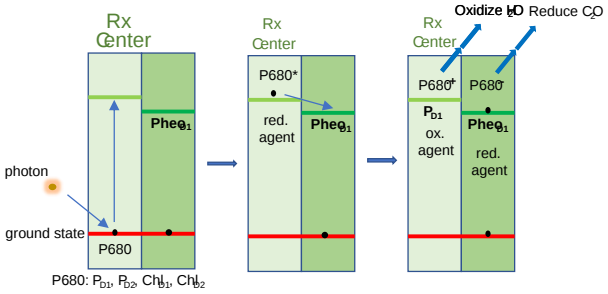

Figure 20.2.11: The reaction center electron transfer reactions in PSII.

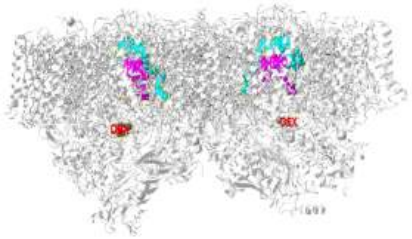
Pheophytin A$^-$ passes its electron to plastoquinone A (in PSII). which passes it on to the lipophilic mobile electron carrier in the thylakoid membrane plastoquinone. It is similar to the mobile electron carrier in mitochondrial electron transport, ubiquinone. Ultimately these are passed to $NADP^+$ to form NADPH for reductive biosynthesis.

Figure 20.2.12 shows an interactive iCn3D model highlighting just the OEX, pheophytin A (PHO), and plastoquinone A (PL9) in photosystem II from Thermostichus vulcanus (3WU2). (long load time).



NCBI iCn3D Figure 20.2.12: the OEX, pheophytin A (PHO), and plastoquinone A (PL9) in photosystem II from Thermostichus vulcanus (3WU2). (long load time). (Copyright; author via source). Click the image for a popup or use this external link:https://structure.ncbi.nlm.nih.gov/i...H7Mycbx1PsFbt6

The OEX (OEC) is shown in spacefill, CPK colors, PHO is shown in spacefill magenta, and PL9 in spacefill cyan. Note the proximity of PHO and PL9 for easy electron transfer to plastoquinone A.

Given the number and proximity of high-energy reactive species in the reaction center, it should not be surprising that side reactions can occur. These would decrease the efficiency of light energy transduction and also could damage molecular components of PSII (and similarly PSI)

Figure 20.2.13s shows a standard reduction potential diagram for the **P**680 - **Phe**ophytin A - Plasto**Q**uinone **A** triad (abbreviated P Phe Q) in PSII.

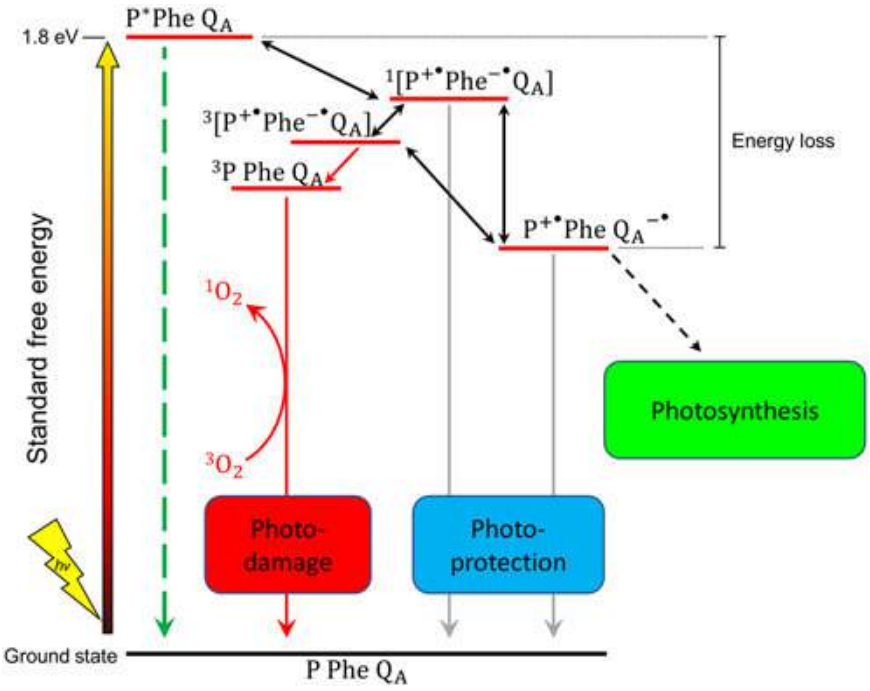


Figure 20.2.13: Charge recombination pathways in PSII (The energy gaps are not drawn to scale). Cardona T, Shao S, Nixon PJ. Enhancing photosynthesis in plants: the light reactions. *Essays Biochem*. 2018;62(1):85-94. Published 2018 Apr 13. doi:10.1042/EBC20170015Creative Commons Attribution License 4.0 (CC BY).

Safe routes for charge recombination between P^+ and Q_A^- are indicated in blue, the damaging route producing $^1O_2$ in red, and the radiative pathway in green. Stabilization of the $P^+PheoQ_A^-$ state helps prevent reverse electron flow to form $P^+Pheo^-Q_A$ and subsequent charge recombination to form $PPheoQ_A$. For clarity, the details of the additional electron transfer steps, including the oxidation of water and the reduction of plastoquinone to plastoquinol by PSII, collectively termed photosynthesis, are omitted. Abbreviations: P, primary electron donor of PSII; Pheo, pheophytin electron acceptor; Q_A, primary plastoquinone electron acceptor; $^1O_2$, singlet oxygen; $^3O_2$, triplet oxygen; ^3P, triplet excited state of P.

20.3: PLANT ELECTRON TRANSPORT AND ATP SYNTHESIS

Search Fundamentals of Biochemistry

20.3.1: INTRODUCTION

In the previous sections, we studied light absorption by chlorophylls, the transfer of energy to the reaction center of photosystem II, the oxidation of H_2O by the oxygen-evolving complex (OEC), and the transfer of electrons from these events to the lipophilic carrier of electrons, plastoquinone. Now we are ready to see how the process continues as electrons are passed on from reduced plastoquinone to the cytochrome b_6f complex, through photosystem I (which has no OEC) and on to the terminal electron acceptor $NADP^+$, which forms NADPH. This is used for reductive biosynthesis of glucose after fixation of atmospheric CO_2 by ribulose bisphosphate carboxylase (RuBisCo). As we saw in mitochondrial electron transport, this passage of electrons is accompanied by the movement of protons from the lumen to the stroma with the ultimate collapse back into the lumen through a rotatory ATP synthase to form the ATP required for reductive biosynthesis. Figure 20.3.1 reviews again the light reactions of photosynthesis.

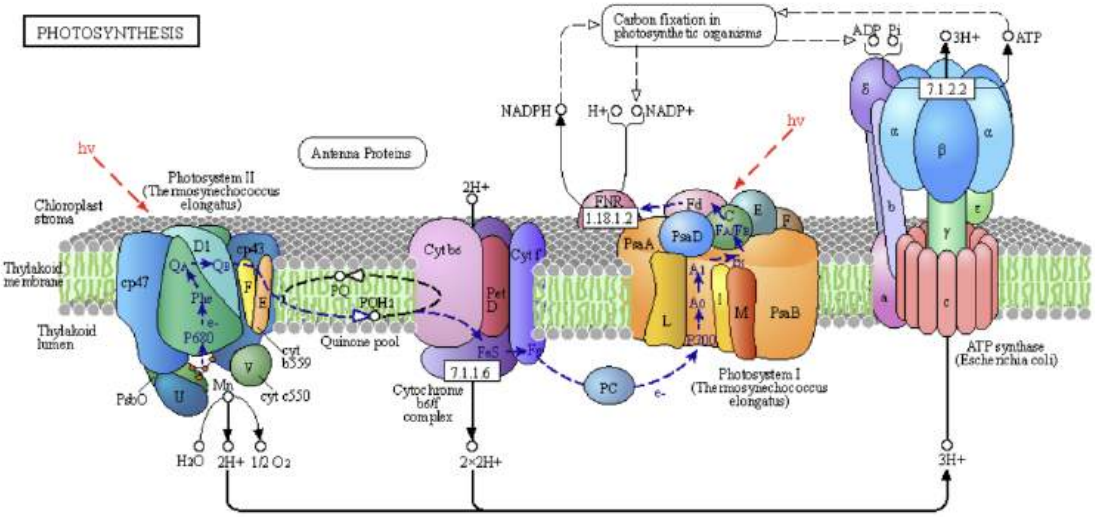

Figure 20.3.1: Light reactions of photosynthesis

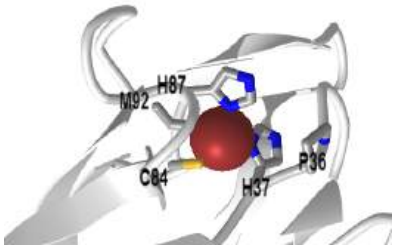
20.3.2: CYTOCHROME B_6F

This complex moves electrons from the mobile lipophilic electron carrier reduced plastoquinol (PQH_2), an isoprenoid quinone, to the mobile Cu-containing protein **plastocyanin**, which plays an analogous role to the mobile protein carrier in mitochondrial electron transport, cytochrome C. It catalyzes the rate-limiting step in electron transport in the light reactions. Figure 20.3.2 shows an interactive iCn3D model of the spinach plastocyanin (1AG6)



NCBI iCn3D Figure 20.3.2: Spinach plastocyanin (1AG6). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...DwSDDrYMUb9Xn7

The complex that mediates electron transfer between reduced plastoquinone and the protein plastocyanin, cytochrome b_6f, is centrally positioned between the two photosystems. In addition, it moves 2 H^+s from the stroma into the lumen. These are joined by 2 H^+s from the oxidation of water by the OEC (on the luminal side of PSII) to create a transmembrane proton gradient, which will power ATP synthesis.

Electrons transfer with cytochrome b_6f takes place through the quinol (Q) cycle in a similar fashion to Complex III in mitochondrial electron transport so we won't go into much detail here. Figure 20.3.3 shows a summary diagram with electron and proton flow.

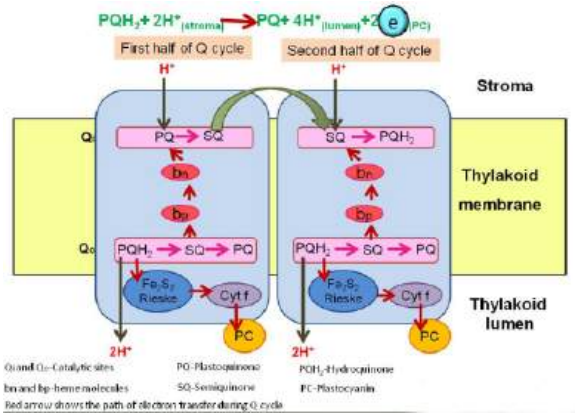


Figure 20.3.3: Q cycle in the cytochrome b6f complex of photosynthesis. https://twitter.com/BiologyNowadays/...232768/photo/1

Figure 20.3.4 shows another version of the Q cycle as an alternative representation.

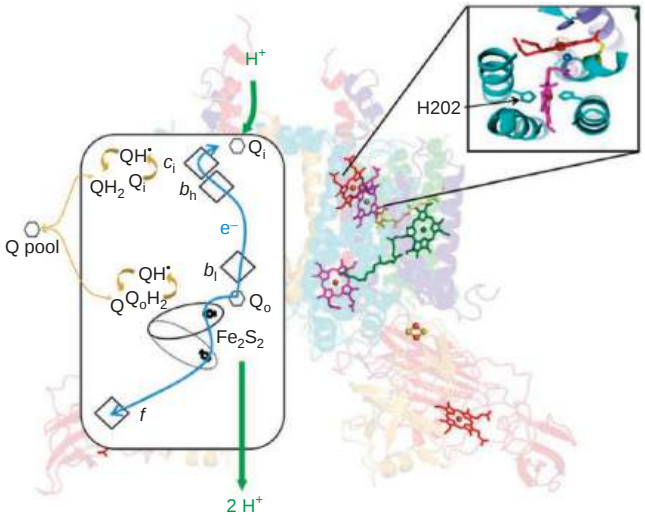

Figure 20.3.4: Alternative version of the photosynthetic cytochrome b_6f Q cycle. Malnoë et al. *Nat Commun* **2,** 301 (2011). https://doi.org/10.1038/ncomms1299. Creative Commons Attribution-NonCommercialShare Alike 3.0 Unported License. http://creativecommons.org/licenses/by-nc-sa/3.0/

The left box shows the *b*$_6$*f* complex transfers two protons (green arrows) per electron transferred (blue arrows) along high (Fe_2S_2 cluster, cytochrome $_f$) and low potential chains (b_l, bh, c_i hemes) as well as Quinol (QH_2) oxidation at Q_o site, Quinone (Q) reduction at Q_i site. The right structure depicts haems *b* (purple), c_i and f (red), Fe_2S_2 cluster (yellow and orange ball-and-stick model), cytochrome b_6 (cyan), subunit IV (blue), Rieske subunit (yellow), cytochrome *f* (red), PetG, L, M and N subunits (green). Magnification of Q_i site comprising b_h and c_i haems.

Both cytochrome bc1 and cytb_6f are dimeric complexes, with 2 Fe_2S_2 clusters, two cytochrome bs, and a cytochrome c. The cytb_6f complex also has 9-cis β-carotene and additional c1 heme. The electrons move from PQH_2 through the complex in a similar fashion as in the bc1 complex.

PQH_2 is oxidized at the Q_p site with a bifurcation of electrons:

- one electron moves through the high potential Fe_2S_2 center and cyt f pathway (bottom left in pathway diagram of Figure 3), with the electron moving to the soluble peripheral protein plastocyanin and one to photosystem I.
- the other moves through the low potential b_l, bh, c_i hemes pathway (top left in pathway diagram of Figure 3), with the electron moving to a plastoquinone at the Qn site near the stroma. A second round of oxidation of PQH_2 at the Q_p site eventually donates another electron to a plastoquinone$^{-\cdot}$ which regenerates PQH_2 after addition of 2 H^+ from the stroma.

Having two successive oxidations of PQH_2 leads to twice the number of protons moving into the lumen. In the process 2 H^+ move into the lumen. Cytochrome b_6f also is a redox sensor of the status of the plastoquinol/plastoquinone pool.

Figure 20.3.5 shows an interactive iCn3D model of the spinach cytochrome b6f complex (6RQF)

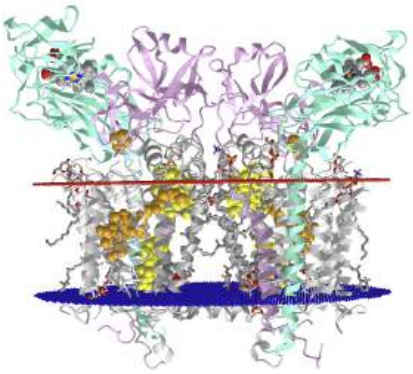

Figure 20.3.5: Spinach cytochrome b6f complex (6RQF). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...tgUhjekB4Tndw6

The region away from the red leaflet represents the lumen side of the complex. The FeS cluster and heme C are in the luminal domains. The coloring scheme is as follows:

- cytochrome bcf subunits 4, 5, 6, 7, and 8: light gray
- cytochrome b6: dark gray
- cytochrome b6 FeS subunit: plum
- cytochrome F: cyan
- chlorophylls: orange spacefill, labeled
- FeS clusters: CPK spacefill, labeled
- HEC - Heme C: CPK spacefill, labeled
- heme - porphoryin IX containing Fe: yellow spacefill

Cytochrome b_6f is the rate-limiting step for electron flow but what it's role in regulating the photosynthetic pathway (light reaction plus the dark reaction of carbon metabolism? Data suggest that the complex regulates electron transport in low light conditions but effects a switch to carbon metabolism under saturating light. Johnson and Berry have analyzed electron flow with carbon metabolism in a fashion analogous to transistors in a circuit board, as illustrated in Figure 20.3.6.

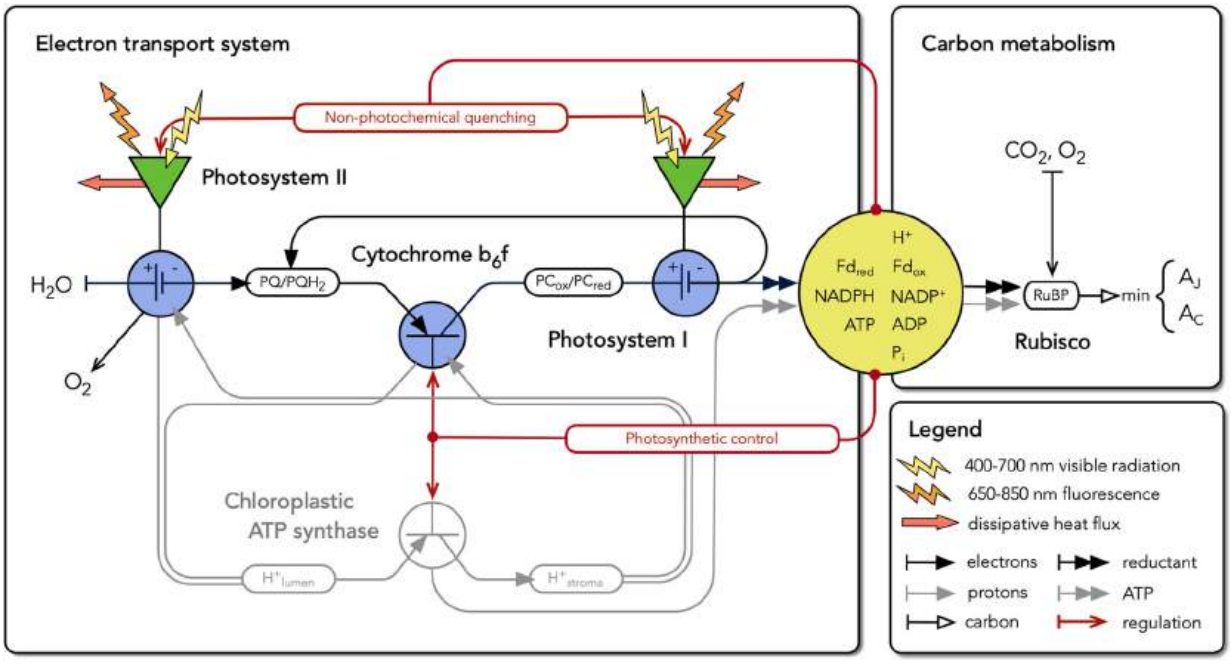

Figure 20.3.6: Electron transport system as an electrical circuit (and associated text below). Johnson and Berry. Photosynthesis Research (2021) 148:101–136. Creative Commons Attribution 4.0 International License. http:// creativecommons.org/ licenses/by/4.0/.

They define a transistor as a regulated circuit element that uses variable conductance to control current flow. The linear flow of electrons from water to reductant is viewed as a light-driven current that is under the control of many regulatory feedbacks stemming from carbon metabolism. In limiting light, Cyt b_6f presents maximal conductance to flow, and feedback from carbon metabolism adjusts the excitation of

PS I and PS II in such a way as to balance the relative rates of linear and cyclic electron flow to the NADPH, Fd, and ATP requirements of the sinks. When the light becomes saturating, feedback from carbon metabolism also decreases the apparent conductance of Cyt b_6f, controlling the linear flow of electrons through the plastoquinone pool and the associated flow of protons into the thylakoid lumen. In this way, the regulation of Cyt b_6f simultaneously permits efficient photosynthesis and protects the system from photodamage.

This model is organized around the idea that the distribution of excitation between PS II and PS I is regulated in such a way as to minimize losses of absorbed light and maximize potential electron transport through Cyt b_6f. The expression for the potential electron transport rate has the form of a Michaelis-Menten expression for a single substrate (i.e., light), but describes the kinetic behavior of the entire electron transport chain (i.e., including both photochemical and biochemical reactions). It predicts that electron transport has a hyperbolic dependence on irradiance, with the maximum efficiency realized at the limit where absorbed irradiance goes to zero and the maximum speed realized at the limit where absorbed irradiance is infinite.

The trade-off between the speed and efficiency of potential electron transport is driven by the need for the supplies of reduced plastoquinone and oxidized plastocyanin to be balanced to sustain Cyt b_6f turnover at the maximum catalytic rate. This causes progressive closure of the PS II and PS I reaction centers, with PS II accumulating in a reduced state and PS I in an oxidized state. As the excitation pressure on PS II and PS I increases, the closure of the reaction centers causes the photochemical yields of PS II and PS I as well as the absorbed quantum yield to decrease as the potential electron flow through Cyt b_6f and the potential photosynthetic rate increase"

The key prediction of the expression for the potential electron transport rate is that the maximum activity of Cyt b_6f defines the upper limit for the theoretical maximum speed of electron transport. The expressions describing feedback control over Cyt b_6f activity are based on the idea that Cyt b_6f functions like a transistor, i.e., a component of an electrical circuit that uses variable conductance to control current.

The fact that Cyt b_6f can modulate its conductance to linear electron flow within milliseconds of a perturbation in light suggests that photosynthetic control is the first line of defense against overexcitation, protecting the acceptor side of PS I from being flooded with highly reduced intermediates.

In response to a sustained increase in light, the induction of photosynthetic control is followed by the induction of PQ_N. As NPQ alleviates the electron overpressure in the PQ pool, photosynthetic control progressively relaxes. The two forms of regulation gradually settle to a steady state at the new light intensity. This interaction seems to allow electron transport to proceed at the Cyt b_6f-limited rate under low light intensities, and then smoothly switch to the Rubisco-limited rate once the light intensity is high enough to become saturating. It also seems to allow photosynthesis to operate safely and efficiently in a wide range of biochemical milieus, from those characteristic of natural variation in photosynthetic capacity (with balanced electron transport and carbon metabolism) to those characteristic of genetic manipulations (with imbalances in electron transport and carbon metabolism).

In this framework, the excitation balance of PS II and PS I and the maximum activities of Cyt b_6f and Rubisco emerge as key limits on system dynamics. For example, the trade-off between the speed and efficiency of electron transport is shown to be controlled by the excitation balance of PS II and PS I and the maximum activity of Cyt b_6f. The development of PQ_N is shown to be controlled by the excitation balance of PS II and PS I and the demand for linear electron flow (LEF) through the light reactions and circular electron flow (CEF) around PSI. The onset of photosynthetic control is shown to be dependent on the maximum activities of Cyt b_6f and Rubisco.

20.3.3: PLANT PHOTOSYSTEM I-LHCI SUPER-COMPLEX

If the goal of the photosystem complexes is to transduce light energy delivered by photons into electrons that can be used for reductive biosynthesis of glucose from atmospheric carbon capture of CO_2, then PSI is quite amazing. It has a "quantum efficiency" close to 1 which implies that one absorbed photon produces 1 electron that can be used to reduce $NADP^+$. This happens since the transfer of photon energy to other molecules in PSI is so quick compared to nonradiative decay processes for the excited state chlorophylls.

The same process for excitation and electron (charge) transfer that we saw in PSII occurs in PSI, with the chlorophyll in the reaction center involved in charge transfers. The light-absorbing molecules of PSI enable light at the far red of the spectra to be absorbed. The complex has 16 proteins, 155 chlorophyll, and 35 carotene derivatives. As with PSII, there is a core complex that is similar to cyanobacterial PSI. The supercomplex has in addition light-harvesting complex I proteins around one side of the complex (looking down on it) that have four LHCI proteins (Lhca 1-4) which allow for more absorption of life. They have 57 chlorophylls and 13 carotene derivatives.

The apoproteins that bind the chlorophylls, including the LHCI proteins, have similar but slightly different topologies, allowing for tuning of the absorbance spectra of the bound chromophores. Seven of the chlorophylls when bound have local environments that allow absorption of far red light. These are not found in PSII. the far red light would be more abundant in the low parts of the plant canopies as photons of lower wavelength would be more filtered out by upper leaves in the canopy.

Because of the complexity of PSI, we will offer several different iCn3D models to illustrate different features of the **photosystem I-LHCI super-complex**. As with PSII, PSI has a core with a surrounding light-harvesting complex (LHCI). Figure 20.3.7 shows an interactive iCn3D model of the Plant (pea) photosystem I-LHCI super-complex (4XK8)

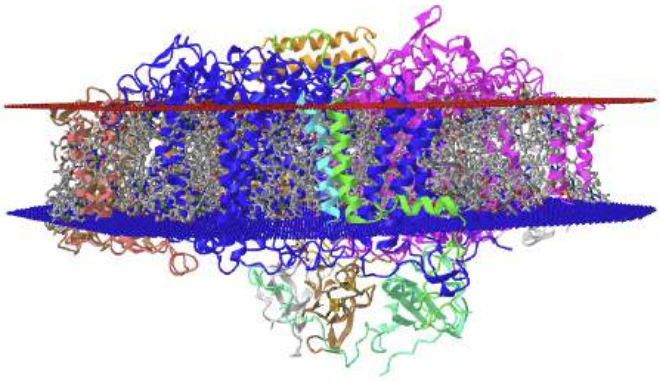

Figure 20.3.7: Plant photosystem I-LHCI super-complex (4XK8). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...uWBzFrVBUDHHQ6 (long load time)

Again the red leaflet represents the lumen side of the complex. Gray represents the chlorophyll and other lipids molecules in the complex. Here is the same complex but just the nonprotein components

Figure 20.3.8 shows an interactive iCn3D model of the lipid and FeS components of Plant photosystem I-LHCI super-complex (4XK8)

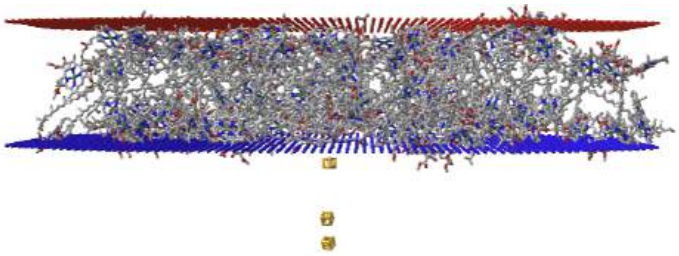

Figure 20.3.8: Lipid and FeS components of plant photosystem I-LHCI super-complex (4XK8). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?VtoCnxLRHQ8RPdESA (long load time)

The LHCI subunits (Lhca 1-4) are shown in alternating magenta and cyan cartoon structure surrounding one side of the core complex. The view in the model above is a top-down view.

We discussed in Chapter 20.1 that PSI absorbance is tilted toward the red end of the spectra, with the effective absorbance ratio over a broad wavelength range for the two photosystems, **PSI**/(**PSI**+PSII) deviating from around 0.5 at the red/far red end of the spectrum (670-730 nm), where the ratio is close to 1. When exposed to far-red light, the systems move to state I. In this state, the major mobile antenna proteins (LHCIIs) move to PSII to restore a "photoabsorption" balance. When exposed to light depleted in the high end of visual spectra, the system moves to state II, in which mobile LHCIIs move to PSI.

The location of LHCs is regulated by the phosphorylation of LHCs controlled by the levels of plastoquinone, which makes great biological sense. When the concentration of plastoquinones in the reduced state, PQH_2 (plastoquinol), is high, it would be optimal to increase the activity of PSI to relieve the high concentration of the substrate for cyto b_6f and shift the system to higher PSI activity and continue electron flow. This regulation is mediated by the phosphorylation of LHCs by LHCII kinase (a Ser/Thr kinase), which is activated by high reduced PQH_2 concentrations. Phosphorylation of LHCs leads to their movement from PSII to PSI. When the oxidized form for plastoquinone is high, LHCII kinase is inactivated by dephosphorylation, causing the mobile LHC to move back to PSII to increase output (PQH_2) from PSII. These events occur in low light. In high-light conditions, when the system is functioning at a high level, the LHCII kinase is inhibited by stromal thioredoxin. Specifically, the phosphorylation status of Lhcb1 and Lhcb2 in LHCII homo- or heterotrimers determine the movement between PSII and PSI. The chloroplastic serine/threonine-protein kinase (STT7 also known as STN7) is another LHCII kinase.

20.3.4: CHLOROPLAST ATP SYNTHASE - CF_1F_OATPASE

Finally, let's take a quick look at the ATP synthase in chloroplasts. It is similar in structure and function to mitochondrial FoF1ATPase so we won't spend much time on the mechanism. Like its mitochondrial counterpart, it is a rotary enzyme that transduces the free energy of a proton gradient collapse into chemical energy in the form of ATP. One difference is the rotary enzyme should be regulated by light levels with its activity decreased at night. This is accomplished in higher plants by conversion between a reduced and oxidized state, an effective redox switch, in one subunit (γ) of the ATP synthase. The deactivation is important at night since if the rotary enzyme runs in reverse, ATP hydrolysis would ensue.

Figure 20.3.11 shows an interactive iCn3D model of the reduced R1 state of chloroplast ATP synthase (R1, CF1FO) (6VON). It should look familiar to you given its similarity to mitochondrial ATP synthase.

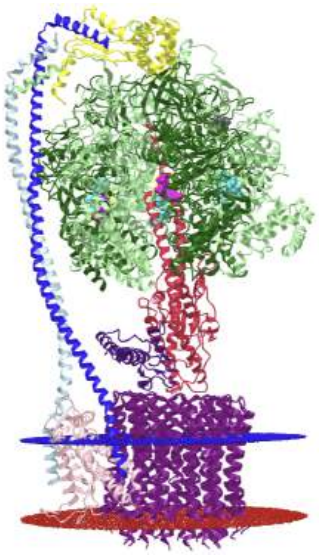

Figure 20.3.11: Reduced R1 state of chloroplast ATP synthase (R1, CF1FO) (6VON) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?hbnDCm1Kgqgu2k1NA (long load)

In the oxidized state, there is a disulfide in the γ subunit which inhibits torsion by stabilizing two β hairpins. This constraint is relieved on reduction and rotation is enhanced. In the reduced structure, tentoxin, an uncompetitive inhibit is present which allowed the structure to be determined.

below Yang, JH., Williams, D., Kandiah, E. *et al*. Structural basis of redox modulation on chloroplast ATP synthase. *Commun Biol* **3,** 482 (2020). https://doi.org/10.1038/s42003-020-01221-8. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

At night, the enzyme is in the low-activity form. When light becomes available in the day, the pH gradient collapse leads to the release of tightly bound ATP from the oxidized state of the enzyme. PSI can engage in photon-induced electron transfer to ferredoxin. This binds to NADP reductase and leads to NADPH formation. These processes are illustrated in Figure 20.3.12.

Figure 20.3.12: Fd bound to PSI is ferrodoxin and FNP is ferrodoxin NADP reductase.

Increased reduced ferredoxin leads to the formation of reduced thioredoxin, a small redox protein involved in redox signaling and protection of cells from oxidative stress. A similar process activates the enzyme sedoheptulose-1,7-bisphosphatase (SBPase) found in the dark reaction Calvin cycle of photosynthesis. Its activation is illustrated in Figure 20.3.13.

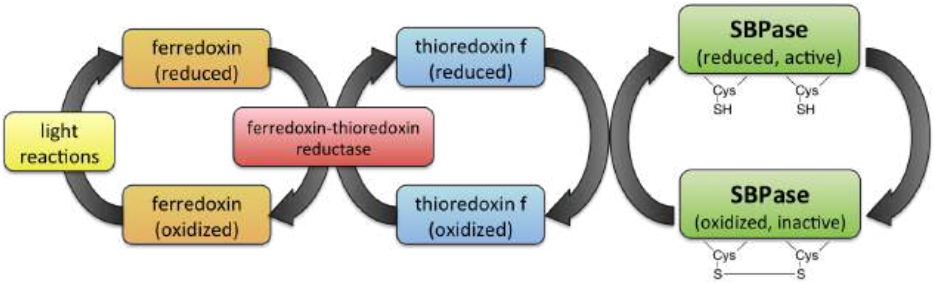

Figure 20.3.13: SBPase regulation by ferredoxin-thioredoxin system. https://commons.wikimedia.org/wiki/F...xin_system.png. Creative Commons Attribution-Share Alike 3.0 Unported l

Reduced thioredoxin also reduces and activates chloroplastic ATP synthase.

Figure 20.3.14 the activities and structures of the ATP synthase (CF_1F_O)

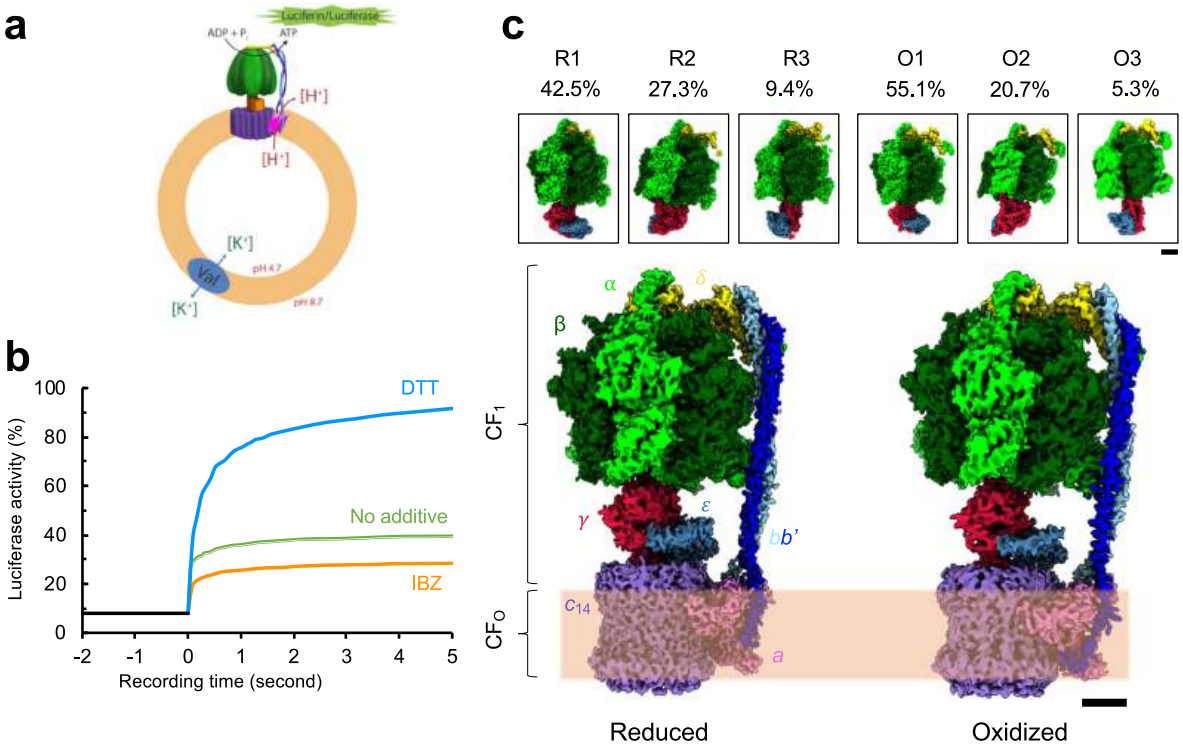

Figure 20.3.14 the activities and structures of the ATP synthase (CF_1F_O). Yang, JH., Williams, D., Kandiah, E. *et al.* Structural basis of redox modulation on chloroplast ATP synthase. *Commun Biol* **3,** 482 (2020). https://doi.org/10.1038/s42003-020-01221-8. Panel a: For the experiments, purified CF_1F_O was reconstituted into a liposome (orange) mixed with lipids of phosphatidylcholine and phosphatidic acid. The generated pH gradient across the membrane drove the reconstituted CF_1F_O to synthesize ATP molecules, which were detected using a luciferin/luciferase assay (green). Val indicates valinomycin.

Pane b: The activity of the enzyme is shown in the reduced state (in the presence of dithiothreitol - DTT, blue curve), oxidized state (in the presence of iodosobenzoate - IBZ, orange curve, and with no additive (green curve). Note that the activity is reduced by about 80% in the oxidized state.

Panel c: The images are from Cryo-EM density maps of the oxidized and reduced forms of the CF_1F_O. The color codes are as follows: α (light green), β (dark green), δ (yellow), *bb'* (blue and light blue), γ (crimson), ε (indigo), *a* (light pink), and *c* ring (purple). R indicates a reduced state, and O indicates an oxidized state. The three-dimensional (3D) reconstructions are categorized into three different rotary states (states 1, 2, and 3). The upper insets are the density maps of the F_1 domains.

Figure 20.3.15 shows the details of the conformation changes in the γ subunit between the oxidized and reduced forms.

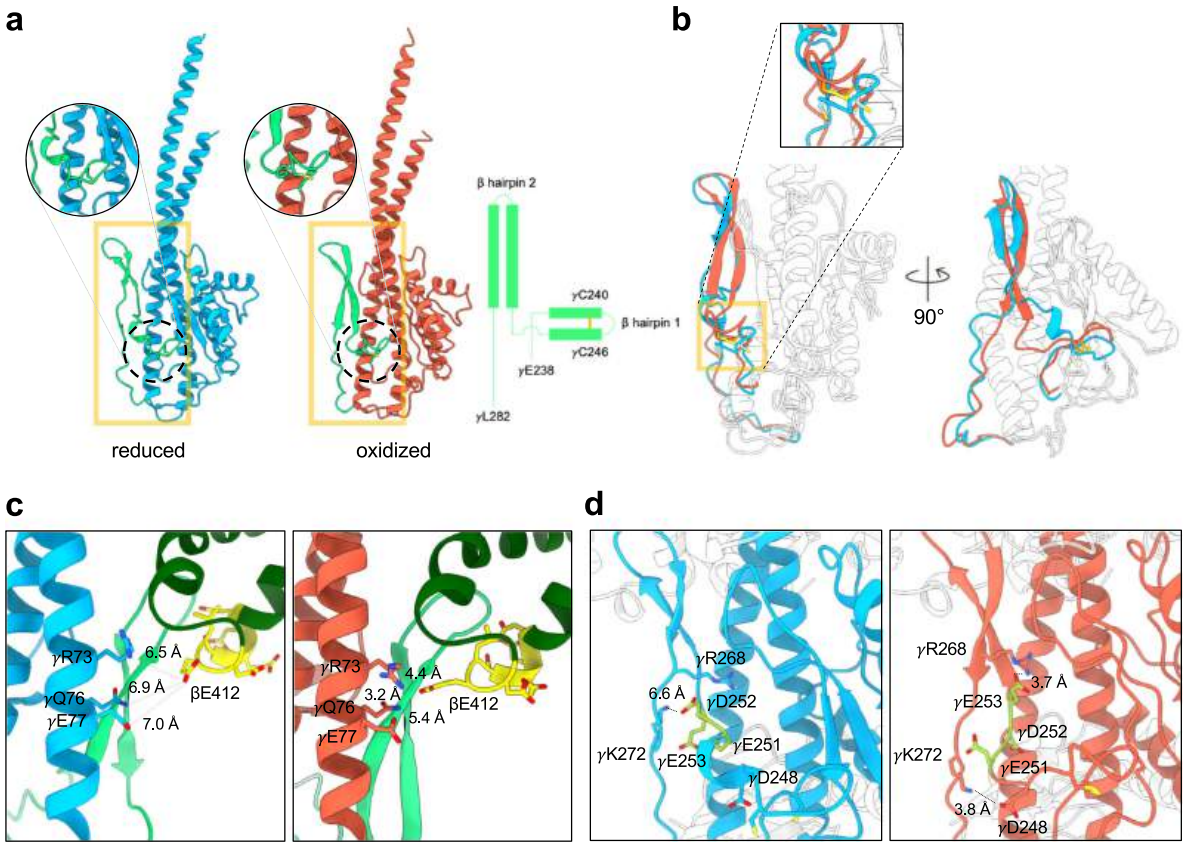

Figure 20.3.15: Conformation changes in the γ subunit between the oxidized and reduced forms

Panel a: Structures of the reduced (light blue) and oxidized (orange) γ subunits. Two β hairpin structures (from γGlu238 to γLeu282) are shown in light green, and the two cysteines of the redox switch are shown in yellow in circular enlarged views. The diagram on right shows the topology of the two β hairpin structures.

Panel b Superposition of the reduced and oxidized γ subunits (RMSD 1.016 Å). The two β hairpins are shown in light blue and orange for the reduced and oxidized forms, respectively. Other regions are shown in white.

Panel c Interaction networks of the β hairpin 2 and βDELSEED motif. The left and right panels are the reduced (γ subunit in light blue) and oxidized (γ subunit in orange) forms. Light green represents the β hairpin 2, dark green for the β subunit, and yellow for the βDELSEED motif. The distances connecting the residues of the γ coiled-coil (γArg73, γGln76, and γGlu77) with the βGlu412 are labeled.

Panel d Interaction of the EDE motif with the γ subunit. The EDE motif (yellow) does not interact with any part of the reduced γ subunit but forms an extensive interaction network with its neighborhood when the γ subunit is oxidized.

Figure 20.3.16 shows a cartoon model illustrating the structures of the overall oxidized and reduced states of ATP synthase

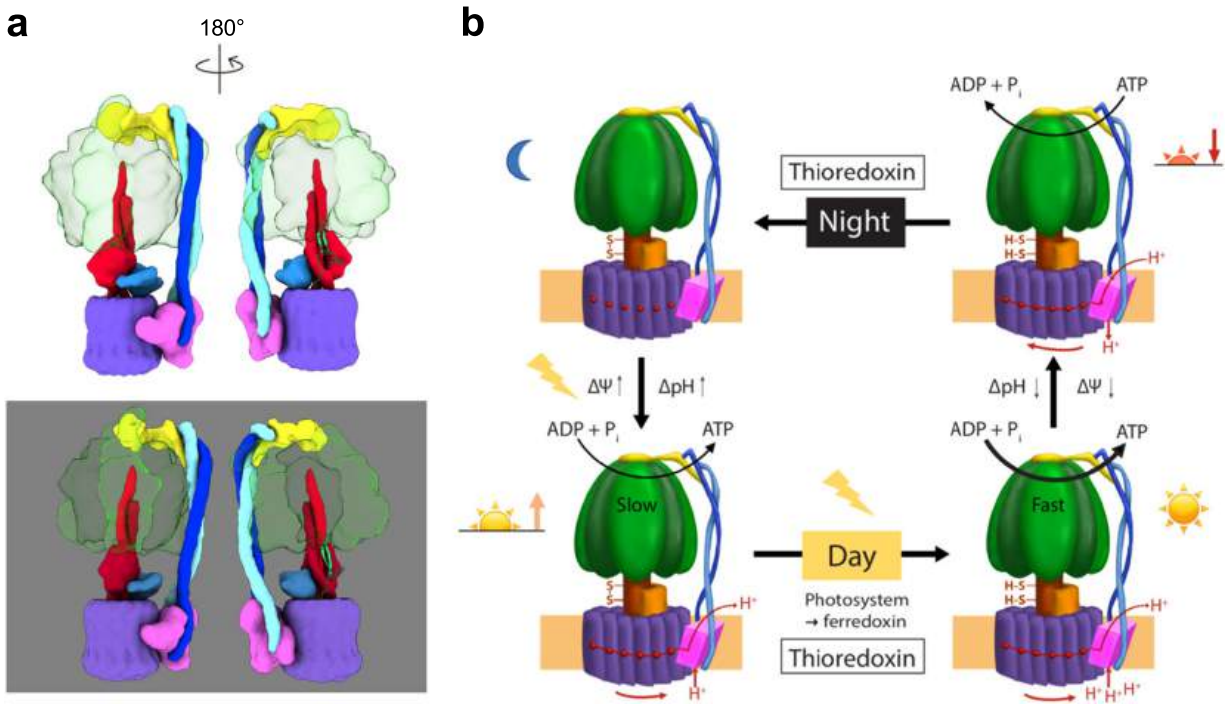

Figure 20.3.16: cartoon model illustrating the structures of the overall oxidized and reduced states of ATP synthase

Panel a: This shows a cartoon schematic of the redox modulation. The upper and lower models are the reduced and oxidized states, respectively. Color codes are the same as in Fig. 1c and the β hairpin structures of the γ subunit are shown in light green. The two redox states are aligned in the same view.

Pane b: At night, no energy input from light is available for the photosynthetic electron transport chain, and thus, no electrochemical potential (ΔΨ) and proton gradient (ΔpH) are generated. The oxidized γ subunit prevents CF_1F_O from hydrolyzing ATP. During the day, light induces charge separation to generate an electrochemical potential across the membrane. Although the CF_1F_O begins to synthesize ATP molecules, the γ subunit is still oxidized while ΔΨ is small. The rate of ATP synthesis is not at its maximum. At sunrise, thioredoxin subsequently reduces the γ subunit, fully activating CF_1F_O. The molecular motor, consisting of the γ-ε central shaft and the c_{14}-ring, is free to rotate at full speed to maximize its ATP synthesis activity. Three ATP molecules per rotation of the c_{14} ring are produced. At sunset, the membrane becomes de-energized, leading to small ΔΨ and ΔpH, and the ATP hydrolysis starts to take place. To prevent ATP loss from excess ATP hydrolysis, the γ subunit is then oxidized again. This process of light regulation and redox modulation on the CF_1F_O will cycle daily.

20.4: CO_2 UPTAKE - CALVIN CYCLE AND C3 ORGANISMS

The source for the organization and some of the text derives from: Sindayigaya and Longhini. https://www.peoi.org/Courses/Courses...chem/biochem18 CC - https://creativecommons.org/licenses...sa/3.0/deed.en

20.4.1: INTRODUCTION

We focused on the light reactions of photosynthesis. Now let's turn our attention to the dark reactions which fix CO_2 from the air and reduce it with NADPH produced, along with O_2, in the light reactions, to produce carbohydrates. The dark reactions don't just occur in the dark. The term is simply used to differentiate them from the light-driven reactions using PSII and PSI. What is so interesting about plants is they produce fuel from CO_2 using photons as a source of energy (they are autotrophs) and also consume the fuels they make, using both anaerobic and aerobic respiration pathways. Their biosynthetic reactions take place mostly in the chloroplast, a type of plastid, which are subcellular organelles with specific functions such as photosynthesis or metabolite synthesis and storage. Plants also can not move to acquire fuel and nutrient molecules. They are subject to a large range of growing conditions (differential light qualities and quantities, temperatures, and rainfall levels). Also, plant cells have cell walls in addition to a cell membrane. A simple cartoon showing the major motifs of photosynthesis is shown in Figure 20.4.1.

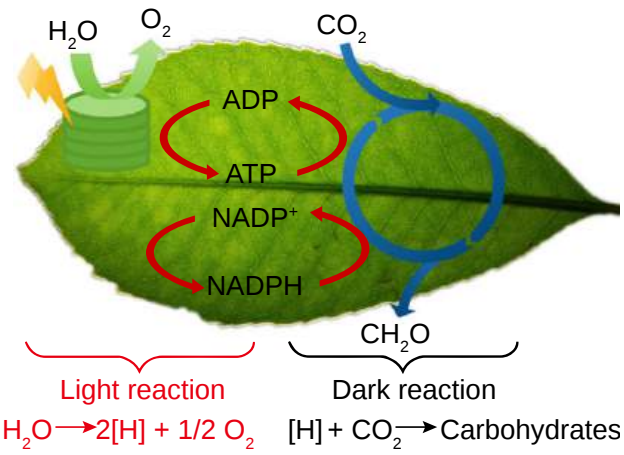

Figure 20.4.1: **a** Schematic depiction of the light and dark reactions in natural photosynthesis. Li, Y., Hui, D., Sun, Y. *et al.* Boosting thermo-photocatalytic CO_2 conversion activity by using photosynthesis-inspired electron-proton-transfer mediators. *Nat Commun* **12,** 123 (2021). https://doi.org/10.1038/s41467-020-20444-1 Creative Commons Attribution 4.0 International License.

In this section, we will discuss how CO_2 from the atmosphere is "fixed" or "captured" in the formation of the simplest sugars (3 carbon molecules like glyceraldehyde-3-phosphate) in a process called the **C3 or Calvin Cycle**, which is also called the Calvin–Benson–Bassham (CBB) cycle, or the reductive pentose phosphate cycle (RPP cycle). Plants that use the C3 cycle are logically called C3 plants There are two other major types of carbon capture pathways, the C4 and CAM pathways, which we discuss in the next section. All use a key enzyme, **ribulose 1,5-bisphosphate carboxylase (RuBisCo)**, to covalently fix CO_2 into small carbohydrates, 3-phosphoglycerate. **RuBisCo** is the most abundant protein in the biosphere. Recent estimates suggest that there are about 0.7 gigatons (Gt = 10^{12} tons) of it, with over 90% in the leaves (about 3% of their weight) of terrestrial plants. It captures about 120 Gt of atmospheric CO_2 each year. This enzyme has a second competing enzymatic activity. It is also an **oxygenase**, which adds to its complexity. That activity captures about 100 Gt of atmospheric O_2 each year. In this chapter section, we will give an overview of the C3 pathway and given the importance of RuBisCo, we will focus on it predominately.

Along RuBisCo, plants have pathways to take the fixed CO_2 to 3C sugars and then a unique pentose pathway which runs in a reductive fashion to ultimately produce the sugar-containing molecules in plants we are most familiar with, sucrose and the glucose polymer starch.

20.4.2: PLASTIDS

There are several types of these organelles. Photosynthesis occurs in chloroplast which has its own genome, like the mitochondria. Another common type is the amyloplasts, which lack pigmented molecules (i.e. they are colorless) and have no inner membrane. In plants, they are filled with starch. Chloroplasts and amyloplasts can interconvert. Chloroplasts are abundant in green leaves while amyloplasts are predominately found in locations like potato tubers where starch is stored. Light can drive the interconversion of plastids as shown in Figure 20.4.2.

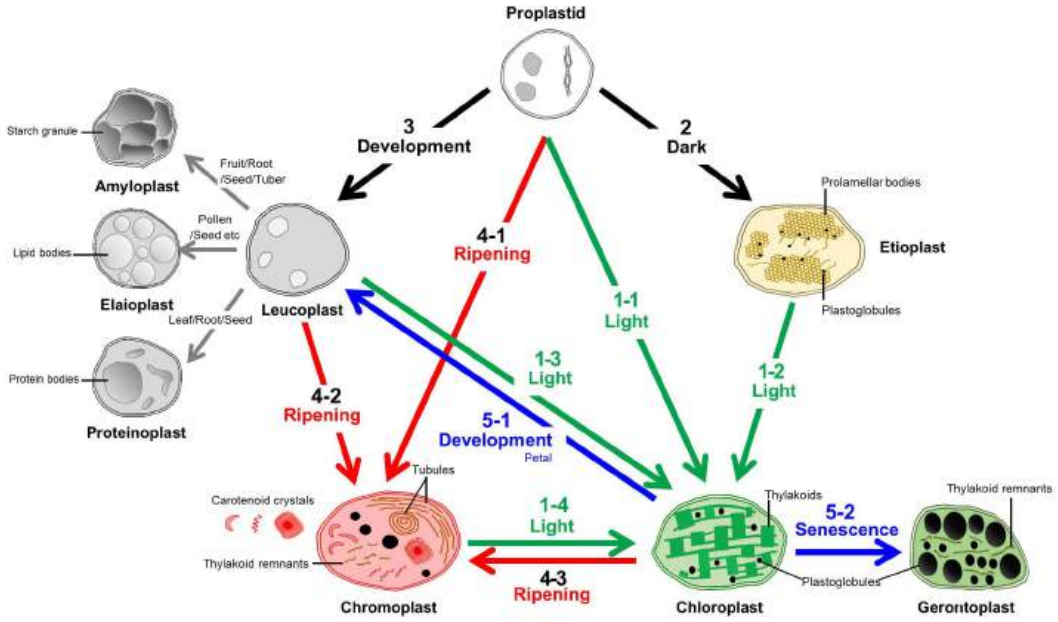

Figure 20.4.2: Transition pathways among various plastids. Choi et al. Frontiers in Plant Science. 12 (2021). https://www.frontiersin.org/article/...ls.2021.692024. DOI=10.3389/fpls.2021.692024 . **Creative Commons Attribution License (CC BY)**

The characteristics and plastid interconversion pathways of the plastids are shown by arrows. The transition to a chloroplast is called “Greening” and is identified with the number “1”. This is mainly triggered by light signals from proplastids, etioplasts, leucoplasts, and chromoplasts. Etioplasts can develop from proplastids in dark conditions and this is identified by the number “2”. The number “3” indicates leucoplast development that is triggered by diverse development processes to generate starch, lipid, and protein-enriched sub-types called amyloplasts, elaioplasts, and proteinoplasts, respectively. Mainly during the ripening stage, diverse types of carotenoid crystals were generated within the plastids called chromoplasts from the proplastids, leucoplasts, and chloroplasts and this is identified with the number “4”. Together with etioplast and leucoplast development (2,3), chromoplast development (4) was identified as a “Non-greening” plastid transition. The loss of green color from the chloroplasts is called “De-greening” and is identified with the number “5”, and these chloroplasts are then transited into leucoplast or gerontoplast by developmental regulation or during senescence, respectively.

20.4.3: CO_2 CAPTURE AND THE C3 CYCLE

There are in the synthesis of the simplest carbohydrates (3 carbon polyhydroxy- aldehydes and ketones:

1. Carbon capture or fixation phase. We prefer the term carbon capture as this term is now used to describe how the world is seeking new ways (other than planting billions of trees) to "capture" excess CO_2 emitted through the use of fossil fuels. In a reaction catalyzed by RuBisCo, atmospheric CO_2 ultimately react with a 5-carbon acceptor molecule, ribulose 1,5-bisphosphate (Ru1,5-BP, 6 carbons in total), to form two molecules of 3-phosphoglycerate (3PG). (2, 3C molecules).
2. Reduction phase: 3-phosphoglycerate is reduced to glyceraldehyde-3-phosphate (G3P). Three CO_2s are captured on reaction with 3 Ru1,5-BP to form 6 glyceraldehyde-3-phosphates (G3P). These can readily interconvert to the keto form, dihydroxyacetone phosphate (DHAP).
3. Regeneration phase: Five of the six G3Ps (15 Cs) react to form 3 three molecules of ribulose 1,5-bisphosphate (15 C2) to allow the catalytic C3 cycle to continue. The other G3P moves into the stroma, in the form of DHAP where it can be used in gluconeogenesis (reductive biosynthesis) of glucose. This can be converted to polymer starch and also the disaccharide sucrose (which we will discuss in a future session).

An overview of the Calvin or C3 cycle is shown below in Figure 20.4.3.

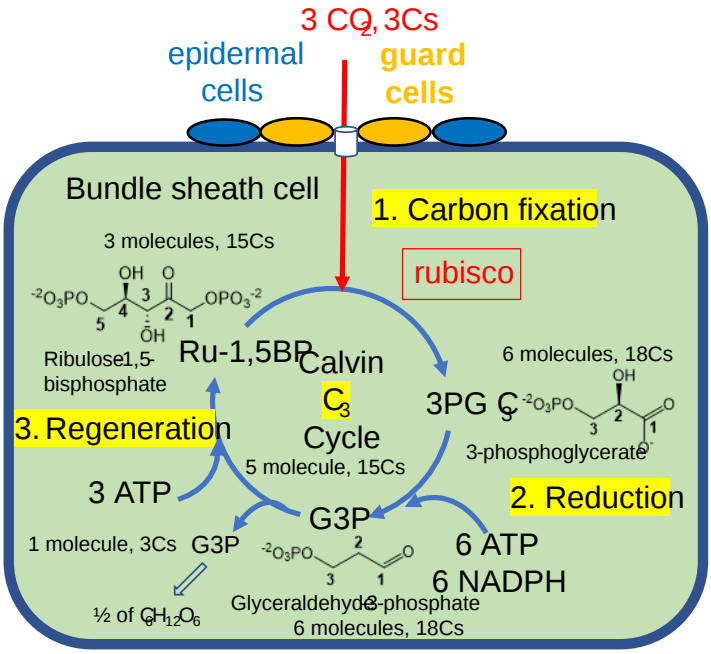

Figure 20.4.3: C3 or Calvin Cycle. The three stages of the cycle in C3 plants and organisms are shown. Three CO2 are captured for the net synthesis of one molecule of glyceraldehyde 3-phosphate.

The stoichiometry can be confusing until you count the actual number of carbon atoms and realize that the cycle has to run 3 times to enable 3 carbon atoms from 3 CO_2 molecules to produce one net glyceraldehyde-3-phosphate (G3P). The G3P leaves the C3 cycle at the low left for glucose synthesis. The conversion of the 5 G3Ps that reform Ru1,5-BP requires ATP as shown below:

$$5\,\text{glyceraldehyde}-3\,\text{P}+3\,\text{ATP}\rightarrow 3\,\text{ribulose}-1\,,5-2\,\text{P}+3\,\text{ADP}+2\,\text{Pi}$$

with Pi indicating inorganic phosphate. Hence the net equation for 3 turns of the cycle, sufficient to produce 1, G3P is:

$$3\,\text{CO}_2+6\,\text{NADPH}+6\,\text{H}^+ +9\,\text{ATP}+5\,\text{H}_2\text{O}\rightarrow \text{glyceraldehyde}-3-\text{phosphate}(\text{G}_3\text{P})+6\,\text{NADP}^+ +9\,\text{ADP}+8\,\text{Pi}$$

Even though glucose is not a product of the Calvin cycle, some texts use the following equation to show the stoichiometry to run the C3 cycle enough times (6) to fix 6 CO_2 molecules, enough to make 1 glucose from a simple carbon atom counting perspective.

$$6\,\text{CO}_2+12\,\text{NADPH}+12\,\text{H}^+ +18\,\text{ATP}+10\,\text{H}_2\text{O}\rightarrow 2\,\text{glyceraldehyde}-3-\text{phosphate}(\text{G}_3\text{P})+12\,\text{NADP}^+ +18\,\text{ADP}+16\,\text{Pi}$$

Remember that NADPH and ATP are produced in the light reactions in about the same ratio as they are used in the C3 cycle (2NADPH/3ATPs). The net 8 P_is made as products will react with 8 ADP to regenerate 8 ATP in the light reaction. The 9th Pi is incorporated in a triose-phosphate in the light reaction, so one Pi must be imported from the cytoplasm by an inner membrane triose-phosphate/phosphate translocator, which we will discuss below. In the dark, when ATP and NADPH are not produced, CO_2 capture also is inhibited.

A more detailed diagram showing the detailed reactions to regenerate ribulose 1,5-bisphosphate (Ru1,5BP) is shown in Figure 20.4.4.

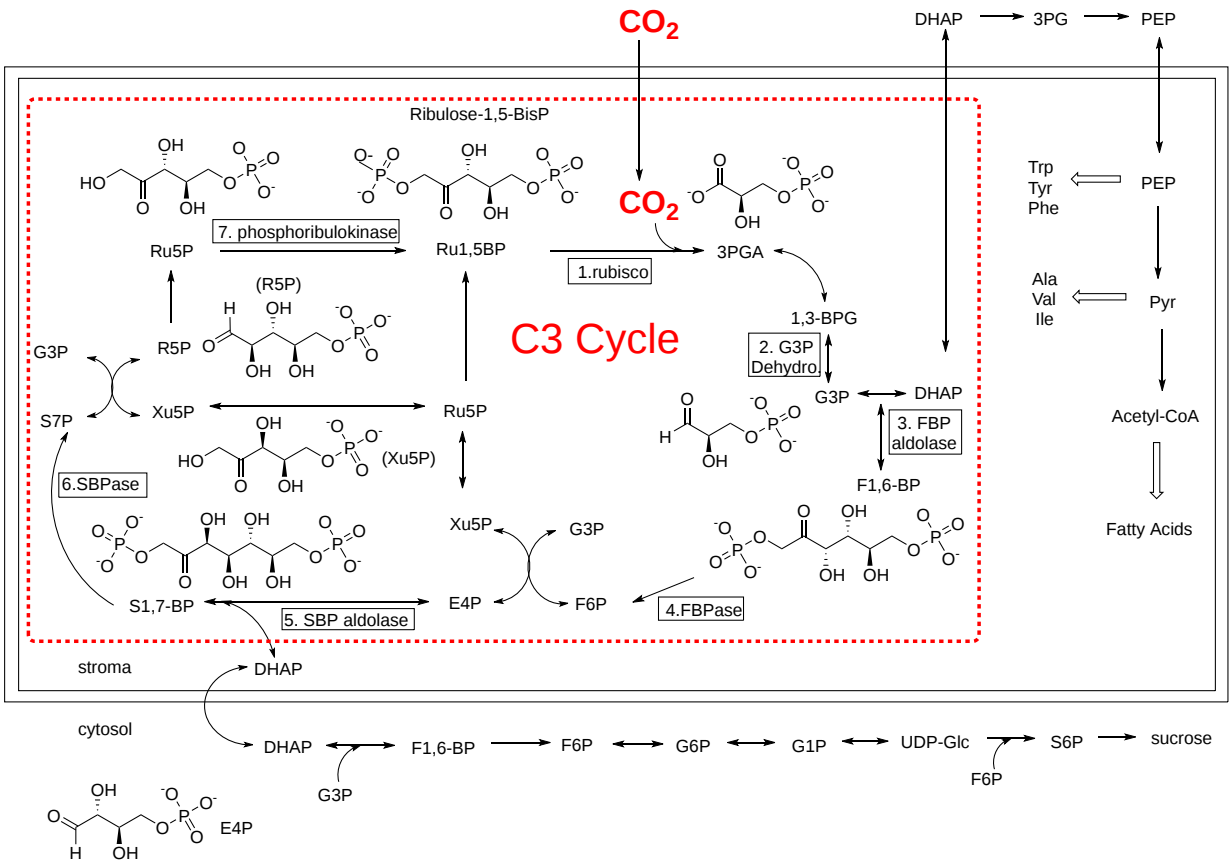

Figure 20.4.4: Detailed reaction diagram for the Calvin (C3) cycle (after Hashunuma et al. Journal of Experimental Botany, 61 (2010). doi:10.1093/jxb/erp374. Creative Commons Attribution Non-Commercial License (http://creativecommons.org/licenses/bync/2.5)

Abbreviated reactions for the synthesis of sucrose, glucogenic amino acids, and fatty acids are also shown.

You should note the reactions for the conversion of the 6C sugar molecule fructose-6-P (F6P) (glycolytic and gluconeogenic intermediate) to the 5C molecule Ru5P and Ru1-5BP, are analogous to the reactions of the nonoxidative part of the pentose phosphate pathway (PPP) pathway which generates 5C sugars for the synthesis of nucleotides, nucleic acids, and some amino acids. Hence we won't discuss them further.

20.4.4: CARBON CAPTURE OF CO2 INTO 3-PHOSPHOGLYCERATE - RUBISCO

This key enzyme requires a Mg^{2+} ion and proceeds through a carbamoylated lysine side chain. The Mg^{2+} ion orients key side chains. The resulting 6C molecule cleaves into two 2 molecules of 3PG.

The RuBisCo family of enzymes can adopt different quaternary structures. A homodimer of two large subunits is the minimum catalytic structure. Often there are in addition two small subunits. The most common form is a 16mer which is found in cyanobacteria, red and brown algae, and all higher plants.

A possible mechanism of RuBisCo from *Synechococcus elongatus*, a unicellular cyanobacterium, is shown in Figure 20.4.5.

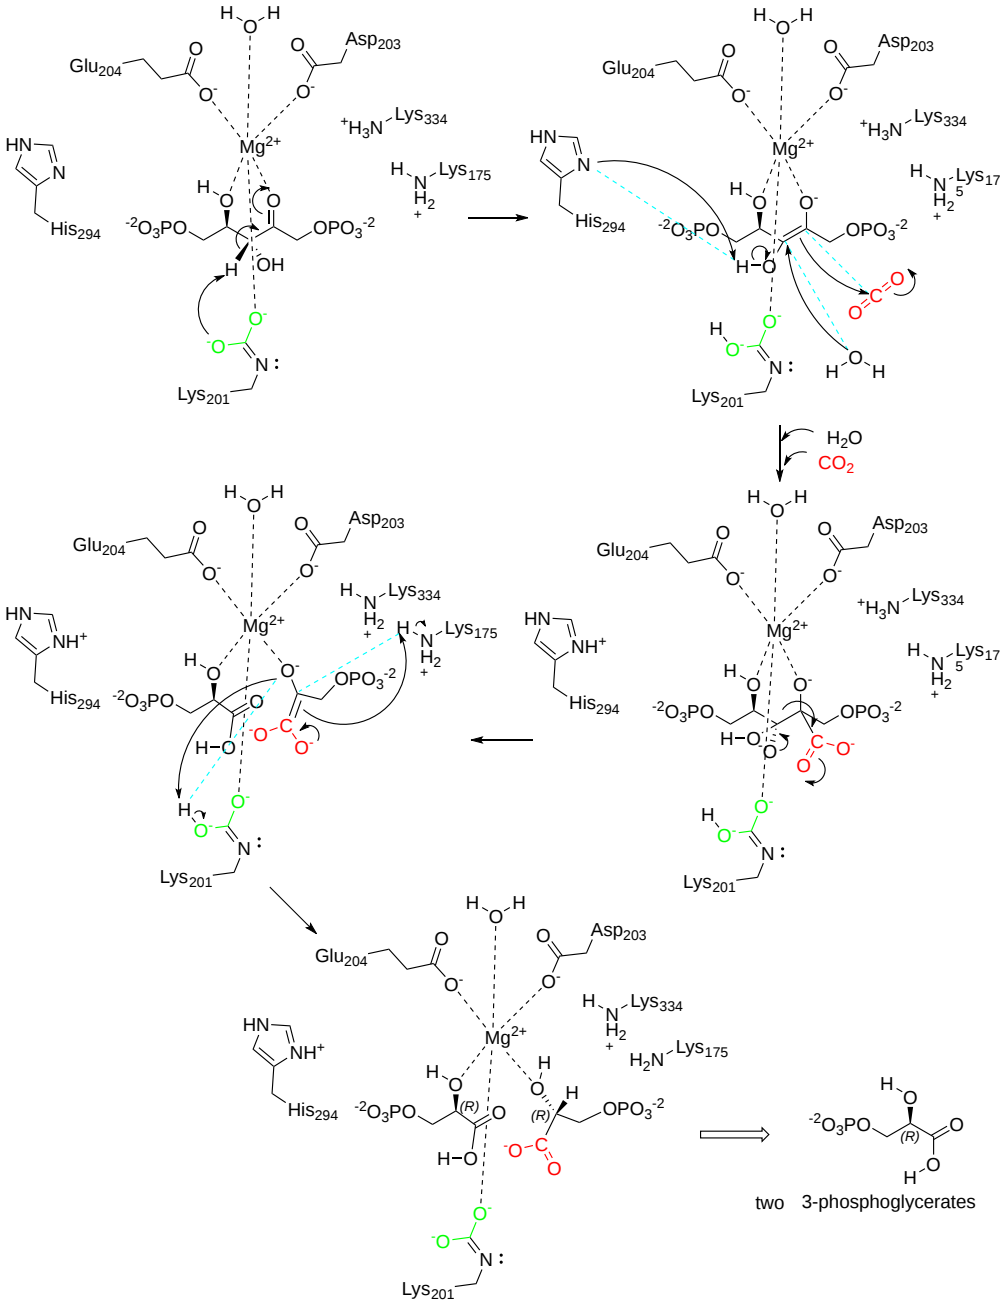

Figure 20.4.5: Mechanism of ribulose-bisphosphate carboxylase (type I) (after https://www.ebi.ac.uk/thornton-srv/m-csa/entry/907/. Creative Commons Attribution 4.0 International (CC BY 4.0) License)

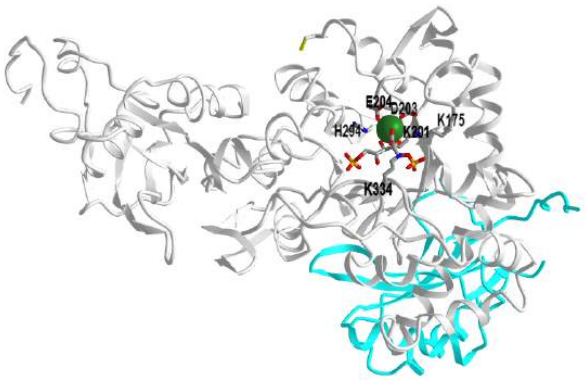
The carbamoylated lysine side chain is shown in green. Ribulose 1,5- bisphosphate is converted to an enediolate which engages in a nucleophilic attack on the CO_2 to form a 6C sugar. Hydroxylation at C-3 of this sugar is followed by aldol cleavage. Ultimately two 3PGs are produced, one of which contains the carbon atom from CO_2 (red).

Figure 20.4.6 shows an interactive iCn3D model of a single heavy and light chain of ribulose 1,5-bisphosphate carboxylase/oxygenase (RuBisCo) from Synechococcus PCC6301 (1RBL). (long load time)



NCBI iCn3D Figure 20.4.6: Ribulose 1,5-bisphosphate carboxylase/oxygenase (RuBisCo) from Synechococcus PCC6301 (1RBL). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...BkwkrBmYVwRJ6A

The light chain is shown in cyan and key residues in the heavy chain are shown in CPK-colored sticks and labeled. Bound to the heavy chain is a substrate analog/inhibitor, 2-carboxyarabinitol-1,5-diphosphate. It is produced in plants and in the dark, it inhibits the enzyme. With increasing lights, its concentration decreases.

Recent Updates (08/14/23) - Rubisco Reacts with both CO_2 and O_2

Rubisco is a slow enzyme with a k_{cat} of around 2-10 CO_2/sec. In addition, it can bind another substrate, O_2, and engage in a competing reaction of photorespiration (oxidation) of ribulose 1,5-bisphosphate to form one molecule of 3-phosphoglycerate (3PG) and one molecule of 2-phosphoglycolate (2PG), as shown (incompletely) in Figure 20.4.7 below.

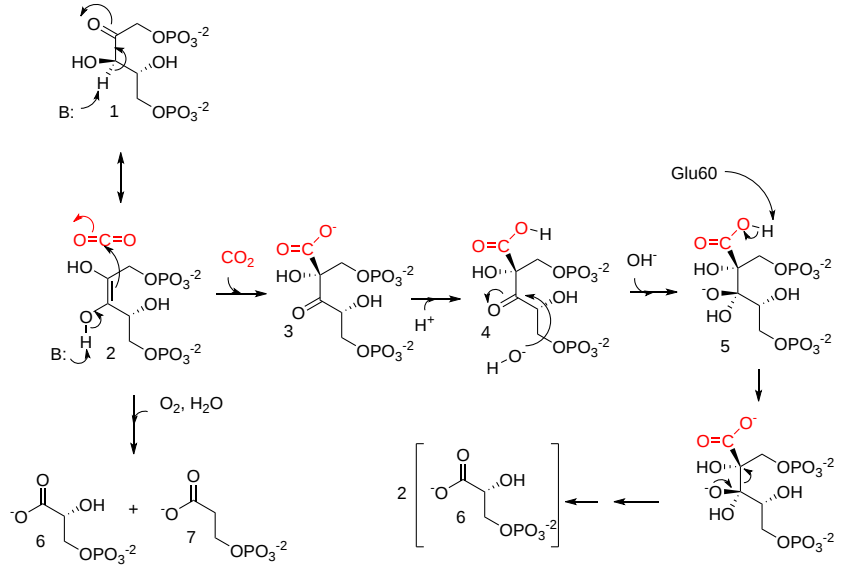


Figure 20.4.7: RuBP conversion by Rubisco through the carboxylase (a) and the oxygenase (b) reactions. Tommasi, I.C. The Mechanism of Rubisco Catalyzed Carboxylation Reaction: Chemical Aspects Involving Acid-Base Chemistry and Functioning of the Molecular Machine. *Catalysts* **2021**, *11*, 813. https://doi.org/10.3390/catal11070813. CC BY) license (https://creativecommons.org/licenses/by/4.0/

Following RuBP (1) enolization, the 2,3-enol(ate) intermediate (2) may react with CO2(a) or O2(b) co-substrates. The carboxylase reaction produces the 2-carboxy-3-keto-arabinitol 1,5-bisphosphate intermediate (3) undergoing protonation to the 2-carboxylic acid before hydration. The C2-C3-scission reaction in C3-gemdiolate (5) is described as occurring in a concerted mechanism upon P1 protonation

producing two molecules of 3-phospho-D-glycerate (3PGA, 6). The oxygenase reaction produces 3-phospho-D-glycerate (3PGA,6) and 2-phosphoglycolate (2PG,7)

How does the enzyme differentiate the two nonpolar substrates, CO_2 and O_2? Given the symmetric arrangement of δ^+ and δ^- charges in CO_2, it has a net 0 dipole, as does O_2, so it would not align/orient in a field generated by two poles (+ and -). However, CO_2, but not O_2, would align in a field generated by four charged poles so it has a **quadrupole moment**, as shown in Figure 20.4.8 below.

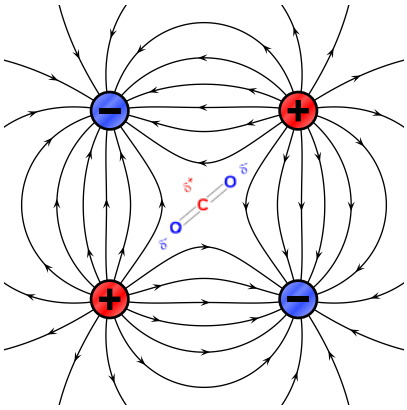

Figure 20.4.8: CO_2 aligning in a quadrupole field. (field lines from https://commons.wikimedia.org/wiki/F...quadrupole.svg)

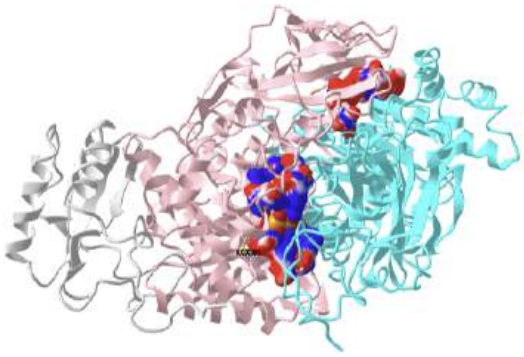
The dipole unit is the debye and the quadrupole unit can be expressed in debye·Angstrom. Table 20.4.1 below shows some values for dipole and quadrupole moments for simple gases. CO_2 has the highest quadrupole moment of all these simple gases.

Molecule	Dipole moment (D)	Quadrupole moment (D Å)
CO_2	0.000	4.30
CH_4	0.000	0.02
H_2	0.000	0.66
O_2	0.000	0.39
CO	0.112	2.5
N_2	0.000	1.52

Table 20.4.1: Dipole and Quadrupole moments for some simple gases. Castro-Muñoz, R., Fíla, V., 2018. Progress on Incorporating Zeolites in Matrimid®5218 Mixed Matrix Membranes towards Gas Separation. Membranes 8, 30.. https://doi.org/10.3390/membranes8020030

The active site has a high electrostatic field gradient in the dimeric form of the enzyme. Figure 20.4.9 shows an interactive iCn3D model showing the electrostatic potential surface in the active site between two heavy chains of spinach ribulose 1,5-bisphosphate carboxylase/oxygenase (RuBisCo) (8RUC). It shows that is complex.



NCBI iCn3D Figure 20.4.9: Electrostatic potential surface in the active site between two heavy chains of spinach ribulose 1,5-bisphosphate carboxylase/oxygenase (RuBisCo) (8RUC). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...2JG3x4csVnEq67

Two heavy chains are shown in light pink and cyan, and one light chain is shown in gray. The active site regions are shown as an electrostatic surface potential with blue positive and red negative. The model has an activated substrate analog, 2-carboxyarabinitol bisphosphate, shown spacefill (hard to see given the electrostatic surface potential). The residue labeled 201KCX is the carbamate of Lys201.

Presumably, the electrostatic field in the active site facilitates through subtle interaction of the quadrupole CO_2 compared to O_2.

The mechanisms that differentiate the binding of CO_2 and O_2 must also overcome the high intracellular concentration of O_2 (around 250 μM) compared to CO_2 (7–8 μM in C3 plants and 80 μM in C4 plants). The enhanced affinity for CO_2 (about 30-fold) compared to O_2 helps overcomes these concentration barriers. No classic "binding pocket" exists for CO_2 and O_2 so diffusion and binding is likely guided by the electrostatic potential gradients along the diffusion surface. Figure 20.4.10 below the electrostatic potential molecular surface of O_2 and CO_2 (top), calculated from electron density measurement using quantum mechanics, and the electrostatic surface of their binding pockets

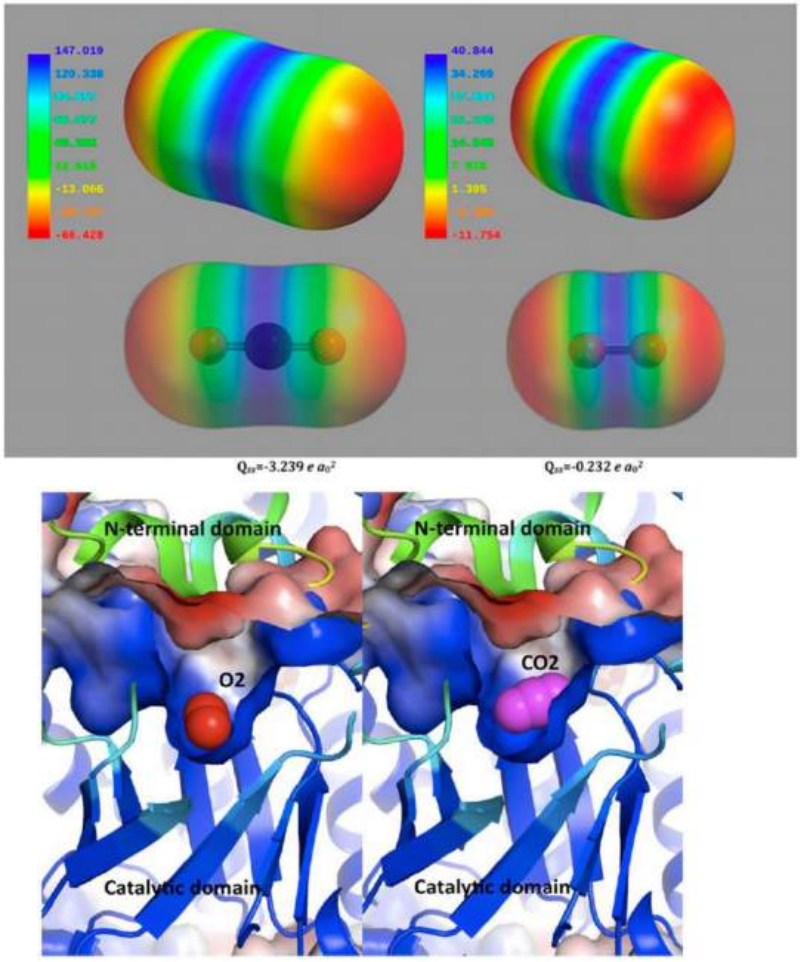


Figure 20.4.10: Electrostatic potential molecular surface of O_2 and CO_2 (top) and the electrostatic surface of their binding pockets. Tommasi, I.C. et al., ibid.

(**top**) Computed electrostatic potential molecular surfaces of CO_2 (left) and O_2 (right). The color scheme follows commonly accepted conventions: blue, positive; red, negative. The value of the Qzz component of the quadrupole moment, as calculated by Stec, is −3.239 e a_0^2 for CO_2 and −0.232 e a_0^2 for O_2. Note that the ratio of these values is about 14, about equal to the earlier quadrupole moments discussed above with units of debeye·Å)

(**bottom**) a ribbon representation of the catalytic domain with bound gaseous ligands and surfaces colored by the electrostatic potential. O_2 (in red) and CO_2 (in purple) lie in a positively charged cavity (blue) of the TIM barrel. (Figure from ref. [15], used by permission of PNAS (copyright © 2012)).

Both CO_2 and O_2 are situated in a tiny "cavity" that is blue (positive potential, C-terminal domain) and just above it red (negative potential, N-terminal domain). The quadrupole moment of CO_2 is 10-15x that of O_2 which helps explain its higher affinity in the localized electrostatic potential gradients around the gas molecules.

Molecular dynamic (MD) simulations show an interaction preference for CO_2. There are many subunit-subunit interfaces and all appear in MD to preferentially interact with CO_2, which probably moves from the solvent through large:small subunit interface to the active site. The CO_2 does not localize long at any residues but seems to occupy areas instead. Since CO_2 has no dipole, it locates more closely to small hydrophobic side chain (Ala, Val, Leu, Ile) and the main chain. CO_2 has more interaction in every active site as well as the large:large subunit interface (whose electrostatic potential in the active site is shown above) and in the large:small subunit interface.

In efforts to quantitate the preference of CO_2 over O_2 using MD, investigators found that over many different species of rubisco, the relative distribution of CO_2 and O_2 to the small and large was on average 1.8 for CO_2 and 1.4 for O_2 with the number of oxygen bound to either subunit lower. This is true even though CO_2 has a lower solvation energy than O_2 in water, so additional energy must be spent to differentially desolvate CO_2. The hydrophobic interactions likely promote the movement of CO_2 to the active site where electrostatic-based potentials likely favor CO_2 binding. These results suggest that the small subunit acts like a "miniresevoir" for O_2 which then diffuse to the large subunit region of the active site. From a simple thermodynamic perspective, CO_2 would be favored to move along the surface and through spaces in the protein guided by transient interactions that be water. The active site in rubisco is not in a deep pocket but rather in shallow groves near the surface. Although the enzyme is slow (2-10 CO_2/s), it's not much slower than the average enzyme. The median turnover number k_{cat} (under saturating conditions) of enzymes is about 10 s^{-1} with most following between 1-100. Its concentration is very high in chloroplasts, which helps increase the fixing of CO_2.

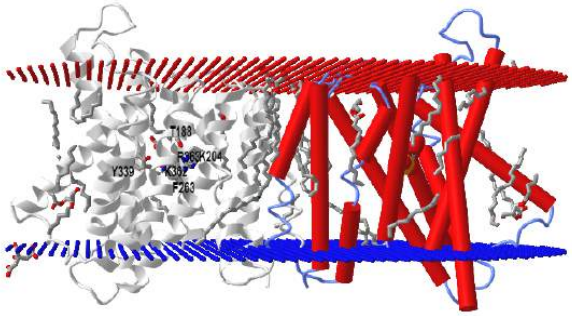
20.4.5: THE NEXT STEP: 3-PHOSPHOGLYCERATE TO GLYCERALDEHYDE 3-PHOSPHATE AND DIHYDROXYACETONE PHOSPHATE

The 3PG produced by RuBisCo is converted to the triose glyceraldehyde-3-P (G3P) (which can readily isomerize to dihydroxyacetone phosphate) using typical glycolytic enzymes run in reverse except that NADPH is used as a reductant instead of NADH. In addition, the stromal and cytosolic enzymes derive from different genes. The remaining G3P not used to resynthesize ribulose 1,5BP can be used for the synthesis of starch, sucrose, etc, as illustrated in Figure 4 above.

20.4.6: EXCHANGE OF TRIOSES AND PHOSPHATE ACROSS THE INNER MEMBRANE

The inner chloroplast membrane has a **triose-phosphate/phosphate translocator (TPT)**, an antiporter that brings into the stroma Pi in exchange for a triose phosphate, either dihydroxyacetone phosphate or 3-phosphoglycerate. The importance of this was discussed above. The exported triose can be used for the synthesis of sucrose, which can be transported around the plant as a source of carbon. Trioses within the chloroplast can also be converted to glucose and onto glycogen as the organelle becomes an amyloplast. If the translocator is inhibited, Pi would decrease in the chloroplast, which would decrease ATP and also starch synthesis.

The structure of TPT has been determined with the bound ligands, 3-phosphoglycerate and inorganic phosphate, in an occluded conformation from *Galdieria sulphuraria*, an extremophilic unicellular species of red algae. Figure 20.4.11 shows an interactive iCn3D model of a triose-phosphate/phosphate translocator from the red algae (5Y78).



NCBI iCn3D Figure 20.4.11: Triose-phosphate/phosphate translocator from red algae (5Y78). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...mVNeFkXibxXr39

The model shows two monomers, one with red cylindrical alpha helices and spacefill 3-phosphoglycerate. The other subunit is shown in gray with the 3PG in colored sticks and conserved residues (T188, K204, F263, Y339, K362, R363) that make interacts with both Pi and 3PG. There would presumably be an outward- and inward-open conformation that is triggered on ligand binding.

20.4.7: ACTIVITY REGULATION BY LIGHT

Given their role in photosynthesis, you would expect even the dark reaction enzymes would be regulated by light. Indeed, four C3 cycle enzymes are. They are ribulose 5-phosphate kinase, fructose 1,6-bisphosphatase, sedoheptulose 1,7-bisphosphatase, and glyceraldehyde 3-phosphate dehydrogenase. The regulation is affected by photon-induced disulfide bond formation between two cysteine side chains in the enzymes. When oxidized (disulfide bond form), the enzymes are inactive. Under light conditions, PSII, cyto b_6f, and PSI work in electron transport to move electrons from H_2O to ferredoxin and onto a small soluble protein thioredoxin which has a disulfide. The enzyme catalyzing this last step is **ferredoxin-thioredoxin reductase.** On reduction, the disulfide in thioredoxin is cleaved, and the now free sulfhydryls in thioredoxin are used to cleave the disulfide in the 4 enzymes mention above, in a similar fashion to how β-mercaptoethanol in excess can cleave disulfides in proteins. This leads to conformational changes in the four enzymes which activate them. In the absence of light, the process reverses, and the enzymes are inhibited. For fuel at night, plants mobilize starch for energy.

A simple mechanism to show how thioredoxin catalyzes disulfide bond reduction in target proteins is shown in Figure 20.4.12.

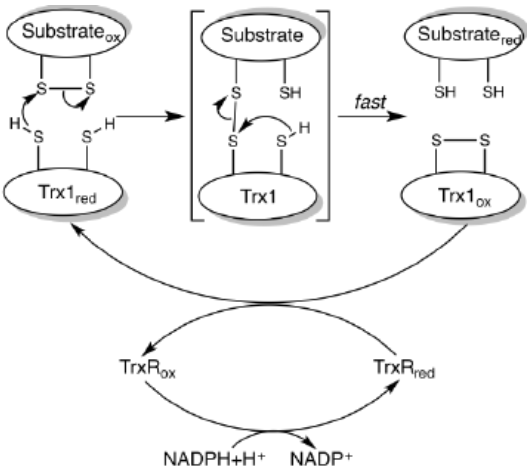


Figure 20.4.12 Mechanism of thioredoxin reduction of target proteins. https://en.Wikipedia.org/wiki/Thiore...le:FigMech.png

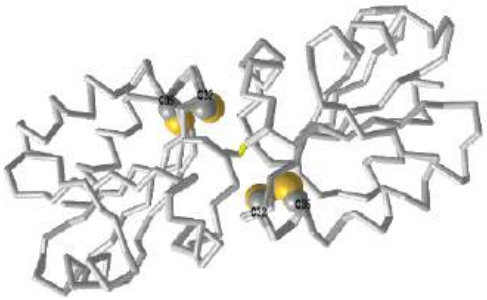
The first enzyme in the oxidative branch of the pentose pathway, glucose 6-phosphate dehydrogenase, uses $NADP^+$ as an oxidizing agent, producing NADPH. In the light, there is lots of NADPH produced from the light reactions of photosynthesis so it makes biological sense that under these conditions, glucose 6-phosphate dehydrogenase activity is inhibited. It is so, also by the cleavage of a critical disulfide bond, but in this case, it results in enzyme inactivation.

We saw the role of thioredoxin in the previous chapter section when we discussed the regulation of photosynthesis as well as the ATP synthase of the chloroplast.

Figure 20.4.13 shows an interactive iCn3D model showing a comparison of the structures of oxidized (1ERU) and reduced (1ERT) human thioredoxin.



NCBI iCn3D Figure 20.4.13: Comparison of the structures of oxidized (1ERU) and reduced (1ERT) human thioredoxin. (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...XPVsErV2JWxdA6.

The two subunits of thioredoxin, linked by a disulfide are shown in gray. Press the "a" key to toggle between the oxidized form, with Cys32-Cys35 disulfide shown as a yellow stick, and the reduced form with the reduced and separated Cys 32 and Cys 35 shown in colored spheres. Not that the hydrogen covalently attached to the free cysteine side chain does not show in a crystal PDB structure.

20.4.8: SUMMARY

Photosynthesis in vascular plants takes place in chloroplasts. In the CO2-assimilating reactions (the Calvin cycle), ATP and NADPH are used to reduce CO2 to triose phosphates. These reactions occur in three stages: the fixation reaction itself, catalyzed by Rubisco; reduction of the resulting 3-phosphoglycerate to glyceraldehyde 3-phosphate; and regeneration of ribulose 1,5-bisphosphate from triose phosphates. Rubisco condenses CO2 with ribulose 1,5-bisphosphate, forming an unstable hexose bisphosphate that splits into two molecules of 3-phosphoglycerate. Rubisco is activated by covalent modification (carbamoylation of Lys201) catalyzed by Rubisco activase and is inhibited by a natural transition-state analog, whose concentration rises in the dark and falls during daylight. Stromal isozymes of the glycolytic enzymes catalyze the reduction of 3-phosphoglycerate to glyceraldehyde 3-phosphate; each molecule reduced requires one ATP and one NADPH. The cost of fixing three CO2 into one triose phosphate is nine ATP and six NADPH, which are provided by the light-dependent reactions of photosynthesis. An antiporter in the inner chloroplast membrane exchanges Pi in the cytosol for 3-phosphoglycerate or dihydroxyacetone phosphate produced by CO2 assimilation in the stroma. Oxidation of dihydroxyacetone phosphate in the cytosol generates ATP and NADH, thus moving ATP and reducing equivalents from the chloroplast to the cytosol. Four enzymes of the Calvin cycle are activated indirectly by light and are inactive in the dark so that hexose synthesis does not compete with glycolysis—which is required to provide energy in the dark.

20.4.9: PHOTORESPIRATION - RUBISCO/OXYGENASE AND THE GLYCOLATE CYCLE

As autotrophs, plants make their fuels. They use that fuel to make ATP to power endergonic reactions like protein synthesis, cell division, etc. As eukaryotic cells, they have mitochondria and can use both aerobic and anaerobic respiration to produce ATP. In the dark, when photons are not present, they carry out mitochondrial aerobic respiration as they break down carbohydrates to CO_2 and water, the reverse of photosynthesis.

They also use O_2 in another process that is driven by light. The same enzyme that captures carbon, RuBisCo, has oxygenase activity. RuBisCo uses O_2 in a process called **photorespiration**, which produces CO_2 in a competing reaction. Same enzyme, different substrates! The final products of the reaction with CO_2 using RuBisCo are two 3C molecules, 3-phosphoglycerate (3PG). Using O_2 as a substrate produces 1 molecule of the 3C 3PG and 1 molecule of a 2C analog, **2-phosphoglycolate** (not 2-phosphoglycerate). 2-phosphoglycolate is also named **carboxymethylphosphate**. About one out of every four turnovers of the enzyme produced this metabolic dead product. Given this non-trivial side reaction, the enzyme should be called **ribulose 1,5-bisphosphate carboxylase/oxygenase**.

You may ask why would such a critical enzyme evolved to a form which is quite inefficient. One explanation is that the enzyme "finished" its evolution before the great oxygenation event when dioxygen rose to the levels we see now (20%). Before that, little oxygen was available to compete with the trace gas CO_2, which is around 0.04% of the atmosphere. (Even though CO_2 is considered a trace gas, its present concentration is around 420 parts per million (ppm), levels which are warming our planet and which have not been seen for 3 million years, when Arctic forests and camels were present).

Compare the K_M values (9 μM for CO_2 and 350 μM for O_2 or 39x higher for O_2) for the enzyme and the equilibrium concentrations of the gases in aqueous solution (11 μM for CO_2 and 250 μM for O_2 or 23x higher for O_2). The higher K_M for O_2 is nearly offset by O^2's greater solubility so modern conditions lead to a significant waste of the CO_2 capture efficiency of RuBisCo/Oxy. At higher temperatures in a warming world, the equilibrium ratio of solution concentrations of O_2/CO_2 increases as does the affinity (based crudely on K_M values) of CO_2. Both of these exacerbate the wasteful oxygenase activity effect. Finally, as CO_2 is captured by the enzyme, the ratio of the local concentrations of O_2/CO_2 also goes up. All of these make the efficiency of RuBisCo worse.

Figure 20.4.14 shows a mechanism for the reaction of both CO_2 and O_2 with RuBisCo/Oxygenase.

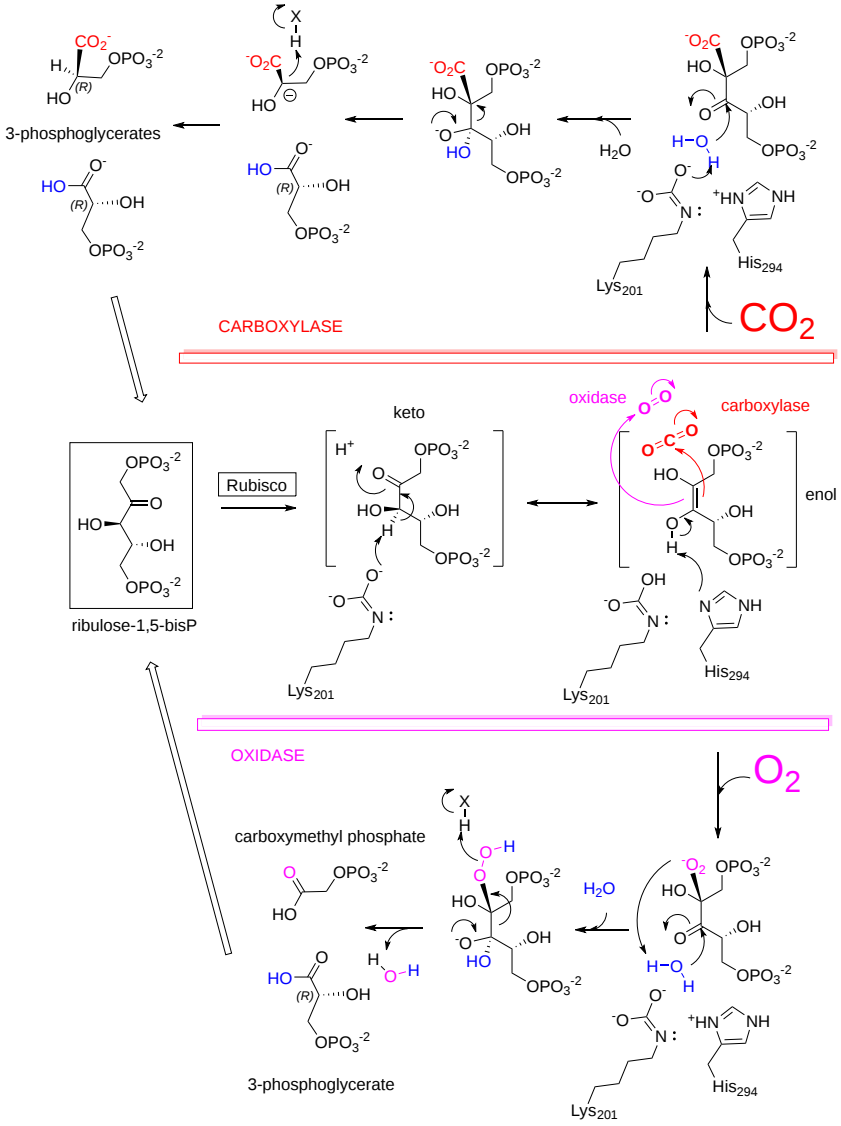


Figure 20.4.14: Mechanism for the reaction of both CO_2 and O_2 with RuBisCo/Oxygenase. (after Kannappan et al. J. Phys. Chem. B 2019, 123, 2833−2843)

Note that in contrast to most oxygenases, no cofactor is required for the RuBisCo/Oxygenase.

20.4.10: THE GLYCOLATE PATHWAY

The 2-phosphoglycolate (carboxylmethyl phosphate) "waste" product of the oxygenase activity of RuBisCo/Oxygenase is recycled through a complex pathway that is called "photorespiration". It occurs in three different organelles, the chloroplast, the peroxisome, and the mitochondria. Part of the generalized pathway is shown in Figure 20.4.15.

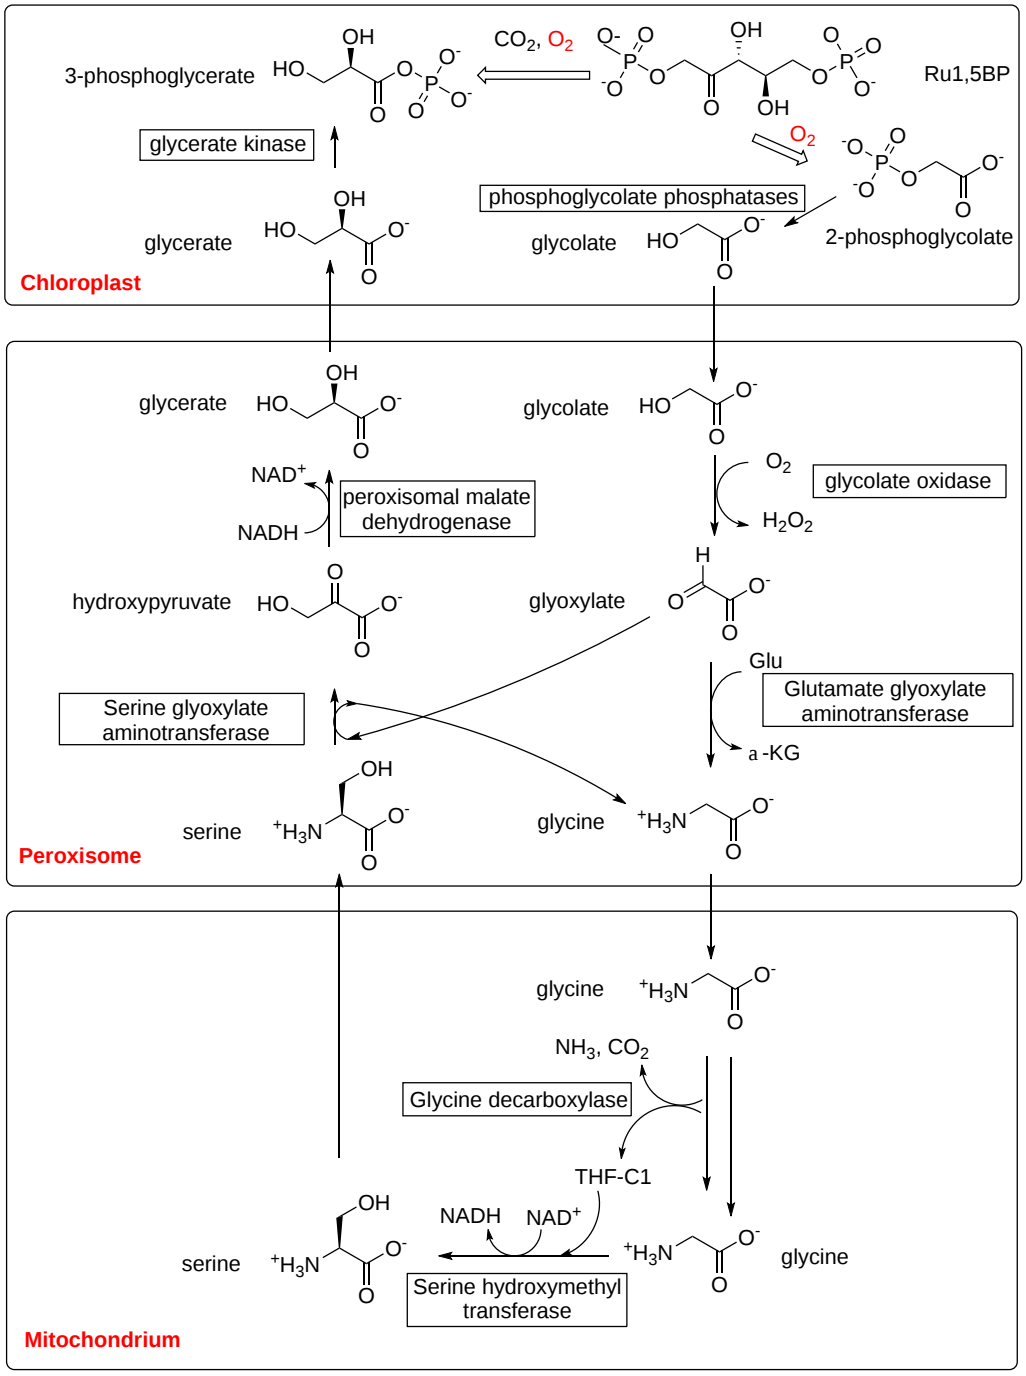

Figure 20.4.15: The glycolate photorespiration salvage pathway (adapted from Hu et al. *Plant Cell*. 2012;24.doi:10.1105/tpc.112.096586)

Multiplying the stoichiometry represented in the figure by 2 shows that 2 molecules of 2-phosphoglycolate produce 2 molecules of glycine. These get converted to two molecules of serine. We will see the mechanisms for some of these reaction in the chapter on amino acid metabolism. The net reaction is:

$$2\,\text{Glycine} + \text{NAD}^{++}\text{H}_2\text{O} \rightarrow \text{serine} + \text{CO}_2 + \text{NH}_3 + \text{NADH}$$

The serine is eventually converted to 3-phosphoglycerate, which can be used again in the C3 cycle. Note that CO_2 is produced in the glycolate pathways that started with the use of O_2 as a substrate by RuBisCo/Oxygenase. Hence the whole system uses O_2 and produces one CO_2 so the combined reactions are usually called **photorespiration**. It's not an ideal term since it is wasteful, compared to mitochondrial respiration. Some prefer to call the combined pathway of Rubisco oxygenase and the glycolate pathways the **C2 cycle**.

20.5: CO2 UPTAKE - C4 AND CAM PATHWAYS

The source for the organization and some of the text derives from Sindayigaya and Longhini. https://www.peoi.org/Courses/Courses...chem/biochem18 CC - https://creativecommons.org/licenses...sa/3.0/deed.en

20.5.1: THE C4 PATHWAY

Photorespiration, caused by the oxygenase activity of RuBisCo/Oxygenase and the ensuring glycolate salvage (C2) pathway, significantly diminishes the efficiency of photosynthesis in C3 plants. Rest assured, some plants have found a way around the problem by adding a few steps before RuBisCo. The altered pathway is called the C4 pathway and plants that use it are called C4 plants. The initial steps involve a temporary capture of CO_2 in the form of HCO_3^-, into a 4C, not 3C sugar. Plants that use the C4 pathway include maize, sorghum, sugar cane, and many tropic plants. An overview of the pathways emphasizing the steps that precede RuBisCo is shown in Figure 20.5.1.

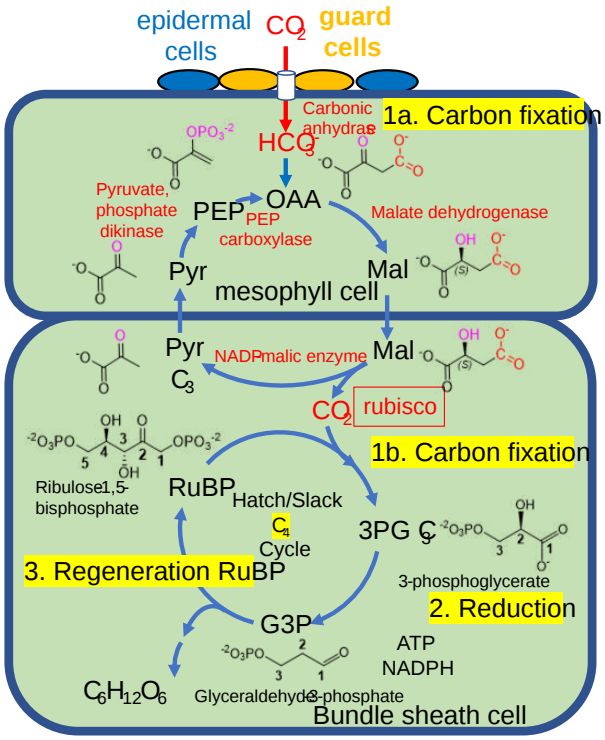

Figure 20.5.1: Carbon assimilation in C4 plant

Experimental evidence shows that radiolabeled $^{14}CO_2$ is captured into the 4C molecule, oxaloacetate (OAA), a citric acid cycle and gluconeogenic intermediate, through the enzyme phosphoenolpyruvate carboxylase, which uses HCO_3^- as a substrate. The reaction takes place in mesophyll cells. OAA can be reduced by NADPH using malate dehydrogenase, or converted to aspartate through a transamination (not shown in the figure). Malate moves in the bundle sheath cell where it is decarboxylated by the NADP-malic enzyme to pyruvate. Pyruvate can move back into the mesophyll cell and be converted to phosphoenolpyruvate (PEP) and then back to OAA by the enzymes **pyruvate phosphate dikinase** and **PEP carboxylase**. CO_2 from the decarboxylation of malate is delivered as a substrate to RuBisCo.

Pyruvate dikinase is used in bacteria, protozoa, C4 plants, and another type, Crassulacean, discussed below. Its non-plant function is to produce ATP, in a fashion similar to pyruvate kinase. The net reaction is:

ATP + phosphate + pyruvate = AMP + PP_i + H^+ + phosphoenolpyruvate

Figure 20.5.2 shows a simplified mechanism for the reaction

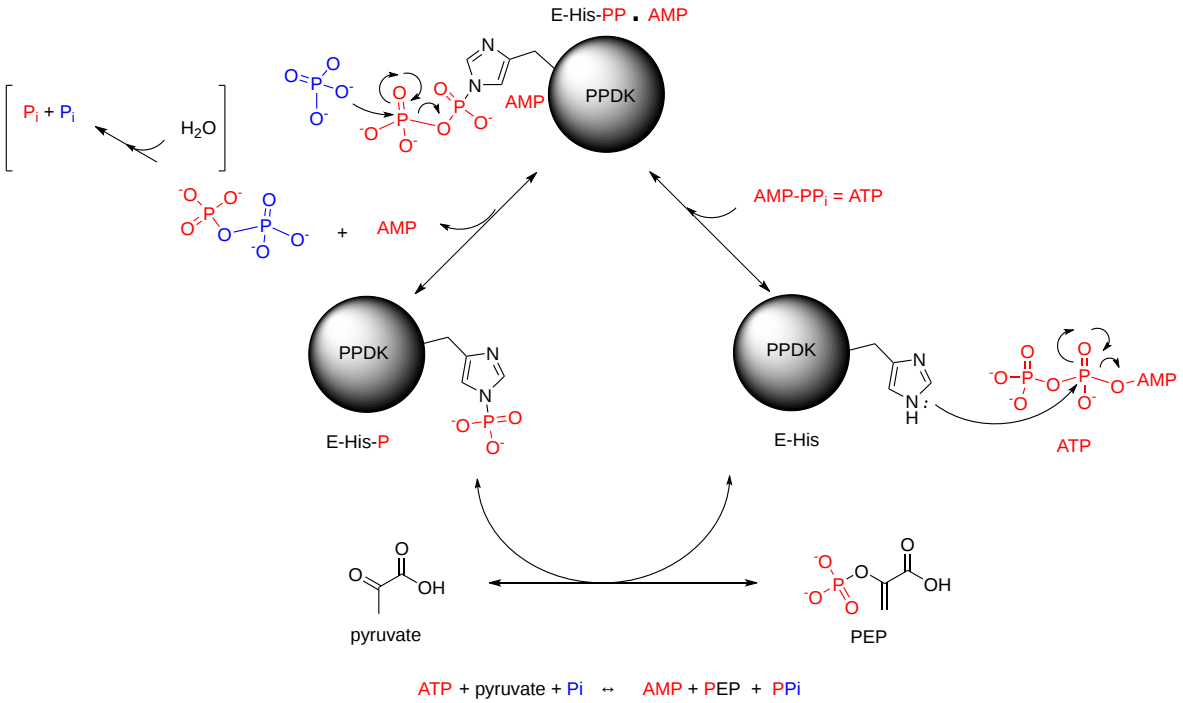

Figure 20.5.2: Mechanism of pyruvate phosphate dikinase

The net reaction shows that in C4 plants, two molecules are phosphorylated by ATP. One is pyruvate and the other is inorganic phosphate (Pi). Hence the name dikinase. The reverse reaction of ATP synthesis occurs in bacteria and protozoan. There are two phosphorylated intermediates, an Enz-His-P, and an Enz-His-PP_i. These served as "activated" phosphate carriers in the phosphotransfer reactions to pyruvate and to P_i, respectively. If PP_i is not hydrolyzed to $2P_i$, as illustrated in the top left of Figure 2 above, the reaction is fully reversible.

In C4 plants there are three reactions

1. Pyr + E-His-P ↔ PEP + E-His
2. E-His + ATP ↔ E-His-PP ·AMP (· indicates a noncovalent interaction)
3. E-His-PP ·AMP + P_i ↔ E-His-P + AMP + PP_i

When PP_i is hydrolyzed, the net input of ATP to phosphorylated pyruvate is two ATP equivalents.

In the next step, PEP is carboxylated in a carbon capture reaction by PEP carboxylase, which as mentioned above used HCO_3^- as a substrate, not CO_2 per se. PEP carboxylase also does not have a competing oxidase activity. The product is malate, which releases locally high "saturating" concentrations of CO_2 in the bundle sheath cells, which significantly suppresses the oxygenase activity of RuBisCo.

Pyruvate phosphate dikinase undergoes a very large change in a conformational change in domain organization during the catalytic cycle. The two kinase activities are located at different sites in the enzyme. The phosphorylation of Pi occurs in the N-terminal domain, while the phosphorylation of pyruvate is in the C-terminal domain. The center domain that links to the N- and C-terminal domains by associated "tethers" is the site of the catalytic histidine involved in phosphotransfer. A swiveling of domains occurs to allow sequential phosphotransfers.

The Pfam domain structure for the protein is shown in Figure 20.5.3.

Figure 20.5.3: The green represents the AMP/ATP nucleotide-binding domain (NBD), the blue the PEP/pyruvate binding domain (PBD), and the red the central domain which catalyzes the phosphotransfer from ATP to pyruvate and from PEP to AMP through phosphorylated histidine intermediates. The NBD has three subdomains.

Figure 20.5.4 shows an interactive iCn3D model of an AlphaFold predicted model of chloroplast pyruvate, phosphate dikinase from *Flaveria brownii (Brown's yellowtops)* (Q39734)

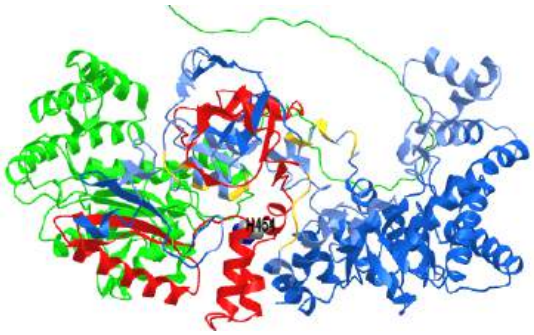

Figure 20.5.4: AlphaFold predicted model of chloroplast pyruvate, phosphate dikinase from *Flaveria brownii (Brown's yellowtops) (*Q39734). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...VB6Aywuc2bLD38

The green represents the N-terminal NBD, the red is the central domain with the catalytic His (side chain shown as CPK-colored spheres and labeled), and the blue the PEP/Pyr PBD).

Figure 20.5.5 illustrates the conformation changes that occur in the central domain (yellow in this figure) and the N-terminal nucleotide-binding domain (NBD, green) in various ligand-bound states.

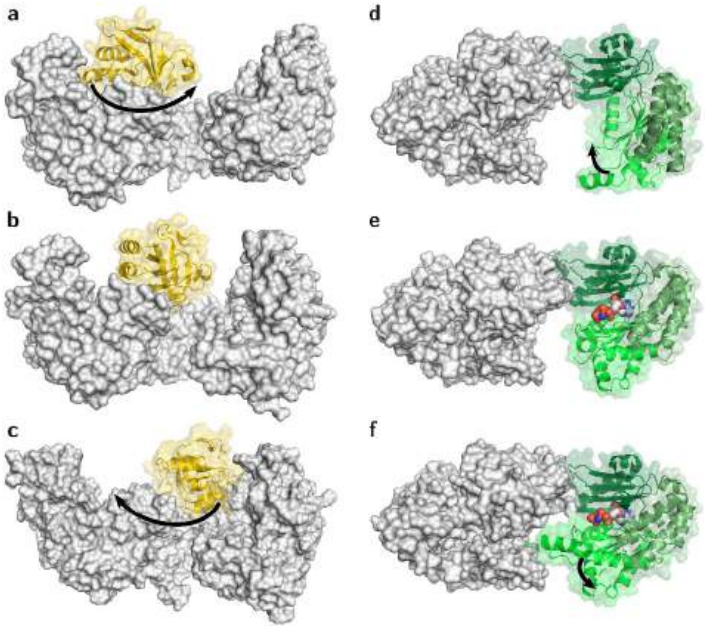

Figure 20.5.5: **Movement of the PPDK domains**

Panel a–c show movement of the central domain (yellow). In (**a**) it swivels to face the PBD domain (PDB 5JVL/C) and in (**c**) it faces the NBD domain (*Tb*PPDK (PDB 2X0S)). In (**b**) it is in an intermediate position.

Panels d-f show the movement of the NBD (the three subdomains are depicted by three different greens). Pane (**d**) is the state without bound nucleotide (PDB 5JVJ/A), while panel (**f**) shows the fully closed, nucleotide-bound state (PDB 5JVL/A). Panel (**e**) shows a semi-closed, nucleotide-bound state (PDB 5JVL/C). Minges, A., Ciupka, D., Winkler, C. *et al.* Structural intermediates and directionality of the swiveling motion of Pyruvate Phosphate Dikinase. *Sci Rep* **7,** 45389 (2017). https://doi.org/10.1038/srep45389. Figure 20.5.6 shows interactions of bound substrates in different conformation states of PPDK.

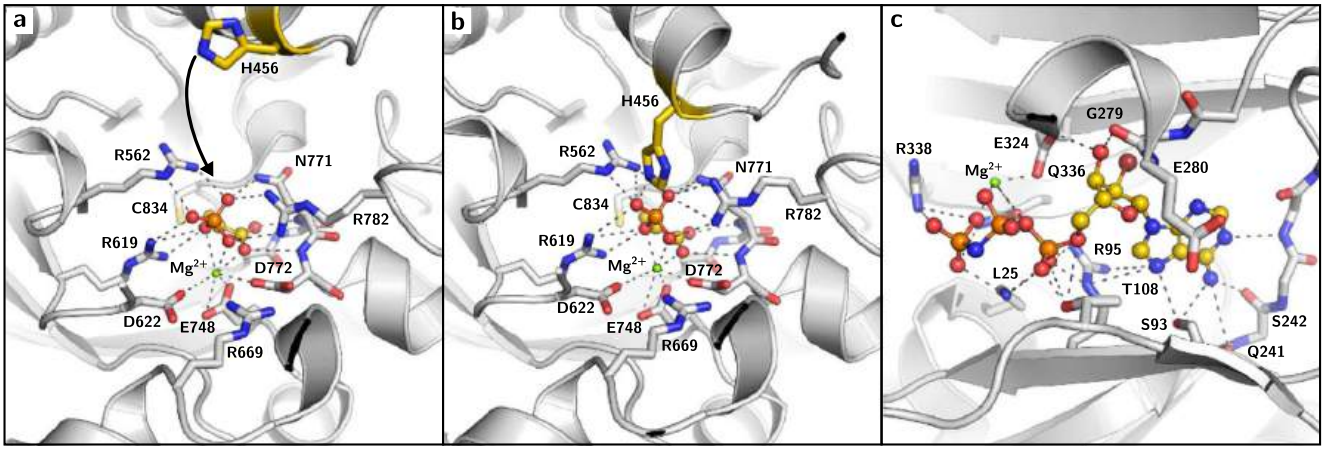

Figure 20.5.6: **Substrate binding sites of *Ft*PPDK.**

Panel (**a**) shows the semi-closed state of the PEP binding site (PDB 5JVL/A) with the catalytic H456 (yellow) pointing away from PEP.

Panel (**b**) shows the closed state of the PEP binding site (PDB 5JVL/C) showing interactions between PEP and surrounding residues, including the catalytic H456 (yellow).

Panel (**c**) shows the closed state of the nucleotide-binding site of 5JVL/D occupied with 2'-Br-dAppNHp, a nonhydrolyzable ATP analog. Interacting residues are highlighted. Minges, A et al. ibid.

After CO_2 is delivered from malate in the bundle sheath cell using RuBisCo, the rest of the reactions are the same as in the C3 pathways.

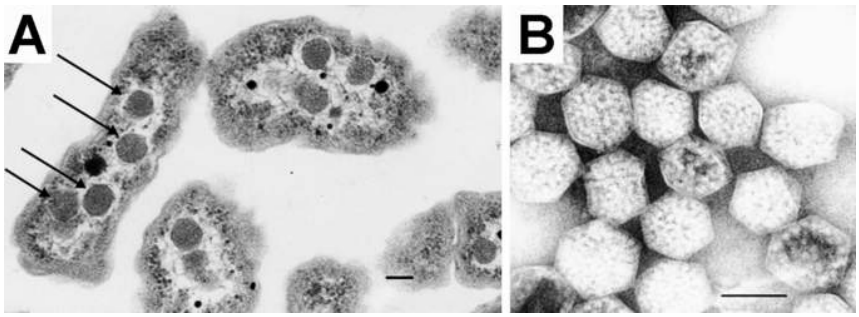
Once CO_2 is fixed into 3-phosphoglycerate in the bundle-sheath cells, the other reactions of the Calvin cycle take place exactly as described earlier. Overall the C4 pathways require more ATP. A molecule of PEP is required for each CO_2 fixed in the C4 pathway which takes the equivalent of two ATPs. So for each CO_2 fixed in the C4 pathway, it takes 5 ATPs compared to 3 ATPs in the C3 pathway. As mentioned above the affinity (estimated from the K_M) of CO_2 for RuBisCo decrease with increasing temperature, which decreases the energetic efficiency of carbon capture. At higher temperatures (28-30 C), the extra energy cost for the C4 pathway balances out with the extra energy cost for the C3 pathway at higher temperatures.

20.5.2: CARBONIC ANHYDRASES

We first encountered carbonic anhydrase when we discussed its mechanism in Chapter x.xx. We'll now discuss its function and activity in the C4 pathway in some detail. Given that we are facing a climate crisis due to the increasing levels of CO_2 in the atmosphere arising from the burning of fossil fuels, removing CO_2 from the atmosphere, a process called for climate purposes carbon sequestration, and understanding the role of carbonic anhydrase in CO_2 sequestration becomes even more important.

Plants have three different genes for carbonic anhydrase (α, β, and γ). Each can be differentially spliced so there many different isoforms of this protein in plants. They are most abundant in the chloroplast, cytoplasm, and in mitochondria and they have many additional roles outside of fixing CO_2 in C4 (and also CAM) plants. In autotrophic (make their own "food") bacteria (such as cyanobacteria, also known as blue-green algae), there are no internal organelles. However, there are **carboxysomes,** which are protein-bounded vesicles (much like a bacteriophage head), which contain in their internal compartment not nucleic acid but RuBisCo and carbonic anhydrase. The carbonic anhydrase converts HCO_3^- to CO_2 for reaction with RuBisCo. The carboxysome hence concentrates the CO2-producing and fixing enzymes for photosynthesis.

Figure 20.5.7:



F

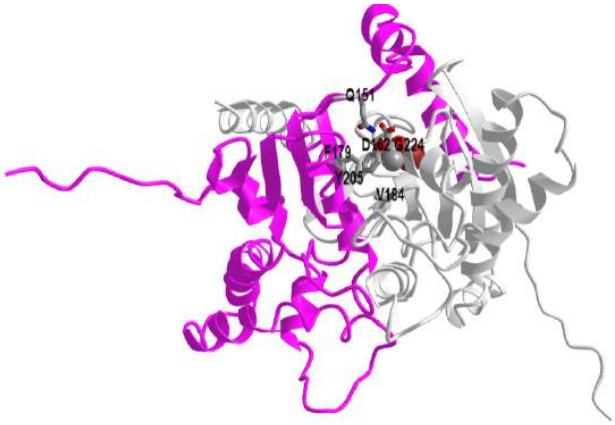
Figure 20.5.7: **Electron Micrograph of a carboxysome**: (A) A thin-section electron micrograph of H. neapolitanus cells with carboxysomes inside. In one of the cells shown, arrows highlight the visible carboxysomes. (B) A negatively stained image of intact carboxysomes isolated from H. neapolitanus. The features visualized arise from the distribution of stains around proteins forming the shell as well as around the RuBisCO molecules that fill the carboxysome interior. Scale bars indicate 100 nm. BioLibreText

In C3 plants, CO_2 (aq), that is dissolved CO_2, is the actual substrate for RuBisCo so available HCO_3^- is converted to CO_2 by carbonic anhydrase. In C4 and CAM plants, CO_2 (aq) is first converted to bicarbonate by carbonic anhydrase. HCO_3^- (aq) is then used as the actual substrate for the "carbon fixation" step. Hence carbonic anhydrase has roles in C3, C4, and CAM plants.

All of the carbonic anhydrases have a Zn^{+2} at the active site. The **alpha** form, the most prominent in plants, was discovered in erythrocytes and is typically active as a monomer. It has one large 10-strand beta sheet surrounded by 7 alpha helices. The Zn ion is tetrahedrally coordinated by 3 histidine side chains and water. **Gamma** carbonic anhydrase is a trimer with three active sites at the interface between pairwise monomers with the Zn-coordinating histidine side chains from two different subunits.

Beta carbonic anhydrase in plants is typically an octamer of identical subunits. The Zn ion is coordinated by two cysteines, one histidine, and water. The monomer has 4 beta strands in a beta-sheet surrounded by alpha helices. An additional beta-strand is involved in monomer interactions. As the active site is in the interface of two subunits, the functional biological unit is the dimer, but a tetramer and even an octamer are typically formed. The substrate binding groups have a one-to-one correspondence with the functional groups in the alpha-carbonic anhydrase active site, with the corresponding residues being closely superimposable by a mirror plane. Therefore, despite differing folds, alpha- and beta-carbonic anhydrases have converged upon a very similar active site design and are likely to share a common mechanism.

Figure 20.5.8 shows an interactive iCn3D model of beta-carbonic anhydrase from Pisum sativum (pea) with bound acetate (1EKJ).



NCBI iCn3D Figure 20.5.8: Beta-carbonic anhydrase from Pisum sativum (pea) with bound acetate (1EKJ). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...VZTEJPy1hPxK27

For the sake of simplicity, only two subunits (A - gray and B - magenta) of the octamer are shown. Acetate, a proxy for HCO_3^{-2}, is shown in spacefill binding between the two subunits in CPK-colored spheres. The side chains involved in Zn^{2+} binding, Cys 160, His 220, and Cys 223 (unlabeled) are on the A chain. The amino acids that bind acetate are distributed between the A chain (Asp 162, Gly 224, Val 184) and the B chain (Gln 151, Phe 169, and Tyr 205) and are labeled. The same groups are involved in substrate binding in alpha carbonic anhydrase but in a mirror image orientation (but with the normal L-amino acids).

Beta carbonic anhydrase has high levels of expression in leaves and is found in chloroplasts, mitochondria, and the cytoplasm. Many plants have it in the cytoplasm and chloroplasts.

- β-carbonic anhydrase (βCA) in C3 plants: Most of βCA in leaves is in chloroplasts in mesophyll cells and may comprise up to 2% of leave protein. Yet studies have shown that you can delete the gene for it with minimal effect on the maximal rate of photosynthesis.

However, plant development was affected so by interference the enzyme is probably most needed to produce HCO_3^- for biosynthesis.

- β-carbonic anhydrase (βCA) in C4 plants: Most of the βCA is found in the cytoplasm of mesophyll cells. There is catalyzes the first reaction of the C4 pathway, CO_2 (aq) to HCO_3^- (aq). Mitochondrial (βCA) and γCA probably function to fix CO_2 arising from oxidative respiration.

20.5.3: CRASSULACEAN ACID METABOLISM (CAM) PATHWAY

Plants that encounter the chronic stress of low water availability have evolved yet another pathway to adapt to low water conditions. Stomata in C3 plants are open during the day to allow carbon capture from CO_2, but they can close when water is limited. This obviously will inhibit plant growth. In the CAM pathway, the stomata stay open at night, allowing carbon capture at a time when water loss through the stomata would be lower. The incoming CO_2 is fixed through carbonic anhydrase and then a series of several enzymes to form malic acid, which is transported for storage and use during the light in vacuoles. This CAM pathway is described in Figure 20.5.9.

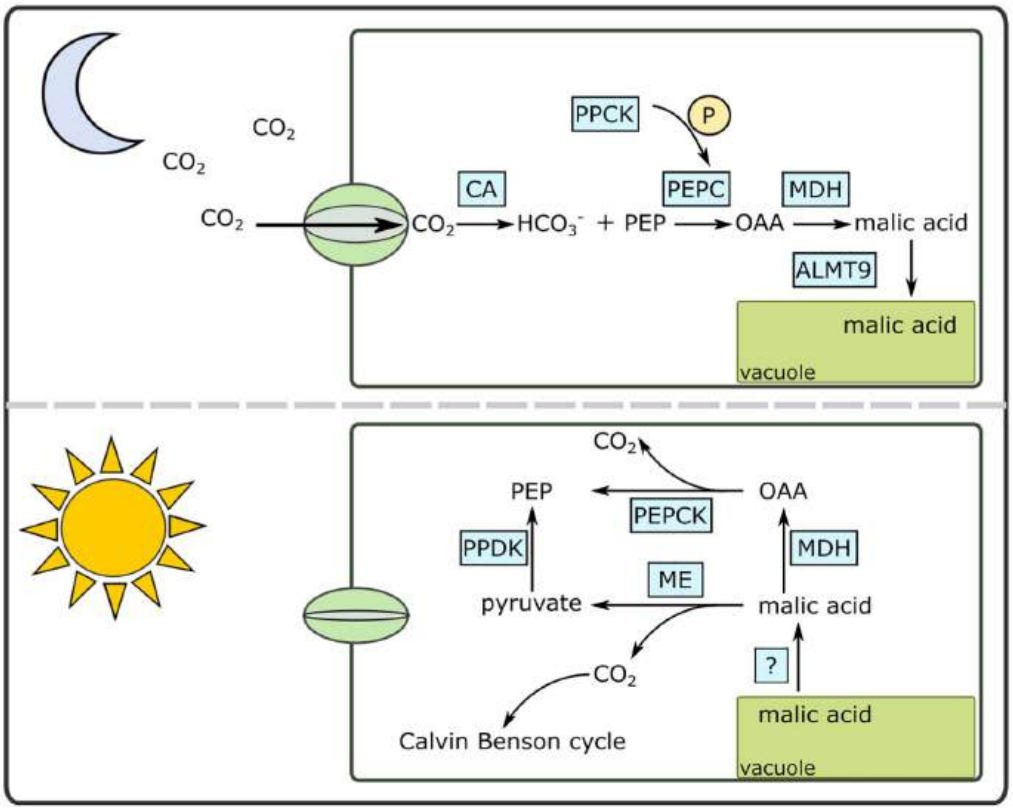


Figure 20.5.9: A simplified diagram of the Crassulacean acid metabolism (CAM) pathway under day and night conditions. Heyduk Karolina, et al. Frontiers in Plant Science.2019. https://www.frontiersin.org/article/...pls.2018.02000. DOI=10.3389/fpls.2018.02000. Creative Commons Attribution License (CC BY).

The proteins and intermediates in the CAM pathways are ALMT9, aluminum-activated malate transporter; CA, carbonic anhydrase; MDH, malate dehydrogenase; OAA, oxaloacetate; ME, malic enzyme (NAD or NADP); P, phosphate; PEPC, phosphoenolpyruvate carboxylase; PEPCK, PEP carboxykinase; PPCK, PEPC kinase; PPDK, pyruvate, phosphate dikinase.

During the day, malic acid moves back into the cytoplasm where it is decarboxylated by malic enzyme and releases locally high CO_2 concentrations for use by RuBisCo in the C3 cycle. In plants that use CAM, a series of other changes occur, including leaf structure and additional regulatory processes that coordinate metabolic genes.

Figure 20.5.10s shows more details of the CAM cycle.

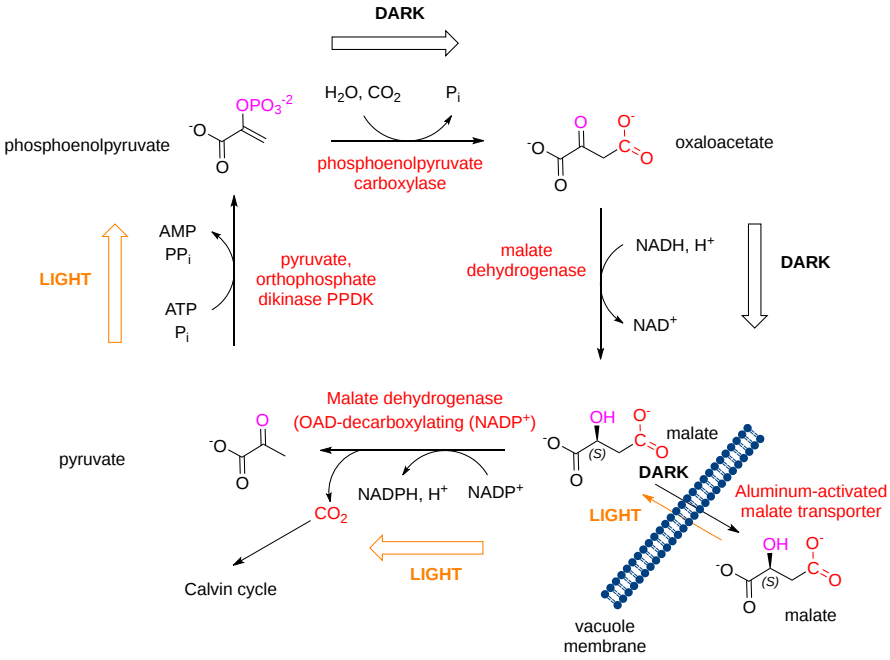

Figure 20.5.10: Details of the CAM cycle

20.5.4: THERMODYNAMIC COMPARISON BETWEEN THE C3/C4 PATHWAYS AND THE OTTO CYCLE

It is interesting to compare the thermodynamic efficiencies of plants and internal combustion engines that are governed by the thermodynamic Otto cycle. In the cycle, chemical energy in the form of gasoline and O_2 are converted to thermal energy which is converted into mechanical energy. Both photosynthesis (the conversion of the energy of photons into chemical energy) have limited efficiencies.

- In internal combustion engines, power is limited in part by air uptake and by different efficiencies when running at non-constant speeds (like stop-and-go).
- In the C3 pathway, efficiency is limited by the oxygenase activity of RuBisCo/Oxygenase (given the much higher concentration of atmospheric O_2 compared to CO_2) and the ensuring photorespiration pathway.
- Water availability also plays a role as the net reaction of photosynthesis and glucose production, in simplified form, is $6CO_2 + 6H_2O \rightarrow 6C(H_2O_6)$ so in high heat and low humidity the process efficiency decreases

Figure 20.5.11 shows a comparison of three stages, the storage component, the basic cycle, and a concentration mechanism, in photosynthesis and the internal combustion engine (ICE).

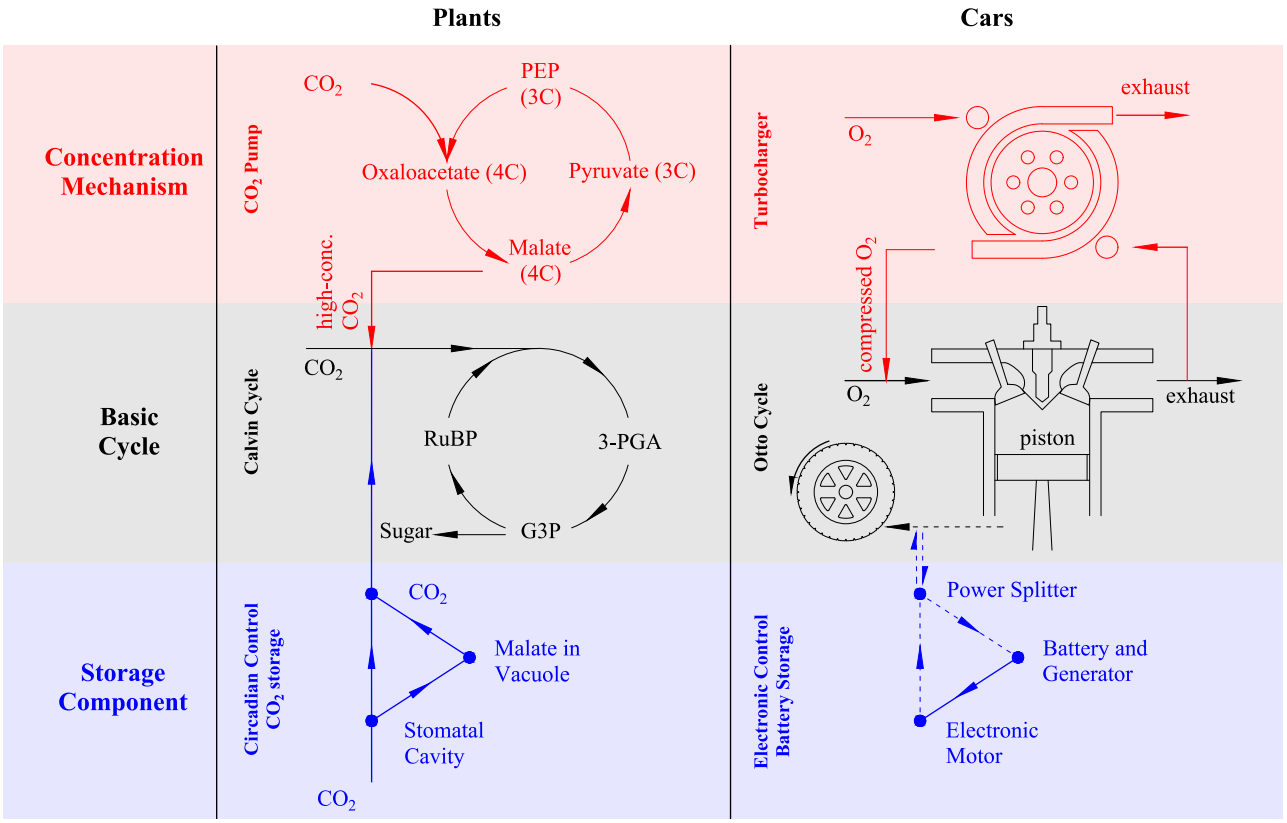

Figure 20.5.11: A comparison of plant photosynthesis and car engine functioning illustrates how the core processes interact with the additional components. Hartzell S, Bartlett M, Yin J, Porporato A (2018) Similarities in the evolution of plants and cars. PLoS ONE 13(6): e0198044. https://doi.org/10.1371/journal.pone.0198044. Creative Commons Attribution License,

A concentrating mechanism in C4 plants and turbocharged cars provides concentrated CO_2 and oxygen, respectively, to the core cycle (upper row). A storage mechanism in CAM plants allows carbon dioxide to be stored as malic acid at night and then passed to the Calvin cycle during the day, while a storage mechanism in hybrid electric vehicles (HEVs) allows energy to be stored in the battery during braking and then passed to the motor to power the drivetrain in parallel with the engine (bottom row).

20.6: BIOSYNTHESIS OF STARCH, SUCROSE AND CELLULOSE

Now that we have seen how carbon is captured and fixed into 3C trioses, which can be converted to fructose and glucose and their derivative, we can now explore the synthesis of the key plant carbohydrates we all know, sucrose, starch, and cellulose.

The source for the organization and some of the text derives from Sindayigaya and Longhini. https://www.peoi.org/Courses/Courses...chem/biochem18. Creative Commons - https://creativecommons.org/licenses...sa/3.0/deed.en

20.6.1: SUCROSE SYNTHESIS

Sucrose is a disaccharide of glucose and fructose with an acetal link between the anomeric carbons to form the nonreducing sugar O-α-D-glucopyranosyl-(1→2)-β-D-fructofuranoside. Its structure is shown in Figure 20.6.1.

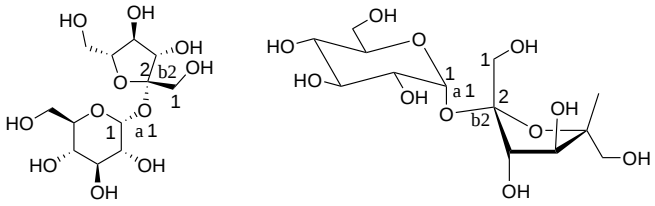

Figure 20.6.1: Sucrose, a disaccharide of glucose and fructose

Sucrose can be considered a transport form of carbon, much like ketone bodies are transport forms of fatty acids. As noted above, the link between the sugars is between the anomeric C-1 link of glucose and the anomeric C-2 link of fructose. As such, it is not cleaved by typical carbohydrate-cleaving enzymes like amylases. Also, it doesn't react with proteins like other sugars with free cyclic hemiacetals that can open and form reactive aldehydes. For example, the cyclic monosaccharide glucose, with its anomeric carbon in a readily reversible hemiacetal link, can form covalent bonds to amine groups in proteins such as hemoglobin, which forms the glycosylated version of HbA1c, as shown in Figure 20.6.2.

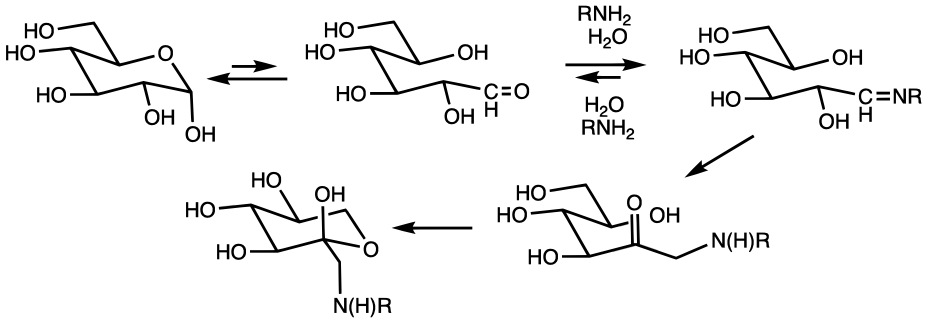

Figure 20.6.2: Reactions of cyclic hemiacetal sugars with amines. https://en.wikipedia.org/wiki/Glycated_hemoglobin. Creative Commons Attribution-ShareAlike License 3.0

The reaction proceeds through the formation of a Schiff base followed by a rearrangement. HbA1c is a marker of diabetes. These features of sucrose may explain its choice as a key form of synthesized carbohydrate in plants.

Sucrose is synthesized in the cytosol, as shown in Figure 20.6.3.

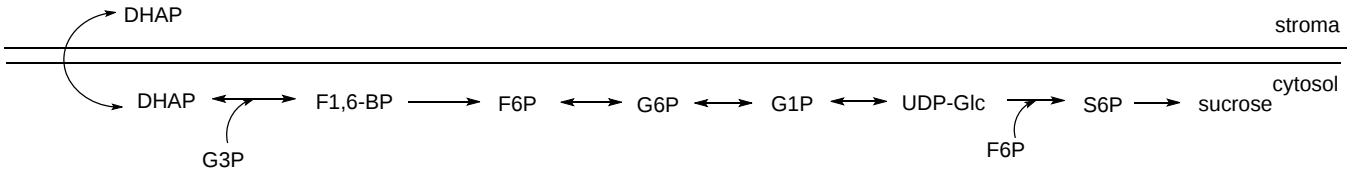

Figure 20.6.3: Synthesis of sucrose in plants.

We have seen the enzymes that catalyze these reactions through G1P before in the glycolytic and gluconeogenesis pathways. Glucose-1-phosphate is then converted to UDP-glucose, which reacts with fructose-6-phosphate to form sucrose 6-phosphate and UDP, catalyzed by the enzyme **sucrose 6-phosphate synthase.** The last reaction is the hydrolysis of sucrose 6-phosphate by sucrose 6-phosphatase, which allows the export and transport of sucrose.

In the reaction scheme above, G1P is converted to UDP-Glc through the following reaction:

$$G1P + H^+ + UTP \leftrightarrow UDP\text{-}Glc + P_i$$

This reaction is just mildly favored thermodynamically.

Before we study the structure of the enzyme, we will first discuss the regulation of the sucrose synthesis pathway and discuss the generic mechanism of glycosyltransferases.

20.6.2: REGULATION

Carbon capture in the light reaction of photosynthesis leads to sucrose (for transport) and starch synthesis. Which product(s) result depends on key regulatory steps. Remember of the 6 trioses formed in the Calvin cycle, 5 are returned into the cycle for the synthesis of ribulose 1,5-bisphosphate, and only 1 is used for the synthesis of sucrose and starch. If too much is removed, the cycle slows. If not enough is used for starch and sucrose synthesis, P_i, which is moved into the stroma from the cytoplasm by an important translocator (see section 20.3) would run low.

The key cytosolic regulatory step is catalyzed by **fructose 1,6-bisphosphatase** (FBPase-1) and also a unique plant enzyme, **PPi-dependent phosphofructokinase** (PP-PFK-1)**,** that catalyzes the reverse reaction of F6P → F1,6BP, in regulatory steps that are similar to ones found in glycolysis and gluconeogenesis.

- **fructose 1,6-bisphosphatase** (FBPase-1) is inhibited by the allosteric modulator **fructose 2,6-bisphosphate** (F2,6BP)
- **PPi-dependent phosphofructokinase (**PP-PFK-1) is activated by **fructose 2,6-bisphosphate**

The coordinate regulation of these two enzymes is shown in Figure 20.6.4.

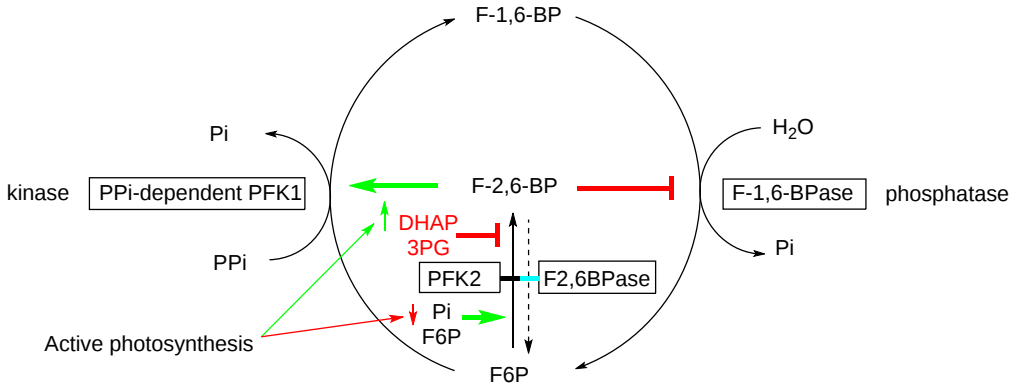

Figure 20.6.4: Regulation of sucrose synthesis at the formation of fructose-6-phosphate

The substrate for the PPi-dependent phosphofructokinase (PP-PFK-1) is PPi, which serves as a phosphodonor. In the plant cytosol, there is no pyrophosphatase to catalyze the cleavage of PP_i into P_i. Also note that Fru-2,6-P_2 itself is synthesized and degraded by the bifunctional enzyme phosphofructokinase 2/fructose-2,6-bisphosphatase, which we studied before in the regulation of the same step in glycolysis/gluconeogenesis.

The levels of F2,6-BP depend on the rate of photosynthesis:

- When photosynthesis is high (in light conditions), [DHAP] and [3PG] increase, which inhibits PFK2, which decreases F26BP, which causes a differential increase in F1,6BPase activity over PP-PFK-1), which increases F6P for sucrose synthesis as well as Pi for the continuation of the light reactions. This allows sucrose synthesis when excess DHAP and 3PG occur in the light reactions, which makes great biological sense.
- When photosynthesis is low (in dark conditions), the same regulations lead to an increase in F2,6BP, which leads to the preferential activation of the glycolytic enzyme PPi-dependent phosphofructokinase-1 (PP-PFK1) and inhibition of the gluconeogenic enzyme fructose 1,6- bisphosphatase (FBPase-1)

We will see later, the main regulatory step in starch synthesis is **ADP-glucose pyrophosphorylase.** In contrast to the inhibition by 3PG of PFK2, 3PG (which increases in active photosynthesis) activates ADP-glucose pyrophosphorylase while Pi inhibits it. Pi increases when the synthesis of ATP from ADP and Pi (by ATP synthase in the light reaction) slows (such as in darker conditions). If sucrose synthesis slows and sufficient 3PG persists, the activation of ADP-glucose pyrophosphorylase stimulates starch synthesis.

20.6.3: GLYCOSYLTRANSFERASES (GTS)

Glycosyltransferases are very important enzymes as they are involved in the synthesis of most of the biomass on the planet. They catalyze the transfer of a monosaccharide from a donor that has been activated by the attachment of a nucleotide in the form of a nucleotide sugar (NDP-sugar) or dolichol-(pyro)phosphate sugar to acceptors. These include other sugars, lipids, and even proteins, which get glycosylated

on alcoholic side chains (Ser, Thr) or amides (Asn). There are over 500,000 different GTs known and deposited in the Carbohydrate-Active enZYmes Database (CAZy database2). Based on sequence and structure there are over 114 different families. Although they depart significantly in primary sequence, only 3 major folds are predominant (GT-A, -B, and -C)

a glycosyl transferase reaction is required for the transfer of glucose from a donor like UDP-glucose to an acceptor like fructose to form sucrose as shown in the reaction below.

NDP-Glc (donor) + F6P (acceptor) → Sucrose-6-P + NDP

Perhaps now is a good time to study their generic reaction mechanisms before we move on to starch synthesis.

About 65% of glycosyltransferase reactions use nucleotide sugars as donors. These enzymes are called Leloir transferases. They are nucleotide-dependent. The activated NDP-sugar donor binds first to the enzyme, followed by the acceptor, to form a ternary complex. A conformational change allows catalysis to occur, which leads to the sequential release of products. The enzyme hence follows a sequential ordered bi-bi mechanism.

The reaction could proceed with either retention or inversion of the anomeric carbon of the donor NDPsugar. This is illustrated for the reaction of a C1 α-NDP donor monosaccharide with a monosaccharide acceptor to produce the α(1,4) link with retention of configuration or the β(1,4) link with inversion as shown in Figure 20.6.5.

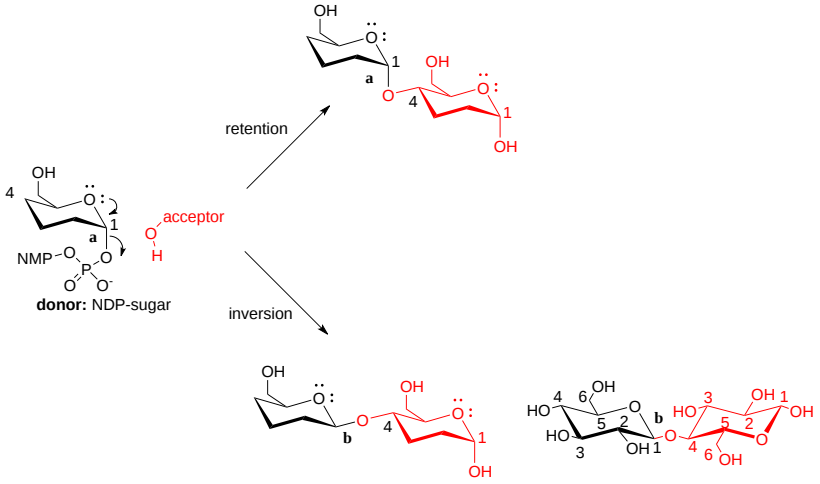

Figure 20.6.5: Reaction of a donor NDP-monosaccharide and an acceptor monosaccharide with retention or inversion of configuration at the anomeric carbon of the donor

The same stereochemical outcomes can occur in the hydrolysis of acetal bonds by glycosyl hydrolases.

Reactions that proceed with inversion react in an S_N2 reaction, similar to the nucleophilic attack on alkyl halides. For the glycosyl transferase that proceeds with inversion, the attacking nucleophile on the acceptor is made more nucleophilic by general base catalysis by a deprotonated glutamic or aspartic acid.

The glycosyl transferase that proceeds with the retention of configuration is less understood. Several alternative mechanisms have been proposed for both inverting and retaining glycosyltransferase in general, as illustrated in Figure 20.6.6.

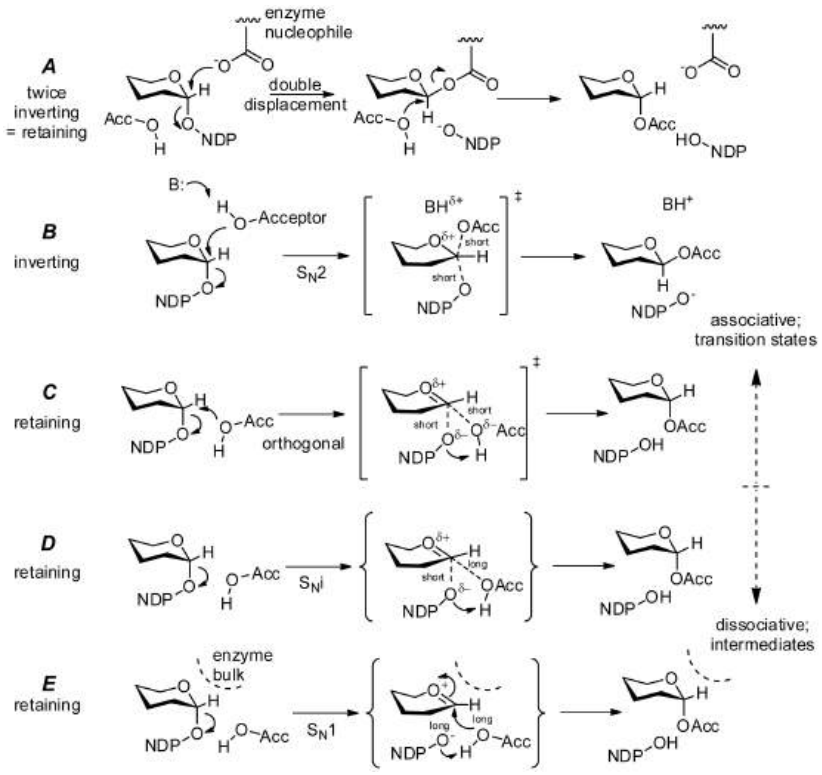

Figure 20.6.6: .Proposed glycosyltransferase mechanisms. Schuman et al. PLOS One (2013). doi:10.1371/journal.pone.0071077.g001. Creative Commons Attribution License

They include the following possible mechanisms:

Panel (A): A double displacement mechanism utilizing two inversions with net retention of stereochemistry involving a covalent glycosyl-enzyme intermediate. The individual steps are inverting via (B) an S_N2 process.

Panel (B): Inverting Leloir glycosyltransferases promote a backside nucleophilic attack on C1 by the acceptor from an inline (usually equatorial) position, resulting in inversion of the anomeric bond stereochemistry.

Panel (C): An orthogonal mechanism consisting of nucleophilic attack on C1 by the acceptor concurrent with leaving group loss from a position approximately at right angles to the C1-leaving group axis.

Panel (D): An S_Ni mechanism involving an intermediate with oxocarbenium character followed by rapid internal nucleophilic attach by the acceptor nucleophile; or

Panel (E): An S_N1 mechanism involving a discrete oxocarbenium intermediate. All mechanisms require proton transfers of the hydroxyl hydrogen of the acceptor to an enzymatic base or the departing leaving group

You will remember from your studies of chemistry that S_N1 reactions are dissociative and form a positively charged carbocation intermediate. In a S_Ni, reaction, the intermediate has cation character but the intermediate is not fully charged. In the case of glycosyltransferase, the intermediates would be oxycarbeniums. (Carbenium ion can be considered carbocations with 3 bonds to the carbon). S_N1 reaction will occur only if the formation of the ion is activated and they are stabilized. A protic solvent is typically required for stabilization if the reaction occurs in solution. In the anhydrous active site of the enzyme, an appropriate arrangement of backbone and side chain negative or partially negative atoms is required to provide stabilization for S_N1 and S_Ni mechanisms.

The double replacement reactions (Panel A) require a side chain nucleophile and likely candidates in retaining glycosyltransferase are not positioned for such a task. The evidence seems to support the orthogonal mechanism. It appears that the binding of the donor is similar in retaining transferase such that it is in a 90^0 position of nucleophilic attack by the acceptor, which leads o a trigonal bipyramidal transition state with the nucleophile axial the leaving group equatorial (orthogonal).

The donor NDP-monosaccharides typically are Mn^2-containing proteins with the inverting and retaining transferase having different coordination geometries for Mn^{2+} binding, as illustrated in Figure 20.6.7.

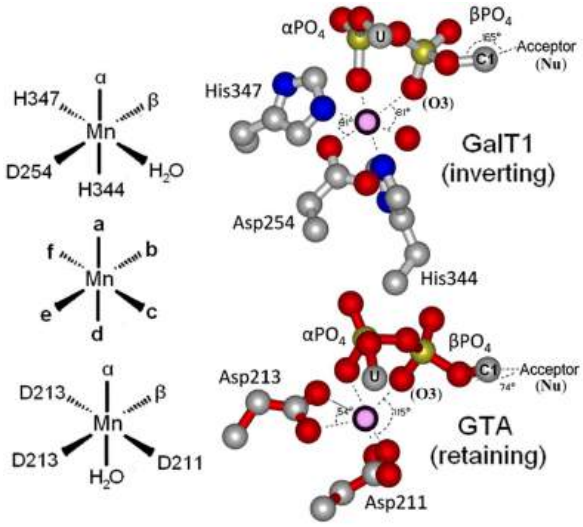

Figure 20.6.7: Coordination geometries for Mn^{2+} binding in glycosyltransferase. Shuman, ibid.

Inverting enzymes such as GalT1 (top) achieve nearly perfect octahedral geometry about the coordinated metal ion (displayed angles of 81° and 91° compared to ideal octahedral 90° bond angles) with subsequent "inline" (approaching 180°) placement of the acceptor nucleophile for classic inverting S_N2 backside attack. Retaining enzymes such as GTA (bottom), however, use an arrangement of acidic residues, often with acute bidentate Asp coordination, which severely skews metal geometry (displayed angles of 54° and 115°) and allows sufficient room between phosphate oxygens for orthogonal attack from the acceptor. **U**is uridine, **C1**is donor galactose **C1**.

Figure 20.6.8 shows a possible mechanism for the transfer of a monosaccharide from the donor ADP-sugar through an oxycarbenium intermediate to an acceptor.

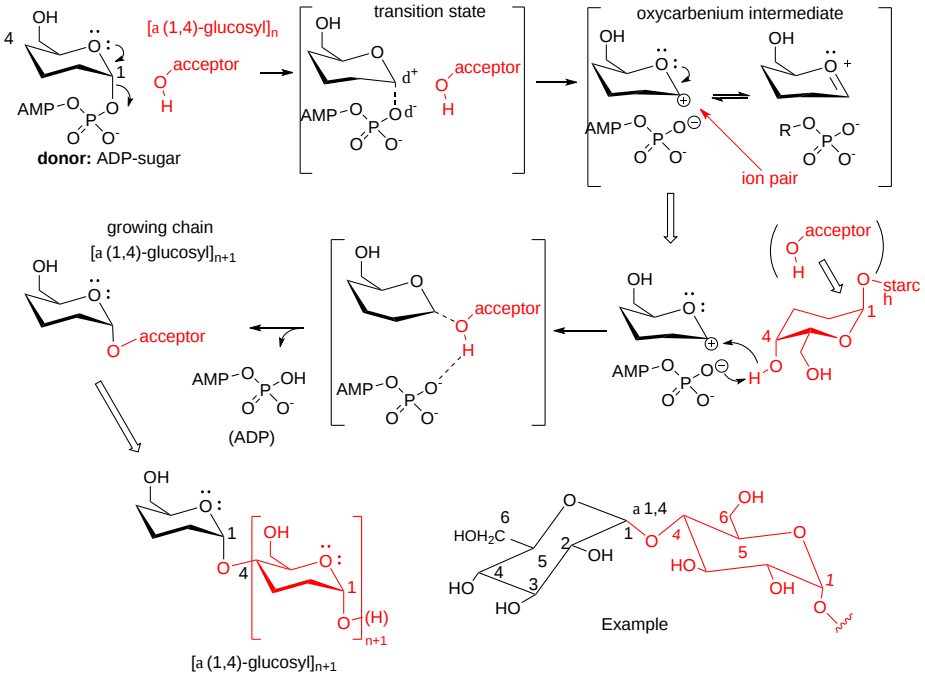

Figure 20.6.8: Possible mechanism for the transfer of a monosaccharide from the donor ADP-sugar through an oxycarbenium intermediate to an acceptor (example - a growing starch chain). Schuman B, Evans SV, Fyles TM (2013) Geometric Attributes of Retaining Glycosyltransferase Enzymes Favor an Orthogonal Mechanism. PLoS ONE 8(8): e71077. doi:10.1371/journal.pone.0071077. Creative Commons Attribution License

As mentioned above, there are three major folds for glycosyltransferases, GT-A, GT-B, and GT-C. Different representations of the structure of the GT-A fold core predicted through analysis by neural networks and deep learning are shown in Figure 20.6.9.

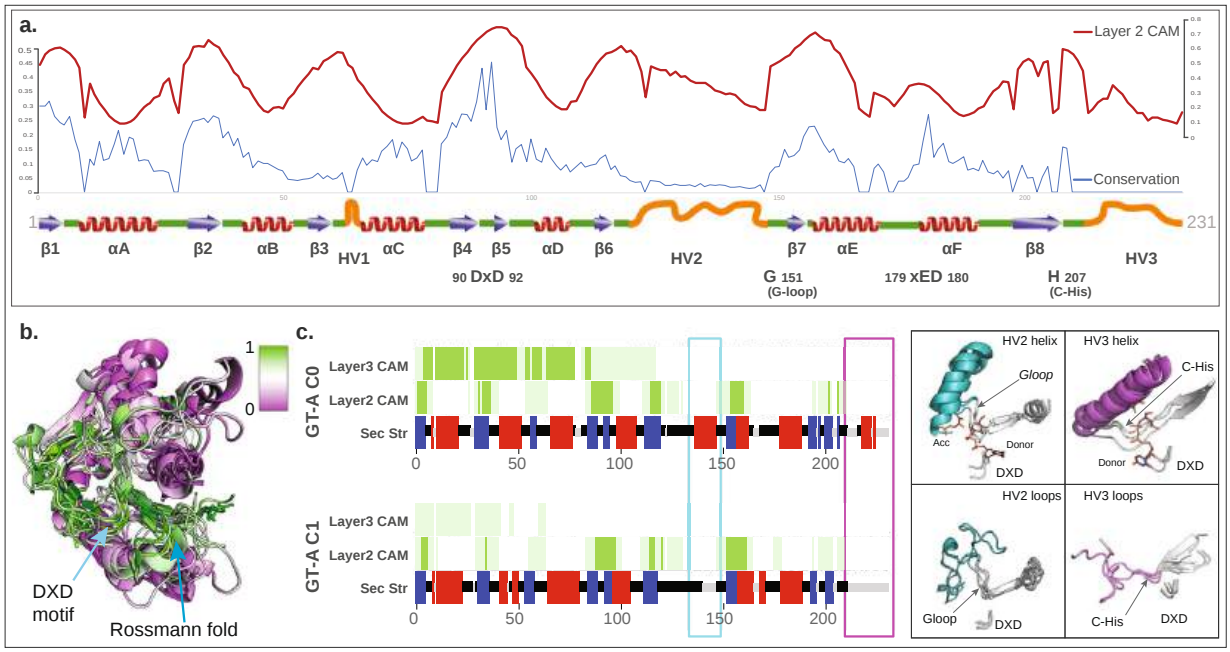

Figure 20.6.9: Fold core of GT-As. Taujale, R., Zhou, Z., Yeung, W. *et al.* Mapping the glycosyltransferase fold landscape using interpretable deep learning. *Nat Commun* **12,** 5656 (2021). https://doi.org/10.1038/s41467-021-25975-9. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

This computational modeling of structure uses simple secondary structure representations generated from primary sequences to predict folds irrespective of sequence. GT folds are predicted with high accuracy by learning secondary structure features free of primary sequence alignments.

Panel (a) shows a linear map of the conserved secondary core structures (below) and graphs (top). The blue line represents a conservation score and the red a CAM score. CAM values correspond to residue positions that distinguish them the most from other class labels (folds and families).

Panel (b) shows a structural alignment of the core with the CAM values mapped onto it. The conserved regions are shown to have a high CAM value indicated by a high intensity of green and a low CAM value of purple.

Panel (c) shows on the left the consensus secondary structure for the aligned positions in the two GT-A fold clusters (blue: beta-sheets; red: helices; green: loops). Average CAM values from using different "layers" of analysis are shown for each aligned position (higher intensity of green corresponds to a higher CAM value). Cyan and magenta boxes highlight the secondary structure differences between the two clusters near the hypervariable HV2 and HV3 region respectively. The conserved DXD motif, G-loop, and C-His are indicated for reference. Donor and acceptor substrates for GT-A0 are shown as sticks

This figure is shown to give readers a sense of the complexity of the analysis required to understand and differentiate structure/function features for these structurally similar but complex enzymes.

20.6.4: STRUCTURE AND ENZYMATIC ACTIVITY OF SUCROSE SYNTHASE (SUSY)

These enzymes are usually homotetramers with a monomeric molecular weight of around 90,000. The monomers typically have an N-terminal domain that directs the targeting of the enzyme to a specific location and a C-terminal GT-B domain. It can be regulated by phosphorylation at a serine near 12 in the N-terminal domain, which presumably regulates its cellular location, and other near 170 that affects its degradation. Two glutamates in the C-terminal GT-B domain (E678 and E686) and phenylalanine (680) are essential for the catalytic activity. Sucrose synthase is reversible as is the synthesis of sucrose-6-P from F6P and UDP-glucose can be reversed in the presence of UDP. The enzyme can also use ADP-glucose as a donor.

The structure of the *Thermosynechococcus elongatus* sucrose phosphate synthase with bound UDP and sucrose-6-Phosphate has been solved and along with other studies a reaction mechanism proposed as shown in Figure 20.6.10.

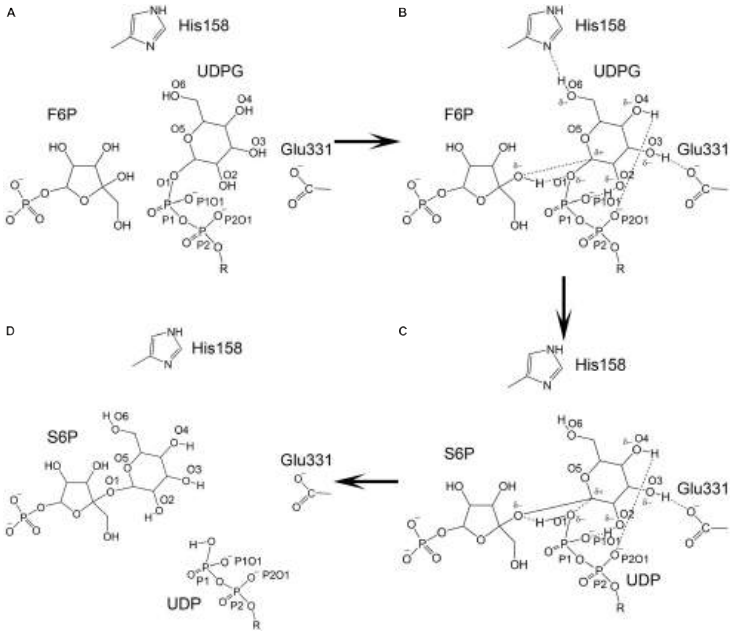

Figure 20.6.10: Catalytic model of TeSPS. Yuying et al. Co-crystal Structure of Thermosynechococcus elongatus Sucrose Phosphate Synthase With UDP and Sucrose-6-Phosphate Provides Insight Into Its Mechanism of Action Involving an Oxocarbenium Ion and the Glycosidic Bond. Frontiers in Microbiology, 11, 2020. https://www.frontiersin.org/article/...icb.2020.01050. **Creative Commons Attribution License (CC BY)**.

(A) The state before the reaction is shown. **(B)**The glucose residue of UDPG forms hydrogen bonds between/among the phosphate groups, His158, Glu331, and F6P. Due to the formation of these hydrogen bonds, the pyranose ring of the glucose becomes negatively charged to promote C1 to form an oxocarbenium ion. **(C)**The relatively weak hydrogen bond formed by His158 and O6 is broken, which causes the pyranose ring to lose some negative charge character and forces the C1 oxocarbenium ion to form a covalent bond with the F6P oxygen atom. **(D)**UDP and S6P are released from the catalytic center.

A 2D view of the active site residues is shown in Figure 20.6.11.

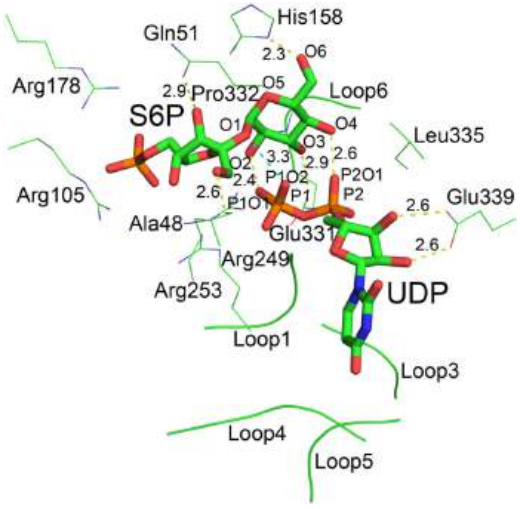

Figure 20.6.11. The catalytic center of TeSPS. Yuying et al. ibid.

The catalytic center of TeSPS. Loops 1, 3, 4, and 5 forms a cave that binds to the uracil moiety of UDP. Glu339 stabilizes the ribose ring via the formation of two hydrogen bonds. Leu335 forces two phosphate groups in UDP to reorient. Several basic amino acids, including Arg105, Arg178, Arg249, and Arg253, interact with the phosphate groups of UDP and S6P via ionic bonds. Pro332 at the turn of loop 6 interacts with the pyranose ring via CH/π bonds. All hydroxyl groups (O2, O3, O4, and O6) of the glucose moiety of S6P form hydrogen bonds with phosphate groups or the side chains of various amino acids. “O2” forms a hydrogen bond with P1O1 of the P1 phosphate group of UDP. “O3” forms a hydrogen bond with the carboxyl group of Glu331. “O4” forms a hydrogen bond with P2O1 of the P2 phosphate

group of UDP. “O6” forms a hydrogen bond with the imidazole side chain of His158. The distances between groups are indicated in the figure

Figure 20.6.12 shows an interactive iCn3D model of the Thermosynechococcus elongatus Sucrose Phosphate Synthase With UDP and Sucrose-6-Phosphate (6KIH)

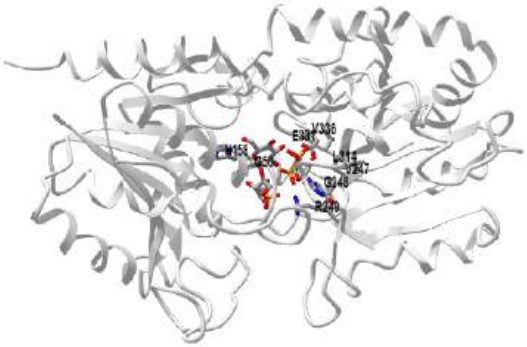

Figure 20.6.12: Thermosynechococcus elongatus Sucrose Phosphate Synthase With UDP and Sucrose-6-Phosphate (6KIH) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...1kCnQ9pxcJjdy7

20.6.5: METABOLISM OF SUCROSE

Sucrose is a primary synthesis product of photosynthesis and is transported to other plant "sink" tissues where it is used for both energy and biosynthetic precursors. Suc transporters can move it from the phloem to the apoplast. It can enter sink cells through Suc transporters or be hydrolyzed by cell-wall invertase (cwINV) to yield glucose (Glc) and fructose (Fru), which enter by hexose transporters. Suc can also pass directly from the phloem to sink cells through plasmodesmata (physical connections between cells). Inside sink cells, Suc can be metabolized or transported to the vacuole, where it can be stored as Suc, transformed into fructans by fructosyltransferases (FTs), or hydrolyzed by vacuolar invertase (vINV) and stored as hexoses. To be metabolized, Suc must be hydrolyzed by either cytosolic invertase (INV) into glucose and fructose, or by the reversible reaction of sucrose synthase (SuSy) using UDP instead of water to yield fructose and UDP-G. These processes are illustrated in Figure 20.6.13.

20.6.5.1:

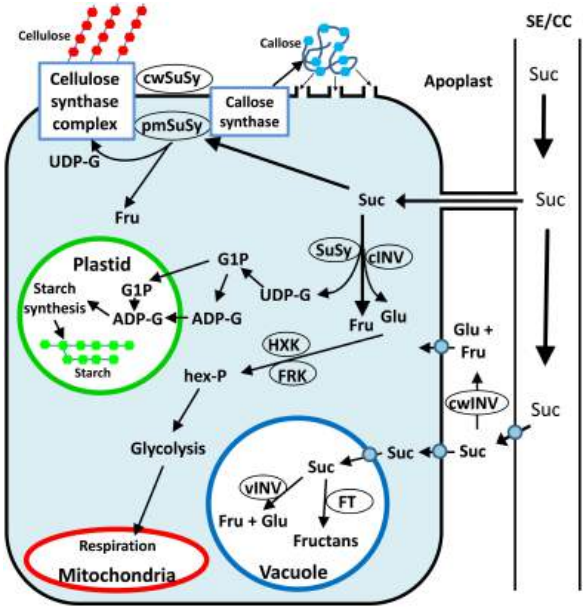

Figure 20.6.13: Simplified schematic presentation of sugar metabolism in sink tissue cells toward cellulose, callose, and starch synthesis. Stein and Granot. Frontiers in Plant Science (10). 2019. https://www.frontiersin.org/article/...pls.2019.00095. DOI=10.3389/fpls.2019.00095 https://www.frontiersin.org/articles...019.00095/full

The hexoses (glucose and fructose) can be phosphorylated to hexose phosphates (hex-P), directed to starch synthesis in the plastid or glycolysis, and then respiration in the mitochondria or directed to other metabolic pathways. Plasma membrane-associated SuSy (pmSuSy)

and cwSUS can generate UDP-G that is used in the synthesis of cellulose for cell walls and callose for plugging plasmodesmata. Callose is a polysaccharide in the form of β-1,3-glucan with some β-1,6-branches in the cell walls of a wide variety of higher plants

20.6.6: BIOSYNTHESIS OF STARCH

During active photosynthesis in bright light, a plant leaf produces more carbohydrates (as triose phosphates) than it needs for generating energy or synthesizing precursors. The excess is converted to sucrose and transported to other parts of the plant, to be used as fuel or stored. In most plants, starch is the main storage form, but in a few plants, such as sugar beet and sugarcane, sucrose is the primary storage form. The synthesis of sucrose and starch occurs in different cellular compartments (cytosol and plastids, respectively), and these processes are coordinated by a variety of regulatory mechanisms that respond to changes in light level and photosynthetic rate.

20.6.6.0.1: STARCH SYNTHESIS

Starch, like glycogen, is a homopolymer of D-glucose in (α1,4) linkage with (α1,6) branches. Glycogen is found in Archaea, Bacteria, and Eukaryotes. In contrast, starch is found in photosynthetic algae, land plants, and in some cyanobacterial species.

Starch is synthesized by starch synthase in chloroplasts for temporary storage and in amyloplasts in seeds, roots, and underground stems (tubers) for long-term storage. As with the synthesis of glycogen, the glycosyltransferase catalyzes the addition of an activated ADP-glucose to the acceptor, the elongating starch polymer.

$$\text{ADP-α-D-glucose-1-phosphate (donor)} + [(1\rightarrow4)\text{-α-D-glucosyl}]_{(n)}\ \text{(acceptor)} \leftrightarrow [(1\rightarrow4)\text{-α-D-glucosyl}]_{(n+1)} + \text{ADP} + H^+$$

The ADP-glucose donor is formed in the following reaction:

$$\text{Glucose 1-phosphate} + \text{ATP} \leftrightarrow \text{ADP-glucose} + \text{PPi}$$

In plastids, there is, in contrast to the cytosol, a pyrophosphatase which makes the reaction irreversible. Hence the next overall reaction is

$$\text{Starch}_n + \text{glucose 1-phosphate} + \text{ATP} \rightarrow \text{starch}_{n+1} + \text{ADP} + 2\text{Pi}$$

Taking into account the hydrolysis by inorganic pyrophosphatase of the PPi produced during ADP-glucose synthesis, the overall reaction for starch formation from glucose 1-phosphate is:

$$\text{Starch}_n + \text{glucose 1-phosphate} + \text{ATP} \rightarrow \text{starch}_{n+1} + \text{ADP} + 2\text{Pi};\ \Delta G'^{o} = -50\ \text{kJ/mol} = -12\ \text{kcal/mole}\ (-50\ \text{kJ/mol})$$

$$\Delta G'^{o} = -50\ \text{kJ/mol} = -12\ \text{kcal/mol}$$

In glycogen synthesis, the donor is UDP-glucose, and it is added to the reducing end (C1) of the growing glycogen polymer (with the C1 OH acting as a nucleophile) so the polymer extends from that end. Kinetic models suggest that starch synthases, which use ADP-glucose, may use two different active sites that appear to alternately add glucose to the nonreducing C4 end (with the C4 OH acting as a nucleophile), with the reducing end of the linear α(1,4) polymer being alternately covalently attached to one site, then the other, with the attachment activating that end for reaction with C4-OH of the polymer at the other site.

Figure 20.6.14 shows a very simplified structure of the starch synthase using two different active sites as the reaction proceeds through the first steps.

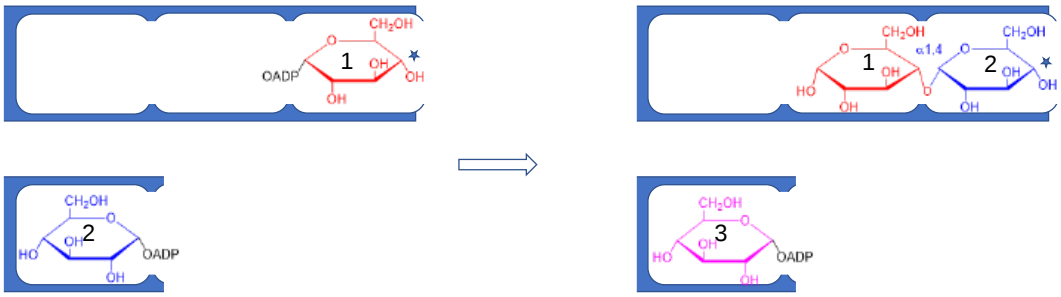

Figure 20.6.14 shows a simplified structure of the starch synthase using two active sites

Note that additional glucose units are added to the nonreducing C4 end denoted by a star. α(1,6) branches are added by branching enzymes as in the case of glycogen. Bacteria starch is made in a fashion similar to glycogen, but they use ADP-glucose as do plant starch synthase. Structural models show that the protein has one active site so the kinetic models suggesting the use of two active sites may refer to a movement of chains between different monomers in oligomeric forms of the protein.

Both the donor (ADP-Glc) and product (starch_{n+1}) have their participating electrophile (ADP) and now substituted nucleophile (C4-O-R) in the α-anomeric form so they are retaining glycosyltransferases. The enzymes could act in two different ways:

- processive mechanism: the acceptor ($starch_n$) stays bound to the enzyme after each addition of the next glucose from the donor ADP-glc, and one chain extends quickly
- distributive mechanism: the enzyme dissociates from the product ($starch_{n+1}$) after the addition of the glucose from ADP-glc, and must rebind to catalyze the next addition, so many new chains start and the growth of each chain is slow

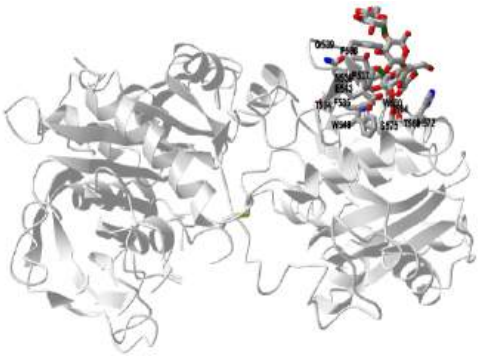
Kinetic evidence suggests that some starch synthases are processive and others are distributive. Along with starch synthase, three other enzymes are involved, ADP-glucose pyrophosphorylase (AGPase), starch branching enzyme (SBE), and starch debranching enzyme (DBE)

Starch synthesis is regulated by gene transcription, phosphorylation, and redox conditions. A key regulatory enzyme is an ADP-glucose pyrophosphorylase (AGPase). This enzyme catalyzes the formation of ADP-glucose (the donor) and PPi from glucose 1-phosphate and ATP. Dithiothreitol, a reducing agent, increases starch synthesis by inactivating AGPase. We will see below that a key disulfide bond is some starch synthases that must be reduced (cleaved) to open an active site cleft between the N-terminal and C-terminal lobes of the catalytic domain. In vivo, thioredoxins are probably involved in redox regulation.

20.6.7: STRUCTURES OF STARCH SYNTHETASES (SS)

The are four classes of soluble starch synthetases (SSI-SSIV) and one starch granule-bound one (GBSS). All have two catalytic domains as noted in the mechanism above except SSII which has 3 CHO binding domains. GBSS appears to form amylose and long chains of amylopectins (amylose with around 5% α(1,6) branching. Loss of function mutants of GBSS have much-reduced amylose concentrations. SSI-SSIII produces most of the amylopectin. SSI is most active with stands (outer ones in branched structures) that have around 7-9 glucoses. In leaves, it generates chains of up to about 10 residues in amylopectin. The SSs can be chloroplastic or amyloplastic.

Figure 20.6.15 shows an interactive iCn3D model of barley starch synthase I in complex with maltooligosaccharide (4HLN).

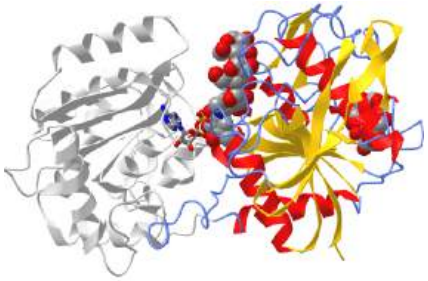


NCBI iCn3D Figure 20.6.15: Barley starch synthase I in complex with maltooligosaccharide (4HLN). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...LGwFUeJAMskBcA

The protein is shown in gray in an open conformation a glucose 5-mer bound on the outside. The protein has a GT-B fold with distinct N- and C-terminal Rossmann-like domains and a central linker. Side chains within 5 Å of oligosaccharide are shown in sticks and labeled. Note especially the disulfide bridge between cysteines 126 and 506 in the central part of the protein that prevents the formation of the active site. This clearly shows the importance of redox signaling to activate the enzyme.

The maltose is not bound in the active site but at a surface secondary binding site (SBS). The role of this site is a bit unclear but may be involved in carbohydrate:carbohydrate interactions. Specifically, they may assist in recruiting starch chains for further elongation. SBSs are found in many but not all starch synthases. Note that in this structure there is only one occluded active site and not two as suggested in Figure 14 above.

Figure 20.6.16 shows an interactive iCn3D model of the catalytic domain of starch synthase IV from Arabidopsis thaliana bound to ADP and acarbose (6GNE).



NCBI iCn3D Figure 20.6.16: Catalytic domain of starch synthase IV from Arabidopsis thaliana bound to ADP and acarbose (6GNE) https://structure.ncbi.nlm.nih.gov/i...MioUaKM73M3Wd9

This structure is just the catalytic domain (representing about half of the total protein sequence). The N-terminal domain is colored by the secondary structure. Acarbose (spacefill, CPK colors) again occupies both the donor and acceptor sites in the active site (central regions). The structure has a secondary binding site (SBS) occupied by the disaccharide maltose. Again there are not two active sites, but the migration of starch chains between monomers in oligomeric forms could support the model shown in Figure 14.

The structure of beta-acarbose, an inhibitor, is shown in Figure 20.6.17.

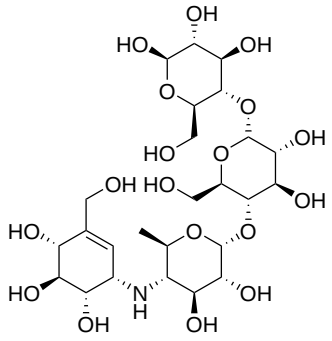


Figure 20.6.17: structure of beta-acarbose

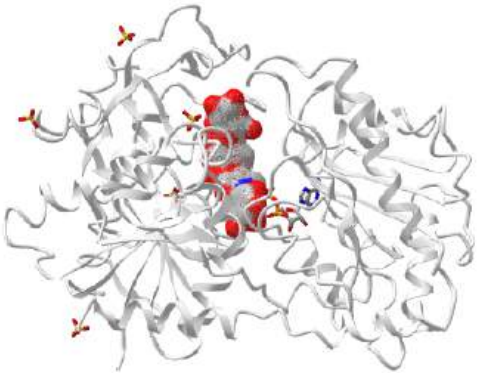
Figure 20.6.x18 below shows an interactive iCn3D model of the Granule Bound Starch Synthase from Cyanobacterium sp. CLg1 bound to acarbose and ADP (6GNF)



NCBI iCn3D Figure 20.6.18: Granule Bound Starch Synthase from Cyanobacterium sp. CLg1 bound to beta-acarbose and ADP (6GNF). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?F1tJBDAh6QRhxpH88

ADP, occupying part of the donor site that would usually bind NTP-Glc, is shown in CPK-colored sticks. The rest of the donor site (where Glc of NTP-Glc would bind) and the acceptor site (growing starch chain) is occupied by beta-acarbose, It is shown in the CPK-colored wire-frame surface. Histidine 181, which probably stabilizes an " oxocarbenium-like anomeric carbon in the transition state", is shown in ball and sticks with CPK colors.

20.6.8: CELLULOSE SYNTHESIS

We can't leave plant carbohydrate metabolism without considering the synthesis of cellulose, which is catalyzed in plants by members of the superfamily cellulose synthase (CesA) and cellulose synthase-like (CsI) enzymes, which are part of the glycosyltransferase GT2 family and have similar structures. Cellulose and hemicellulose are, of course, chief components of the 1^0 and 2^0 cell walls. Members of the CesA family have a conserved motif (DDDQxxRW) as well as a zinc-finger domain. Different members catalyze the synthesis of the 1^0 and 2^0 cell walls. Members of the Csl family are involved in additional cell wall glycans including (1,4)-β-D-mannan (CsIA) and xyloglucan cytoskeleton (CslC). UDP-glucose is the donor in the creation of the β(1,4) acetal linkages between glucose monomers.

Plant growth must respond to environmental triggers through a balance of cell expansion and cell division and a key regulator of these processes is the flexibility of the cell walls which can maintain turgor pressure by expansion. Cells that are nonexpanding (for example those that line the xylem vessels and in woody tissue) have secondary cell walls beneath their primary walls.

We have previously discussed the structure of the primary and secondary cell walls in Chapter 7.3. In brief, the primary cell walls contain cellulose, hemicellulose, and pectins. Cellulose, the main component that provides strength, is synthesized by CesA which forms a very

large rosette-shaped complex (CSC). These complexes seem to move intracellular microtubules which guide that synthase complex through the interactions of microtubule-associated cellulose synthase compartments (MASCs), whose numbers increase during stress. Likewise, there are uncoupling proteins that inhibit microtubule movement from the CSC. These protein complexes stay aligned during cell growth. The cell wall hence is a key player in signal transduction that allows growth and cell division.

The structure of the rosette-shaped complex (CSC) has been determined by cyroEM and is shown in Figure 20.6.19.

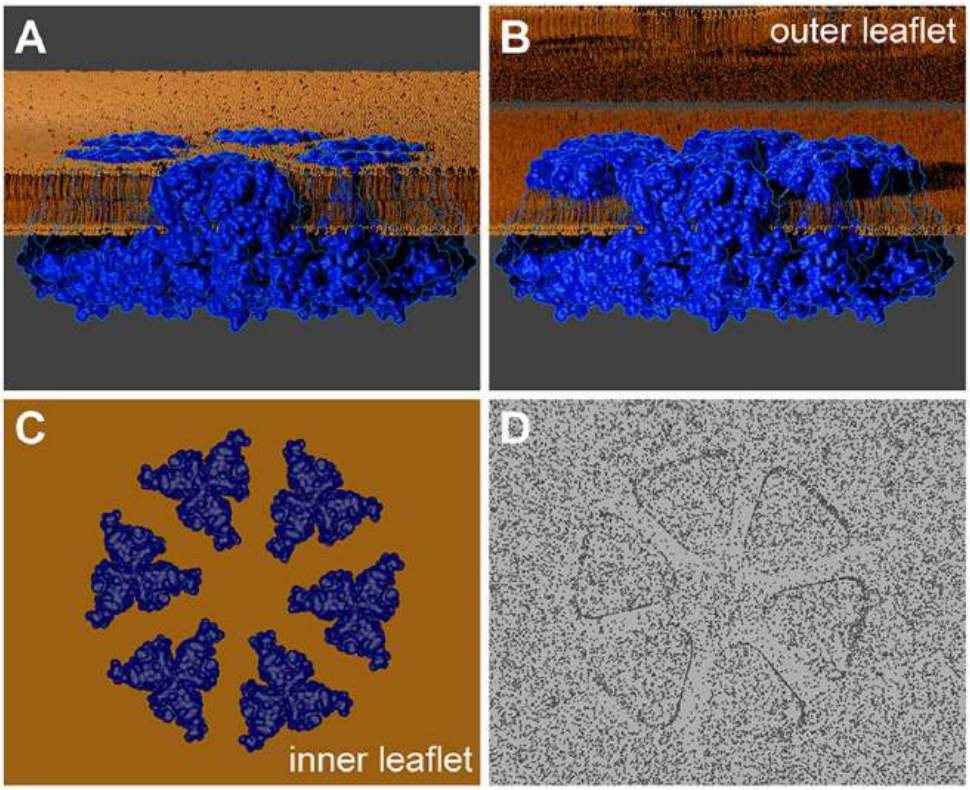


Figure 20.6.19: Structural cartoons of the CESA CSC complex. Nixon, B., Mansouri, K., Singh, A., *et al.* Comparative Structural and Computational Analysis Supports Eighteen Cellulose Synthases in the Plant Cellulose Synthesis Complex. *Sci Rep* **6,** 28696 (2016). https://doi.org/10.1038/srep28696. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/

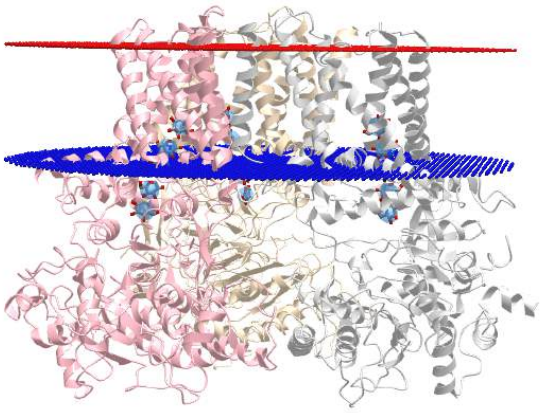
Panel (A) shows the complex as a series of trimers of CESAs, with each monomer spanning the membrane with 7 alpha helices. The catalytic domain is in the cytoplasm.

Panel (B) shows the CSC complex with the top leaflet removed

Panel (C) shows a top-down view showing 6 sets of trimers of CESA.

Panel (D) shows a metal replica viewed in the TEM after the removal of the biological material.

Each trimer synthesizes a cellulose strand. There are 18 trimers in the complex allowing the concomitant synthesis of cellulose strands that can easily self-associate through hydrogen bonding to form near the extracellular surface cellulose protofibrils.Figure 20.6.20 shows an interactive iCn3D model of the catalytically active homotrimeric poplar cellulose synthase (6WLB)



NCBI iCn3D Figure 20.6.20: Catalytically active homotrimeric poplar cellulose synthase (6WLB). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...zCm6fYSwAFA897

Each of the monomers within the trimers is given a different color. A 5 residue β(1,4) glycan is shown in cartoon form emerging into the middle of the membrane complex.

Figure 20.6.21 shows an interactive iCn3D model of the homotrimeric poplar cellulose synthase isoform glycan binding site (6WLB).

The actual transmembrane channels start just above the active site. Key amino acid side chains (Trp 718, Phe 513, Val 529, and Gln 494) help form the portal opening. The actual channel is lined with both aromatic and hydrophilic residues, which supply sufficient but not too strong noncovalent interactions that allow sequential movement of the continually-synthesized cellulose as it ratchets forward toward the extracellular side of the membrane. The aromatic residues interact through pi stacking with the glucose residues and through interactions with equatorial OH groups on the β-glucose polymer. Remember that cellulose is especially stable from a steric perspective since all its OH groups and the acetal linkage are equatorial.

CHAPTER OVERVIEW

21: LIPID BIOSYNTHESIS

21.1: Biosynthesis of Fatty Acids and Eicosanoids
21.2: Biosynthesis of Triacylglycerols

21.6: Biosynthesis of Isoprenoids

21.1: BIOSYNTHESIS OF FATTY ACIDS AND EICOSANOIDS

21.1.1: INTRODUCTION

We present the full fatty acid synthase pathway based on the structure of the yeast fatty acid synthase (FAS) complex, whose full structure is known. Then we will explore each step in more detail. The mammalian FAS complex is a bit different and we will summarize those differences next. We will end with a summary of the bacterial pathway.

Let's look at the net reaction first and then go back to the structure and mechanism from that. Equation 1 below shows the net reaction.

$$8\ \text{Acetyl-CoA}\ (2\text{C}) + 14\text{NADPH} + 14\text{H}^+ + 7\text{ATP} \rightarrow 1\ \text{Palmitate}\ (16:0) + 8\text{CoA} + 6\text{H}_2\text{O} + 14\text{NADP}^+ + 7\text{ADP} + 7\text{Pi} \qquad (21.1.1)$$

Eight 2C-acetyl-CoAs condense to make the 16:0 fatty acid palmitate. That acetyl-CoA is used to synthesize and elongate fatty acids suggests an immediate explanation for the fact that most fatty acids have an even number of carbon atoms. The net reaction is a reductive biosynthesis making one long molecule from multiple short ones. Hence there must be an energy source to drive the reaction (7ATPs) and a reducing agent (typically NADPH). This reaction takes place in the cytosol and uses the nicotinamide-based redox pair (NADPH/$NADP^+$). These factors differentiate fatty acid synthesis from beta-oxidation, which occurs in the mitochondria and which uses the redox pair NAD^+/NADH.

From a chemical perspective, the acetyl-CoAs, high-energy molecules with respect to their hydrolysis products, must be activated using ATP in some way to drive C-C bond formations. That reaction is catalyzed by the enzyme **acetyl-CoA carboxylase**, which uses the ATP already mentioned and the bound cofactor biotin that adds CO_2 to acetyl-CoA to form malonyl-CoA. Neither malonyl-CoA nor CO_2 is shown in the above equation since they are present on both sides of the net reaction and cancel out from the final balanced equation. C-C bond formation occurs on the addition of the growing acyl group with the 3C malonyl with the actual addition reaction driven by the release of CO_2. The malonyl-CoA produced by acetyl-CoA carboxylase feeds now into the fatty acid synthesis cycle.

Only one other enzyme complex is required for the entire reaction, the **fatty acid synthase (FAS) complex**. Don't let that fool you into thinking the mechanism is simple though! There are two types of fatty acid synthase complexes, I and II. Type II FAS is found in plants, most bacteria, and in mitochondria. (Its presence in the mitochondria might seem odd since fatty acid oxidation occurs there. We will discuss that in a bit.) There are multiple separate enzymes to catalyze the synthesis of fatty acids in the Type II FAS systems. We won't discuss those. Instead, we will focus on the **Type I FAS complex** found in some bacteria, fungi like yeast, and higher eukaryotes. The Type I FAS is one very large complex. In mammals, it consists of two α chains with a total molecular weight of 540,000. In yeast, it is an $\alpha_6\beta_6$ heterododecamer with a molecular weight of 2.6 million. In either complex, the alpha and beta chains have multiple different enzyme catalytic domains.

Large enzymatic complexes typically allow bound substrates to proceed to products without dissociation, with the bound intermediates moving through "channels" to the next active site. In the case of Type I FAS, the growing intermediate, which eventually reaches the end product size 16:0 is tethered to an **acyl-carrier protein (ACP)**. The tethered intermediate can "swing" from one active site to another to allow the iterative stepwise chemical reactions to complete before the addition of another 2C acetyl CA to the growing chain. The actual extra 2Cs come from the 3C malonyl-CoA (formed by the extracyclic (outside of the pathway) enzyme acetyl-CoA carboxylase) and immediate release of CO_2 which helps drive the reaction forward.

Now we can introduce the fatty acid synthase cycle and feeder acetyl-CoA carboxylase reaction in its entirely, as shown in Figure 21.1.1 for yeast FAS1.

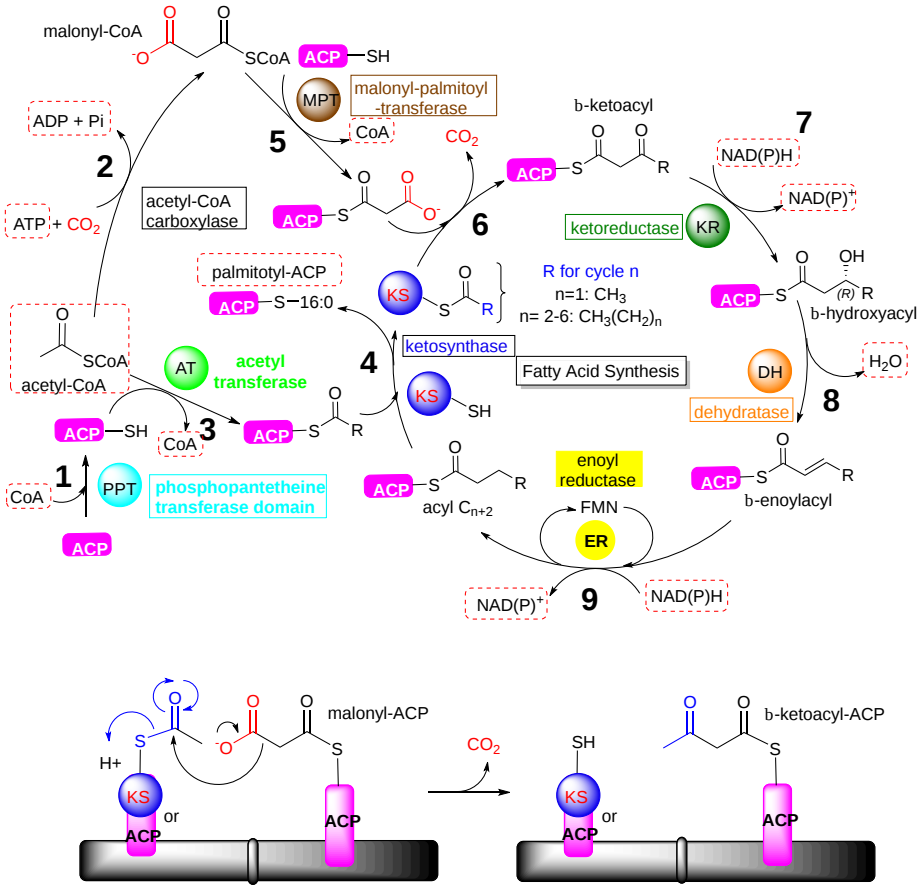

Figure 21.1.1: The Yeast Fatty Acid synthesis cycle with the feeder acetyl-CoA carboxylase reaction. The bottom part of the figure shows a mechanism for the condensation between acetyl-CoA attached to ACP or KS and malonyl-CoA, driven by the release of CO_2. (adapted from Singh et al. Cell, 180 (2020), https://doi.org/10.1016/j.cell.2020.02.034 and Fischer et al. *Sci Rep* **10,** 895 (2020). https://doi.org/10.1038/s41598-020-57418-8. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/

This is a difficult figure to understand but keep in mind that it scales down the complexity of FAS1 enormously. Let's deconstruct the figure to make it more understandable.

The dotted red boxes show the substrates and products that match chemical equation 1. The substrate acetyl-CoA comes into the cycle in two places shown in the extracyclic section to the upper left. It comes in as acetyl-CoA from **reaction 3** after attachment to the acyl carrier protein (part of FAS1). It also comes in "effectively" after it has been carboxylated by acetyl-CoA carboxylase in **reaction 2** to malonyl-CoA, which enters the cycle as malonyl-ACP after **reaction 5**. The other substrates/products include CoAs the NAD(P)H/$NADP^+$ couples and H_2O shown around the right-hand side of the circular fatty acid synthesis cycle (2 -6 o'clock positions) as well as the final product, 16:0-ACP (9:30 clock position), which forms 16:0-SCoA.

The individual enzymatic domains in the $\alpha_6\beta_6$ hetero-dodecamer yeast FAS1 are shown in colored spheres as shown in Figure 21.1.2.

Domain	Chain	Name
ACP	α FAS2	acyl carrier protein
PPT	α FAS2	Phosphopantetheine transferase
AT	β FAS1	acetyl transferase
MPT	β FAS1	malonyl-palmitoyl transferase
KR	α FAS2	keto reductase
DH	β FAS1	dehydratase
ER	β FAS1	Enoyl reductase
KS	α FAS2	ketosynthase

Figure 21.1.2: Enzymatic domains in the $\alpha_6\beta_6$ heterododecamer yeast FAS1

Figure 21.1.3 summarizes pictorially the repetitive Claisen condensation reactions of acetyl-ACP and malonyl-ACP in the first step, and the growing acyl-ACP chain and malonyl-CoA in the next two cycles.

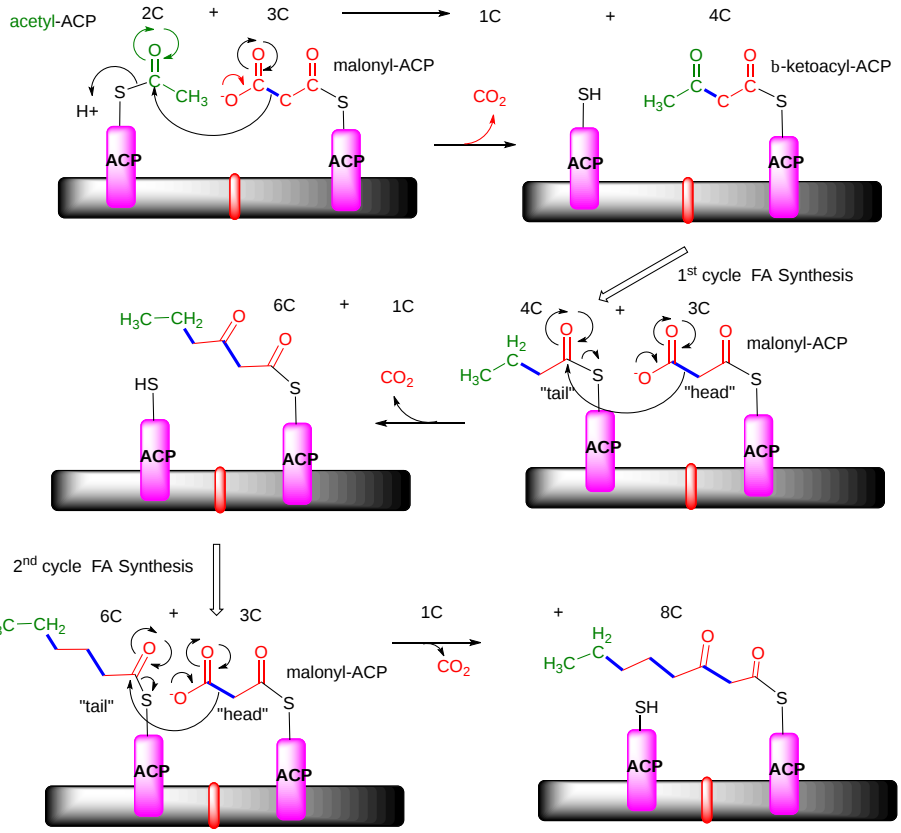

Figure 21.1.3: Pictorial summary of the first three condensation reactions in fatty acid synthesis. Each acyl group is shown connected to ACP for simplicity.

In each step, the condensation (C-C bond formation) is driven by the decarboxylation of malonyl-CoA. (Of course, earlier expenditure of ATP in step 1 is required). Electrons in malonyl-CoA that form a bond with acetyl-ACP in the first condensation step and acyl-ACP in subsequent condensations are shown as **bold blue lines**. Note that the condensation is from the head of the malonyl-ACP to the tail of the elongating acyl chain. The ACP or equivalent chains are in the interior of the complex which allows movement of the acyl groups attached to pantetheine chains to interactively reach nearby catalytic domains for each step in the cycle.

21.1.2: MECHANISM OF INDIVIDUAL REACTIONS

Now we can explore some of the reactions in more detail. Then we will look at the structure of yeast FAS and its domain organization.

21.1.2.1: REACTION 1: PHOSPHOPANTETHEINE TRANSFERASE

Holo-(acyl carrier protein) synthase (AcpS) from *Bacillus subtilis* is a member of the phosphopantetheinyl transferase superfamily. AcpS post-translationally modifies ACP to its holo form to activate it. AcpS catalyzes the transfer of the 4'-phosphopantetheinyl (P-pant) moiety of coenzyme A to a serine residue on the ACP. This gives the activated ACP enzyme and adenosine 3'5'-bisphosphate as products. This process is important as ACP enzymes play important roles in several biosynthetic pathways, such as the synthesis of fatty acids, and vitamins, AcpS is essential in the initiation of the biosynthesis of fatty acids, polyketide antibiotics, and non-ribosomal peptide

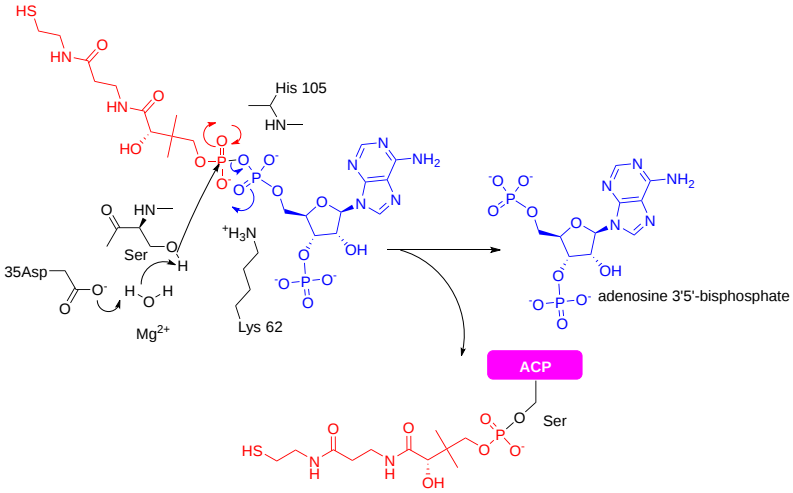

Figure 21.1.4: https://www.ebi.ac.uk/thornton-srv/m-csa/entry/152/

21.1.2.2: REACTION 2: ACETYL-COA CARBOXYLASE (ACC)

This enzyme catalyzes the carboxylation of acetyl-CoA to malonyl-CoA. which then enters the fatty acid synthesis cycle. This is a key enzyme as it is the rate-limiting step, and is regulated. The reaction has two steps:

- carboxylation of biotin on a biotin carboxyl carrier domain of the enzyme at the expense of ATP hydrolysis. The carboxylation, using bicarbonate as a substrate, leads to the formation of a molecule with high energy (with respect to its hydrolysis product), the carboxylated biotin intermediate. (**Remember, there is no such thing as a "high energy" bond.**)
- transfer of the carboxyl group to acetyl-CoA to form malonyl-CoA which requires the formation of a C-C covalent bond.

Biotin, an essential nutrient and cofactor, "carries" activated carboxyl groups for transfer. It is a carboxyl (not acetyl) donor. It is linked to a lysine side chain in the protein through an amide link.

The enzyme is downregulated by 16:0-SCoA, the end product of the pathway for fatty synthesis by FAS, and by phosphorylation by kinase activation through the cAMP pathways from glucagon binding. You don't want to synthesize fatty acids when your energy state is low (signaled by increases in glucagon). Its activity is upregulated by the binding of citrate to an allosteric site. This makes sense since high citrate, a citric acid cycle intermediate, signifies abundant energy reserves are available so fatty acids would be synthesized for future needs. The dephosphorylated form of the enzyme would signify the need to increase fatty acid synthesis.

Figure 21.1.5 shows a few steps in the carboxylation of biotin and the subsequent transfer of the carboxy group to acetyl-CoA, forming malonyl-CoA.

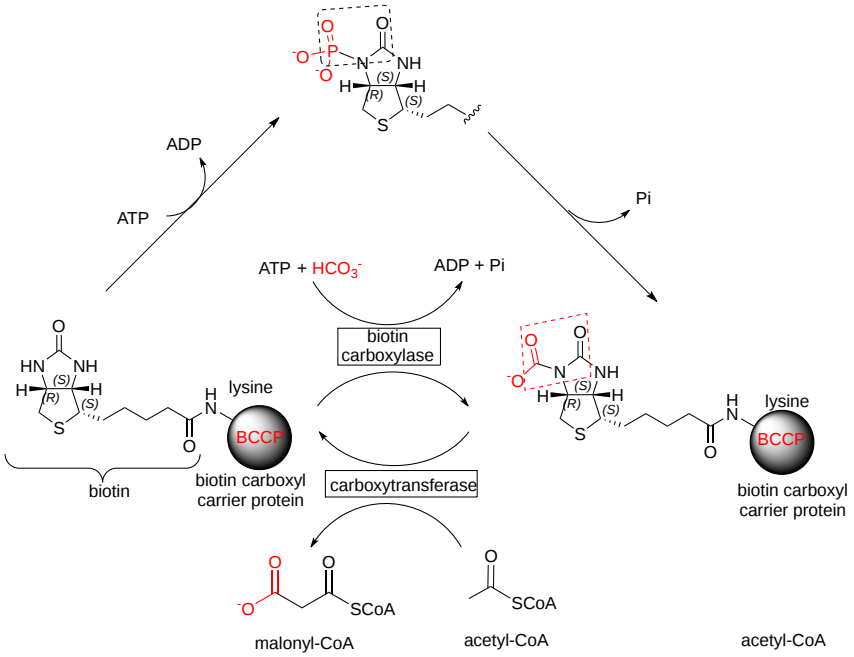

Figure 21.1.5: Simplified reactions of acetyl-CoA carboxylase

BCCP represents the biotin carboxyl carrier domain of acetyl-CoA carboxylase.

Biotin carboxylases are found in many enzymes and pathways, not just fatty acid synthesis. Scientists are trying to devise new pathways and enhanced carboxylases to pull CO_2 from the air into biosynthetic reactions producing fuels, which could be burned. This would release CO_2 back into the atmosphere, in a process that would theoretically but perhaps not practically carbon neutral with respect to greenhouse gas emission.

The abbreviated mechanism shown above shows two of the three activities of acetyl-CoA carboxylase. They are **biotin carboxylase (BC)** and **carboxyltransferase (CT)** activity. The third is the **biotin carboxyl carrier protein (BCCP)** which links biotin to it through a lysine side chain. Different enzymes have different acceptors (acetyl-CoA, pyruvate, etc) of the activated carboxy group so the structure of those centers varies significantly. The BC and BCCP components are structurally similar for different carboxylases.

A mechanism for the E. Coli biotin carboxylase component of the reaction is shown in Figure 21.1.6.

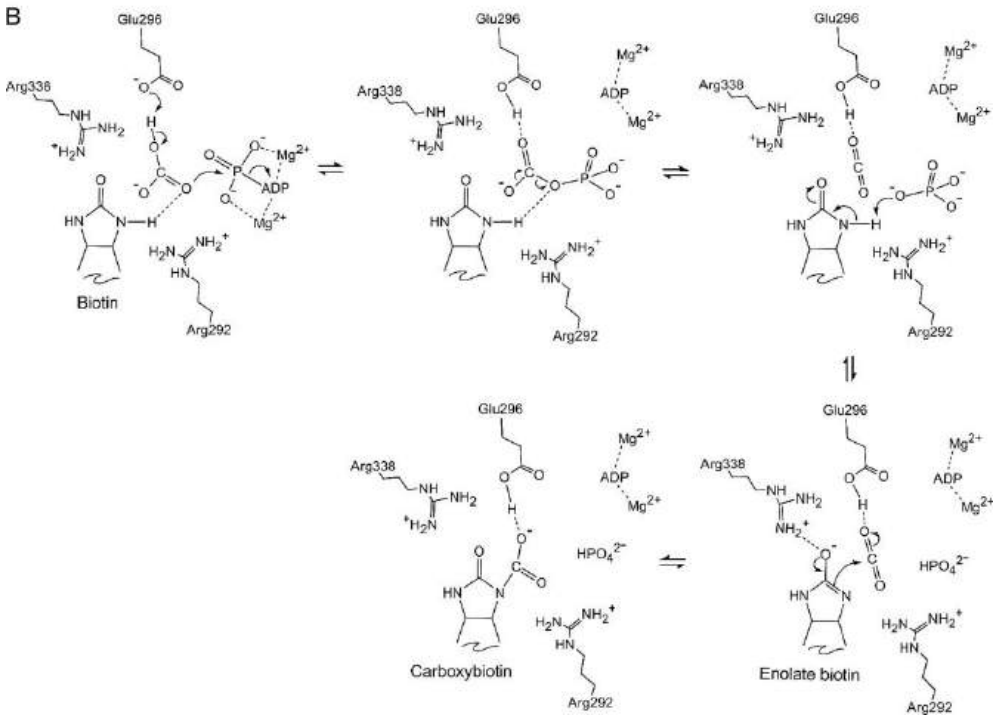

Figure 21.1.6 Reaction mechanism for E. Coli biotin carboxylase. Chou et al. J Biol Chem. 2009 Apr 24; 284(17): 11690–11697. doi:10.1074/jbc.M805783200. Creative Commons Attribution (CC BY 4.0)

Glu 296 acts as a general acid/base while Arg 338 stabilizes negative charge in intermediates and transition states.

Structure of acetyl-CoA carboxylase (ACC)

There are two forms of ACC, soluble cytosolic ACC1 and mitochondrial membrane-associated ACC2 (the latter which regulates beta-oxidation of fatty acids. The overall domain structure of yeast acetyl-CoA carboxylase is in Figure 21.1.7.

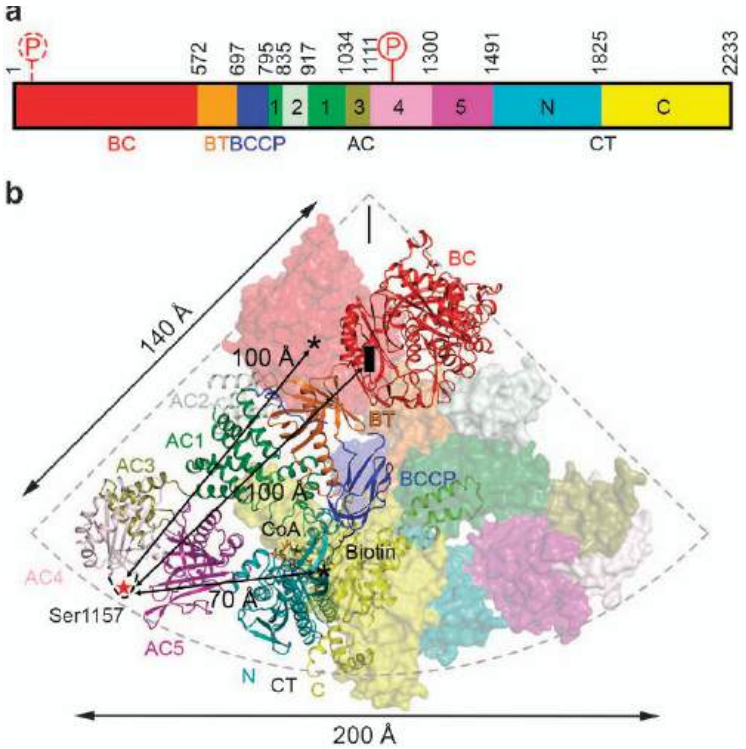

Figure 21.1.7: Overall structure of yeast acetyl-CoA carboxylase (ACC) (ScACC). Wei et al. Cell Discovery (2016) 2, 16044; doi:10.1038/celldisc.2016.44. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

Panel (a) shows the domain organization of ScACC. The domains are labeled and given different colors. The five domains of ACC Central (AC1–AC5) are labeled 1–5. The phosphorylation site in the central region is indicated. The phosphorylation site before the biotin carboxylase (BC) domain core is indicated with the dashed lines, as it is absent in ScACC.

Panel (b) shows the structure of the ScACC holoenzyme dimer [7]. One protomer is shown as ribbons, while the other as a surface. The domains in the monomers are colored according to panel (a) and labeled. Ser1157 (red star) is located in a loop missing in the structure (dashed lines), and its distances to the BC and carboxyltransferase (CT) active sites (black asterisks) and the BC dimer interface (black rectangle) in the holoenzyme are indicated.

A chain domain structure 5CSKA_Yeast Acety-lCoA Carboxylase is shown in Figure 21.1.8.

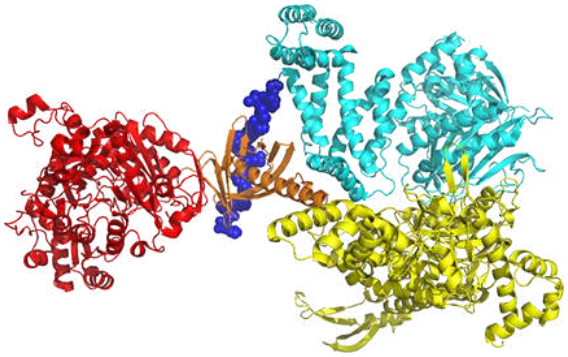

Figure 21.1.8: General domain structure of yeast acetyl-CoA carboxylase A monomer

The colors used to show the domains are matched to Figure 21.1.x above and are as follows:

- Red - BC, biotin carboxylase (has enzymatic activity)
- Gold - BT, an interaction domain
- Blue - BCCP (biotin carboxyl carrier protein (disordered blue spheres)
- Cyan - AC (central bridging noncatalytic domain comprising AC1-AC5).
- Yellow - CT, carboxyl transferase (has enzymatic activity), comprising the N and C subdomains

A similar domain structure is found in human ACC1. The central bridging domain in human ACC1 is called the Central Domain (CD) with four parts, CD_N, CD_L, $CD_{C1,}$ and CD_{C2}.

Regulation of ACC

ACC1 activity is regulated by product inhibition, allosteric effector, and phosphorylation by different kinases. The enzyme is inhibited by its product, malonyl-CoA, and also the end product of fatty acid synthesis, 16:0-CoA.

The protein is inactive as a monomer and is active as a dimer. Anything that can perturb that equilibrium can affect ACC activity. Phosphorylation generally inhibits the protein by promoting the dissociation of the active dimer. The active dimer, in the presence of the allosteric activator, citrate can aggregate to form fibrils, which are even more active than the dimer.

The protein is post-translationally modified by phosphorylation at several sites but a few stand out. AMP-activated protein kinase (AMPK) phosphorylates human ACC at AMP-activated protein kinase at Ser 80 (in the BC domain). In yeast, the kinase SNF1 (equivalent to human AMPK) does not phosphorylate Ser 80 but it phosphorylates a key Ser 1157 in the AC subdomain AC4 in yeast.

- In humans, phosphorylation at Ser 80 in the BC domain prevents dimerization of the protein, through the BC domain and hence inhibits activity;
- In yeast, phosphorylation st Ser 1157 in AC subdomain AC4 in yeast produces a conformational change in the BC domain region that appears to lead to dimer dissociation.

Human ACC is phosphorylated at a multitude of sites with Ser 80 and 1201 (which is phosphorylated both by AMPK and PKA) being the most important in regulation. In addition, it is phosphorylated at Ser 1263 by a cyclin-dependent protein kinase (CDK). When phosphorylated, the pSer 1263 facilitates the binding of BRAC1, the tumor suppressor protein which when mutated can dramatically increase breast cancer. The binding of BRAC1 leads to an inactive fibril form of ACC. Figure 21.1.9 summarizes the regulation of human CoA carboxylase.

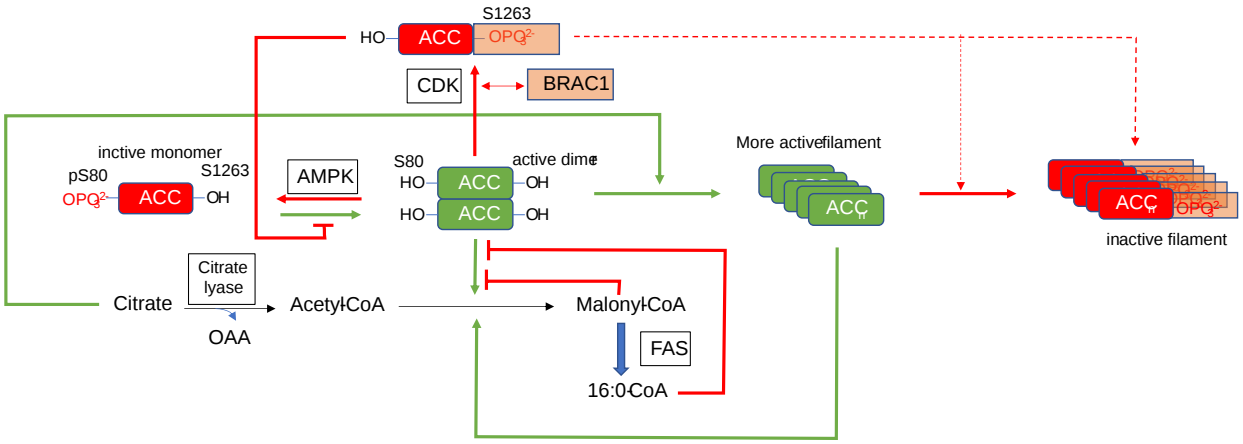

Figure 21.1.9: Regulation of human acetyl-CoA carboxylase. Red indicates inactive states or inactivating reactions, while green indicates active states and activating reactions.

21.1.2.3: 5. MALONYL-PALMITOYL TRANSFERASE (MPT)/MALONYL-COA-ACYL CARRIER PROTEIN TRANSACYLASE (MAT)

These protein activities are found in the yeast (MPT) and human (MAT) domains. The mechanism is shown in Figure 21.1.10.

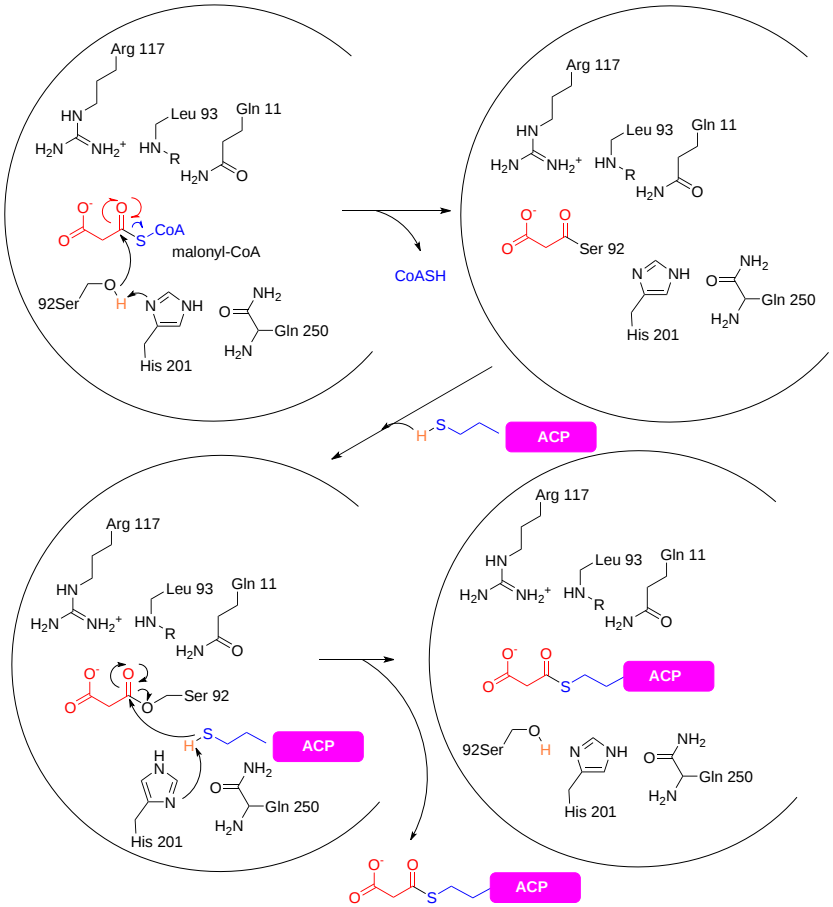

Figure 21.1.10: Reaction mechanism for Malonyl-Palmitoyl Transferase (MPT)/Malonyl-CoA-acyl carrier protein transacylase (MAT). (after https://www.ebi.ac.uk/thornton-srv/m-csa/entry/291/, Creative Commons Attribution 4.0 International (CC BY 4.0) License.

Two key catalytic residues, Ser 92 and His 201, are involved in an acylation/deacylation of the catalytic serine.

The mechanism is shown in Figure 21.1.11.

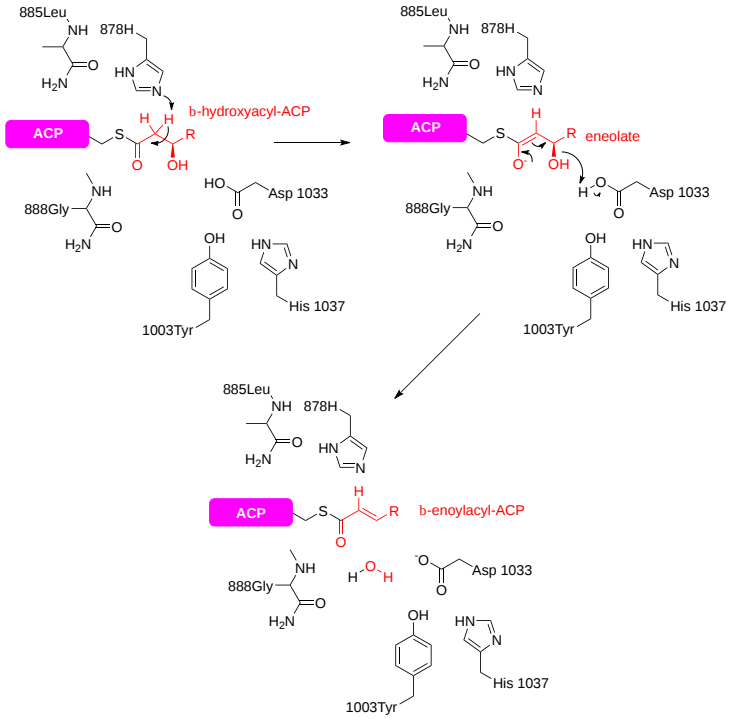

Figure 21.1.11: Reaction mechanism for β-ketodehydratase (after https://www.ebi.ac.uk/thornton-srv/m-csa/entry/972/, Creative Commons Attribution 4.0 International (CC BY 4.0) License.

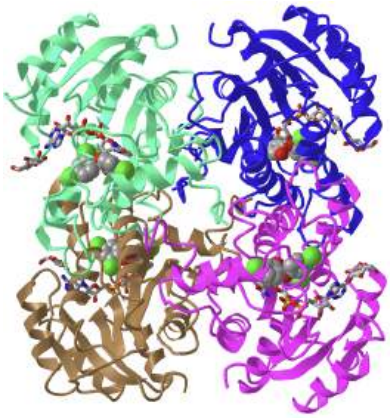
21.1.2.4: REACTION 9. ENOYL REDUCTASE

This is the last reaction in the fatty acid synthase cycle, which of course repeats until a 16:0-SCoA is made. The yeast enzyme is different in that it has a tightly-bound FMN which is involved in electron transfer (reduction) along with NADPH. The mechanism is likely ping-pong with $NADP^+$ released before the enoyl acyl-CoA binds.

Figure 21.1.12 shows an interactive iCn3D model of the enoyl-acyl carrier protein reductase (ER) in complex with NAD^+ and triclosan (1QSG)



NCBI iCn3D Figure 21.1.12: enoyl-acyl carrier protein reductase (ER) in complex with NAD^+ and triclosan (1QSG) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...Z2ZCQaTYabQWa9

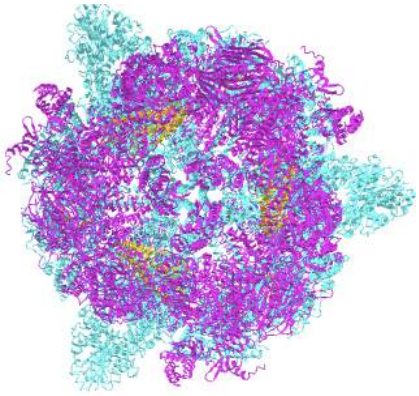
Triclosan is used in many commercial products, even soaps, as it has broad-spectrum antimicrobial activity. In a world with increasing antibiotic resistance, it is unwise to use triclosan in soaps since the evidence shows that the surfactant properties of soaps are sufficient to remove bacteria from the skin. Triclosan is an active site inhibitor of bacterial enoyl-reductases but in humans, it appears to be an allosteric inhibitor, since it is bound at a protein-protein interface and not the active site.

21.1.3: STRUCTURE OF YEAST FATTY ACID SYNTHASE I (FAS1)

Now you have enough background to explore the actual structure of fatty acid synthase. Animal FAS1 is an α_2 homodimer, some bacterial FASs are α_6 hexamers, while fungal FASs are $\alpha_6\beta_6$ dodecamers. In both cases, the monomers are multi-domain proteins with each domain

having a different catalytic activity. There is another type of fatty acid synthase II (FAS2), that consists of separate enzymes each with their own catalytic function. Type II FAS around found in plants, most bacteria, and in mitochondria.

We'll explore the "more interesting" Type I and start with yeast (Saccharomyces cerevisiae) FAS (6QL5), whose structure has been solved with a regulatory γ subunit that 2.8 angstrom 6QL5. Figure 21.1.13 shows an interactive iCn3D model of the fatty acid synthase complex with bound gamma subunit from Saccharomyces cerevisiae (6QL5) very long load time.



NCBI iCn3D Figure 21.1.13: Fatty acid synthase complex with bound gamma subunit from Saccharomyces cerevisiae 6QL5. (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...YnMNSaTbTXYGe7 (very long load time).

The alpha subunits are shown in cyan and the beta subunits are shown in magenta. The regulatory γ subunit is shown in orange.

The 6 alpha subunits are arranged in an equatorial wheel or disk. The beta subunits are arranged in trimer top and bottom "domes" that cover the alpha subunit disk. Inside are 3 spaces or chambers where the reactions occur. 5 openings allow outside substrate access and six openings allow internal metabolite access. The FAS is more porous than in large structures with encapsulated volumes like the proteasome or viral capsids. It is more similar to pyruvate dehydrogenase. The ACP protein domain is found inside the structure and is tethered and "swingable" to allow the transfer internal transfer of acyl intermediates to the different enzymatic functional domains of the complex.

Figure 21.1.14 shows animated images of yeast fatty acid synthase complex, which should give you a sense of the arrangement of the equatorial alpha-helical wheel, the two beta subunit domes, and the interior and interior volumes available for reaction chemistry and intermediate movement. They switch between the full structure, followed by separate views of the alpha (cyan), beta (magenta), and regulatory (orange) chains.

fatty acid synthase complex - side view	fatty acid synthase complex - top view

Figure 21.1.14: Alpha chains (cyan), beta chains (magenta), regulatory (orange)

The α and β monomers are multi-domain proteins with different domains having different catalytic properties. Just color coding the monomers in just one color doesn't give insight into the amazing catalytic properties of each chain. Figure 21.1.15 shows colored-coded domain and protein structures for yeast $\alpha_6\beta_6$ dodecamer. The color-coding for the domains for each subunit shown at the bottom of panel A is also used for the domain structures in the actual protein structures.

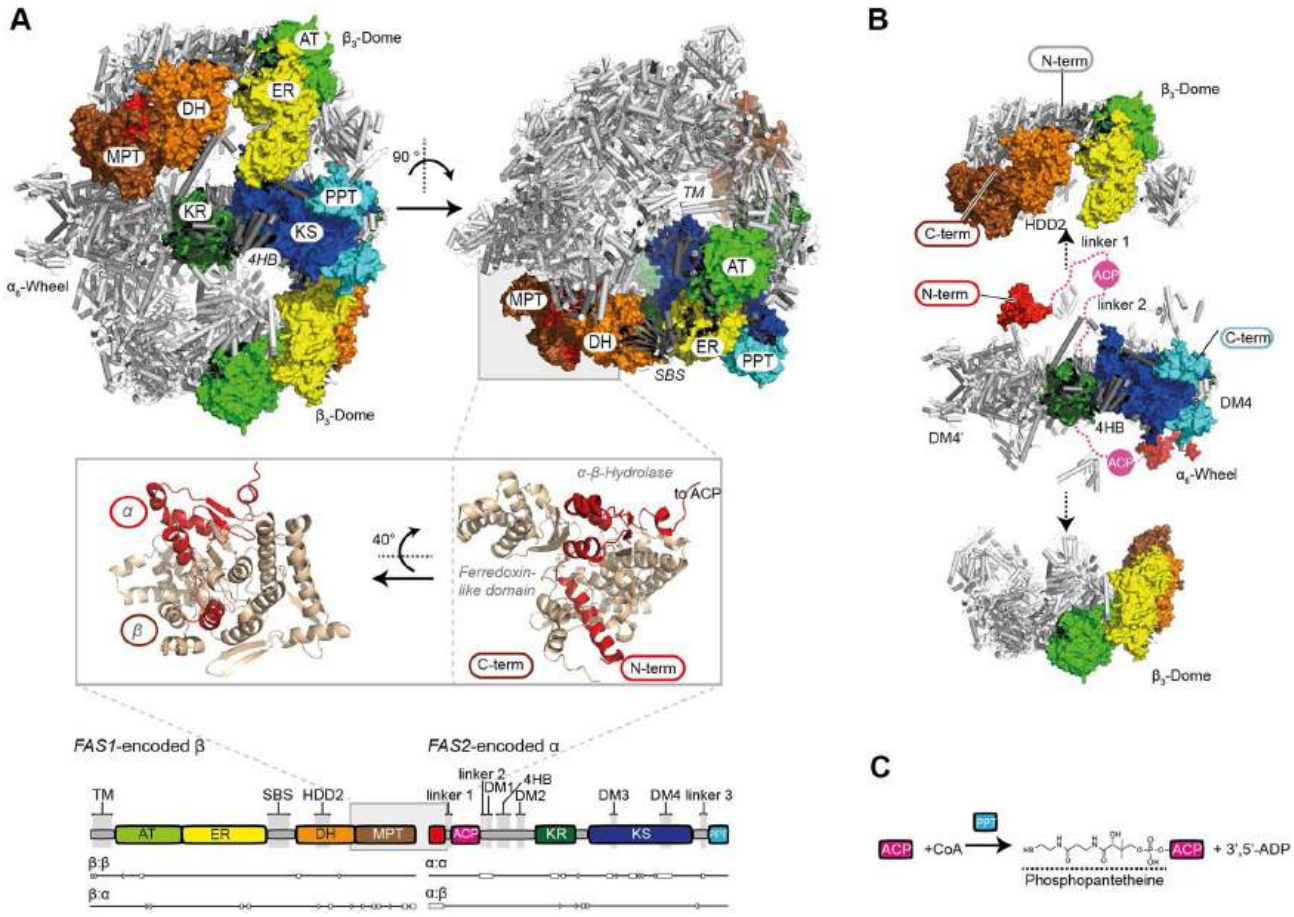


Figure 21.1.15: Structure of yeast FAS.

Panel (**A**) shows the structure of *S. cerevisiae* FAS (3hmj). The side (left) and top view (right) with two β-subunits and two α-subunits are shown. Note that ACP is in the FAS interior, but is not shown. The MPT fold is comprised of both subunits and shown in cartoon representation (β part in brown and its α part in red). Nomenclature: acetyltransferase (AT), enoyl reductase (ER), dehydratase (DH), malonyl-palmitoyl-transferase (MPT), an acyl carrier protein (ACP), ketoacyl reductase (KR), ketoacyl synthase (KS) and phosphopantetheine transferase domain (PPT). Insertion elements are highlighted in grey; trimerization module (TM), 6-stranded β-sheet (SBS), hotdog-domain 2 (HDD2), dimerization module 1–4 (DM1-4), 4-helical bundle (4HB)). Please note that DM2 is not visible in this structure.

Panel(**B**) shows three yeast FAS barrels as a central D3-symmetric α hexamer (α_6-wheel) and two C3-symmetric β trimers (β_3-domes). β_3-domes have been shifted for clarity (see arrows). ACP domains are shown for two α-subunits and are modeled by spheres in magenta. ACP linkers are indicated by dashed lines.

Panel (**C**) shows the post-translational modification of ACP. For phosphopantetheinylation, ACP and PPT have to physically interact. Fischer, M., Joppe, M., Mulinacci, B. *et al.* Analysis of the co-translational assembly of the fungal fatty acid synthase (FAS). *Sci Rep* **10,** 895 (2020). https://doi.org/10.1038/s41598-020-57418-8. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/

In Figure 21.1.16 we connect the domain structures of each monomer to the actual catalytic cycle of yeast FAS.

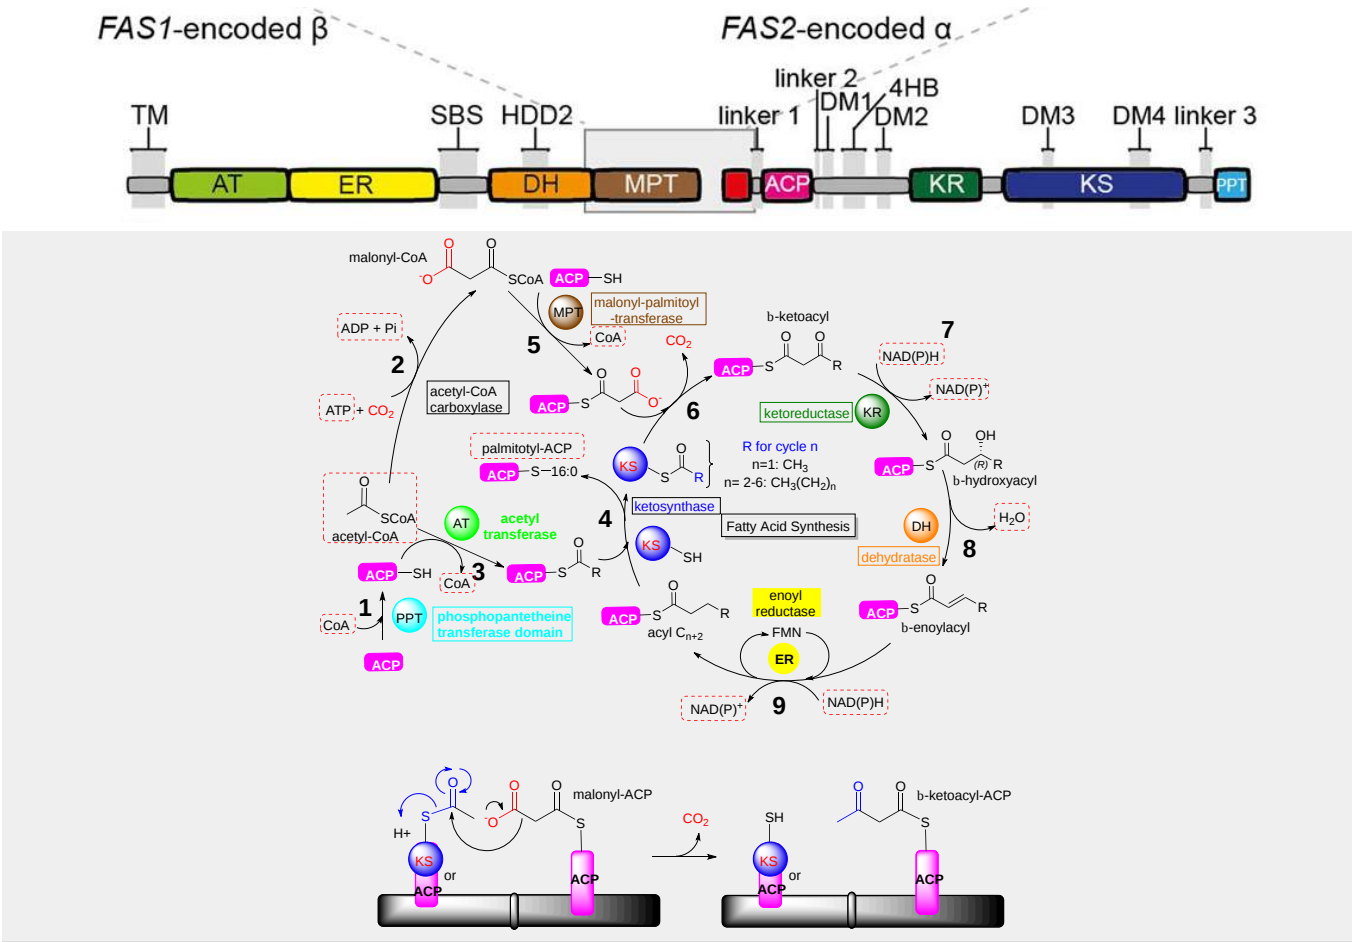

Figure 21.1.16: Domain structure and the catalytic cycle of yeast fatty acid synthase (adapted from Singh et al. Cell, 180 (2020), https://doi.org/10.1016/j.cell.2020.02.034 and Fischer et al. *Sci Rep* **10,** 895 (2020). https://doi.org/10.1038/s41598-020-57418-8. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/

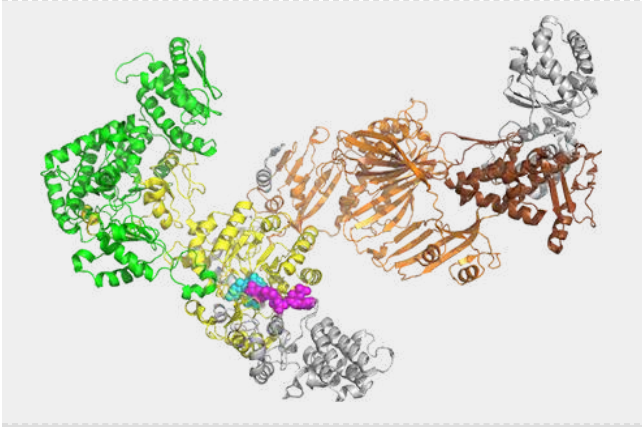
Figure 21.1.17 shows the actual structure of the isolated α and β monomers. The color coding of the domains is the same as used above.

Fatty acid synthase 1 (FAS1) beta subunit (FAS1) (6U5U G chain)



Fatty acid synthase 2 (FAS2) alpha subunit (2UV8A - P19097 AlphaFold)

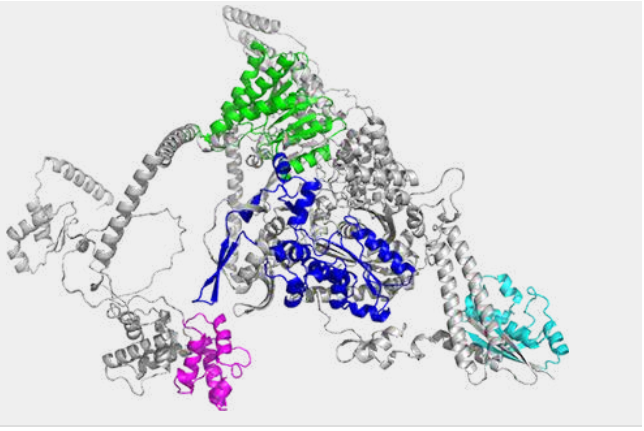


Figure 21.1.17 shows the approximate domain structures and locations for the yeast **fatty acid synthase 1 (FAS1) beta** subunit (6U5U G chain) and fatty acid synthase 2 (FAS2) alpha subunit**.**

The color coding for the domains in each subunit is as follows: FAS1 beta subunit: AT, ER, DH, MPT, flavin mononucleotide (FMN) spacefill cyan NADP nicotinamide-adenine dinucleotide phosphate (NAP), spacefill magenta; FAS2 alpha subunit: ACP, KR, KS, PPT

Now, let's zoom in to see the actual interactions of bound 4'-phosphopantetheine and flavin mononucleotide (FMN). Phosphopantetheine is bound between the alpha (cyan) and beta (magenta) subunits as shown in Figure 21.1.18.

4'-phosphopantetheine between alpha (cyan) and beta (magenta) subunits

flavin mononucleotide (FMN) within beta (FAS1) subunit

Figure 21.1.18:

The γ subunit crosses the entire inner cavity of FAS interfering with the activities of the reductases.

A central difference in the FAS1 found in humans and other animals occurs in the first reaction in which the acetyl group of acetyl-CoA is transferred to the pantetheine sulfhydryl of the acyl carrier protein (ACP) domain catalyzed by the malonyl-/acetyltransferase (MAT) domain. It is then transferred to the active site cysteine of the β-ketoacyl synthase (KS) domain. This allows the malonyl group to be transferred to the now free ACP domain for a second transfer reaction. A Claisen condensation reaction driven by the decarboxylation of the malonyl-ACP occurs to form the β-ketoacyl intermediate bond to the KS domain. An alternative view of the mammalian fatty acid cycle is shown in Figure 21.1.19.

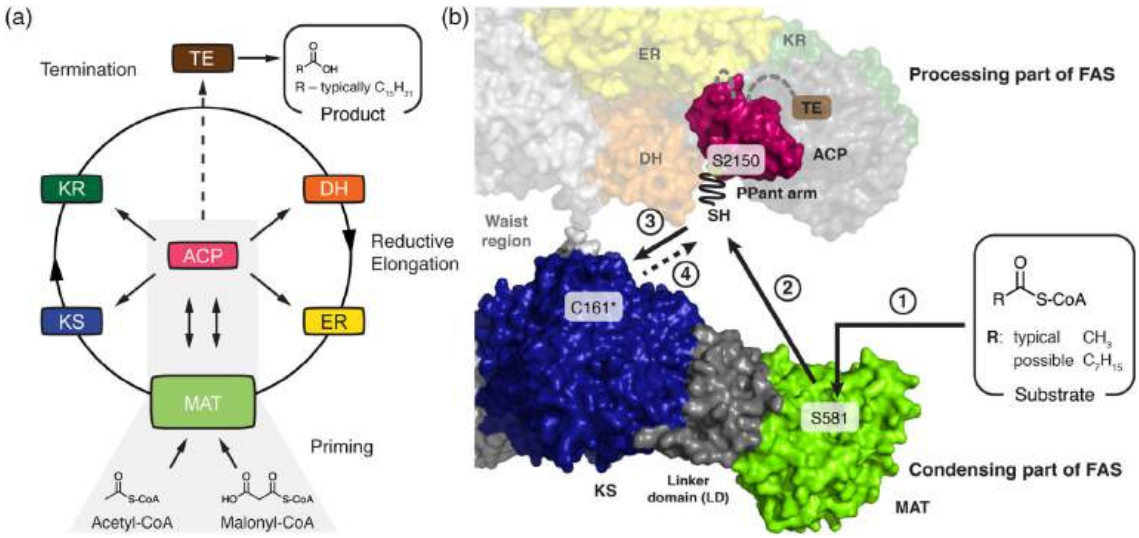

Figure 21.1.19: Mammalian fatty acid synthase cycle. Rittner et al. Protein Sci. 2020 Feb; 29(2): 589–605. doi:10.1002/pro.3797. Creative Commons Attribution License. http://creativecommons.org/licenses/by/4.0/

Panel (a) shows the priming of animal fatty acid synthesis. Panel (b) shows how in the first step, the substrate is selected by the MAT domain and transferred to the ACP domain (Step 2) from where it is passed on to the KS domain (Step 3). Important active site residues are highlighted and C161 is marked with an asterisk. The porcine FAS structure (2png) is shown. Domains of one protomer of FAS homodimer are colored. ACP, acyl carrier protein; DH, dehydratase; ER, enoyl reductase; FAS, fatty acid synthase; KR, ketoreductase; KS, ketosynthase; MAT, malonyl-/acetyltransferase; PPant arm, expand fully in the figure; TE, thioesterase

Figure 21.1.20 shows the yeast FAS cycle (as a proxy for the mammalian cycle) placed in context with the mitochondrial matrix pathways that feed acetyl-Coa and NADPH into the fatty acid synthesis pathway.

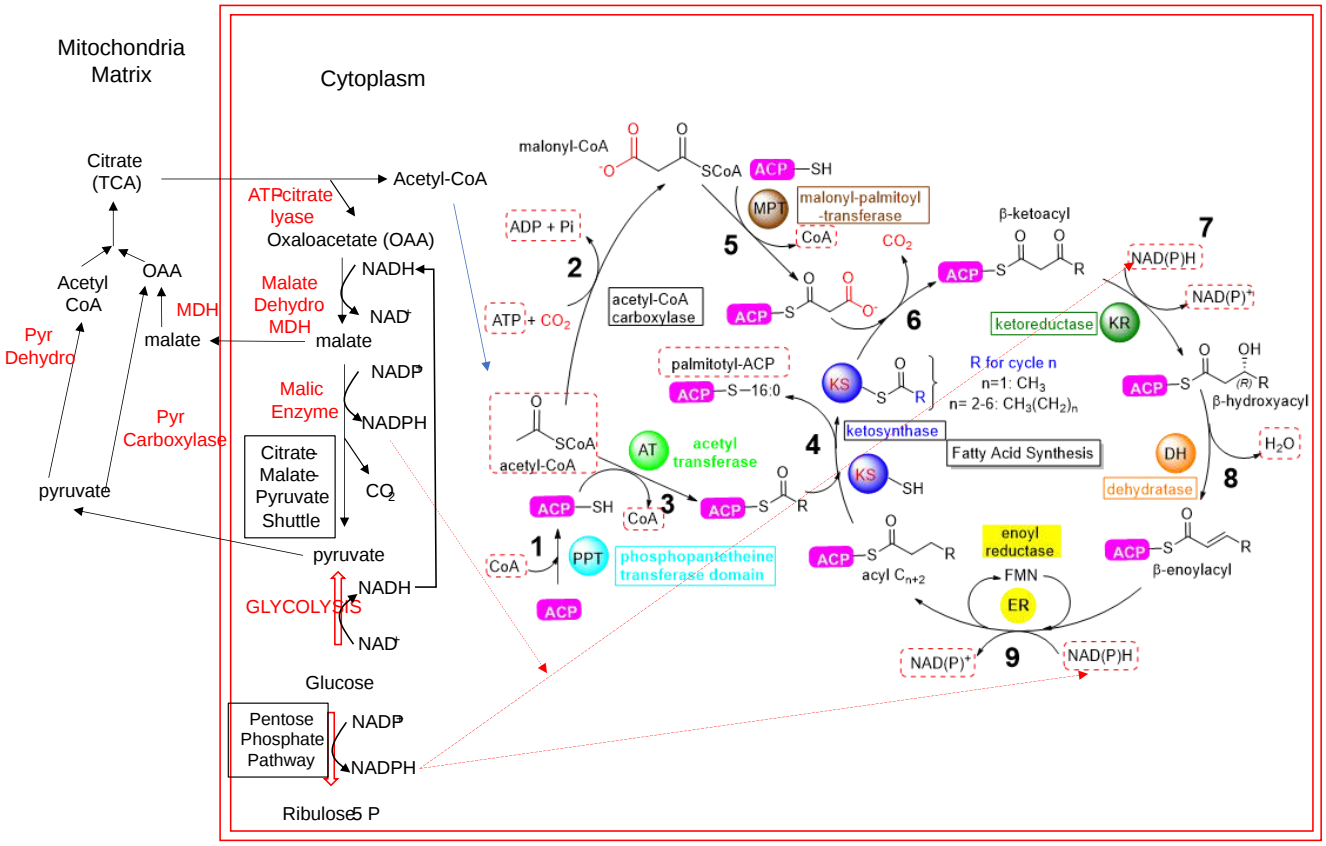

Figure 21.1.20: yeast FAS cycle (as a proxy for the mammalian cycle) placed in context with the mitochondrial matrix pathways that acetyl-Coa and NADPH into fatty acid synthesis

21.1.4: FATTY ACID ELONGATION AND DESATURATION

21.1.4.1: OVERVIEW

Elongation of fatty acids occurs in the cytoplasm of mammals from 16:0 made through fatty acid synthase. As with the synthesis of 16:0 by FAS, the elongation consists of two carbon addition driven by the decarboxylation of a malonyl-CoA substrate. Elongation is carried out by a family of **ELOngation of Very Long-chain fatty acid enzymes (ELOVLs)**. Desaturation is catalyzed by **Stearoyl-CoA Desaturases (SCD1 and SCD2**) and **Fatty Acid Desaturases (FADS1 and FADS2)**.

Figure 21.1.21 shows an overview of de novo fatty acid synthesis with elongation and desaturation in mammals as well as elongation and desaturation of dietary fatty acids.

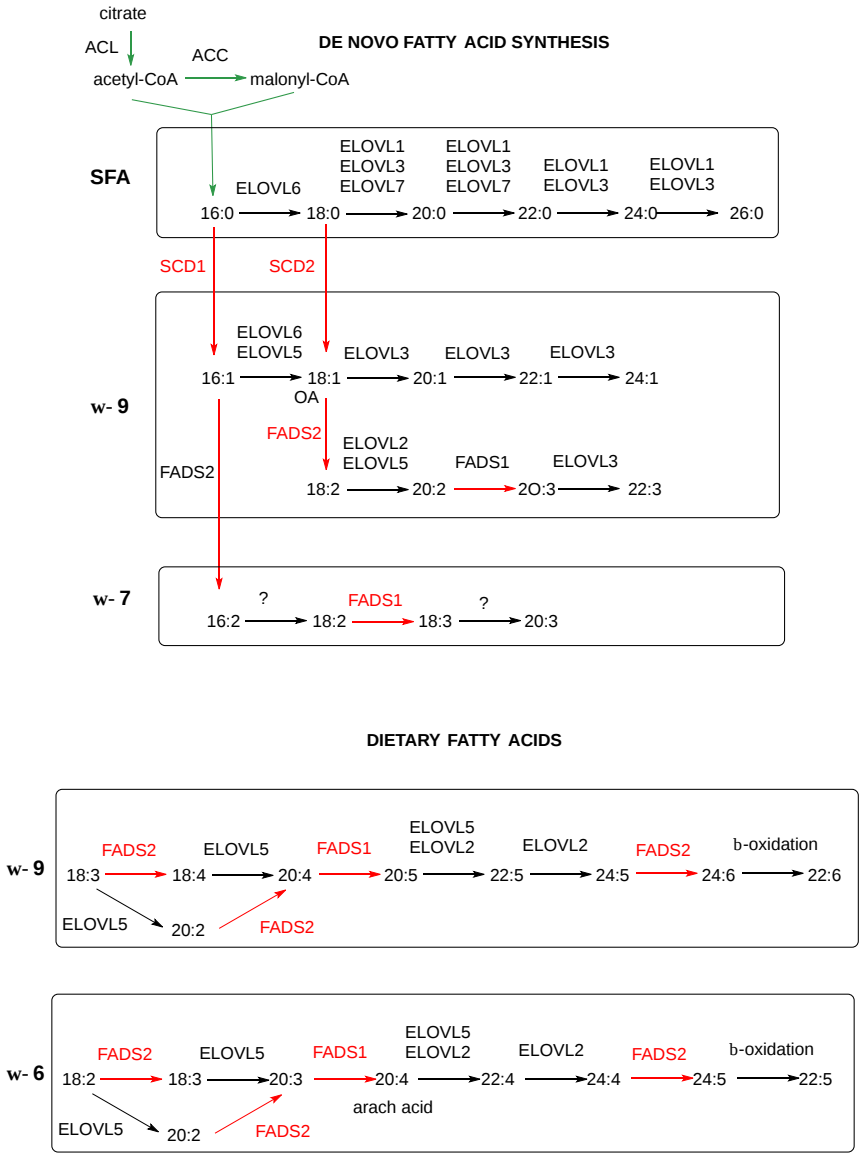

Figure 21.1.21: Scheme of FA synthesis in mammals. After *Corrales et al. Int. J. Mol. Sci.* **2021**, *22*(15), 8159; https://doi.org/10.3390/ijms22158159. Creative Commons Attribution (CC BY) license (https://creativecommons.org/licenses/by/4.0/)

FAs are elongated (ELOVL1–7) and/or desaturated (SCD, FADS) to generate complex FAs. Long-chain saturated FAs (LCSFA) and unsaturated FAs of ω9 and ω7 can be synthesized from palmitic acid (PA, C16:0) produced by the *de novo* FA synthesis. Long-chain unsaturated FAs of the ω6 and ω3 series can only be synthesized from essential diet-derived FAs (OA, oleic acid; NA, nervonic acid; ALA, α-linolenic acid; DHA, docosahexaenoic acids; LA, linoleic acid; ARA, arachidonic acid). SFA are saturated fatty acids.

21.1.4.2: ELONGATION

Mammals use endoplasmic reticulum very long-chain fatty acid enzymes (ELOVLs). There appear to be seven in mammals with different substrate specificities as shown in the figure above. The nomenclature for fatty acids is a bit strange. Those with 11-20 carbons are called long-chain FAs (LCFAs) and those with more than 20 carbons are very long-chain FAs (VLCFAs). Those with more than 26 carbons are called ultra long-chain FAs (ULCFAs), which are found in the skin, retina, meibomian gland, testis, and brain. The same four steps (condensation, reduction, dehydration, and reduction) used in FAS are used in elongation. The enzymes are abbreviated a bit differently (3-ketoacyl-CoA reductase or KAR, 3-hydroxyacyl-CoA dehydratase or HACD, *trans*-2-enoyl-CoA reductase or TER and LCFA). The enzyme is separate and not part of a multifunction complex like FAS. The elongation cycle is shown in Figure 21.1.22.

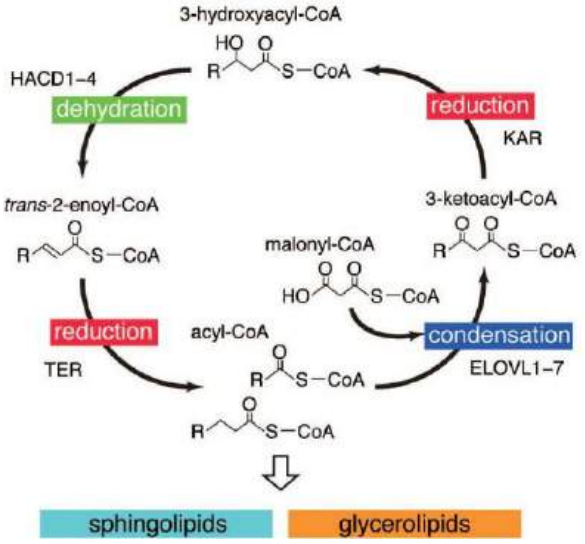

Figure 21.1.22 Mammalian FA elongation cycle. In each cycle, acyl-CoA incorporates two carbon units from malonyl-CoA. Sassa et al. 21.1.4.3: MECHANISM OF ELOVL7

ELOVL condensing enzymes have a long hydrophobic tunnel and an active site nucleophilic histidine. More traditional nucleophiles like serine or cysteine were eliminated as potential candidates for the active site nucleophile since none were in proximity. The active site with a key HxxHH motif lies deep in the membrane. Nucleophilic catalysis leads to an N-acyl intermediate and is consistent with the observed ping-pong kinetics. An alternative reaction for a "bisubstrate" reaction is the formation of a ternary complex with both substrates. The narrow size of the binding pockets precludes this mechanism, so one product, after it is formed, must dissociate before the next substrate can bind. ELOVL7 preferentially catalyzes the elongation of C18-CoA presumably arising from the size of the acyl-binding product.

A plausible mechanism for human long-chain fatty acid enzyme 7 (ELOVL7) elongation is shown in Figure 21.1.24 and Figure 21.1.25. Figure 21.1.24 shows the beginning acylation step of the reaction.

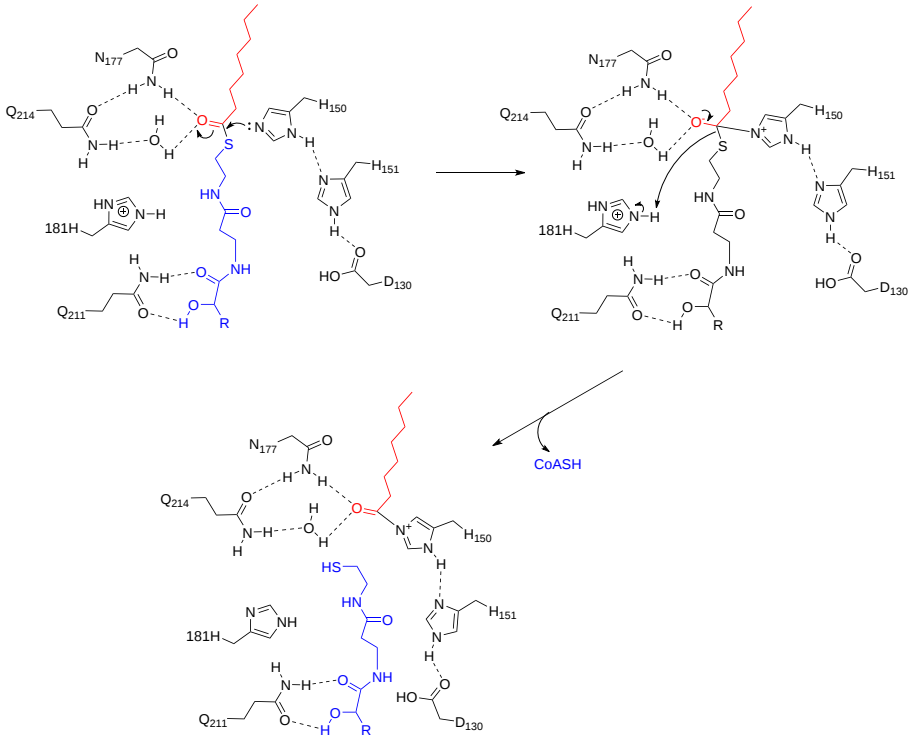

Figure 21.1.24: Acylation step in the human long-chain fatty acid enzyme 7 (ELOVL7) elongation reaction

Figure 21.1.25 shows the condensation (with the elimination of CO_2), followed by the reduction and dehydration of human ELOVL7.

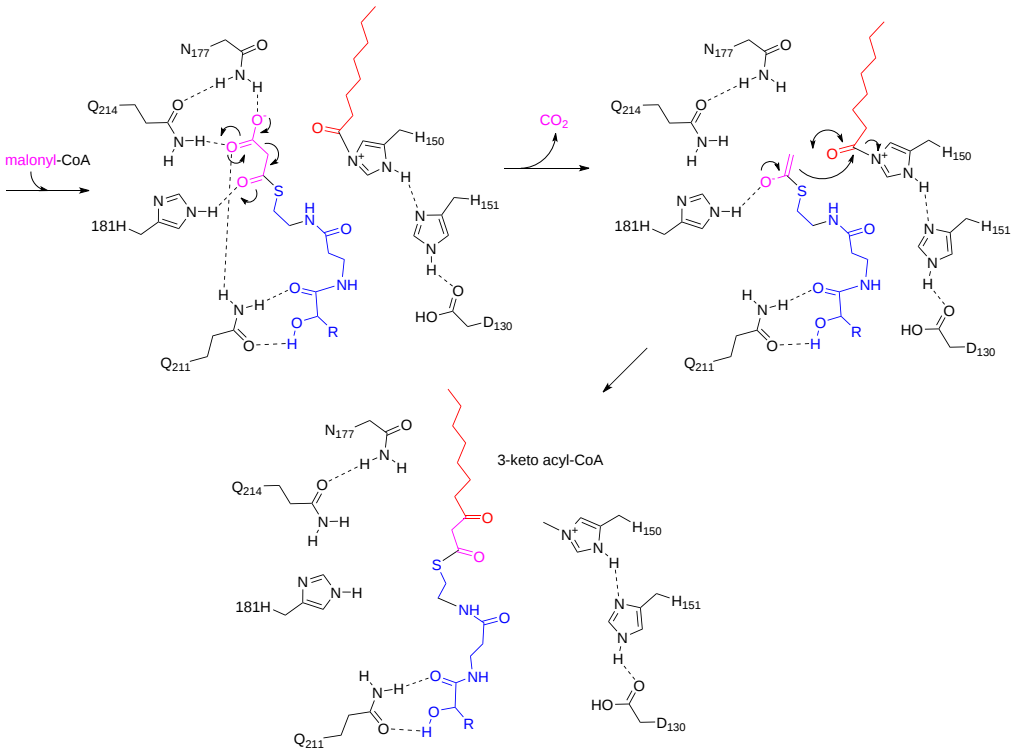

Figure 21.1.25: Part 2 - Plausible mechanism for mammalian fatty acid elongase 7 (ELOVL7) - condensation (with the elimination of CO_2), followed by reduction and dehydration. (adapted from Nie et al. *Nat Struct Mol Biol* **28,** 512–520 (2021). https://doi.org/10.1038/s41594-021-00605-6)

Figure 21.1.26 shows an interactive iCn3D model of the human ELOVL fatty acid elongase 7 (ELOVL7) with bound 3-keto eicosanoyl CoA (6Y7F).

The bound 3-keto eicosanoyl CoA is shown in spacefill, CPK colors. Key amino acids involved in catalysis are shown in sticks, CPK colors, and labeled.

21.1.4.4: DESATURATION

The introduction of double bonds requires a different set of enzymes, acyl-coenzyme A (CoA) desaturases. Mammals have desaturases that can produce double bonds at Δ^9, Δ^6, and Δ^5. There are two types, stearoyl-CoA desaturases (SCDs), which introduce a double bond at C9 of saturated fatty acid, and fatty acid desaturases (FADS), which work on unsaturated fatty acids. These are shown in Figure 21.1.20. Plants, but not mammals, have Δ^{12} and Δ^{15}-desaturases, so they, but not mammals, can synthesize ω6 and ω3 fatty acids. These must be supplied by the diet as essential fatty acids and are precursors for the synthesis of longer fatty acids like arachidonic acid (20:4$^{\Delta 5,8,11,14}$), necessary for prostaglandin synthesis (see below) and docosahexaenoic acids (DHA). A plausible mechanism for the stearoyl-CoA desaturase from castor seeds is shown below in Figures 27-30. The mechanisms and explanations are adapted from https://www.ebi.ac.uk/thornton-srv/m-csa/entry/136/. Creative Commons Attribution 4.0 International (CC BY 4.0) License

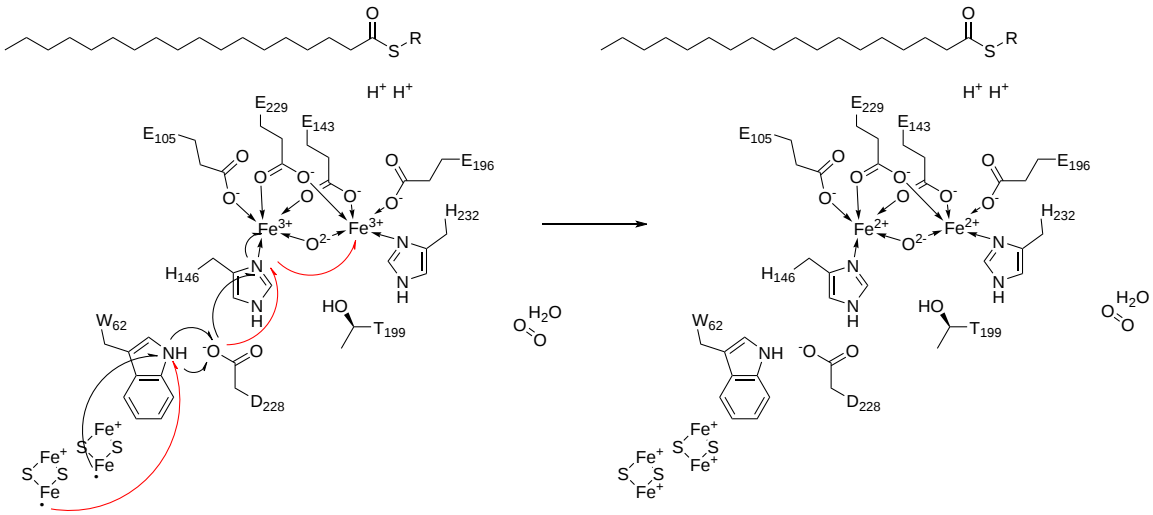

Figure 21.1.27: Part 1 of the stearoyl-CoA desaturase

At the start of the reaction, ferredoxin, a small iron-sulfur protein donates a single electron, through Trp62, Asp228, and His146, to one of the Fe(III) centers in the desaturase. Ferredoxin then donates a second single electron, through Trp62, Asp228, and His146, to the second Fe(III) center. Both of these are shown in Figure 21.1.27

Part 2 of the reaction is shown in Figure 21.1.28.

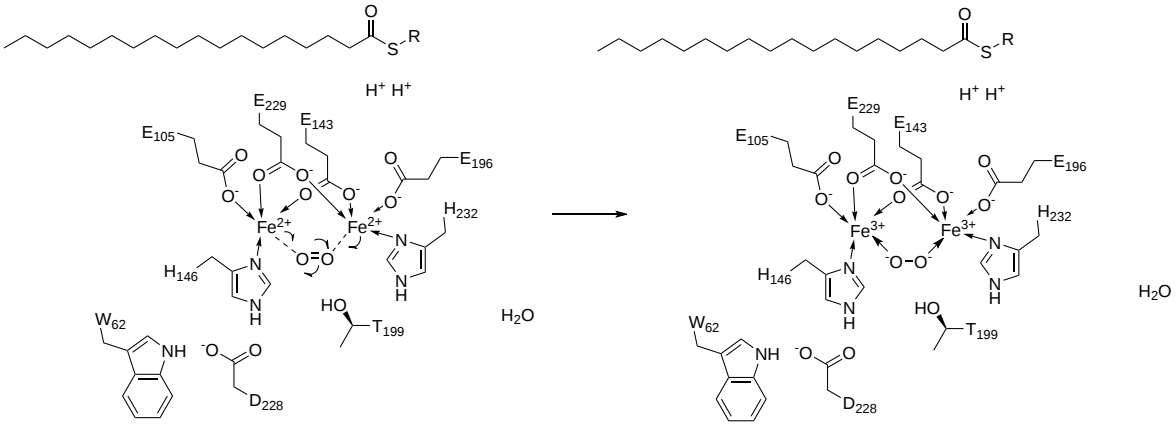

Figure 21.1.28: Part 2 of the stearoyl-CoA desaturase

The reduced charges on the Fe ions lead to loss of the oxide bridging ion (O^{2-}) and its replacement with dioxygen. Water coordinates to one of the Fe(II)s, which causes it to donate a single electron to the dioxide molecule. This starts the first of two homolytic additions of the dioxygen molecule to both Fe(II) centers and the second Fe(II) center also donates a single electron to the dioxygen bridge.

Part 3 of the stearoyl-CoA desaturaseFigure 21.1.29 is shown below.

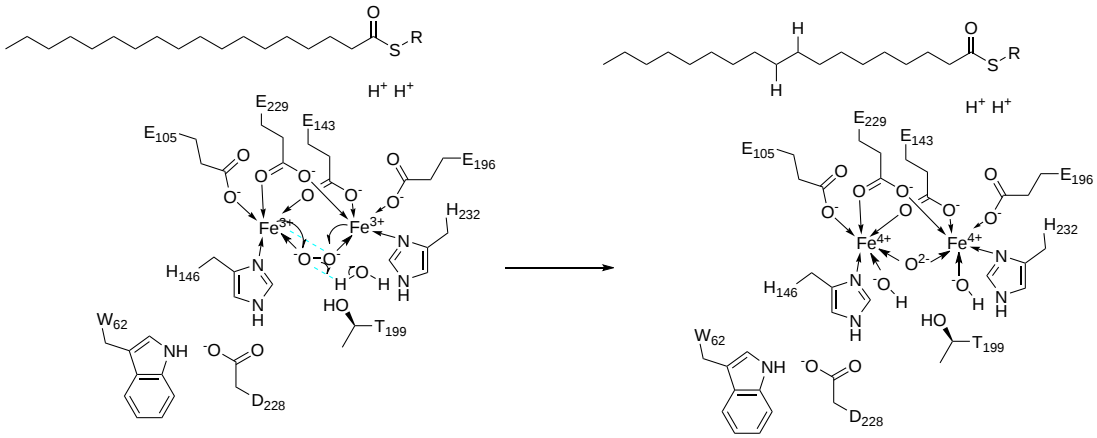

Figure 21.1.29: Part 3 of the stearoyl-CoA desaturase

Part 4 of the stearoyl-CoA desaturase is shown in Figure 21.1.30.

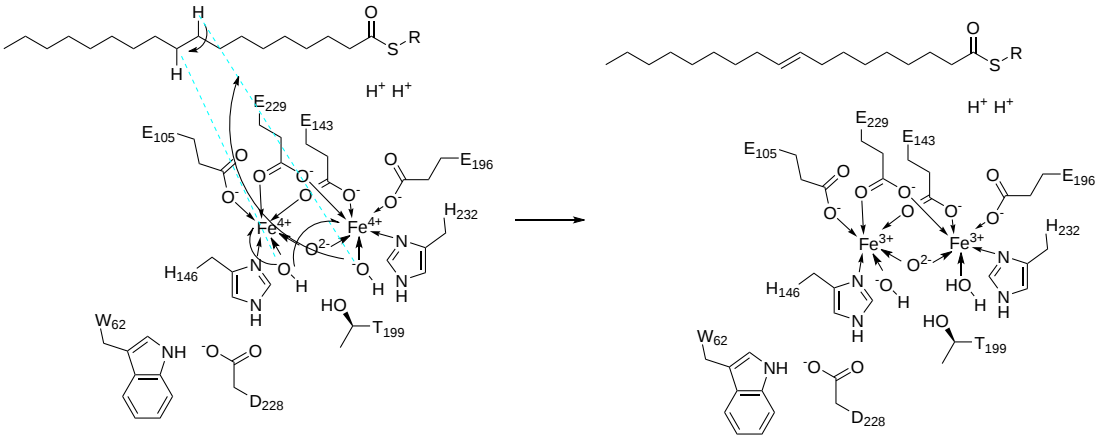

Figure 21.1.30: Part 4 of the stearoyl-CoA desaturase

In this reaction the hydroxide on the first Fe(IV) center deprotonates the stearoyl-[acyl-carrier protein] substrate, initiating the elimination of a hydride ion, which attacks the second Fe(IV) bound hydroxide. The excess electrons are donated singly to both Fe(IV) centers, regenerating the enzyme.

Figure 21.1.31 shows an interactive iCn3D model of the Stearoyl-acyl-carrier protein desaturase from castor seeds (1afr)

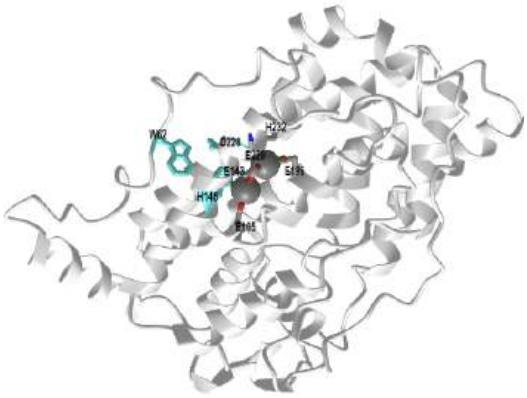

Figure 21.1.31: Stearoyl-acyl-carrier protein desaturase from castor seeds (1afr) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...UonrwyWfcg9wU8

An electron transport chain carries an electron from ferredoxin to one of the iron centers via several residues. A second electron is then carried to the second iron center. Several redox reactions take place involving oxygen, water, and iron centers, which result in the deprotonation of the substrate and the formation of a double bond.

There are two possible paths for the electron transport chain - the one described here has been chosen because of its analogy to what has been suggested for *E. coli* ribonucleotide reductase protein R2.

21.1.5: MITOCHONDRIAL FA SYNTHESIS

Mitochondria also engage in limited fatty acid synthesis. They use separate discrete enzymes (at least 6) as do most bacteria. They don't employ a multienzyme complex as described above for yeast and mammals. Nevertheless, there are commonalities. Synthesis proceeds by the addition of two carbon units to a growing acyl-ACP chain using malonyl-CoA and the release of CO_2 to drive the condensation process (in addition of course to ATP cleavage). The cytoplasmic fatty acid synthesis produces 16:0 (palmitate). In contrast, mitochondrial FAS produces two major products, 8:0 (octanoate). This is then converted to the 8C derivative lipoic acid. Their structures are shown in Figure 21.1.32.

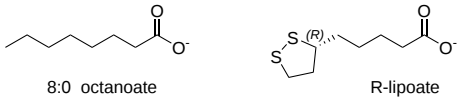

Figure 21.1.32 Structure of octanoate and R-lipoate

We have seen lipoic acid before as a cofactor in pyruvate dehydrogenase and α-ketoglutarate dehydrogenase, two enzymes that catalyze the more difficult decarboxylation of α-ketoacids (which don't have a built-in electron sink at a β carbon adjacent to the departing carboxyl group. It is also used in branched-chain amino acid dehydrogenases. The absence of lipoic acid is lethal in mice.

Figure 21.1.33 shows the fatty acid synthesis pathway in mitochondria.

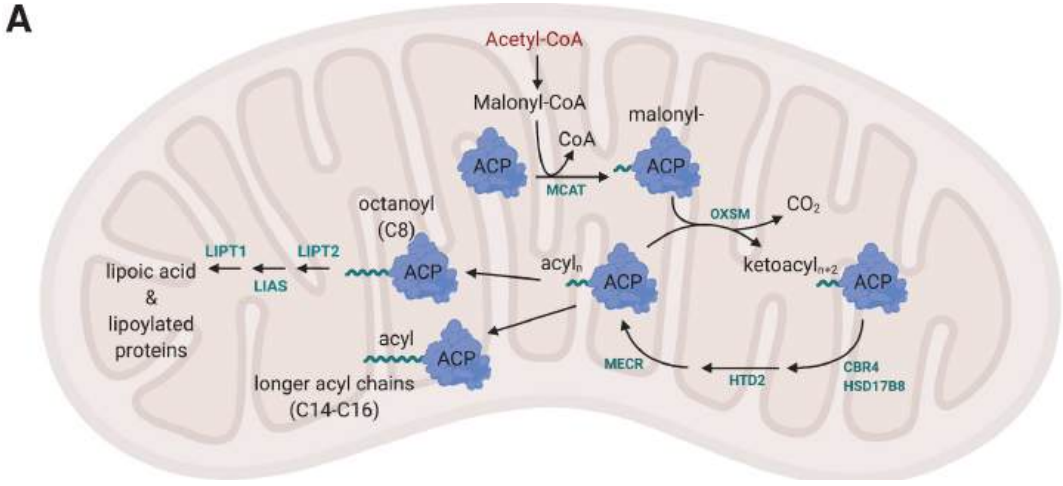

Figure 21.1.33: mitochondrial fatty acid synthesis pathway and downstream lipoic acid synthesis. Nowinski et al. eLife 2020;9:e58041. DOI: https://doi.org/10.7554/eLife.58041. Creative Commons Attribution License

Some of the enzymes in the pathway include the following: **Mcat** is malonyl-CoA ACP transacylase, and **Ox**sm is beta-ketoacyl synthase that catalyzes the Claisen condensation of malonyl-ACP with the growing acyl chain. **CBR4** is 3-oxoacyl-[acyl-carrier-protein] reductase. **HSD17B8** is (3R)-3-hydroxyacyl-CoA dehydrogenase. **HTD2** is hydroxyacyl-thioester dehydratase type 2). **Mecr** is the terminal enoyl-[acyl-carrier-protein] reductase. **LIPT2** is lipoyltransferase 2. **LIAS** is lipoyl synthase. **LIPT1** (Lipoyltransferase 1) catalyzes the terminal step in lipoic acid and lipoylated protein synthesis.

It now appears that longer fatty acyl chains (up to 14C) are synthesized in mitochondria. Mutations in key enzymes above have been made that don't affect lipoic acid synthesis but impair mitochondrial function.

21.1.6: EICOSINOID AND PROSTAGLANDIN SYNTHESIS

As shown in Fig 20, arachidonic acid, $20{:}4^{\Delta 5,8,11,14}$, an ω-6 fatty acid (5,8,11,14- eicosatetraenoic acid), is synthesized from linoleic acid, $18{:}2^{\Delta 9,12}$, another ω-6 polyunsaturated fatty acid, through a series of elongation and desaturation steps. Arachidonic acid is released from membrane phospholipids on activation of phospholipase A2 and converted to a class of molecules called prostaglandins, which have powerful hormone-like effects.

The prostaglandins are part of a group of icosanoids derived from cleavage of membrane ω-3 ($20{:}5^{\Delta 5,8,11,14,17}$, eicosapentaenoic acid) and ω-6 C_{20} fatty acids, which are metabolized to form leukotrienes (LTs), prostaglandins (PGs), prostacyclins (PCs), and thromboxanes (TXAs). These have differing and sometimes opposing physiologically effects in animals. Prostaglandins have been found in almost every tissue in humans and other animals

Ω-3 AND Ω-3 AND FATTY ACIDS

The most common polyunsaturated fats (PUFAs) in our diet are the ω-3 and ω-6 classes. Most abundant in the ω-6 class in plant food is linoleic acid (18:2 ω-6, or $18{:}2^{\Delta 9,12}$), while linolenic acid (18:3 ω-3 or $18{:}3^{\Delta 9,12,15}$) is the most abundant in the n-3ω class. These fatty acids are essential in that they are biological precursors for other PUFAs. Specifically,

- linoleic acid (18:2 ω-6, or $18{:}2^{\Delta 9,12}$) is a biosynthetic precursor of arachidonic acid (20:4 ω-6 or $20{:}4^{\Delta 5,8,11,14}$)
- linolenic acid (18:3 ω-3, or $18{:}3^{\Delta 9,12,15}$) is a biosynthetic precursor of eicosapentaenoic acid (EPA, 20:5 ω-3 or $20{:}5^{\Delta 5,8,11,14,17}$) and to a much smaller extent, docosahexaenoic acid (DHA, 22:6 ω-3 or $22{:}6^{\Delta 4,7,10,13,16,19}$).

These essential precursor fatty acids are substrates for intracellular enzymes such as elongases, desaturases, and beta-oxidation type enzymes in the endoplasmic reticulum and another organelle, the peroxisome (involved in the oxidative metabolism of straight chain and branched fatty acids, peroxide metabolism, and cholesterol/bile salt synthesis). Animals fed diets high in plant 18:2(n-6) fats accumulate 20:4(n-6) fatty acids in their tissues while those fed diets high in plant 18:3(n-3) accumulate 22:6(n-3). Animals fed diets high in fish oils accumulate 20:5 (EPA) and 22:6 (DHA) at the expense of 20:4(n-6).

Figure 21.1.34

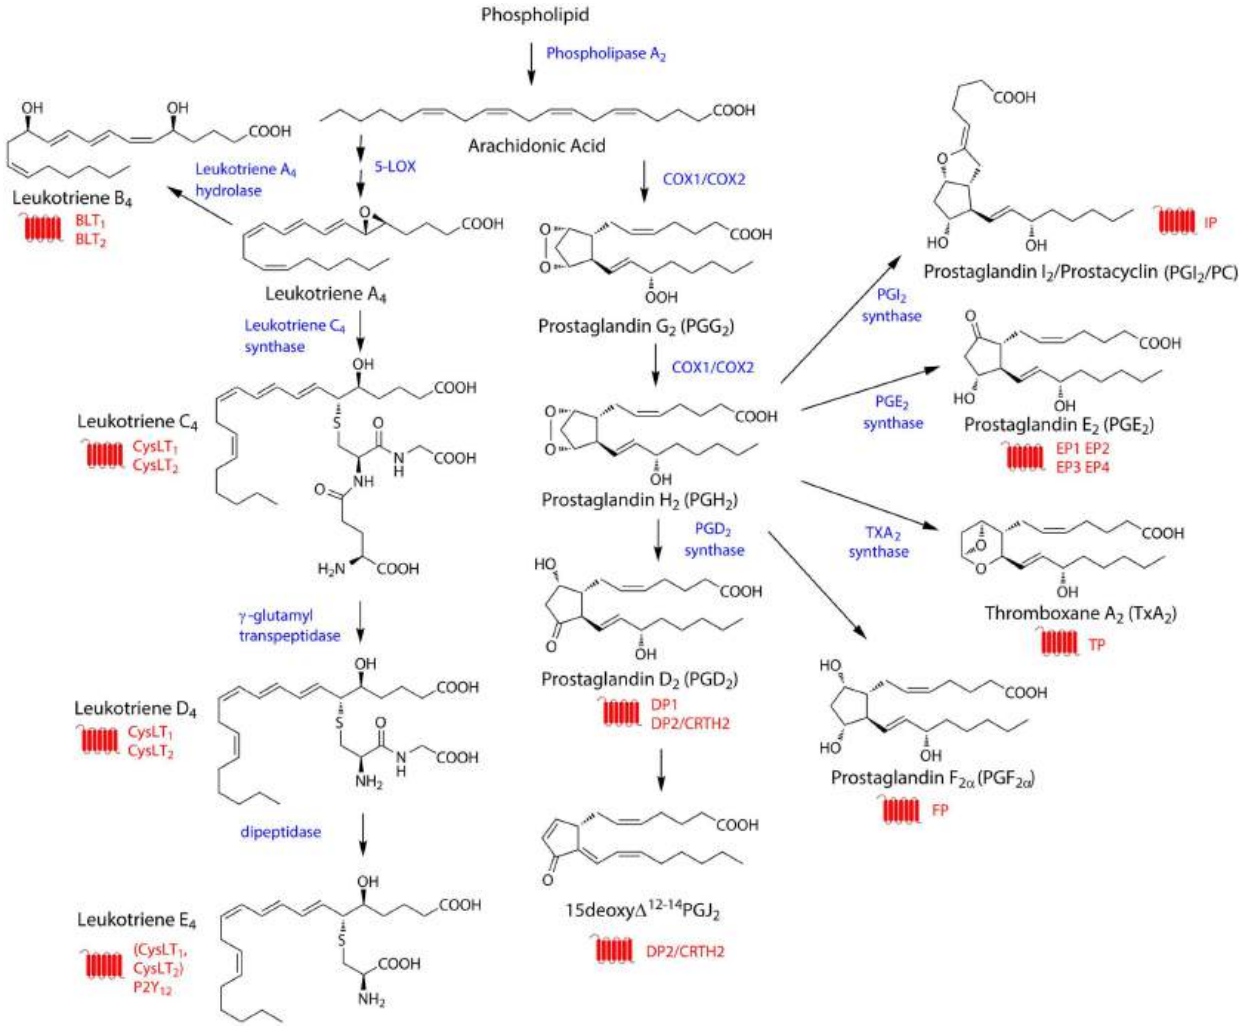

Figure 21.1.34Lone, Anna & Taskén, Kjetil. (2013). Proinflammatory and Immunoregulatory Roles of Eicosanoids in T Cells. Frontiers in immunology. . https://doi.org/10.3389/fimmu.2013.00130. https://creativecommons.org/licenses/by/3.0/

We will focus our attention on the conversion of arachidonic acid (20:4 ω-6 or $20{:}4^{\Delta 5,8,11,14}$) to prostaglandin G_2 (PGG_2) and H_2 (PGH_2) by the enzyme cyclooxygenase I and II. These enzymes are also called by their more formal names, prostaglandin endoperoxide H synthases (PGHSs) I and II. COX-1 prefers arachidonic acid as a substrate, while COX-2 has a broader substrate specificity and can use eicosapentaenoic acid (EPA, 20:5 ω-3 or $20{:}5^{\Delta 5,8,11,14,17}$) and even neutral substrate derivatives of arachidonic acid, including 2-arachidonoylglycerol and anandamide, both ligands for cannabinoid receptors.

COX 1/2 use two dioxygens and 2 electrons to make PGH_2. Two different, separate but connected catalytic sites are used to catalyze the two steps (shown in Figure 21.1.34)

1. Arachidonic acid ($20{:}4^{\Delta 5,8,11,14}$) is converted to PGG_2. This step is catalyzed by a **bis-oxygenase** domain. The word oxygenase is used since both atoms of dioxygen are added to the reactant. Bis indicates that two different molecules of dioxygen are added. Since one of the dioxygens added forms an endoperoxide cyclic bridge in PGG_2, this enzymatic domain, and the entire enzyme is usually called **cyclooxygenase** (COX). The second dioxygen is added as a peroxide (both oxygen atoms of dioxygen added);
2. Prostaglandin G_2 (PGG_2) is then converted to prostaglandin H_2 (PGH_2) in which the noncyclic peroxide form in the first step is converted to hydroxide. This is also a **reduction** step since the oxidation numbers of the oxygen atoms in the peroxide, -1, change to -2 (a gain of electrons) in the hydroxide in PGH_2. This reaction is catalyzed by the peroxidase (POX) activity of the enzyme. A cofactor heme in the POX site facilitates catalysis.

The COX reaction proceeds through radical intermediates. but it requires the activation of peroxide by the heme in the POX site. We'll show two different mechanisms for both reactions (COX and POX) catalyzed by the enzyme prostaglandin endoperoxide H synthase, which we will also call COX.

The first mechanism shown below in Figure 21.1.35 emphasizes the free radical nature of the reactions. It shows just one amino acid (Tyr 385) involved in the reaction. Note that the first step in the reaction shows the added dioxygen as an excited state "singlet" O_2, but it is

parenthetically noted that it most likely involves O_2 binding to and being activated by the heme iron in POX site.

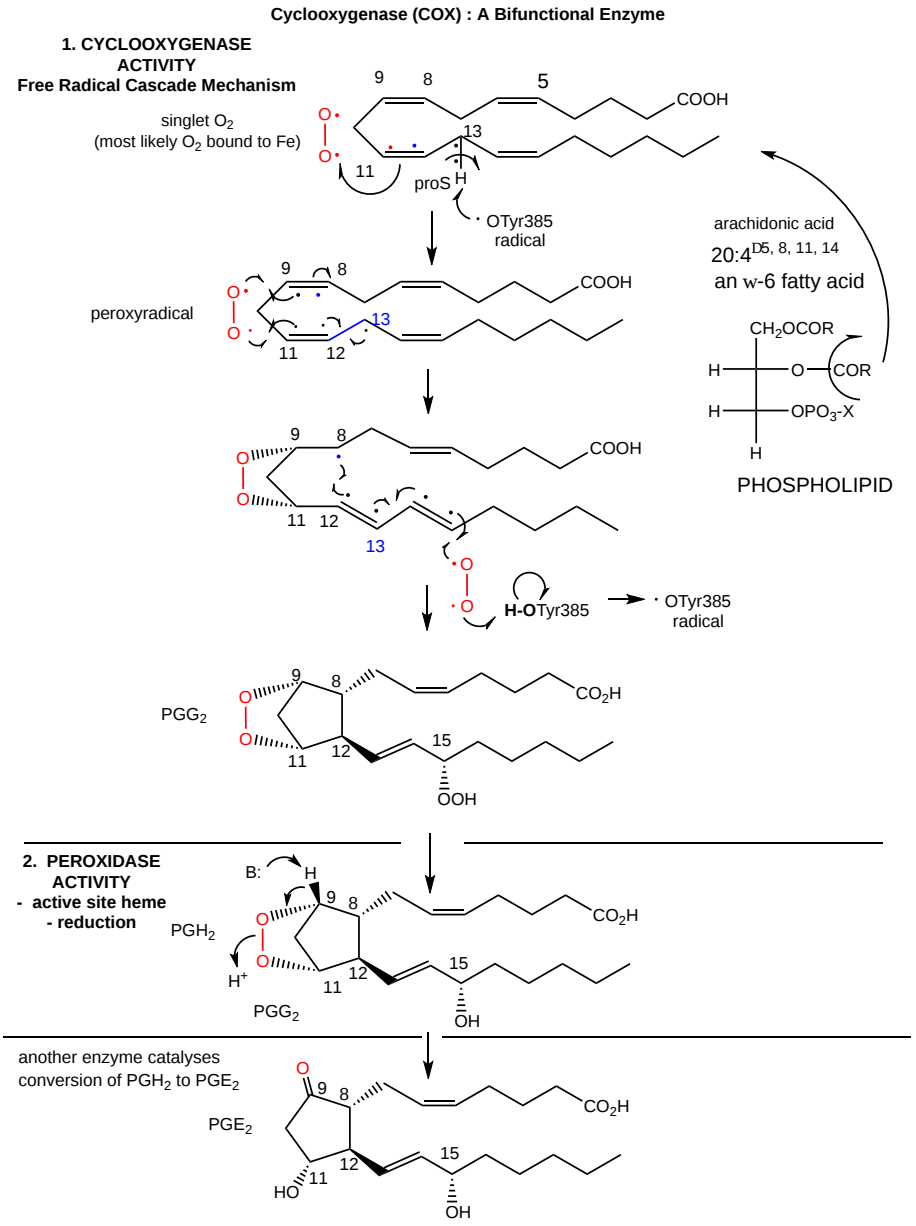

Figure 21.1.35: Simplified mechanism of prostaglandin endoperoxide H synthase (COX) emphasizing the radical nature of the mechanism.

A more detailed reaction mechanism for the synthesis of PGG_2 by prostaglandin endoperoxide H synthase (COX), emphasizing the role of active site amino acid and the heme in the POX site, is shown in Figures 36-38 below. (The mechanism and its explanation are adapted from https://www.ebi.ac.uk/thornton-srv/m-csa/entry/37/. Creative Commons Attribution 4.0 International (CC BY 4.0) License)

The 1st step involves a peroxide (denoted H-O-O*) but it might also be a ROO peroxide or NO. The generation of a Tyr-385· free radical in the COX site. is critical for the reaction. This is preceded by the heme radical cation in the POX site.

Figure \(\PageIndex{36}\) below shows the first step in which His 207 deprotonates the alkyl peroxide, which then coordinates to the heme Fe(III) in the POX site.

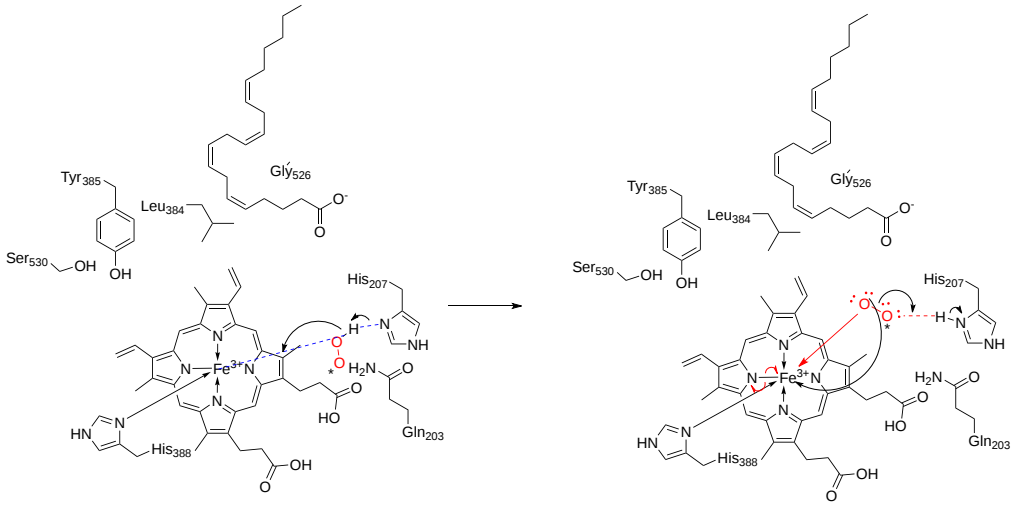

Figure 21.1.36: First step in the prostaglandin endoperoxide H synthase (COX) reaction.

In the next step, the peroxy bond donates two electrons to the heme Fe(III), one of which moves into the heme ring, forming Fe(IV). The heme ring then removes an electron from Tyr 385. This then removes a H. from the substrate, arachidonic acid. These steps are illustrated in Figure 21.1.37.

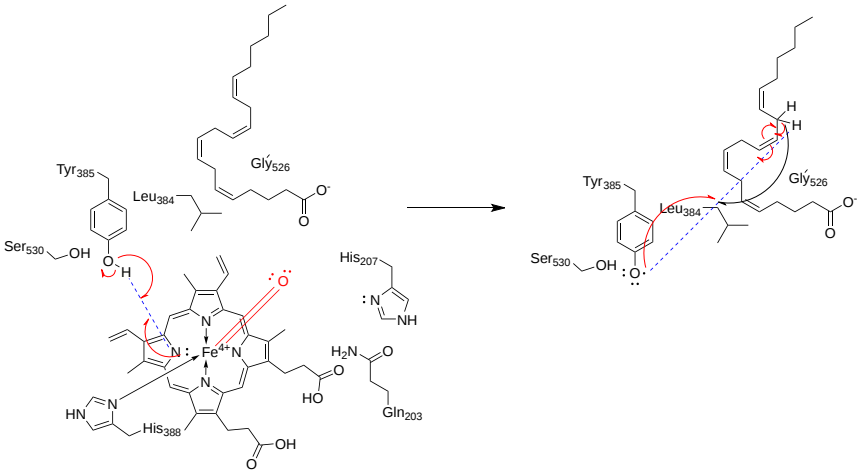

Figure 21.1.37: Next steps in the prostaglandin endoperoxide H synthase (COX) reaction.

The heme site is not shown in the next steps. Next, the reactive dioxygen, itself a ground state diradical, form a bound to the carbon-free radical in arachidonic acid. The rest of the reaction ensues as shown in Figure 21.1.38.

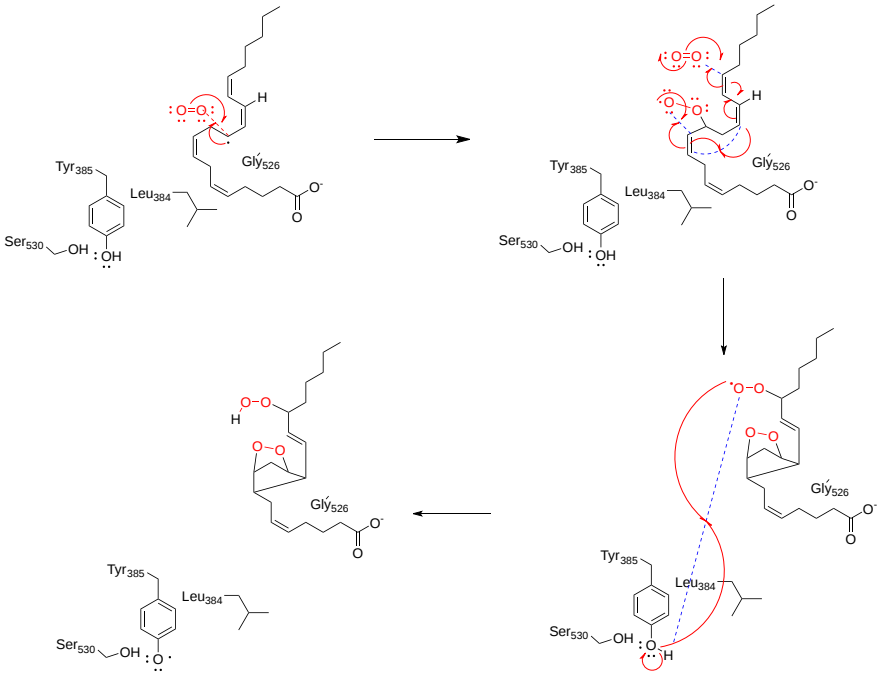

Figure 21.1.38 Figure 21.1.37: Final steps in the formation of PGG_2 by prostaglandin endoperoxide H synthase (COX) reaction.

Figure 21.1.39 shows an interactive iCn3D model of the mouse COX-2 with bound arachidonic acid (3KRK)

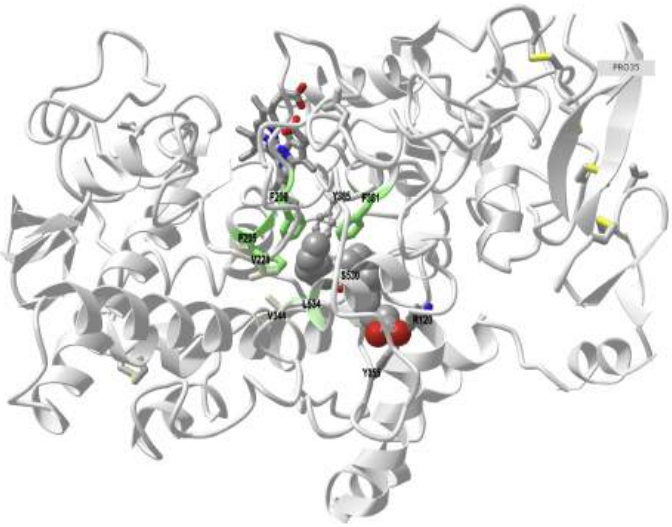

Figure 21.1.39: Mouse COX-2 with bound arachidonic acid (3KRK) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...yAtJnTkTmuNreA

The following key binding and catalytic residues are shown and labeled:

- Arg-120 and Tyr-355 are close to the carboxylate of AA
- Phe205, Phe209, Val228, Val344, Phe381, and Leu534 form a hydrophobic groove for the ω-end of AA.
- Ser 530, which is above this, gets acetylated by aspirin
- Tyr 385, near C13 in arachidonic acid, forms the free radical which removes a single electron from C13

Prostaglandins, which were first isolated from prostate glands, serve as powerful, but labile local hormones which are mediators of pain, inflammation, and immune and clotting activity. The cyclooxygenase activity is inhibited by aspirin, which probably accounts for most of its anti-inflammatory and analgesic properties. Aspirin, acetylsalicylic acid, acetylates a reactive Ser 530 in the active site. Another nonsteroidal anti-inflammatory drug (NSAID) with similar properties is Ibuprofen (Advil). Acetaminophen (Tylenol) is also considered a member of this drug class, even though it doesn't have anti-inflammatory properties. The question has arisen as to why. It now turns out that there are three different types of COX, I, II, and III. COX III is expressed in the brain and might be involved in pain pathways. Acetaminophen appears to work on this COX, as shown in Table 21.1.1 below (Bazan et al.).

Cyclooxygenase Activities

COX	Expression	Function	Inhibitors
COX 1	constitutively	organ pain, platelet function, stomach protection	NSAIDs including aspirin
COX 2	induced by growth factors, neurotransmitters, inflammatory cytokines, oxidative stress, and injury. Constitutively in the brain, kidney	Inducible COX2: inflammation, pain, fever Constitutive COX2: synaptic plasticity	NSAIDs, COX 2 inhibitors including celecoxib (Celebrex) which has few GI problems associated with its use
COX 3	constitutively, high in brain, heart	pain pathways, not inflammation pathways	acetaminophen (no GI problems, great fever reducer), some NSAIDs

21.1.7: FISH N-3 FATTY ACIDS AND HEALTH

We mentioned the importance of arachidonic acid in signal transduction in the lipid chapter. In addition, the importance of n-3 fatty acids to health was discussed as well. As mentioned above, arachidonic acid is cleaved from the C2 or sn-2 position of membrane phospholipids and modified by cyclooxygenase or lipoxygenase to form prostaglandins and leukotrienes, both potent local biological mediators. Linoleic acid and 22:6n-3 (DHA or docosahexaenoic acid) are also found in membrane phospholipids at the sn-2 position. What is the mechanism for the health-protective effects of n-3 fatty acids like DHA?

In human tissue, DHA, 22:6n-3 or $22{:}6^{\Delta 5,8,11,14,17,20}$ is the most abundant n-3 polyunsaturated fatty acids (PUFAs). Since it is synthesized from linolenic acid (as is EPA), a deficiency of linolenic acid in the diet will lead to lowered levels of 22:6n-3 in tissues, with ensuing health effects. Since these lipids are involved in membrane structure, signal transduction, and hormone synthesis, diverse effects of dietary n-3 PUFA deficiency will be observed. 50% of all fatty acids in the sn1 and sn2 position of membrane phospholipids of rod outer segments (in the retina) are 22:6(n-3). Cognitive dysfunctions (loss of memory, etc.) have been linked to decreased levels of 22:6(n-3) in the brain. This fatty acid binds to retinoid X receptors which then activate (through linked binding reactions) nuclear receptors, leading to alterations in gene transcription in the CNS.

In other tissues, 22:6(n-3) rarely exceeds 10% of membrane fatty acids, but this percentage can be increased in cells with increases in a precursor, 20:5(n-3). DHA might affect lipid rafts in the membrane, which would affect the movement of important membrane protein receptors (and associated proteins) in the membrane, altering cell response to environmental stimuli. DHA and EPA affect arachidonic acid conversion to prostaglandins and leukotrienes. EPA binds less tightly to cyclooxygenase I and is a poor substrate for the enzyme, both effects which inhibit the formation of prostaglandins and signaling processes mediated by them. This explains why n-3 fatty acids have anti-inflammatory effects.

In addition, n-3 fatty acids have noticeable effects on gene transcription, which remain as long as these fatty acids are present in high levels in the diet These and other fatty acids bind to fatty acid-activated transcription factors called PPARs (peroxisome proliferator receptors - alpha, beta and gamma 1 and 2). These receptors regulate, through alterations in gene expression, proteins involved in lipid metabolism. Other fatty acid-dependent transcription factors are known as well. PPARs bind 20:5(n-3) with a micromolar Kd and change the conformation of the protein to a form than can bind other proteins, ultimately altering gene expression.

Table 21.1.2: Some biological effects of n-3 polyunsaturated fatty acids EPA (20:5) and DHA (22:6). Adapted from Jump D. The Biochemistry of n-3 Polyunsaturated fatty acids. J. Biol. Chem. 277, pg 8755 (200)

Organ(s)	Effect	Mechanism acts through
central nervous system	improve cognitive function	membrane composition; retinoic X receptor alpha
retina	improve acuity	membrane composition

cardiovascular	anti-arrhythmia; anti-clotting	membrane composition; rafts; eicosanoids
serum lipids	lowers triglycerides (a risk factor for cardiovascular. disease)	peroxisome proliferator receptor alpha and gamma
liver	decrease lipid synthesis; increase fatty acid oxid. decrease VLDL synthesis	sterol reg. element bind. protein; PPAR alpha PPAR alpha

21.1.8: RECOGNITION OF UNSATURATED FATTY ACIDS BY MEMBRANE G-PROTEIN-COUPLED RECEPTORS

The positive health effects of the n-3 (ω-3) fatty acids appear to involve those fatty acids acting as hormones that bind to a special membrane receptor called G protein-coupled receptor 120 (GPCR120). We will discuss GPCRs in greater detail in Chapter 28.2. When a hormone bounds to the membrane GPCR (a transmembrane protein with 7 membrane-spanning helices), the intracellular domain of the GPC alters how it interacts with a variety of binding partners inside the cell. The GPCRs are given that name since most interact with heterotrimeric G proteins inside the cell. These G proteins have a β, γ, and a variety of different α subunits (α_q, α_i, α_s). Activation of different α subunits leads to different downstream effects as part of an elaborate signaling system in the cell. When the health-promoting polyunsaturated n-3 (ω-3) fatty bind to GPCR120, here are some of the beneficial health effects on metabolism, as outlined in Table 21.1.3 below.

Protein involved in GPCR120 signaling	Downstream effect
$G\alpha_q$	Increases Ca^{2+} levels in the cell, which act as a second signal (messenger) Increases GLUT4 (glucose transporter) translocation to the cell membrane; Increases secretion of glucagon-like peptide 1 (GLP1)
$G\alpha_i$	Increases insulin secretion Inhibits Ghrelin (hunger hormone) secretion
$G\alpha_s$	Controls fat synthesis
non G protein GPCR kinase (GRK)/β-arrestin 2	Inhibits the NLRP3 inflammasome and is ant-iinflammatory

The data in the table above is summarized in Figure 21.1.40 below.

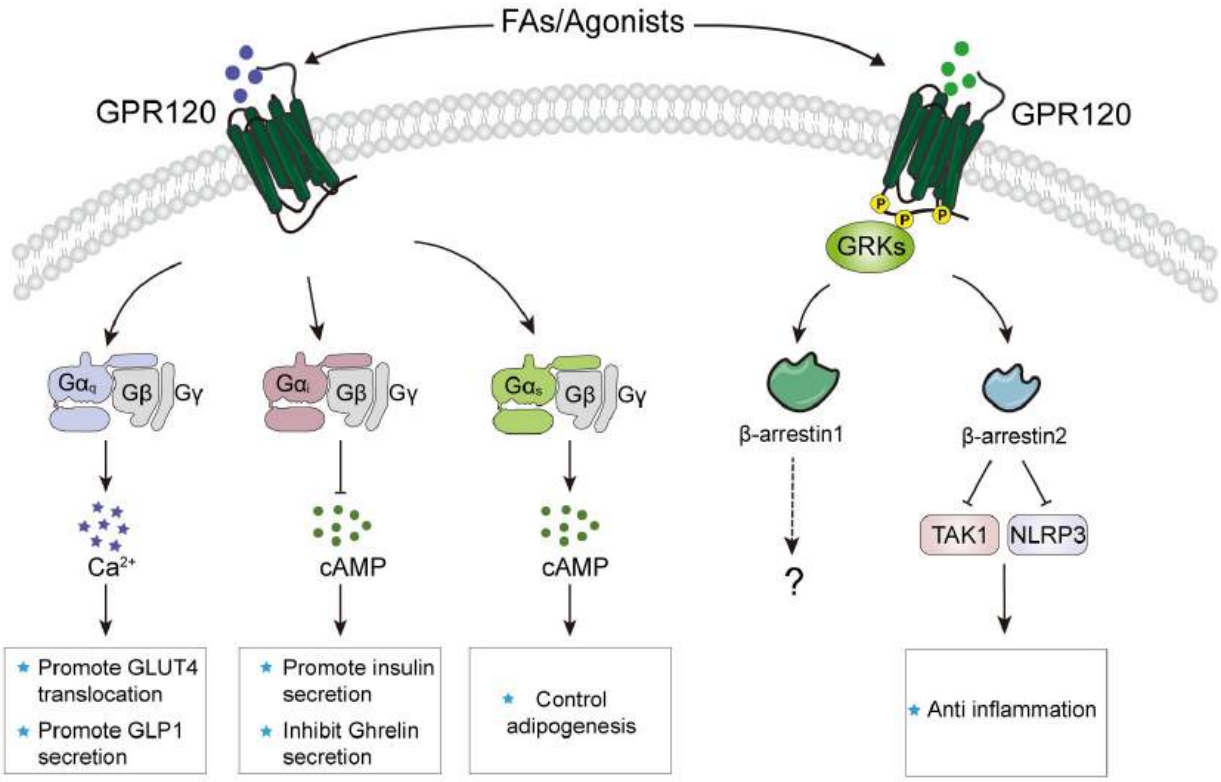

Figure 21.1.40: Schematic overview of G protein–and arrestin–mediated GPR120 signaling and related functions. Chunyou Mao et al. *Science* **380**, eadd6220 (2023). https://www.science.org/doi/10.1126/science.add6220. With permission from the AAAS.

GPCR120 and differentiate fatty acids based on the number and position of the double bond in the acyl chain of the ligand. Even though saturated fatty acids can bind to GPCR 120, only the n-3 (ω-3) fatty acids elicit the health effects.

CryoEM structures show the fatty acids buried in an L-shaped conformation in the GPCR. The protein engages in noncovalent interactions, specifically π:π interactions, with the double bonds in acyl chain. These interactions, which depend on the number of double bonds in the n-3 (ω-3) fatty acid differentially biases the GPCR towards the promotion of the specific effects for each different fatty acid.

Figure 21.1.41 shows an interactive iCn3D model of the eicosapentaenoic acid bound GPR120-Gi complex (8ID9).

21.2: BIOSYNTHESIS OF TRIACYLGLYCEROLS

by William (Bill) W. Christie and Henry Jakubowski.

This section is an abbreviated and modified version of material from the Lipid Web, an introduction to the chemistry and biochemistry of individual lipid classes, written by William Christie.

21.2.1: INTRODUCTION

All eukaryotic organisms and even a few prokaryotes can synthesize triacylglycerols, and in animals, many cell types and organs have this ability, but the liver, intestines, and adipose tissue are most active with most of the body stores in the last of these. Within all cell types, even those of the brain, triacylglycerols are stored as cytoplasmic '**lipid droplets**' enclosed by a monolayer of phospholipids and hydrophobic proteins such as the perilipins in adipose tissue or oleosins in seeds. These lipid droplets are now treated as distinctive organelles, with their own characteristic metabolic pathways and associated enzymes - no longer boring blobs of fat. However, they are not unique to animals and plants, as Mycobacteria and yeasts have similar lipid inclusions.

The lipid serves as a store of fatty acids for energy, which can be released rapidly on demand, and as a reserve of fatty acids for structural purposes or as precursors for eicosanoids. In addition, lipid droplets serve as a protective agency in cells to sequester any excess of biologically active and potentially harmful lipids such as free fatty acids, oxylipins, diacylglycerols, cholesterol (as cholesterol esters), retinol esters, and coenzyme A esters.

While triacylglycerols are essential for normal physiology, an excessive accumulation in human adipose tissue and other organs results in obesity and other health problems, including insulin resistance, steatohepatitis, and cardiomyopathy. Accordingly, there is considerable pharmaceutical interest in drugs that affect triacylglycerol biosynthesis and metabolism.

21.2.2: BIOSYNTHESIS OF TRIACYLGLYCEROLS

Three main pathways for triacylglycerol biosynthesis include the *sn*-glycerol-3-phosphate and dihydroxyacetone phosphate pathways, which predominate in liver and adipose tissue, and a monoacylglycerol pathway in the intestines. In maturing plant seeds and some animal tissues, a fourth pathway has been recognized in which a diacylglycerol transferase is involved.

The most important route to triacylglycerols is the *sn*-glycerol-3-phosphate or Kennedy pathway, first described by Eugene Kennedy and colleagues in the 1950s, from which more than 90% of liver triacylglycerols are produced. Figure 21.2.1 shows the pathway from glycerol-3-phosphate to triacylglycerols (the Kennedy pathway) and some preceding reactions that generate glycerol-3-phosphate.

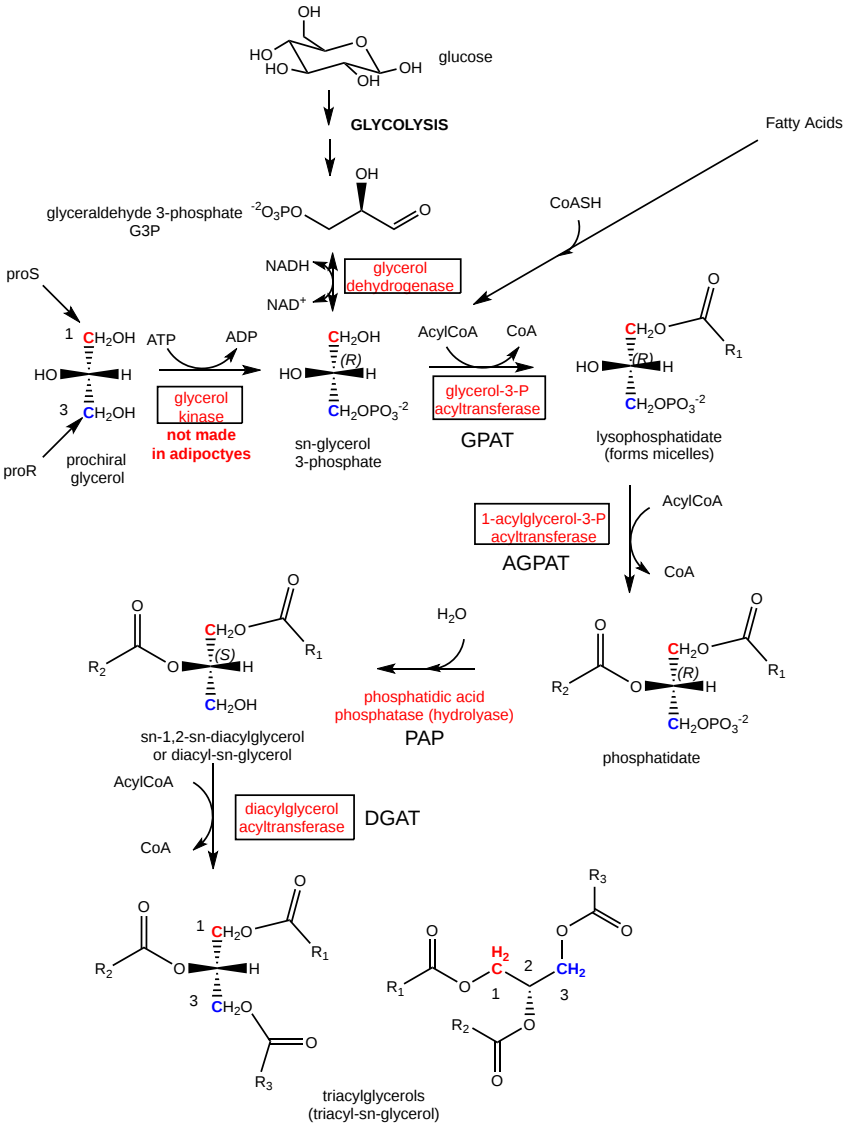

Figure 21.2.1: Synthesis of triacylglycerols from glycerol-3-phosphate (Kennedy pathway) and some preceding reactions that generate glycerol-3-phosphate.

In this pathway, the main source of the glycerol backbone has long been believed to be *sn*-glycerol-3-phosphate produced by the catabolism of glucose (glycolysis) or to a lesser extent by the action of the enzyme glycerol kinase on free glycerol. However, there is increasing evidence that a significant proportion of glycerol is produced *de novo* by a process known as glyceroneogenesis via pyruvate. Indeed, this may be the main source in adipose tissue.

Subsequent reactions occur primarily in or at the endoplasmic reticulum. First, the precursor *sn*-glycerol-3-phosphate is esterified by a fatty acid coenzyme A ester in a reaction catalyzed by a glycerol-3-phosphate acyltransferase (GPAT) at position *sn*-1 to form lysophosphatidic acid, and this is in turn acylated by an acylglycerophosphate acyltransferase (AGPAT) in position *sn*-2 to form a key intermediate in the biosynthesis of all glycerolipids - **phosphatidic acid.** Numerous isoforms of these enzymes are known; they are expressed with specific tissue and membrane distributions, and they are regulated in different ways.

Let's look at some of the enzymes involved in some key reactions in the synthesis of triacylglycerols.

GPAT Enzymes

Glycerol-3-phosphate acyltransferase (GPAT) catalyzes the first step in the pathway in most tissue. From an enzymatic perspective, it can be considered rate-limiting for the pathways since its specific activity is slow. In mammals, there are four isoforms (GPAT1 in the outer membrane of the mitochondria, GPAT2 also in the mitochondria, and GPAT3 and 4, both in the ER. The activity of GPAT1 is activated by insulin, presumably through phosphorylation) and inhibited by AMP-activated protein kinase (AMPK).

Fatty acyl-CoA in the outer membrane could be used for TAG synthesis through the Kennedy pathway in times of energy abundance or imported into the matrix through the carnitine-acyl-CoA cycle in times of energy need. Overexpression of GPAT1 in liver cells increases

TAG synthesis and decreases β-oxidation. GPAT1 deficient mice in contrast have higher levels of β-oxidation.

Figure 21.2.2 shows an interactive iCn3D model of the AlphaFold predicted structure of human mitochondrial glycerol-3-phosphate acyltransferase 1 - GPAT1 (Q9HCL2).

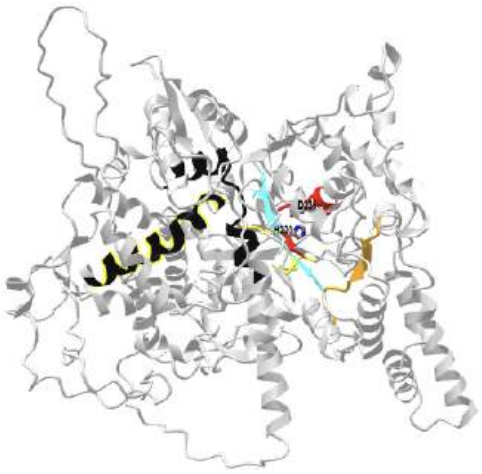

Figure 21.2.2: AlphaFold predicted structure ofhuman mitochondrial glycerol-3-phosphate acyltransferase 1 - GPAT1 (Q9HCL2). (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...kuvBTPo5mNK8p9

Four conserved motifs involved in catalysis (red and cyan) and binding (orange and yellow) are shown. Significant sections are still disordered in the model. Two highly conserved amino acids, His 230 and Asp 235 in the red catalytic motif are shown in CPK-colored sticks and labeled. The black helices are predicted outer mitochondrial membrane transmembrane helices. Both the N- and C-terminal amino acids project into the cytoplasm.

Phosphatidic acid phosphohydrolases (PAPs or 'phosphatidate phosphatases' or 'lipid phosphate phosphatases').

PAPs are also important as they produce ***sn*-1,2-diacylglycerols** as essential intermediates in the biosynthesis not only of triacylglycerols but also of phosphatidylcholine and phosphatidylethanolamine (and of monogalactosyldiacylglycerols in plants). This is a key branch-point in lipid biosynthesis as it may dictate the flow of lipids for storage or membrane biogenesis.

Much of this phosphatase activity leading to triacylglycerol biosynthesis in animals reside in three related cytoplasmic proteins, termed **lipins**, i.e., lipin-1, lipin-2 and lipin-3, which have tissue-specific roles in glycerolipid synthesis. Unusually, these were characterized and named before the nature of their enzymatic activities was determined. Each of the lipins appears to have distinctive expression and functions, but lipin-1 (PAP1) in three isoforms (designated 1α, 1β, and 1γ) accounts for most of the PAP activity in adipose tissue and skeletal muscle in humans. Lipin 2 is the most abundant lipin in the liver but is also expressed substantially in the small intestine, macrophages, and some regions of the brain, while lipin 3 activity overlaps with that of lipin 1 and lipin 2 and is found in the gastrointestinal tract and liver. Lipins are cytosolic enzymes but associate transiently with membranes to access their substrate, i.e., they are translocated to the endoplasmic reticulum in response to elevated levels of fatty acids within cells, although they do not have trans-membrane domains. Lipin-1 activity requires Mg^{2+} ions and is inhibited by *N*-ethylmaleimide, whereas the membrane-bound activity responsible for synthesizing diacylglycerols as a phospholipid intermediate is independent of Mg^{2+} concentration and is not sensitive to the inhibitor.

Perhaps surprisingly, lipin-1 has a dual role in that it operates in collaboration with known nuclear receptors as a transcriptional coactivator to modulate lipid metabolism (lipin 1α) while lipin 1β is associated with the induction of lipogenic genes such as fatty acid synthase, stearoyl-CoA desaturase, and DGAT. They can have profound effects on signaling in a variety of cell types. Abnormalities in lipin-1 expression are known to be involved in some human disease states that may lead to metabolic syndrome and inflammatory disorders. Lipin 2 is a similar phosphatidate phosphohydrolase, which is regulated dynamically by fasting and obesity (in mice).

PAP depend on divalent Mg^{2+} ions and are sensitive to N-ethylmaleimide. Lipin has a N-Lip (N-terminal) and C-Lip (C-terminal) domain. The crystal structure of lipin with a 250 amino acid regions between the two domains removed has been solved. The domain structures of humans, the yeast Saccharomyces cerevisiae (SC) and its truncated form (Tt-Pah2), and the structure of the Tt-Pah2 truncated fragment of the enzyme from Tetrahymena thermophila, are shown in Figure 21.2.3.

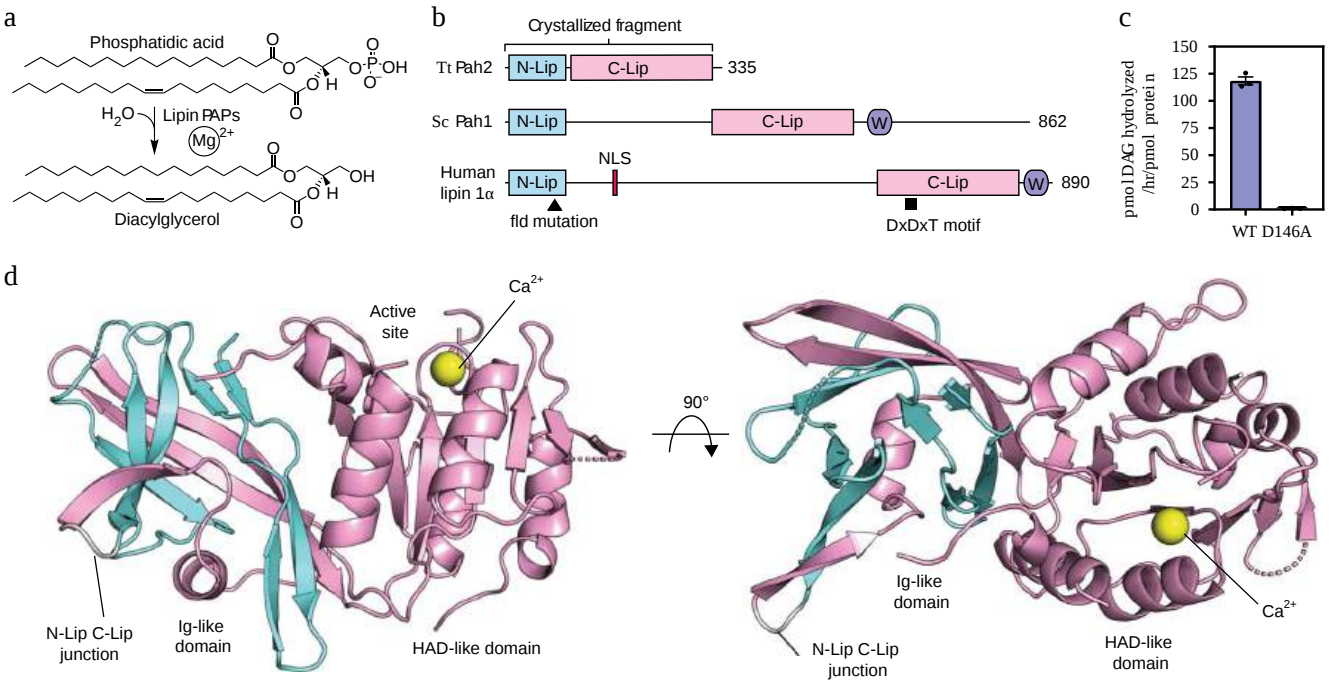

Figure 21.2.3: The domain structures of human, yeast Saccharomyces cerevisiae (SC) and a truncated form (Tt-Pah2) of the Tetrahymena thermophila enzyme. Panel (a) shows the PAP-catalyzed dephosphorylation reaction.

Panel (b) shows the domain architecture of PAPs drawn to scale. The positions of the nuclear localization signal (NLS), conserved Trp-motif (purple W), catalytic DxDxT motif, and fatty liver dystrophy (fld^{2J}) mutation are indicated.

Panel (c) shows the the wild-type (WT) *Tt* Pah2 is catalytically active and the D146A mutant of the DxDxT motif eliminates activity.

Panel (d) shows the overall structure of *Tt* Pah2, which contains an immunoglobulin-like (Ig-like) domain and a HAD-like catalytic domain. The Ig-like domain is formed by the N-Lip (cyan) and C-Lip (pink) regions connected by a short linker (gray loop) that would be replaced by the extended 500-residue linker in human lipins and a 250-residue linker in *Sc* Pah1. A calcium ion (Ca^{2+}, yellow sphere) is bound in the active site of the HAD-like catalytic domain. The top view (right) of the enzyme shows the N-Lip co-folding with the C-Lip to form the Ig-like domain.

Figure 21.2.4s shows a closeup of the active site of *Tt* Pah2 and a mechanism for the hydrolytic removal of the phosphate on DAG.

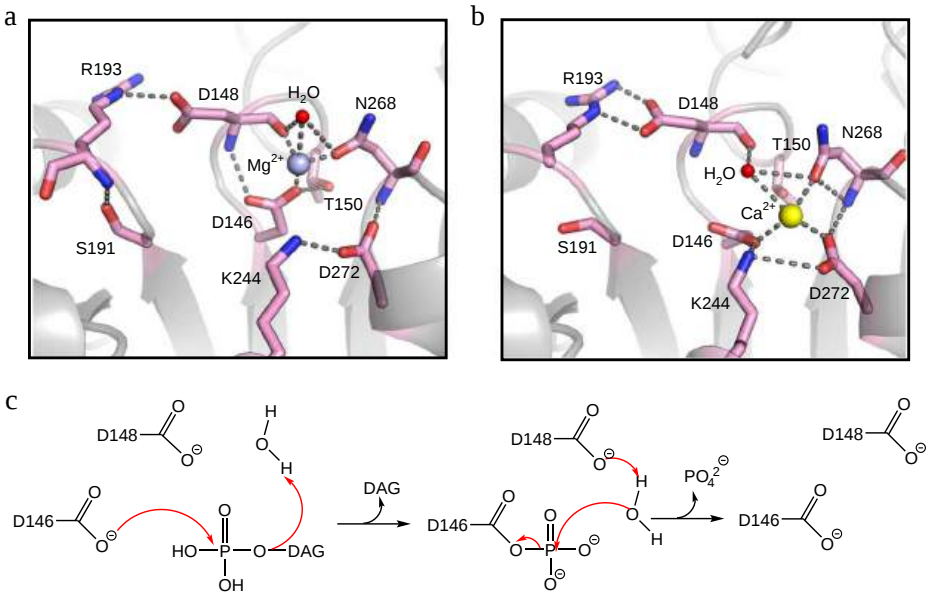

Figure 21.2.4: **a** Detailed view of the *Tt* Pah2 active site with magnesium bound (light blue sphere). Polar contacts are indicated by gray dashes. **b** Detailed view of the structural rearrangement of key residue interactions in the active site with calcium bound (yellow sphere). **c** Proposed schematic of lipin/Pah PAPs catalytic mechanism. Catalysis proceeds through a trigonal bipyramidal intermediate. Khayyo, V.I. et al, ibid.

Figure 21.2.5 shows an interactive iCn3D model of the Tetrahymena Thermophila lipin phosphatidic acid phosphatase with magnesium (6TZZ).

The N-terminal domain is shown in lavender and the C-terminal domain is in gray. Key amino acids in the active site are shown in CPK-colored sticks and labeled.

Diacylglycerol acyltransferases (DGAT)

In the final step in this pathway, the 1,2-diacyl-*sn*-glycerol intermediate is acylated by **diacylglycerol acyltransferases (DGAT)**, which can utilize a wide range of fatty acyl-CoA esters to form the triacyl-*sn*-glycerol. There are two DGAT enzymes, which are structurally and functionally distinct. In animals, DGAT1 is located mainly in the endoplasmic reticulum and is expressed in skeletal muscle, skin, and intestine, with lower levels of expression in the liver and adipose tissue. It is believed to have dual topology contributing to triacylglycerol synthesis on both sides of the membrane of the endoplasmic reticulum but esterifying only pre-formed fatty acids of exogenous origin. Perhaps surprisingly, DGAT1 is the only one present in the epithelial cells that synthesize milk fat in the mammary gland. Also, DGAT1 can utilize a wider range of substrates, including monoacylglycerols, long-chain alcohols (for wax synthesis), and retinol, and it is reported to have an important role in protecting the endoplasmic reticulum from the lipotoxic effects of high-fat diets. Orthologs of this enzyme are present in most eukaryotes, other than yeasts, and they are especially important in plants.

Figure 21.2.6 shows an interactive iCn3D model of Human Diacylglycerol Acyltransferase 1 in complex with oleoyl-CoA (6VP0)

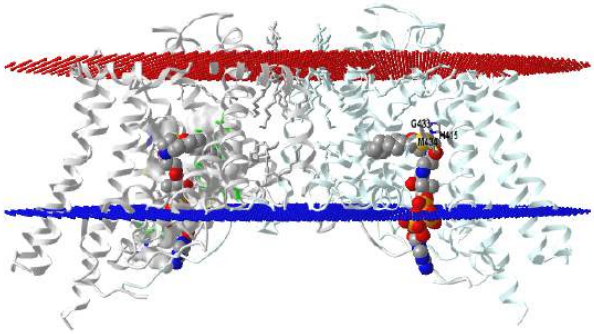

Figure 21.2.6: Human Diacylglycerol Acyltransferase 1 in complex with oleoyl-CoA (6VP0) (Copyright; author via source). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...adyWg9fy2hh8r8

The red layer is the extracellular leaflet and the blue is the intracellular leaflet. The protein is a dimer with one subunit shown in gray and one in light. A substrate, oleoyl-CoA, is shown in spacefill with CPK colors in both monomers. The acyl chain with a clear kink induced by the double bond in the oleoyl acyl group is clearly in the hydrophobic interior of the bilayer. The gray monomer shows the atoms within 4 Å from the oleoly-CoA is shown as surface color-coded by hydrophobicity with the green most hydrophobic. The active site His 415 and Met 434 which hydrogen bonds to it are shown in the light cyan subunit in sticks, CPK colors, and labeled. Three other conserved polar side chains, Asn378, Gln437, and Gln465, which are in the active site region, are also shown.

Each monomer in the homodimer has 9 transmembrane helices with 8 forming a unique fold called the MBOAT which encloses a chamber with catalytic side chains. The substrates, fatty acyl-CoA, and DAG have different entrances to the chamber with the acyl-CoA occupying a cytosolic tunnel. The cytosolic face interacts with the CoA and the acyl chain extends into the ER membrane. The channel appears bent which probably allows the acylation of DAGs and long-chain alcohols, but not cholesterol, a rigid, planar molecule that is acylated to form an ester by a different enzyme, acyl CoA:cholesterol acyltransferases. Hence it appears that DAG, the acyl-acceptor, binds in a hydrophobic tunnel from within the bilayer and the acyl-CoA binds in another tunnel, allowing the transfer of the acyl group.

DGAT2 is the main form of the enzyme in hepatocytes and adipocytes (lipid droplets), although it is expressed much more widely in tissues. It is associated with distinct regions of the endoplasmic reticulum, at the surface of lipid droplets, and in mitochondria, and it esterifies fatty acids of both endogenous and exogenous origin. DGAT2 is believed to have a targeting domain that enables it to tether between the endoplasmic reticulum and lipid droplet thereby channeling triacylglycerols from the synthesis site in the endoplasmic reticulum to the nascent lipid droplet, where they accumulate and lead to the expansion of the latter (see **below**). Both enzymes are important modulators of energy metabolism, although DGAT2 appears to be especially important in controlling the homeostasis of triacylglycerols *in vivo*. As the glycerol-3-phosphate acyltransferase (GPAT) has the lowest specific activity of these enzymes, this step may be the rate-limiting one. However, DGATs are the dedicated triacylglycerol-forming enzymes, and they are seen as the best target for pharmaceutical intervention in obesity and attendant ailments; clinical studies of DGAT1 inhibitors are at an early stage.

In a second pathway for triacylglycerol biosynthesis, dihydroxyacetone-phosphate in peroxisomes or endoplasmic reticulum can be acylated with fatty acid CoA esters by a specific acyltransferase to form 1-acyl dihydroxyacetone-phosphate, which is reduced by dihydroxyacetone-phosphate oxidoreductase to lysophosphatidic acid; this can then enter the pathway above to triacylglycerols. The precursor dihydroxyacetone-phosphate is important also as part of the biosynthetic route to **plasmalogens**, and neutral plasmalogens can be significant components of cytoplasmic droplets in many mammalian cells types but not in adipose tissue.

Figure 21.2.7: Biosynthesis of triacylglycerols from dihydroxyacetone-phosphate

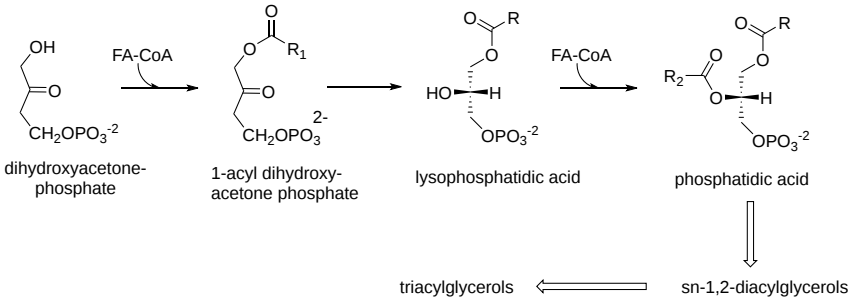

Figure 21.2.7: Biosynthesis of triacylglycerols from dihydroxyacetone-phosphate

In prokaryotes, the glycerol-3-phosphate pathway of triacylglycerol biosynthesis only occurs, but in yeast, both glycerol-3-phosphate and dihydroxyacetone-phosphate can be the primary precursors and synthesis takes place in cytoplasmic lipid droplets and the endoplasmic reticulum. In plants, the glycerol-3-phosphate pathway is most important.

In the enterocytes of the intestines after a meal, up to 75% of the triacylglycerols are formed via a monoacylglycerol pathway. In this, 2-monoacyl-*sn*-glycerols and free fatty acids released from dietary triacylglycerols by the action of pancreatic lipase within the intestines (see below) are taken up by the enterocytes. There, the monoacylglycerols are first acylated by an acyl-coenzyme A:monoacylglycerol acyltransferase with the formation of *sn*-1,2-diacylglycerols mainly as the first intermediate in the process, though some *sn*-2,3-diacylglycerols (~10%) are produced. In addition, 1-monoacylglycerols can be synthesized by acylation of glycerol for further acylation. There are three isoforms of the monoacylglycerol acyltransferase in humans of which MGAT2 is most active in the intestines, but also in the liver where an appreciable proportion of the triacylglycerols are formed by the monoacylglycerol pathway, while MGAT1 functions in adipose tissue; the role of MGAT3 is not clear. Finally, the acyl-coenzyme A:diacylglycerol acyltransferase (DGAT1) reacts with the *sn*-1,2-diacylglycerols (not the *sn*-2,3 form) to produce triacylglycerols (DGAT1 can also acylate monoacylglycerols). Figure 21.2.8 shows the biosynthesis of triacylglycerols from monoacylglycerols.

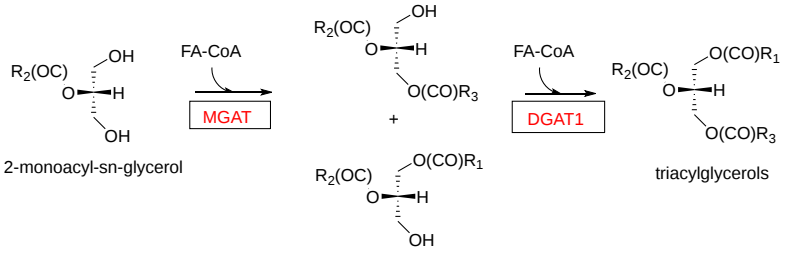

Figure 21.2.8: Biosynthesis of triacylglycerols from monoacylglycerols

Other pathways: In a fourth biosynthetic pathway, which is less well known, triacylglycerols are synthesized by a transacylation reaction between two racemic diacylglycerols that are independent of acyl-CoA. The reaction was first detected in the endoplasmic reticulum of intestinal micro villus cells and is catalyzed by a diacylglycerol transacylase. Both diacylglycerol enantiomers participate in the reaction with equal facility to transfer a fatty acyl group with the formation of triacylglycerols and a 2-monoacyl-*sn*-glycerol. A similar reaction has been observed in seed oils. Figure 21.2.9: Biosynthesis of triacylglycerols from diacylglycerol transacylases

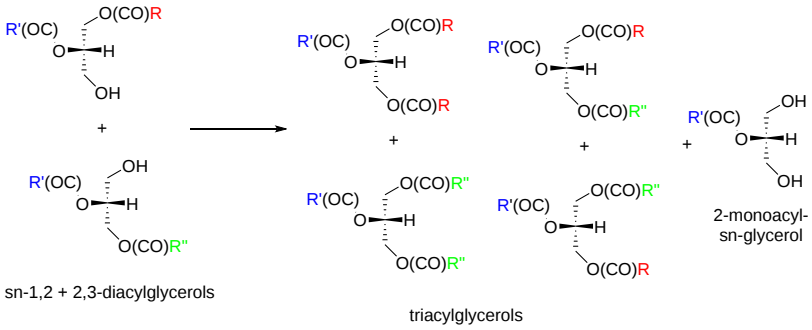

Figure 21.2.9: Biosynthesis of triacylglycerols from diacylglycerol transacylases

It has been suggested that this enzyme may function in remodeling triacylglycerols post-synthesis, especially in oil seeds, and it may be involved in similar processes in the liver and adipose tissue, where extensive hydrolysis/re-esterification is known to occur. There is evidence for selectivity in the biosynthesis of different molecular species in a variety of tissues and organisms, which may be a consequence of the varying biosynthetic pathways. Also in adipose tissue, fatty acids synthesized *de novo* are utilized in different ways from those from external sources in that they enter positions *sn*-1 and 2 predominantly, while a high proportion of the oleic acid synthesized in the tissue by desaturation of exogenous stearic acid is esterified to position *sn*-3.

Among other potential routes to the various intermediates, lysophosphatidic acid and phosphatidic acid can be synthesized in mitochondria, but they must then be transported to the endoplasmic reticulum before they enter the pathway for triacylglycerol production. 1,2-Diacyl-*sn*-glycerols are also produced by the action of phospholipase C on phospholipids and can be utilized for triacylglycerol biosynthesis.

In the glycerol-3-phosphate and other pathways, the starting material is of defined stereochemistry and each of the enzymes catalyzing the various steps in the process is distinctive and can have preferences for particular fatty acids (as their coenzyme A esters) and for particular fatty acid combinations in the partially acylated intermediates. It should not be surprising, therefore, that natural triacylglycerols exist in enantiomeric forms with each position of the *sn*-glycerol moiety esterified by different fatty acids.

21.2.3: TRIACYLGLYCEROL METABOLISM IN THE INTESTINES, LIVER, AND MAMMARY GLAND

Fat comprises up to 40% of the energy intake in the human diet in Western countries, and a high proportion of this is in the form of triacylglycerols. The process of fat digestion is begun in the stomach with acid-stable gastric or lingual lipases, the extent of which depends on species but may be important for efficient emulsification. However, this is insignificant in quantitative terms in comparison to the

reaction with pancreatic lipase, which occurs in the duodenum. Entry of triacylglycerol degradation products into the duodenum stimulates the synthesis of the hormone cholecystokinin and causes the gall bladder to release **bile acids**, which are strong detergents and act to emulsify the hydrophobic triacylglycerols so increasing the available surface area. In turn, cholecystokinin stimulates the release of the hydrolytic enzyme pancreatic lipase together with a co-lipase, which is essential for the activity of the enzyme. Pancreatic lipase, co-lipase, bile salts, and calcium ions act together in a complex at the surface of the emulsified fat droplets to hydrolyze the triacylglycerols. The process is regiospecific and results in the release of the fatty acids from the 1 and 3 positions and the formation of 2-monoacyl-*sn*-glycerols as shown in Figure 21.2.10.

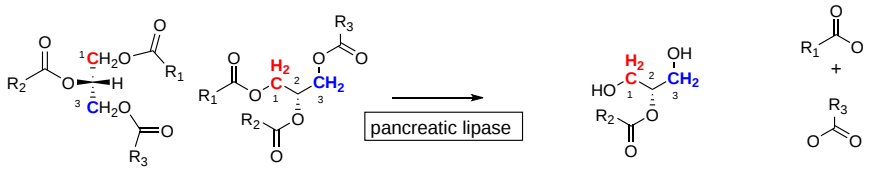

Figure 21.2.10: Hydrolysis of triacylglycerols in the intestines

Spontaneous isomerization of the latter to 1(3)-monoacyl-*sn*-glycerols occurs to some extent, and these can be degraded completely by the enzyme to glycerol and free fatty acids. Other lipases hydrolyze the phospholipids and other complex lipids in foods at the same time.

This process is somewhat different in neonates and young infants, in whom pancreatic lipase is less active but is effectively replaced by lipases in breast milk and by an acid gastric lipase (pH optimum 4-6).

There is evidence that the regiospecific structure of dietary triacylglycerols affects the uptake of particular fatty acids and may influence further lipid metabolism in humans. Incorporation of palmitic acid into the position *sn*-2 of milk fat may be of benefit to the human infant (as a source of energy for growth and development), although it increases the atherogenic potential for adults. In addition, 2-monoacylglycerols and 2-oleoylglycerol especially have a signaling function in the intestines by activating a specific G-protein coupled receptor GPR119, sometimes termed the 'fat sensor'. When stimulated, this causes a reduction in food intake and body weight gain in rats and regulates glucose-stimulated insulin secretion. The free fatty acids released have a similar effect, though by a very different mechanism, via the receptor GPR40. Overall, it has become evident that triacylglycerol metabolism in the intestine has regulatory effects on the secretion of gut hormones and subsequently on systemic lipid metabolism and energy balance.

The free fatty acids and 2-monoacyl-*sn*-glycerols are rapidly taken up by the intestinal cells, from the distal duodenum to the jejunum, via specific carrier molecules but also by passive diffusion. A specific fatty acid binding protein prevents a potentially toxic build-up of unesterified fatty acids and targets them for triacylglycerol biosynthesis. The long-chain fatty acids are converted to the CoA esters and esterified into triacylglycerols by the monoacylglycerol pathway as described above. In contrast, short and medium-chain fatty acids (C_{12} and below) are absorbed in unesterified form and pass directly into the portal blood stream, where they are transported to the liver to be oxidized.

Subsequently, the triacylglycerols are incorporated into **lipoprotein complexes** termed **chylomicrons** in the enterocytes in the small intestines. In brief, these consist of a core of triacylglycerols together with some cholesterol esters that is stabilized and rendered compatible with an aqueous environment by a surface film consisting of phospholipids, free cholesterol, and one molecule of a truncated form of apoprotein B (called apo B48). A cartoon structure of a chylomicron is shown in Figure 21.2.11.

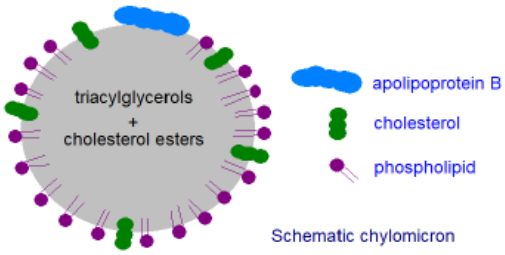

Figure 21.2.11: Cartoon structure of a chylomicron

These particles are secreted into the lymph and thence into the plasma for transport to the peripheral tissues for storage or structural purposes. Adipose tissue in particular exports appreciable amounts of the enzyme **lipoprotein lipase**, which binds to the luminal membrane of endothelial cells facing into the blood, where it rapidly hydrolyses the passing triacylglycerols at the cell surface releasing free fatty acids, most of which are absorbed into the adjacent adipocytes and re-utilized for triacylglycerol synthesis within the cell.

The chylomicrons remnants eventually reach the liver, where the remaining lipids are hydrolyzed at the external membranes by a hepatic lipase and absorbed. The fatty acids within the liver can be utilized for a variety of purposes, from oxidation to the synthesis of structural lipids, but a proportion is re-converted into triacylglycerols, and some of this is stored as lipid droplets within the cytoplasm of the cells (see

next section). In addition, phosphatidylcholine from the high-density lipoproteins is taken up by the liver, and a high proportion of this is eventually converted to triacylglycerols. In a healthy liver, the levels of triacylglycerols are low (<5% of the total lipids), because the rates of acquisition of fatty acid from plasma and synthesis *de novo* within the liver are balanced by rates of oxidation and secretion into plasma. On the other hand, excessive accumulation of storage triacylglycerols is associated with fatty liver, insulin resistance, and type 2 diabetes.

Most of the newly synthesized triacylglycerols are exported into the plasma in the form of very-low-density lipoproteins (VLDL), consisting again of a triacylglycerol and cholesterol ester core, surrounded by phospholipids and free cholesterol, together with one molecule of full-length apoprotein B (100 kDa), apoprotein C and sometimes apoprotein E. These particles in turn are transported to the peripheral tissues, where they are hydrolyzed and the free acids absorbed. Eventually, the remnants are returned to the liver.

In the **mammary gland**, triacylglycerols are synthesized in the endoplasmic reticulum and large lipid droplets are produced with a monolayer of phospholipids derived from this membrane. These are transported to the plasma membrane and bud off into the milk with an envelope comprised of the phospholipid membrane to form milk fat globules as food for the newborn. The process is thus very different from that involved in the secretion of triacylglycerol-rich lipoproteins from other organs.

21.2.4: TRIACYLGLYCEROL SYNTHESIS AND CATABOLISM (LIPOLYSIS) IN ADIPOCYTES AND LIPID DROPLETS

Adipose tissue and the adipocytes are characterized by accumulations of triacylglycerols, which act as the main energy store for animals, although they also cushion and insulate the body. Large fat depots occur around internal organs such as the liver, and also subcutaneously, and each of these may react differently to metabolic constraints. Thus, triacylglycerols stored when there is a surplus of nutrients are mobilized for energy production during starvation. Adipose tissue also functions as a reserve of bioactive lipids, such as eicosanoids and lipid-soluble vitamins, and when required provides structural components, including fatty acids, cholesterol, and retinol, for membrane synthesis and repair. By buffering against fatty acid accumulation that might exceed their capacity, non-adipose cells defend themselves in this way against lipotoxicity while providing a rapid source of energy and essential metabolites by sensing and responding rapidly to changes in systemic energy balance. Brown and beige fat have special properties and are discussed below, while bone marrow adipocytes (70% of the available space) have distinctive functions also.

Similarly, within most other animal cells, including most cell types in the brain, a proportion of the fatty acids taken up from the circulation is converted to triacylglycerols as described above and incorporated into cytoplasmic lipid droplets (also termed 'fat globules', 'oil bodies', 'lipid particles' or 'adiposomes'). In adipocytes, the lipid droplets can range from up to 200 μm in diameter, while other cell types contain smaller lipid droplets of the order of 50 nm in diameter. The triacylglycerol droplets together with cholesterol esters and other neutral lipids are surrounded by a protective monolayer that includes phospholipids, cholesterol, and hydrophobic proteins. The phospholipid component of the monolayer consists mainly of phosphatidylcholine and phosphatidylethanolamine derived from cytosolic leaflets of the endoplasmic reticulum and plasma membrane. Among the proteins are many that function directly in lipid metabolism, and they include acyltransferases, lipases, perilipins, caveolins, and the Adipose Differentiation Related Protein (ADRP or adipophilin). Acting in concert with other cellular organelles, they function in many different metabolic processes facilitating coordination and communication between different organelles and acting as vital hubs of cellular metabolism.

Cytosolic lipid droplets with similar metabolic activities are found in most eukaryotic cells, including those of the fruit fly *Drosophila melanogaster*, and many aspects of triacylglycerol processing and regulation parallel those in humans. They are also present in the cytoplasm of some prokaryotes and in the plastids and other organelles of plants (see below).

Lipid droplet assembly

This process takes place in sub-domains of the endoplasmic reticulum, where at least one isoform of each of the enzymes of triacylglycerol biosynthesis, from acyl-CoA synthetases through to glycerol-3-phosphate acyltransferases, is located probably in a protein assembly or 'interactome'. As triacylglycerols accumulate, they reach a critical level when a spontaneous condensation or nucleation by phase separation occurs, leading to the formation of an oil blister within the hydrophobic bilayer region so attracting perilipins and other proteins that allow lipid droplets to grow further in patches of the membrane as lens-like swellings between the two membrane leaflets.

The protein **seipin** stabilizes the nascent droplets with minimal disruption to the membrane and enables them to mature. Seipin monomers assemble into a decameric cage-like structure and sit in the ER to provide a space that permits triacylglycerol molecules to interact with each other, rather than with phospholipid acyl chains, a process that is probably aided by trans-membrane protein segments. This enables phase separation of the triacylglycerols, lens formation, and growth to a point where the seipin oligomer opens toward the cytoplasm so the lens can form a budding lipid droplet.

Figure 21.2.12 presents a cartoon that shows the role of ER membrane seipins and other proteins in the assembly of lipid droplets.

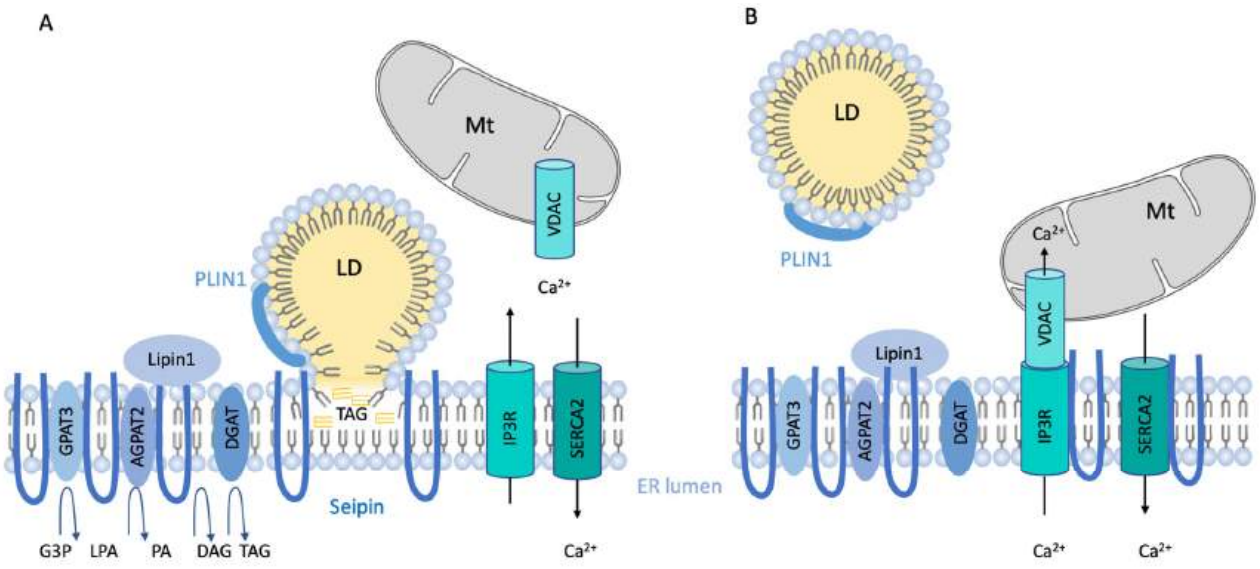

Figure 21.2.12 Seipin function in mature adipocytes. Magré J, Prieur X. Seipin Deficiency as a Model of Severe Adipocyte Dysfunction: Lessons from Rodent Models and Teaching for Human Disease. Int J Mol Sci. 2022 Jan 11;23(2):740. doi: 10.3390/ijms23020740. Creative Commons Attribution (CC BY) license (https://creativecommons.org/licenses/by/4.0/

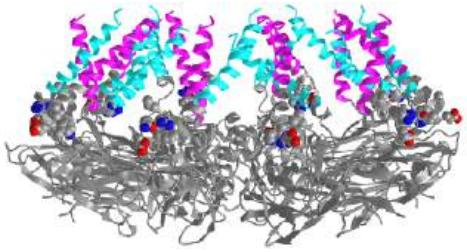
In panel (A), seipin is enriched at the endoplasmic reticulum (ER)/lipid droplet (LD) contact sites and is crucial in triglycerides (TAG) flow from the ER to the LD. Seipin interacts with Perilipin1 (PLIN1) and with several TAG synthetic enzymes such as glycerol-3-phosphate acyltransferase (GPAT3), 1-acyl-sn-glycerol-3-phosphate acyltransferase beta (AGPAT2), and LIPIN. No interaction with diacylglycerol acyltransferases (DGAT) has been formally reported. Magré J et al, Int J Mol Sci. 2022 Jan 11;23(2):740. doi: 10.3390/ijms23020740. Creative Commons Attribution (CC BY) license (https://creativecommons.org/licenses/by/4.0/

In panel (B), representing the fasting state, seipin is enriched at the ER/mitochondria (Mt) contact sites, also named mitochondria-associated membranes (MAM) and participates in ER/mitochondria calcium (Ca^{2+}) flux and mitochondrial activity. Seipin is near MAM Ca^{2+} regulators IP3(inositol 1,4,5-trisphosphate) receptor (IP3R), voltage-dependent anion channel (VDAC), and sarco-/ER Ca^{2+} ATPase 2 (SERCA2) as well as glycerol-3-phosphate (G3P), lysophosphatidic acid (LPA), phosphatidic acid (PA), and diacylglycerol (DAG).

Figure 21.2.13 shows an interactive iCn3D model of the S. cerevisiae seipin Homo 10-mer flexible cage at lipid droplet formation sites (7RSL).



NCBI iCn3D Figure 21.2.13: S. cerevisiae seipin homo 10-mer flexible cage at lipid droplet formation sites (7RSL). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...BjYLiQXVJjBpk8

The N-terminal transmembrane segment (TMS) on each monomer is shown in cyan while the C-terminal TMS is shown in magenta. These form the cage sides and top and anchor the complex in the ER membrane. The side chains of a conserved switch sequence (F_{232}xxGLR) on each monomer are shown in spacefill, CPK colors. The gray ribbons represent the part of the complex that is in the lumen of the ER.

Adjacent monomers in the homo 10-mer cage, even though they are identical in sequences, adopt different orientations for two helices that enable a binary switch in the conformation of the complex. Two adjacent subunits, the A chain in blue and the B chain in orange, are shown, along with their overlap, in Figure 21.2.14.

Figure 21.2.14: Conformational flexibility in adjacent monomers in the seipin homo 10-mer.

A highly conserved "switch" region is shown in green with its highly conserved motif F_{232}xxGLR shown as sticks with CPK colors. Note the large conformational change in the switch region which occurs with a large conformational change of the two helices. This suggests that there are two overall conformations of the complex, a closed form allowing accumulation of TAGs and an open form which allows the budding and release of lipid droplets. A possible model for the formation and budding of lipid droplets is illustrated in Figure 21.2.15. As in the above figure, the A (open) chain is shown in blue while the B (closed) chain is shown in orange.

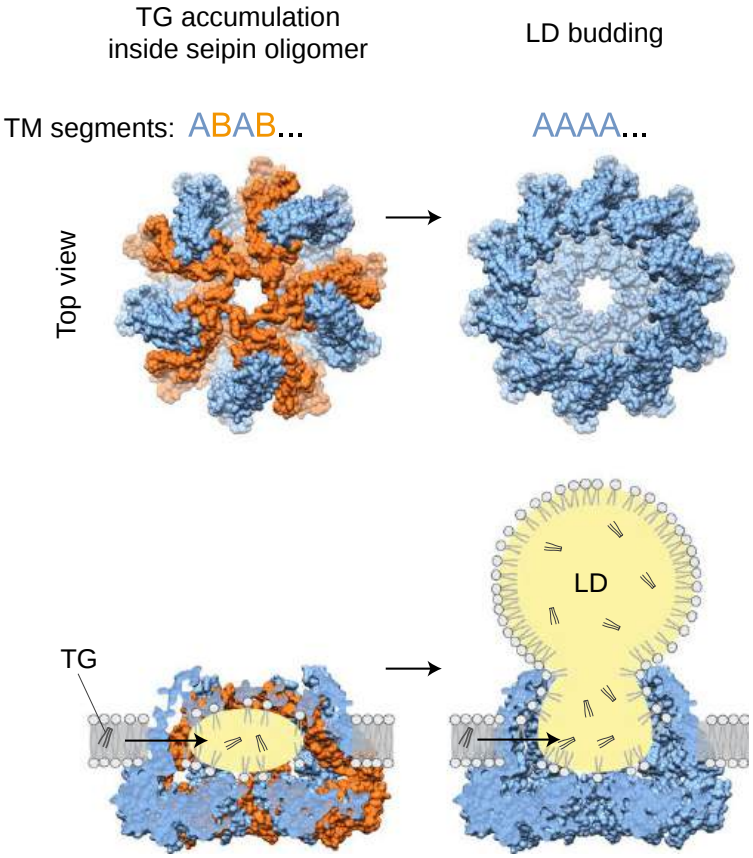


Figure 21.2.15: Accumulation and phase separation of triacylglycerides (TG) and budding of lipid droplets (LD) from the seipin complex. Arlt et al. https://doi.org/10.1038/s41594-021-00718-y. Nature Structural & Molecular Biology, 194–202 (2022). Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0l. The left-hand side shows alternating monomer conformations (A in blue and B in orange, based on the solved structure), which forms an overall "closed" form of the complex, allowing the accumulation of TGs. The right-hand side shows a possible open form, with all monomers in the A or blue form, which allows lipid droplet formation and release.

Some of the surface proteins on lipid droplets can extend long helical hairpins of hydrophobic peptides deep into the lipid core. For example, perilipins constitute a family of at least five phosphorylated proteins that bind to droplets in animals and share a common region, the so-called ‘PAT’ domain, named for the three original members of the family that include perilipin and ADRP. Proteins related evolutionarily to these are found in more primitive organisms, including insects, slime molds, and fungi, but not in the nematode *Caenorhabditis elegans*. In mammals, perilipin A (or 'PLIN1' or more accurately the splice variant 'PLIN1a') is a well-established regulator

of lipolysis in adipocytes, and it is believed to be involved in the formation of the large lipid droplets in white adipose tissue. The perilipins PLIN1 and PLIN2 have functions in triacylglycerol metabolism in tissues other than adipocytes, and PLIN2 is the main perilipin in hepatocytes; PLIN5 operates in tissues that oxidize fatty acids such as the heart. Other surface proteins of lipid droplets are enzymes intimately involved in triacylglycerol metabolism, although there is a suggestion that cytoplasmic droplets may act as a storage organelle for hydrophobic proteins whose function is elsewhere in the cell.

Lipolysis

When fatty acids are required by other tissues for energy or other purposes, they are released from the triacylglycerols by the sequential actions of three cytosolic enzymes at neutral pH, i.e., adipose triacylglycerol lipase (ATGL), hormone-sensitive lipase (HSL) and monoacylglycerol lipase, which cycle between the cytoplasmic surfaces of the endoplasmic reticulum and the surface layer of lipid droplets. Simplistically, ATGL hydrolyses triacylglycerols to diacylglycerols, which are hydrolyzed by HSL to monoacylglycerols before these are hydrolyzed by the monoacylglycerol lipase to complete the process. Lipolysis proceeds in a highly ordered manner with stimulation through cell-surface receptors via neurotransmitters, hormones, and autocrine/paracrine factors that activate various intracellular signaling pathways and increase kinase activity. A protein perilipin (PLIN1) has been described as "the gatekeeper of the adipocyte lipid storehouse" that regulates lipolysis by acting as a barrier to lipolysis in non-stimulated cells. However, on β-adrenergic stimulation during fasting, it is phosphorylated by the cAMP-protein kinase, which changes its shape and reduces its hydrophobicity, and in the process activates lipolysis. An isoform, perilipin A, is the main regulatory factor in white adipose tissue. However, many other proteins interact with the three enzymes to modulate their activity, location, and stability.

The **adipose triacylglycerol lipase**, which initiates the process, was discovered surprisingly recently. It is structurally related to the plant acyl-hydrolases in that it has a patatin-like domain in the NH_2-terminal region (patatin is a non-specific acyl-hydrolase in potatoes). Specific transport mechanisms guide ATGL from the endoplasmic reticulum membrane to lipid droplets, where it is located on the surface both in the basal and activated states. This lipase is specific for triacylglycerols containing long-chain fatty acids, preferentially cleaving ester bonds in the *sn*-1 or *sn*-2 position (but not *sn*-3), and it yields diacylglycerols and free fatty acids as the main products, with low activity only towards diacylglycerols, and none to monoacylglycerols and cholesterol esters. However, it also has transacylase and phospholipase activities, and it hydrolyses retinol esters in hepatic stellate cells. Adipose triacylglycerol lipase can be activated at the same time as hormone-sensitive lipase and is now believed to be rate-limiting for the first step in triacylglycerol hydrolysis. Figure 21.2.16 shows the sequential hydrolysis of TAGs in adipocytes and lipid droplets.

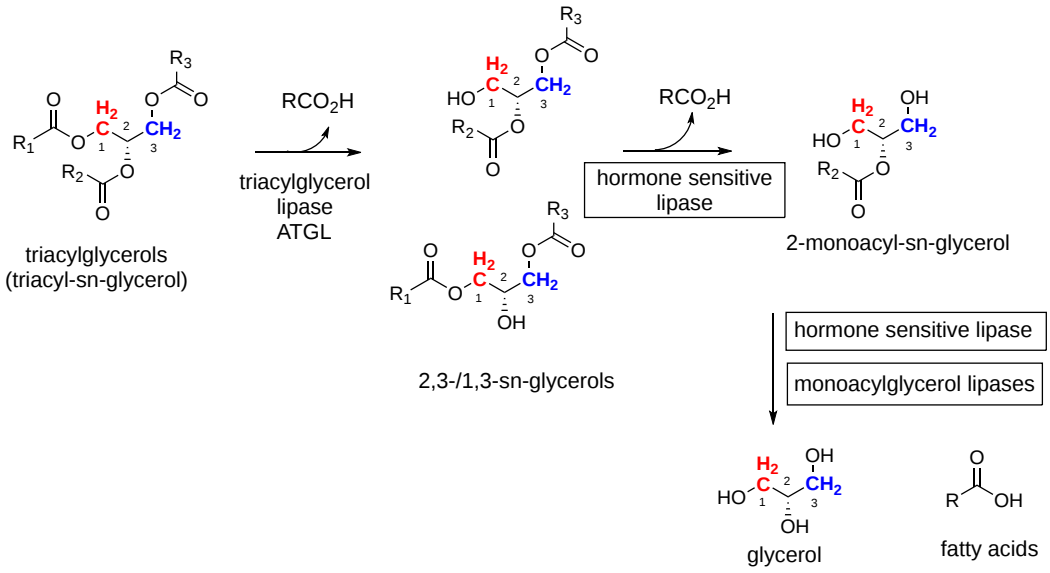

Figure 21.2.16: Sequential hydrolysis of TAGs in adipocytes and lipid droplets

Regulation of the enzymatic activity is a complex process, and for example, a lipid droplet protein designated Gene identification-58 (CGI-58 or ABHD5), is known to be an important activating factor and is required for hydrolysis of fatty acids from position *sn*-1. In the resting state, this protein binds to perilipin (PLIN1), but on hormonal stimulation, the latter is phosphorylated leading to dissociation and interaction of CGI-58 with phosphorylated ATGL to commence the first step in triacylglycerol hydrolysis. Mutations in adipose triacylglycerol lipase or CGI-58 are believed to be responsible for a syndrome in humans known as ‘neutral lipid storage disease’. A second protein (G0S2) inhibits the enzyme.

Hormone-sensitive lipase in various isoforms is a structurally unique member of the large Ser-lipase/esterase family of enzymes in animals. It is regulated by the action of the hormones insulin and noradrenaline by a mechanism that ultimately involves phosphorylation of the enzyme by cAMP-protein kinase (as with perilipin), thereby increasing its activity and causing it to translocate from the cytosol to the

lipid droplet to initiate the second step in hydrolysis. Its activity is regulated further by a variety of proteins that include PLINs and fatty acid binding proteins (FABP). Hormone-sensitive lipase has a broad substrate specificity compared to other neutral lipases, and in addition to its activity towards triacylglycerols, it will rapidly hydrolyze diacylglycerols, monoacylglycerols, retinol esters, and cholesterol esters. Diacylglycerols are hydrolyzed ten times as rapidly as triacylglycerols. Within the triacylglycerol molecule, hormone-sensitive lipase preferentially hydrolyses ester bonds in the *sn*-1 and *sn*-3 positions, leaving free acids and 2-monoacylglycerols as the main end products.

The **monoacylglycerol lipase** is believed to be the rate-limiting enzyme in lipolysis, i.e., the final step in triacylglycerol catabolism releasing free glycerol and fatty acids, and it is found in the cytoplasm, the plasma membrane, and in lipid droplets. It is specific for monoacylglycerols, but with no positional specificity, and has no activity against di- or triacylglycerols. As it is the enzyme mainly responsible for the deactivation of the endocannabinoid **2-arachidonylglycerol** and is highly active in malignant cancers, it is attracting pharmaceutical interest. A further enzyme, α/β hydrolase containing-6 (ABHD6), is located on the inner leaflet of the plasma membrane and preferentially hydrolyses fatty acids at the *sn*-1 position over the *sn*-2 position of monoacylglycerols, and it also hydrolyses lysophospholipids and bis(monoacylglycerol)-phosphate. This has been associated with the development of insulin resistance and the progression of cancer. Additional lipolytic enzymes, including carboxyesterases, are believed to operate against triacylglycerols in cytoplasmic lipid droplets in the liver.

Unesterified fatty acids released by the combined action of these three lipases are exported into the plasma for transport to other tissues in the form of albumin complexes, while the glycerol released is transported to the liver for metabolism by either glycolysis or gluconeogenesis.

Eventually, the whole organelle can disappear, including the proteins, when they undergo a process of autophagy (**lipophagy**), i.e., the delivery of the organelles to lytic compartments for degradation. This can occur through direct lysosomal invagination or more often by a multistep process involving the formation of double-membrane vesicles termed 'autophagosomes' around droplets with subsequent lysosomal fusion and degradation of the triacylglycerols by the lysosomal acid lipase. This process is important for the regulation of cellular lipid levels in various tissues and disease conditions, especially during starvation. It is relevant to tumorigenesis and cancer metastasis, and to neurodegenerative and neuroinflammatory diseases. While lipophagy is mechanistically distinct from lipolysis, there is cross-talk between the two.

THE STRUCTURE OF LIPASES

Lipases carry out hydrolysis reactions (nucleophilic substitution with water as the nucleophile), alcoholysis reactions (with an ROH as the nucleophile), and even transesterification reactions with other fatty acid esters. Lipases are critical enzymes yet there are no good structures available for hormone-sensitive lipase for example. Yet much is known about the structure and activity of lipases. Lipases have a catalytic Ser-His-Asp triad like serine proteases, which also carry out hydrolysis reactions. However, the substrates for lipase are nonpolar and could be part of larger structures such as lipid droplets. As such, the lipases work at the interface between aqueous and non-aqueous interfaces. They are **interfacially** activated.

Lipases appear to have low activity in aqueous solutions but more in solutions that are more nonpolar. Many appear to have two conformations, a closed one with lower activity and poor lipid substrate binding properties, and an open one with higher activity and activation by nonpolar solvents. An alpha-helical lid appears to close off the active site in the closed conformation. In a more nonpolar solvent or the presents of bulk lipids, such as lipid droplets, the alpha-helical lid moves exposing the enzyme's hydrophobic binding site to substrate interactions.

Figure 21.2.17 shows an interactive iCn3D model comparing the structure of a *Thermomyces lanuginosus* lipase in its closed (1DT3) and its open conformation (1EIN).

NCBI iCn3D Figure 21.2.17: The structure of a *Thermomyces lanuginosus* lipase in its closed (1DT3) and its open conformation (1EIN). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/icn3d/share.html?C9yEwy6SR6MZ9Q1S7

The closed structure (1DT3) is shown in magenta and the open (1EIN) is in cyan. The active site triad Ser146, His258, and Asp201 is shown in CPK-colored sticks and labeled for each. The lid is shown in yellow with its side chains as sticks. Toggle between the two states using the "a" key. Note how the lid covers the active site in the closed (1DT3) structure. You will have to rotate the molecule to see the optimal orientation. Also, close out menu boxes for a larger and more centered display.

Endocrine functions

Not only does the adipocyte provide a store of energy but it is an endocrine organ that manages the flow of energy through the formation of the hormone **leptin**, which signals through the adiponectin receptors (AdipoR)1 and AdipoR2 and binds to the non-signaling interacting protein, T-cadherin. The result is the stimulation of signaling cascades to communicate with other tissues through the secretion of cytokines and other mediators. The synthesis of leptin is tightly controlled by adipocytes mainly, although it is also produced by the stomach, placenta, and mammary gland, and its principal function is the provision of information on the state of fat stores to other tissues. In so doing, it regulates food intake and energy expenditure. Leptin was initially described as an anti-obesity hormone, but it serves as an adiposity signal with a vital function in maintaining adipose tissue mass to ensure survival under conditions of negative energy balance and so protect against either a deficit or an excess of adiposity. Lipid droplets have a role in this process, sinc perilipin is required for the sensing function.

Adiponectin is a potent insulin sensitizer and suppressor of cell death and inflammation, directly promoting anti-diabetic and anti-atherosclerotic outcomes. Insulin is the main hormone that affects metabolism and its receptor at the plasma membrane is located in caveolae. The release of proinflammatory cytokines can stimulate lipolysis and cause insulin resistance, in turn leading to dysfunction of adipose tissue and systemic disruption of metabolism. Thus, adipose tissue metabolism has profound effects on whole-body metabolism, and defects in these processes can have severe implications for such serious pathological conditions as diabetes, obesity, cardiovascular disease, fatty liver disease, and cancer in humans. It is hoped that the development of specific inhibitors for hormone-sensitive lipase will improve the treatment of such metabolic complications. As **caveolae**, which contain the proteins caveolins (and presumably sphingolipids) and are particularly abundant in adipocytes, modulate the flux of fatty acids across the plasma membrane and are involved in signal transduction and membrane trafficking pathways, it is evident that they have a major role in this aspect of lipid metabolism.

White fat acts as an endocrine organ and can release a variety of hormones including **adipokines** (analogous to cytokines, chemokines, lymphokines) **adipsin,** and **leptin** as well as tumor necrosis factor α (TNF-α), adiponectin, resistin, and RBP4.

Functions other than energy management

Lipid droplets accumulate within many cell types other than adipocytes, including leukocytes, epithelial cells, hepatocytes, and even astrocytes, especially during infections, cancer, and other inflammatory conditions. They are important for the cellular storage and release of hydrophobic vitamins, signaling precursors, and other lipids that are not related to energy homeostasis while reducing the dangers of lipotoxicity. On the other hand, excessive fatty acid accumulation is associated with lipotoxicity, endoplasmic reticulum stress, and mitochondrial damage and dysfunction, so lipid storage in lipid droplets must be balanced for health.

A variety of enzymes are associated with lipid droplets, including protein kinases, which are involved in many different aspects of lipid metabolism, such as cell signaling, membrane trafficking, and control of the production of inflammatory mediators like the eicosanoids. Lipolysis enables the secretion of lipid species termed **lipokines** (more generally 'adipokines') from adipocytes that may signal in a hormone-like fashion to other tissues, thereby modulating gene expression and physiological function, including food intake, insulin sensitivity, insulin secretion, and related processes. These include **palmitoleic acid (9-16:1)** and **fatty acid esters of hydroxy fatty acids (FAHFA)**, though the circulating proteins adiponectin and leptin have been studied more intensively. Adiponectin is a powerful insulin sensitizer and suppressor of apoptosis and inflammation with anti-diabetic and anti-atherosclerotic functions, often operating through its effects on sphingolipids, while leptin exerts most of its effects on the brain to trigger behavioral, metabolic, and endocrine responses to control the body's fuel reserves.

Indeed, there are now suggestions that lipid droplets in all cell types are essential for the response mechanisms to cellular stress, including autophagy, inflammation, and immunity, and act as hubs to integrate metabolic and inflammatory processes. Via their lipolytic machinery, they regulate the availability of fatty acids for the activation of signaling pathways and the production of oxylipins from polyunsaturated fatty acids. For example, triacylglycerols in cytoplasmic lipid droplets of human mast cells, which are potent mediators of immune reactions and influence many inflammatory diseases, have a high content of arachidonic acid and this can be released by adipose triacylglycerol lipases as a substrate for production of specific eicosanoids when the cells are stimulated appropriately. Active metabolism in lipid droplets is important for the differentiation of monocytes, and it is essential for the sustained functional activity of differentiated macrophages, especially in relation to inflammation.

During apoptosis, triacylglycerols enriched in polyunsaturated fatty acids accumulate in lipid droplets, possibly as a protective mechanism against membrane damage caused by oxidative stress and hydroperoxide formation in this process. Triacylglycerols in lipid droplets of the skin are a highly specific source of linoleic acid that is required for the formation of the ***O*-acylceramides**, which are essential for epidermal barrier function. An organelle termed the midbody in dividing cells in humans and rodents contains a unique triacylglycerol that is a single molecular species consisting of three fatty acids 16:1-12:0-18:1 (12:0 especially is rarely detected in human lipids), but its function is not known.

Vitamin E (tocopherols) and vitamin A in the form of retinyl esters are stored in cytoplasmic lipid droplets, and the latter are present in appreciable concentrations in the stellate cells of the liver, for example. In endocrine cells of the gonads and adrenals, cholesterol esters stored in lipid droplets are an important source of cholesterol for the mitochondrial biosynthesis of various steroid hormones. In the nucleus

of the cell, in addition to providing a reservoir of fatty acids for membrane remodeling, lipid droplets can sequester transcription factors and chromatin components and generate the lipid ligands for certain nuclear receptors.

In addition to their role in lipid biochemistry, lipid droplets participate in protein degradation and glycosylation. Their metabolism can be manipulated by pathogenic viruses and bacteria such as *Mycobacterium tuberculosis* with unfortunate consequences for the host, but they also serve as reservoirs for proteins that fight intracellular pathogens. In consequence, such lipid droplets and their enzyme systems may be markers for disease states and are also considered to targets for pharmaceutical intervention.

Insects

In insects, the fat body is a multifunctional tissue that is the main metabolic organ. It integrates signals that control the immune system, molting, metamorphosis, and synthesis of hormones that regulate innumerable aspects of metabolism. In fat body cells, lipids, carbohydrates, and proteins are the substrates and products of many pathways for use in energy production or to act as reserves for mobilization at the appropriate stage of life (diapause, metamorphosis, and flight). In relation to innate and acquired humoral immunity, the fat body produces bactericidal proteins and polypeptides, i.e., lysozyme. It is also important in the early stages of an insect's life due to the production of vitellogenin, the yolk protein needed for the development of oocytes.

21.2.5: BROWN ADIPOSE TISSUE

Most adipose tissue depots ('white fat') serve primarily as storage and endocrine organs that provide a reservoir of nutrients for release when the food supply is low. However, a second specialized form of adipose tissue, brown fat, is multilocular, highly vascularized, and rich in mitochondria and the iron-containing pigments that transport oxygen and give the tissue its color and name. Brown adipocytes arise from progenitor cells that are closer to those of skeletal muscle than white adipocytes. In humans, these depots tend to be located in specific anatomical regions such as subcutaneous areas around the neck, where their function may be to supply warm venous blood directly to the spinal cord and brain, and elsewhere to the heart, kidney, pancreas, and liver. Brown fat can oxidize fat so rapidly that heat is generated (“non-shivering thermogenesis”), and it is especially important in young animals and those recovering from hibernation.

In brief, during cold exposure, the release of noradrenaline and stimulation of β-adrenergic receptors in the nervous system initiates a catabolic program that commences with a rapid breakdown of cellular triacylglycerol stores and release of unesterified fatty acids and transient activation of a co-activator of peroxisome proliferator-activated receptor gamma (PPARγ). These set in motion a signaling process that results in the efficient **β-oxidation** of fatty acids to produce heat. The key molecule is believed to be the **uncoupling protein-1 (UCP1)**, which acts as a valve to uncouple electron transport in the respiratory chain from ATP production with a highly exothermic release of chemical energy, i.e., as heat rather than as ATP. Its actions are illustrated in Figure 21.2.18.

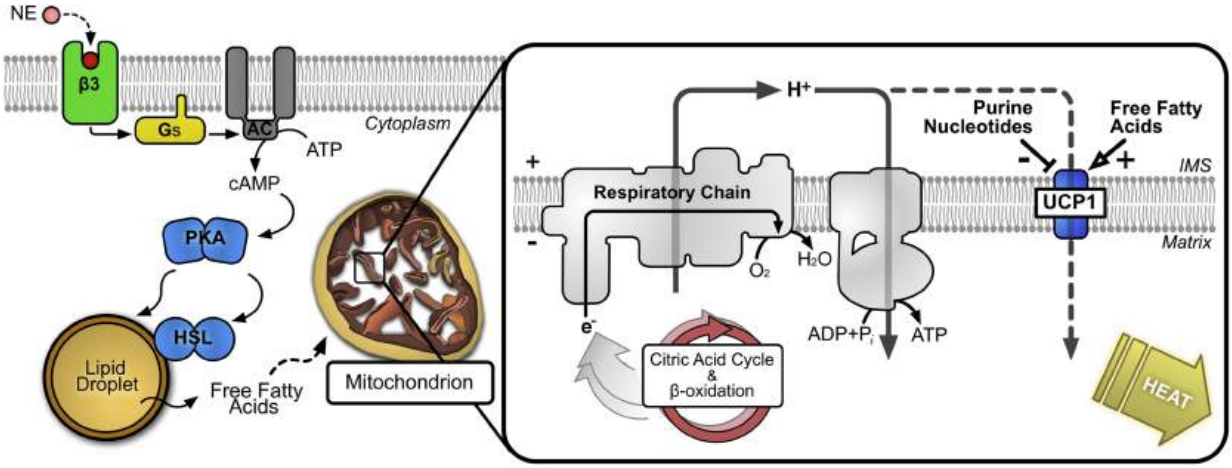

Figure 21.2.18: Role of UCP1 in generation of heat. https://commons.wikimedia.org/wiki/F...n_the_cell.jpg. Creative Commons Attribution-Share Alike 4.0 Internationa

This is an example of a futile cycle that releases heat. Although many aspects of the mechanism are uncertain, it is clear that proton conductance by UCP1 is highly regulated and inducible. It is activated by free long-chain fatty acids and inhibited by purine nucleotides, i.e., fatty acids are not only the substrate for thermogenesis but act also as self-regulating second messengers. The mitochondrial phospholipid **cardiolipin**, which is intimately involved in oxidative phosphorylation, is indispensable for stimulating and sustaining the function of thermogenic fat. Upon activation of brown adipose tissue, the dense vasculature increases the delivery of fatty acids and glucose to the brown adipocytes and warms the blood passing through the tissue.

Long-chain fatty acids bind to UCP1 and may be transported through the membrane along with a proton. Alternatively, it may just bind and activate the transport of a proton. Figure 21.2.19 shows an interactive iCn3D model of the AlphaFold predicted structure of human UCP1 (P25874).

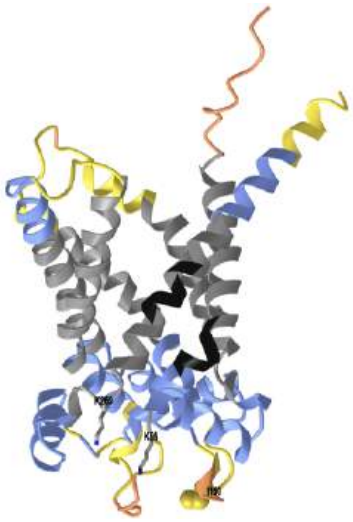

Figure 21.2.19: AlphaFold predicted structure of human UCP1 (P25874). Click the image for a popup or use this external link: https://structure.ncbi.nlm.nih.gov/i...FkfrEqWE3D2dX6

Imagine a bilayer orienting perpendicularly to the gray helices representing the transmembrane helical segments that imbed the protein into the inner mitochondrial membrane. The spacefill Ile150 denotes the matrix domain. Two key residues (K56, K29) involved in the binding of the carboxyl end of the fatty acids are shown on the matrix side of the protein is CPK-colored sticks and labeled. The black faces of the helices in the inner membrane region show the most probable binding site for the acyl chain of the fatty acid. The lighter yellow/orange regions have greater predicted uncertainty in the AlphaFold computational model.

There is evidence that **acylcarnitines** produced in the liver from fatty acids released from white adipose tissue in response to cold exposure are transported in plasma to brown adipose tissue and can serve as a substrate for thermogenesis. Indeed, a wide array of circulating lipids contributes to thermogenic potential, including free fatty acids and triacylglycerols.

The activities of acyl-CoA synthetases and acyl-CoA thioesterases determine the availability of substrates for β-oxidation and consequently the thermogenic capacity. Synthesis of the lipokine (or 'batokine') **octadecanoid** 12,13-dihydroxy-9*Z*-octadecenoic acid (12,13-diHOME), is induced by cold also, and this stimulates the activity of brown adipose tissue by promoting the uptake of fatty acids, acting via G-protein-coupled receptors. It increases cardiac function and cardiomyocyte respiration via enhanced calcium cycling. Similarly, there are suggestions that *n*-3 polyunsaturated fatty acids may promote adaptive thermogenesis, for example through the activity of the 12-lipoxygenase metabolite and batokine 12-hydroxyeicosapentaenoic acid (12-HEPE) by improving glucose metabolism via increased glucose uptake into adipocytes and skeletal muscle. (**FAHFA**) are relevant in this context. Peroxisomal synthesis of **plasmenyl-phospholipids** is believed to regulate adipose tissue thermogenesis by mediating mitochondrial fission.

In hibernating mammals, brown adipose tissue is especially important metabolically, and even in laboratory animals such as mice, it can consume about 50% of dietary lipids and glucose when the animals are exposed to cold. Similarly, in even humans, the activity of brown adipose tissue is induced acutely by cold and is stimulated via the sympathetic nervous system, and the relevance of this tissue to human metabolism is now becoming apparent. For example, there are suggestions that brown adipose tissue can behave as an endocrine system to secrete endocrine factors ('batokines') that may be favorable in reducing cardiovascular risk. For obvious reasons, there are efforts to determine whether sustained activation of brown fat by pharmaceutical means could be beneficial for human disease states, including obesity, diabetes, and cardiovascular disease.

Such research has been stimulated by the observation that clusters of distinct adipocytes with thermogenic capacity in addition to their storage function can be present in white adipose tissue and emerge in response to various physiological signals, especially reactive oxygen species. They are termed '**beige** or brite' adipocytes and arise from multipotent pre-adipocytes. Brown adipose tissue is a discrete organ in animals, but beige adipose tissue is interspersed with white, and the two forms have different developmental origins. In adult humans, most of the deposits once thought to be classical brown adipose tissue do not contain the genetic markers for this tissue and are now recognized to be beige/brite fat, although brown adipose tissue *per se* is present in significant amounts in human newborns and infants. However, beige adipocytes utilize the same machinery to release heat by oxidation of fatty acids under β-adrenergic stimulation.

The uncoupler protein 1 (UCP1) appears to be expressed only in brown and beige fat cells and is a marker for those cells. It can be regulated transcriptionally and posttranscriptionally by ROS modification of a cysteine to produce a sulfenyl group. The more classical brown adipocyte arises developmentally from the skeletal muscle-like cell, whereas the beige appears to develop to some extent from vascular smooth muscle cells. The beige cells can differentiate into more white adipocytes or more brown ones, by the factors described in Figure 21.2.20.

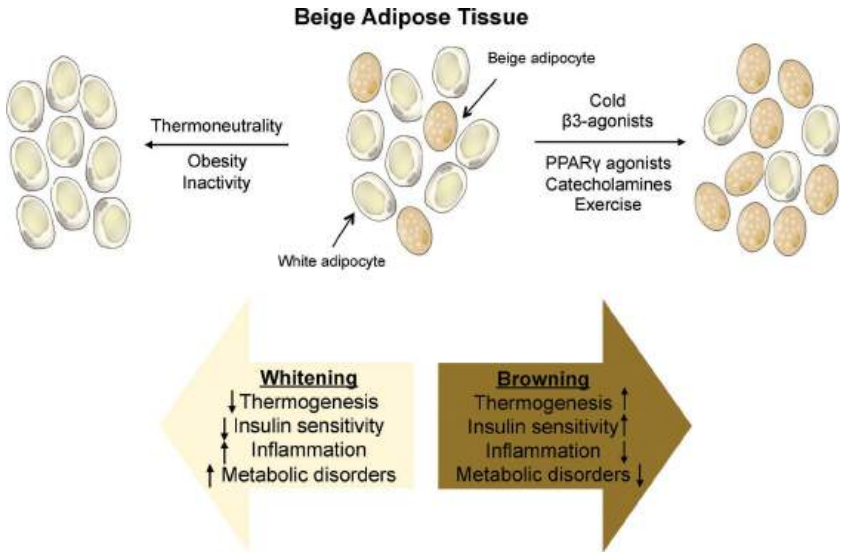

Figure (\PageIndex{20}\): Factors altering beige adipose tissue. Paul Cohen and Bruce M. Spiegelman. **Molecular Biology of the** Cell, 27, 2017. https://doi.org/10.1091/mbc.e15-10-0749. FAT CELL SIZE

In addition to the type of fat cell, the location and size of the adipocyte also affect health risks. Obesity, cardiovascular disease, type II diabetes, and nonalcoholic fatty liver disease all depend on and are correlated with fat cell dysfunction. The endocrine role of adipose tissue plays a key role in the development of dysfunction. The main depots of fat are the subcutaneous adipose tissue (SAT) and the visceral adipose tissue (VAT), the latter of which is associated with proinflammatory effects and associated greater health risks (type II diabetes, hypertension, metabolic syndrome, obesity, etc.). Figure (\PageIndex{21}\) below summarizes the health consequence as the size of the SAT and VAT adipocytes increase (in the direction of the red arrow).

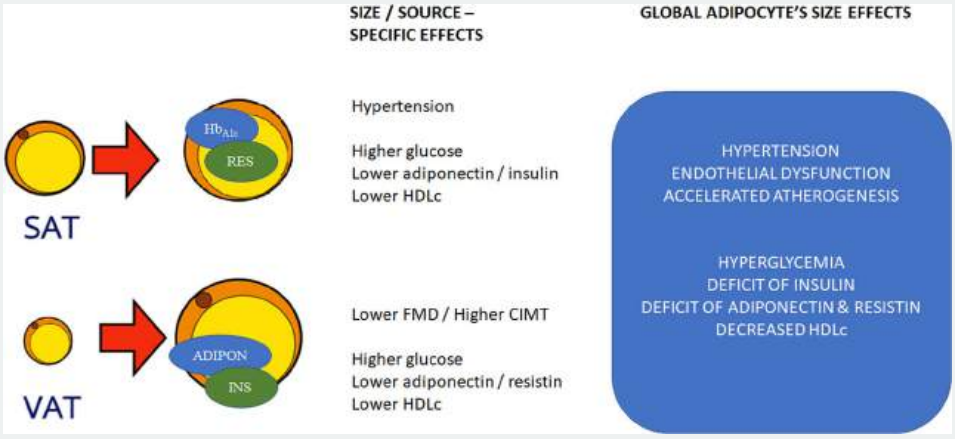

Figure (\PageIndex{2}\): Adipocyte characteristics and cardiovascular risk. The diagram describes a proposed model, based on the results of adipocyte size/source, potential interactions with metabolic mediators, and pathophysiological effects. SAT, subcutaneous adipose tissue; VAT, visceral adipose tissue; HbA1c, glycated hemoglobin (a marker of elevated blood sugar associated with diabetes); RES, resistin; ADIPON, adiponectin; INS, insulin; HDLc; high-density lipoprotein cholesterol; FMD, flow-mediated dilation; CIMT, carotid intima media thickness. Suárez-Cuenca et al. *Sci Rep* **11**, 1831 (2021). https://doi.org/10.1038/s41598-021-81289-2. Creative Commons Attribution 4.0 International License. http://creativecommons.org/licenses/by/4.0/.

It appears that the larger the adipocyte, the greater the inflammatory response. This condition is called adipocyte hypertrophy and it may be more important than obesity per se as a risk factor for inflammation, as indicated by inflammatory cytokine levels and macrophage infiltration into adipose tissue. The adipose-derived hormone leptin, when released under normal conditions, leads to

appetite suppression and also decreases liver and muscle fat. Higher fat storage is associated with increased blood leptin levels. It also correlates with greater lymphocyte size.

In contrast, the adipose hormone adiponectin leads to positive health consequences including increased sensitivity to insulin, decreased inflammation, and the formation of adipocytes from stem cells (adipogenesis). The larger the fat cell, the lower the serum levels of adiponectin. However, the link between fat cell size and adiponectin levels may be determined more by obesity.

21.2.6: OTHER FUNCTIONS OF TRIACYLGLYCEROL DEPOTS

Subcutaneous depots act as a cushion around joints and serve as insulation against the cold in many terrestrial animals, as is obvious in the pig, which is surrounded by a layer of fat, and it is especially true for marine mammals such as seals. Those adipocytes embedded in the skin differ from the general subcutaneous depots and support the growth of hair follicles and regenerating skin, and they may also have a defensive role both as a physical barrier and by responding metabolically to bacterial infection.

In marine mammals and fish, the fat depots are less dense than water and so aid buoyancy with the result that less energy is expended in swimming. More surprisingly perhaps, triacylglycerols together with the structurally related glyceryl ether diesters and wax esters are the main components of the sonar lens used in echo location by dolphins and toothed whales. The triacylglycerols are distinctive in that they contain two molecules of 3-methylbutyric (isovaleric) acid with one long-chain fatty acid. It appears that the relative concentrations of the various lipids in an organ in the head of the animals (termed the ‘melon’) are arranged anatomically in a three-dimensional topographical pattern to enable them to focus sound waves.

In cold climates, many insects do not feed over winter and must manage their energy stores to meet the energetic demands of development and reproduction in the spring. Some insect species that are tolerant of freezing produce triacylglycerols containing acetic acid, and these remain liquid at low temperatures; by interacting with water, they may play a role in cryoprotection.

21.2.7: TRIACYLGLYCEROL METABOLISM IN PLANTS AND YEASTS

Fruit and seed oils are major agricultural products with appreciable economic and nutritional value to humans. The mesocarp of fruits is a highly nutritious energy source that attracts animals that help to disperse the seeds, and in plants such as the oil palm and olive trees a high proportion of the fruit flesh contains triacylglycerols. Similarly in seeds, triacylglycerols are the main storage lipid and can comprise as much as 60% of their weight. Fruit lipids are not intended for use by the plant *per se* and are stored in lipid droplets in large irregular structures that break down readily, but seed lipids are required for the development of the plant embryo, so their metabolism is of particular importance. However, triacylglycerol biosynthesis and metabolism are required also for pollen viability and to maintain lipid homeostasis in chloroplasts (see the note on plastoglobules below).

Seed oils: In seeds and other plant tissues, biosynthesis of fatty acids takes place in plastids, and these are stored in the form of triacylglycerols in lipid droplets with a coherent surface layer of proteins and lipids in the embryo (e.g., Arabidopsis, soybean or sunflower) or endosperm (e.g., castor bean) tissues of seeds. In addition to the common range of fatty acids synthesized in plastids, mainly palmitate, and oleate, some plant species produce novel fatty acids, including medium- and very-long-chain components and those with oxygenated and other functional moieties. A specific means of diverting these to seeds for triacylglycerol production exists to prevent disruption of the plant membranes. Seed development occurs in three stages - rapid cell division with no accumulation of storage material, rapid deposition of triacylglycerols and other energy-rich metabolites, and finally desiccation.

During the period of oil accumulation in seeds, the newly formed ACP esters of fatty acids are first hydrolyzed by two different classes of acyl-ACP thioesterases at the inner plastid envelope membrane, before the unesterified fatty acids are transported to the endoplasmic reticulum (ER), by a family of fatty acid export proteins (FAX) of which there are seven isoforms in Arabidopsis, two of which (FAX2 and FAX4) are highly expressed during the early stage of seed development. The unesterified fatty acids are shuttled across the plastid outer envelope, probably by vectorial acylation by long-chain acyl-CoA synthases, which catalyze the formation of CoA esters.

In the ER, triacylglycerols and membrane lipids are synthesized by the Kennedy and other pathways described above. In yeast and plants, 1,2-diacyl-*sn*-glycerol esterification is the only committed step in triacylglycerol production, and this occurs by mechanisms that can be both dependent or independent of acyl-CoA esters. The acyl-CoA-dependent route is catalyzed by diacylglycerol:acyl-CoA acyltransferases (DGATs) with acyl-CoA and diacylglycerols as substrates, and two membrane-bound isoenzymes (DGAT1 and DGAT2) and a cytosolic isoenzyme (DGAT3) are known, DGAT1 is a key enzyme involved in triacylglycerol formation in developing seeds, while DGAT2 is especially important in those plant species with unusual fatty acid compositions. In Arabidopsis, DGAT3 has some specificity for polyunsaturated fatty acids in seed development. Figure 21.2.22 summarizes TAG synthesis in plant ER.

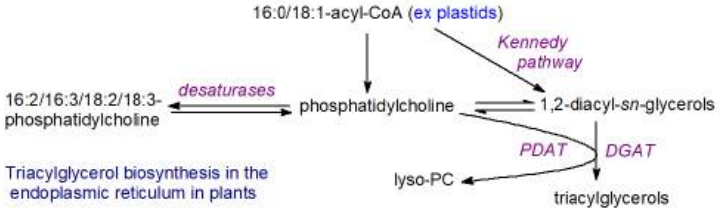

Figure 21.2.22 TAG biosynthesis in plant ER

In addition, a substantial proportion of triacylglycerol biosynthesis in some plant species is synthesized by flux through the membrane phospholipid **phosphatidylcholine**, produced by what are sometimes termed inaccurately the 'eukaryotic and prokaryotic pathways' with differing positional distributions, in which diacylglycerols are generated from phosphatidic acid by the action of a phosphatidate phosphatase as an intermediate. In the acyl-CoA-independent reaction, the direct transfer of one fatty acid from phosphatidylcholine to diacylglycerol by the action of the phospholipid:1,2-diacyl-*sn*-glycerol-acyltransferase (PDAT) enzyme also occurs, with the formation of lysophosphatidylcholine as a byproduct, which can be re-esterified for further reaction. As phosphatidylcholine undergoes extensive remodeling and its fatty acid components are subject to modification, for example by desaturation to form linoleic and linolenic acids, the compositions and especially the positional distributions of triacylglycerols produced in this way can be very different from those synthesized by the ‘classical’ pathways. Phosphatidylcholine may also function as a carrier for the trafficking of acyl groups between organelles and membrane subdomains, and it has been suggested that an assembly of interacting enzymes may facilitate the transfer of polyunsaturated fatty acids from this phospholipid to triacylglycerols in seeds. Both sterol and sphingolipid biosynthesis appear to be important factors for efficient seed oil production.

As triacylglycerol synthesis continues, oil droplets accumulate between the leaflets of the endoplasmic reticulum and are surrounded by a monolayer of phospholipids, sterols, and proteins, which in Arabidopsis include oleosins, a caleosin, a steroleosin, a putative aquaporin, and a glycosylphosphatidylinositol-anchored protein. Oleosins are the most abundant of these (~65%) and are small proteins (15-30 kDa) that contain cytosolic-facing N- and C-termini and a large hydrophobic domain necessary to target them to lipid droplets, where they are important for control of their size and stability. Eventually, lipid droplets “bud off” from the endoplasmic reticulum with their monolayer of phospholipids and proteins, and they are released into the cytosol by a yet-to-be-defined mechanism.

At the onset of germination, water is absorbed, and esterases/lipases are activated. The process of lipolysis begins at the surface of oil bodies, where the oleosins, which are the most abundant structural proteins, are believed to assist in the docking of lipases and to control the size and stability of lipid droplets in seeds. A number of esterases/lipases have been cloned from various plant species and possess a conserved catalytic triad of Ser, His, and Asp or Glu, somewhat different from the animal lipases, as in patatin (an especially abundant lipolytic protein in potatoes), which can hydrolyze triacylglycerols but not phospho- or galactolipids. The most important of these is believed to be the 'sugar-dependent lipase 1 (SDP1)', which is a patatin-like lipase similar in function to the mammalian adipose triacylglycerol lipase discussed above and is located on the surface of the oil body. This is active mainly against triacylglycerols to generate diacylglycerols but presumably works in conjunction with di- and monoacylglycerol lipases to generate free fatty acids and glycerol.

The lipid droplets in seeds exist near glyoxysomes (broadly equivalent to peroxisomes). These are the membrane-bound organelles that contain most of the enzymes required to oxidize fatty acids derived from the triacylglycerols via acetyl-CoA to four-carbon compounds, such as succinate, which are then converted to soluble sugars to provide germinating seeds with energy to fuel the growth of the seedlings and to produce shoots and leaves. In addition, they supply structural elements before the seedlings develop the capacity to photosynthesize. How the products of lipolysis are transported to the glyoxysomes for further metabolism has still to be determined, but a specific ‘ABC’ transporter is required to import fatty acids into the glyoxysomes in Arabidopsis. The free acids are converted to their coenzyme A esters by two long-chain acyl-CoA synthetases located on the inner face of the peroxisome membrane before entry into the β-oxidation pathway. All these processes are controlled by an intricate regulatory network, involving transcription factors that crosstalk with signaling events from the seed maturation phase through to embryo development. After about two days of the germination process, the glyoxysomes begin to break down, but β-oxidation can continue in peroxisomes in leaf tissue.

Lipid droplets - plastoglobules: Triacylglycerol-rich lipid droplets (LD) have been observed in most cell types in vegetative tissues of plants as well as in seeds, and although their origin and function are poorly understood, they contain all the enzymes required for triacylglycerol metabolism together with phospholipases, lipoxygenases, and other oxidative enzymes. Instead of oleosins, these lipid droplets in plants and algae contain a family of ubiquitously expressed 'LD-associated proteins' on the surface, together with a monolayer of phospholipids (mainly phosphatidylcholine), galactolipids such as sulfoquinovosyldiacylglycerol and in some species betaine lipids. As in yeast and humans, seipins (three in Arabidopsis) are necessary for normal LD biogenesis. Again, LD forms within the bilayer of the endoplasmic reticulum and pinch off into the cytoplasm. Abiotic stresses can induce the remodeling of lipid membranes through lipase action with the formation of toxic lipid intermediates, and these can be sequestered by triacylglycerols in lipid droplets to inhibit membrane damage and potentially prevent cell death. While they are believed to be involved mainly in stress responses, lipid droplets may have other specialized roles, for example in anther and pollen development, where triacylglycerols serve as a source of fatty acids for membrane

biosynthesis. Fatty acids derived from triacylglycerols in lipid droplets are believed to be subjected to peroxisomal β-oxidation to produce the ATP required for stomatal opening and no doubt many other purposes.

In addition, lipid droplets that have been termed 'plastoglobules' are produced by a localized accumulation of triacylglycerols and other neutral lipids between the membrane leaflets of the thylakoid cisternae and then pinch off into the stroma, where they are involved in a wide range of biological functions from biogenesis to senescence via the recruitment of specific proteins. During senescence, for example, lipid droplets accumulate rapidly in the leaves of *A. thaliana*. In reproductive tissues, may have a more direct function by recruiting and transporting proteins, both for organ formation and successful pollination. Antifungal compounds such as **2-hydroxy-octadecatrienoic acid** and other oxylipins are produced from α-linolenic acid in these organelles, and it has been suggested that the latter function as intracellular factories to produce stable metabolites via unstable intermediates by concentrating the enzymes and hydrophobic substrates efficiently. Plastoglobules are also implicated in the biosynthesis and metabolism of vitamins E and K.

Microalgae: Triacylglycerol metabolism in lipid droplets in microalgae is under intensive study because of their potential for nutraceutical and biodiesel production. It seems that similar processes occur in higher plants, but with a simpler genome encoding few redundant proteins. In the unicellular green model microalga *Chlamydomonas reinhardtii*, for example, key lipid droplet proteins, lipases, and enzymes of β-oxidation have been characterized.

Yeasts: Lipid droplets in yeast are a highly dynamic and functionally diverse hub that ensures stress resistance and cell survival by promoting membrane and organelle homeostasis. As most of the important biosynthetic and catabolic enzymes involved in triacylglycerol metabolism are conserved between yeasts and mammals, the former proving to be useful models for the study of triacylglycerol production. The size and triacylglycerol content of lipid droplets in yeasts change appreciably in different stages of growth and development, and *Saccharomyces cerevisiae* contains a single phosphatidic acid phosphatase (Pah1), which has an essential role in this process. During vegetative growth, Pah1 in the cytosol is phosphorylated by multiple protein kinases, and this enables the synthesis of phospholipids rather than triacylglycerols. As cells progress into stasis, the Pah1 is dephosphorylated and translocates to the endoplasmic reticulum, which ultimately leads to triacylglycerol synthesis for storage in lipid droplets. Some fatty acids derived from phospholipids are utilized for triacylglycerol biosynthesis at the inner nuclear membrane, and this is important for nuclear integrity.

21.2.8: TRIACYLGLYCEROL METABOLISM IN PROKARYOTES

The study of the biosynthesis of triacylglycerols in bacteria has been stimulated by an awareness of the role of this lipid class in the pathogenesis of *Mycobacterium tuberculosis* and the relationship with antibiotic biosynthesis by *Streptomyces coelicolor*. For example, triacylglycerols are believed to be an energy reserve for the long-term survival of *M. tuberculosis* during the persistence phase of infection as well as a means by which unesterified fatty acids are detoxified. Increasing numbers of bacterial species, for example from the genera *Mycobacterium*, *Nocardia*, *Rhodococcus*, *Micromonospora*, *Dietzia*, and *Gordonia*, are now known to produce triacylglycerols (sometimes wax esters), and these can be stored in lipid droplets in the organisms. The first three steps in triacylglycerol biosynthesis are catalyzed by GPAT, LPAT, and PAP enzymes comparable to those in other organisms. However, it has become apparent that the DGAT can be a dual-function CoA-dependent acyltransferase known as wax ester synthase/diacylglycerol acyltransferase, which accepts a broad diversity of acyl-CoA substrates for esterification of diacylglycerols or long-chain fatty alcohols for the synthesis of triacylglycerols or wax esters, respectively, depending on which intermediates are present in the organisms. Bacteria that lack such an enzyme are unable to produce these non-polar lipids.

21.3: BIOSYNTHESIS OF MEMBRANE GLYCEROLIPIDS

by William (Bill) W. Christie and Henry Jakubowski.

This section is an abbreviated and modified version of material from the Lipid Web, an introduction to the chemistry and biochemistry of individual lipid classes, written by William Christie.

21.3.1: INTRODUCTION

In this section will be explore the synthesis of the membrane glycerophospholipids and their metabolic derivatives. We will start with the simplest one, phosphatidic acids, and end with phosphatidylinositols.

21.3.2: PHOSPHATIDIC ACIDS AND DERIVATIVES

Phosphatidic acid or 1,2-diacyl-*sn*-glycero-3-phosphate is a key intermediate in the biosynthesis both of other glycerophospholipids and of triacylglycerols. It is structurally one of the simplest of the phospholipids and was long thought to be important only as a precursor of other lipids, where it is indeed a key molecule, but it is now known to have many other functions in animals, plants, and other organisms by its influence on membrane structure and dynamics, and by its interactions with various proteins. As a lipid mediator, it modulates various signaling and cellular processes, such as membrane tethering, conformational changes and enzymatic activities of specific proteins, and vesicular trafficking. Moreover, its metabolite **lysophosphatidic acid** is recognized as a key signaling molecule with a myriad of biological effects mediated through specific receptors.

21.3.2.1: PHOSPHATIDIC ACID – OCCURRENCE AND BIOSYNTHESIS

Phosphatidic acid is not an abundant lipid constituent of any living organism, seldom greater than picomolar concentrations in cells, but it is extremely important both as an intermediate in the biosynthesis of other glycerophospholipids and triacylglycerols and as a signaling molecule or a precursor of signaling molecules. Indeed, it is often over-estimated in tissues as it can arise by inadvertent enzymatic hydrolysis during inappropriate storage or extraction conditions during analysis. It is the simplest diacyl-glycerophospholipid, and the only one with a phosphomonoester as the head group. The molecule is acidic and carries a negative charge, i.e., it is an anionic lipid. The structure of phosphatidic acid is shown in Figure 21.3.1.

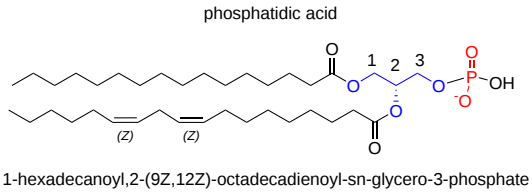

Figure 21.3.1: Phosphatidic acid

There are at least four important biosynthetic pathways for phosphatidic acid biosynthesis in different organelles under various stimuli, and possibly resulting in the formation of different molecular species. The main pathway involves sequential acylation of *sn*-glycerol-3-phosphate, derived from catabolism of glucose, by acyl-coA derivatives of fatty acids. First, one acyltransferases catalyses the acylation of position *sn*-1 to form lysophosphatidic acid (1-acyl-*sn*-glycerol-3-phosphate), and then a second specific acyltransferase catalyses the acylation of position *sn*-2 to yield phosphatidic acid. The synthesis of phosphatidic acid from glycerol-3-phosphate is shown in Figure 21.3.2.
